The Anaerobic Bag (BD Microbiology Systems, Sparks, MD) consists of a clear-plastic bag (sold in varying sizes capable of holding one to three, 100-mm-diameter Petri dishes), an H_2–CO_2 gas generator that generates an atmosphere when water is added (analogous to the generator used in a GasPak jar), cold palladium catalyst pellets, and a resazurin indicator. The bag is heat-sealed following activation of the generator to permit maintenance of anaerobic conditions according to the same principle as described for the GasPak jar system.

On the other hand, the AnaeroPouch (Mitsubishi, New York, NY) and the Anaerocult (Merck, Darmstadt, Germany) both achieve anaerobic conditions differently, without a catalyst, to remove oxygen from the atmosphere and generate CO_2. Oxygen is removed from within the sealed Anaerocult pouch by combining with iron powder to produce iron oxides. These anaerobic bag systems appear to be practical alternatives to anaerobic jar or glove box systems for the incubation of anaerobes when only a few plates are to be incubated. Additional bag systems are the Anaerogen (Oxoid) and the Anabag (Hardy Diagnostics). A study from 1990 that evaluated the pouches that were available at that time reported that although they performed well, the anaerobic chamber was superior for recovery of maximum number of anaerobes.[125] An example of an anaerobic pouch is shown in Figure 16-6.

Use of the Anaerobic Holding Jar

A modification of the Martin holding jar procedure is a convenient and inexpensive adjunct to the jar and glove box anaerobic systems that allows primary plating, inspection of cultures and subculture of colonies at the bench with only minimal exposure of anaerobic bacteria to atmospheric oxygen.[238,463,468] The holding jar assembly is illustrated in Figure 16-7, and its use is briefly described in Box 16-10.

Anoxomat. The Anoxomat (Mart Microbiology, Lichtenvoorde, the Netherlands) is an automated evacuation/replacement system. Although it is similar in principle to the procedure described by Whaley and Gorman, studies have shown somewhat better growth using the Anoxomat than with the other anaerobic systems with which it was compared.[54,429,464]

Incubation of Anaerobic Cultures

In most instances, 35°C to 37°C is the recommended temperature for primary isolation of anaerobic bacteria from clinical specimens. Plates inoculated at the bench and placed in anaerobic jars should be incubated for at least 48 hours, and reincubated for another 2 to 4 days to allow slow-growing organisms to form colonies; some anaerobes, such as certain species of NSF anaerobic gram-positive bacilli grow rather slowly, and colonies may not be detected if jars are opened sooner. Also, if the jar is opened too soon, some of the slow-growing organisms may be killed owing to oxygen exposure. In emergency situations, duplicate sets of plating media can be incubated in two different jars, one set incubated for 18 to 24 hours and the other for 3 to 5 days. This procedure allows rapid isolation of fast-growing anaerobes in the 18- to 24-hour jar and the later recovery of slow growers in the jars left for delayed incubation. If clostridial myonecrosis is suspected clinically, plates can be inspected as early as 6 to 12 hours after inoculation. This, however, is dependent on the volume of specimen received in the laboratory and the ability to plate more than one set of agar media.

■ **FIGURE 16-7** Schematic of the anaerobic holding jar system. The flow rate of nitrogen to each jar is regulated by the needle valves on the manifold (three-gang valve, available where aquarium supplies are sold). Jars A, B, and C contain uninoculated plates, plates with colonies to be subcultured, and freshly inoculated plates, respectively.

BOX 16-10

Anaerobic Holding Jar Procedure

1. Three holding jars are used, the first to hold uninoculated media, the second for plates on which colonies to be subcultured are growing, and the third to receive freshly inoculated plates of media.

2. Commercially prepared agar plates or agar media freshly prepared in the laboratory can be used. These may be held in a refrigerator for up to 6 weeks if bagged in cellophane.
3. The plates to be used on any given day should first be placed in an anaerobic glove box or an anaerobic jar for 4–15 hours before use to reduce the media.
4. As needed, the reduced media are placed in the first holding jar and continuously flushed with a gentle stream of N_2.
5. The plates of reduced media are surface-inoculated, one at a time, in ambient air and immediately placed in the third holding jar, which is also flushed with N_2. The second holding jar is used to hold any plates removed from the GasPak jar that require subculture.
6. After the jar, containing the newly inoculated plates, is filled, the plates can be transferred to a conventional anaerobic system, such as a GasPak jar, or into an anaerobic glove box for incubation at 35°C.

Prolonged exposure of freshly inoculated plates to ambient air must be avoided. Certain anaerobes commonly

encountered in clinical specimens, such as *Peptostreptococcus anaerobius*, may either fail to grow or may exhibit a prolonged lag in growth when freshly inoculated plates are held in ambient air for as short a time as 2 hours. Thus, if a holding jar procedure is not used, inoculated plates must be immediately placed in an anaerobic system (anaerobic jar or anaerobic glove box) to allow for effective cultivation of these anaerobes.

Enriched thioglycolate and chopped-meat glucose media should also be inoculated with clinical materials incubated in an anaerobic system to allow maximum recovery of anaerobes. It is not necessary to boil the tubes of enriched thioglycolate or chopped-meat glucose broth if they are prepared in tight-fitting screw-capped tubes and gassed in a glove box after autoclaving. Unless growth is apparent visually, broth cultures should be held a minimum of 5 to 7 days before discarding them as negative, with the exception of specimens for which *P. acnes* or *Actinomyces* spp. are common pathogens. These specimens would include prosthetic joint implant infections (PJI), specimens of aqueous humor or specimens from patients suspected to have endophthalmitis, cultures of postcataract specimens, CSF specimens from shunts, and specimens with request for *Actinomyces* spp. and/or those that demonstrate the presence of sulfur granules on Gram's stain.[65,66,224,324,431,499] There has been some controversy about the length of time needed for broths when *P. acnes* in particular is

being considered as a pathogen in infected prosthetic joints, especially when measures such as sonication of the joint are being used to prepare the inoculum. Some labs would incubate these broths for 10 days and others longer. Most recent articles have focused on incubation of at least 12 days before discarding these as negative. It is not certain whether this holds true for all specimens in which *P. acnes* is being suspected, but there will probably be continuing work and publications in this area.[65,66,275,419,431,480]

In regard to the processing of orthopedic specimens for culture in general, there is literature to support the sending of multiple specimens to the laboratory for aerobic and possibly anaerobic culture as well from the same site. The principle behind this practice is that many of the infecting organisms are normal skin microbiota organisms, in particular coagulase-negative staphylococci, and if the organism appears from three or more specimens, there is a higher likelihood that it is the pathogen in the infection; if it only grows from one or two of the specimens from the same site, then it is likely not the pathogen. This has at times led to the sending of >8 to 10 samples from one site, which is likely more than is necessary; there is evidence for sending 4 to 5 samples from a particular site.[17,115] Most of the work supporting these practices has been done with periprosthetic joint infections and revision arthroplasty. Each laboratory that receives such samples should work with their orthopedic colleagues to come to an agreement about the type and number of samples that is acceptable. There is no data to support the sending of multiple samples for fungal and mycobacterial cultures, however. Much work has been done with using molecular techniques for the identification of organisms directly in these orthopedic revision arthroplasty specimens and these techniques may be used more commonly in the future.[261,494]

Procedures for Handling Anaerobic Cultures

Inspection and Subculture of Colonies

After incubation, plates incubated in 5% to 10% CO_2 atmospheres should be examined with a hand lens or, preferably, a dissecting microscope. If anaerobic jars are used, a holding jar system should be used at the time of colony examination and subculture to minimize exposure of oxygen-sensitive isolates to air. The anaerobic glove box and the anaerobic disposable bag systems (Fig. 16-6) allow inspection of colonies in the absence of air. Use of the stereoscopic dissecting microscope during examination of colonies is extremely helpful because a number of anaerobes have distinctive colonial features. The dissecting microscope is also a valuable aid during the subculture of colonies to obtain pure cultures. During the inspection of colonies, any distinguishing characteristics on the medium, such as hemolysis of blood agar or clearing of EYA, as

well as the size and distinctive features of the colonies should be recorded. A number of characteristic colonies of anaerobes are illustrated in Image Plates 16-1, 16-2, 16-3, and 16-4. When recording colony characteristics, the following should be noted: the age of the culture and the type of medium, the diameter in millimeters of each colony in addition to the color, surface features (glistening, dull), density (opaque, translucent), consistency (butyrous, viscid, membranous, brittle), and other descriptive features (see Chapters 1 and 2).

Gram-stained smears of colonies from the anaerobic and CO_2-incubated plates should also be examined. Do not assume on the basis of colony and microscopic features only that colonies on plates that have been incubated in an anaerobic system are obligate anaerobes. Although the morphology and colony characteristics of certain anaerobes are distinctive, it is often impossible to distinguish some facultative anaerobes from obligate anaerobes without aerotolerance tests, even when the CO_2-incubated plates show no growth. Aerotolerance testing is very important to confirm that an isolate is an anaerobe.

The number of different colony types on the anaerobe plates should be determined and a semiquantitative estimate of the number of each type should be recorded (light, moderate, or heavy growth). Using a needle or a sterile Pasteur capillary pipette, transfer each different colony to another anaerobe blood agar plate to obtain a pure culture and an aerobic blood agar plate for aerotolerance testing (described below). If colonies are well separated on the primary isolation plate, a tube of enrichment broth, such as enriched thioglycolate or chopped-meat glucose medium, should be inoculated to provide a source of inoculum for differential tests. After incubation, the media should be inspected for turbidity or other evidence of growth. Once there is evidence of growth in the liquid media, Gram's stain should be performed. If the organisms appear to be in pure culture, they can be used to inoculate appropriate differential media for identification of isolates.

Examine the primary enriched thioglycolate and chopped-meat glucose cultures along with all primary isolation plates. If no growth is evident on the primary anaerobic plates, or if the colonies isolated fail to account for all the morphologic types found in the direct Gram-stained smear

of the specimen, the broth medium, if turbid, should be subcultured to two anaerobe blood agar plates, one for anaerobic incubation and the other incubated in a 5% to 10% CO_2–air incubator. Alternatively, a chocolate agar plate can be used for the subculture plate to be incubated in the 5% to 10% CO_2–air incubator. These subculture plates should then be examined as described above.

Aerotolerance Tests

Each colony type from the anaerobic isolation plate is subcultured to an aerobic (5% to 10% CO_2) and anaerobic blood agar plate for overnight incubation. An assessment is then made regarding the ability of the organism to grow in 5% to 10% CO_2, as well as the preference of the organism (i.e., if it grew in 5% to 10% CO_2, did it grow better than under anaerobic conditions or, conversely, were the anaerobic conditions preferential for growth.) (Figure. 16-8).

Preliminary Reporting of Results

Results of the direct Gram's stain and information about the probable presence of anaerobes should be reported to clinicians as quickly as possible so that appropriate therapy can be instituted. Unfortunately, a period of 3 days or longer is often required for these studies to be completed. Clinicians should be made aware that this extended time frame cannot be avoided with some slow-growing anaerobes (e.g., some species of *Actinomyces* and *Propionibacterium*). Fortunately, the colonial and microscopic morphology of certain anaerobic bacteria is often so distinctive that preliminary or presumptive reports of these isolates can be made prior to aerotolerance studies. Examples include *Clostridium perfringens*, members of the *Bacteroides fragilis* group and the pigmented *Prevotella* and *Porphyromonas* group, among others.

Identification of Anaerobic Isolates

Determination of Cultural and Biochemical Characteristics

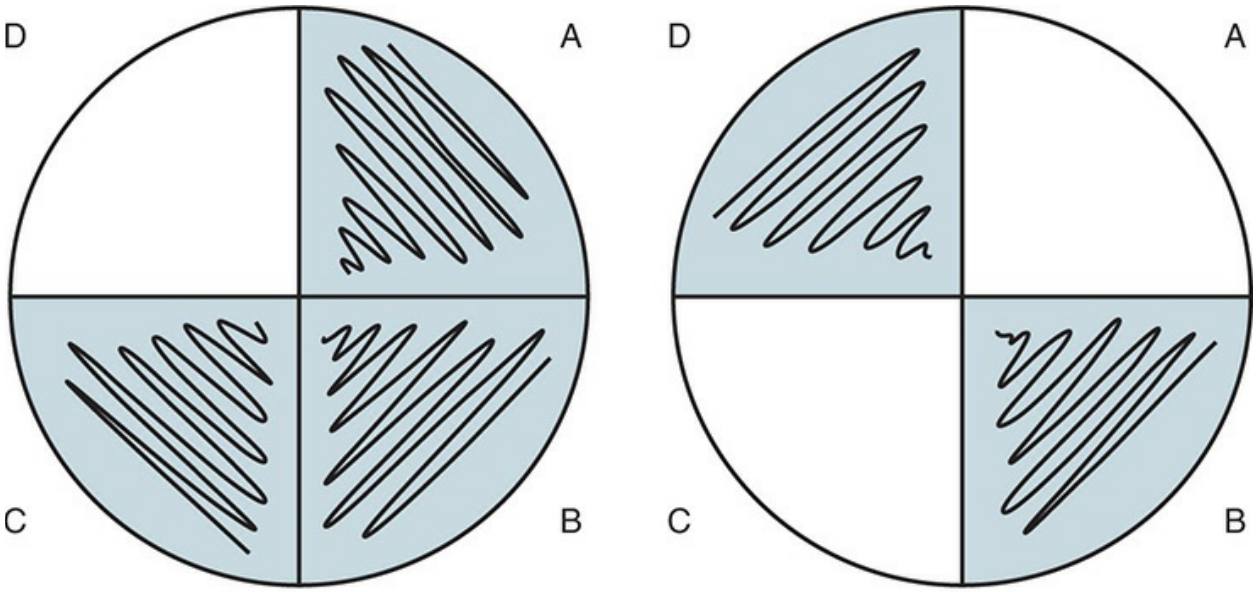
Once the presence of anaerobes has been confirmed by aerotolerance tests and a description of morphologic features has been reported, the next priority is to identify the pure culture isolates and to report the results to the clinician as rapidly and as accurately as possible. Although several hundred species of anaerobes are currently recognized by taxonomists, the task of identifying anaerobes for the clinical microbiologist is not nearly as formidable as it might seem because only a relatively small number are involved in anaerobic infections with any frequency.[160,238] Molecular methods and mass spectrometry (MALDI-TOF) are currently being employed to greatly reduce the time to identification.

Presumptive Identification

Nearly all clinically significant isolates are moderate obligate or aerotolerant anaerobes, and with practice are not particularly difficult to isolate and identify. In addition to organisms of the *Bacteroides fragilis* group, the pigmented *Prevotella-*

Porphyromonas group, *F. nucleatum,* and the anaerobic cocci that are quite frequently isolated, certain other, less common, anaerobes nonetheless have major pathogenic potential. Consequently, it is important to be familiar with and be able to recognize *Actinomyces israelii*, *A. naeslundii*, *A. meyeri, Propionibacterium acnes,* and *P. propionicum,* all of which may cause serious acute suppurative and chronic inflammatory disease; *Fusobacterium necrophorum*, which can be a highly virulent pathogen; *C. septicum*, an organism frequently associated with carcinoma of the colon or hematopoietic malignancy when isolated from blood cultures; the "histotoxic" clostridia in addition to *C. perfringens*, which can cause gas gangrene and various wound infections; *C. difficile*, a major cause of AAD and colitis; and *C. tetani* and *C. botulinum* because of the diseases they cause.[160,238,464]

Reference laboratories commonly use large batteries of tests in characterizing anaerobe isolates referred to them for identification or confirmation, similar to that listed in Box 16-11. In addition, new species are being recognized based on use of chemotaxonomic methods, nucleic acid sequencing and MALDI-TOF, which is becoming more common especially in reference laboratories. The data derived from the characterization of cultures with large numbers of tests has provided valuable databases for compiling tables of differential characteristics such as those published by the CDC, VPI, and State University and Wadsworth Anaerobe Laboratories. However, in most clinical diagnostic laboratories, it is not practical or economically feasible to use such a large number of differential media and biochemical determinations to identify isolates from clinical specimens.



Anaerobe blood agar incubated anaerobically

Aerobic blood agar plate incubated in candle jar

■ **FIGURE 16-8** Quadrant plating technique used for aerotolerance testing of four anaerobe isolates. The left plate has been incubated in an anaerobe jar for 18 to 24 hours, whereas the plate on the right was incubated in a candle jar. Isolates A and C are obligate anaerobes. Isolate B is facultatively anaerobic. Isolate D is possibly a microaerophile and should be tested further for its ability to grow in ambient air compared with an environment containing CO_2. A candle jar is not adequate for testing Campylobacter jejuni; this species grows optimally in 5% to 10% CO_2, 10% CO_2, and 85% N_2.

1020

BOX 16-11

Key Identification Characteristics of Anaerobic Bacteria

Relation to O_2 after aerotolerance testing is complete
Colony morphology: use of hand lens or dissecting microscope recommended
- Description of edges, internal structure, size
- Key characteristics: pigment, hemolysis, fluorescence, pitting of agar
- Time of incubation until appearance of colonies

Gram's stain characterization and morphology
- Include shape and arrangement of cells
- Comment on spores, filaments, branching, irregular staining

Type of growth in liquid media
Rapid or spot tests: growth in presence of 20% bile (BBE); catalase, indole, inhibition by sodium polyanetholsulfonate (SPS)
- EYA plate for lecithinase and lipase

Antibiotics potency disk tests: vancomycin, kanamycin, colistin; sometimes rifampin
Biochemical tests (often in kit format):
- Hydrolysis of starch, esculin, and gelatin
- Reduction of nitrate
- Fermentation of key carbohydrates: glucose, arabinose, cellibiose, sucrose, lactose, and others

Mass Spectrometry (MALDI-TOF)
16S rRNA Sequencing
Antibiotic susceptibility, if part of laboratory protocol or upon request
Optional:
- Metabolic products (GLC)
- Polyacrylamide gel electrophoresis of soluble proteins
- Cell wall long-chain fatty acids; menaquinones

Performed in reference laboratories only:

Toxicity, toxin neutralization, pathogenicity in animals

Fortunately, certain characteristics are especially useful in the identification of anaerobes (Chart 16-2). These characteristics form the basis of a practical approach for identifying anaerobic isolates that are commonly encountered in the clinical laboratory and additional species that either are less common or are potential major pathogens, even if they are rare.

Use of Differential Agar Media and Spot Tests

Several important characteristics for identifying anaerobic bacteria can be obtained with pure cultures on CDC anaerobic blood agar and in enriched thioglycolate medium. These characteristics, outlined in Chart 16-2, provide important clues for differentiating anaerobes in general. Additional characteristics are determined by use of differential antibiotic disks, which are added to freshly inoculated anaerobe blood agar plates. A 2-U penicillin disk, 1,000-mg kanamycin disk and 15-mg rifampin disk (available from Becton Dickinson Microbiology Systems) aid in the differentiation of anaerobic gram-negative bacilli and other anaerobes. The method for inoculation and use of these antibiotic potency disks is available in Chart 16-3. Colistin and vancomycin disks may also be extremely useful, as described elsewhere.[238] A sodium polyanetholsulfonate disk test is a practical way to separate *Peptostreptococcus anaerobius* from other anaerobic cocci. A nitrate disk test is a convenient method to demonstrate nitrate reduction during the workup of selected anaerobic bacteria. Three types of quadrant plates, labeled Presumpto Plate 1, Plate 2, and Plate 3, were developed by anaerobic microbiologists, Dowell and Lombard, and their associates in the 1980s to provide a system that would determine 20 phenotypic characteristics of anaerobes at a minimal cost. More information about the contents of, inoculation of and interpretation of these plates can be found in Image Plate 16-5, as well as in Charts16-2, 16-3, 16-4, and 16-5. Presumpto Plate 1 was available from Remel (now Thermoscientific); Anaerobe Systems (CA) can prepare EYA and at one time did make the other media upon request, but this author could not find anyone who sold all three-quadrant plates as of this writing.

Characteristics that can be determined with each of the three-quadrant plates are shown in Chart 16-5. The method for Inoculation of the Presumpto Quadrant Plates can be found in Chart 16-3.

Antibiotic Special Potency Disk Tests

Growth Inhibition on Anaerobe Blood Agar Using Antibiotic Disk Test. Zones of inhibition around the antibiotic disks are observed and recorded as follows:

Penicillin, 2-U disk: susceptible (S) if zone of growth inhibition is >12 mm in diameter; and resistant (R) if the zone is <12 mm.

1021

Rifampin, 15-mg disk: susceptible (S) if zone of growth inhibition is >15 mm; and resistant (R) if zone is <12 mm.
Kanamycin, 1,000-mg disk: susceptible (S) if zone of growth inhibition is >12 mm; and resistant (R) if zone is <12 mm.

The antibiotic disk potency tests are particular useful for differentiating between various gram-negative bacilli and gaining a presumptive identification. However, with the large number of anaerobes that are now being identified using molecular methods or MALDI-TOF, as well as the increasing resistance seen among many anaerobic bacteria, the utility of this assay may wane. Tables 16-11 and 16-27 provide information about how this can be used for the presumptive identification of anaerobic gram-negative bacilli and gram-positive cocci, respectively.

Use of SPS and Nitrate Disk Tests

(Inoculation of the sodium polyanethol sulfonate (SPS) and nitrate disks can be found in Chart 16-3).

SPS Disk Test. Measure the zone of inhibition around the 1-inch disk. A >12-mm zone of inhibition is recorded as susceptible (S). This test is specifically useful for the identification of *Peptostreptococcus anaerobius* and not for the determination of susceptibility testing for therapeutic guidance.

Nitrate Disk Test. Test for nitrate reduction by adding one drop of nitrate A reagent (sulfanilic acid) and one drop of nitrate B reagent (1,6 Cleave's acid) to the disk.[238] A pink or red color indicates that nitrate has been reduced to nitrite. If the disk was colorless after the addition of reagents A and B, then sprinkle zinc dust on the disk to confirm a negative reaction. The development of a red color after zinc dust is added confirms that nitrate is still present in the disk (a negative reaction).

The anaerobe blood agar (CDC anaerobe and other formulations), selective and nonselective media for primary plating, and PRAS media are available commercially from ThermoScientific Remel Microbiology products (www.remel.com), Hardy Diagnostics (www.hardydiagnostics.com), Anaerobe Systems (www.anaerobesystems.com), and BBL Microbiology Systems (www.bd.com) Remel. Details for preparation of the media and reagents may be found in previous editions of this textbook and elsewhere.[18,123] If prepared in one's own laboratory, there is the option of putting a single differential medium in a plate and not using quadrant Petri dishes. This approach increases the flexibility of the system for microbiologists who

would prefer to use other combinations of tests.

Identification of Anaerobes Using Phenotypic Characteristics

Conventional Approaches. It is not possible in this textbook to discuss all the procedures that are available for biochemical characterization of anaerobes. Tubed media can be purchased from some of the vendors mentioned above that also supply agar media for anaerobes. For further details on the use of conventional tube media, refer to the laboratory manuals on anaerobic bacteriology.[123,238]

Use of conventional media in Hungate or other large tubes is relatively time-consuming, and the media are costly to prepare or purchase. As alternatives to conventional media and methods, as well as to the Presumpto Quadrant Plate system, a variety of other procedures for characterizing and identifying isolates and alternative identification schemas have been described.[9,238] A number of these contain smaller volumes of media in containers that can be manipulated with reasonable speed at the bench. One of the more popular alternative approaches has been to test for certain key characteristics of isolates on differential agar media (e.g., BBE agar). Another has been to use disks impregnated with antibiotics or various other chemicals to test for growth inhibition or growth stimulation. Another excellent approach has been to use small tablets (e.g., WEE-TABS, Key Scientific Products, www.keyscientific.com) for determining certain enzyme-chromogenic substrate reactions. WEE-TABS have been used both as supplemental or stand-alone tests for differentiating various anaerobes. Details for their use and descriptions of several other tests for characterization of anaerobe isolates are given in the *Wadsworth Anaerobic Bacteriology Manual*,[238] on the Key scientific website and reviewed elsewhere.

Commercial Microsystems for the Identification of Anaerobes. Historically, two commercial packaged micromethod kits developed in the 1970s have continued to be used in clinical microbiology laboratories for identification of anaerobes, namely the API-20A (bioMérieux Vitek) and the Minitek (Becton Dickinson Microbiology Systems). The construction and use of these systems have been reviewed by Stargel et al.[460] These required overnight incubation and the use of manual or computerized databases for identification.

In addition, several manufacturers have marketed packaged kits that test for preformed enzymes, eliminating the need for overnight incubation. Most of these systems utilize a battery of chromogenic substrates to rapidly test for a number of amino peptidases and glycosidases. Each system requires the preparation of a heavy cell suspension from the surface of a purity plate culture. These packaged kits enable the microbiologist to determine multiple enzymatic characteristics of a pure culture isolate after 4 hours or less of aerobic incubation. Except for the API-ZYM kit,[27,314]

all of these packaged systems provide numerical codes, computerized databases and identification tables to aid in identification once an isolate has been characterized using the system. In a survey of laboratory methods being used in clinical laboratories in 2008, preformed enzyme kits were used by 66% of laboratories, whereas 30% used special potency disks (discussed above) for identification.[191] The list of products used for performing these tests includes the following:

API ZYM (bioMérieux Vitek)[314,460]
Crystal Anaerobe Identification System (Becton Dickinson Microbiology Systems)[43,79]
MicroScan Specialty Rapid Anaerobe Panel (Siemens Diagnostics)
RapID-ANA II (Thermoscientific Remel or Oxoid Products)[315]Rapid ID 32A (bioMérieux Vitek)
Vitek 2 ANC Card (bioMérieux Vitek).[43,286,391]

These kits are popular with microbiologists and are being used widely in diagnostic microbiology laboratories. In general, they are simple to use and less time-consuming than

conventional methods. A detailed description of each of the systems, including the substrates, procedures for use, interpretation of test results and a discussion of performance evaluations is available elsewhere or at each of the manufacturer's websites. Many of the packaged microsystems listed above must be supplemented with additional tests for accurate and definitive identification of selected groups of anaerobes (e.g., use of EYA for clostridia other than *C. perfringens*; the use of rapidity of growth and growth appearance in liquid as well as solid media, several additional supplemental tests, plus gas-liquid chromatography (GLC) for the complete identification of anaerobic gram-positive NSF rods; the use of 20% bile, esculin, selected conventional carbohydrate tests for *Bacteroides* spp., as well as additional tests for other anaerobes. Of course, it is still necessary to observe and correctly interpret Gram's stain reactions, consider microscopic and colony morphology and incorporate the results of aerotolerance tests. Pure cultures must always be used when attempting to differentiate anaerobes with the commercial packaged systems. When a kit produces an identification of a rare species, one should not accept this identification without repeat testing with alternative procedures, or perhaps confirmation from a reference laboratory when relevant clinically.

Determination of Metabolic Products by Gas-Liquid Chromatography. Metabolic products, released into broth culture media during anaerobic growth, are

key characteristics of anaerobic bacteria and many facultatively anaerobic bacteria. Together with determining the relationship to oxygen, most anaerobic bacteria can be identified to the genus level based on presence or lack of spores, Gram reaction, cellular morphology, and results of GLC analysis. This technique improves the speed and accuracy of identification; cost actually decreases because of the time saved.[338] Use of GLC in many clinical laboratories has, however, been greatly reduced and in many cases eliminated. It is still performed in reference and research laboratories and if needed, one could send isolates out for testing. Examples of GLC testing are included in Figures 16-9 and 16-10, as well as in Chart 16-6; additional information is also available in past editions of this textbook and anaerobe texts, if needed.[238,519] The definition of genera based on metabolic pathways remains scientifically valid, since the metabolic pathways of these organisms represent genetically stable or conserved traits of the bacteria. The schemas in Tables 16-9 and 16-10 illustrate the value of acid metabolic product analysis for differentiating genera of anaerobic bacteria. Although GLC analysis is not mandatory for presumptive identification of the *B. fragilis* group, the pigmenting anaerobic gram-negative bacilli, *F. nucleatum, C. perfringens, P. anaerobius,* and a few other anaerobes commonly recovered from clinical specimens, it is necessary for definitive identification of many species of *Bacteroides* and *Fusobacterium*, for most *Actinomyces, Bifidobacterium, Clostridium* species other than *C. perfringens, Eubacterium, Lactobacillus, Propionibacterium*, and for nearly all of the anaerobic cocci, unless molecular or mass spectrometry methods are utilized.[238]

Gas chromatography instruments are now relatively inexpensive, safe, simple to operate, reliable and are commercially available from various scientific instrument manufacturing companies. Equipment and procedures for determining metabolic products by GLC are described in more detail elsewhere.[238,338] Charts 16-6 and 16-7 provide procedures for inoculation of a gas chromatography instrument for detection of volatile and nonvolatile fatty acids, respectively.

Inject

■ **FIGURE 16-9** A typical volatile acid standard chromatogram. The time elapsed between the injection of an ether extract of the standard solution and the peak for each acid (i.e., the retention time) is used to identify the acids. Note, for example, that the retention time for acetic acid is 1.8 minutes and for valeric acid is 6 minutes (instrument used: Dohrmann Anabac, Clinical Analysis Products, Sunnyvale, CA; Detector: thermal conductivity; column packing: 15%, SP–1220/1% H_3PO_4 on 100/120 Chromasorb W/AW from Supelco, Bellefonte, PA).

Identification of Volatile Fatty Acids. GLC is used for identifying short-chain, volatile fatty acids that are soluble in ether. The acids detected with this procedure include acetic, propionic, isobutyric, butyric isovaleric, valeric, isocaproic, and caproic. The procedure is explained in Chart 16-6.

Volatile fatty acids can be identified by comparing elution times of products in extracts with those of a known acid mixture (volatile fatty acid standard) separated under the same conditions on the same day. A representative standard tracing is shown in Figure 16-9.

Identification of Nonvolatile Acids. Pyruvic, lactic, fumaric, succinic, hydrocinnamic, and phenylacetic acids are not detected with the ether extraction procedure for volatile fatty acids (above). These nonvolatile acids are identified after preparation of methylated derivatives. The procedure is outlined in Chart 16-7. Analysis of chloroform extracts is performed using the same chromatographic conditions as for the volatile acids. The identification of nonvolatile or methylated acids is achieved by comparing elution times of products in extracts with those of known acids separated by chromatography on the same day.

The metabolic products of common species of anaerobic gram-negative rods are listed in Tables 16-16 and 16-21.

Use of Molecular and Mass Spectrometric Methods (MALDI-TOF) for Identification of Anaerobic Bacteria

Use of 16S rRNA Sequencing for the Identification of Anaerobes. Anaerobes are responsible as single pathogens or in polymicrobial infections in many clinical situations and yet there is often limited capability for their isolation and identification in many clinical laboratories. The various methods for recovery of anaerobes have been discussed in this chapter, as well as the use of specialized media and prolonged incubation in appropriate anaerobic conditions to enhance recovery. Most laboratories use phenotypic methods of identification and hence this often requires prolonged periods of time from isolation to identification, and at times, significant anaerobes may remain unrecognized, unidentified, or identified incorrectly. The use of molecular techniques, especially sequencing of the 16S rRNA, is rapidly changing these issues and may in time enhance the level of our understanding of the incidence and relevance of anaerobes in clinical disease. Whether or not all anaerobes in a culture should be characterized and reported because they may now be identified accurately and rapidly will remain an issue that warrants study, but use of sequencing can expand our knowledge of common and more fastidious organisms, which includes anaerobic bacteria. As with most molecular tools, the creation of a robust and consistent database is crucial to correct identification and this is still in its infancy in regard to anaerobes. However, numerous examples can be given in which use of sequencing has led to clarification of which anaerobes are involved in common and less common infections.[412,430,442,472,520,523] It has become the reference method used in studies of other methods for identification, especially the ongoing MALDI-TOF studies, and the

methods used to determine taxonomy and relatedness of anaerobic organisms.[106,179,279,491] Its use in determining the anaerobic normal microbiota of the GI and GU tract may change how we approach the identification of anaerobes in clinical infection, as well as, treatment practices in diseases such as bacterial vaginosis and recurrent *C. difficile* disease.[212,434,504] If only phenotypic characteristics are used to identify anaerobes in the GI tract, for example, only about 24% of the species in feces can be described as compared to the number of species detected when using molecular tools.[238] The same is probably true for the cause of clinical diseases in which traditional tools may not be adequate for definitive identification. Use of direct PCR and sequencing has been shown to have an advantage in patients presently on antimicrobial therapy and for the identification of pathogens, like anaerobes, that have specific growth requirements.[387]

Use of Mass Spectrometry for Identification of Anaerobes. There is a great deal of literature on the use of MALDI-TOF for the identification of bacteria and yeasts in clinical microbiology laboratories. This method is a soft ionization method which allows desorption of peptides and proteins from colonies of bacteria as well as crude bacterial extracts. Minimal preparation is required and the time to identification may be as little as minutes, as compared to the hours and sometime days needed for conventional biochemical identification of bacteria. Certainly, for many anaerobes, identification times can be very lengthy and in some cases still not definitive, especially if the isolate is not one commonly encountered in the laboratory. The initial capital cost of the mass spectrometer instrument may appear prohibitive for some laboratories. However, the low cost per identification compared to conventional methods can be used to readily cost-justify the instrument in most instances. There have already been many studies demonstrating the utility of MALDI-TOF for the identification of anaerobes (Table 16-8).

1024

TABLE 16-8 The Use of MALDI-TOF for the Identification of Anaerobes

Isolates Tested	MALDI-TOF System Used	Comparator	Results	Comments	Reference/Year
193 *Bacteroides* spp.	Bruker	Rapid 32A and 16S rRNA	MALDI: 87% correct ID and 93% agreed with PCR RAPID 32A: 52% species agreement with PCR	Easy and cost-effective and better identification than Rapid 32A; need to enhance databases	111; 2012
152 Clinical isolates: 45% GPB 35% GNB 20% Cocci	Bruker	Phenotypic and 16S rRNA	79% agreement to genus and species (using score of >2.0) 86% agreement to genus (>1.8) 92% *Actinomyces* spp. were correct	Most problems with *Fusobacterium* identification to species level; need expansion of database; Successfully used BBE medium for some isolates	154; 2012
238 Clinical isolates	Bruker	16S rRNA	**With extraction:** 78% genus and species, 14% genus only,8% with incorrect or no identification **No extraction:** 66% to genus and species 20%–13% incorrect or no ID	Direct smear not inferior to extraction	171; 2012
290 Clinical isolates: 73 *Clostridium* spp. 11 *Bacteroides* spp. 11 *Actinomyces* spp.	Both	16S rRNA	**Vitek:** 44%–49% for genus and species, 12% genus only, 1.4% incorrect identification, 13% no identification **Bruker:** 67% to genus and species, 8% incorrect identification	Bruker gave more correct identifications but also more incorrect identifications as compared to Vitek MS. Pretreatment with formic acid with the Bruker system enhanced identification of *C. ramosum*. Metronidazole-resistant gram-positive rods posed a problem with identification.	242; 2011
544 Isolates of 79 species 130 *P. acnes* 52 *Fusobacterium* spp. 117 *B. fragilis* group	Bruker	16S rRNA	MALDI identified 61% overall 16/212 isolates with no identification were not in the database Were able to identify 11 new organisms with MALDI and sequencing	*P. acnes* performed well Labs will be faced with "burden" of "new" anaerobes with MALDI and sequencing	276; 2011
283 Clinical isolates: 140 GNB 73 *Clostridium* spp. 8 *Actinomyces* spp.	Bruker	Conventional ID and then 16S rRNA for discordants	77% Identified to genus and species 11% to genus level 12% Nonreliable identification; after sequencing of discordants, 0.7% were incorrect MALDI results	Enhanced results using lower MS scores *P. acnes* did well Discussed need to enhance database Discovered many incorrect *B. fragilis* group identifications with phenotypic method	352; 2012
253 Clinical isolates: 40% GPB 27% GNB 32% Cocci	Bruker	16S rRNA	71% identified to genus and species and another 20% to genus level using manufacturer cut-offs 4% misidentifications at score of >2.0 and <1% at score of >1.7	Enhanced database useful; on-plate extraction worked well MALDI offered a rapid, inexpensive method for identification of anaerobes	417; 2013

1025

107 Isolates of GPC	Vitek	16S rRNA and FISH	90% good identification; only three isolates could not be identified	Excellent tool for identification of phylogenetically heterogeneous groups of anaerobes like the GPC	490; 2011
79 isolates	Both	16S rRNA	**Vitek:** 61% to genus and species; up to 71% to genus **Bruker:** 51% to genus and species; up to 61% to genus	Correct identifications for both were improved if organisms not in database were removed. Vitek performed better with GPCs and Bruker with the *B. fragilis* group.	492; 2011
102 *Prevotella* spp.	Bruker	16S rRNA	63% identified to species and 73.5% to genus level only Improvement to 83% to species and 89% to genus if database was extended	Identification of *Prevotella* is good, but database needs to be expanded	527; 2012
651 isolates of 11 genera	Vitek	16S rRNA	>90% correct ID to species level	Performed poorly (no identification) for some *B. uniformis*, *Fusobacterium* sp. and *Actinomyces* spp. Overall, the system provided excellent accuracy with rapid turnaround time	179; 2013
73 isolates (Part of large study of aerobes and anaerobes)	Both	16S rRNA	**Vitek:** 75% to genus and species 3% more to genus 18% no identification **Bruker:** 62% to genus and species 22% more to genus 15% no identification	Both performed very well with equivalent efficiency for all isolates. *Fusobacterium* spp. were poorly identified to species level with Bruker and Vitek misidentified more *Bacteroides* spp.	318; 2012
274 isolates	Both	API 20A; discrepant results with 16S rRNA	**Vitek:** 100% identified at the genus and species level **Bruker:** 89% identified at the genus and species level, 10% more at only genus level, and 0.72% misidentifications	Both platforms performed well and MALDI could be used as the first line of anaerobic identification to save time.	231; 2013

1026

Biswas and Rolain reviewed the literature that used both or either of the Bruker and Vitek instruments; these were able to demonstrate a >85% accuracy in 10 of 13 published papers, although the majority of the work was done with more common anaerobe species.[42] The need for a robust extraction method prior to testing remains

unresolved.[171,242] The importance of a robust database has been denoted by many researchers, not only for anaerobes, but for most organisms for which MALDI-TOF has been evaluated.[154,242,254,279,318,352,492] A multicenter study reported that >90% of the 651 anaerobes, which included 11 different genera, were correctly identified to species level using the Vitek MS system as compared to 16S rRNA sequencing; furthermore, these identifications were achieved without the need for extraction. There were some strains of gram-negative bacilli (*Fusobacterium* and *B. uniformis*) and *Actinomyces* that gave no identification results, but the authors felt the system overall provided excellent accuracy with rapid turnaround time.[179] Another large study in France evaluated MALDI-TOF for 1,325 anaerobes and found that 92.5% were correctly identified to the species level, including several uncommon or rare species. These authors felt that MALDIT-TOF was becoming the "gold standard" for the identification of anaerobes in the routine clinical laboratory.[31]

Use of the Bruker MALDI-TOF system for the identification of 484 anaerobes (>75% *Clostridium* spp. with >70% of these being *C. difficile*) resulted in >94% with correct identification versus 16S rRNA sequencing confirmation and 100% specificity for the *Clostridium* spp. tested. Performance was not good for *Fusobacterium* and *P. acnes* isolates; however, pretreatment of the colonies solved that problem in most instances.[106] Another study using a more diverse mixture of gram-positive and gram-negative anaerobes, analyzed 253 isolates of which 71% were correctly identified to species level and 92% to genus level (compared to phenotypic and molecular methods for comparison) using the Bruker system and on-plate extraction.[417] At least three comparative studies of both of the commercially available mass spectrometry instruments are in the literature analyzing the identification of anaerobes: one analyzed 290 anaerobes, demonstrating more species identifications with Bruker over Vitek MS (67% vs. 49%), but Bruker also had more incorrect identifications (8% vs. 1%). Sequencing was used for confirmation of discrepancies. The authors felt both systems showed real promise for anaerobic identification, but each database needed to be optimized for better performance, since many isolates were identified but were not found in the respective databases; in the case of Bruker, the manufacturer-suggested cut-offs for identification need to be adjusted for better results.[242] The second comparative study only analyzed 79 clinical isolates and found >61% correct identification for both systems and concluded, like the study above, that the databases needed to be further enhanced.[492] The third comparative study analyzed 274 clinically significant anaerobes, comparing results of MALD-TOF to API 20AN and found 100% correct identifications for the Vitek MS and 89% for Bruker after molecular confirmation was performed.[231] A large laboratory in France compared the identification of 1,506 isolates of anaerobes using conventional phenotypic methods during a specific time frame over 11 years versus MALDI-TOF in which 1,564

anaerobe isolates were identified. Forty distinct species were identified in the 1,506 isolates characterized by conventional methods, whereas 103 distinct species were identified within the 1,564 isolates characterized by MALDI, more than doubling the number that could be identified; the authors felt that MALDI might be used in place of molecular methods even for identification of rare human pathogens since the study also involved >280,000 isolates of aerobic isolates.[422] There are some anaerobic species (similar to aerobes) in which MALDI may not perform as well as molecular methods or even phenotypic methods for differentiation between species. For example, a recently described *Bacteroides fragilis* group member, *B. dorei* could not be differentiated from *B. ovatus, B. vulgatus,* and *B. xylanisolvens* with MALDI, but these could be distinguished using β-glucosidase and catalase tests; these could also be differentiated using sequencing-based methods.[370]

A potential advantage of the use of sequencing or MALDI-TOF is the direct identification of anaerobes in the clinical specimen by sequencing and more rapid isolate identification by MALDI-TOF to provide even more rapid results to the clinician. MALDI-TOF has been evaluated for the identification of positive BacT/Alert blood culture bottles and results were good; a >24-hour time-to-result was achieved when the MALDI-TOF was used in contrast to conventional methods.[168,327] The combination of sequencing and MALDI-TOF is certainly going to continue to be used to further clarify microorganism taxonomy, and will likely help to define the clinical relevance of many anaerobes not readily identified by phenotypic means. It may well be that MALDI-TOF, if improved as suggested, will become a routine tool for the identification of anaerobic bacteria, as it has for aerobes in many clinical laboratories. Individuals who are teaching the new generation of medical technology students need to incorporate the traditional methods of identification with these newer methods so that laboratorians retain expertise in Gram's stain interpretation and colonial morphology, which remain important skill sets. In many ways, the best method for identification is a combination of the "old" and the "new."

Identification of Specific Groups of Anaerobic Bacteria

Levels of Identification in Different Laboratories

An extensive update on the nomenclature (current names and former names) of the anaerobic bacteria is provided in Table 16-2. Fortunately, the anaerobes most important clinically and/or those most frequently isolated from properly selected and collected clinical specimens comprise a much smaller list (Table 16-3). Only about 12 to 15 groups or species account for about 75% or more of the isolates from properly

collected specimens, at least using phenotypic means for identification. These include the *Bacteroides fragilis* group, the pigmented *Prevotella–Porphyromonas* group, *Fusobacterium nucleatum, Peptostreptococcus anaerobius, Finegoldia magna* (and a few other species of anaerobic cocci), *Propionibacterium acnes, Clostridium perfringens, C. ramosum,* and *Veillonella* spp. Laboratory personnel should be familiar with

1027

these species, because they are so common and often clinically significant. It is also especially important that clinical microbiologists know about and are able to recognize *Fusobacterium necrophorum, Actinomyces israelii, Propionibacterium propionicum,* the *C. clostridioforme* group, *C. septicum, C. difficile, C. botulinum, C. tetani* and a few other species (discussed later in the text), because these organisms may be highly pathogenic for patients.

Beyond considerations of the need to be familiar with the common and/or medically significant anaerobes, it has been proposed that microbiologists in clinical laboratories may wish to limit the extent of anaerobe identification, based on levels of capability.[9] All laboratories, even those with limited capability should be able to isolate anaerobes in pure culture and to evaluate the microscopic and colony morphology. Together with results of aerotolerance testing, this information would then be reported to the clinician, as a preliminary report. In a laboratory with limited capability for identification of anaerobes, if the isolate(s) is (are) deemed clinically relevant, the identification should be completed either in the laboratory, and if this is technically not possible, then it should be sent to a reference laboratory that can complete the identification. The following factors are important considerations in determining clinical relevance: there is a strong clinical opinion by an experienced clinician that the isolate is an etiologic agent of disease; the direct Gram-stained smear of a wound or abscess, peritoneal fluid or other sterile specimen, demonstrates evidence of acute inflammation (i.e., numerous polymorphonuclear leukocytes, but a lack or limited number of squamous epithelial cells) or necrosis; the direct Gram's stain contains a microorganism that correlates with the culture findings (e.g., microscopic evidence of clostridial myonecrosis (Plate 16-3D); sulfur granules suggestive of actinomycetes are present (Image Plate 16-2C and D); there are additional cultures from another body site that demonstrates the same microorganism that was recovered from the primary site (e.g., positive blood cultures contain *C. perfringins* in a patient with clostridial myonecrosis). Even laboratories with full capability of definitive identification of anaerobic isolates may wish to limit the extent of processing when there is no clinical reason to take the identification further. For example, if the laboratory receives a swab from surgery labeled "fecal spillage into the abdomen"; the culture and identification is

unnecessary as this specimen predictably will have a predictable mixture of anaerobic and aerobic microbiota. Identification of any or all of these organisms would have no clinical usefulness and would be inordinately expensive to complete full identification of everything isolated.

The second level of anaerobic workup would require, in addition to what can be done in laboratories with limited capability, some identification capability. Specifically, the differentiation of the *B. fragilis* group from the other gram-negative anaerobes and identification of *C. perfringens* are skills that should be retained, even in laboratories with limited capabilities. Isolates, which cannot be further identified in the laboratory of limited capabilities, that are considered to be clinically relevant should be transported to a reference laboratory for definitive identification of isolates.

The third level of capability would require the ability to accomplish a full identification of the 12 or so common anaerobe groups and species mentioned previously, by use of growth and phenotypic characteristics obtained by rapid tests, kit systems, GLC, nucleic acid sequencing and/or MALDI-TOF. Details of how morphology, growth characteristics, aerotolerance, some rapid spot tests, the Presumpto plate system and other practical methods permit recognition and separation of these groups and species are given in the text that follows. Laboratories capable of definitive identification have the choice of limiting identifications to the preliminary or presumptive levels described previously depending upon the quality of the specimen and the medical necessity for full identification. Laboratories capable of performing definitive identification might include those at large university medical centers, reference laboratories and state and federal public health laboratories.

There is little doubt that definitive identification is required to better define the role of anaerobic bacteria in diseases, to provide an accurate microbiologic diagnosis that can aid in the optimal choice of antibiotics and clinical treatment of the patient, for public health purposes (e.g., nosocomial diarrhea caused by *C. difficile*) and to help educate both clinicians and clinical microbiologists. The level of anaerobe identification depends on several considerations that will differ among laboratories; not all laboratories can be expected to perform the same levels of anaerobic bacteriologic studies. Factors that influence decision-making for the extent of identification include the technical competence and experience of the technologists, the number of personnel available, supplies and capital equipment, the patient population being served and the needs of the clinicians who have responsibility for their patients. Clinical microbiologists must be competent in the work that they do and should not hesitate to use the services of reference laboratories for aid in definitive identification or for reference confirmation of isolates, as well as antimicrobial susceptibility testing, toxigenicity testing, nucleic acid studies, or other procedures, when relevant clinically. Additional approaches and current information on anaerobe identification, based on various combinations of tests at different levels, is given elsewhere.[238] It is expected

that in the future many laboratories will have the capability for MALDI-TOF and/or molecular methods for identification, which would reduce even further the routine need for many of the above-mentioned biochemical tests and GLC. However, when working with anaerobes, it continues to be vital to always include information about the Gram's stain and colonial morphology of the organism, and to perform necessary aerotolerance testing to assist in confirmation of the newer identifications.

Tables 16-9 and 16-10 provide a key to the genus-level identification of anaerobic gram-negative rods and anaerobic gram-positive NSF rods. The discussion below will give information on the laboratory identification of each group of anaerobes.

Identification of Anaerobic Gram-Negative Bacilli

The anaerobic, gram-negative, NSF bacteria are now classified in the genera listed in Table 16-1. Key characteristics for presumptive or level 1 differentiation of these are given in Table 16-11. In spite of many exciting new taxonomic breakthroughs based on molecular genetic research, phenotypic tests are still important for clinical diagnostic purposes, and must be relied on in most hospital laboratories to identify anaerobes until simple, user-friendly, low cost molecular identification procedures or MALDI-TOF become widely available for these bacteria. Thus, for identification of isolates in diagnostic laboratories, clinical microbiologists continue to depend on key morphologic features, biochemical and physiologic characteristics, and in many instances, susceptibility or resistance to certain antimicrobial agents by use of antibiotic disk tests.

TABLE 16-9 Differentiation of Anaerobic, Gram-Negative, Non–Spore-Forming Rods to the Genus Level

I. Nonmotile or motile with peritrichous flagella; straight or coccobacillary rods	
A. Proposal by Shah and Collins[227] to include only the highly fermentative and bile-resistant species resembling *B. fragilis* (i.e., *B. distasonis, B. caccae, B. ovatus, B. thetaiotaomicron, B. merdae, B. vulgatus, B. uniformis, B. eggerthii, and B. stercoris*). Several other species remain in this genus; further studies are needed to determine their correct taxonomic location (e.g., *B. capillosus, B. coagulans, B. cellulosolvens, B. pectinophilus, B. tectum, B. ureolyticus*, and others). Until the latter group is reassigned, this genus remains heterogeneous.	*Bacteroides*[a]
B. Most often black-pigmented colonies; produces acetic, butyric, and succinic acids, with minor amounts of propionic, isobutyric, and	*Porphyromonas*[b]

isovaleric acids. All are asaccharolytic and indole-positive.	
C. Nonpigmented to pigmented colonies; bile-inhibited and saccharolytic; usually oral microbiota	*Prevotella*[a]
D. Bile-resistant, catalase-positive, nitrate-reduced, and urease-positive	*Bilophila*[b]
E. Found as a part of the human normal microbiota, but rarely encountered in properly selected clinical specimens	*Alistipes*[c] *Anaerostipes*[c] *Anaerorhabdus*[c] *Catonella*[c] *Cetobacterium*[c] *Dialister*[c] *Faecalibacter*[c] *Fibrobacter*[c] *Johnsonella* *Megamonas*[c] *Mitsuokella*[c] *Oxalobacter*[c] *Sneathia*[c] *Sutterella*[c] *Tannerella*[c] *Tissierella*[c]
F. Found in animals and nature.	*Dichelobacter*[c] *Pectinatus*[c] *Rikenella*[c] *Roseburia*[c] *Ruminobacter*[c] *Sebaldella*[c]
G. Produces major amounts of butyric acid (but little or no isoacids) as the major metabolic product; succinic acid is not produced; all species are nonmotile	*Fusobacterium*[a]
H. Lactic acid is the only major product; *L. buccalis*, the only species, is nonmotile.	*Leptotrichia*[b]
I. Acetic acid is the major acid metabolic product; produces hydrogen sulfide; reduces sulfate; *D. pigra*, the only species, is nonmotile.	*Desulfomonas*[c]
II. Motile, peritrichous flagella not produced	

A. Curved rods with monotrichous or lophotrichous polar flagella or subpolar flagella; butyric acid is a major product of fermentation.	*Butyrivibrio*[b]
B. Succinic and acetic acids are major products of fermentation.	*Succinimonas*[c]
1. Short, straight rods to coccobacilli; a single polar flagellum; found only in bovine rumen.	*Succinivibrio*[b]
2. Curved, helically twisted rods with pointed ends; vibrating-type motility by a single polar flagellum	*Anaerobiospirillum*[b]
3. Helical, curved rods; bipolar tufts of flagella	*Campylobacter*[d]
C. Microaerophilic; oxidase-positive, curved and spiral rods; single polar flagellum, with absence of a flagellar sheath; carbohydrates not fermented; produce succinic acid from fumaric acid	*Wollinella*[e]
D. Propionic and acetic acids are major fermentation products	
1. Tufts of flagella on concave side of crescent-shaped cells	*Selenomonas*[b]
2. Single polar flagellum; lipolytic; curved rods	*Anaerovibrio*[b]
3. Flagella are inserted in a spiral along the cell	*Centipeda*[c]

[a] Commonly found in clinical specimens.
[b] Rarely found in clinical specimens.
[c] Normal flora of humans or other animals only.
[d] *Campylobacter gracilis* is oxidase-negative and lacks flagella, but has "twitching motility"; it differs from other *Campylobacter* species in these two respects.
[e] *Wolinella succinogenes* has been isolated from the bovine rumen and is now the only species remaining in the genus *Wolinella*. It is difficult to differentiate from organism from the genus *Campylobacter*.

1029

TABLE 16-10 Differentiation of Anaerobic, Gram-Positive Bacilli to the Genus Level

I. Bacterial endospores not produced

A. Produce major amounts of propionic and acetic acids; catalase usually produced; irregular or regular-shaped rods, coccoid cells; occasional branching	*Propionibacterium*
B. Produce acetic and lactic acids (>1:1 ratio); very irregular rods with bifid forms and branching	*Bifidobacterium*
C. Produce lactic acid as sole major product	
1. Short to long and slender rods; chain formation common; irregular rods uncommon; usually grows on tomato juice agar at pH ≤4.5 (see Chapter 14)	*Lactobacillus*
2. Small, elongated cocci that occur singly, in pairs, or in short chains	*Atopobium*
D. Produce moderate acetic, lactic and major succinic acids; irregular rods predominant; filamentous forms with branching	*Actinomyces*
E. Produce mixtures of acetic, butyric, lactic and sometimes formic acids; pleomorphic diphtheroid rods; saccharolytic	*Eubacterium*
F. Produces minor amounts of acetic acid and traces of lactic and succinic acids; asaccharolytic	*Eggerthella*
G. Produces major amounts of acetic acid and a small amount of succinate; straight to curved rods with some branching ("*Actinomyces*-like")	*Actinobaculum*
H. Acetate and butyrate are the only acid metabolic products; saccharolytic; thin rods	*Anaerotruncus*
I. Produces major amount of lactate with variable amounts of formic, acetic and succinic acids; coccobacilli, pleomorphic, short diphtheroidal rods; facultatively anaerobic; saccharolytic; *A. pyogenes* is β-hemolytic on sheep blood agar	*Arcanobacterium*
J. Produces moderate amount of acetate and lactate, and trace amount of succinic acid; saccharolytic; short rods	*Bulleidia*
K. Acetic, butyric, isobutyric, and lactic acids produced; saccharolytic; occur as short rods in tangled chains	*Catenibacterium*
L. No metabolic products detected in peptone yeast extract glucose broth; asaccharolytic; very short rods	*Cryptobacterium*
M. Produces acetic, formic, and lactic acids, sometimes with a trace of succinic acid; abundant ethanol; saccharolytic; often in the form of	*Collinsella*

pleomorphic cocci to short rods; may be confused with streptococci or lactobacilli, but is distinguished by producing abundant H_2	*Collinsella*
N. Acetate and lactate are major products with a small amount of succinate; saccharolytic (weakly); short to long rods occur in pairs and short chains	*Holdemania*
O. Phenylacetic acid produced as sole metabolic product in peptone yeast extract glucose broth; asaccharolytic; short rods occur singly, in short chains, or clumps	*Mogibacterium*
P. Succinic and acetic acids are major fermentation products, with or without lactic acid; oxidase-negative, curved rods, motile with multiple subterminal flagella; fermentative in peptone yeast glycogen broth, supplemented with rabbit serum	*Mobiluncus*
Q. Produces formate, acetate, butyrate, caproate, and H_2; pleomorphic rods occur in pairs resembling birds in flight, clumps, or Chinese letters (formerly *Eubacterium alactolyticum*)	*Pseudoramibacter*
R. Produce only acetic acid or no acid metabolic products; occur in rods, cocci or coccobacilli in chains and clumps	*Slackia*
II. Bacterial endospores produced	*Clostridium*

Adapted from Winn et al.[519] and other references cited elsewhere in the text.

As previously indicated, the first major goal of identification should be to determine whether anaerobic bacteria are present and to isolate them in pure culture. The presence of anaerobic gram-negative rods suggestive of *Bacteroides, Prevotella, Porphyromonas,* or *Fusobacterium* spp., based on determining relationships to oxygen, together with the Gram's stain results and colony observations, should be promptly reported to the clinician. Presumptive or preliminary identification of the *B. fragilis* group, and the *Prevotella-Porphyromonas* group, along with other obligately anaerobic, gram-negative rods, can be done using differential characteristics obtained with growth characteristics (e.g., growth on blood agar, BBE, and EYA), fluorescence and a few simple disk/spot tests (Table 16-11). Additional clues for group identification along with key characteristics for various species are provided in Tables 16-12 through 16-16.

The *Bacteroides fragilis* Group. Organisms of the *B. fragilis* group are nonmotile, gram-negative rods with rounded ends, and are 0.5 to 0.8 mm in diameter × 1.5 to 9

mm long (Image Plate 16-1A).[238,464] Cells from broth culture tend to be pleomorphic, often with vacuoles; many strains are encapsulated which, as was described above in the section on human infections, contributes to the virulence of the species (Chart 16-10). Colonies of *B. fragilis* on CDC anaerobe blood agar are 1 to 4 mm in diameter, nonhemolytic, gray, entire, and semiopaque with concentric whorls or ring-like structures inside the colonies (Image Plate 16-1B). Colonies of other species of the group are similar in size and shape, but some of them differ with regard to their internal structures. A key characteristic of all species of the *B. fragilis* group is their resistance to 20% bile and ability to hydrolyze esculin, hence the utility of primary plating onto BBE agar along with nonselective blood agar. Colonies of the *B. fragilis* group on BBE after 18 to 24 hours will be large and black with blackening around the colony; they are nonhemolytic on blood agar. They are all resistant to penicillin, kanamycin, colistin, and vancomycin, but susceptible to the rifampin 15 µg disk (Table 16-11) All are saccharolytic and their carbohydrate fermentation patterns, along with indole, help to differentiate between the species. Detailed characteristics of the more common species of the *B. fragilis* group are given in Table 16-12. There are many of the 23 members of the *Bacteroides fragilis* group not included in Table 16-12; these have been isolated from feces and rarely if at all identified in clinical infections using traditional methods. These may be recognized, however, in clinical specimens if molecular methods are used for full identification. In many infections, it is not important to identify past the *B. fragilis* group level; however, this too may change as MALDI-TOF methods can provide species-level identification quite quickly.

1030

TABLE 16-11 Presumptive or Preliminary Identification of Anaerobic Gram-Negative Bacilli

Groups or Species	Grow on 20% Bile Agar (BBE)	Red Fluorescence (UV Light)	Brown or Black Colonies	PEN (2 U Disk)	RIF (15 μg Disk)	KANA (1 μg Disk)	COL (10 μg Disk)	Indole	H_2S	Lipase
B. fragilis group	+	–	–	R	S	R	R	V	–	–
Pigmenting *Prevotella/ Porphyromonas*	–$^{+}$	+	+	S or R[a]	S	R	R	+$^{-}$	–	–$^{+}$
B. ureolyticus[b]	–	–	–	S	S	S		–	–	–
F. nucleatum	–	–	–	S	S	S	S	+	–	–
F. necrophorum	V	–	–	S	S	S	S	+	+	+
F. mortiferum	+	–	–	R or S	R	S	S	–	+	–
F. varium	+	–	–	R or S	R	S	S	V	+	V
Bilophila wadsworthia	+[c]	–	–	R	S	S	S	–	+	–

[a] In the group, there is variability to the antibiotics and some strains may be resistant.
[b] *B. ureolyticus* is urease-positive and will corrode or "pit" the agar around their colonies; colonies are also small as compared to others in the table, <1 mm in diameter.
[c] *B. wadsworthia* on BBE agar will appear as a "black-eyed" colonies; it is strongly catalase-positive and urease-positive.
PEN, Penicillin; RIF, Rifampin; KANA, Kanamycin; COL, Colistin; R, Resistant; S, Susceptible; +, positive; –, negative; +$^{-}$, most strains are positive, but some strains negative; –+, most strains negative, but some positive; V, variable reactions among the strains.
Adapted from references 178, 238, and 263.

TABLE 16-15 Phenotypic Characteristics of *Fusobacterium* spp.

Species	Bile	IND	LIP	ESC	Conversion to Propionate From: Lactate	Conversion to Propionate From: Threonine	Gram's Stain Morphology	Colonial Morphology
F. gonidiaformans	−	+	−	−	−	+	Gonidial	
F. mortiferum	+	−	−	+	−	+	Round bodies; pleomorphic cells; often described as "bizarre"; irregular staining	Fried-egg appearing
F. naviforme		+	−	−	−	−	Boat-shaped	Mottled internal structure
F. necrophorumam[a]								
subsp. *fundiliforme*	−+	+	−+	−	+	+	Coccobacillary; no tapered ends; some filaments; bizarre forms	Yellow to cream color; smooth, round and entire; may fluoresce chartreuse under UV; greening of agar
subsp. *necrophorum*	−+	+	+	−	+	+	Pleomorphic; rod-shaped with round ends and bizarre forms	Dull, umbonate; may be β-hemolytic; may fluoresce chartreuse under UV light
F. nucleatum	−	+	−	−	−	+	Thin, tapered, pointed or fusiform ends	Speckled or opalescent colonies; bread-crumb-like; may cause greening of blood agar; fluoresce chartreuse under UV
F. periodonticum[b]	−	+	−	−	−	+	Slender. Long cells	Resembles *F. nucleatum*
F. russii	−	−	−	−	−	−	Large with rounded ends	Smooth colonies
F. ulcerans[c]	+	−	−	−	−	+	Large, rounded ends	Smooth colonies
F. varium[c]	+	+−	−+	−	−	+	Large with round, not tapered ends	Fried-egg, but smooth colonies

[a] *F. necrophorum* has two subspecies that can be found in humans: *F. necrophorum* subsp. *fundiliforme* is the more common human isolate and is the virulent subspecies, responsible for Lemierre's syndrome, postanginal sepsis and many other severs infections. *F. necrophorum* subsp. *necrophorum* is more commonly isolated from animals, like cattle.
[b] *F. periodonticum* cannot be distinguished from *F. nucleatum* with biochemicals; both are found in oral cavity as normal microbiota.
[c] *F. ulcerans* and *F. varium* are very similar biochemically. However *F. ulcerans* is indole-negative, whereas *F. varium* is usually positive. Additionally, *F. ulcerans* does not ferment fructose, whereas *F. varium* is a weak fructose fermenter. *F. ulcerans* is responsible for causing tropical ulcers.[41c]
+, positive; −, negative; +−, most strains are positive but a few may give a negative reaction; −+, most strains are negative but a few strains may give positive reaction.

[a] These species require formate and fumarate in media for growth.
[b] *B. wadsworthia* produces "black-eyed" looking colonies on BBE agar.
[c] *Desulfovibrio desulfuricans* is urease-positive; other species are negative.
[d] These species may grow under microaerophilic conditions.
[e] Rare positive strains have been reported.
[f] Although *Sutterella wadsworthensis* will be resistant to a 20% bile disk, it does not usually grow on BE agar.
[g] Data taken from results of one strain. Required >7 days for initial growth.
+, positive; –, negative; +⁻, most strains positive, but a few may be negative; –⁺, most strains negative, but a few may have positive reactions; +[w], positive but weak reaction; A, major acetic acid peak; a, minor acetic acid peak; Bile, growth in presence of 20% bile; FERM, fermentation, if +, the organism ferments one or more carbohydrates; IV, major isovaleric acid peak; L, major lactic acid peak; MOT, motility; NIT, nitrate reduction; P, major proprionic acid peak; PIT, colonies corrode or pit the agar; R, Resistant; S, Susceptible; s, minor succinic acid peak; Unk, Unknown; URE, urease production; V, variable reactions among strains.
Antibiotic potency disks: Vancomycin, Kanamycin, Colistin.

1034

A recently described genus of anaerobic gram-negative rods, *Parabacteroides,* includes *P. distasonis, P. goldsteinii, P. johnsonii*, *P. gordonii,* and *P. merdae*; all of these are indole- and α-fucosidase-negative. These are still considered part of the *B. fragilis* group, at least for clinical relevance purposes, and will grow on the BBE plate and hydrolyze esculin.[238,464] These have been included in Table 16-12 along with other *B. fragilis* group members.

Pigmented Anaerobic Gram-Negative Bacilli. Shah and Collins proposed that the genus *Bacteroides* be restricted to the *Bacteroides fragilis* group and related species, which actively ferment glucose (pH 5.4) (highly saccharolytic), grow in the presence of 20% bile and hydrolyze esculin.[426] Their major acid metabolic products from

glucose metabolism are acetic and succinic acids, although smaller amounts of other short-chain fatty acids may be produced.[426] Thus, the pigmenting anaerobic gram-negative bacilli are no longer classified in the genus *Bacteroides*. The moderately saccharolytic, pigmenting species were placed in the genus *Prevotella*. In 1988, the asaccharolytic, pigmented *Bacteroides*, all isolated from humans, were reclassified in the genus *Porphyromonas* as *P. asaccharolytica, P. gingivalis* and *P. endodontalis* (Chart 16-10) (Image Plate 16-1C and 16-1D).[425] All are susceptible to 20% bile. Additional *Porphyromonas* species of human origin now include *P. uenonis, P. bennonis, P. somerae,* and *P. catoniae* (nonpigmented).[263] All except *P. bennonis* and *P. gingivalis* will exhibit some fluorescence before pigmentation and all except *P. bennonis* are catalase-negative. There are many *Porphyromonas* spp. that are only isolated from animals; these are pigmented and indole-positive. They are usually catalase-positive in contrast to the catalase-negative species of human origin. The animal species of *Porphyromonas* that are not included in Table 16-13 include *P. cangingivalis, P. canoris, P. cansulci, P. macacae,* and *P. levii*. Some of these have been isolated from animal bite wounds.[1]

Clues for the presumptive recognition of anaerobic gram-negative bacilli that belong to the genus *Porphyromonas* include the formation of tan to buff colonies that fluoresce brick-red under long-wave ultraviolet light or brown-black colonies (most species), inhibition of growth in the presence of vancomycin (i.e., failure to grow on kanamycin–vancomycin blood agar), inhibition by bile, inhibition by penicillin and rifampin, but resistance to kanamycin, formation of indole and failure of most species to ferment glucose or other carbohydrates. Definitive identification of *Porphyromonas* to the species level based on phenotypic characteristics is difficult. Some key differential characteristics of the asaccharolytic, pigmented, and catalase-negative species encountered in human illnesses are listed in Table 16-13. The determination of enzyme activities through the use of a rapid, 4-hour test system (i.e., the Rapid ID 32A system or RapID-ANA II) is a practical aid to identify *Porphyromonas* species encountered in humans.[116,238,263]

The genus *Prevotella* consists of pigmented and nonpigmented species as is designated in Table 16-2. In contrast to *Porphyromonas*, all of the pigmented species of *Prevotella* ferment glucose and other carbohydrates (Table 16-14). It is emphasized that the "pigmenting" *Prevotella* group described in Table 16-14 may take 2 days to 3 weeks to form pigment on CDC anaerobic blood agar or may even fail to produce pigmented colonies. All of the pigmented *Prevotella* spp. are gelatin-positive and do not ferment arabinose; all but *P. corporis* are fermenters of sucrose and produce α-fucosidase. *Prevotella intermedia* is distinctive in that it forms black colonies on blood agar, produces indole, is lipase-positive on EYA and ferments sucrose. *Prevotella nigrescens* is a species derived from a genetically distinct group of strains formerly included in *Prevotella intermedia*.[427] Some of these strains were from patients with

periodontitis; others were from healthy individuals. As can be seen in Table 16-14, there are no phenotypic characteristics that can distinguish these two species. *P. denticola, P. loeschii* and some strains of *P. melaninogenica* are the only esculin-positive, pigmented *Prevotella* sp.; like *P. intermedia/nigrescens*, *P. loeschii* may be lipase-positive and these are the only lipase-positive strains of pigmented *Prevotella*. *P. denticola* is slow to produce pigment; some strains may not produce pigment even after 3 weeks of incubation. There are four more recently described species of saccharolytic, pigmenting *Prevotella* that may be isolated from humans: *P. micans, P. pallens, P. shahii,* and *P. tannerae*. They are all esculin-negative, and α-fucosidase-positive. *P. micans* is very active metabolically among these four, fermenting cellibiose, lactose, salicin and sucrose. *P. shahii* and *P. tannerae* are almost indistinguishable from each other phenotypically. *P. pallens* is indole-positive and does not ferment any sugars, except sucrose as shown in Table 16-14.

A major problem in identifying members of the pigmented *Prevotella* group to species is that they are often fastidious and slow-growing. These bacteria may require anywhere from 2 days to a full 3 weeks to form pigment (on laked rabbit blood or on sheep blood agar). Certain species, in particular *Prevotella intermedia* (and possibly *P. nigrescens*), are of special clinical interest because they commonly produce β-lactamase and may be resistant in vitro to

penicillin G and other antibiotics to which other pigmented gram-negative rods are susceptible.[160,238] Prior to pigmentation, young colonies often exhibit a brick-red fluorescence when examined under long-wave (365 nm) ultraviolet light. In Gram-stained preparations, the cells are short, coccoid, gram-negative rods, usually 0.3 to 0.4 mm in diameter × 0.6 to 1 mm long (Image Plate 16-1). For a presumptive identification of the *Porphyromonas* spp. (Image Plate 16-2A) and the pigmented *Prevotella* spp, all are inhibited by bile, usually (but not always) sensitive by the 2-U penicillin disk test, susceptible to rifampin, and resistant to kanamycin (Table 16-11) Further characteristics for differentiation include those given in Tables 16-13 and 16-14, or may be determined using kit systems for enzymatic activities.[116]

The Nonpigmented *Prevotella* spp. There are over 20 species of nonpigmented *Prevotella,* many of which have only recently been identified, and in some instances, only by using molecular methods. None of these are lipase-positive and only *P. heparinolytica* and some strains of *P. zoogleoformans* are indole-positive. All but *P. disiens* and *P. marshii* ferment lactose. *P. disiens* and *P. bivia* are two very common members of the nonpigmented *Prevotella*. These are similar phenotypically, except *P. bivia* ferments lactose and is esculin, whereas *P. disiens* does not. Similarly, α-

fucosidase and NAG (*N*-acetyl-β-glucosaminidase) are positive for *P. bivia,* in contrast to *P. disiens*. *P. bivia* is found in the urogenital tract and mouth, and *P. disiens* is commonly isolated from the urogenital tract (Table 16-14). Characteristics useful for separating *P. bivia* and *P. disiens* from other *Prevotella* species are given in Table 16-14. In addition to *Prevotella tannerae*, Moore and associates described another species that inhabits the human gingival crevice, *Prevotella enoeca*, and emended the description of *Prevotella zoogleoformans*.[337] Both species have been isolated from patients with periodontitis. Key features that aid in distinguishing *P. enoeca* from other species of *Prevotella* are its inability to digest gelatin, its failure to ferment sucrose and its cellular fatty acid profile. Fermentation of cellobiose and lactose, lack of pigment, and its cellular fatty acid profile, are key characteristics that aid in differentiating *P. zoogleoformans* from other indole-positive *Prevotella* species, especially *P. intermedia* and *P. nigrescens*, which share many phenotypic characteristics, although it lacks pigment.[337] An additional taxonomic change in 1995 was the reclassification of *Hallella seregens* and *Mitsuokella dentalis* as *Prevotella dentalis*.[514] Isolated from dental root canals, the colonies of *P. dentalis* are not pigmented; they differ from those of other *Prevotella* species by having a characteristic "water drop appearance."

Prevotella buccalis, *P. veroralis,* and *B. oralis* were all previously called *B. oralis*. They are all inhibited by 20% bile, are indole-negative, are esculin hydrolysis–positive, and ferment several carbohydrates. If they fail to produce pigment, *P. denticola* and *P. melaninogenica* can be easily confused with *P. buccalis*, *P. veroralis,* and *P. oralis*. However, the latter three species ferment cellobiose; *P. denticola* and *P. melaninogenica* are cellobiose-negative. *P. oris* and *P. buccae* have been isolated from periodontal infections and various other sites of infection in humans. The production of acid from either arabinose separates *P. oris* and *P. buccae* from *P. oralis.* The fermentation of salicin helps to separate *P. buccae* and *P. oris* from *P. buccalis* and *P. veroralis*, which are salicin-negative. *P. buccae* has β-glucosidase activity, whereas *P. oris* does not, which is a feature that aids in separating these species. Reactions obtained using the RapID-ANA II system may also be useful as a supplement to the tests in Table 16-13, to help differentiate these species.[116]

Bacteroides ureolyticus. *Bacteroides ureolyticus* (formerly *B. corrodens*), is a microaerophilic, fastidious, relatively small gram-negative rod (about 0.5 mm in diameter × 1.5 to 2 mm in length) that produces pitting of anaerobic blood agar. The cells do not produce flagella and are nonmotile. Characteristically, the colonies may be of two types: (1) 0.5 to 1 mm diameter after 2 or more days incubation, circular, convex and translucent with entire or erose margins, or (2) thin, flat, spreading, irregular translucent colonies that extend out from a slightly raised central area. These latter colony types produce depressions or "pits" within the surface of agar, resembling to some the "corrosion" of pitted sheet metal. *B. ureolyticus* is inhibited by penicillin

(2-U disk), rifampin (15-mg disk) and kanamycin (1-mg disk), does not grow in the presence of 20% bile and is asaccharolytic. *Campylobacter gracilis*, formerly called *Bacteroides gracilis*, is also microaerophilic, and has growth characteristics similar to those of *B. ureolyticus*. A positive test for urease activity and gelatin and casein hydrolysis separates *B. ureolyticus* from *C. gracilis* and phenotypically similar species of *Campylobacter* and *Wollinella succinogenes* which are all urease-negative. There is presently a proposal to move place *B. ureolyticus* in the genus *Campylobacter* as *C. ureolyticus*.[485] If this occurs, the only remaining *Bacteroides* spp. of clinical relevance would be members of the B. *fragilis* group. The 10th edition of the Manual of Clinical Microbiology now includes *B. ureolyticus* in chapter on *Campylobacter* instead of the anaerobe chapter.[263] *S. wadsworthensis* is an organism similar to *B. ureolyticus* and *Campylobacter gracilis*. It may pit the agar like *B. ureolyticus*, but is urease-negative and may grow in presence of 20% bile. The other *Bacteroides* spp., non-*B. fragilis* group, are encountered only rarely in human clinical specimens. For excellent reviews of their role in infections and their susceptibility to antimicrobial agents, see Kirby et al. and Wexler.[259,507]

***Bilophila* Species.** During a study of bacteria isolated from appendicitis specimens and human feces, a unique new anaerobic gram-negative bacillus was isolated on BBE agar by Baron and associates.[30] This new species was reported to show the characteristics listed in Box 16-4. Although *Bilophila wadsworthia* is similar to species of the *B. fragilis* group and to certain *Fusobacterium* species that grow in the presence of 20% bile, several of the phenotypic properties of *Bilophila wadsworthia* are different from those of the *Bacteroides fragilis* group and *Fusobacterium* spp. *Bilophila wadsworthia* differs from the *B. fragilis* group by its failure to ferment carbohydrates, its production of urease, and its failure to produce a major amount of succinic acid. The production of strong catalase activity and lack of butyric acid production are key characteristics that separate *B. wadsworthia* from *Fusobacterium* species. In addition, *B. wadsworthia* is bile-resistant and on a BBE plate will produce large colonies like

B. fragilis group, but there will be a "black-eyed" appearance, rather than a completely blackening of the colony.[238]

***Fusobacterium* spp.** The genus *Fusobacterium* includes several species of anaerobic, gram-negative, NSF rods that can be differentiated from species of *Bacteroides, Prevotella, Porphyromonas,* and *Leptotrichia* by their production of major amounts of butyric acid but no isobutyric or isovaleric acid (Table 16-15) (Chart 16-10). The

species of *Bacteroides* and *Porphyromonas* that produce butyric acid also produce isobutyric and isovaleric acids. Although the name *Fusobacterium* would seem to suggest that all of the fusobacteria are "fusiform" or "spindle-shaped," only a few of them have this morphology. Although *F. nucleatum* is fusiform, the majority of other species are rod-shaped with parallel sides and rounded (not pointed) ends (Image Plate 16-1E and 16-1G). Additionally, some have a very bizarre and pleomorphic appearance on Gram's stain. While they grow well on anaerobic blood agar under anaerobic conditions, they are readily killed by exposure to ambient air. Most species are either nonfermentative or only weakly fermentative.[238,263] They are resistant to the vancomycin antibiotic potency disk, but susceptible to colistin and kanamycin. Most species are bile-susceptible; however, *F. mortiferum, F. ulcerans,* and *F. varium* can grow on BBE agar.[238]

The most common and well-known species of *Fusobacterium* is *F. nucleatum*. As mentioned, in the Gram's stain, it is gram-negative and the cells are spindle-shaped, long, and slender with tapered ends (Image Plate 16-1).[238,263,313] There are also spherical swellings found in the cells. Cells are usually 5 to 10 μm long, but shorter forms are also often seen. Colonies on anaerobe blood agar are 1 to 2 mm in diameter, slightly convex with slightly irregular margins, and have a characteristic internal flecking referred to as crystalline internal structures; some describe *F. nucleatum* colonies as "breadcrumb-like" (Image Plate 16-1F). Biochemically, *F. nucleatum* is relatively inactive (Table 16-15).

The cells of *F. necrophorum* measure about 0.6 × 5 μm, and are pleomorphic, often with curved forms and spherical areas within the cells (Image Plate 16-1G). Like *F. mortiferum* (discussed below), they also produce free coccoid bodies which, on direct examination, sometimes resemble degenerated leukocytes (i.e., neutrophilic debris). *F. necrophorum* has been divided into at least two subspecies: *F. necrophorum* subsp. *fundiliforme*, the more pathogenic strain and *F. necrophorum* subsp. *necrophorum*. Colonies are yellow to cream colored, round and smooth with entire edges (Image Plate 16-1H). They may fluoresce chartreuse under UV light like *F. nucleatum*, and they may green the blood agar. Both are usually lipase-positive on EYA; however, the reaction is weaker with subspecies *fundiliforme*. *F. necrophorum* can be occasionally misidentified as *F. nucleatum*; evaluations of the commercial anaerobic kit systems have included very few isolates of *F. necrophorum* to judge their performance. Initial studies with molecular techniques are still pending, so accurate identification can be difficult. If GLC is performed, butyric acid will be predominant, but that is true of the genus *Fusobacterium* and does not help with species level differentiation.[95,238] The cells of *F. mortiferum* are 0.5 to 2 μm wide by 2 to 10 μm long, highly pleomorphic, coccoid to filamentous, with spherical swellings near the center or one end of unevenly stained rods. Colonies on blood agar are 1 to 2 mm in diameter and have a distinctive fried-egg appearance, with raised, opaque centers and a flat, translucent margin (Table

16-15).

Other *Fusobacterium* species may be encountered rarely in infections. *F. ulcerans* is a rare isolate responsible for tropical ulcers, and resembles *F. varium* on Gram's stain. *F. varium*, however, is usually indole-positive and can be lipase-positive, whereas *F. ulcerans* is negative for both of these reactions.[98,238,263] For additional characteristics of these and other species, the following references are recommended.[95,98,238,263,302]

The differential characteristics of many other anaerobic gram-negative bacilli are shown in Table 16-16. References are included for many of the organisms for your interest in Table 16-2.

Identification of the Anaerobic NSF Gram-Positive Bacilli

Included in this group of anaerobes are species of the genera *Actinomyces, Arcanobacterium, Bifidobacterium, Eggerthella, Eubacterium, Lactobacillus, Propionibacterium, Pseudoramibacter,* and many others (Chart 16-11). An extensive list of recent changes in the taxonomy of these bacteria is provided in Table 16-2. Some key differential characteristics of the genera of NSF, gram-positive bacilli are given in Table 16-10. The microscopic morphology and colonial characteristics of *Actinomyces israelii* and *Eggerthella lenta* (formerly *Eubacterium lentum*) are shown in Image Plate 16-2 (Image Plate 16-2E and 16-2F).

Identification of the anaerobic, gram-positive NSF bacilli requires the use of GLC for metabolic product analysis and/or newer identification methods including sequencing and MALDI-TOF. Cellular morphology of many of these organisms tends to vary with the type of culture medium and growth conditions. On morphologic grounds alone, these bacteria can sometimes be confused with several other genera, including *Clostridium, Corynebacterium, Lactobacillus, Leptotrichia, Listeria, Nocardia, Peptostreptococcus,* and *Streptococcus*. Thus, GLC results and morphologic characteristics, considered together, aid in practical differentiation. At times, some strains of anaerobic bacilli resemble cocci, particularly in Gram-stained preparations of young colonies on blood agar. In addition, some streptococci, such *as S. mutans, S. intermedius, S. constellatus* and *Gemella morbillorum* and certain anaerobic gram-positive cocci, may appear rod-shaped when cells from colonies on blood agar are examined microscopically. Conversely, these latter bacteria usually form long chains of cells in enriched thioglycolate broth and other liquid media. It should be remembered that many gram-positive bacteria tend to stain in a gram-negative manner as they age. Also, some clostridia (e.g., *C. perfringens, C. ramosum* and *C. clostridioforme*) fail to produce spores in media routinely used in the clinical laboratory, whereas other clostridia do so as they age. Thus, Gram-stained preparations of very young cultures may aid in demonstration of gram-variability, and observation of smears from older cultures may aid in demonstrating spores of clostridia.

***Actinomyces* spp.** As discussed in the section on human infections with *Actinomyces* spp., *A. israelii* has long been associated with thoracic, abdominal, and pelvic actinomycosis. In Gram-stained smears prepared from

lesions, one may observe characteristic sulfur granules, which are granular microcolonies of the organism surrounded by purulent exudate. There are many

species of *Actinomyces,* as well as *Propionibacterium propionicum,* that are recognized as potential causes of actinomycosis and may produce sulfur granules (Chart 16-11). The cells of *A. israelii* are gram-positive rods, usually 1 μm in diameter, but they are extremely variable in length. The cells may be short diphtheroid rods, club-shaped, branched, or unbranched filaments (Image Plate 16-2). Rough colonies composed of branched rods or filaments usually develop slowly on blood agar. Young colonies (2 to 3 days old), when viewed with the dissecting microscope, appear as thin radiating filaments known as spider colonies. When the colonies are from 7 to 14 days old, they are often raised, heaped-up, white, opaque and glistening; the colonies have irregular or lobate margins, and are sometimes called "molar tooth" colonies (Image Plate 16-2F). However, smooth strains (about one-third of *A. israelii*) produce colonies more rapidly than rough strains. Smooth strains may produce 1- to 2-mm, circular, slightly raised white, opaque, smooth, glistening colonies after only 2 to 3 days of incubation. *A. naeslundii* may also produce smooth or rough colonies. Colonies of *A. viscosus* are most often 0.5 to 2 mm in diameter, entire, convex, grayish, and translucent. In *A. odontolyticus* colonies, a red color may develop on blood agar after 7 to 14 days of anaerobic incubation or after the plates have been left out in room air at ambient temperature for several days. As mentioned previously, cellular and colony characteristics of *Propionibacterium propionicum* are similar to those of the other *Actinomyces*. There is now a long list of other species of *Actinomyces*, as can be seen in Table 16-2, 16-17 and 16-18. Some of the species demonstrate the branching filaments on Gram's stain that are characteristically recognized as *Actinomyces* sp.; others appear more diphtheroidal and can be confused with *Corynebacterium* spp. Some species are quite aerotolerant, in some instances appearing more like aerobes than anaerobes. Most *Actinomyces* spp. are metronidazole-resistant, but highly penicillin susceptible, as well as being susceptible to many other anaerobic antibiotics.

Besides morphology, colony characteristics and metabolic products, characteristics useful for identification of the actinomycetes include relationship to oxygen, appearance and rapidity of growth in enriched thioglycolate medium, indole production, esculin and gelatin hydrolysis, fermentation of certain carbohydrates, results of testing with several rapid enzyme tests, 16S rRNA sequencing and other molecular methods. For further information relative to characterization and identification of isolates beyond that given in Tables 16-17 and 16-18, the following references are recommended.[99,238,414,499]

TABLE 16-17 Morphology of *Actinomyces, Propionibacterium,* and Related Species

Species	Gram's Stain Morphology	Colonial Morphology	Normal Flora/Clinical Relevance
***Actinomyces* spp.**			
A. cardiffensis	Pleomorphic, slender, straight to curved rods; beaded, branching filaments occurs	Pinpoint, convex, smooth colonies; opaque; cream to pinkish; nonhemolytic	Many clinical specimens; bacteremia; pulmonary infections
A. dentalis	Filamentous, beaded rod-shaped cells	Tiny, white, bread-crumb-like; can pit the agar	Oral cavity; dental abscesses
A. europaeus	Short rods; no filaments or branching	Smooth, translucent gray colonies; slightly β-hemolytic	Breast abscesses; UTI
A. funkei	Slender, curved rods with some branching	Small gray, nonhemolytic colonies; appear like "fried-egg" with age	Endocarditis
A. georgiae	Short rods that may have swellings; branching is seldom seen	1 mm colonies; circular, convex, entire; translucent; white, shiny and smooth; some strains may be tan	Gingival crevices; Endocarditis
A. gerencseriae	Short rod; filamentous; branches or beads	Difference strains produce pleomorphic colony types: Circular, white; smaller colonies are translucent or transparent; irregular opaque; "lumpy."	Cervicofacial, thoracic, & abdominal-pelvic actinomycosis
A. gravenitzii	Short rods; some swollen ends; some branching	Opaque colonies; may adhere to agar; may form molar tooth colonies like *A. israelii;* may produce pinkish pigment on laked rabbit blood agar	Cervicofacial, thoracic, & abdominal-pelvic actinomycosis
A. hongkongensis	Straight rods	Nonhemolytic, pinpoint colonies	Isolated from case of pelvic actinomycosis
A. israelii	Short rods; characteristic branching; pleomorphic	White, opaque; "molar tooth" colonies	GU tract; pulmonary; all forms of actinomycosis; pericarditis; IUD-association infections
A. johnsonii	Short rods; branching or beading	Gray-white; translucent	Gingival crevices
A. massiliensis	Straight rods	Circular, white, shiny; pinpoint at 48 hours	Bacteremia

1038

A. meyeri	Short rod; branching or beading with some swollen cells; clubbing	White colonies; strict anaerobe	Pulmonary; osteomyelitis; abscesses; pericarditis
A. naeslundii	Short rods; branching or beading	Gray-white; translucent	Oral flora; bacteremia; IUD-associated infections
A. nasicola	Branching rods; pleomorphic; some coccoid forms	Pinpoint, white, or gray; opaque, shiny, convex, and entire	Isolated from pus in the nose of patient during polypectomy
A. neuii	Diphtheroids and coccoid forms; in clusters or "X" and "Y" forms	Circular, smooth, convex; opaque, white, entire edge; subsp. *neuii* is α-hemolytic, but subsp. *anitratus* is nonhemolytic.	IUD-associated infections; abscesses; soft tissue infections; endophthalmitis; endocarditis
A. odontolyticus	Short rods; branching filaments or beading	Smooth and granular colonies; may have orange-reddish pigment	Oral flora; bacteremia; IUD-associated infections; soft tissue infections in head and neck
A. oricola	Rods with branching filaments	Pinpoint, bread-crumb-like; white; nonhemolytic	Dental abscess
A. oris	Short rods with clubbed ends	Smooth to granular surface with an irregular edge	Oral
A. radicidentis	Coccoid	Smooth and brown pigmented	Oral; isolated from infected root canals
A. radingae	Coccoid; pseudobranching	Small gray convex colony; butyrous; α-hemolytic	Abscesses; IUD-associated infections
A. turicensis	Straight to curved rods; pseudobranching; gram-variable	Glistening; opaque; butyrous; originally described as aerotolerant	Abscesses; IUD-associated infections
A. urogenitalis	Slightly curved rods	Smooth, nonadherent possibly with reddish pigment	Isolated from GU tract; pelvic actinomycosis; bacteremia
A.viscosus	Short diphtheroidal rods with branching and beading	Circular, convex, smooth; entire; creamy white; soft to mucoid; opaque	Oral organism; involved in cases of actinomycosis
***Actinobaculum* spp.**			
A. massilae	Straight or slightly curved rods; may branch singly or in clusters	1 mm nonhemolytic colonies	UTI and bacteremia
A. schaali	Straight to slightly curved rods; some branching	Circular with irregular margins	UTI; endocarditis
A. urinale	Straight to slightly curved rods; no branching seen	Small colonies (<1 mm), convex, smooth, entire edge; gray or white; weakly β-hemolytic	Isolated from urine
Varibaculum cambriense	Short, straight or slightly curved rods; diphtheroidal	Nonhemolytic, translucent colonies that are gray-to-white, pinpoint, convex and entire	Skin & soft tissue infections; IUD-associated
***Propionibacterium* spp.**			
P. acnes	Pleomorphic short rods; diphtheroidal; some may appear club-shaped; some may appear to branch; the term *anaerobic diphtheroids* is often used to describe them.	1–2 mm in diameter early on, becoming larger with age; circular, convex, white to gray-white, opaque, with an entire edge and a butyrous consistency	Skin flora; bacteremia; endocarditis; post–cataract-surgery endophthalmitis; shunt infections; implant infections, esp. shoulder implants
P. avidum	Not well described	Similar to *P. acnes*; β-hemolytic	Cutaneous abscess
P. granulosum	Not well described	White to gray colonies that are smooth and entire	Rarely, endocarditis
P. propionicum	Pleomorphic rods; may branch and look like *Actinomyces* spp.	Colonies similar to *A. israelii*	Cervicofacial, thoracic, & abdominal-pelvic actinomycosis; lacrimal canaliculitis
Propionimicrobium lymphophilum	Pleomorphic; diphtheroid-like; singly, pairs or short chains or clumps; may form "X" and "Y" forms.	Small white colonies; punctate, circular, convex; glistening with age	Initial clinical isolate was from a lymph node

Adapted from a variety of references including 178, 238, 477, and 499.

[a] *A. graevenitzii* produces brown colonies on RLB, but no pigment on Brucella blood agar; other *Actinomyces* that pigment on Brucella agar produce pinkish/brownish colonies and on rabbit laked blood agar (RLB), darker colonies.
(+), the organism is aerotolerant, but grows better anaerobically; +, positive reaction; −, negative reaction; V, some strains positive and some negative; w, weak reaction; NA, data not available; AERO, aerotolerant, grows in CO_2 incubator; CAT, catalase; URE, urease; ESC, esculin hydrolysis; NIT, nitrate reduction; MANN, fermentation of mannitol; RAFF, fermentation of raffinose; NAG, β-*N*-acetyl-glucosaminidase; PIG, pigment production; usually seen as pink-brown colonies on Brucella blood agar.
Adapted from references 178, 238, and 499.

***Propionibacterium* spp. and Related Genera.** *Propionibacterium acnes* is by far the most common gram-positive, NSF anaerobic rod encountered in clinical specimens. *P. avidum* and *P. granulosum* are seldom encountered in the clinical laboratory, and usually are not clinically significant. The cells of *P. acnes* usually measure 0.3 to 1.3 µm in diameter × 1 to 10 µm in length.[238] Their morphology has often been described as diphtheroidal or in appearance. The cells are markedly pleomorphic and occur in varying shapes and sizes, ranging from coccoid to definite rods. Cells are often unevenly stained by Gram's procedure. Like the corynebacteria, the cells reveal "Chinese letters," "birds-in-flight," and "picket-fence" arrangements, presumably because of "snapping" after they divide. *P. acnes* typically grows as an obligate anaerobe on primary isolation. Although some strains show growth when incubated in a CO_2 incubator, they usually grow better anaerobically, and hence have been described as aerotolerant or microaerophilic. Colonies of *P. acnes* on anaerobe blood agar are 1 to 2 mm in diameter, circular, entire, convex, glistening and opaque. Some strains produce a narrow zone of hemolysis. Analysis of short-chain acid metabolic products by GLC reveals the production of a major amount of propionic acid, a smaller amount of acetic acid, and only a minor amount of isovaleric acid [abbreviated aP (iv)]. *P. acnes* can be recognized without the use of GLC when it produces both indole and catalase. *Actinomyces viscosus*, which has a similar morphology on some media, produces catalase (Chart 16-11).

***Propionibacterium propionicum*.** In 1988, *Arachnia propionica* was reclassified as *Propionibacterium propionicum*.[89] Previously, the name *Arachnia propionica* had been created to accommodate the bacteria once called *Actinomyces propionicus*. This species, while its pathogenicity and morphologic characteristics resemble those of certain species of *Actinomyces*, differs from *Actinomyces* spp. by producing propionic acid as a major metabolic product, by its cell wall murein content and menaquinone composition that resemble those of *Propionibacterium* spp. *P. propionicum* is morphologically indistinguishable, in tissue and in culture, from *Actinomyces israelii*. Both *P. propionicum* and *A. israelii* form pleomorphic "diphtheroidal" rods and long, branched, filaments (described in more detail in the section on *Actinomyces* spp.). Both species are microaerophilic to anaerobic and grow optimally under anaerobic conditions. Tables 16-17 and 16-19 provide specific information on the characteristics of *Propionibacterium* spp. and the clinical relevance of selected species.

***Eubacterium* spp., *Eggerthella* spp., and Related Genera.** Most *Eubacterium* spp. and related genera produce small gray colonies on anaerobic blood agar, often requiring ≥48 hours for visible growth to be detected (Image Plate 16-2H). Strains of *Eggerthella lenta* are biochemically quite inert small rods without any branching; they are arginine dihydrolase positive and alkaline phosphatase-negative; catalase-positive and nitrate-positive, but usually urease- and indole-negative; they are sensitive to

kanamycin and vancomycin, but resistant to colistin on antibiotic disk tests (Chart 16-11). *Eubacterium* spp. are similar, but can be spot indole-positive and are catalase- and nitrate reduction-negative (Image Plate 16-2G). *Paraeggerthella hongkongensis* (i.e., the new nomenclature of what previously was *Eggerthella hongkongensis*) and *E. sinensis* are similar to *E. lenta* but nitrate negative. There are some data about using API 20A or Rapid ID 32 tests for identification of these organisms.[280] Definitive identification requires nucleic acid sequencing or MALDI-TOF assessment. Table 16-20 provides information on the phenotypic differentiation of these organisms.

***Bifidobacterium* spp. and Related Genera.** Currently, more than 30 species of the genus *Bifidobacterium* are recognized taxonomically (Chart 16-11). Recent changes in this group include the transfer of *B. inopinatum* to *Scardovia* as *Scardovia inopinata*, and the transfer of *B. denticolens* to *Parascardovia* as *Parascardovia denticolens.*[233] The morphology of *B. dentium* is somewhat similar to that of *Actinomyces*, but it differs in not producing branched filaments in thioglycolate medium. Gram-stained smears prepared from solid media or broth cultures show gram-positive diphtheroidal forms that are much more variable in size and shape than *P. acnes*. Cells vary from coccoid forms to long, often curved forms, with characteristic swollen ends and/or bifid forms that are regularly produced by *B. dentium*. Using the antibiotic potency disks, most of the *Bifidobacterium* and related genera are susceptible to kanamycin and vancomycin, but resistant to colistin. *Alloscardovia omnicolens* are catalase-negative, arginine dihydrolase-negative, nitrate-negative, but do ferment glucose and a number of other sugars with exception of rhamnose, sorbitol and mannose.[227] On GLC analysis of short-chain acid metabolic products, the bifidobacteria produce major amounts of acetic and lactic acids. For more information on the species of this group and their phenotypic characteristics, refer to Table 16-2 and 16-20.

TABLE 16-19 Characteristics of *Propionibacterium* spp. and *Propionimicrobium lymphophilum*

Species	Aerotolerance	CAT	IND	NIT	ESC	Comments
P. acidifaciens	–	–	–	–	–	Pleomorphic rods; colonies are circular, convex to domes, opaque, white to cream colored; nontranslucent internal appearance
P. acnes	+	+	+	+	–	Short rods; diphtheroidal
P. avidum	+	+	–	–	+	Pleomorphic and irregular rods; may have slight branching
P. granulosum	+	+	–	–	–	Pleomorphic rods, with slight branching; colonies gray and creamy
P. propionicum	–	–	–	+	–	Can see branching on Gram's stain; resembles *A. israelii* in colonial and microscopic morphology
Propionimicrobium lymphophilum[a]	–	V	–	+	–	Small colonies; circular, convex, white, and glistening; pleomorphic rods, can be diphtheroidal or club-shaped and some coccoid; arranged singly, in pairs and chains; may form X and Y forms

[a] *P. lymphophilum* may grow weakly on 20% bile agar; it is a fermenter.
+, positive reaction; −, negative reaction; V, variable reaction; CAT, catalase; IND, indole production; NIT, nitrate reduction; ESC, esculin hydrolysis.
Modified from references 178, 238, and, 499, and others as indicated in Table 16-2 for each organism.

1041

TABLE 16-20 Characteristics of *Bifidobacterium* spp. and Related Species, *Eubacterium* spp., and *Eggerthella* spp. and *Eubacterium*-Like Species

Species	AERO	CAT	IND	NIT	ESC	ADH	GLC Products	Prior Designation	Morphology
Bifidobacterium spp.	−/+	−	−	−	+	−	A,L		Rods with some bifurcation or "fork-like" branching; usually larger in diameter than cells of *Actinomyces* spp. or *Propionibacterium* spp.
B. scardovii	+	−	−	−	+	−	A,L	None	Rod with some curving; colonies are convex, shiny, with dense white centers
Alloscardovia omnicolens	−[a]	−	−	−	+	−	A,L	New genus and species	Short, irregular rods singly or pairs; with rudimentary branching; colonies are small
Parascardovia denticolens	−	−	−	−	NA	NA	A,L	*Bifidobacterium denticolens*	Slender rods; some may branch; some "V" forms colonies are smooth, Convex, irregular edges; cream-white
Scardovia inopinata	−	−	−	−	NA	−	A,L	*Bifidobacterium inopinatum*	Small coccoid cells, singly and in pairs; colonies are smooth, convex, irregular edges; cream-white
Eubacterium spp.	−	−	V	−+	NA	V	A or B,L or AB or A,B,L		Variable: straight rods to coccobacillus; some may branch. Many different colonial morphologies
Eggerthella. lenta[b]		+	−	+	−	+	a(l,s)	*Eubacterium lentum*	Pleomorphic bacilli; speckled colonies that fluoresce red
Eggerthella. sinensis		+	−	−	NA	+	NA	New species	
Paraeggeggerthella hongkongensis		+	−	−	NA	+	NA	*Eggerthella hongkongensis*	

[a] CO_2 enhances growth anaerobically; no growth aerobically.
[b] H_2S +; can grow in presence of 20% bile.
Most of the *Bifidobacterium* spp. are glucose fermenters; most of the *Eubacterium* spp. are non–glucose-fermenters.
+, positive reactions; −, negative reactions; −+, most species are negative, although an occasion species might be positive; NA, data is not available; AERO, growth under aerobic conditions; CAT, catalase; IND, Indole production; NIT, nitrate reduction; ESC, esculin hydrolysis; ADH, arginine hydrolysis.
Adapted from references 178, 238, and 499.

***Lactobacillus* spp.** Although the majority of *Lactobacillus* isolates are not strictly anaerobic, many grow better anaerobically. Clues that aid in the recognition of lactobacilli include their growth on Rogosa's selective tomato juice agar at relatively low pH (Becton Dickinson Microbiology Systems), their negative catalase reaction, their tendency to form chains of relatively uniform gram-positive rods, and their production of lactic acid as a major product with only a small amount of acetate or succinate (detected using GLC). The biochemical characteristics of some of the *Lactobacillus*-like organisms can be found in Table 16-21. However, the identification of most of the *Lactobacillus* spp. and related organisms are beyond a presumptive level is difficult and beyond the scope of this textbook. It is noteworthy that many of the lactobacilli are resistant to vancomycin. For additional information on identification and the susceptibility of *Lactobacillus* species to antimicrobial agents, see Chapter 17.

***Mobiluncus* spp.** *Mobiluncus* spp. grow on several kinds of nonselective plating media, including anaerobe blood agar (e.g., brain–heart infusion, Brucella agar, and

CDC anaerobe blood agar–based media) and chocolate agar. After 3 to 5 days of incubation, colonies are 2 to 4 mm in diameter, colorless, translucent, smooth, and flat, sometimes with a spreading appearance. The cells are less than 0.5 µm in width by about 1.5 to 3 µm in length. Succinate and acetate are major products (with or without minor amounts of lactate) after growth in peptone yeast extract broth supplemented with glycogen and 2% rabbit serum. Differentiation between the two currently recognized species, *M. curtisii* and *M. mulieris*, based on differences in morphology, negative reactions for indole and catalase, growth in the presence of arginine, hippurate hydrolysis, variable nitrate reduction and other characteristics is difficult.[238,456]

1042

TABLE 16-21 Characteristics of *Lactobacillus* spp. and Related Genera

Species	AERO	CAT	IND	NIT	ESC	ADH	Acid Phospatase	β-GAL	FERM	GLC	MORPH	Prior Designation
Lactobacillus spp.	V	–	–	$-^{+}$	$+^{-}$	V	V	V	+	L,a,s	Variable, but usually rods with straight sides; chains of rods common; no branching	
Olsenella uli	–	–	–	–	+	+	NA	NA	+	L	Small elliptical rods, singly, pairs or short chains; colonies are 1–2 mm, translucent to transparent, convex and entire.	*Lactobacillus uli*
O. profusa	–	–	–	–	+	–	NA	NA	+	L	Small elliptical rods, singly, pair and short chains; circular, entire, cream colored and opaque.	*Lactobacillus profusa*
Atopobium minutum[a]	–	–	–	–	ND	+	–	–	+	a,L,s	Small, elliptical rods, singly or in short chains; pinpoint colonies, convex, entire, gray, white, or yellow.	*Lactobacillus minutus*
A. parvulum	–	–	–	–	V	–	+	+	+	a,L,s	Small cocci singly, in pairs or short chains; some may have swellings; pinpoint colonies, raised, convex, entire edges' may be white or gray	*Streptococcus parvulus*
A. rimae	–	–	–	–	V	V	+	–	+	a,L,s	Small, elliptical rods which may have central swellings singly or in pairs or short chains; small colonies, convex, entire, translucent or transparent.	*Lactobacillus rimae*
A. vaginae[b]	–	–	–	–	–	+	+	–	+	a,L,s	Very small, elliptical cells singly, pairs or in short chains; colonies are very small.	New species

[a] *A. minutum* has been shown to carry a vancomycin resistance gene[166e]
[b] *A. vaginae* was initially described as a facultative anaerobe[198d]
+, positive reaction; −, negative reaction; $+^{-}$, most strains are positive, but may have occasional negative reactions; $-^{+}$, most strains are negative, but an occasional strain may be positive; a, minor acetic acid peak; L, major lactic acid peak; s, minor succinic acid peak; V, variable reactions among the species; AERO, ability to grow aerobically; CAT, catalase; IND, indole production; NIT, nitrate reduction; ESC, esculin hydrolysis; ADH, arginine dihydrolase; FERM, fermentative; β-GAL, β-galactosidase.
Adapted from references 178, 238, and 499.

Other Anaerobic NSF Gram-Positive Bacilli. Table 16-2 lists many additional changes in taxonomy and the new genera of NSF anaerobic gram-positive rods that have been described. Table 16-22 provides some phenotypic and morphologic information on these organisms, but definitive identification of the gram-positive NSF bacilli can be quite difficult and requires either nucleic acid sequencing or a combination of morphology, phenotypic characterization and GLC. The only way to assess their clinical significance, however, will be to correctly identify them, correlate the culture results with the clinical and pathologic findings and publish the findings. At this point, it is important to recognize these at least at the genus level, if possible, in routine clinical laboratories and to refer isolates that are thought to be clinically relevant to specialized labs for definitive identification.

Identification of Clostridium *Species*

Overview. The anaerobic gram-positive, spore-forming bacilli encountered in human clinical materials are members of the genus *Clostridium*. In 1994, Collins and associates,[104] on the basis of 16S rRNA gene sequences, found that the genus *Clostridium* is extremely heterogeneous. Thus, Collins et al. named five new genera of spore-forming rods.[104] Included were the following: *Caloramator, Filifactor*, *Moorella, Oxobacter,* and *Oxalophagus* species. In addition, 11 new species combinations were proposed. None of these new genera and species designations were relevant to infectious diseases of humans. Newly named clinically relevant species at the time of this writing include *Clostridium bartlettii*,[452] *C. bolteae*,[451] *C. hathewayi,*[461] and *C. neonatale*.[7] The original manuscripts should be consulted for information on their clinical significance.

1043

TABLE 16-22 Characteristics of Other Anaerobic Gram-Positive, Non–Spore-Forming Bacilli

Species	Site in Body or Clinical Relevance	CAT	IND	NIT	ESC	ADH	FERM	Clues to ID	GS and Colonial Morphology	Prior Designation
Anaerofustis stercorihominis	GI microbiota	–	NA	NA	NA	NA	+	Resistant to 20% bile; GLC = A, B	Thin rods in short chains	New genus and species
Anaerotruncus colihominis	GI microbiota; a case of bacteremia		+	–	–	+	+		Thin rods	New genus and species
Bulleidia extructa	Oral cavity; prosthetic hip infections	–	–	–	–	+	+	Stimulated by Tween	Short slightly curved rods singly and in pairs	New genus and species
Catabacter hongkongensis	GI microbiota; bacteremia cases	+	–	–	v	–	+	Motile; sensitive to kanamycin	Short rods or coccobacillus	New genus and species
Catenibacterium mitsuokai	GI microbiota	–	NA	–	–	NA	+	+	Short rods; long tangled chains	New genus and species
Colinsella aerofaciens	GI microbiota	–	–	–	V	V	+	Stimulated by Tween; H_2S +	Coccoid to short rods in chains	*Eubacterium aerofaciens*
Colinsella intestinalis	GI microbiota	NA	NA	NA	NA	NA	+	NAG + *	Rods in chains; white or gray colonies in center with clear margins	New species
Colinsella stercoris	GI microbiota	NA	NA	NA	NA	NA	+	NAG +	Rods in chains; white or gray colonies in center with clear margins	New species
Cryptobacterium curtum	Oral microbiota; chronic periodontitis	–	–	–	–	+	–	May decolorize with age	Short rods; diphtheroidal	*Eubacterium curtum*
Dorea formicigenerans	GI microbiota	–	–	–	–	NA	+	Produces H_2S; growth inhibited by 6.5% salt; GLC = a, F, I	Short or long rods in pairs and chains; colonies are circular, irregular, convex, opaque; white to tan and shiny, smooth	*Eubacterium formicigenerans*
D. longicatana	GI microbiota	–	–	–	+	NA	+	May decolorize with age	Short or long rods in pairs and long chains; opaques colonies that are circular, convex, entire, smooth and sticky	
Flavonifractor plautii	GI microbiota; isolates from blood, abdominal wounds; soft tissue infections	ND	V	–	+	–	+[w]	May become gram-negative with age; variably motile; variably H_2S +; reduced susceptibility to vancomycin; GLC = A,B	Straight or slightly curved rods singly or in pairs; small colonies, circular, convex, gray or white, smooth	*Eubacterium plautii* and some strains of *Clostridium orbiscindens.*
Holdemania filiformis	GI microbiota	–	–	–	+	–	+	Stimulated by Tween; may be resistant to 20% bile; GLC = A,L,S	Short to longer cells; may have swellings in cells; arranged in pairs and chains; colonies are circular, convex, granular	New genus and species; *Eubacterium*-like
Mobiluncus curtisii	Vagina; Associated with Bacterial Vaginosis	–	–	–	–	+	+	In fresh preparations, these have a corkscrew motility. GLC = S, L, A	Curved, gram-variable bacilli	

1044

Mogibacterium spp.		–	–	–	–	–	–	May decolorize with age	Rod-shaped	
Mogibacterium timidum	Oral; periodontal infections	–	–	–	–	–	–	Growth is very slow with tiny colonies even after 5 days	Short rods; diphteroidal, in clumps; colonies are round, white or cream; entire; rough appearance	*Eubacterium timidum*
Moryella indoligenes	GI microbiota probably; isolated from abdominal abscess	–	+	–	–	NA	+[w]	Indole +	"Warped" cells, singly and pairs and in short chains; nonpigmented and non-hemolytic colonies	New genus and species
Pseudoramibacter alactolyticus	Oral	–	–	–	–	–	+	F,a,B	Rods in pairs resembling flying birds, clumps, or Chinese characters; colonies are punctuate, circular, smooth or shiny; translucent and opaque colony types	*Eubacterium alactolyticum*
Roseburia spp.	GI microbiota	–	NA	NA	+	NA	+	Produces H_2S; gram-variable; motile	Thin pleomorphic rods; translucent colonies with entire edges	New genus and species
Shuttleworthia satelles	Oral cavity; endocarditis case	–	+	–	+	+	+	GLC = A,B,L	Short or slightly curved; diphtheroidal in pairs and short chains; very variable colonial morphologies; many with satellite colonies	New genus and species
Slackia exigua	Oral; periodontitis	–	–	–	–	+	–	Growth stimulated by 0.5% arginine; may stain gram-negative with age	Coccobacilli or short rods, singly or in clumps; colonies are circular, convex, translucent	*Eubacterium exiguum*
Solobacterium moorei	GI microbiota; bacteremia cases; wound infections	–	–	–	+	+	+		Straight or slightly curved rods, singly or in pairs	New genus and species
Turicibacter sanguinis	GI microbiota; blood culture isolate	–	–	–			+		Irregular long rods in long chains; colonies are gray-white, convex, undulating margins	New genus and species

*PCR primers sets have been described that effectively differentiate *C. intestinalis* from *C. stercoris*.[244]
+, positive reaction; –, negative reaction; +⁻, most strains are positive, but may have occasional negative reactions; –⁺, most strains are negative, but an occasional strain may be positive; V, variable reactions among the species; w, weak reactions; CAT, catalase; IND, indole production; NIT, nitrate reduction; ESC, esculin hydrolysis; ADH, arginine dihydrolase; FERM, fermentative; GS, Gram's stain.
Adapted from references 178, 238, 499.

1045

Currently, species of *Clostridium* encountered clinically vary in their relationships to oxygen and in their anabolic and catabolic physiologic activities (Chart 16-12). Certain clostridia, for example *C. haemolyticum* and *C. novyi* type B, are among the strictest of obligate anaerobes. At the other end of the spectrum, *C. histolyticum, C. tertium* and *C. carnis* are aerotolerant, and form colonies on anaerobe blood agar plates incubated in a candle jar or in a 5% to 10% CO_2 incubator. In the clinical laboratory the problem sometimes arises of determining whether an isolate is an aerotolerant *Clostridium* or a facultatively anaerobic *Bacillus*. Aerotolerant clostridia rarely form spores when grown aerobically and are catalase-negative, whereas species of the genus *Bacillus* rarely form spores when grown under anaerobic conditions, and they produce catalase.[238,464] Although the clostridia are considered gram-positive, many stain gram-negative by the time smears of growing cultures are prepared. For example, *Clostridium ramosum, C. symbiosum,* and *C. clostridioforme* group are usually stained gram-negative.

The demonstration of spores is frequently difficult with some species, such as *C. perfringens, C. ramosum,* and *C. clostridioforme* group. In those species in which spores are usually present, Gram-stained preparations are usually sufficient; special spore stains generally offer no particular advantage. In order to enhance spore

formation, a heat shock or alcohol spore selection technique may be used.[238,264] Identifying characteristics for most of the clostridia encountered in human infections are given in Tables 16-23 and 16-24.

C. perfringens. Some of the key reactions for identifying *C. perfringens* are illustrated in Image Plate 16-3C and 16-3E. The double zone of hemolysis on blood agar, production of lecithinase on EYA and stormy fermentation of litmus milk (or proteolysis of milk agar) are characteristic of this species. The cells of *C. perfringens* are usually 0.8 to 1.5 µm in diameter × 2 to 4 µm long and have blunt ends (Image Plate 16-3A, 16-3B and 16-3D). They are often described as boxcar-shaped. However, cells examined during early growth in broth culture tend to be short and coccoid, while older cultures contain longer cells that may be almost filamentous. After overnight incubation on blood agar, colonies are usually 1 to 3 mm in diameter, but may reach a diameter of 4 to 15 mm after prolonged incubation. Colonies are usually flat, somewhat rhizoid, and raised centrally. Some colonies tend to spread, but they do not swarm. *C. perfringens* is nonmotile. Traditionally, the Nagler has been used for the identification of *C. perfringens*; similarly, the "Reverse CAMP" test has also been used. These are not commonly performed in clinical practice, but the principles are reviewed in Chart 16-8.

Identification of Other Selected *Clostridium* spp. *C. perfringens* is by far the most commonly isolated species of *Clostridium* from human sources. However, there are many other clostridia that are isolated from clinical specimens. Cells of *C. ramosum* are usually less than 0.6 µm in diameter × 2 to 5 µm long, but are extremely pleomorphic, sometimes producing short chains or long filaments; many strains will be gram-negative. On blood agar, colonies are often 1 to 2 mm in diameter, usually nonhemolytic, slightly irregular or circular, entire, low convex and translucent. Isolates of *C. ramosum* are characteristically resistant to rifampin by the 15-mg disk method discussed above, but inhibited by the 2-U penicillin disk and the 1-mg kanamycin disk, similar to *F. mortiferum* and *F. varium*. *C. ramosum* is indole-negative, whereas *F. mortiferum* and *F. varium* are indole-positive. *C. ramosum* also shows enhanced growth on bile agar, hydrolyzes esculin, but is negative for catalase, lipase and lecithinase. It is among the few clostridia that ferment mannitol. Acetic, lactic and succinic acids are the major metabolic products. The cells of *C. septicum* are usually about 0.6 µm wide and 3 to 6 µm long (Image Plate 16-3H). It tends to be pleomorphic, sometimes producing long, thin filaments. Chain formation is common, as are intensely staining citron (lemon-shaped) forms. Spores are oval, subterminal and distend the organism. After 48 hours of incubation on blood agar, colonies are 2 to 5 mm in diameter, surrounded by a 1- to 4-mm zone of complete hemolysis; they are flat, slightly raised, gray, glistening, semitranslucent and have markedly irregular to rhizoid margins, often surrounded by a zone of swarming (Image Plate 16-3G).

Extremely motile strains may swarm across a wide area of the plate. Stiff blood agar, which contains 4% to 6% agar, instead of the usual 1.5%, is sometimes used in plating media to minimize swarming. Some key characteristics of *C. septicum* are that it hydrolyzes gelatin, does not produce indole, lipase, or lecithinase and ferments lactose but not mannitol, rhamnose, or sucrose. Acetic and butyric acids are the major metabolic products.

C. clostridioforme complex is made up of at least six species, *C. aldense, C. bolteae, C. citroniae, C. clostridioforme, C. hathewayi,* and *C. lavalense*. They all stain predominantly gram-negative, and they have been referred to as containing cigar-shaped cells. All ferment glucose and are negative for gelatin hydrolysis. Three are indole-positive, *C. aldense, C. citroniae,* and *C. lavalense*; two can be esculin-positive, *C. bolteae* and *C. hathewayi*. *C. hathewayi* is β-NAG positive and the others negative or have an unknown reaction. *C. symbiosum* also stains gram-negative and may have cigar-shaped cells like the *C. clostridioforme* complex, but it is usually gelatin hydrolysis–positive, although weakly, and urea-positive. *C. symbiosum* grows very slowly and usually forms a film of growth on the agar surface, so it is distinguishable from the complex.

C. innocuum, a commonly isolated *Clostridium*, is a gram-positive bacillus with oval, terminal spores; colonies will fluoresce chartreuse under UV light similar to *C. difficile* but *C. innocuum* is negative for motility and gelatin hydrolysis, whereas *C. difficile* should be positive for these biochemicals. *C. tertium* is the most commonly isolated of the aerotolerant *Clostridium* spp.; it has oval, terminal spores and is motile and esculin hydrolysis–positive.

1046

TABLE 16-23 Phenotypic and Colonial Characteristics of *Clostridium* spp.

Species	Gel	Glu	Lec	LIP	IND	URE	ESC	NIT	MOT	Spores	Colony[a]
C. aldenense	–	+	NA	NA	+	–	–	–	NA	ST, but rarely seen; α-galactosidase +; β-galactosidase +; Stains gram-negative; β-NAG –	Part of *C. clostridioforme* complex; spores are rarely seen. Colonies are 1–2 mm, flat, opaque to white, nonhemolytic; found in GI tract
C. argitenense	+	–	–	–	–	NA	–	–	NA	ST	
C. barati	–	+	+	–	–	–	+	–	–	ST; rarely seen on Gram's stain	Small, nonhemolytic colonies
C. bifermentans	+	+	+	–	+	–	+	–	+	O; ST	Gray; irregular edge; narrow zone of hemolysis; **chalk white on EYA**; may swarm or spread; translucent to opaque; flat or raised; mottled internal structures
C. bolteae	–	+	–	–	–	NA	–[+]	–	NA	ST, but rarely seen; cigar-shaped cells stain gram-negative; can contain the vanB gene;β-NAG –	A member of *C. clostridioforme* complex
C. botulinum	+	+	–	+	–	NA	V	–	+	ST or T	Variable hemolysis seen
C. butyricum	–	+	–	–	–	–	+	–	+	O; ST	Large, irregular colonies with mottled to mosaic internal structures
C. cadaveris	+	+	–	–	+	–	–	–	+	O;T	White to gray; entire or slightly irregular edges; raised to slightly convex
C. carnis	–	+	–	–	–		+	–	NA	ST	**Aerotolerant**
C. citroniae	–	+	NA	NA	+	–	–	–		ST; spores rarely seen; stain gram-negative; β-NAG –	Flat, opaque to white, nonhemolytic; member of *C. clostridioforme* complex
C. clostridioforme	–	+	–	–	–	–	+	–	+	O; ST; cigar or football-shaped cells that may taper but spores rarely seen on Gram's stain; stains gram-negative; can be β-lactamase positive	Small; convex and translucent colonies; mottled or mosaic internal surface; when exposed to air, colonies may cause greening of blood agar
C. difficile	+	+	–	–	–	–	+	–	+	O;ST or T	Slightly raised; umbonate with filamentous edge; translucent with crystalline internal speckling; **chartreuse fluorescence**; **horse barn odor**
C. hastiforme	+	–	–	–	–	–	–	–[+]	+	T	
C. hathewayi[d]	–	NA	–	–	–	NA	+[w]	–	NA	ST; spores rarely seen; cigar-shaped cells stains gram-negative; rods with non-tapered ends; β-NAG +; **can contain *vanB* gene**	Nonhemolytic; gray-white, convex, shiny colonies with irregular margins; member of *C. clostridioforme* complex
C. histolyticum	+	–	–	–	–	–	–	–	+	O; ST	Smooth or rough colonies; if rough, have rhizoid edges; **aerotolerant**

1047

C. innocuum	–	+	–	–	–	–	+	–	–	O;T	White, glossy, raised colonies; **chartreuse fluorescence**
C. lavalense	–	+	–	–	+	–	–	NA	NA	ST large rods with tapered ends; **stains gram-negative**; spores are rarely seen; α-galactosidase – and β-galactosidase +; may be vancomycin resistant	Large colonies that are gray-white; nonhemolytic; strongly adhere to agar; member of *C. clostridioforme* complex
C. limosum	+	–	+	–	–	–	–	–	+	ST	
C. novyi A	+	+	+	+	–	–	–	–	+	O; ST	Gray, translucent; irregular surface; **may have double zone of hemolysis**
C. perfringens[b]	+	+	+	–	–	–	–	+⁻	–	ST; rarely seen in Gram's stain	Gray; opaque; flat; edges somewhat rhizoid, but tend to spread and not swarm; **double zone of hemolysis**
C. putrificum	+	+	–	–	–	–	–⁺	–	+	T or ST	Not distinctive
C. ramosum	–	+	–	–	–	–	+	–	–	O or R; T; cells are thin variable rods	Translucent; circular or slightly irregular edges; convex; brownish discoloration on blood agar with air exposure; **red fluorescence**
C. septicum	+	+	–	–	–	–	+	V	+	O or ST	Medusa-head like growth; becomes heavy film that cover agar surface; **(swarms)**; glistening flat gray colonies
C. sordellii	+	+	+	–	+	+⁻	–⁺	–	+	O; ST; free spores often seen	Translucent to opaque; flat or raised; can have mottled internal structure; colonies may spread over agar surface (Image Plate 16-4G and 16-4H)
C. sporogenes	+	+	–	+	–	–	+	–	+	O; ST; many free spores	Raised gray-yellow center; rhizoid edges; colonies adhere firmly to agar; may show some swarming (Image Plate 16-4C)
C. subterminale	+	–	–⁺	–	–	–	–⁺	–	+	O;SR; rarely seen in Gram's stain	
C. symbiosum	W	+ʷ	–	–	–	+	–	–	+	ST; stains gram-negative; may have cigar-shaped cells that form chains; spores may or may not be seen	Very slow growing; sometimes produces only a film of growth, described as "dusty growth"
C. tertium[c]	–	+	–	–	–	–	+	–	+	O;T	Small; translucent; glossy colonies; **aerotolerant**
C. tetani	+	–	–	–ʷ	V	–	–	–	+	R;T; drumstick shape	Translucent; gray; irregular edges; may form thin film of growth on entire plate; may have narrow zone of hemolysis

[a] If there is a unique characteristic of the species, it has been bolded.
[b] Some strains of *C. perfringens* may be catalase-positive; some may be slightly aerotolerant.
[c] *C. tertium*, many strains of *C. histolyticum*, and *C. carnis* (not in Table) are aerotolerant *Clostridium* spp.
[d] There is a proposal to rename *C. hathewayi* to *Hungatella hathewayi*.[249]
+, positive; –, negative; –⁺, most strains negative with an occasional strain positive; +⁻, most strains positive with an occasional strain negative; w, weak reaction; ND, not determined; V, variable reactions, Gel, gelatin hydrolysis; Glu, glucose fermentation; Lec, lecithinase; LIP, lipase; IND, indole production; URE, urease; ESC, esculin hydrolysis; NIT, nitrate reduction; MOT, motility; β-NAG, *N*-acetyl-β-glucosaminidase, O, oval shape; R, round spores; T, terminal spore location; ST, subterminal spore location; EYA, Egg yolk agar.
Adapted from references 178, 238, 464.

1048

TABLE 16-24 Useful Characteristics for Identifying *Clostridium* Species

Characteristic	Species
Aerotolerant	*C. carnis, C. histolyticum, C. tertium*
Nonmotile[a]	*C. innocuum, C. perfringens, C. ramosum*
Usually stains gram-negative	*C. clostridioforme complex (C. clostridioforme, C. aldenense, C. bolteae, C. citroniae, C. hathewayi, C. lavalense), C. symbiosum*
Terminal spores	*C. baratii, C. cadaveris, C. innocuum, C. ramosum, C. tertium, C. tetani* (Image Plate 16-4D)
	C. perfringens, C. clostridioforme complex (see above

Spores not seen in stains	*for species); C. symbiosum, C. baratii, C. ramosum, C. citroniae, C. subterminale*
Lecithinase produced on EYA	*C. bifermentans, C. limosum, C. novyi, C. perfringens, C. sordellii, C. subterminale, C. baratii*
Lipase produced on EYA	*C. botulinum, C. novyi A, C. sporogenes* (Image Plate 16-3F)
Both lecithinase and lipase produced	*C. novyii A, C. sporogenes*
Asaccharolytic and proteolytic (i.e., gelatin-positive)	*C. histolyticum, C. limosum, C. subterminale, C. tetani, C. hastiforme*
Urease-positive	*C. sordellii*[b], *C. symbiosum (original description)*
Do not hydrolyze gelatin	*C. butyricum, C. clostridioforme complex, C. paraputrificum, C. baratii, C. ramosum*
Mannitol fermented[c]	*C. difficile, C. innocuum, C. ramosum, C. tertium*
Rhamnose fermented	*C. clostridioforme, C. ramosum, C. sporogenes*
Saccharolytic and proteolytic	*C. bifermentans, C. botulinum, C. cadaveris, C. difficile, C. perfringens, C. putrificum, C. septicum, C. sordellii, C. novyi A, C. sporogenes, C. symbiosum*
Saccharolytic but nonproteolytic	*C. baratii, C. butyricum, C. clostridioforme, C. innocuum, C. ramosum, C. tertium, C. carnis, C. aldenense, C. bolteae, C. carnis, C. lavalense*

[a] There may be other nonmotile species of *Clostridium*, that have been more recently described.
[b] *C. sordellii* resembles *C. bifermentans*, but *C. bifermentans* is urease-negative; *C. symbios*um stains gram-negative and may have tapered ends so it is easy to distinguish from *C. sordellii.*
[c] There are a few other species that are mostly negative, but an occasional strain may be positive: *C. botulinum*, Type B, E, F; *C. butyricum* and possibly other species not in Table 16-26.
EYA, egg yolk agar.

C. difficile-*Associated Intestinal Diseases: Epidemiology and Laboratory Identification*

Description of Disease and Epidemiology. *C. difficile*, first isolated in 1935, was believed to be nonpathogenic for humans until the late 1970s, when it was implicated

as a causative agent in AAD and PMC.[33,34,464] Benign, self-limited diarrhea frequently develops in hospitalized patients who are being treated with antibiotics. *C. difficile* has been found responsible for 25% to 30% of the cases of AAD.[74] The diarrhea often subsides once the inciting antibiotic is discontinued. In other patients, the intestinal symptoms may be more severe, and the diarrhea persists. These patients may have antibiotic-associated colitis (AAC), a condition caused by *C. difficile* 60% to 75% of the time. The more severe and life-threatening PMC is caused primarily by *C. difficile*, although may be infrequently caused by *S. aureus* or other pathogens.[33,34,139,464] In the United States, there are >300,000 cases per year of AAD, AAC, or PMC caused by toxigenic *C. difficile*. One review reported that their hospital had medical expenditures associated with *C. difficile*-associated disease were almost $1,000,000 per year and another review article suggested that healthcare costs in the United States were approaching $1 billion annually.[453] The severity of illness, as well as pathologic findings, are highly variable, depending on whether the patient has PMC, AAC, AAD or is simply colonized with *C. difficile* or is an asymptomatic carrier. The pathologic findings in PMC and AAC have been adequately reviewed elsewhere.[34,35,139] In a report of gastroenteritis-associated deaths in the United States, 1999 to 2007, the CDC reported that *C. difficile* mortality increased fivefold from 10/1,000,000 person years in 1999 to 2000 to 48/1,000,000 person years in 2006 to 2007. This was statistically significant. Norovirus was found to be the second leading infectious cause of death in this report.[201] *C. difficile* can also be a rare cause of abscesses, wound infections, osteomyelitis, pleuritis, peritonitis, bacteremia, and urogenital tract infections.[323,464]

Two toxins are involved in *C. difficile*-associated GI disease: toxin A, which is an enterotoxin capable of producing fluid accumulation in ligated rabbit ileal loop assays, and toxin B, which is a potent cytotoxin capable of producing cytopathogenic effects in several tissue culture cell lines.[464] Toxin A is also cytotoxic in certain cell lines, but is not as cytotoxic as toxin B in the cell lines that have long been used for toxin B testing.[306] The majority of isolates of toxigenic *C. difficile* carry the genes for both toxin A (*tcd*A) and toxin B (*tcd*B). In addition, there are strains in which a third gene,

1049

*tcd*C, is present, which causes the overproduction of *C. difficile* toxins, resulting in more severe disease. These hypervirulent strains have been called NAP1/027 or PCR ribotype 027, and the toxin is called a binary toxin. These latter hypervirulent strains have caused outbreaks of disease in Canada, Europe, and the United States, and there is some evidence that they may be triggered by extensive use of fluoroquinolones.[326,464] Decreased cure and increased recurrence rates are associated

with this hypervirulent strain as well.[375] For additional information on *C. difficile* and its toxins, the following references are recommended.[33,34,49,64,306,464,496]

C. difficile is ubiquitous in nature, and has been isolated from soil, water, intestinal contents of various animals, the vagina and urethra of humans, and feces of many healthy infants, but from the stools of only about 3% of healthy adult volunteers. However, the organism is more prevalent in the feces of some hospitalized adults who do not have diarrhea or colitis. It has been found in the feces of about 13% to 30% of hospitalized adults who were colonized but had no evidence of disease caused by *C. difficile* nor any antecedent antibiotic treatment. Toxigenic *C. difficile* can commonly be found in the feces of many healthy infants, and may remain as colonizers for long periods of time. It is often difficult to evaluate what role *C. difficile* has in a infantile diarrhea in hospitalized children; in many laboratories, *C. difficile* tests are not routinely performed on the stool of infants less than 2 years old.[2] Some infants, however, with severe and protracted diarrhea, associated with antecedent antibiotic therapy, have had PMC and at the same time, *C. difficile* cytotoxin present in their feces without any other putative etiologic agent. These patients have often responded clinically to oral vancomycin. There are some issues as well with association of *C. difficile* and diarrhea in children greater than 2 years, but recent review articles address this and can be referred to if the question arises in the laboratory.[64,344,411] The American Academy of Pediatrics recently issued a policy with information and recommendations in regard to *C. difficile* in children.[418]

The great majority of patients with *C. difficile* infection have had prior exposure to antibiotics whether they have been diagnosed while in the hospital or long-term care facility or are seen in an ambulatory care setting when the diagnosis is made. In a study of patients recently discharged from an acute-care hospital, Chang et al. found that 92% of patients diagnosed in the ambulatory care setting had received antibiotics during a prior hospitalization and 65% of these patients received antibiotics both as an in and outpatient.[86] Antimicrobial agents implicated in *C. difficile*-associated GI illness have included most antibiotics; however, the disease is most commonly associated with clindamycin, cephalosporins, and the fluoroquinolones.[33–35,180,464] For more information on the clinical findings and clinical diagnosis of AAD, AAC, and PMC, the reader is referred to other sources.[33,34,35,101,464]

Collection and Transport of Specimens Containing *C. difficile*. Ordinarily, watery or semisolid, unformed fecal specimens (about 5 g or 1,020 mL of liquid stool) are the preferred specimens for testing. Swab specimens, because of the small volume obtained, are inadequate. Formed stool specimens are inappropriate for diagnostic testing unless an epidemiologic study of stool carriage is being conducted. Other suitable specimens include biopsy material or lumen contents obtained by colonoscopy

and involved bowel (surgical removal; autopsy). However, lumen contents or biopsy material from colonoscopic procedures may excessively dilute the sample, or the quantity obtained by biopsy may be insufficient for the laboratory work required. The testing of biopsy specimens, however, is less sensitive than the testing of stool, which is the preferred specimen. Leak-proof plastic containers should be used for the transport of specimens. If specimens are to be processed by the laboratory on the same day they are collected, then transportation at room temperature will suffice. If a specimen arrives late in the day and cannot be processed by assays that detect toxin until the following day, it may be held in the refrigerator without demonstrable loss of cytotoxic activity, but the directions for any commercial tests should always be followed. Optimally, specimens should not remain at room temperature longer than 2 hours before being cultured; if processing for culture cannot occur within 2 hours of collection, then refrigerate in an anaerobic environment (transport vial or bag), although this may reduce the number of vegetative cells. If specimens are to be shipped a reference laboratory for a toxin assay, they should be shipped on dry ice and stored in lab at −70°C before shipment. Storage at −20°C will not guarantee the stability of the toxins. Most laboratories have migrated to PCR for the detection of *C. difficile.* If this is the case, then the manufacturer's guidelines for specimen transport should be followed.

Laboratory Diagnosis of Toxigenic *C. difficile*. To diagnose C. *difficile* infections, stool samples are submitted to the laboratory to detect the presence of toxigenic *C. difficile*. Culture for the recovery of toxigenic *C. difficile* was the first method used in clinical laboratories in the late 1970s when the association of *C. difficile* and diarrhea was initially recognized, and it continues to be considered the "gold standard" for detection and the reference method when evaluating newer tests. Plating of samples of stool, with or without prior heat or alcohol shocking, onto selective CCFA agar (Cycloserine, cefoxitin, fructose agar) and nonselective media (anaerobic blood agar) is used for the recovery of *C. difficile* (Image Plate 16-4E). Then, any *C. difficile* isolate recovered is tested for the production of toxins. (Culture media and methods are discussed below). The cytotoxin B tissue culture assay is the test most commonly performed to determine if the *C. difficile* isolate recovered is toxigenic. Alternatively, direct cytotoxin B tissue culture assays for detection of toxigenic *C. difficile* could also be performed directly on stool samples instead of culture. Many refer to this test as the cell culture neutralization assay (CCNA). The procedure for the tissue culture assays consist of inoculation of specific tissue culture panels, usually containing McCoy epithelial cells or human foreskin cells with the stool sample and examining it in 24 to 28 hours for presence of cytopathic effect (CPE), a rounding up of the fibroblast cells as a result of the presence of Toxin B (Chart 16-9). *C. difficile* antitoxin added to a companion well would neutralize the toxin, confirming that the CPE was indeed due specifically to *C. difficile*. For many years, the cytotoxin B

assay was felt to be equivalent to culture for detection of toxigenic *C. difficile*, but more recently with the advent of molecular methods of detection, the sensitivity of the Toxin B assay when used directly, as

1050

compared to toxigenic culture, was found to be <70% with a specificity of 99%, thus limiting its use as a primary test in most situations.[458] Information on the cytotoxin procedure is in Chart 16-9. Extended turnaround times for culture and the need to keep confirmatory tests available for detection of the toxin in isolated colonies have limited the usefulness of these tests in most clinical laboratories. However, culture is the method used for epidemiology, when susceptibility testing is requested, and as the preferred comparator method when new tests are being evaluated. Tissue culture assays are still used in some laboratories for confirmation of newer screening assays and for the purpose of confirming culture results, but less commonly as the primary diagnostic test.

Culture Methods and Cytotoxin Identification. *C. difficile* can be isolated from stool specimens by the use of a spore selection technique (i.e., heat shock or alcohol spore selection procedures) in conjunction with use of selective plating media such as PEA blood agar (Remel, Lenexa, KS; or BD Microbiology Systems) or CCFA plus nonselective CDC anaerobe blood agar.[464] Detailed descriptions of the alcohol and heat-treatment spore selection procedures are given elsewhere.[238] If either of these procedures is used, the alcohol or heat-treated sample is inoculated onto anaerobe blood agar and/or EYA. Selective media like CCFA could also be inoculated since typical morphology may be easier to identify, but should not be used alone since it might be too inhibitory after the stool has been treated to reduce other microbiota organisms. There is a third method of stool treatment that has been described more recently which optimizes recovery of *C. difficile* with the use of an enrichment broth that has been supplemented with sodium taurcholate to enhance spore germination. In two separate studies, results were superior to pretreatment with alcohol or heat before plating.[16,220] Following 48 hours of incubation anaerobically, colonies of *C. difficile* on anaerobe blood agar are nonhemolytic, about 2 to 4 mm in diameter, grayish translucent, slightly raised, flat, and spreading, with rhizoid margins. As seen through a dissecting microscope, the colonies show an iridescent, "speckled-opalescent" appearance. *C. difficile* is negative for lipase and lecithinase on EYA and produces the characteristic flat, irregular to circular colonies with a rhizoid edge. The colonies have ground glass appearance on the surface and a yellowish to white pigmentation on CCFA agar. If a UV lamp is shone on the colonies, they will fluoresce a chartreuse color. In addition, there is a characteristic horse manure (horse barn) odor due to production of *para*-cresol (Table 16-24). Often when an anaerobic jar is opened, the

odor will be immediately detected.[238]

In addition to the spore selection procedure, a plate of PEA medium and a CCFA plate should be inoculated with untreated stool, or a stool suspension prepared in buffered gelatin diluent. After 48 hours of incubation, colonies of *C. difficile* on PEA medium will be virtually identical to those on anaerobe blood agar (described above). The appearance of *C. difficile* colonies on CCFA medium is described above and in Table 16-24. The gram-positive to gram-variable rods have subterminal spores and are motile. Metabolic product analysis reveals acetic, propionic, isobutyric, butyric, isovaleric, valeric, and isocaproic acids. Esculin and gelatin are hydrolyzed. Indole, nitrate, and urease are negative. Most strains ferment glucose, mannitol and mannose. Salicin and xylose are variable. Once a typical colony of *C. difficile* is isolated and phenotypic identification is complete, evidence that it is toxigenic needs to be accomplished using the cytotoxin B assay or a molecular test for detection of a toxin gene(s).

Two new culture media have been developed to select for strains of toxigenic *C. difficile* to avoid the necessity of performing a confirmatory toxin assay. One is called the Cdifftox plate assay, reported on by Darkoh et al. in which CCFA, along with sodium taurocholate, added to enhance the germination of spores, blood and a chromogenic substrate (X-gal) provide a single plate upon which toxigenic *C. difficile* strains will produce a blue color and nontoxigenic strains a white colony. The toxins, if present, will cleave the chromogenic substrate in place of their natural substrate, UDP glucose. Culture results are usually available in 24 to 48 hours. The product was described to have 99.8% accuracy when testing 528 isolates that came from 50 tissue culture cytotoxicity assay positive specimens.[112] There is a commercially produced chromogenic media, chromID *C. difficile*, that can detect toxigenic *C. difficile* in <3days. It has been evaluated in a few laboratories and the results were very good and available more rapidly than what can be obtained on CCFA agar plus toxin detection.[77,140,304,432]

Enzyme Immunoassays for Toxin Detection. Because of the labor-intensive and time-consuming nature of culture and lack of sensitivity of the cytotoxin tissue culture assay, enzyme immunoassays (EIAs) have been developed for the detection of *C. difficile* toxin(s). Assays to detect toxin A were introduced into clinical laboratories over 20 years ago. These were more rapid and less time-consuming than culture or CCNA and provided good information in formats that allowed for batch or individual specimen testing. A number of these tests in a variety of formats were developed and adapted by the majority of routine laboratories. When a few toxin B-positive/toxin A-negative strains were discovered, a number of EIA products that detected both toxin A and toxin B were developed and implemented in most clinical laboratories to replace the Toxin A EIA assays.[243] With the widespread use of PCR and the use of culture as gold standard in more recent comparator studies, the EIA for toxin A + B assays were

determined to be performing at sensitivities as low as 52% and not much higher than 81%.[440,510] Authors who have compared EIA or lateral flow assays for detection of toxins A and B have in general concluded that the assays should not be the only test that is done routinely for the diagnosis of *C. difficile*. Even when these tests were examined to detect severe disease versus mild disease, EIA assays were still much less sensitive even with severe disease than would be acceptable for primary stool testing.[226] Although insensitive, the specificity of the EIA toxin assays is good, in the range of 91% to 94% or greater. Therefore, they can be used for confirmation of a positive result by an antigen assay, for example, or another highly sensitive, but less specific methods.[49,138,226] Today, laboratories should no longer rely on these EIAs alone for the diagnosis of toxigenic *C. difficile*.

Nucleic Acid Amplification Test for *C. difficile.* Amplification of the *tcd*B or *tcd*A genes has consistently demonstrated good sensitivity and specificity when compared to toxigenic culture as the gold standard.[49,138,362,458] Although laboratories have developed their own real-time PCR assays,

1051

there are many commercial products available. There is ample evidence indicating that these molecular methods can significantly increase the sensitivity over EIA assays and consequently the incidence of *C. difficile* detected in the stool of hospitalized patients, in some cases by as much >50% with good specificity as compared to culture.[74,138,297,458,335,366,373] Table 16-25 lists many of the commercially available assays in the US presently and a few bullet points of where they may differ from each other. Table 16-26 provides results of published studies comparing the most commonly used nucleic acid amplification tests (NAATs) alone, against other NAATs or versus toxigenic culture as the "gold standard." A review article in 2011 provided excellent information on the then commercially available PCR assays; the author's conclusion were that the NAAT assays all compared well with culture and were superior to EIAs and tissue culture. The turnaround time was adequate, ranging from 45 to 180 minutes and would allow for same shift resulting.[374] A meta-analysis of 25 publications that evaluated NAAT for the detection of *C. difficile,* which included >11,000 stool specimens that met inclusion criteria, found that most labs that presented data on a *C. difficile* molecular test were using BD GeneOhm, followed by Cepheid GeneXpert. In addition, laboratories also used a Light Cycler PCR (Roche Molecular, IND), or Hologic's ProGastro CD. A few laboratories reported use of Illumigene's LAMP assay, but were not included in the analysis because the studies were too heterogeneous for comparison at that time. The authors concluded that molecular tests were highly accurate for detection of *C. difficile* toxins and that the

LAMP assay looked promising, which has subsequently been proven.[362]

There are often questions about repeat testing for the presence of *C. difficile* with molecular assays. The utility of repeat testing for *C. difficile* has been evaluated and in most studies, it has not proved useful for the diagnosis of *C. difficile*, but if done, it should always be done using a different method than what was initially done. Once a cohort of patients has initially been determined to be negative for *C. difficile* by a highly sensitive assay, such as a NAAT, then repeat testing is more likely to generated false-positive results than true-positive results. Furthermore, laboratory testing should not be performed as a "test of cure." The resolution of *C. difficile* disease should be assessed on a clinical basis, regardless of whether or not *C. difficile* remains as part of the microbiota of the patient. The Society for Healthcare Epidemiology of America (SHEA) also discourages repeat testing for *C. difficile*.[74,101,305]

***C. difficile* GDH Antigen Testing.** As an alternative to primary PCR testing, there are at least three commercially available assays that detect glutamate dehydrogenase (GDH), an antigen common to *C. difficile* and other *Clostridium* spp.[73,110,138,390,476]These assays are very highly sensitive, but are not specific enough for *C. difficile* to be used alone. However, they can be used as a negative screen initially for *C. difficile* stool requests; when positive, confirmatory tests that detect *C. difficile* toxins specifically, can be employed before reporting results. *C. DIFF CHEK*-60 (TechLab, Blacksburg, VA) is a 96-well ELISA that can be performed in 60 minutes. The sensitivity of this assay is very high (>99%) as reported in most studies; in one study, only 22 of 37 GDH positive/cytotoxin assay positive, were positive with a well-known EIA for toxin A and B (59.5% sensitivity). The positive predictive value of the GDH was only 50%, so it must be used in an algorithmic fashion with an assay that confirms presence of cytotoxin.[183]A combination GDH antigen + toxin EIA assay is now available from the same manufacturer to run both tests simultaneously; C. DIFF Quik Chek Complete (TechLab, Blacksburg, VA) is a rapid membrane enzyme immunoassay to which the diluted stool sample is added and incubated for 15 minutes. The formation of a blue line on the left of the reaction window would indicate the presence of GDH and a blue line on right would indicate the presence of *C. difficile* toxin. Use of the antigen as a negative screen, followed by a cytotoxin B assay on the samples that are positive, has been shown to produce very sensitive results with high negative predictive values in a cost-effective approach.[390,476] When the antigen assay is negative, and this can usually be done in less than 10 minutes, then the results of a negative *C. difficile* can be reported immediately. However, nontoxigenic *C. difficile* can also produce a positive GDH result; hence the need to confirm the antigen positive stool samples.[75] This can be done as mentioned above by means of an EIA for toxin A/B, a cytotoxin assay in tissue culture or PCR.[110,362] The latter approach would provide the best overall sensitivity and specificity as a one-step confirmation.

However, many labs use a three-step approach as follows: positive antigen results are followed up with toxin A/B EIA; if the two are positive, results are signed out as positive for toxigenic *C. difficile*, but if negative, further confirmation testing is performed with PCR or culture. One study examined the use of two different molecular assays for this confirmation; they performed equally well, although the authors felt one was slightly more efficient than the other.[3]

TABLE 16-25 Characteristics of Commercial NAAT for the Detection of Toxigenic *C. difficile*

NAAT	Manufacturer	Target[a]	Format	Turnaround Time[b] (minutes)
Prodesse ProGastro Cd Assay[248,421,458,488]	Hologics, Inc, CA	*tcd*B	Smart Cycler	75–90
Gen-Ohm Cdiff Assay[3,248,421,473,488]	BD-GeneOhm, CA	*tcd*B	Smart Cycler	180
BD Max[226,288, c]	BD Gene Ohm, CA	*tcd*B	BD-Max	160

[a] Toxgenic cultures were used as the gold standard in study unless otherwise indicated.
GeneOhm (BD, MD); XPert (Cepheid); ProGastroCd (GenProbe, Inc., CA); Portrait (Great Basin, WI); Illumigene (Meridian Bioscience, Inc.); Light Cycler (Roche, Ind); Verigene; Simplexa (Focus Diag., CA); Amplivue (Quidel Corp).
[b] PCR was a laboratory-developed assay.
[c] Culture only done on discordants.
[d] Frozen stools; pediatric patients.
[e] Culture not performed.
[f] For comparison, two cultures were performed, one with CCFA and one with CCFA containing taurcholate to enhance spore germination. Assay detects *tcd*A and *tcd*B and *tcd* C; 24% of positives were hypervirulent (mostly ribotype 027) strains.
EIA, enzyme immunoassay for toxin A and/or B; QuikChek, combination test with GDH and EIA for toxin B; CCNA, cytotoxin neutralization assay.

There is also a latex agglutination assay for GDH combined with a toxin A immunoassay from Biosite Labs. One study examined 557 fresh stool samples comparing its performance to a toxin A/B immunoassay and cytotoxin B tissue culture assay. The sensitivity of the GDH was 97%, with a specificity of 87%. Seventeen percent of the positive GDH samples were not confirmed with the toxin A assay and another confirmatory test was needed.[322] No toxigenic culture or PCR was used as a comparator, however, so it is difficult to know if the sensitivity was as high as reported since tissue culture sensitivity, the comparator arm of the study, does not have sensitivity as high as toxigenic culture and/or PCR. Laboratories that have the capability for performing PCR routinely on all stool specimens may instead perform amplification on all samples routinely in order to reduce the amount of steps and potentially the time-to-results. This approach may provide the best overall sensitivity and specificity, PPV and NPV as compared to toxigenic culture. SHEA has suggested that NAAT appears to be sensitive and specific for detection but more data is needed before they would endorse PCR as primary test for all laboratories.[101] The two- or three-step algorithm does have the advantage of more rapid reporting, especially with specimens that are antigen and toxin A/B positive and those that are negative. More time, however, is needed for further confirmation of those specimens that are positive for the GDH antigen, but EIA negative. In a study examining results of the GDH/toxin A/B assay two-step algorithm, the authors reported that they were able to report 36% of the *C. difficile* positive results and 94% of the negative results within 30 minutes. Only 13% of their workload was utilized to confirm GDH antigen positive/toxin A/B negative specimens before reporting results.[110] In another study using Premier EIA for GDH, positive results were followed by a Illumigene's LAMP assay for confirmation; the sensitivity was 92% compared to other algorithms used and the authors suggested that the LAMP assay was much less expensive than other PCR assays and was very user friendly; they found no advantage to a three-step assay.[23]

Prevention of *C. difficile*. Prevention of *C. difficile* disease is the most important way to reduce the disease. Stewardship programs in healthcare systems that work toward reducing the inappropriate use of antibiotics, and implementation of hand washing, use of chlorine-containing cleaning agents in the hospital, and other infection control precautions to limit spread of toxigenic *C. difficile* are the ways in which this can be done.[101,152,272] Using appropriate tests that are sensitive and specific and enforcing appropriate specimen collection and transport guidelines are procedures that laboratories can do to participate in prevention and control. Culture of *C. difficile*, although not a timely nor efficient routine method for laboratory diagnosis, remains a useful tool in epidemiologic studies when strain typing and/or antimicrobial testing may be useful in defining an outbreak and preventing further disease. For routine testing,

use of an algorithm that includes glutamate dehydrogenase antigen testing or direct amplification tests would be good choices for laboratories to consider.[52,110,390,464,488] A cost-effectiveness study was performed on a two-step algorithm using the C. DIFF Quik Check (GDH plus EIA assay) confirmed with a PCR assay when the antigen and EIA were discordant. Eighty-six percent of the stool sample results could be resulted quickly; the remaining 14% required a PCR for confirmation of the result before it was resulted. The cost per test was $13.50 for this approach versus performing a PCR on all samples, which they estimated to cost $26 per test.[488] Possible algorithms for processing *C. difficile* specimens is given in Box 16-12. Box 16-13 presents some bullet points to remember when handling requests for toxigenic *C. difficile.*

Identification of the Anaerobic Cocci

Anaerobic Gram-Positive Cocci. *P. anaerobius* is a large, elongated coccus occurring in pairs and chains; colonies are larger than other anaerobic cocci and are gray-white and opaque in appearance. A sweet odor due to the production of isocaproic acid and susceptibility to the SPS disk can be distinguishing characteristics. *P. anaerobius* is catalase-, indole-, and urease-negative, but is positive for production of α-glucosidase. *Finegoldia magna* and *Parvimonas micra* can commonly appear in similar clinical situations, but can be distinguished in the laboratory because of their size initially. *P. micra* cells are <0.6 µm and colonies have a milky halo which is quite distinctive; the cells of *F. magna*, in contrast, are >0.6 µm. Both of these organisms are catalase-, indole-, α-glucosidase-, and urease-negative. Colonies of *Peptoniphilus asaccharolyticus* have a musty odor and are positive for indole, which helps distinguish them for the above-mentioned common cocci. *Staphylococcus saccharolyticus* is one of the few anaerobic gram-positive cocci that can reduce nitrate; it is also somewhat aerotolerant on transfers. It appears in clusters on Gram's stain. It is coagulase-negative, although that test would not usually be performed on an anaerobe. It is also a fermenter of glucose, lactose and maltose. Identifying characteristics of the most commonly encountered species are given in Table 16-27. For additional information, the following references are recommended.[238,351,499] A series of 16S rRNA-based fluorescent probes have been used to successfully identify many of the common anaerobic gram-positive cocci; these may prove useful to clinical laboratories in the future in conjunction with other newer methods.[513]

1054

BOX 16-12

Algorithms for *C. difficile* Testing

A. **Perform PCR on all stool samples and result when completed**
   a. Advantage:
      i. High sensitivity and specificity
      ii. Relatively rapid turnaround time
      iii. Need to have only one procedure and QC for *C. difficile* testing
   b. Disadvantage: instrumentation and reagents may be expensive
      i. Contamination issues need to be monitored
      ii. Both infected patients and asymptomatic carriers will be detected.

B. Perform toxigenic culture on all stool samples
   a. Advantage:
      i. High sensitivity and specificity
      ii. Isolate is available for epidemiologic testing, AST, or other studies
   b. Disadvantage:
      i. Long turnaround time
      ii. Need to have assay for confirming that isolate is toxigenic
      iii. Processing of samples for culture can be laborious

C. Two-step algorithm
   a. Step 1. Perform assay, such as Quik Chek, which combines detection of GDH antigen and EIA for toxin A and B or B alone
      i. If positive for both: sign out as positive
      ii. If negative for both, sign out as negative
      iii. If positive for antigen and negative for toxin, perform another confirmatory assay
   b. Step 2. Perform toxigenic culture or PCR for confirmation of toxigenic C. *difficile* and sign out according to results
      OR a two-step could be performance of a GDH assay and reflex a positive result to PCR or culture

D. Three-step algorithm
   a. Step 1 Perform GDH assay
      i. If negative, sign out as negative
      ii. If positive, move to next step
   b. Step 2. Perform EIA for toxin B or toxin A and B or CCNA
      i. If positive, sign out as positive
      ii. If negative, go to next step
   c. Step 3. Perform PCR or toxigenic culture and sign out accordingly

Anaerobic Gram-Negative Cocci. The most commonly encountered anaerobic gram-negative coccus is *Veillonella parvula*. Cells are <0.5 μm and colonies are small,

transparent to opaque, and yellowish gray. Some are catalase-positive; they are susceptible to kanamycin and colistin when the special antibiotic potency disks are examined. It is a nonfermenter, and positive for nitrate reduction. One new species, *V. montipelliernsis* is different from other *Veillonella* species in being resistant to colistin on the antibiotic disk test. *Acidaminococcus* spp. are nitrate- and catalase-negative, but do weakly ferment carbohydrates; the cells of this organism are larger than those of *Veillonella*. Cells of *Megasphaera* spp. are usually >1.7 μm, a very distinguishing characteristic; the organisms are fermentative, catalase and nitrate negative and this genus is susceptible to vancomycin, whereas most gram-negative cocci are resistant. A newly named species, *Negativicoccus* has very small cells, <0.4 μm and they can be microaerophilic. They are also colistin resistant on the antibiotic disk test. Other characteristics can be seen in Table 16-28.

Box 16-14 provides approaches to the identification of an anaerobic isolate in the routine clinical laboratory. There are also additional references for alternative approaches, especially for presumptive or less than full identification for instances where that is appropriate.[28,202,238]

Management of Diseases Involving Anaerobic Bacteria

Comments on Usual Antibiotic Susceptibility/Treatment Protocols for Anaerobes

Successful management of diseases involving anaerobic bacteria requires selection and treatment with appropriate antimicrobial agents, often in conjunction with removal of bacteria by drainage of abscesses, elimination of foreign bodies, debridement of necrotic tissue, and other surgical measures. It was once believed that most anaerobes had predictable antimicrobial susceptibility patterns and that accurate identification of isolates was all that was necessary to predict the susceptibility of individual isolates to various antibiotics. This is an oversimplification. While some antimicrobial agents are active against nearly all anaerobic bacteria (e.g., carbapenems, piperacillin-tazobactam, ampicillin-sulbactam, and metronidazole), there are several other antimicrobial agents that might be used in treatment, the susceptibility of which are not nearly as predictable. Most members of the *B. fragilis* group are resistant to penicillins and cephalosporins and there is increasing resistance to clindamycin. Resistance genes for tetracycline, clindamycin, cefoxitin, carbapenems, chloramphenicol, and metronidazole have been identified in many anaerobes and are usually found to be transferable in in vitro mating experiments.[214,215] Metronidazole remains highly active against most gram-negative anaerobic bacteria, including the *B. fragilis* group tested in the United

States, but resistance to metronidazole has emerged in *B. fragilis* strains in other countries.[190,214,215] A recent CDC report supported the fact that isolates of *B. fragilis* group that demonstrate metronidazole resistance in the United States should be investigated for acquisition outside of the United States. They report of a case of a multidrug-resistant (MDR)-*B. fragilis* group isolate in a patient whose intra-abdominal abscess and bloodstream infection were a result of health care given in India, prior to the patient traveling to the United States for diagnosis and treatment.[83] Metronidazole resistance does, however, occur innately in *Actinomyces* species, *Propionibacterium* species, *Lactobacillus* species, some of the anaerobic cocci, and other gram-positive anaerobes.[190] Although some of the fluoroquinolones, especially moxifloxacin, showed good activity against anaerobes initially, resistance to these agents has developed rapidly.[190,214] In a 2010 survey by Snydman et al., 27% of *B. fragilis* and 55% of *B. vulgatus* were resistant to moxifloxacin, as compared to an earlier surveillance in which >86% of the anaerobes tested were susceptible to moxifloxacin, again indicating variability of susceptibility in isolates tested.[190] The penicillins and ureidopenicillins, the second- and third-generation cephalosporins, and clindamycin may or may not be active against certain commonly encountered species of anaerobic gram-negative bacilli and clostridia; resistance to these agents can be quite variable.[5,214] Resistance to the carbapenems is very rare among anaerobes; however, in Japan, where imipenem is highly prescribed, resistance to it is as high as 3.2%.[215]

BOX 16-13

Important Consideration Points to Consider About Processing Specimens for Toxigenic *C. difficile* Requests:

1. Do not perform any diagnostic tests on formed stools.
2. Only one specimen per patient per day. If PCR is used on all samples, no repeat testing should be done.
   a. Repeat PCR testing on patients with previous PCR positive results should not be performed for "test of cure."
   b. Repeat PCR testing on patients with previous PCR negative results should not be performed, unless there is a change in the clinical findings suggesting a new onset of disease.
3. Appropriate patients only should be tested: patient with diarrhea (>3 watery stools in a 24-hour period of time).
4. Rectal swabs should not be performed for diagnosis of toxigenic *C. difficile*,

although they might be used for epidemiologic studies.

5. Do not perform an enzyme immunoassay for toxin A/B as the only *C. difficile* test.
6. If a toxigenic cell culture neutralization assay (CCNA) is performed alone, there will be a reduced sensitivity as compared to toxigenic culture or PCR, but CCNA is very specific and can be used to confirm that culture isolates are toxigenic.
7. If a PCR alone is performed on all stool samples, carriers as well as infected individuals will be detected.
8. Toxigenic culture is still considered the gold standard (i.e., has the highest sensitivity and specificity) for recovery of *C. difficile*, but does have the longest turnaround time (TAT).
   a. Confirmation that isolates are toxigenic needs to be performed before reporting a positive result.
   b. Chromogenic media may be used to decrease TAT for initial recovery of *C. difficile*; if the media is selective for toxigenic *C. difficile* culture, this may further reduce the TAT.
9. In patients who have been hospitalized for >3 days, the detection of toxigenic *C. difficile* should be the primary request for new onset diarrhea that meets the criteria given above; the yield for common bacterial and parasite GI pathogens is low in this setting and often such requests will be rejected.

Because of the time it takes for recovery and identification of anaerobes, it is usually necessary for the attending physician to start antimicrobial therapy empirically before results of susceptibility testing are available. Therefore, tabulated susceptibility results and treatment protocols reported in the literature or in the local hospital, and clinical experience of the physician may be the basis for the initial choice of antibiotics. Excellent sources of additional information relative to selection of antimicrobial agents for treatment purposes have been published recently elsewhere.[182,214,215,232,302] Publication of antibiograms for anaerobes specifically should be developed by clinical laboratories, even if they include data of more than 1 year in order to accumulate enough data to validate the results. CLSI provides a document to help us with development of such an antibiogram and have published national statistics of anaerobe susceptibilities.[100] However, there is enough variability in the susceptibility patterns of clinically significant anaerobes that in vitro susceptibility testing of individual isolates is indicated at times to aid clinicians with the management of serious infections, particularly those that require prolonged therapy such as brain abscess, endocarditis, lung abscess, infections involving joints, osteomyelitis, infections involving prosthetic devices, vascular grafts, recurrent or refractory bacteremia or when infection does not respond to empirical therapy. A survey of isolates from intra-abdominal and diabetic

foot infections recently even demonstrated that there were not only differences in what organisms were found but also differences in susceptibility patterns of similar anaerobes from the different infections, providing another reason for performing susceptibilities on selected isolates.[97]

TABLE 16-27 Phenotypic Characteristics of Anaerobic Gram-Positive Cocci

Species	IND	NIT	URE	PYR	Glucose FERM	GLC	Gram's Morph	Colonial Morph	Previous Name
Peptostreptococcus anaerobius[a]	–	–	–	–	–	A,IC	Large cocci in pairs and chains; usually much larger than other cocci	Gray with raised center; opaque; nonhemolytic; sweet odor	None
Parvimonas micra	–	–	–	+	–	A	Clusters, short chains or pairs; <6 μm	Small; domed; dull-white; yellow-brown "halo" around colonies	*Micromonas micros, Peptostreptococcus micros*
Finegoldia magna	–	–	–	+	–[w]	A	Pairs, chains, tetrads and clusters; ≥6 μm	Small white colonies; some may be translucent	*Peptostreptococcus magna*
Peptoniphilus spp.									
P. asaccharolyticus	d	–	–	–	–	A,b	Appear in clumps; may almost appear gram-negative due to poor staining	Small, white to yellow; convex; musty odor	*Peptostreptococcus asaccharolyticus*
P. gorbachii	D		–	–	–	A,b	Large cells, >7 μm; round, entire, opaque	Gray, flat, convex. circular, opaque; entire edge	New species
P .harei	d		–	–	–	A,b	Variable in size and shape	Flat, translucent colonies	*Peptostreptococcus harei*
P. indolicus	+	+	–	–	–	A,b	Clumps, like *P. asaccharolyticus*	Small convex white to yellow colonies	*Peptostreptococcus indolicus*
P. ivorii	–		–	–	–	IV	Variable in size; in clumps	Convex, slightly yellow	*Peptostreptococcus ivorii*
P. lacrimalis	–		–	–	–	A,b	Short chains or clumps	White to pink colonies	*Peptostreptococcus lacrimalis*
P. olsenii	D		–	–	–	A,b	Larger cocci; ≥7 μm	Gray, flat, convex; circular; opaque with a whiter central peak; entire edge	New species
***Anaerococcus* spp.**									
A. hydrogenalis	+	–	d	–	+	B,a	Variable size; tetrads, clumps and short chains	Gray-white; convex; unpleasant odor	*Peptostreptococcus hydrogenalis*
A. lactolyticus	–	NA	+	–	+	B,a	Short chains or clumps	Pink or white colonies	*Peptostreptococcus lactolyticus*
A. murdochii	–	–	–	+	+	B,A	Larger cocci, ≥7 μm	Gray with a whiter center; flat, convex, circular, opaque	New species

1057

A. octavius	d	NA	–	+[w]	+	B,a,c	Clumps	Yellow-white; glistening; raised; entire edge	*Peptostreptococcus octavius*
A. prevotii	–	–[+]	+	+	–	B,a	Variable size; clumps or tetrads	Nonglistening; gray, convex	*Peptostreptococcus prevotii*
A. tetradius	–	–	+	+[w]	+	B,a	Variable in size; clumps and tetrads	Nonglistening; gray; convex	*Peptostreptococcus tetradius*
A. vaginalis	d		–	–	+	B,a	Variable in size; clumps and tetrads	Nonglistening; gray; convex	*Peptostreptococcus vaginalis*
Atopobium parvulum[b]	–	ND	ND	ND	+	ND	Elongated cocci; short chains	Resemble lactobacilli on agar	*Streptococcus parvulum*
***Staphylococcus* spp.**									
S. saccharolyticus	NA	+	+	+	+	A	Clusters and tetrads	Small and smooth; nonhemolytic; glistening; opaque; coagulase-negative	*Peptostreptococcus saccharolyticus*
S. aureus subsp. *anaerobius*	NA	+	NA	+	+	NA	Clusters	Small white colonies	None
***Blautia* spp.**[c]									
B. producta	–	–	–		+	A	Ovoid; in pairs or chains	Gray and glistening	*Peptostreptococcus productus*
B. wexlerae	–	NA	+		+	A,S	Coccobacillus	Gray; opaque; umbonate; entire edge; esculin-positive	New species
Gallicola barnesae	w	NA	–	NA	–	A,B	Single and in pairs	NA	*Peptostreptococcus barnesae*
Murdochiella asaccharolyticus	+	–	–	–	–	L,a,b,s	Pairs and chains; <0.6 μm	Gray-white; convex; flat	New species

[a] *P. anaerobius* is inhibited by sodium polyanetholsulfonate (SPS), which is present in most blood culture bottle. It is the only species inhibited so that can be used as a distinguishing characteristic.
[b] *Atopobium parvulum* is a coccus; however, other members of this genus are considered non–spore-forming rods and will be described in those tables.
[c] *Blautia* is a genus of non–spore-forming rods, which have a lineage with Clostridium more than cocci. *B. wexlerae* and *B. producta* appear as cocci and are included here, but other species may be considered as rods and not cocci.
+, positive; –, negative; w, weak reaction; IND, indole production; NIT, nitrate reduction; URE, urease; PYR, pyrrolidonyl arylamidase test; Glucose FERM, glucose fermentation; GLC, from PYG broth.

TABLE 16-28 Characteristics of Anaerobic Gram-Negative Cocci

Species	CAT	NIT	Gluc FERM	Microaero Growth	Gas Prod	Main GLC Products	Antibiotic Disk Test	Size of Cells on Gram's Stain (μm)	Comments	Clinical Comment
Acidaminococcus spp.[a]	–	–	–	–	+	A,B (P,L)	R,S,S	<1.0 (ovoid and in pairs)	Entire, slightly raised colonies, round; transparent. GI flora	Found very rarely in clinical specimens with unknown significance
Anaeroglobus spp.	–	–	+[w]	–	–	A,P,IB,B,IV	R,S,S	<1.0 (ovoid—ellipsoidal cells in pairs and short chains)	Circular, convex, translucent colonies. Oral and GI flora	None
Megasphaera spp.[b]	–	–	+	–	+	A,P,B,V,C	V,S,S	>1.5 (chains; may stain gram-positive)	Circular, entire, translucent colonies. GI flora	Reported as a cause of endocarditis[50]
Negativicoccus spp.[c]	–	–	–	+	–	A,P	R,S,R	<0.5 (ovoid cells)	Small colonies; circular and convex; translucent. Recently described.	Isolated from blood culture of patient with underlying illness[94]
Veillonella spp.[b,c]	V	+	–	–	+	A,P, (L)	R,S,V[d]	<0.5 (spherical; pairs and short chains)	Smooth, entire, opaque colonies; butyrous, gray-white. Oral and GI flora; most commonly isolated	Bacteremia and endocarditis, as well as recovered in other clinical specimens, wherein the significance was unknown[94,312]

[a] *Acidaminococcus* can use amino acids as its main source of energy.
[b] These species can ferment lactate.
[c] These species can decarboxylate succinate.
[d] *V. montipellierensis* is resistant to colistin disk.
+, positive; –, negative; w, weak; V, some strains are positive and strains are negative; CAT, catalase; NIT, nitrate reduction; Gluc FERM, fermentation of glucose; Gas Prod, production of gas.
Antibiotic disks: Vanco, 5 μg disk; Kanamycin, 1,000 μg disk, Colistin, 10 μg disk; S, Susceptible; R, Resistant.

BOX 16-14

Strategies for Identification of Anaerobic Isolates in Routine Laboratories

1. Aerotolerance testing confirms presence of an anaerobe and it is in pure culture or felt to be clinically relevant, warranting further identification (ID).
   Consider Gram's stain and colonial morphology to group the anaerobe.
   Observe selective and/or differential media where appropriate, such as BBE and EYA, and perform antibiotic potency disk test.
   Perform commercial ID kit and if identification agrees with above results, consider that as the identification, especially if the ID is a well-known species
   If GLC is available, could consider using this in conjunction with above.
   If commercial ID is performed and does not match Gram's stain and colonial morphology and/or the organism is not a common species, consider reporting to the genus (i.e., if certain of that level) or refer for sequencing or MALDI-TOF. This decision can also depend on request of clinician.
2. Aerotolerance testing confirms presence of an anaerobe and it is in pure culture or felt to be clinically relevant, warranting further ID.
   Consider Gram's stain and colonial morphology to group the anaerobe. Observe selective and/or differential media where appropriate, such as BBE and EYA, and perform antibiotic potency disk test.
   OR
   Go directly to nucleic acid sequencing or MALDI-TOF, if available, or refer to a reference or commercial lab for this testing.
   Compare ID to morphology and report ID; if new name for old genus and species, sign out with new name and old name in parenthesis; if new genus/species without prior designation, include on report any information known about the organism, such as description about Gram's morphology and/or potential clinical relevance.

For either scenario above, one could stratify workup based on whether the site of specimen collection was sterile or nonsterile; whether monomicrobial or polymicrobial culture; whether organism is considered clinically relevant by clinician. Full identification should be considered for blood culture isolates, CSF isolates (although rarely found); endocarditis and osteomyelitis.

Another indication for testing is the setting in which there has not been a clear-cut clinical precedent on which to base treatment decisions because the identification of the organism is new or an uncommon isolate is found in a disease usually attributed to another anaerobe or aerobe. In addition, clinical microbiologists experienced with anaerobes are encouraged to investigate the activities of newly marketed and/or investigational antimicrobial agents against anaerobes isolated in their hospital

laboratory. Lastly, there is a need to monitor susceptibility patterns of anaerobes at the local, regional, national, and worldwide levels.

Organisms to be considered for antimicrobial susceptibility testing, because of their virulence, or because they are commonly resistant to certain antimicrobial agents include species of the *Bacteroides fragilis* group, species of the pigmented *Prevotella-Porphyromonas* group, other *Prevotella*, *Fusobacterium mortiferum, F. varium* and *F. necrophorum*, *Bilophila, Sutterrella*, and some *Clostridium* species. Information on what antibiotics to test versus a particular anaerobe or groups of anaerobes can be found in the CLSI document and in handbooks that provide information on therapeutic options for various anaerobic infections.[32,100,182]

Methods for Antimicrobial Susceptibility Testing of Anaerobes

At present, CLSI recommends the agar dilution method for antimicrobial susceptibility testing (AST) for most anaerobes in the routine clinical laboratory. However, for *B. fragilis* group isolates, they do provide a broth microdilution method as an alternative. Also included in the newest

1060

document (CLSI M11-A8, 2012) is a method for β-lactamase testing of anaerobic isolates.[100] AST is suggested in specific situations in the document; minimally, laboratories should consider testing isolates (or sending isolates out to reference laboratories) from sterile sites, especially BSI and in infections with uncommon anaerobes for which the susceptibility is unknown. On a routine basis, some surveillance studies of susceptibilities should be performed to monitor for the development of new resistance patterns.

The medium recommended for agar dilution is Brucella agar supplemented with 5 μg of hemin and 1 μg of vitamin K_1 per mL, and 5% (v/v) laked sheep blood. Dilutions of appropriate antibiotics and sheep blood are added after the agar has been prepared. After preparation, agar plates can be stored for up to 72 hours at 2°C to 8°C. Inoculation of the plates is done using a replicating device that will deliver 1 to 2 μL of inocula (e.g., Steers replicator). This inoculum "spot" is delivered to obtain approximately 10^5 CFU for *B. fragilis* and *B. thetaiotaomicron*; some variation in colony counts may occur with other organisms. After about 10 minutes to allow for absorption of the inocula, plates are inverted and incubated in an anaerobic jar or chamber at 35°C to 37°C for 42 to 48 hours. The CLSI document includes images of end points and their interpretations to assist in reading the plates to best determine the MIC of each isolate. These are very helpful for the laboratory to use especially when first employing anaerobic AST in your laboratory or training new personnel. With agar

dilution, at least 30 isolates can be tested at one time, making this method excellent for performing those surveillance studies. For broth microdilution of the *B. fragilis* group, the recommended medium for this Brucella broth supplemented with 5 μg/mL hemin, 1 μg/mL vitamin K_1, and lysed horse blood (5%). Methods for performing both agar and broth microdilution AST are provided in appendices of the CLSI document.[100] Another, perhaps more user-friendly method for performing anaerobic AST is the Etest (bioMérieux Vitek) gradient test strip method. Procedures for this are not provided in the CLSI document, but rather, from the manufacturer, or from the literature. Both the Etest procedure and the broth microdilution procedure are practical ways for testing individual isolates against a limited number of antimicrobial agents; these and other methods, including the spiral gradient methods are reviewed in detail elsewhere.[61,263,266] Broth disk elution and disk agar diffusion techniques have been used in the past but should not be used for routine anaerobe testing despite their convenience. Most anaerobes other than *Bacteroides* spp. grow too slowly for the disk diffusion procedure to work; the Bauer–Kirby interpretive charts were not designed for anaerobes, and interpretive charts based on standardized media and methods for disk diffusion testing of anaerobes are lacking; also, there has been poor correlation between zone size measurements and the results from minimal inhibitory concentration dilution tests.[232]

In 2008, a survey of whether routine laboratories performed anti-anaerobe susceptibility testing demonstrated that susceptibility testing was performed in-house by 21% of hospital laboratories and sent out to reference laboratories an additional 20% of the time. Susceptibility testing was attempted for all blood culture isolates by both hospital (21% of total laboratories) and reference laboratories, but only performed by 17% for sterile body site and 14% of the time for wound isolates. Etest was used most often followed by broth microdilution.[191] For details of the recommended procedures, the reader is referred to the most current Clinical Laboratory Standards Institute document.[100]

Antimicrobial Susceptibility Results for Groups of Anaerobes

Susceptibility of the Gram-Negative Bacilli. *B. fragilis* group isolates produce β-lactamases and consequently are resistant to penicillin (ampicillin, amoxicillin) and most cephalosporins, but are usually susceptible to ampicillin-sulbactam and piperacillin-tazobactam. They are uniformly susceptible to metronidazole and the carbapenems (at least in the United States), but increasingly resistant to clindamycin. In the most recent National Survey for the Susceptibility of *Bacteroides fragilis* group (2005 to 2007) that tracks emergence of resistance among this group of anaerobes, the carbapenems and piperacillin-tazobactam were again found to be the most active anti-anaerobic agents, but there was some resistance seen in certain members of the group

to other agents: *P. distasonis* had a 21% resistance to ampicillin/sulbactam and proved to be the most resistant species overall among the >5,000 isolates included in their study; *B. uniformis* and *B. egegerthii* were approximately 7% resistant to tigecycline; and *B. vulgatus* was >50% resistant to moxifloxacin. Overall, the resistance to clindamycin by the *Bacteroides* spp. in general was high, at >40%. There was some metronidazole-resistant *Bacteroides* spp. found in their survey.[444] The authors suggest that the increased resistance seen in non-*B. fragilis* specifically makes a case for species-level identification of isolates in the *B. fragilis* group which is not always timely or possible without the use of newer identification tools in the routine laboratory. Attempts at such differentiation should at least be considered for isolates from blood and other sterile sites. In a survey of the in vitro susceptibility of anaerobes in eight Belgian hospitals, there were not many changes noted in 2011 to 2012 as compared to a survey in 2004. However, *Prevotella* and other anaerobic gram-negative bacilli were found to have declining susceptibility to clindamycin, with 61% susceptible in 2011 to 2012 as compared to 82% in 2004.[528] In addition, *Fusobacterium* spp. had decreased susceptibility to moxifloxacin in 2011 to 2012, with 71% susceptible compared to 90% susceptibility in 2004.[528] Data from a survey in Taiwan reported that the proportion of susceptible isolates of *Bacteroides* spp, *Prevotella* spp. and/or *Fusobacterium* spp. to many antibiotics, including clindamycin and ampicillin-sulbactam, decreased from 2000 to 2007. In addition, there were some carbapenem resistant isolates found among all three groups.[263] Species of *Prevotella* have been found that are resistant to metronidazole and this certainly needs to be monitored in the future along with all trends toward resistance.[345] Data on metronidazole susceptibilities from ~1,100 anaerobes in 2001 in the United States showed that *Bacteroides fragilis, B. distasonis, B. ovatus, B. thetaiotaomicron, B. vulgatus, Fusobacterium,* and *Clostridium* spp. were among the groups that met the FDA criteria of >90% susceptibility (MIC ≤8 μg/mL). *Eubacterium* and the gram-negative cocci were the only isolates that did not meet the criteria for susceptibility.[147]

1061

B. ureolyticus are uniformly susceptible to the various penicillins, cephalosporins, and other antimicrobial agents tested (i.e., clindamycin, chloramphenicol, metronidazole, and even aminoglycosides), whereas the related *C. gracilis* isolates were commonly resistant to the penicillins, cephalosporins, and clindamycin.[234]

Susceptibility of Anaerobic Gram-Positive NSF Bacilli. Gram-positive NSF are so diverse that a single susceptibility pattern does not exist; in general, isolates are susceptible to penicillins (with and without β-lactamase inhibitors combinations),

metronidazole and carbapenems, but resistant to aminoglycosides and colistin. As mentioned above, however, *Actinomyces, Propionibacterium*, *Atopobium,* and other more aerotolerant strains of NSF are resistant to metronidazole. These species and many others are susceptible to vancomycin and other glycopeptides, but there are notable exceptions to this as well; for example, *Lactobacillus* spp. are often resistant to vancomycin.[499]

Susceptibility of *Clostridium* spp. Including C. *difficile*. *Clostridium* spp. are usually susceptible to penicillins and cephalosporins, metronidazole, carbapenems, and other agents. However, this varies among the species. In a survey of *Clostridium* spp. susceptibilities in 2011 to 2012 in eight Belgian hospitals, not many changes were noted except that moxifloxacin susceptibility had decreased from 88% to 66%.[528] The susceptibility of *C. perfringens* to clindamycin is still high, but many other species of *Clostridium*, including *C. difficile*, can be resistant. *C. difficile* is most often treated with vancomycin or metronidazole; there is still controversy about whether one is better than the other, although there are studies which have shown equivalent efficacy. There is evidence, however, that vancomycin is superior to metronidazole in patients with severe disease.[533] In vitro susceptibility is not often performed because all isolates are predictably susceptible to these agents as well as many penicillins, cephalosporins and carbapenems. In the anaerobic bacteria antibiogram in the Appendix of the associated CLSI document, *C. difficile* isolates were 100% susceptible to metronidazole, ampicillin/sulbactam, piperacillin/tazobactam, cefoxitin. Only 5% were susceptible to clindamycin, whereas 78% were susceptible to moxifloxacin. All were 100% resistant to penicillin. MICs to ertapenem were very low, but isolates were resistant to imipenem and meropenem.[100]

A study in Ireland found an outbreak of toxin A-negative and toxin B-positive strains of *C. difficile* that were resistant to fluoroquinolones, clindamycin, and clarithromycin. Toxin A- and B-positive isolates, not involved in the outbreak, had much lower MICs to the fluoroquinolones and were susceptible to the macrolides and clindamycin.[136] It is difficult to know how widespread this pattern of susceptibility is since most laboratories do not isolate *C. difficile* nor perform susceptibility tests.

About 22% to 26% of patients who experience *C. difficile* disease will go on to have at least one recurrence due to either relapse with same strain or reinfection with a new strain.[35,75] For recurrent disease, many nonantibiotic methods have been tried along with or in place of vancomycin and metronidazole. These include the use of probiotics, fecal implantation, anion exchange resins to absorb the toxins, immune therapy with intravenous immunoglobulins, the yeast *Saccharomyces boulardii* and pulsed doses or tapering doses of vancomycin, all with variable success.[35,38,194] Fidaxomicin, a drug more recently approved for treatment of *C. difficile*, was found

noninferior and as safe as vancomycin in a double-blind controlled study.[107,239] In patients who are being treated for other infections along with their *C. difficile*, fidaxomicin was found to be more efficacious than vancomycin in achieving clinical cure, suggesting that the action of vancomycin on toxigenic *C. difficile* may be diminished with concomitant antibiotic use.[347] There is no in vitro activity of fidaxomicin versus gram-negative aerobes or anaerobes nor against yeast.[189] There is some evidence that neither fidaxomicin is nor vancomycin are as effective in patients who are infected with the hypervirulent, NAP1 strain of *C. difficile*, as compared to infections caused by non-NAP1 strains.[375]

Susceptibility of Anaerobic Cocci. The in vitro susceptibility of the anaerobic cocci to antimicrobial agents has been described in the past in review articles.[348,351] According to recent guidelines, the antimicrobial agents of choice for the empirical treatment of patients with infections involving anaerobic cocci are penicillin (e.g., penicillin G, ampicillin, amoxicillin) or clindamycin.[32,182] Although not commonly isolated as a pathogen, several *P. anaerobius* isolates have demonstrated resistance to penicillin G.[5] Metronidazole is active against >90% of the obligately anaerobic cocci, but is not active against most strains of the microaerophilic streptococci (e.g., *Streptococcus intermedius*).[182] Other compounds that are active in vitro against most of the anaerobic cocci include chloramphenicol, imipenem, ampicillin/sulbactam, piperacillin/tazobactam and cefoxitin, but not cefoperazone, cefotaxime or cefotetan.[5,348] Compounds that show promise against the gram-positive anaerobic cocci include moxifloxacin, quinupristin/dalfopristin and linezolid.[182,320,446] A study in the Netherlands of susceptibilities of 115 anaerobic gram-positive cocci demonstrated some variability in MICs among the various genera tested. All were resistant to doxycycline. Of the three most often tested, *F. magna* had the highest MIC_{90} values for penicillin G, amoxicillin-clavulanic acid, clindamycin, tigecycline, levofloxacin and moxifloxacin. *P. micra* has the lowest MIC_{90} for levofloxacin, metronidazole, doxycycline and amoxicillin-clavulanic acid. *P. harei* has the highest MIC_{50} for levofloxacin and doxycycline and the lowest MIC_{90} for cefoxitin, ertapenem, meropenem and chloramphenicol. This isolate can be easily mistaken for *P. asaccharolyticus*, and the authors point this out in the paper as well. There was one strain of *P. micra* found resistant to metronidazole.[489]A European study with data from 10 countries of the susceptibilities of 299 anaerobic gram-positive cocci (predominantly *F. magna* and *P. micra*) showed susceptibility overall to imipenem, vancomycin, metronidazole, and linezolid. There was a little resistance (7%) to penicillin and clindamycin, mostly among *F. magna* isolates from blood, abscesses and soft tissue infections.[53] *Veillonella* species are resistant to vancomycin and some of

the quinolones. The US study of metronidazole mentioned above did show resistance to metronidazole among some of the anaerobic cocci.[147]

1062

Comments on Susceptibility Testing of Anaerobes

What we can anticipate in the future is much more information about the response to antibiotics by newly named organisms with the increased use of sequencing and MALDI-TOF for anaerobic identification, and subsequent publication of their susceptibilities to antibiotics. In addition, as more molecular methods are developed for detection of specific resistance markers, these may be used alone or in combination with more conventional susceptibility testing methods. Such methods were used in a study of carbapenem resistant *B. fragilis* isolates in Spain and demonstrated agreement with AST testing. The authors concluded that AST should be done at least periodically in order to detect emerging resistance.[481] An example of an antibiogram for anaerobes that can then be developed for use by clinicians and laboratories for empiric treatment and for monitoring purposes, is given in the 2012 CLSI document in Appendix D for the *B. fragilis* group and Appendix E for other anaerobes.[100] Table 16-29 provides a summary of overall susceptibilities for selected anaerobes based on those data and from the literature as noted in the table for specific isolates.

Summary

First, much credit for this chapter needs to be given where it is due, to Dr. Stephen Allen, who passed away in 2013 and left behind a great void in the area of anaerobic bacteriology. Much of what he wrote in prior editions of this text was work that he pioneered throughout his years at the University of Indiana. The Image Plates throughout and figures were mainly his and those of colleagues including Jean Siders and Linda Marler and we owe all of them for what they contributed to this great field. I only hope that Dr. Allen is not unhappy with the results of this 7th edition. Dr. Allen, you will be greatly missed.

The contribution of anaerobic bacteria to the maintenance of the health and well-being of the human host as well as their role in various infectious syndromes continues to be well recognized in clinical microbiology. Their taxonomy can be complex and confusing, only heightened by newer methods of genetic analysis and identification. Sometimes there is a disparity between the latter and the more conventional morphologic and phenotypic approaches to identification and classification. Keeping up with the changes in taxonomy can appear over-whelming at times. We are in a

period of time

1063

where the new and old are colliding or intermingling, depending on one's perspective, but it is important for all of us to try to understand the differences between the old and new methods and devise a rational approach to their incorporation in our routine laboratories. In this chapter, an attempt was made to provide information available in older editions for those who wish to continue to pursue presumptive identifications of anaerobes using spot tests, biochemicals and even GLC, which can be very appropriate in routine situations. We have, however, also tried to delineate places where full identification may be needed and to emphasize that the use of sequencing and/or MALDI-TOF methods may be needed. Understanding the principles and results of the newer methods is as essential in anaerobic bacteriology as it has become in the identification of aerobes, fungi, and mycobacteria.

TABLE 16-29 Percent Susceptibility of Selected Anaerobes

Organism	Amp/Sulb	Pip/Tazo	Cefox	Carb	Pen	Clinda	Moxi	Metron
B. fragilis group	86	95	65	>96	0	~50	~50	100
B. fragilis	89	98	85	>96	0	>60	~50	100
Fusobacterium[a]	100	100	100	100	40	100	95	100
Prevotella	98	99	99	100	40	66	59	100
Gram-positive cocci	98	100	100	100	96	78	82	98
Veillonella	100	61	100	100	57	89	79	86
P. acnes[b]	100	100	100	100	100	100	100	3
C. perfringens	100	100	100	100	100	96	99	100
C. difficile	100	100	100	V[c]	0	5	78	100
C. bifermentans MCM; stevens	100	100		100	100	100		100
C. clostridioforme MCM; stevens	75				67	90		100
C. ramosum	100	100		100	100	82		98
C. septicum						100		100
C. sordellii	100				100	94		95
C. tertium	100				100	100		100

[a] *F. nucleatum* and *F. necrophorum*.
[b] Isolates of *P. acnes* are susceptible to vancomycin.
[c] *C. difficile* is resistant to imipenem and meropenem, but MIC are very low versus ertapenem. Data for all agents is from intestinal sources, but does not imply efficacy; vancomycin MICs are all low and indicate susceptibility.
Modified from reference 100, 463, and 464. Data is given in % susceptible.
Amp/Sulb, ampicillin/sulbactam; Pip/Tazo, piperacillin/tazobactam; Cefox, cefoxitin; Carb, carbapenems; Pen, penicillin (or ampicillin); Clinda, clindamycin; Moxi, moxifloxacin; Metron, metronidazole.

The chapter has increased the amount of information on specific diseases such as

Lemierre's syndrome, *C. difficile*-associated diarrhea and bacterial vaginosis, along with some increased information on the association of newly named organisms and the associated infections. There is a combination of older and newer references given throughout the chapter because in some cases, there may not be anything new, but the older classical works need to be shared and remembered. Finally, we have attempted to update information on developments in anaerobic antibiotic resistance and its detection and surveillance. Not everything that is new in the area of anaerobic microbiology could be included, but for those of us who have been anaerobe addicts over the years, the authors hope this chapter will be helpful to keep that enthusiasm going.

Future Perspectives

Evolution and Spread of Antibiotic Resistance

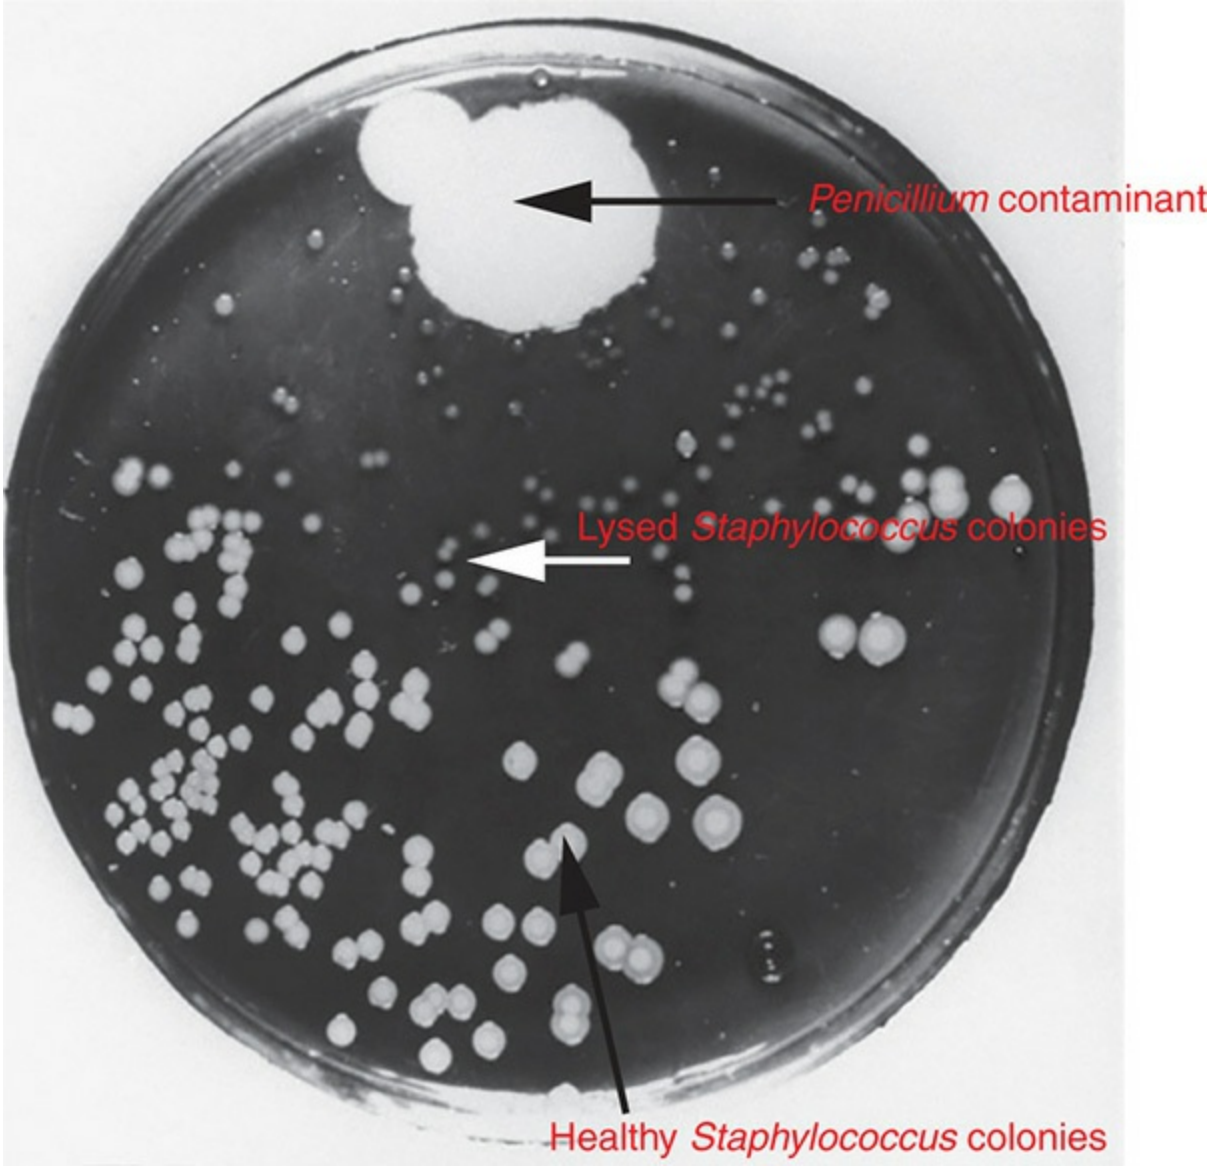
An antibiotic is a compound that is either derived from nature or chemically synthesized, which acts on bacteria through inhibiting normal biochemical functions (i.e., cell wall synthesis, protein synthesis, DNA replication/transcription, or cellular respiration). Bacteria in turn have developed several mechanisms to increase their resistance to the action of commonly prescribed antibiotics, and some types of resistance have globally spread to such an extent that the effectiveness of many drugs and even drug classes are being rapidly eroded. Rapid emergence of many types of antibiotic resistance is one of the major threats to modern medicine and public health of this age.[340] Without an acceleration in the development of new compounds that are effective against many different types of antibiotic-resistant organisms (AROs), modern medical progress will be slowed because of the risk of an adverse clinical outcome from an ARO infection.[66,101,257,562,614]

It is remarkable that we have gone from one of the great medical advances of the 20th century—the discovery of penicillin—to this current worldwide situation over the course of several decades. In 1928, Alexander Fleming observed that a strain of *Penicillium notatum* was producing a diffusible bacteriolytic substance capable of killing bacteria (Fig. 17-1).[196] The discovery of penicillin and its manufacture in sufficient purity to be used as a human drug heralded the advent of the modern antibiotic era. Penicillin production was limited and extremely expensive during World War II, but other antibiotics were discovered and the antibiogram profiles of various organisms were established. Streptomycin was discovered in 1943 because of Waksman's interest in soil organisms,[645] and gramicidin and tyrocidin soon followed. Chlortetracycline (Aureomycin) was also discovered by Duggar at Lederle Laboratories (Pearl River, NY) in 1944. Since that time, the pharmaceutical industry has developed a large number of antimicrobial agents (Table 17-1), but unfortunately

the ability and feasibility of producing novel compounds has not kept pace with the emergence of many types of drug resistance.[257,614]

Despite the initial optimism that antimicrobial agents would put an end to bacterial infection, it did not take long before resistant bacterial strains emerged after introduction and clinical prescription of new drugs. Rapid development of various types of antibiotic resistance has been driven by inaccurate prescribing and overuse of these "life-saving" drugs both in human and veterinary medicine as well as in animal husbandry. Several public health and clinical groups have now published guidelines for prudent prescription of antibiotics because of the recent recognition that chemotherapeutic resources must be managed wisely to control the development and spread of antibiotic resistance.[155,340,365,521,552,614]

Antibiotic susceptibility testing of clinical pathogens then became a clinical necessity in order for effective therapy to be prescribed. It is important to emphasize, however, that antimicrobial agent susceptibility tests are intended to be a guide for the clinician, not a guarantee that a particular agent or drug combination will be effective in therapy. Clinical microbiology laboratories can be of great assistance to clinicians. They can evaluate the *Klebsiella* in vitro interactions between an isolated microbe and antimicrobial agents that would be appropriate for treatment of an infection in vivo. The laboratory data also help the clinician decide whether the selected dose of an antimicrobial agent is adequate to provide effective levels at the site of infection. This chapter outlines procedures for the routine antimicrobial susceptibility testing of aerobic and facultative anaerobic bacteria. Testing of anaerobic bacteria, mycobacteria, and fungi is discussed in Chapters 16, 19, and 21, respectively.



■ **FIGURE 17-1** Fleming's discovery of the action of the antibiotic penicillin produced by the mold *Penicillium*. *Staphylococcus* growing around the mold, which was contaminating the culture, is being lysed by the antibiotic. *Staphylococcus* colonies growing further away from the mold are unaffected.

1076

TABLE 17-1 Major Classes of Antimicrobial Agents and Their Antibacterial Activity

Class	Major Subclasses	Agents Included	Mechanism of Action	Spectrum of Activity
Penicillins	Penicillin	Penicillin G, penicillin V, procaine penicillin, benzathine penicillin	Inhibits cell wall synthesis by binding to PBPs in the cell wall and inhibits cross-linking	Gram-positive aerobic bacteria including streptococci and enterococci. Most staphylococci are now resistant. Susceptible anaerobes (*Clostridium, Peptoniphilus, Finegoldia, Peptostreptococcus, Fusobacterium*), *Pasteurella, Treponema pallidum* (syphilis) and *Borrelia* (Lyme disease).
	Aminopenicillin	Amoxicillin, ampicillin	Same as penicillin	Same as penicillin but gram-negative spectrum also includes β-lactamase-negative *H. influenzae*, some *Enterobacteriaceae* genera (*Proteus mirabilis, E. coli, Salmonella, Shigella*) but susceptibility must be confirmed before use.
	Ureidopenicillin	Azlocillin, mezlocillin, piperacillin	Same as penicillin	Enhanced gram-negative activity including most *Enterobacteriaceae*. Piperacillin is active against *P. aeruginosa*.
	Carboxypenicillin	Carbenicillin, ticarcillin	Same as penicillin	Enhanced gram-negative activity but rarely used. Ticarcillin is active against enterococci.
	Penicillinase-stable penicillins	Cloxacillin, dicloxacillin, methicillin, nafcillin, oxacillin	Same as penicillin	Used for serious infection due to methicillin-sensitive *S. aureus*. No activity against enterococci, gram-negative or anaerobic bacteria.
β-Lactam/β-lactamase inhibitor combinations		Amoxicillin-clavulanic acid Ampicillin sulbactam Ceftaroline-avibactam Ceftazidime-avibactam Piperacillin-tazobactam Ticarcillin-clavulanic acid	Restores activity of the primary β-lactam antibiotic by inhibition of the β-lactamase activity via the inhibitor binding to enzyme's active site	Addition of a β-lactamase inhibitor extends the spectrum of the primary compound. Ticarcillin-clavulanic acid has activity against some *S. maltophilia*. Amoxicillin-clavulanic acid has broad activity against oral aerobes and anaerobes causing bite wound infection. Ampicillin sulbactam active against multidrug resistant *Acinetobacter* spp. Piperacillin-tazobactam has an extended gram-negative spectrum that includes *P. aeruginosa*, MSSA, and some anaerobes including *B. fragilis*.
Cephems	First generation	*Parenteral:* cephalothin, cefazolin, and cephapirin. *Oral:* cephalexin, cephradine, cefadroxil	Inhibits cell wall synthesis by binding to PBPs in the cell wall and inhibit cross-linking	Gram-positive bacteria including MSSA, β-hemolytic streptococci (A, B, C, and G), *Klebsiella* spp., and some *E. coli* and *Proteus mirabilis* but susceptibility must be checked before use.
	Second generation	*Parenteral:* cefamandole, cefonicid, cefuroxime. *Oral:* cefaclor, cefdinir, cefprozil, cefuroxime		Improved gram-negative activity with some loss of gram-positive activity compared to first-generation agents. Cefuroxime has good activity against community-acquired respiratory pathogens (MSSA, *H. influenzae*, and *S. pneumoniae*).
	Third generation	*Parenteral:* cefperazone, cefotaxime, ceftazidime, ceftizoxime, ceftriaxone. *Oral:* cefpodoxime, ceftibuten, cefditoren, cefetamet.		Enhanced gram-negative activity compared with second-generation agents. Ceftazidime has less gram-positive activity but is the only drug with *P. aeruginosa* activity. Cefotaxime/ceftriax; both have enhanced CNS penetration for treatment of bacterial meningitis pathogens. Good streptococcal activity and moderate activity against MSSA. Cefixime and ceftibuten have the best gram-negative activity of oral cephalosporins but neither is very active against gram-positive bacteria. Cefpodoxime and cefdinir have better gram-positive activity against staphylococci and streptococci.
	Fourth generation	*Parenteral:* cefepime. *Oral:* cefixime		Cefipime is highly active against gram-negative bacteria including *P. aeruginosa* and *Enterobacter* spp. Gram-positive activity is similar to ceftriaxone/cefotaxime.
	Cephamycin	Cefoxitin, cefotetan, cefmetazole		Expanded gram-negative and anaerobic activities useful for obstetric-gynecologic and colorectal surgery prophylaxis. Some resistance to *B. fragilis* make these agents less optimal for primary treatment of intra-abdominal and pelvic infections.

	Cephalosporins with activity against MRSA	*Parenteral:* ceftaroline, ceftobiprole		Only cephalosporins with activity against MRSA. Ceftaroline also has activity against CAP pathogens. Ceftobiprole has been approved for use in Canada and Europe but not in the United States.
Monobactams		*Parenteral:* aztreonam	Same as cephems	Active against most gram-negative bacteria including *P. aeruginosa*. Not active against gram-positive bacteria or anaerobes.
Penems	Carbapenem	*Parenteral:* doripenem, ertapenem, imipenem, meropenem, razupenem	Same as cephems	Very broad spectrum of activity against most gram-positive and gram-negative bacteria and anaerobes. Ertapenem is not active against enterococci, and *Acinetobacter* spp. or *P. aeruginosa*.
	Penems	*Parenteral:* sulopenem. *Oral:* faropenem	Same as cephems	Similar to carbapenems
Aminocyclitols		Spectinomycin	Same as aminoglycosides	Used for treatment of genital *N. gonorrhoeae* infections due to susceptible strains
Aminoglycosides		Amikacin, gentamicin, kanamycin, netilmicin, plazomicin, streptomycin, tobramycin	Inhibits protein synthesis by binding to the 30S subunit of the bacterial ribosome	Active against most aerobic gram-negative bacilli, *Nocardia* (amikacin), agents of bioterrorism (*Brucella* [streptomycin], *Francisella tularensis* [streptomycin], *Yersinia pestis* [streptomycin]), and some mycobacteria, but the activity is variable depending on the drug. Synergistic with some β-lactam drugs and vancomycin against enterococci (gentamicin and streptomycin), *P. aeruginosa* and some other gram-negatives and staphylococci, but these drugs are not used alone for gram-positive infections.
Ansamycins		Rifampin	Inhibits protein synthesis by binding to the β-subunit of DNA-dependent RNA polymerase	Active against mycobacteria and staphylococci
Folate pathway inhibitors		Sulfonamides, trimethoprim, trimethoprim-sulfamethoxazole	Interferes with folic acid synthesis at sequential steps in the pathway	Broad-spectrum gram-negative activity including many *Enterobacteriaceae*, *H. influenzae*, *Moraxella catarrhalis*, and *Stenotrophomonas* but not *P. aeruginosa*. Moderate activity against staphylococci including coagulase-negative strains and MRSA, but it has no activity against group A streptococci or enterococci. Also active against *Listeria monocytogenes*, *Nocardia*, and *Pneumocystis jiroveci* (PJP).
Glycopeptides	Glycopeptide	*Parenteral:* vancomycin	Inhibits cell wall synthesis at an earlier step than β-lactam compounds	Active against staphylococci including coagulase-negative strains and MRSA, susceptible enterococci, and *S. pneumoniae* including highly penicillin-resistant strains. Not active against *Lactobacillus*, *Leuconostoc*, *Actinomyces* and VRE. Also active against gram-positive anaerobes and oral formulation is used to treat *C. difficile* induced diarrhea.
	Lipoglycopeptides	Dalbavancin, oritavancin, teicoplanin, telvancin, ramoplanin	Same as vancomycin	Similar to vancomycin
Lincosamides		*Parenteral and oral:* clindamycin	Inhibits protein synthesis by binding to the 50S ribosomal subunit	Active against aerobic and anaerobic gram-positive bacteria including *Actinomyces* spp., *Clostridium* except for *C. difficile*, *Peptostreptococcus*, staphylococci, and group A streptococci, but resistance is increasing.

Lipopeptides		*Parenteral:* daptomycin	Inhibits nucleic acid and protein synthesis by causing rapid bacterial cell membrane depolarization and an influx of potassium ions	Active against aerobic gram-positives, including MRSA, group A *Streptococcus*, and VRE
	Polymyxins	Colistin, polymyxin B	Disrupts bacterial cell membrane permeability	Broad-spectrum activity against gram-negative aerobic bacteria
Macrocyclic		Fidoxomicin	Inhibits protein synthesis by blocking RNA polymerase	Active against gram-positive bacteria especially *Clostridium difficile*
Macrolides		*Parenteral and oral:* erythromycin (parent compound for other macrolides) *Oral:* azithromycin, clarithromycin, dirithromycin, erythromycin	Inhibits protein synthesis by binding to the 50S ribosomal subunit	Active against gram-positive bacteria including β-hemolytic streptococci, susceptible *S. pneumoniae* strains, and some MSSA strains. Active against atypical infections, including *Bordetella pertussis*, *Campylobacter jejuni*, *T. pallidum*, *Ureaplasma*, *M. pneumoniae*, *Legionella*, *Chlamydia* spp., and some mycobacteria. Azithromycin and clarithromycin have better activity against *H. influenzae* and mycobacteria than erythromycin.
	Ketolide	*Oral:* telithromycin	Same as macrolides	Similar to macrolides except it has enhanced activity against *S. pneumoniae* including penicillin-resistant strains
	Fluoroketolide	Solithromycin	Same as macrolides	Similar to telithromycin. First fluoroketolide in development.
Nitrofurans		*Oral:* nitrofurantoin	Highly active metabolites damage bacterial DNA	Active against enteric gram-negatives and enterococci causing urinary tract infection. Susceptibility should be tested before use.
Nitroimidazoles		*Parenteral or oral:* Metronidazole, tinidazole	Disrupts bacterial DNA by production of radical anions	Broad-spectrum activity against anaerobes
Oxazolidinones		*Parenteral or oral:* linezolid, tedizolid	Inhibits protein synthesis by inhibiting bacterial ribosome assemble	Linezolid is used for serious infections caused by MRSA. Tedizolid is a second-generation oxazolidinone undergoing clinical trials for use against MRSA infections.
Phenicols		*Parenteral:* chloramphenicol	Inhibits protein synthesis by inhibiting the peptidyl transferase activity of the bacterial ribosome	Broad-spectrum bacteriostatic activity against gram-positive and gram-negative bacteria including anaerobes
Pseudomonic acid		*Topical:* mupirocin	Inhibits protein and RNA synthesis in *S. aureus*	Active against gram-positive bacteria including MRSA
Quinolones	Quinolone	Cinoxacin, garenoxacin, nalidixic acid	Inhibits nucleic acid synthesis by binding to DNA topoisomerases II and IV	Parent compounds for development of fluoroquinolones
	Fluoroquinolone	*Parenteral or oral:* ciprofloxacin, finafloxacin, gatifloxacin, gemifloxacin, levofloxacin, grapafloxacin, lemefloxacin, moxifloxacin *Oral:* norfloxacin, ofloxacin	Same as quinolones	Active against most aerobic gram-negative bacilli in the *Enterobacteriaceae*, *H. influenzae,* and staphylococci. Ciprofloxacin has the best activity against *P. aeruginosa*. Ciprofloxacin has poor activity against *S. pneumoniae*. Levofloxacin, moxifloxacin, and gemifloxacin have good activity against gram-positive bacteria including *S. pneumonia*e, and atypical pathogens causing CAP (*Chlamydophila pneumoniae*, *M. pneumoniae,* and *Legionella*). Ciprofloxacin is also used for postexposure prophylaxis for inhalational anthrax. Levofloxacin is approved for treatment of inhalational anthrax. Moxifloxacin and gemifloxacin also have some anaerobic activity but are not the drugs

				of choice for serious infections. Norfloxacin is active against enteric gram-negatives causing urinary tract infection but it has no activity against enterococci or *P. aeruginosa*. Norfloxacin use has been restricted in many countries due to side effects.
Steroidal	Fusidanes	*Topical:* fusidic acid	Inhibits protein synthesis by preventing the turnover of elongation factor-G from the bacterial ribosome	Gram-positive activity includes staphylococci, β-hemolytic streptococci and corynebacteria. Many strains of MRSA remain susceptible but resistance may develop on therapy.
Streptogramins		*Parenteral:* quinupristin-dalfopristin	Two agents are synergistic in blocking protein synthesis by binding to the 50S ribosomal subunit	Active against gram-positive cocci including vancomycin-resistant *E. faecium* and MRSA. Drug is less active against *E. faecalis*.
Tetracyclines		*Parenteral or oral:* doxycycline, minocycline. *Oral:* tetracycline	Inhibit protein synthesis by binding to the 30S ribosomal subunit	Some broad-spectrum gram-negative but more limited gram-positive activity but prevalent resistance, so susceptibility should be tested before use. Active against some atypical pneumonia agents (*Chlamydophila, M. pneumoniae*), *Rickettsia, Borrelia burgdorferi* (early-stage disease), *Helicobacter pylori, Vibrio, Brucella, Treponema pallidum,* and some mycobacteria. Minocycline is active against MRSA, *Stenotrophomonas,* and *M. marinum*.
	Glycylcyclines	*Parenteral:* tigecycline	Same as tetracyclines	Expanded activity spectrum compared to the tetracyclines. Gram-positive activity includes MRSA and VRE. Gram-negative activity is broad (*Enterobacteriaceae, Acinetobacter* spp., *Stenotrophomonas, Haemophilus,* and *Moraxella*) but does not include *P. aeruginosa* or *Proteus*. Also good anaerobic and mycobacterial activity.
Fosfomycins		*Oral:* fosfomycin	Inhibits cell wall biogenesis as a mimic of phosphoenol-pyruvate (PEP) thereby blocking the action of MurA in catalyzing peptidoglycan	Active against *E. coli* and *Klebsiella* spp. that produce extended-spectrum β-lactamases

Mechanisms of Action of Major Antibiotic Classes

Antibiotics are designed to inhibit or block some essential cellular process, thereby controlling growth of the bacteria (i.e., bacteriostatic compound) or killing it outright (i.e., bactericidal). The effect of a bacteriostatic versus bactericidal antibiotic on a logarithmically growing bacterial culture is shown in Figure 17-2. Most of the major classes of antibiotics used in human medicine are derived from natural products, but three classes have been synthesized, including the sulfa drugs, the fluoroquinolones, and more recently an oxazolidinone. Development of available and new antibiotics is an expensive and arduous process. A stepwise procedure is followed in bringing forward new compounds of interest.[257,614] A set of pathogenic bacterial strains, including those that have developed clinically important resistance, are first tested using the new compound to determine its spectrum of activity and potency. The compound will move forward to be tested on animals with induced invasive infection

to determine the efficacy of the agent. Finally, the new compound may then be used in first phase clinical trials and compared with the efficacy of available antibiotics for infections caused by both susceptible and resistant bacteria. Potential toxicity of each compound is also established during animal testing before using the drug in human trials.

Antibiotics used in human medicine are grouped into major classes based on their mechanisms of action. Table 17-1 outlines the major classes of available antibiotics along with their structural targets and their spectrum of activity. Despite intensive research efforts into the mechanism of antibiotic action in bacterial pathogens, only four major targets exist: (1) inhibition of cell wall biosynthesis, (2) inhibition of protein synthesis, (3) inhibition of DNA replication and repair, and (4) inhibition of folate coenzyme biosynthesis. Antibiotic resistance therefore develops by three major mechanisms: (1) destruction of the compound by an enzyme produced by the bacterium, (2) cell impermeability and/or efflux, or (3) alteration of one of the drug target(s).Figure 17-3 provides a schematic outline of each of these mechanisms of antibiotic action and resistance development. A detailed description of the biochemical structure and mechanism of action of each antibiotic is beyond the scope of this chapter. Interested readers should consult *Mandell's Principles and Practice of Infectious Diseases*[370] as well as several other texts and reviews on this topic.[79,135,646]

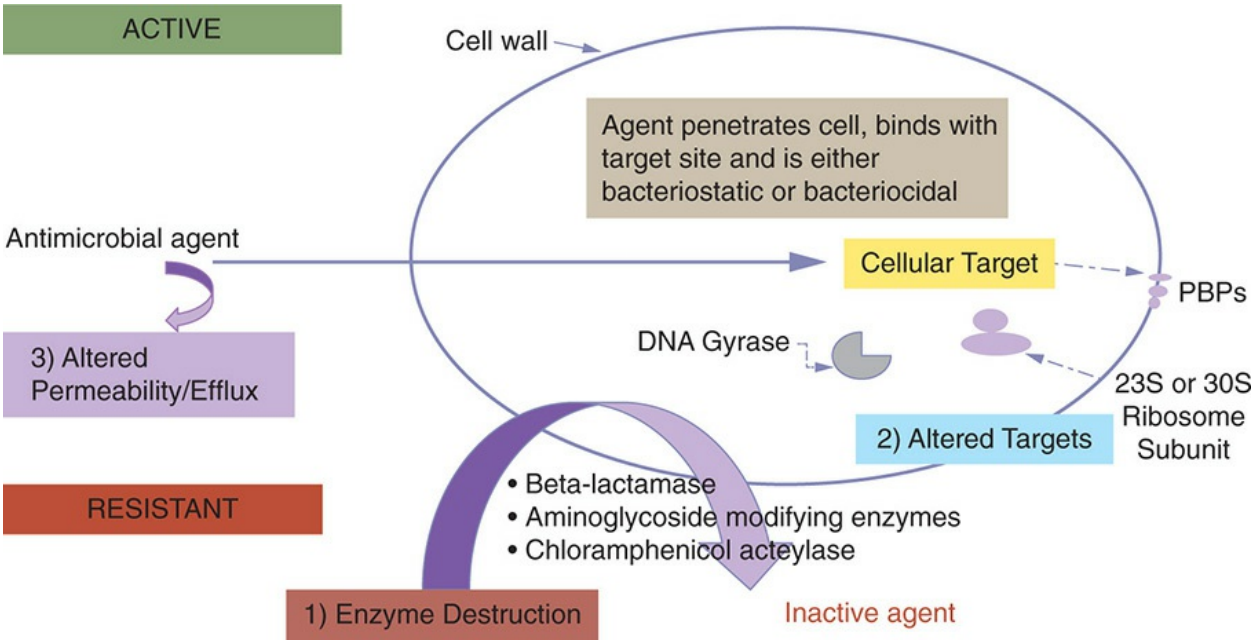
■ **FIGURE 17-2** Bacteriostatic versus bactericidal action of antibiotics on bacterial growth. Bacterial growth curves compare the following: (1) culture growing without antibiotics present (*Blue line*), (2) culture growing in the presence of a bacteriostatic antibiotic (*Green line*), and (3) culture growing in the presence of a bactericidal antibiotic (*Red line*).



■ **FIGURE 17-3** Main mechanisms of antimicrobial resistance in bacteria.

Genetic Basis of Resistance to Major Antibiotic Classes

To understand the mechanisms of bacterial resistance, it is necessary to understand bacterial physiology, the pharmacology of antimicrobial drugs, and the molecular biology of infectious agents. Bacteria are incredibly resilient and rapidly adapt to develop resistance under selection pressure from antibiotic use. A fascinating, but disturbing, finding is the documentation that some antibiotics elicit a transient increase in the mutation rate of bacteria.[48] Thus, antibiotics may not only serve as selectors of antibiotic-resistant clones, but also as primary promoters of de novo resistance.

The genes encoding for resistance may be located either on the chromosome or an extrachromosomal element called a plasmid. Plasmids are circularized pieces of DNA that act independently of the chromosome. The practical significance of the difference is that the chromosomal DNA

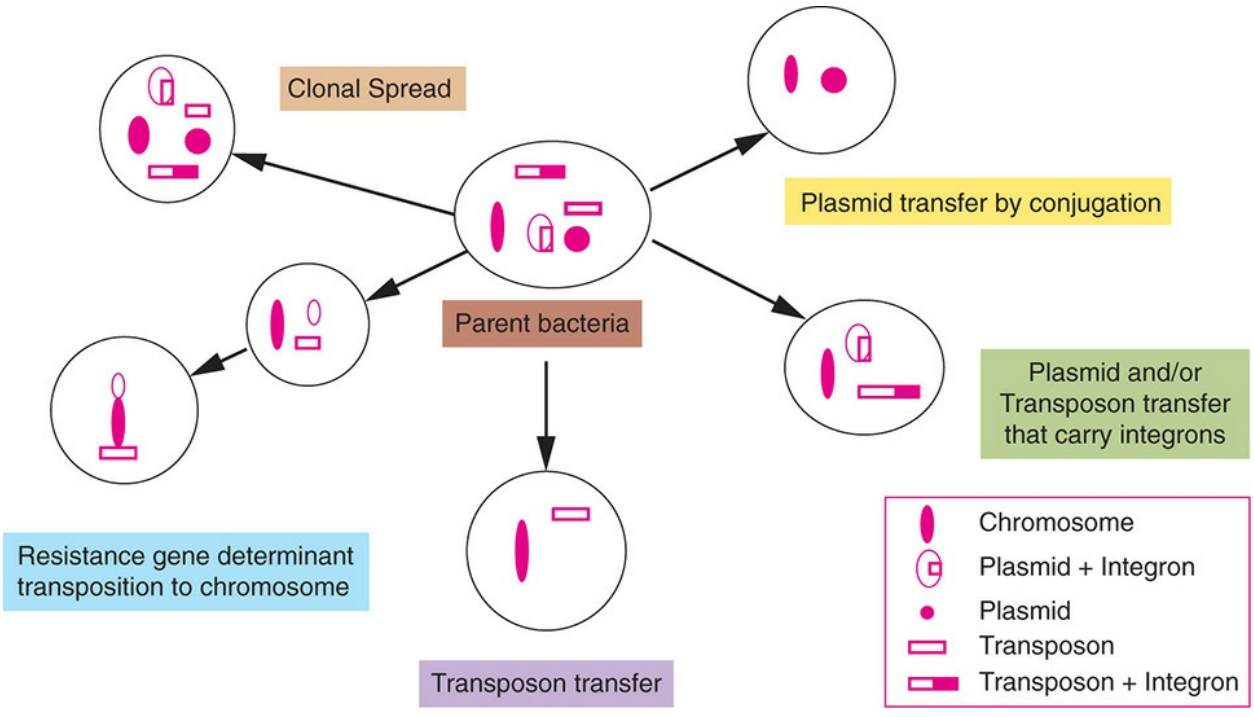
is relatively stable, whereas the plasmid DNA is easily mobilized from one strain to another, one species to another, or even one genus to another. The variables involved in bacterial horizontal gene transfer are described in Table 17-2, and various transfer mechanisms are illustrated in Figure 17-4. In addition, the linking of resistance genes for multiple antimicrobial agents on a plasmid allows the bulk transfer of resistance determinants that characterizes many newly resistant organisms.[37,533,585,684]

Bacteria can resist the effects of antibiotics by chromosomal mutation or inductive expression of a latent chromosomal gene. More commonly though, bacteria exchange genetic information and transfer one or more antibiotic resistance genes by several mechanisms. The most common mechanism by which resistance genes are transferred is conjugation. Most commonly, antibiotic resistance genes are carried on plasmids as part of a transposable genetic element called a transposon or "jumping gene."[134,510,546,574,675] Transposons have the ability to enter transmissible plasmids or chromosomes and subsequently undergo block conjugal horizontal transfer to other related or even unrelated bacterial species. The result may be a mosaic of genetic material from the donor and recipient bacteria.[366] Conjugation with plasmid transfer is particularly common among the *Enterobacteriaceae*, *Pseudomonas,* and anaerobic species.[78,99, 162,211,283,366] Transfer of antibiotic resistance determinants across a major barrier between gram-positive and gram-negative bacteria has also been documented,[133] but the reverse is uncommon. For example, spread of resistance can occur between staphylococci and enterococci and between *Enterobacteriaceae* and *Pseudomonas* or anaerobes such as *Bacteroides*.[19,69,596,621,651]

Bacterial transposons, plasmids, or chromosomes may contain an integron (Fig. 17-4), which is a two-component gene capture and dissemination system in bacteria that was initially discovered in relation to antibiotic resistance.[128,215,228,229,381,530–532] An integron consists of a first component gene encoding a site-specific recombinase along with a specific site for recombination, while fragments of DNA called gene cassettes that can be incorporated or shuffled make up the second component (Fig. 17-5). Integrons also contain an integrase (*int1*) similar to that found in bacteriophage, followed by an *attl* site for recognition of the integrase and integration of cassettes, and a promoter to drive expression. A repeat sequence that flanks the cassettes encoded by an *attC* sequence (also called 59-be) enables integration of the integron at the *attl* site, as well as excision and subsequent horizontal gene transfer. Because an integron cassette may encode several genes for antibiotic resistance to different classes of antibiotics, horizontal gene transfer by this mechanism is a very effective way for the bacterium to rapidly spread multidrug resistance determinants.

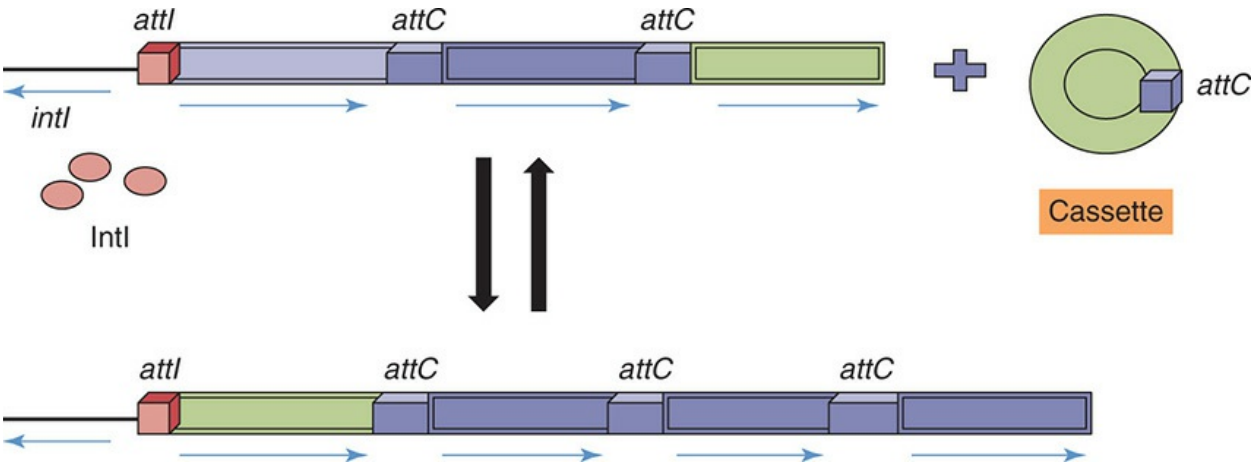
TABLE 17-2 Variables in the Expression and Transfer of Bacterial Resistance

Characteristic	Variable	Comments
Location	Chromosomal	Genetic stability; expression often constitutive
	Extrachromosomal	Plasmids easily mobilized for transfer from bacterial cell to cell
	Transposon	Moves genetic material between chromosome and plasmid or between bacteria
Transfer	Conjugation	Either by plasmids (R-factor) or a transposon
	Transduction	Transfer by bacteriophage
	Transformation	Direct transfer of DNA between compatible species
Expression	Constitutive	Produced with or without exposure to a stimulus
	Inducible	Produced only after exposure to a stimulus
	Constitutive-inducible	Produced at low level without stimulus; production greatly increased after stimulation



■ **FIGURE 17-4** Horizontal transfer of resistance determinants in bacteria.

1082



■ **FIGURE 17-5** Integrons carry multiple drug resistance determinants. Naturally occurring integrons use site-specific recombination for storing, expressing, and transferring genes. Integrons consist of a recombinase gene and a recombination site *attI* (integron attachment site) into which a circular gene cassette containing an *attC* (cassette attachment site) can be integrated. There is also a strong promoter upstream from *attI* that allows gene cassettes to be transcribed into mRNA. Cassettes can be deleted by recombination between pairs of *attC* sites, or by recombination between an *attC* and *attI* site. The order of genes in an integron can therefore be changed by excision and reintegration of the excised cassette into *attI*. (Adapted from references 215 and 381.)

Antibiotic resistance genes may be expressed continuously regardless of exposure to an antibiotic, or be inducible whereby expression only occurs in the presence of the drug (i.e., during antibiotic therapy). Staphylococcal β-lactamase (penicillinase) is an example of an inducible enzyme.[511] It is present on a plasmid and is not produced unless the bacteria are exposed to a β-lactam antibiotic, such as penicillin, after which production of the enzyme is turned on. Many β-lactamases of gram-negative bacteria are present on the chromosome and are produced constitutively, but may be induced to produce even greater levels of the enzyme when exposed to a β-lactam agent.

Finally, some resistance mechanisms are expressed homogeneously, while others are expressed heterogeneously. Homogeneous or uniform expression of a resistance factor facilitates detection of antibiotic resistance in the laboratory. If only a small fraction of the bacteria expresses the resistance mechanism (heterogeneous expression or heteroresistance), however, sampling error may compromise detection of the

resistance in the laboratory.

Mechanisms of Antibiotic Resistance in Bacteria

The mechanisms by which resistance is expressed in bacteria are summarized in Table 17-3 and Figure 17-3. The activity

of antimicrobial agents is diminished by three major mechanisms: (1) prevention of access to the target, (2) inactivation of the compound by destruction or modification, and (3) alteration of the target site of the antibiotic.[76,419,646] Inactivation of antimicrobials by bacterial β-lactamases and aminoglycoside-inactivating enzymes is the most common way that resistance develops to these two major drug classes. Cell wall impermeability or efflux, which prevents transport of the antibiotic to its intracellular site of action, also occurs for β-lactams, aminoglycosides, and the tetracyclines.[419] Antibiotic target modification is the primary mechanism of resistance to the fluoroquinolones, macrolides, and folate synthesis antagonist agents, but it may also occur for β-lactams.[419] It should be emphasized at the outset, however, that virtually any resistance mechanism may be found in most bacteria and that multiple mechanisms are often found in a single organism (Table 17-4).

TABLE 17-3 Mechanisms of Bacterial Resistance to Antimicrobial Agents

Mechanism	Antimicrobial Agent Group	Examples
Enzymatic inactivation	β-Lactams	β-Lactamases; penicillinases; cephalosporinases; carbapenemases
	Aminoglycosides	Aminoglycoside modifying enzymes
Altered receptors	β-Lactams	Altered penicillin-binding proteins (PBPs)
	Ribosomal alterations	Tetracycline; erythromycin; aminoglycosides
	DNA gyrase alterations	Fluoroquinolones
	Altered bacterial enzymes	Sulfamethoxazole; trimethoprim
Altered antibiotic		

transport		
	Reduced protein motive force	Aminoglycosides and gram-negative bacteria; decreased influx
	Active transport from bacterial cells	Tetracycline; erythromycin; active efflux

Prevention of Access to the Target

Accumulation of antimicrobial agents at their site of action in the bacterial cell is the sum of transport into the cell, inactivation during the transport process, and clearance of the antimicrobial agent from the cell. To understand transport of molecules to the active site, it is necessary to consider the structural differences between gram-positive and gram-negative bacteria. Bacteria are prokaryotes, and in both gram-positive and gram-negative species, the cell membrane is surrounded by the cell wall, and the cytoplasm contains nucleic acids, ribosomes, and other cellular components (Fig. 17-6). The cell wall is considerably different in gram-positive bacteria compared to that found in gram-negative species. Gram-positive bacteria have a single cell membrane with a thick external cell wall that is composed of peptidoglycan that is interwoven with lipoteichoic acid (Figs. 17-6 and 17-7). For β-lactam and glycopeptide antibiotics, transport to the target site is not an issue in gram-positive species because their penicillin-binding protein (PBP) targets in the cell wall are freely accessible and the plasma membrane does not have to be crossed.

The cell wall of gram-negative bacteria is far more complex and is composed of an internal plasma membrane and an outer cell membrane, between which is the periplasmic space that contains an attenuated peptidoglycan layer (Figs. 17-6 and 17-7). The outer membrane (OM) of gram-negative bacteria not only performs an important protective role for the bacterium, but also the permeability of this layer has a major impact on the susceptibility of the microorganisms to antibiotics that have intracellular targets. Several excellent reviews of OM permeability and antibiotic resistance have been published.[152,233,441,485] The OM is made up of an asymmetric bilayer of phospholipid and lipopolysaccharides (LPS), with LPS being located in the outer leaflet. The OM phospholipids composition is similar to the cytoplasmic membrane, being made up of mostly phosphatidylethanolamine with lesser amounts of phosphatidylglycerol and cardiolipin.[152] This lipid bilayer is impermeable to large, charged molecules. LPS is composed of three parts: (1) hydrophobic, fatty acid chains bearing lipid A (a glucosamine-based phospholipid), (2) a short core oligosaccharide, and (3) a distal polysaccharide, the O-antigen.[501] *E. coli* strains can have varying lengths of these structures (e.g., R or "rough" mutants or Ra to Re chemotypes have varying lengths of core oligosaccharide while "deep rough" mutants have a truncated

varying lengths of core oligosaccharide while "deep rough" mutants have a truncated core and "smooth" strains have an intact O-antigen) because only the inner part of LPS, consisting of lipid A and two 3-deoxy-D-manno-oct-2-ulsonic acid molecules linked to the core oligosaccharide, is required for growth.[501] A large number of other different types of proteins are also found in the OM, including murein lipoprotein (Lpp), OmpA, and several general diffusion porins. Lpp and OmpA together play a structural role in maintaining the shape of the cell.

Porins. Influx into the bacterial cell is largely controlled by porins, which are water-filled open "pores" or channels that span the OM and allow the passive transport of hydrophilic molecules (Figs. 17-6 and 17-8).[425,427,428,441,681] Porins in gram-negative bacteria have been characterized and classified according to their functional structure (monomeric to trimeric), their activity (nonspecific or specific channel/selective pore), and their regulation and expression.[152,425,427,428,681] The classical porins produced by *E. coli* have been the best studied, and this has formed the basis for studies of other porins in gram-negative species. *E. coli* produces three major trimeric porins: (1) a large porin channel called OM protein F (OmpF), (2) a small porin channel called OM protein C (OmpC), and (3) PhoE.[681] The third channel called PhoE is produced in mutants that lack both OmpF and OmpC, but this channel does not appear to be important for movement of antimicrobial agents.[427] PhoE selects for inorganic phosphate and anions while the other two trimeric porins regulate cations.[428,441,681] Most porin proteins involved in antibiotic transport in other enteric gram-negative bacteria also belong to the classical OmpC and OmpF families and behave in a similar fashion to those of ***E. coli***. However, ***P. aeruginosa*** and ***A. baumannii*** have an intrinsic low susceptibility to β-lactams because of their reduced **OM** permeability. ***P. aeruginosa*** has a low number of distinct porins called OprD, which have different properties compared to the ***Enterobacteriaceae***.[356]Imipenem is the only antimicrobial agent for which resistance in ***P. aeruginosa*** occurs by altered membrane transport. However, in some situations, imipenem gains entry, not through the main porin protein, but through a specific transport protein, designated OprD.[499,500] It appears, however, that the presence of a chromosomal class C β-lactamase is necessary for resistance in addition to the altered porin protein.[354] ***A. baumannii***, *Neisseria gonorrhoeae,* and other gram-negative species also utilize nonclassical porins.[189,439]

For many antimicrobial agents with intracellular targets, efficient transport across the OM of enteric bacteria is critical for their effective action. Small hydrophilic drugs such as the β-lactams use the porins to gain access to the interior of the cell, while hydrophobic drugs such as the macrolides are able to directly diffuse across the lipid bilayer. Factors such as the charge on the molecule and the hydrophobicity of the compound play an important role in the movement of antibiotics through the OM (Fig.

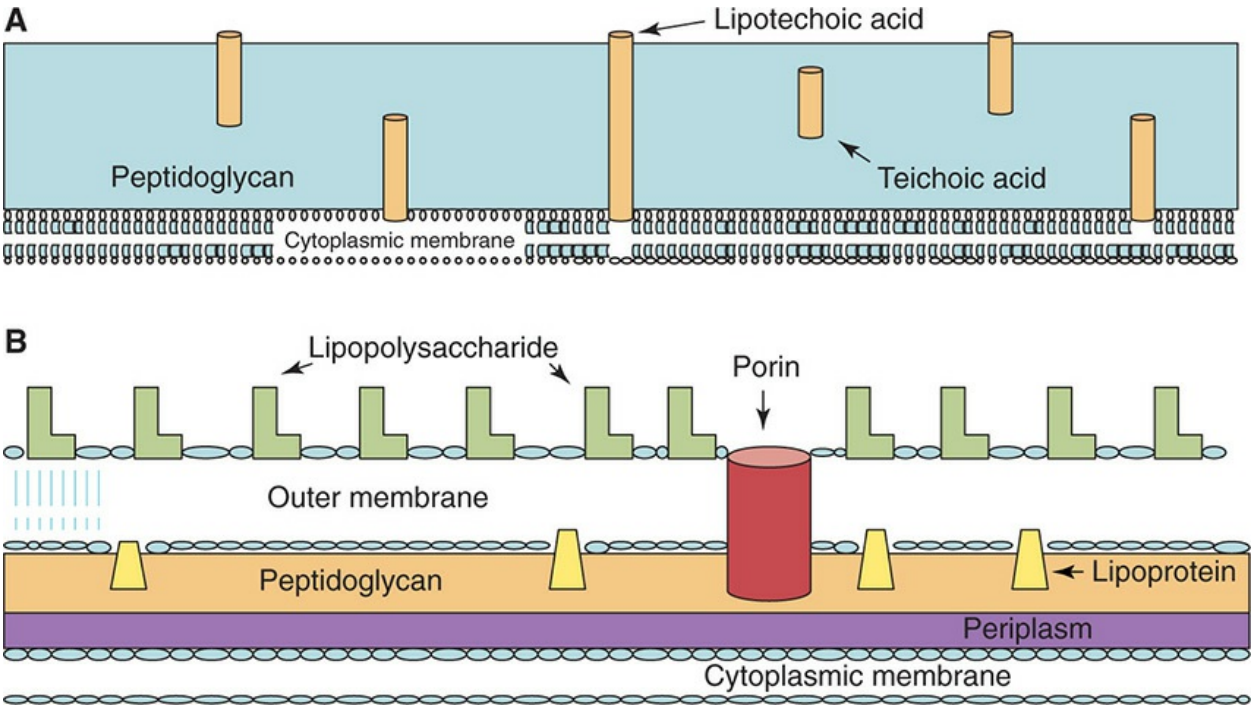
positively charged molecules or zwitterions (i.e., compounds with balanced positive and negative charges). Presumably, the negative charges cause the antibiotic to "hang up" as it crosses the negatively charged porin channel. The exclusion of hydrophobic compounds from the aqueous environment of the porin may explain the lack of efficacy of the hydrophobic compound methicillin against gram-negative bacteria. Likewise, β-lactam antibiotics with large bulky side chains, such as mezlocillin, piperacillin, and cefoperazone, also cross the membrane poorly. In one study, the "best performer" among the β-lactam antibiotics was imipenem, which is a zwitterionic, hydrophilic compound with a very compact structure.[109] It has been proposed that the explanation for susceptibility of *Enterobacter cloacae* to imipenem in the presence of resistance to third-generation cephalosporin drugs is the greater accessibility of imipenem to targets, mediated by rapid transit probably through several porin channels.[454]

1084

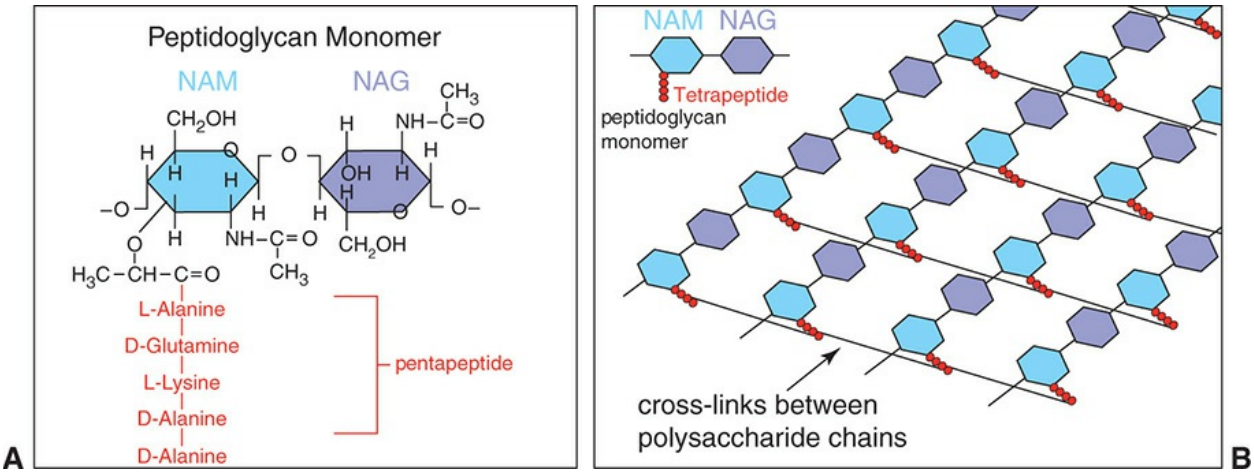
TABLE 17-4 Mechanism(s) of Antimicrobial Resistance in Clinically Important Bacteria

Bacterial Type	Antibiotic Group	Common Mechanism(s)	Other Mechanism(s)
Staphylococcus spp.	Penicillins	β-Lactamase (penicillinase)	Altered penicillin-binding proteins (PBPs)
	Penicillinase-resistant penicillins	Altered PBPs (*mecA* and *mecC* genes)	Borderline: altered PBPs; methicillinase; hyperproduction of β-lactamase
	Fluoroquinolones	Active reflux; altered DNA gyrase	Poor transport across membrane
	Erythromycin and/or clindamycin	Altered ribosomal targets (Constitutive or inducible)	Active efflux of erythromycin
	Glycopeptides	Altered cell wall binding proteins	Acquisition of a *vanA/B* gene (rare to date)
S. pneumoniae	β-Lactams	Altered cell wall; low-affinity PBPs	
	Erythromycin and/or clindamycin	Altered ribosomal targets (*erm* gene) (Constitutive or inducible)	Active efflux of erythromycin
Enterococcus spp.	β-Lactams	Altered cell wall; low-affinity PBPs	β-Lactamase
	Aminoglycosides	Intrinsic; poor transport across membrane	Altered ribosomal binding sites
		High level: aminoglycoside modifying enzymes (AME)	
	Glycopeptides	Altered cell wall binding proteins	
H. influenzae	Penicillins	β-Lactamase (penicillinase)	Altered PBPs
	Trimethoprim-sulfamethoxazole	Altered enzyme targets	
	Chloramphenicol	Chloramphenicol acetyltransferase	Altered membrane transport
N. gonorrhoeae	Penicillins	β-Lactamase (penicillinase)	Altered PBPs
	Cephalosporins	Altered PBPs	Altered membrane transport
	Fluoroquinolones	Altered DNA gyrase	Altered transport through outer membrane
	Tetracycline	Active efflux	
	Spectinomycin	Altered ribosomal target	AME
Enterobacteriaceae	β-Lactams	β-lactamases; poor diffusion or altered porins	Altered PBPs; low protein motive force; extended-spectrum β-lactamases (ESBLs); carbapenamases (e.g., KPCs, NDMs, etc.)
	Aminoglycosides	AME; poor diffusion or altered porins	
	Fluoroquinolones	Altered DNA gyrase	Altered transport through outer membrane
	Tetracycline	Active efflux	
	Trimethoprim-sulfamethoxazole	Altered enzyme targets	
Pseudomonads	β-Lactams	β-lactamases; poor diffusion or altered porins	Altered PBPs; low protein motive force; metallo-β-lactamases (MBLs) (e.g., VIM, IMP etc.)
	Aminoglycosides	AME; poor diffusion or altered porins	
	Fluoroquinolones	Altered DNA gyrase	Altered transport through outer membrane
Acinetobacter spp.	β-Lactams	β-Lactamases; poor diffusion or altered porins	Altered PBPs; low protein motive force; carbapenemases (e.g., OXA enzymes)
	Aminoglycosides	AME; poor diffusion or altered porins	
	Fluoroquinolones	Altered DNA gyrase	Altered transport through outer membrane

1085



■ **FIGURE 17-6** Gram-positive and gram-negative cell walls. **A.** The gram-positive cell wall is composed of a thick, multilayered peptidoglycan (PG) sheath outside of the cytoplasmic membrane. Techoic acids are linked to and embedded in the PG, and lipoteichoic acids extend into the cytoplasmic membrane. **B.** The gram-negative cell wall is composed of an outer membrane linked by lipoproteins to thin, mainly single-layered PG. The PG is located within the periplasmic space that is created between the outer and inner membranes. The outer membrane includes porins, which allow the passage of small hydrophilic molecules across the membrane, and lipopolysaccharide molecules that extend into extracellular space. (Adapted from Cabeen, MT, Jacobs-Wagner C. Bacterial cell shape. Nat Rev Microbiol 2005;3:601–610.)

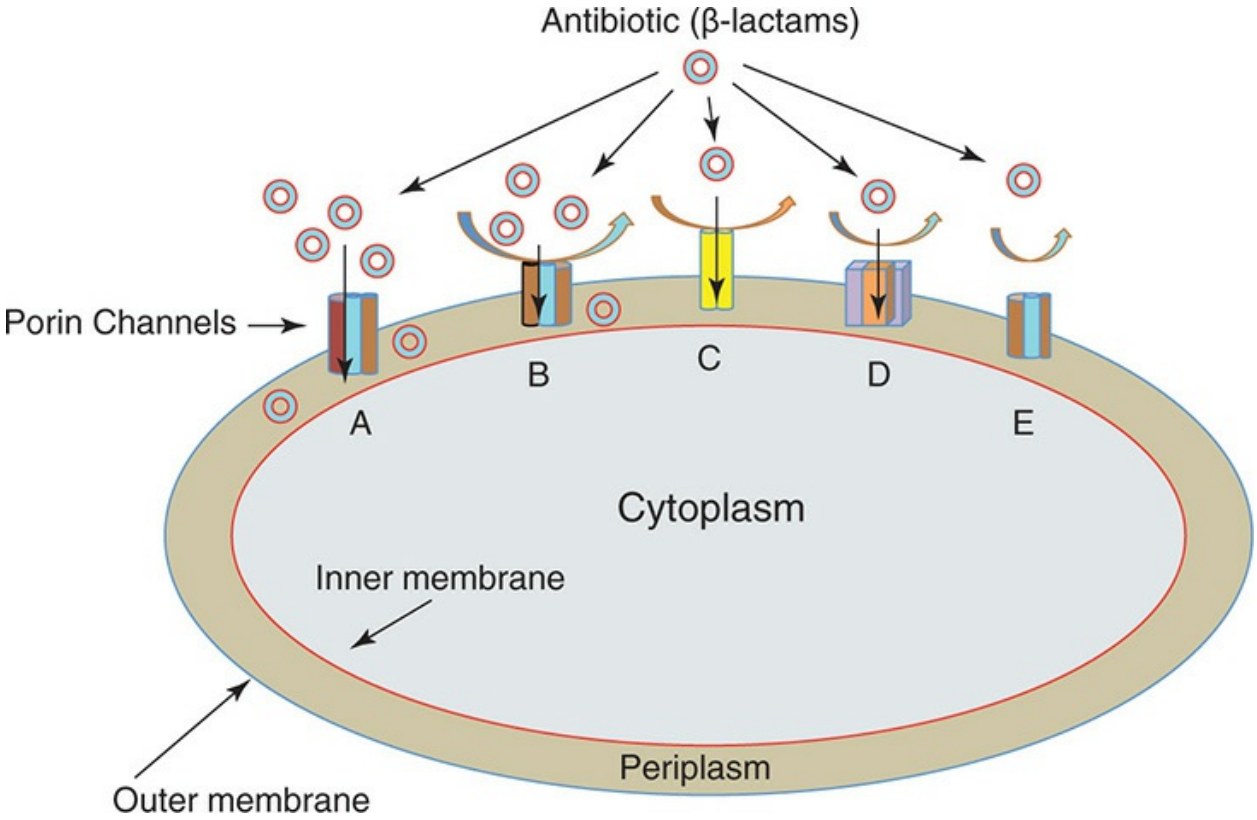


■ **FIGURE 17-7** Structure of peptidoglycan in the bacterial cell wall. **A.** Peptidoglycan

(PG) is composed of chains of PG monomers (NAG–NAM–tetrapeptide). **B.** PG monomers join together to form chains, and the chains are then joined by cross-links between the tetrapeptides to provide strength. (Courtesy of Gary E Kaiser.)

Gram-negative species have, however, developed mutations in the porin expression or composition of their OM as a means to confer drug resistance, and a large number of strains have been characterized that have this type of resistance.[441] The influence of the balance of porin expression and β-lactam susceptibility is well illustrated by an interesting case reported by Medeiros and colleagues.[389] Two strains of *Salmonella enterica* serovar Typhimurium developed complete resistance to all cephalosporin drugs while a patient was on therapy. Although the original isolates were susceptible to the cephalosporins, shortly after starting therapy with cephalexin, a cephalosporin-resistant strain was isolated from a wound sample. Both strains failed to show an increase in β-lactamase activity, but further studies demonstrated disruption in the osmoregulation of porin synthesis in the clonal descendants of the original pretherapy strain. Osmoregulation of porin synthesis in the susceptible parent strain was normal with both OmpC and OmpF porins being present in low osmolality conditions, but in high osmolality conditions only OmpC porins were expressed. The expression of OmpC porin was thought to be favored in vivo because of the high osmolarity conditions in the tissues of the patient. The resistant isolate, however, expressed only OmpF porins in low osmolarity conditions, while the synthesis of both types of porins was repressed at high osmolarity conditions. Porin expression modification may occur stepwise during exposure in vivo to subinhibitory levels of a β-lactam, or in this case, be totally repressed, resulting in loss of the OmpC channel and high-level resistance because of complete cellular impermeability.

1086



■ **FIGURE 17-8** Effects of porin mutations on antibiotic permeability of the bacterial cell wall. **A.** Normal synthesis of porin with passage of the β-lactam into the periplasm. **B.** Decreased synthesis of wild-type porin with decreased passage of β-lactam into the periplasm. **C.** Normal synthesis of restricted-channel porin with restricted passage of β-lactam into the periplasm. **D.** Normal synthesis of mutated porin with decreased passage of β-lactam into the periplasm. **E.** Normal synthesis of wild-type porin with a channel blocker so that no drug crosses into the periplasm. (Adapted from reference 441.)
Schematic representation of various porin modifications that confer multidrug resistance to β-lactams. The thickness of the straight arrows reflects the level of β-lactam penetration through porin channels. The curved arrows illustrate the uptake failure that occurs with various porin modifications: (1) decreased porin expression, (2) restricted porin channel: An exchange in the type of porin that is expressed, and (3) mutated porin: mutation or modification that impairs the functional properties of a porin channel. Porin-blocking molecules may also decrease antibiotic access. (Reprinted with permission from Pages JM, James CE, Winterhalter M. The porin and the permeating antibiotic: a selective diffusion barrier in gram-negative bacteria. Nat Rev Microbiol 2008;6:893–903.)

Complete porin exchange may also occur during antimicrobial therapy to an altered porin phenotype that confers resistance. One study of *K. pneumoniae* strains collected during patient treatment showed that the OmpF porin type (OmpK35) had been replaced with an OmpC porin type (OmpK36), which has a small channel size.[240]

Because strains expressing OmpK35 have a much higher susceptibility to β-lactams (cefepime, cefotetan, cefotaxime, and cefpirome), the porin exchange to OmpK36 in these isolates conferred differential susceptibility to these drugs, and in most cases severely decreased the intracellular drug concentrations.[240] Development of resistance to β-lactams (cephalosporin) and imipenem has also been reported for *E. aerogenes* during the course of imipenem therapy. Resistance emerged within 5 days of starting antibacterial therapy and the posttherapy isolate was shown to have undergone a porin exchange to OmpK36.[53] These studies demonstrate that a resistant phenotype due to porin loss or exchange may occur during a course of antibiotic treatment. Porins may also undergo successive mutations leading to progressively increased levels of antibiotic resistance. A longitudinal 2-year study of *E. coli* strains recovered from patients on long-term complex antibiotic regimens showed that fluoroquinolones, cephalosporin, and carbapenem agents were clearly affected by this mechanism.[362] Liver and blood culture isolates demonstrated longitudinal increased levels of antibiotic resistance, and all of these strains had two mutations (D18E and S274F) in the OmpC porin that likely resulted in decreased drug influx. Porin mutations have also been reported in *E. aerogenes* clinical isolates shown to have high-level resistance to β-lactams.[368]

Antimicrobial agents other than β-lactam compounds may also depend on porin channels for access to the cell. Resistance to chloramphenicol, which is usually caused by enzymatic degradation, may also be mediated by altered porin proteins in enteric bacteria[620] and *Haemophilus influenzae*.[83] Similarly, resistance to aminoglycosides in *Serratia marcescens* may be mediated by alterations in porin proteins, although the primary mechanism for resistance is enzymatic degradation.[220] Resistance to fluoroquinolones, which is principally mediated by changes in the structure of the target enzyme, may also be caused by alterations in membrane proteins.[541]

A second permeability barrier also exists for some bacteria for agents that must gain entrance to the bacterial cytoplasm. Crossing the second membrane is accomplished by a process that requires expenditure of energy and a minimal negative charge in the cytoplasm, the proton motive force, in order to "pull" aminoglycoside antibiotics into the cytoplasm. This transport mechanism has been demonstrated in both gram-positive[378] and gram-negative bacteria.[77] Mutant *Enterobacteriaceae* have been described that were resistant to antimicrobial agents in vitro because of deficiencies in this transport mechanism, but their clinical significance was

unclear.[534] These variants appeared as small colonies on agar media, but they may revert to normal colony morphology.

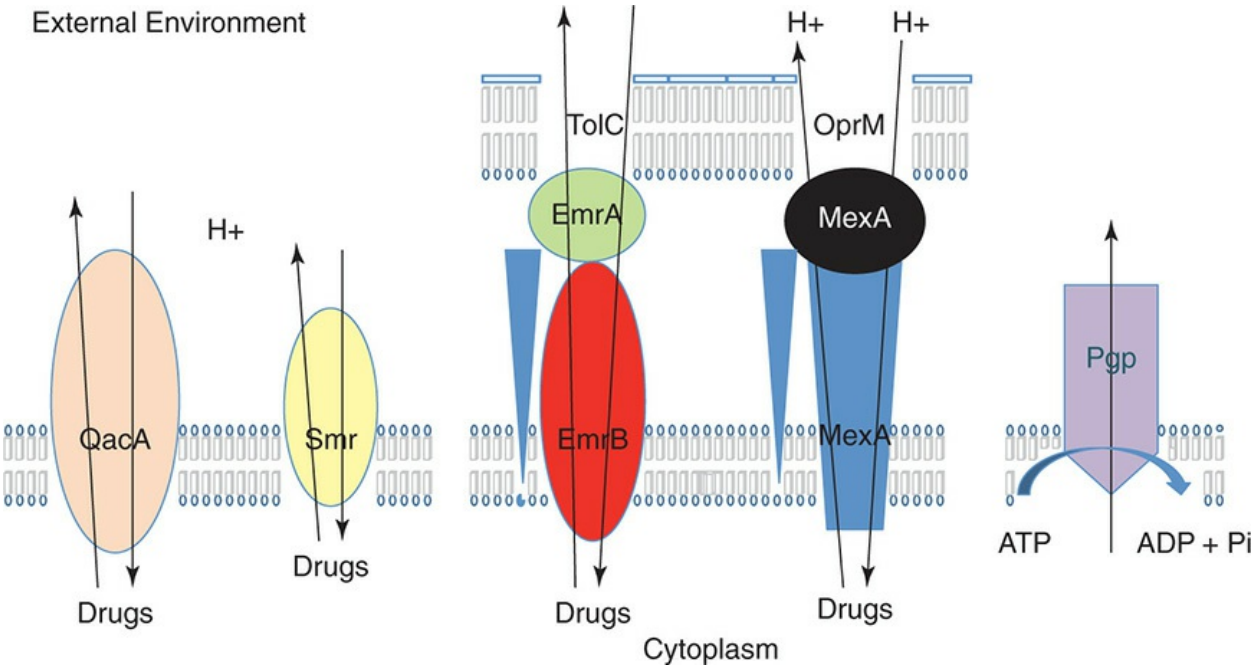
Efflux Pumps. Efflux pumps are a naturally occurring mechanism that bacteria use to excrete a solute out of the cell. Active transport mechanisms are biologically useful for removal of a variety of potentially toxic substances, of which antimicrobial agents may not even be the most important.[468,545] However, in some susceptible bacterial strains, efflux pumps can be induced by an antibiotic substrate, and subverted from natural functions to expeditiously pump the drug out of the cell; thereby, the bacterium becomes resistant to its intracellular action of the drug. Antimicrobial resistance in efflux mutants may be due to either increased expression of the efflux pump protein or mutation in the protein due to amino acid substitutions that make a substrate more efficiently exported.[342,426,467,468,545,680] Specific efflux pumps export one substrate, but others may transport a variety of dissimilar substrates, including antibiotics of multiple classes. Efflux pumps of the later type are associated with multiple-drug resistance (MDR) for antibiotics in several major classes.[426,468,545] In either case, the effect is to lower the intracellular concentration of antimicrobial agents so that drug concentrations never reach a sufficiently high level to exert effective antimicrobial activity. Efflux pumps are encoded by chromosomal genes or on plasmids (e.g., *tet* gene for tetracycline resistance and *qac* gene for resistance to quaternary ammonium compounds).[467] Structurally efflux pump proteins have 12 transmembrane-spanning regions, and this along with genomic studies has been used to identify proteins involved in multidrug efflux.[467,680] Efflux pumps may also work in concert with other resistance mechanisms in the bacterial cell to confer complete resistance to a particular class of antibiotics, most notably the fluoroquinolones.[436]

Microorganisms with larger genome size possess more genes for efflux pumps, and multiple MDR efflux pumps can be found in the same organism such as the Acr systems of *Enterobacteriaceae* or the Mex systems in *P. aeruginosa*.[545,467] Five families of efflux pump proteins have been described (Fig. 17-9).[342,426,467,468,545,680] Each of these families encodes bacterial MDR efflux and includes the multidrug and toxic compound extrusion (MATE), major facilitator superfamily (MFS), staphylococcal multiresistance (SMR), resistance nodulation division (RND), and ATP binding cassette (ABC) superfamily. Although ABC transporters are located in the genomes of pathogenic bacteria, to date, *Lactococcus lactis* LmrA is the only organism so far shown to develop MDR resistance by this efflux pump superfamily.[638]

The RND family is the most important efflux pump systems in *E. coli* and other gram-negative bacteria. It has a tripartite structure. The three components include a transporter (efflux) protein in the inner membrane (AcrB), a periplasmic accessory protein (AcrA), and an outer membrane protein (OMP) channel (TolC).[322] Genomic studies have shown that efflux pump genes among different bacterial species have a high degree of similarity, including *E. coli* AcrB/AcrB, *P. aeruginosa* MexB/MexB,*Campylobacter jejuni* CmeB/CmeB, and *Neisseria gonorrhoeae*

MtrD/MtrD.[467] The RND family efflux pumps have a similar function in other gram-negative species to that shown in *E. coli*. In *E. coli*, the AcrB transporter takes its substrate from within either the phospholipid bilayer or the cytoplasm and transports them into the external cellular medium by cooperation with TolC.[183,322,342] The cooperative interaction of AcrB and TolC is facilitated by AcrA.[322] RND efflux pumps have subsequently been characterized in many other gram-negative species, including *P. aeruginosa* (i.e., MexAB-OprM, MexXY-OprM, MexCD-OprJ, and MexEF-OprN),[467,486,545] *S. enterica* serovar Typhimurium,[80] and other *Enterobacteriaceae,* including *E. aerogenes*,[491]*Klebsiella* spp.,[383] *Serratia marcescens*,[328] *Morganella morganii*,[535] *H. influenzae*,[540] *Proteus mirabilis*, and *Helicobacter pylori*.[633] The RND pumps use the proton gradient across

the bacterial cell membrane to export one drug molecule per hydrogen ion used.[452] MATE MDR efflux pumps use both proton motive force and sodium ion gradients to export substrates. This type of transporter has been described in many different bacterial pathogens, including *P. aeruginosa* (PmpM),[244] *E. cloacae*,[245] *A. baumannii*, *Clostridium difficile* (CdeA),[172] *S. aureus* (MepA),[384] *Bacteroides thetaiotaomicron* (BexA),[396] *Brucella melitensis* (NorMI),[65] *Haemophilus influenzae* (HmrM),[673] and both *Vibrio cholerae* (McrM and VcnA)[35] and *Vibrio parahaemolyticus* (NorM).[108] Several efflux pumps also operate in gram-positive and gram-negative bacteria that are important in the development of fluoroquinolone resistance, and these transporters are members of the MFS family. NorA in *Staphylococcus aureus* has been shown to cause fluoroquinolone resistance.[213] The efflux pump pmrA has also been shown to confer fluoroquinolone resistance in clinical isolates of *S. pneumoniae*.[465,466] QepA is a plasmid-mediated efflux pump that has recently been characterized that confers high-level fluoroquinolone resistance in *E. coli* and other gram-negative bacteria.[99,100] Efflux in both of these transporters also uses the proton motive force across the cell membrane.



■ **FIGURE 17-9** Schematic illustrations of efflux pumps. Qac and Smr represent pumps found in gram-positive bacteria. EmrAB and MexAB-OprM represent pumps found in gram-negative bacteria. P-glycoprotein (Pgp) is found in mammalian cells and represents an ATP-binding cassette superfamily of pumps. ADP, adenosine diphosphate; Pi, inorganic phosphate. (Adapted from references 467 and 545.)

The energy-dependent efflux mechanism is a prime defense for bacteria against tetracyclines,[387] newer glycylcyclines,[151] and macrolides,[219] three groups of antibiotics that interfere with protein synthesis at the ribosomal level. Similarly, removal of the antibiotic is a resistance mechanism of staphylococci against the fluoroquinolones, which interfere with DNA gyrase.[213] Aminoglycosides have also been shown to be substrates for a number of multidrug efflux pumps, including members of the five superfamilies of bacterial transporters.[286] The resistance of gram-negative bacilli to many antibiotics was originally attributed to poor entry of the antibiotic into the bacterial cell because of size, hydrophobicity or charge. Active efflux of these antibiotics from the bacterial cell has been shown to be equally important because the pumps can excrete chemical compounds, including antimicrobial agents, directly into the extracellular medium, where their reentry is restricted.[342,426,467,468,545,680]

Antibiotic Inactivation by Destruction or Modification

β-Lactamases. β-lactamases are a family of enzymes produced by bacteria that vary in their spectrum of activity against the β-lactam class of antibiotics. β-lactamases are

the primary cause of bacterial resistance to β-lactam antibiotics. β-lactamases have now been described that can inactivate one or more β-lactam antibiotics or the entire group of antibiotics. These bacterial enzymes inactivate this major class of antibiotics by cleaving the amide bond in the four-atom β-lactam ring structure (Fig. 17-10).[90] One of the earliest β-lactamases found is a penicillinase that confers staphylococcal resistance to penicillin,[511] but more recently extended-spectrum β-lactamases have been characterized in enteric bacteria that can inactivate a wide spectrum of penicillin and cephalosporin drugs.[90,285,450] Due to molecular techniques, the genes encoding β-lactamases in many β-lactam-resistant clinical isolates have been sequenced and their amino acid sequences deduced (G. Jacoby and K. Bush, http://www.lahey.org/Studies/). By 2009, the number of unique protein sequences for β-lactamases exceeded 890, and this growth will likely continue as more bacterial strains are studied.[90,281,285,450,497] The specificity of a β-lactamase for a particular β-lactam antibiotic is an important determinant in the efficiency with which the enzyme hydrolyzes and inactivates the compound. A point mutation in one or more amino acids can change the specificity of the molecule if it occurs in a structurally critical area of the enzyme,[49,88,90] causing the rapid development of β-lactam resistance, even to more recently marketed drugs.

Group	Structure
Penicillins	Cephalosporins	Monobactams	Carbapenems	
■ **FIGURE 17-10** Structure of the main groups ofβ-lactam antibiotics—the β-lactam ring is designated by the dotted line. (Reprinted with permission from Robtsovam MY, Ulyashova MM, Bachmann TT, et al. Multiparametric determination of genes and their point mutations for identification of β-lactamases. Biochemistry (Moscow) 2010;75:1628–1649.)

Bacteria naturally produced β-lactamase enzymes prior to the introduction of a relevant antibiotic substrate. Two groups of investigators have presented evidence to support the concept that the physiologic role of β-lactamases is to restructure the peptidoglycan during bacterial cell growth.[43,624] They found that synthesis of β-lactamase was induced both by the presence of β-lactam antibiotics and cell wall precursors in the extracellular environment, recalling the structural similarity of penicillin and the D-alanine-D-alanine dipeptide terminus of peptidoglycan chains. It is now evident that the β-lactamases and the PBPs have a common, albeit distant

evolutionary origin.[566] Both classes of compounds must interact with β-lactam antibiotics in order to perform their function. Similar amino acid sequences have been demonstrated in PBPs of high and low molecular weight and certain types of β-lactamase. Similarities in conformation and three-dimensional structure between β-lactamases and PBPs have also been documented, and some PBPs have weak β-lactamase function.[388,423] Furthermore, the mechanism of action of both β-lactamases and the transpeptidase PBP is cleavage of an amide bond by an acyl-enzyme mechanism.[88]

Functional β-lactamase classification schemes also include the ability of various β-lactamases to be inhibited by inhibitors.[85,87,90,353] The three inhibitors of β-lactamase activity that are used in clinical medicine are clavulanic acid, sulbactam and tazobactam. These compounds resemble β-lactam antibiotics and can bind to the β-lactamase, either reversibly or irreversibly, protecting the antibiotic from destruction.[353] Although these enzyme inhibitors must mimic β-lactams in order to function, they have limited antibacterial activity in their own right.[85] However, when a β-lactamase inhibitor is combined with a potent β-lactam antibiotic, the presence of the inhibitor either partially or completely restores the bactericidal activity of the antibiotic. All three inhibitors are effective against staphylococcal penicillinase but have variable effectiveness against the chromosomal enzymes of gram-negative bacteria. Clavulanate and tazobactam are superior to sulbactam in activity against plasmid-mediatedβ-lactamases of gram-negative bacteria, including the extended-spectrum β-lactamases,[453] but there is no significant difference between the inhibitory activities of

clavulanate and tazobactam (Table 17-5). Some β-lactamases such as the class A carbapenemases (e.g., KPC-2) are resistant or only weakly inhibited by the activity of all three compounds.[310] Clavulanate is a more efficient inducer of class C/group 1 AmpC β-lactamases than is either tazobactam or sulbactam.

A variety of β-lactamase classification schemes has been developed to group these complex and varied enzymes, leading to some confusion in nomenclature. A useful early classification scheme was provided by Richmond and Sykes,[512] but the number and variety of enzymes have proliferated beyond the scope of their scheme. A more modern scheme, based on molecular structure proposed by Ambler,[9] includes, of necessity, only enzymes that have been characterized. Subsequently, Bush–Jacoby–Medeiros developed a β-lactamase classification scheme that integrates functional and molecular characteristics.[91] Recently, Bush and Jacoby have provided an updated classification scheme for β-lactamases based on alignment by structural and functional classifications which is summarized and compared to the Ambler molecular scheme in Table 17-5.[90] New functional subgroups have also had to be added to the scheme because of the identification and expansion of major β-lactamase families, and variants will continue to be identified on a regular basis.[90] As in previous functional classification schemes, enzymes have been grouped based on their ability to hydrolyze specific β-lactam classes and on the inactivation properties of the β-lactamase inhibitors clavulanic acid, sulbactam and tazobactam. Because many β-lactamases have only been described on the basis of a protein sequence with little functional description, a set of structural and functional criteria has been proposed by Bush and Jacoby for the scientific characterization of newly discovered enzymes.[90] Box 17-1 outlines some key educational points about β-lactamases. A brief description is provided of each of the three functional enzyme groups, as well as their subgroups.

Group 1 Cephalosporinases. Ambler Class C/Bush–Jacoby Group 1 enzymes are primarily cephalosporinases, either constitutive or inducible, that are found on the chromosomes of many *Enterobacteriaceae* and a few other gram-negative bacteria.[281]Plasmid-mediated group 1 enzymes such as CMY, FOX, MIR, ACT, and DHA have been known for the past two decades, but CMY enzymes (1 to 50) are most commonly found in clinical isolates.[281] AmpC β-lactamases primarily have activity on the cephalosporins and are usually resistant to inhibition by clavulanic acid and active on cephamycins, such as cefoxitin and cefotetan (i.e., these drugs are resistant). They also have a high affinity for aztreonam (Ki values as low as 1 to 2 nM), which distinguish these enzymes from the class A cephalosporinases.[89,281] Exceptions to the usual activity profile of AmpC enzymes have also been described, including a novel AAC-1 enzyme in a *K. pneumoniae* strain that was not active on cefoxitin,[32] a novel enzyme that demonstrated inhibition by clavulanic acid or

tazobactam in *E. coli* and *K. pneumoniae* isolates,[23,666] and a novel enzyme in an *E. coli* isolate that demonstrated resistance to cefotaxime but not ceftazidime.[683] Carbapenem resistance may also occur, particularly to ertapenem, in gram-negative strains that produce a high level of AmpC β-lactamase in combination with loss of OM porins.[64,284,494] AmpC expression in many organisms including *Serratia marcescens, Citrobacter freundii, Enterobacter* spp., *Morganella* spp., *Providencia* spp., *Acinetobacter baumannii,* and *Pseudomonas aeruginosa* is constitutive at a low level, but induced on exposure to certain β-lactams (amoxicillin, ampicillin, imipenem, and clavulanic acid).[281,352,653]

Subgroup 1e enzymes are newly described variants of group 1 enzymes called extended-spectrum cephalosporinases that have increased activity against ceftazidime and other oxyimino-β-lactams because of amino acid substitutions caused by mutations.[433] Production of high levels of this type of enzyme in combination with a porin mutation may confer clinically significant carbapenem resistance.[369] Several new enzymes in this subgroup have been described recently, including CMY-37 in *Citrobacter freundii*, CMY-10 in *Enterobacter cloacae,* and CMY-19 in *E. coli*.[90]

Group 2 Serine β-Lactamases. This is the largest group of β-lactamases and includes molecular classes A and D. The dramatic increase in the number of enzymes within functional group 2 in the last two decades is due to the discovery and increasing identification worldwide of extended-spectrum β-lactamases (ESBLs). Subgroup 2a penicillinases have a limited spectrum of activity for benzylpenicillin and penicillin derivatives, and are the primary β-lactamases in gram-positive cocci such as staphylococci and less commonly enterococci.[90] These enzymes have poor hydrolytic activity for cephalosporin, carbapenem or monobactam compounds, except that they readily hydrolyze nitrocefin. Most of these enzymes are chromosomal although some staphylococcal penicillinases may be carried on a plasmid, and all subgroup 2a enzymes are inhibited by clavulanic acid and tazobactam.

Subgroup 2b β-lactamases include TEM-1, TEM-2, and SHV-1 enzymes, some of the most common plasmid-mediated β-lactamases identified several decades ago.[90] These enzymes readily hydrolyze penicillins and early cephalosporins including cephaloridine and cephalothin, and they are strongly inhibited by clavulanic acid and tazobactam. Subgroup 2be β-lactamases are ESBLs. Characteristics of these ESBL "wide-spectrum β-lactamases" are summarized in Table 17-5. These broad-spectrum enzymes not only retain activity against penicillins and cephalosporins similar to 2b enzymes, but also hydrolyze one or more oxyimino-β-lactams, such as ceftotaxime, ceftazidime, and aztreonam. Initially, ESBLs developed because of amino acid substitutions in TEM-1, TEM-2, and SHV-1 enzymes, which are inhibited by clavulanic acid.[90,496] A rapidly evolving group of ESBLs, the CTX-M enzymes have been more recently described, which most likely originated from and are related to

chromosomally determined β-lactamases in *Kluyvera*.[51] Most CTX-M enzymes hydrolyze cefotaxime more efficiently than ceftazidime, and many are able to also hydrolyze other β-lactam substrates including cefepime.[450] CTX-M enzymes are inhibited by tazobactam and to a lesser extent by clavulanic acid.[90] Other less commonly encountered ESBLs are members of the PER, VEB, and other families (Table 17-5).[217,477,489] Subgroup 2br enzymes are broad-spectrum β-lactamases that retain subgroup 2b activity but have developed resistance to clavulanic acid and related β-lactamase inhibitors. Although TEM enzymes (TEM 30 and 31) and some SHV enzymes (SHV-10 and others) have been functionally characterized within this group, no CTX-M enzymes have so far been found with this activity profile.[90] Another subgroup of 2b enzymes, the 2ber β-lactamases have been called CMT (complex mutant TEM) (i.e., TEM-50), and are all classified within the TEM family. CMT enzymes combine an extended-spectrum activity with modest resistance to clavulanic acid inhibition.[90]

TABLE 17-5 Bush–Jacoby β-Lactamase Classification Compared to the Ambler Molecular Class System[a]

Bush–Jacoby (2010)[a]	Ambler Molecular Class	Enzymes	Active Site	Antibiotic Substrate(s)	Enzyme Inhibitors[b]	Found in
Group 1 Cephalosporinase	C	AmpC, ACT-1, CMY-2, FOX-1, MIR-1	Serine	Hydrolyzes cephalosporins including cephamycins	PBA, DPA, Cloxacillin	*Enterobacteriaceae, Acinetobacter* spp.
Group 1e Cephalosporinase	C	GC1, CMY-37	Serine	Increased hydrolysis of ceftazidime and other oxymino-β-lactams[c]	Not inhibited by CV of PTZ	*Enterobacteriaceae*
Group 2a Penicillinases	A	PC1	Serine	Increased hydrolysis of penicillin	CV or PTZ	*S. aureus*
Group 2b Penicillinases	A	TEM-1, TEM-2, SHV-1	Serine	Penicillin, first-generation cephalosporins	CV or PTZ	*Enterobacteriaceae*
Group 2be ESBLs	A	TEM-3, SHV-2, CTX-Ms, PER-1, VEB-1	Serine	Increased hydrolysis of oxymino-β-lactams[c]	CV or PTZ	*E. coli, Klebsiella pneumoniae, K. oxytoca, P. mirabilis, Salmonella* spp., *Kluyvera* spp. (*CTX-Ms*)
Group 2ber ESBLs	A	TEM-50	Serine	Increased hydrolysis of oxymino-β-lactams[c] + resistance to inhibitors	Not inhibited by CV of PTZ	*Enterobacteriaceae*
Group 2d	D	OXA-01, OXA-10		Hydrolysis of cloxacillin or oxacillin	Variable with CV or PTZ	*Enterobacteriaceae*
Group 2de ESBLs	D	OXA-11, OXA-15	Serine	Hydrolysis of cloxacillin or oxacillin + oxymino-β-lactams[c]	Variable with CV or PTZ	*P. aeruginosa*
Group 2df Carbepenemase	D	OXA-23, OXA-48	Serine	Hydrolyzes carbapenems	Variable with CV or PTZ	*A. baumannii, Enterobacteriaceae*
Group 2e ESBL	A	CepA	Serine	Hydrolyzes cephalosporins	CV but not aztreonam	*Proteae*
Group 2f Carbapenemases	A	KPC-2, SME-1, IMI-1	Serine	Hydrolyzes carbapenems, oxymino-cephalosporins[c] and cephamycins[d]	Variable with CV or PTZ	*Enterobacteriaceae*
Group 3 Metallo-Carbapenemases	B	IMP-1. VIM-2, IND-1, L1	Zinc	Hydrolysis of carbapenems but not monobactams	EDTA	*P. aeruginosa, A. baumannii*
Group 4	Not included	Unknown				

[a] Updated Bush–Jacoby classification adapted from reference 90.
[b] β-Lactamase inhibitors: PBA, phenylboronic acid; DPA, dipicolinic acid; CV, clavulanic acid; TZ, tazobactam; EDTA, ethylenediaminetetraacetic acid.
[c] Oxymino-cephalosporins = ceftotaxime, ceftazidime, ceftriaxone, cefepime, aztreonam.
[d] Cephamycins = cefoxitin and cefotetan.

1091

BOX 17-1

Key Educational Points About β-Lactamases

- Each enzyme has different affinities for variousβ-lactam antibiotics:
  - Penicillinases break down penicillin drugs.
  - Cephalosporinases break down cephalosporin drugs.
  - Extended-spectrumβ-lactamases hydrolyze most β-lactams except carbapenems.

- Carbapenemases hydrolyze carbapenems.
- Different β-lactamase classification systems differentiate these enzymes based on their structure (Ambler) or structure and function (Bush).
- Multiple β-lactamases of different types may be present and expressed in the same isolate, especially among gram-negative bacteria:
  - *Enterobacteriaceae*—strains with BOTH an AmpC β-lactamase + an ESBL.
  - *P. aeruginosa*—strains with BOTH an AmpC β-lactamase + an MBL.
  - *Acinetobacter baumannii*—strains with BOTH an AmpC β-lactamase + MBL + OXA enzyme(s).
- Acquisition of an integron gene cassette with one or moreβ-lactamase genes often results in multidrug resistance because these determinants carry other antibiotic resistance genes (e.g., fluoroquinolones, aminoglycosides, etc.).
- Multidrug-resistant bacteria often have multiple mechanisms of resistance operative that confer the final resistance phenotype.
  - β-Lactamase + porin mutation that decreased cell wall permeability.
  - β-Lactamase + efflux system that pumps the antibiotic out of the cell.

Subgroup 2c penicillinases hydrolyze carbenicillin or ticarcillin almost as rapidly as benzylpenicillin, but have weaker hydrolysis rates for cloxacillin or oxacillin. They are readily inhibited by tazobactam and clavulanic acid. Few new enzymes in this subgroup have been recently described because both of these drugs are no longer available for clinical use. Extended-spectrum carbenicillinase RTG-4(CARB-10) have more recently been described from *Acinetobacter baumannii*, which has activity against cefepime and cefpirome.[488]

Subgroup 2d β-lactamases hydrolyze cloxacillin or oxacillin and are therefore called OXA enzymes. These enzymes are in molecular class D, and may or may not be inhibited by clavulanic acid or tazobactam. OXA enzymes are currently the second largest family of β-lactamases (Table 17-5). A new subgroup 2de of OXA enzymes has recently been described in *P. aeruginosa* isolates in France and Turkey.[90,450] These enzymes (e.g., OXA-11 and -15) evolved from OXA-10 due to amino acid substitutions, and have retained 2d activity with an extended spectrum that includes oxyimino-β-lactams such as ceftazidime but not carbapenems.[90] Another new subgroup of OXA enzymes designated as 2df has carbapenem-hydrolyzing activity, albeit weak for some carbapenem substrates.[648] Most of these enzymes are chromosomal and have been characterized from *A. baumannii*,[648] but some plasmid-encoded OXA enzymes have been described in *Enterobacteriaceae* (e.g., OXA-23 and -48).[478]Typically, 2df OXA β-lactamases are not inhibited by clavulanic acid.

Subgroup 2e cephalosporinases may be confused in the clinical laboratory as group

1 AmpC enzymes or as ESBLs because they are found in similar gram-negative organisms and have similar resistance profiles. However, this group now mainly refers to the inducible, chromosomal cephalosporinases in the *Proteus*. These enzymes can be differentiated by demonstrating poor affinity for aztreonam and inhibition by clavulanic acid.[86]

Subgroup 2f β-lactamases are serine carbapenemases from molecular class A, which primarily hydrolyze carbapenems, and are better inhibited by tazobactam than clavulanic acid. Most of these enzymes are chromosomal and include the SME family as well as IMI-1 and NMC-1 β-lactamases.[430,495,498] More recently, plasmid-encoded serine carbapenemases including KPC and some GES enzymes have emerged in this subgroup and have rapidly spread worldwide.[63] KPC carbapenemases carried in *Klebsiella pneumoniae* have caused major outbreaks in hospitals, particularly in the eastern part of the United States.[63,495]

Group 3 Metallo-β-Lactamases (MBLs). MBLs are a unique group of β-lactamases that have a zinc ion at the active site (Table 17-5). These metalloenzymes hydrolyze carbapenems but have poor ability to hydrolyze monobactams.[647] They are not inhibited by tazobactam or clavulanic acid, but are readily inhibited by EDTA, dipicolinic acid or 1, 10-o-phenanthroline.[373] Two functional subgroups are now proposed, the major one being subgroup 3a that includes the major plasmid-encoded IMP and VIM family of enzymes (subclass B1), which have been described worldwide in *P. aeruginosa* as well as *Enterobacteriaceae*.[498,647] These enzymes have similar amino acid sequences that act as ligands for the two zinc ions in their active site, which provide broad hydrolyzing activity.[90] Several other MBL enzymes have been added to subgroup 3a including the L1 MBL from Stenotrophomonas maltophilia and subclass B3

MBLs (i.e., CAU-1, GOB-1 and FEZ-1) because they have similar broad-spectrum substrate profiles (i.e., high hydrolysis rates for penicillin, cephalosporin and carbapenem but not monobactam compounds); these enzymes, however, differ in the amino acid sequence involved in zinc ion binding at their active site.[90] In contrast, the subgroup 3b MBLs preferentially hydrolyze carbapenems, so that they are not detected by using a chromogenic cephalosporin substrate (i.e., nitrocephin) to test for β-lactamase activity.[495] These enzymes also work best if only one zinc binding site is occupied. The chromosomal MBLs in *Aeromonas* spp. are an example of a subgroup 3b metalloenzyme.[678]

Aminoglycoside Modifying Enzymes. The aminoglycoside drugs contain a nucleus

that is an aminocyclitol ring that can be either streptidine or 2-deoxystreptamine, and two or more sugars linked by glycoside bonds to the nucleus. Aminoglycosides are naturally occurring molecules produced by actinomycetes. Semisynthetic derivatives produced from *Streptomyces* are labeled -"cins" and include netilmicin, sisomicin, gentamicin, isepamicin, dibekacin, and amikacin.[503] *Micromonospora* derivatives are labeled -"mycins" and include streptomycin, kanamycin, neomycin, tobramycin, and paramomycin.[503] These compounds bind to the bacterial 30S ribosomal subunit rendering the ribosome unavailable for translation, resulting in inhibition of protein synthesis and cell death.[324,503] Most resistance to aminoglycosides results from inactivation of the compound by intracellular bacterial modifying enzymes, although efflux pumps and target site alterations also contribute to a lesser extent.[286,503] Amikacin is not inactivated by the common enzymes that inactivate gentamicin and tobramycin because of structural differences between these drugs. However, all aminoglycoside antibiotics are at risk for inactivation by one of these enzymes.[286,503,618] Aminoglycoside modifying enzymes catalyze the modification at –OH or $–NH_2$ groups of the 2-deoxystreptamine nucleus or the sugar moieties and can be either phosphotransferases (APHs), acetyltransferases (AACs), or nucleotidyltransferases (ANTs) (Fig. 17-11).[359,503,618] These enzymes are present in virtually all bacterial types due to the continuous emergence of new enzyme variants that can utilize a growing number of antibiotic substrates along with the fact that their encoding genes can undergo horizontal transfer as part of integrons, gene cassettes, transposons or conjugative plasmids.[618] Aminoglycoside nomenclature for the various modifying enzymes has been confusing because the original system used only letters.[435] Most scientists now use a three-letter identifier of the activity followed by the site of modification between parenthesis **(class)**, a roman number for the resistant profile **(subclass)** and a lowercase letter as the individual identifier (i.e., **AAC** (6′)-I enzymes are designated **AAC** (6′)-Ib through to **AAC** (6′)-Iaf).[550]The number of aminoglycoside modifying enzymes described to date is extensive and beyond the scope of this chapter, but interested readers are referred to several excellent reviews.[286,503,618]

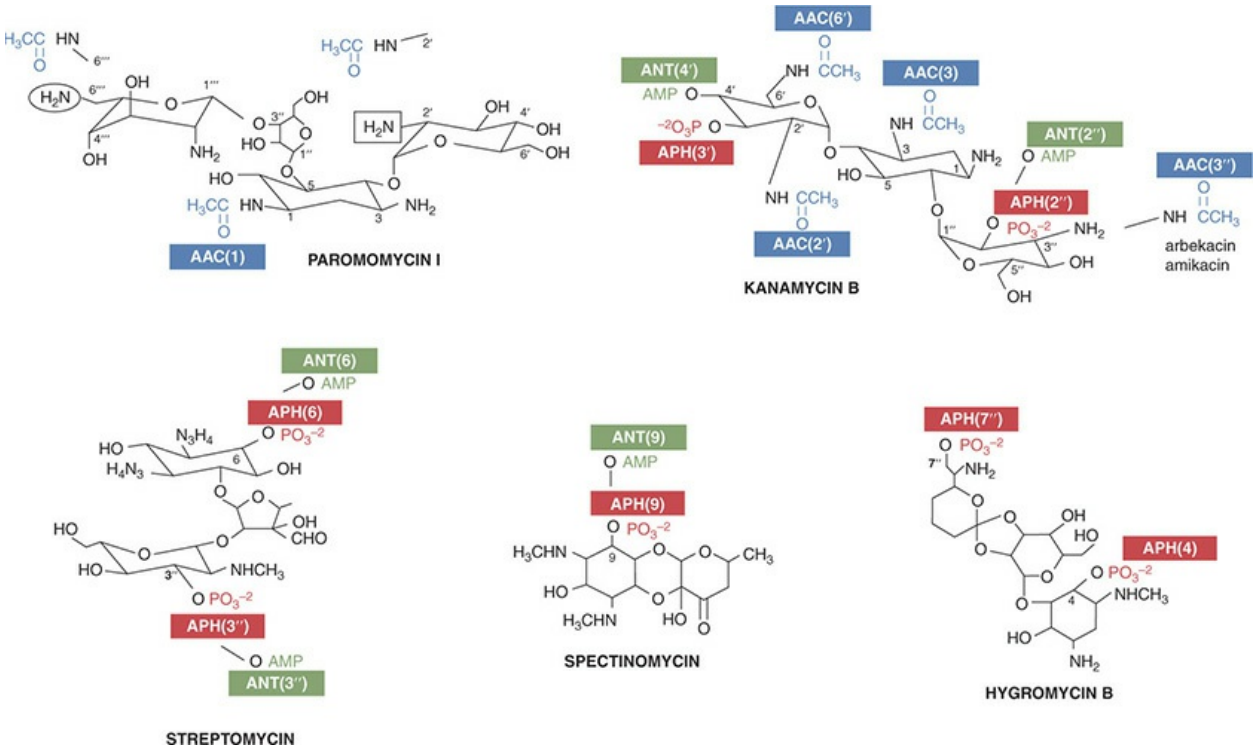
Aminoglycoside acetyltransferases (AACs) belong to the GCN5-related *N*-acetyltransferases (GNAT) superfamily of proteins, and catalyze the acetylating of one of the four amino groups ($–NH_2$) of the compound. AACs have been classified based on their specificity of acetyl transfer on the aminoglycoside molecule, and catalyze acetylating at the 1[AAC (1)], 3[AAC (3)], 2′ [AAC (2′)], or 6′ [AAC (6′)] positions (Fig. 17-11). All types of AAC enzymes have mainly been found in gram-negative bacteria, although some types have also been found in actinomycetes [AAC (1)], mycobacteria [AAC (2′)], and gram-positives [AAC (6′)].[503] AAC (6′) enzymes are

the most commonly found enzymes in gram-negative as well as gram-positive bacteria, and the genes have been found encoded in chromosomes and plasmids, often as part of mobile genetic elements. The two main subclasses of AAC (6′) enzymes differ in their activity against amikacin and gentamicin C1. AAC (6′)-I enzymes have high activity against amikacin and gentamicin C1a and C2 but low activity against gentamicin C1. The AAC (6′)-II enzymes catalyze acetylating of all three forms of gentamicin but have no activity against amikacin. AAC(6′)-Ib is the most clinically relevant acetyltransferase and is responsible for the resistance to amikacin and other aminoglycosides in several gram-negatives, including *Acinetobacter*, *Enterobacteriaceae*, *Pseudomonadaceae,* and *Vibrionaceae*.[503] A novel class of AAC enzyme has also recently been described that also uses fluoroquinolones as substrates, and has been designated AAC (6′)-Ib-cr because it likely originated from AAC(6′)-Ib by modification of only two amino acids (Trp102Arg and Asp179Tyr). Horizontal transfer of the AAC (6′)-Ib-cr determinant, will therefore confer high-level resistance to both aminoglycosides and fluoroquinolone antibiotics.[523,576] Given the rapid pace of new discovery of aminoglycoside modifying enzymes of the AAC type, many more will likely be described in the future. ANTs catalyze the transfer of an AMP group from ATP to a –OH group in the aminoglycoside molecule, thereby inactivating the compound. Five classes of ANTs have been described that catalyze adenylation at the 6[ANT(6)], 9[ANT(9)], 4′ [ANT(4′)], 2″ [ANT(2″], and 3″ [ANT(3″)] positions, but only ANT(4′) contains two subclasses, I and II.[678] ANT enzymes of various types have more commonly been found in gram-positive bacteria species, including *Enterococcus*, *Staphylococcus,* and *Bacillus*.[107,503,631] However, ANT(4′)-IIa was identified in plasmids of *Pseudomonas* and *Enterobacteriaceae*,[282] and a transposon carrying ANT(4′)-IIb has been described in a *P. aeruginosa* isolate.[136] APHs catalyze the transfer of a phosphate group to the aminoglycoside molecule. The classes and subclasses within the APH enzymes include APH(4)-I, APH(6)-I, APH(9)-I, APH(3′)-I through VII, APH(2′)-I through IV, APH(3″)-I, and APH(7″)-I.[503] APH enzymes of various types have been mainly found in gram-negative species, including *P. aeruginosa*, *S. maltophilia*, *A. baumannii*, *K. pneumoniae*, *C. jejuni,* and *Legionella pneumophila*, but the APH(3′)-1c determinants have also been distributed into *Corynebacterium* spp.[136,282,437,503,632]

Although aminoglycosides have fallen into clinical disfavor due to their inherent toxicity profile and the availability of other potent agents that are active against gram-negative bacteria, increased antibiotic resistance to one or more of these drugs has also diminished their use. Aminoglycoside resistance has developed in epidemic proportions at hospitals around the world since their introduction into clinical practice.[203,204,676] Miller and colleagues, who summarized the results of multiple studies, found variations over time and among geographic areas.[395] There appeared to be a correlation of

resistance with patterns of antibiotic use in these and more recent studies.[5,644] Some aminoglycoside modifying enzymes in gram-negative bacteria have now become so widely distributed that certain drugs such as kanamycin are no longer used, and others such as streptomycin are reserved for specific clinical situations. Rate of resistance to other aminoglycosides such gentamicin and tobramycin also vary widely across different jurisdictions. Even amikacin which is least vulnerable to inactivation may be rendered ineffective by other mechanisms such as efflux, particularly in *Pseudomonas aeruginosa*.[400]

1093



■ **FIGURE 17-11** Actions of aminoglycoside modifying enzymes on common agents representative of aminoglycosides and modification sites by AAC, ANT, and APH enzymes. An example of each kind of modification is shown on one of the substrates. The square and oval on positions 2′ and 6″ in paromomycin I indicate that this molecule is preferentially acetylated at the position 1. Kanamycin, streptomycin, spectinomycin, and hygromycin B can be modified in multiple positions. (Adapted from reference 503.)

Other Enzymes. Several other major classes of antibiotics may be inactivated by bacterial enzymes. In the case of chloramphenicol, the acetyltransferase enzyme is responsible for most clinical resistance.[201] A minor mechanism for resistance to the

tetracyclines is enzymatic inactivation.[602] Antibiotic resistance to both macrolides and lincosamides in gram-positive bacteria may be produced by several mechanisms alone or in combination including enzymatic inactivation, alteration of ribosomal targets or active efflux.[332] Many rRNA methylase genes (*erm*) have been identified that bring about methylation of the 23S rRNA component of the 50S ribosomal subunit involving key adenine bases in the peptidyl transferase functional domain.[522] The MLSB phenotype conveyed by the *erm* genes are widespread in gram-positive and gram-negative bacteria and confer resistance to all macrolides (including clarithromycin and azithromycin), lincosamides **(clindamycin),** and streptogramins (quinupristin-dalfopristin).

Target Modification

Alteration of the target sites where antibiotics act is a common mechanism of resistance. Most antibiotic target sites in bacterial cells also play essential roles in microbial growth and/or metabolic systems. Mutations in the target site must therefore occur such that the bacterium evades antimicrobial action but normal cellular function continues unabated. Frequently, bacterial mutations that result in decreased susceptibility to one or more major classes of antibiotic, not only result in permanent modification of the target structure but also invoke other changes in the cell to compensate for the altered target site (i.e., addition of new genes). This section provides a brief description of the most important types of target site modification that result in clinically significant resistance to one or more classes of antibiotics.

Penicillin-Binding Proteins. One of the most clinically relevant target site changes that occurred primarily in gram-positive bacteria is the acquisition of an altered transpeptidase (PBP) structure, so that β-lactams have reduced noncovalent binding with an acylation by their target site.[200] Methicillin-resistant *S. aureus* (MRSA) strains

have a high level of resistance to methicillin and other β-lactam antibiotics because of acquisition and expression of the *mec*A gene.[628] This gene encodes for an altered PBP 2a (i.e., also designated as PBP2′) that belongs to a group of transpeptidases involved in the synthesis of the bacterial cell wall.[237,239] Exposure of methicillin-susceptible staphylococci to methicillin induced an alteration of the PBP 2 to form a variant (PBP 2a); variants that lost resistance did not contain the variant binding protein.[239]Subsequently, it has been shown that the *mec*A gene is carried on a large genetic element called the staphylococcal cassette chromosome *mec* **(SCC*mec*)** that is carried on the chromosome and integrated near the origin of replication.[255] *S. aureus*

most likely acquired SCC*mec* via horizontal transfer from a coagulase-negative *Staphylococcus* species. To date, 11 different types of SCC*mec*, designated I to XI are currently recognized; along with several variants.[255,625] Different types of SCC*mec* encode other antibiotic resistance genes and range in size from 21 to 67 kb.

MRSA strains have also recently been described in Europe from animal and human sources that carry a novel *mec*A homologue that was originally called *mecALGA*$_{251}$ because it was discovered in strain LG251, but is now designated as the *mecC*gene.[205,553] The *mecC* gene has only 69% sequence identity to the *mec*A gene, and also has quite different homology to the PBP2a encoded by *mec*A.[276]

Resistance to β-lactam antibiotics in *S. pneumoniae* also occurs due to decreased affinity with PBPs. Penicillin resistance occurs because of alteration in PBP2b while resistance to third-generation cephalosporin drugs is due to altered structures of PBP1a and PBP2x.[225,323,412] The mechanism of alteration of the PBP structure in *S. pneumoniae* occurs in a different way than that described for *S. aureus*. Alterations of multiple PBPs result in a multistep process of increasing resistance due to recombination events between the PBP genes of *S. pneumoniae* and those from closely related *Streptococcus* spp. through a process of transformational exchanges of genetic information between these closely related bacteria.[125,170] Successful genetic recombination events result in a mosaic gene structure for the *PenA* and *PenB* genes that encode penicillin resistance in this organism by alterations in PBP.

Enterococci also develop resistance to glycopeptide antibiotics due to the development of intrinsically low-affinity PBPs.[17,334] Both *Enterococcus faecium* and *Enterococcus faecalis* use several PBPs as targets for binding β-lactams. Acquisition of one or two related gene clusters, called VanA and VanB, by enterococci confers high-level resistance to glycopeptide drugs due to the overproduction of low-affinity PBP 5 (PBP5fm) that has reduced binding capability for β-lactams.[20,319] The VanA and Van gene clusters are located on transposons and plasmids, and have been horizontally transferred from enterococci to other bacterial species. The Van gene cluster encodes enzymes that produce a modified peptidoglycan precursor terminating in D-Alanyl-D-Lactate (D-Ala-D-Lac) instead to D-Ala-D-Ala.[20,319,334,335] The peptide loop of mutant PBP 5fm of *Enterococcus* is more rigid than that of PBPs with high-affinity β-lactams binding, and the active site contains a hydrophobic Valine residue that could also decrease access to β-lactams. PBPs structure appears similar to that of low-affinity PBP2a in MRSA strains. The VanA and VanB gene cluster is made up of three genes thought to originate from glycopeptide producing bacteria including: the Van H or Van H_B genes genes that encode a dehydrogenase that reduces pyruvate to D-lactate, 2) the VanA or VanB genes encodes a ligase that synthesizes D-Ala-D-lac, and 3) Van X or VanX_B encodes D-dipeptidase that hydrolyzes preexisting D-Ala-D-

Ala.[334,634] Glycopeptide resistance in enterococci is inducible in the presence of vancomycin or teicoplanin, and a two-component regulatory system VanRS and $VanR_BS_B$ controls expression of the Van genes.[20,334,335] Other glycopeptide resistance gene clusters characterized in *E. faecium* include VanD, VanE, and VanM, while VanG and VanN may also occur in *E. faecalis*.[57,394,429,672] *Enterococcus casseliflavus* and *Enterococcus gallinarum* are inherently resistant due to the presence of a VanC gene cluster.[111,336]

S. aureus strains with reduced susceptibility to vancomycin, or vancomycin-intermediate *S. aureus*/vancomycin-resistant *S. aureus* (VISA/VRSA), were initially discovered in Japan in 1997 and had minimum inhibitory concentrations (MICs) = 8 μg/mL (i.e., also called glycopeptide-intermediate *S. aureus* or GISA).[253,567] These strains demonstrated several cell wall changes compared to control isolates including an increase in cell wall thickness. An increased proportion of peptidoglycan stems from peptides that contain nonamidated glutamine residues that result in decreased peptidoglycan cross-linking.[253,607] Therefore, a decreased amount of the glycopeptide drug reaches the cell wall targets in VISA/VRSA strains because the thicker cell wall entraps the antibiotic molecules before it reaches the cytoplasm membrane.[140] In 2002, a new mechanism for high-level resistance to vancomycin was found in an MRSA strain with an MIC = 32 μg/mL.[235] The strain had acquired the VanA gene cluster from enterococci, but it also had an SCC*mec*A gene cassette and together these genes encoded for multiple changes in the bacterial peptidoglycan composition bringing about high-level resistance to glycopeptides. To date, reports of vancomycin resistance in *S. aureus* and MRSA strains have remained isolated,[560,612] but the future dissemination of this type of resistance would have serious clinical consequences.

β-lactam resistance due to PBP changes in other organisms has also been described. In Japan, *H. influenzae* strains have been characterized that are β-lactam resistant due to acquisition of the *ftsI* gene that encoded mutations in PBP3.[241,379] Nontolerant group A streptococci have decreased binding of penicillin to PBP 3, increased binding to PBP 5, and replacement of PBP 2 with a new PBP 2a′ that has decreased affinity for penicillin-binding.[174] PBP 3 affinity for penicillin is also reduced in *Listeria monocytogenes* strains with decreased susceptibility to imipenem and penicillin.[635] Several gram-negative bacterial strains have been characterized that have decreased affinity of PBP 2 for imipenem, including *P. mirabilis*, *P. aeruginosa,* and *A. baumannii*.[36,212,420] Amoxicillin resistance in *Helicobacter pylori* has also been shown to be due to mutations in *pbp1*.[451]

DNA Gyrase. Resistance to the fluoroquinolones is mainly caused by chromosomal mutations in two enzymes involved in DNA synthesis, DNA gyrase and topoisomerase

IV. DNA gyrase produces negative super helical coils in the bacterial DNA in front of the replication fork. This enzyme complex is composed of two subunits including GyrA and two GryB

1095

subunits that are encoded by their respective *gyrA* and *gyrB* genes. Topoisomerase **IV** decatenates interlinked daughter chromosomes following replication. This enzyme complex in most bacteria is comprised to two ParC and two ParE subunits encoded by their respective *parC* and *parE* genes. In *S. aureus,* topoisomerase **IV** is encoded by two subunits called GrlA and GrlB.[543] Fluoroquinolones bind to the **DNA–DNA** gyrase or topoisomerase enzyme complexes bringing about conformational changes in these enzymes that block replication of **DNA** and introduce double-stranded **DNA** breaks.[262] Mutations in *gyrA* that alter the GyrA subunit of the **DNA** gyrase occur in a region of the protein that is highly conserved between different bacterial species called the fluoroquinolone resistance-determining region **(QRDR)**, and specifies the active site of the enzyme (i.e., between amino acids 67 and 106).[261] Two known mutations *nalC* and *nalD* in the **DNA** gyrase B subunit result in amino acid substitutions in the central part of the molecule between positions 426 and 447 that confer a moderate level of resistance to nalidixic acid, and these mutations have so far only been rarely detected in clinical isolates.[261] The level of resistance to fluoroquinolones may therefore differ according to the site of mutation, and the substituted amino acid in a particular clinical isolate.

In gram-negative bacteria, high-level fluoroquinolone resistance commonly occurs due to mutations in the GyrA subunit. Although GyrB subunit alterations (i.e., *gyrB* gene mutations) occur, they are much less common than GyrA mutations, and produce lower levels of fluoroquinolone resistance than mutations in *gyrA*. Mutations encoded by the *gyrA* gene result in alterations in the portion of the GyrA subunit that is bound to the DNA during replication (i.e., active site), and result in drug resistance in *Enterobacteriaceae* due to decreased affinity for the altered DNA gyrase–DNA complex.[262,551,654] Topoisomerase IV serves as a secondary target for fluoroquinolone drugs in gram-negative bacteria, and mutations are less commonly found in *ParC* or *ParE* genes.[262]

Although mutations in *ParC* or *ParE* genes that result in alteration of the topoisomerase IV enzyme–DNA complex have been described in *E. coli*, concomitant mutations in *gyrA* in some strains result in high-level fluoroquinolone resistance.[262,380,551]Topoisomerase IV enzyme mutations occur most often in gram-positive bacteria, particularly in *S. aureus* and *S. pneumoniae* where alterations in either subunit may result in high-level fluoroquinolone resistance. However, mutations

in *ParC* or *GrlA* in *S. aureus* occur more frequently than mutations in *ParE* or *GrlB* in *S. aureus*.[260,304,305] Similar mechanisms bring about fluoroquinolone resistance in gram-positive bacteria. Mutations in *ParC* result in reduced drug affinity for the DNA–topoisomerase IV complex.[68,260,405]

The development and identification of several mechanisms of plasmid-mediated fluoroquinolone resistance, primarily in gram-negative bacteria is cause for concern.[99,380,523] Plasmid-mediated fluoroquinolone resistance was initially reported in *K. pneumoniae* isolates due to acquisition of a *qnr* gene that conferred high-level ciprofloxacin resistance (i.e., MICs as high as 32 μg/mL).[524] Drug resistance was found to be due to a plasmid-mediated *qnrA1* gene which encoded a QnrA1 protein, a pentapeptide repeat protein that acts by protecting DNA gyrase from fluoroquinolone binding. Five other QnrA variant proteins (Qnr2 to Qnr6) have since been identified, and three other plasmid-mediated bacterial *qnr* determinants that share some similarity to *qnrA1* have been reported (i.e., *qnrB1*, *qnrC1,* and *qnrS1*).[99] The prevalence of *qnr* genes in gram-negative bacteria has been reported to range from 1% to 5%.[99] So far, two other major plasmid-mediated mechanisms have been described that also confer high-level fluoroquinolone resistance including the aminoglycoside modifying enzyme acetyltransferase AAC(6′)-Ib-cr (See Aminoglycoside Modifying Enzymes),[523] and the QepA efflux pump related to the MFS system (See Efflux Pumps).[99]

Other Targets. Resistance to the action of antibiotics that block protein synthesis by binding to the 50S ribosomal subunits such as the macrolides, lincosides, and streptogramin B may also occur by alteration in the target site. Mutation in the 23S rRNA component of the 50S subunit close to sites where methylation resistance occurs is also independently associated with resistance to the macrolides in many bacterial species.[332] Alteration in the L4 and L22 proteins of the 50S subunit as well as mutations in its 23 rRNA component has been described in *S. pneumoniae*.[61,93]

Oxazolidinones (i.e., Linezolid) also inhibit protein synthesis by binding to the 50S ribosomal subunit, as well as inhibition of the formation of the initiation complex and translocation of peptidyl-tRNA for the A to the P site.[60] Resistance to linezolid has recently been described in both *S. aureus* and vancomycin-resistant enterococci (VRE) due to mutation in the 23S rRNA subunit, which results in decreased antibiotic affinity for its target site.[391,492]

Rifampin is an important drug that is used to treat *Mycobacterium tuberculosis* and *H. pylori*, and as an adjuvant agent in combination with other antibiotics for serious invasive *S. aureus* infections. This drug acts on the RNA polymerase encoded by the *rpoB* gene. Point mutations, insertions, and deletions readily develop in the β-subunit

of this enzyme, particularly when patients are treated with rifampin alone.[11,248,249,519]

Trimethoprim resistance in *S. aureus* and *S. pneumoniae* occurs by mutation in the *dhfr* gene resulting in modification of the dihydrofolate reductase and decreased antibiotic affinity for the target enzyme.[270,271,544] Many different types of transferable trimethoprim-resistant genes located on integrons, transposons, and plasmids have also been described in gram-negative bacteria.[33,476,643,650]

Finally, antibiotic resistance to mupirocin and fusidic acid that are used to decrease the bacterial load at skin and mucosal surfaces due to *S. aureus* also occurs by target site modification. High-level resistance to mupirocin (i.e., MIC 512 μg/mL) in *S. aureus* involves acquisition of the *mupA* gene that results in changes in the target enzyme, isoleucyl-tRNA synthetase.[129] More recently, a novel *mupB* gene has been reported that conferred high-level mupirocin resistance in *S. aureus*, but the encoded class I tRNA synthetase had limited homology to either the *mupA* or *ileS* gene products.[547] In contrast, low-level mupirocin resistance results when point mutations occur in the chromosomal isoleucyl-tRNA synthetase gene,*ileS*.[10] Fusidic acid also blocks protein synthesis in staphylococci by inhibiting the function of elongation factor (EF-G). Fusidic acid-resistant isolates of *S. aureus* have

point mutations within the chromosomal *fusA* gene that encodes EF-G.[321,626]

Bypass as a Resistance Mechanism

Bacteria may also become resistant to the action of specific antibiotics by developing an alternate metabolic pathway for normal functions while bypassing the action of the drug. The most clinically important example of a bypass mechanism is the ability of naturally occurring strains of *Enterococcus* species to use compounds such as folinic acid for growth in vivo in the presence of trimethoprim-sulfamethoxazole.[221,685] Strains may appear susceptible in vitro, although they do not respond to chemotherapy in vivo. The in vitro result can be converted from susceptible to resistant by the addition of folinic acid to the testing medium. Enterococci should not, therefore, be tested against trimethoprim-sulfamethoxazole. Enterococci have also been described that have developed an alternate mechanism for cell wall synthesis that produces an alternate way of cross-linking components of peptidoglycan that bypasses the target sites for both β-lactam and glycopeptide antibiotics.[137]

Multiple Antibiotic Resistance Mechanisms in

Bacteria

Bacteria have developed multiple resistance mechanisms, and one or more similar or different types of resistance mechanism are found in multidrug-resistant pathogens. Several gram-negative bacteria are prime examples of MDR organisms including *P. aeruginosa*, *A. baumannii,* and *Salmonella* spp. where pan-resistance is now being found in some strains due to the presence of integron gene cassettes with multiple resistance genes that encode one or more β-lactamases, aminoglycoside modifying enzymes, fluoroquinolone resistance determinants, tetracycline resistance, and resistance to disinfectants.[476,487,643]

Another extremely effective synergistic defense mechanism in gram-negative bacteria is the combination of β-lactamase production in addition to decreased permeability of the OM or increased efflux out of drug out of the cell. *P. aeruginosa* is perhaps the best example of where this combination of resistance mechanisms may be encountered in the same strain.[619] *S. marcescans* is another example of an isolate that normally produces a low level of an AmpC β-lactamase but is usually susceptible to third-generation cephalosporins and carbapenems. When the organism overproduces β-lactamase in the periplasmic space and also has decreased OM permeability, then the isolate becomes highly resistant to the action of these important compounds.[246]

Laboratory Guidance of Antimicrobial Susceptibility Testing

Clinical microbiology laboratories play an essential role in guiding the prescription of antimicrobial agents for effective treatment of not only serious invasive infections in hospitalized patients, but also a wide range of infections in ambulatory patients. The primary goal of antimicrobial susceptibility testing is to provide accurate in vitro testing of a bacterial pathogen to a cadre of available antibiotics to determine its "antibiogram" or susceptibility profile in order to predict the in vivo effectiveness of a particular antibiotic or antibiotic regimen being used to treat a patient. A second function of antibiotic susceptibility tests is to monitor the effectiveness of therapy. Although antibiotic susceptibility results must be performed in such a way that an accurate in vitro result is achieved for each drug tested against the isolate. Testing must also be performed in such a manner that the results are available to clinicians in a timely fashion.[603] Rapid identification of cultured isolates facilitates production of timely antibiotic susceptibility results reporting, and may currently be done the same day using a rapid nucleic acid amplification method,[603] or one of the commercially

available automated biochemical systems[303,347,536,615,667] or matrix-assisted laser desorption/ionization time of flight (MALDI-TOF).[94,413,563] Immediate inoculation of an automated antibiotic susceptibility system can also provide expedited results allowing for the same day reporting of the susceptibility profile of an isolate.

Rapid reporting of antibiotic susceptibility results is important for all patients with infection, but essential for those who are critically ill. Box 17-2 outlines the improved clinical outcomes of prompt appropriate antibiotic therapy in patients with serious invasive infections. In contrast, inappropriate antibiotic prescriptions are associated with a decrease in quality of care and an increase in healthcare costs. For example, studies of patients admitted to ICU with septic shock due to bacteremia have shown that 20% initially received inappropriate empiric antibiotic regimens (i.e., antibiotics that are ineffective against the infecting bacteria due to either inherent or acquired resistance), and resulted in a fivefold decrease in survival (i.e., 52.0% of patients survived when prescribed the appropriate empiric antibiotic regimens versus 10.3% of patient who were prescribed the inappropriate empiric antibiotic regions [$p < 0.0001$]).[327] Delayed detection and reporting of bloodstream infections also has been shown to increase the length of hospitalization and hospital costs.[34] Similar findings have also been documented for

other types of serious invasive infections including bacterial peritonitis and pneumonia whether community-, hospital-, or ventilator-acquired.[147,208,422] Although clinicians must prescribe broad-spectrum therapy initially that covers all types of pathogens of concern, the clinical microbiology laboratory also must be able to expedite reporting of antibiotic susceptibility results to facilitate early treatment with the best therapeutic regimen.

BOX 17-2

Improved Clinical Outcomes From Rapid Reporting of Antimicrobial Susceptibility Results

- Improved patient outcomes
- Lower mortality rates
- Less diagnostic procedures ordered including:
  - Laboratory tests
  - Diagnostic imaging procedures
- Shortened ICU stays

- Decreased ventilator days
- Fewer prescriptions for inadequate antibiotic therapy
- Shortened length of stay
- Lower total cost of hospitalization

Several studies have clearly shown that the rapid reporting of antibiotic susceptibility results may influence the patient outcome from infection, shorten hospital stays, and allow improved tailoring of antibiotic regimens resulting in cost savings and potentially decreased development of antibiotic resistance due to inappropriate or sub-inhibitory drug exposure of the bacterium.[603] Doern and colleagues performed one of the earliest assessments of the clinical impact of "rapid" reporting.[161] For 1 year, bacterial isolates were tested using an expedited commercial method (rapid group) or traditional overnight methods (conventional group). The mean time to reporting results was 11.3 hours and 19.6 hours in the rapid and conventional groups, respectively. The length of hospitalization was comparable in the two groups, but there were significant improvements in the rapid group for the factors listed in Box 17-2.

A subsequent study of isolates from blood cultures demonstrated a statistical correlation of increased time from collection of blood cultures to initial reporting of results with increased length of hospital stay.[34] In this case more rapid detection of bacteremia isolates with instruments that continuously evaluate growth in blood culture bottles was responsible for the effect. More recent studies have confirmed that more rapid detection and more rapid reporting of susceptibility results produce additive, if not synergistic, results. Recent studies by clinical microbiology laboratories in Europe confirm and expand these early findings. Eveillard and colleagues demonstrated that provision of a 24 hours a day bacterial identification and antibiotic susceptibility testing service including nights led to earlier implementation of antibiotic therapy in 22.6% of the patients, and a change to narrower spectrum effective regimens in another 5.3% of patients.[184] Galar and colleagues compared two groups of hospitalized patients with bacterial infections including a control group where microbiology results were available the day following analysis, and an intervention group where results were available the same day of analysis.[202] Although the mortality rates were not significantly different between these two groups of patients, the faster reporting of identification and susceptibility results was associated with a significant reduction in hospital stay and in the overall costs of patient care for those with wound or urinary tract infections or abscesses, but not those with bacteremia.[202]

Antimicrobial test procedures are summarized in Table 17-6, which includes a brief description of each test and information regarding testing. The tests may be divided conveniently into two groups: (1) tests that *predict* the

effectiveness of therapy and (2) tests that *monitor* the effectiveness of therapy.

TABLE 17-6 Guidance of Antimicrobial Therapy

Procedure	Specimen	Definition	Interpretation
Tests That Predict the Effectiveness of Therapy			
Minimum inhibitory concentration (MIC)	Isolate	Lowest concentration of drug that inhibits visible growth	MIC
Disk diffusion	Isolate	Diameter of zone of inhibition around antibiotic impregnated disk	Zone diameter approximates MIC
Gradient diffusion (Etest strip)	Isolate	Read at point of intersection of zone of inhibition with the scale on the strip	MIC
Growth curve calculation (e.g., Vitek 2)	Isolate	Calculated MIC based on the growth of the organism in the presence of the antibiotic	Computer-generated MIC
Tests That Monitor the Effectiveness of Therapy			
Molecular detection	Isolate	Molecular detection of antibiotic resistance gene(s) or gene product(s) (i.e., *mecA* in *S. aureus*, Van genes in enterococci, etc.)	Strain positive or negative
Minimum bactericidal concentration	Isolate	Lowest concentration of antibiotic that kills 99.9% of the inoculum	Predictive of bactericidal activity level
Serum bactericidal titers	Peak serum, trough serum, Isolate	Dilution of serum that kills 99.9% of the inoculum Rarely performed; no indication for test except is some cases of endocarditis	Predictive of response to current antibiotic regimen
Antimicrobial levels	Peak serum, trough serum	Concentration (μg/mL) of antibiotic in serum just before the antibiotic is given (trough level) and 15–20 minutes after the dose is administered (peak level)	Peak level = therapeutic indicator Trough level = toxicity indicator
Antibiotic Synergy Test	Isolate	Predicts the antagonistic, indifferent or additive effects or two or more antibiotics in combination Rarely performed except for respiratory isolates from patients with cystic fibrosis	Additative activity predicts synergistic effect

Several types of antimicrobial susceptibility tests for the prediction of drug effectiveness have been devised. The two reference methods are the macroscopic broth dilution and agar dilution procedures. Both are designed to quantify the lowest concentration of an antimicrobial agent that inhibits visible in vitro growth of the microbe designated the MIC. The test used most widely in both small and large clinical microbiology laboratories to guide antimicrobial agent therapy is the disk diffusion procedure (Kirby–Bauer test), in which clinical interpretations are derived from correlations with the reference test (Chart 17-1). An increasing number of laboratories, however, routinely use a miniaturized broth test (microbroth dilution test) or an automated commercial system. The broth microdilution test has become so prevalent and so well studied that it has become the reference standard for many investigators (Chart 17-2).

A variety of options for antimicrobial susceptibility studies are now commercially available, including commercially available MIC plates (both frozen and dehydrated), computer-assisted growth analysis and gradient diffusion (Chart 17-3). For the

purposes of discussion in this chapter these approaches will be included in the designation "dilution tests" or "MIC tests."

The remaining supplemental tests used to monitor the bactericidal activity of a specific drug regimen are now rarely used, and thus a discussion of these procedures is beyond the scope of this chapter. The monitoring of the peak and trough levels of specific antibiotics (i.e., aminoglycosides and vancomycin) is usually performed in clinical chemistry laboratories. The interested reader is referred to several excellent references that detail methods for performing Minimum Bactericidal Tests (MBT), Antibiotic Synergy Tests (AST), and Serum Bactericidal Tests (SBT).[113,116,469] A brief description of the application of ASTs for multidrug-resistant pulmonary isolates from patients with cystic fibrosis is provided later in the chapter.

The most useful means for assessing the adequacy of antimicrobial therapy in many infections is to monitor the clinical outcomes listed in Box 17-2. Ultimately, the response of the patient to treatment and a "cure" is the aim of antibiotic therapy and, if requested, the laboratory may need to demonstrate by repeated culture that the infecting organism either has been eliminated (bacterial cure) or persists (bacterial failure). Unfortunately, a bacterial cure does not always ensure a successful clinical outcome.

A goal of microbiologists has been, and should continue to be, the provision of standardized in vitro tests that can be reproduced from day to day and from laboratory to laboratory. Without reproducibility, there is no scientific basis for reporting accurate antibiotic susceptibility results on which to base therapy. Unfortunately for patients, a high number of serious errors in laboratory performance of antibiotic susceptibility testing have been documented by surveillance studies either because of in-house errors in test performance or policy and procedure, or frequently to methodologic failure to accurately detect a particular resistance phenotype.[132,156,382,575,587,613] Although standardization of the variables outlined herein is required for the accurate reproducible susceptibility testing, the in vitro result is at best a prediction of a treatment response in a given patient.

The factors that determine the outcome of an infectious process are complex and, in many instances, are incompletely addressed by in vitro tests.[278,652] Pharmacokinetic (PK) and pharmacodynamics (PD) (PK/PD) thresholds for a particular antibiotic also influence the clinical outcome of infection treatment,[175,194] and increasingly clinically relevant antibiotic susceptibility breakpoints are based on the appropriate dosing of an antimicrobial agent calculated on available PK/PD data for a given antibiotic agent.[121,122,278,333] Based on PK/PD data, Clinical and Laboratory Standards Institute (CLSI) has introduced a "susceptible-dose dependent" or SDD interpretation for antibacterial susceptibility testing, although it has been applied for interpretation of antifungal susceptibility test results for several years.[122] The SDD category implies that susceptibility of an isolate is dependent on the dosing regimen that is used in the

patient. The SDD had previously been included in an intermediate result, but this concept was often not evident or understood by clinicians. If the laboratory reports the isolate as having an MIC or zone diameter that equates to an SDD result, it is necessary to use a dosing regimen that results in a higher drug exposure than the dose that was used to establish the susceptible breakpoint (i.e., clinicians should use the maximum approved dosage regimen in order to achieve adequate therapeutic effect against an SDD isolate. For example, CLSI has recently recommended SDD category reporting instead of "intermediate" when reporting cefepime results for *Enterobacteriaceae* isolates because there are multiple approved dosing options for cefepime. A report of SDD for an *Enterobacteriaceae* isolate indicates to the clinician that higher cefepime doses (i.e., greater than 1 g every 12 hours) should be used to treat infections caused by isolates when the cefipime MIC is 4 or 8 μg/mL or the zone is 19 to 24 mm.[122]

The inflammatory and immune defenses of the patient are also essential to a successful clinical outcome. It is clear that suboptimal concentrations of antimicrobial agents, below the concentration necessary to kill the bacterium, may enhance the ability of phagocytes to ingest and kill an infecting microorganism.[251,583] The penetration of antimicrobial agents into sites of infection is another important variable that cannot be addressed in vitro. High concentrations of antimicrobial agents may be achieved in sites where they are excreted from the body, usually the urine or the bile. In contrast, low concentrations relative to serum may be found in tissues such as prostatic fluid, bone or cerebrospinal fluid. In the case of chloramphenicol or clindamycin, excretion is primarily via the biliary tract, and a minimum amount of the drug is found in the urine. The reverse holds for other drugs such as nitrofurantoin and norfloxacin, which do not achieve effective levels in sites other than the urinary tract.

The ineffectiveness of many antimicrobial agents, such as the aminoglycosides, in the treatment of *Legionella* infections, despite their excellent activity in vitro, is probably caused by the poor penetration of the antibiotics into macrophages where the bacteria are growing.[4,234] In other situations, bacterial physiology is a significant determinant (e.g., metabolic bypass of trimethoprim and sulfonamide effects by enterococci). Many infections, particularly those caused by obligate anaerobic bacteria, are synergistic; that is, the bacteria depend on each other for survival.[377,528] Such an infection may be cured by drugs that are ineffective against

1099

some of the infecting bacteria if the essential participants are eliminated.[72,529] Considering all the factors that influence the outcome of an infection, it is imperative that the laboratory provide physicians with the "track record" of the antimicrobial agent to guide them in the selection of appropriate antimicrobial agent therapy. Well-

designed clinical studies have demonstrated a correlation of outcome with the appropriateness of therapy.[147,327] Physicians must, therefore, correlate the results of antimicrobial agent susceptibility tests and clinical experience when selecting therapeutic regimens for patients with similar infections.

The following section discusses the methods used to perform routine antibiotic susceptibility testing of commonly isolated bacterial pathogens. Insight into the limitations of current procedures, as well as bacteria for which no standardized testing or interpretation guidelines are highlighted, which serve to clarify the reasons that an absolute correlation should not be made in these cases between laboratory results and clinical outcome.

Antibiotic Susceptibility Testing Methods

Methods to test the inhibitory activity of antimicrobial agents have mainly been standardized for aerobic bacteria that grow well after overnight incubation in air and have unpredictable susceptibilities.[114,117,121,122] Decreased susceptibility trends and special procedures for reliable detection of particular types of resistance in commonly isolated aerobic bacteria are also outlined within this section. Fastidious bacteria, which grow more slowly or require nutritional or atmospheric supplements, require specialized test procedures, and should be tested with the careful use of control bacterial strains in order to demonstrate the absence of inhibitory effects of the method on the isolate.[114] The disk diffusion test may be modified for such organisms if the procedure has been validated by comparison to reference tests and to clinical experience.[114]

Microbiologists should resist requests from clinicians to extend the standardized procedures beyond their established limits. Laboratories may be requested to perform unwarranted susceptibility tests that will not provide a valid result (e.g., trimethoprim-sulfamethoxazole testing on enterococci), or susceptibility testing on isolates for which there are no established interpretation guidelines. Table 17-7 summarizes a variety of situations where antibiotic susceptibility tests should be performed but the results may or may not be reported. Some of these issues are considered more thoroughly in appropriate sections of this chapter.

Only isolates producing an infection should be tested. Bacteria recovered from a normally sterile body fluid are usually pathogenic. If the potentially pathogenic bacterium is isolated from a site that contains colonizing flora, such as the upper respiratory tract or the skin, the culture should be scrutinized more closely before a susceptibility test is performed, particularly if multiple species of organisms are present. Examination of a Gram-stained smear may document the inclusion of squamous epithelial cells, which suggests contamination by colonized secretions, or the

absence of segmented neutrophils, which indicates the lack of an inflammatory response. In situations in which the microbiologist cannot determine the suitability of a susceptibility test, consultation with the clinician is appropriate.

The list of bacteria that have consistently predictable susceptibilities is, unfortunately, becoming shorter, which necessitates changing CLSI recommendations about the use of specific antibiotic agents as surrogates to predict susceptibility within a class of drugs. The prevalence of β-lactamase-producing strains of *Haemophilus influenzae* and *Neisseria gonorrhoeae* is sufficiently high that susceptibility to penicillin analogs cannot be predicted.[256,601] β-lactam, aminoglycoside and fluoroquinolone drug resistance has also become widespread in other types of gram-negatives including *Enterobacteriaceae*, *Acinetobacter* and *Pseudomonas*.[380,400,487,619] CLSI recently changed its recommendation for surrogate testing of urine isolates in patients with uncomplicated urinary tract infections because of changing cephalosporin resistance profiles in *Enterobacteriaceae*.[122] CLSI now recommends using cefazolin instead of cephalothin as the surrogate first-generation drug to more reliably predict the susceptibility of *Enterobacteriaceae* urine isolates to oral agents (i.e., cefadroxil, cephalexin, cefpodoxime, and loracarbef). Other cephalosporins including cefpodoxime, cefdinir, and cefuroxime axetil may also be tested individually as required because some isolates may be susceptible to these agents while testing resistant to cefazolin. Pneumococci that are relatively resistant to penicillin (i.e., MIC, 0.12 to 1.0 μg/mL) or have high-level resistance (i.e., MIC > 1.0 μg/mL) are increasingly common in the United States.[160,290] Pneumococcal strains isolated from serious infections should be tested for resistance because *Streptococcus pneumoniae* with multidrug resistance to β-lactams, macrolides, and fluoroquinolones is also increasingly isolated.[193,490] Although clinical *Streptococcus pyogenes* and *Streptococcus agalactiae* isolates remain susceptible to penicillin, resistance to macrolide antibiotics has become common in these two important genera.[269,314,444] Vancomycin has become the mainstay of treatment against serious invasive gram-positive infections due to the nosocomial transmission, and the emergence of community-acquired MRSA strains,[148,623] while the increased use of vancomycin that has subsequently resulted in VRE also becoming a major nosocomial problem.[17] Vancomycin resistance in staphylococci has also emerged.[253] Increasing ampicillin resistance and high-level aminoglycoside resistance with a loss of synergy between a cell wall agent and the aminoglycoside have been reported from many jurisdictions.[16] These trends in antimicrobial resistance in many common bacterial pathogens has meant that clinical laboratories must perform much more routine susceptibility testing in order for clinicians to be able to accurately prescribe therapy even for common types of ambulatory infections.

There remain a few clinical situations where susceptibility or resistance is still

predictable and routine testing is not indicated. Although clinical and/or bacteriologic infection relapses may occur for reasons other than antibiotic resistance including inadequate antibiotic penetration into the site of infection and reinoculation, antibiotic resistance should be ruled out by testing the isolate when the clinical response is not as expected (i.e., potentially treatment failure) or when the patient has one or more listed antibiotic allergies. Although *Streptococcus pyogenes* remains susceptible to penicillin, treatment failure has been documented due to treatment of acute bacterial pharyngitis with a macrolide when the strain was resistant.[41] Treatment failure has also been recently reported for routine intrapartum antibiotic prophylaxis due to macrolide-resistant group B *Streptococcus,* which resulted in neonatal infection.[110] Microbiologists must be cognizant of trends in antibiotic resistance in pathogens not only in their respective geographic location, but globally so that antibiotic testing of previously susceptible bacterial species can be routinely implemented when appropriate.

1100

TABLE 17-7 Situations in Which Antimicrobial Susceptibility Testing (AST) Should Not Be Performed and/or the Results Not Reported

Category	Antibiotic(s)	Organism(s)	Site	Action	Rationale
Susceptibility predictable	Penicillin/oxacillin	*S. aureus* *S. pneumoniae* β-Hemolytic streptococci (*S. pyogenes*, *S. agalactiae,* etc.)	All	Do not test other β-lactams	Results of these primary agents predict susceptibility to other β-lactams.
Organisms identification and AST confirmation required	Varies by organism	See M100-S24 appendix A	All	Confirm ID and AST for the listed resistance phenotype according to organism	Uncommon resistance phenotype in most institutions (e.g., *S. aureus* that are Vancomycin I or R, *Enterobacteriaceae* that are carbapenem I or R etc.)
Intrinsic resistance[a]	Varies by organism	See M100-S24 appendix B	All	Do not test listed drugs according to species	Some drugs may be reported as R depending on organism.
In vitro resistance not predictable	Cephalosporins	*Enterococcus* spp.; *Listeria monocytogenes*	All	Do not test	Results may be misleading.
	Aminoglycosides (low dose)	*Enterococcus* spp.	All	Do not test	High-dose testing for synergy; results may be misleading.
	Clindamycin; trimethoprim; trimethoprim-sulfamethoxazole	*Enterococcus* spp.	All	Do not test	Results may be misleading.
	All β-lactam antibiotics	*Staphylococcus* spp. resistant to oxacillin	All	Do not test or report as R	AST results do not predict clinical efficacy and will be misleading.
	Salmonella spp.; *Shigella* spp.	All	All		
Antimicrobial agent does not accumulate at site of infection	First- and second-generation cephalosporins; clindamycin; macrolides; tetracyclines; fluoroquinolones; antibiotics administered orally	All; including *S. pneumoniae*	CSF	Do not test	Antimicrobial agents do not penetrate into CSF or do not accumulate in therapeutic concentrations across the blood–brain barrier.
	Chloramphenicol; tigecycline	All	Urinary tract	Do not test	Antibiotic not excreted in urine
	Daptomycin	All	Lower respiratory tract	Do not test	Antibiotic inhibited by surfactant in lungs
	Norfloxacin; nitrofurantoin	All	Non-urine sites	Do not test	Antibiotic does not reach therapeutic levels in sites other than the urinary tract.
Infants and children	Fluoroquinolones tetracyclines	All	All	Test but do not report unless requested	These agents may be contraindicated in infants and young children.[b]
Pregnant of lactating women	All antimicrobial agents that are contraindicated	All	All	Test and report antimicrobial agents that are safe to administer[b]	

[a] See M100-S4 appendix B. Intrinsic resistance is defined as inherent or innate (not acquired) antimicrobial resistance, which is reflected in wild-type antimicrobial patterns of all or almost all representatives of a species. Intrinsic resistance is so common that susceptibility testing is unnecessary. For example, *Citrobacter* species and many other *Enterobacteriaceae* are intrinsically resistant to ampicillin.[122]
[b] See M100-S24 Table 1A, 1B, 1C drugs recommended for testing and reporting.

1101

Standardization of Antibiotic Susceptibility Testing Methods

The most important improvement in laboratory guidance of susceptibility testing over the past several decades has come from the development of standardized published procedures by the CLSI (www.clsi.org) in the United States, the European Committee Consensus on Antimicrobial Susceptibility Testing (EUCAST), and other groups that have been widely adopted. The methods outlined in this chapter are compliant with CLSI recommendations,[114,117,121,122] but readers can go to the websites for EUCAST (www.eucast.org), the British Society for Antimicrobial Chemotherapy (BSAC) (www.bsac.org.uk), Deutsches Institut für Normung (German Institut for Standardization) (www.DIN.de), and the Committé Antiobiogramme—Société Française de Microbiologie (CA-SFM) (www.ca-sfm.org)—to compare methods published by these other groups. It is important that revised procedures and current recommendations be promptly promulgated and implemented into practice in all clinical laboratories. An institutional membership in the CLSI ensures the timely receipt of all new and revised recommendations. The following parameters are some of the important facets of susceptibility testing that have been standardized.

Growth Medium. Müeller–Hinton broth (MHB) and agar (MHA) have been selected for testing aerobic and facultative anaerobic isolates. These formulations have been standardized in order to produce highly reproducible susceptibility results, and typically contain dehydrated beef infusion, acid digest of casein, and cornstarch.[122,480] Cooled molten agar should routinely be poured into plates as soon as possible after mixing, and generally 20 to 25 mL of molten agar in a 90-mm plate is used to achieve an agar depth of no more than 3 to 4 mm.

Müeller–Hinton medium, however, also contains agar, a natural compound that is prepared from red seaweed of the *Rhodophyceae* class.[331] Agar is mainly composed of polysaccharides, agarose and agaropectin. Variation initially occurred in the composition of agar among manufacturers and even among lots produced by a single company, depending on the source of the seaweed. Diffusion of chemicals can also be affected by the presence of sulfate ions that change the charge of the polysaccharides. Variable cation concentration also had a significant effect on the activity of aminoglycosides against *P. aeruginosa*.[141,508] Most of the problems in the variation among lots of MHA were overcome by the development of a reference standard for manufacturers to provide greater reproducibility.[480]

Limitations. Most pathogens grow satisfactorily on MHA, and the medium has minimal inhibitory effects on sulfonamides, trimethoprim and tetracycline. Large quantities of thymidine are present in some lots of media. Some organisms can use the thymidine to bypass the mechanism of action of trimethoprim and grow, even though they are innately resistant to the antibiotic. Enterococci are particularly affected; isolated colonies may appear within the established zone of inhibition around disks that contain trimethoprim.

Agar depth may also effect antibiotic susceptibility results, particularly too thick an agar depth.[298]

Specialized Medium and Additives. Some bacteria require the use of specialized media or the use of additives to ensure adequate growth. Most commonly blood, usually sheep of horse blood, is added to MHA in a 5% concentration in order to get adequate growth of *Streptococcus* spp., including *S. pneumoniae*, β-hemolytic streptococci, *Neisseria meningitidis*, *Campylobacter* spp., and *Helicobacter pylori*.[114,121,122,302] However, when testing sulfonamide activity, the use of horse blood–supplemented MHA is preferred because of its low levels of antagonists. *Haemophilus* organisms require hemin (factor X) and/or nicotinamide adenine dinucleotide (NAD) (factor V) for growth.[301] A specially formulated medium, *Haemophilus* Test Medium **(HTM)** which contains hematin, **NAD** and yeast extract supplements has been developed and recommended by the CLSI for routine testing of *Haemophilus influenzae*.[121,122] The advantages of HTM include visual clarity and reliability of testing with trimethoprim-sulfamethoxazole.[301] Some investigators, however, have experienced problems with the performance of both homemade and commercially prepared *Haemophilus* test medium.[392] Chocolate agar or HTM can also be used for *Haemophilus* spp. and other fastidious bacteria in the "HACEK" group (i.e., *Aggregatibacter, Cardiobacterium, Eikenella*, or *Kingella*) as well as *Pasteurella* and *Moraxella* if adequate growth is not achieved using CAMHA supplemented with 5% sheep blood.[114,121,122]

The bacteria previously known of as "nutritionally deficient streptococci," *Abiotrophia* and *Granulicatella,* require pyridoxal for growth. MHA with 5% horse blood plus 0.001% pyridoxal added allows for growth of these genera so that results can be interpreted.[114,298] *Neisseria gonorrhoeae* should be tested using GC agar to which a 1% cysteine-free defined growth supplement is added after autoclaving.[121,122]

Plain MHA does not contain sodium chloride (NaCl). Detection of resistance of certain strains of staphylococci to semisynthetic penicillins (i.e., oxacillin, nafcillin, methicillin) is improved by including 2% NaCl in the media for dilution susceptibility tests.[121,122]

pH. Microbial susceptibility tests are performed using media for which the pH has been standardized at physiologic levels. Media pH should be between 7.2 and 7.4 at room temperature. The pH of broth media may be tested directly with a pH electrode, and agar media may be tested by macerating enough of the agar so that the tip of the electrode can be submerged, by allowing a portion of agar to solidify around the electrode, or by using a properly calibrated surface electrode.

Limitations. Major variation in pH of the test medium can change the activity of aminoglycoside, macrolide and tetracycline compounds. Tetracyclines are more active in acidic environments but some antimicrobial agents (e.g., aminoglycosides and macrolides, such as erythromycin) are less effective in acidic environments than at neutral pH. In contrast, β-lactams such as the penicillin and the cephalosporins function well at a wide range of pH. Nonphysiologic levels of pH often develop at the sites of purulent infections such as bacterial meningitis[578] or abscesses,[243] and the pH of urine may also range from alkaline to acidic. Ideally then, in vitro susceptibility test conditions should perhaps reflect the in vivo conditions encountered by antibiotics in specific clinical situations (i.e., acidic inflammatory exudates, urine etc.) rather than those in laboratory culture media.

Serum. Antibiotics differ greatly in the degree to which they bind to proteins. In the bloodstream, free antibiotic is in equilibrium with serum protein-bound antibiotic. Free and protein-bound antibiotic can be measured, but it is not clear which is the more useful result. The **CLSI** method does not include added serum because of the difficulty in standardization of the product and uncertainty about how to interpret the results.

Limitations. In the laboratory, different values can be obtained for highly protein-bound antibiotics if serum is added to the medium. Perl and colleagues studied the effect of serum on 11 broad-spectrum antibiotics used to treat nosocomial gram-negative bacillary infections.[458] The results were identical with 9 of the 11 antibiotics. Only in the case of ceftriaxone (>95% protein-bound) and cefoperazone (90% protein-bound) were there substantial differences when serum was incorporated into the reference procedure.

Cation Concentration. Agar and broth media vary greatly in the concentration of divalent cations. By convention, antibiotic susceptibility testing is done under physiologic conditions. **MHA** has very low concentrations of divalent cations, but is adjusted to physiologic concentrations (20 to 35 mg/L $Mg^{2}+$ and 50 to 100 mg/L $Ca^{2}+$) during production. Some batches of **MHA** may actually have an abnormally high cation concentration, so that small inhibitory zones are produced when *P. aeruginosa* is tested against aminoglycosides. Such lots, which can be identified by testing with reference strains of known reactivity, should be discarded.

Limitations. The concentration of the divalent cations $Ca^{2}+$ and $Mg^{2}+$ affects the susceptibility results when certain combinations of bacterial species and antibiotics are tested.[508] With certain combinations of bacterium and antimicrobial agent, most notably *Pseudomonas aeruginosa* and aminoglycosides, the concentration of divalent

cations, particularly calcium (Ca^2+) and magnesium (Mg^2+), has a dramatic effect on the apparent in vitro susceptibility. A result that ranges from susceptible to resistant can be achieved by varying the cation concentration,[141,508] because of changes in transport of the antimicrobial agent across the cell membrane. The mechanism by which cation concentration affects the activity of *Pseudomonas aeruginosa*, for example, may involve the permeability of the bacterial cell wall.[78] The LPS in the cell wall of *P. aeruginosa* are cross-linked with divalent cations, providing stability. When the organisms are grown in media deficient in cations, cell wall permeability to the aminoglycoside antibiotics and other compounds is increased. The organisms, therefore, are more sensitive to the action of the aminoglycosides, producing falsely low MIC results or large inhibitory zone sizes.

Daptomycin activity also varies greatly with alterations in the calcium concentration in test media, and physiologic levels of this cation are required for accurate interpretation of test results on solid media.[30,199,292]

High levels of zinc ions can also reduce the activity of carbapenems, and again, the effect is greatest for gram-negative bacteria, particularly *P. aeruginosa*.[21,145]

Environmental Conditions. The conditions and duration of test incubation must be performed correctly in order to get accurate results. Antibiotic susceptibility tests are routinely incubated in ambient air at 35°C. Agar or broth is incubated in an ambient air incubator. A CO_2 incubator should not be used for routine tests. The carbonic acid formed on the surface of the agar or in the broth can cause a decrease in pH, which can affect the antibacterial activity of certain antibiotics, as previously discussed. In smaller laboratories where only a CO_2 incubator is available, it is acceptable to place the susceptibility plates or tubes in a sealed jar to prevent access of the CO_2 from the incubation.

Plates and tubes should be incubated routinely at 35°C. At higher temperatures, the detection of oxacillin-resistant staphylococci is compromised. If oxacillin resistance is suspected and not manifested at 35°C, the plates or tubes may be incubated at 30°C.

Incubation times vary depending on the test system used. The recommended incubation time for conventional disk diffusion systems is 16 to 18 hours, while that for dilution tests is longer at 16 to 20 hours. However, tests to determine the MICs of staphylococci for oxacillin and vancomycin, and the MIC of enterococci for vancomycin should be incubated a full 24 hours.

Inoculum. The inoculum is usually prepared from a broth culture that has been incubated for 4 to 6 hours, when growth is considered to be in the logarithmic phase. Several similar-appearing colonies should be sampled to minimize variation in the bacterial population. The density of the suspension is adjusted to approximately 10^8

colony-forming units (CFUs) per milliliter by comparing its turbidity to a McFarland 0.5 $BaSO_4$ standard. The standard is prepared by adding 0.5 mL of 0.048 M $BaCl_2$ (1.175% w/v $BaCl_2.H_2O$) to 99.5 mL of 0.36 N H_2SO_4. Aliquots of 4 to 6 mL of the barium sulfate turbidity standard are distributed to screw-capped tubes of the same size, sealed tightly and stored in the dark at room temperature. Alternatively, a 0.5 MacFarland standard prepared using latex particles can be purchased to calibrate turbidity from several commercial suppliers (i.e., ThermoScientific (Remel), KS, Lenexa). Nephelometers may be used to determine turbidity. Commonly, the degree of cloudiness in the broth is compared with the standard, visualizing the two against a white background on which black lines have been drawn. Further adjustments to the inoculum depend on the type of test used. Alternatively, commercially available devices for preparing a standardized inoculum have worked well.[24,29]

1103

If the organism is fastidious or time does not permit incubation for 4 to 6 hours, the direct colony suspension method can be used to calibrate the inoculum. Briefly, young colonies may be removed from the surface of an agar plate that has been incubated overnight and diluted to the proper density. This method is recommended when staphylococci are tested for resistance to methicillin and when testing isolates of *Streptococcus pneumoniae* and *Haemophilus influenzae*.

If a McFarland standard is used to prepare the inoculum, the density of the standard should be checked, using a spectrophotometer with a 1-cm light path and matched cuvettes. The 0.5 McFarland standard absorbance at 625 nm should be 0.08 to 0.10. The standard should be replaced or checked for adequacy monthly.[117] It is useful, but not essential, to document the number of organisms in the inoculum periodically by inoculating serial dilutions of the suspension onto agar plates.

Limitations. The number of bacteria in infected patients varies greatly, so the standardized inoculum used in the laboratory represent a reasonable compromise rather than a reproduction of in vivo conditions. For some combinations of bacterium and antimicrobial agent, the inoculum is of great importance in determining the in vitro susceptibility; called the inoculum effect.[181,397,496,594] Enzymatic inactivation of β-lactam antibiotics, such as the penicillins and the cephalosporins, is an important mechanism of bacterial resistance. These enzymes are always expressed in some bacteria, but under the right conditions enzyme production may be induced by the presence of the antibiotic. If small numbers of *Staphylococcus aureus* that contain an inducible β-lactamase are incubated in vitro with penicillin, the inoculum may be killed before the enzyme is produced in a sufficient amount to be detected.[418,629] Whereas in vivo the large numbers of bacteria present at the site of infection are producing the β-lactamase that inactivates the antibiotic. Inducible β-lactamases may also not be

detected in *Enterobacteriaceae*, if a small inoculum is used due to interactions between the gram-negative membrane and the enzyme.[351,496] Heteroresistance also occurs in staphylococci, whereby only a small fraction of bacterial cells in a colony express β-lactamase, particularly in the presence of a semisynthetic penicillin such as methicillin. Vancomycin-intermediate-resistant MRSA is also heteroresistant, and the ability to detect this type of resistance is greatly affected by inoculum.[526] The use of a small inoculum may therefore "miss" this type of resistance, because cells carrying the resistance phenotype may not be selected.

Antimicrobial Agents. Reference antimicrobial agent powders for use in dilution tests need to be "pure" and should be obtained from the manufacturer (Sigma Chemical Co.), or from the US Pharmacopeia in Rockville, MD. These reference powders are documented with an assay of antimicrobial activity. For example, the label may indicate that the powder contains 1,075 mg of active chemical in each 1,000 mg of powder. The amount of powder weighed must be adjusted for the activity of each lot. Vials should not be obtained from the hospital pharmacy because they may contain fillers and are not assayed for biologic activity. The antimicrobial agents should be stored in a desiccator as indicated for each agent. Many antimicrobial agents, especially those of the β-lactam class, are more stable at temperatures below −20°C. Suspensions of antimicrobial agent should be stored at −20°C or less, preferably at −70°C; they should not be refrozen after dispensing. Imipenem, which is particularly affected by freezing and thawing,[661] should be reconstituted each time a batch of plates or tubes is prepared. A frost-free freezer should not be used because repeated cycles of freezing and thawing occur.

Antimicrobial-impregnated disks should be stored at −20°C or lower in an anhydrous condition. Under guidelines established by the US Food and Drug Administration (FDA), manufacturers of antimicrobial agent disks must carefully control the concentration of antimicrobial agents in the disks to within 60% to 120% of the stated content; the actual variation is usually considerably less. A small working supply may be maintained at refrigerator temperatures in a desiccator. Disks should always be allowed to warm to room temperature before opening the desiccator, so that condensation of moisture from the air does not partially rehydrate the disks. The reporting of erroneous, spurious resistance of *Staphylococcus aureus* to oxacillin has resulted from use of a defective lot of disks.[56]

Selection of Antimicrobial Agents. The final selection of antimicrobial agents for the hospital formulary should be decided in consultation with members of the medical staff. However, laboratories should use the **CLSI** guidelines for deciding which antibiotics should be primarily tested and reported, or only selectively reported according to the definitions outlined in Table 17-8 for Group A, B, C, or U agents.

Specific assignment of different drug classes according to these testing and reporting groups are outlined in the specific organism tables published by **CLSI**,[121,122] and summarized in standards M100-S23 and M100-S24 for nonfastidious bacteria in Table 1A, fastidious bacteria in Table 1B, and anaerobic bacteria in Table 1C.[121,122] The **CLSI** recommendations for cascade **(selective)** testing and reporting are briefly outlined later in the chapter recognizing that the issues are complex and vary from institution to institution. It is not necessary to test each antimicrobial agent in the list, provided the organism is susceptible to all or most of the Group A and B agents. However, the patterns of antimicrobial agent usage and incidence of important types of bacterial resistance in each community should be known and considered when selecting antimicrobial agents for testing. Distinctions may be made between antimicrobial agents that are tested routinely and those for which results are reported routinely to physicians. Because automated systems allow susceptibility testing of many more drugs for most pathogens than those listed by **CLSI** as Group A and B agents, laboratory policy and procedures for routine cascade reporting within a particular drug class should be in place.[121,122]

Several antimicrobial agents may be therapeutically equivalent in some cases because they provide a similar spectrum of antimicrobial activity. The results of in vitro testing of a specific isolate for one agent, however, may not predict the in vitro result for other antimicrobial agents in the group; in effect, these antimicrobial agents are equivalent but not necessarily equally effective against every isolate. Each agent in the group that is considered for therapeutic use must be tested. Laboratories also need to test more antibiotics within a class of drugs in order to establish the resistance phenotype of an organism (e.g., *E. coli* that is ertapenem resistant but susceptible to all other carbapenems). In contrast the results of in vitro testing of some antimicrobial agents may be applied to close relatives so that it is not necessary to test each agent in the group; some of these situations are detailed in Tables 17-7 and 17-21.[114,117,121,122]

1104

TABLE 17-8 CLSI Grouping of Recommended Antimicrobial Agents for Testing and Reporting

Group	Category	Type of Antimicrobial Agent
A	Primary test and report	All agents should be tested and reported
		All agents should be tested but only selectively reported: 1. Primary agent in the same class is resistant 2. Patient has reported allergy to one or more primary

B	Primary test, selectively report	agents 3. Always reported on specific sites/sources infection (i.e., a third-generation cephalosporin for CSF isolates) 4. Failure of primary therapy 5. Polymicrobial or disseminated infection involving multiple body sites 6. Epidemiologic aid to infection control
C	Supplemental testing, selectively report	Test and report for specific resistance problems, or in patients with reported allergy to Group A and/or B agents, or in unusual infections
U	Supplemental	Testing of urine isolates only
O	Other	Antimicrobial agents that are indicated for the organism group but are not candidates for routine testing and reporting in the United States
Inv.	Investigational	Antimicrobial agents that are investigational for the organisms group that have not yet been approved by the FDA for use in the United States

Adapted from reference 122.

Reference Strains. The clinical microbiology laboratory must acquire and stock appropriate positive and negative quality control organisms in order to monitor the performance of antibiotic susceptibility tests. Reference strains for quality control (QC) have been selected and standardized for quality control of susceptibility tests that give reproducible reactions of expected test performance (Table 17-9). The ideal control strains have susceptibility end points in the midrange of antimicrobial concentrations tested and have minimal tendencies to change susceptibility patterns over time. These reference strains must be stored in a condition that minimizes the possibility of mutation. They may be stored frozen (below −20°C or preferably below −60°C) after suspension in a stabilizer, such as defibrinated whole blood, 50% fetal-calf serum in bacteriologic broth or 10% glycerol in broth. Alternatively, the strains may be lyophilized. For short-term storage, the bacteria may be grown on soybean–casein digest agar and stored at 2°C to 8°C. Fresh slants should be prepared every 2 weeks, and a new stock culture should be obtained when aberrant results are noted. A fresh subculture should be prepared each day the control strain is used. Procedures for reconstituting stock cultures have been published.[117]

QC organisms can be obtained from the American Type Culture Collection (ATCC; 12301 Parklawn Drive, Rockville, MD 20852) in the form of freeze-dried vials, and specific QC testing should be done with the recommended ATCC control strain(s). ThermoScientific (Remel), Lenexa, Kansas (Bacti-Disks) and Difco Laboratories, Detroit, Michigan (Bactrol Disks) supply cultures dried on paper disks, which are stable at 4°C for up to a year. Paper disk cultures can be easily removed from a vial and grown in broth for 4 to 6 hours before plating onto solid media for QC tests.

Quality Control. Rigorous QC is important for antimicrobial susceptibility testing because of the large numbers of variables that may affect the results. Several methods are commonly used for testing the susceptibility of bacterial isolates against a wide range of antimicrobial agents including disk diffusion, agar dilution, and macrobroth and microbroth dilution methods. Extensive QC guidelines have been published by the CLSI that describe disk diffusion[118,121,122] and broth agar dilution MIC procedures.[117,121,122] Laboratories should follow these guidelines so that reliable antimicrobial susceptibility results are obtained, and procedures should be updated as CLSI standards are revised. Rules for the frequency of a 20- to 30-day QC plan for antimicrobial susceptibility testing have been established by the CLSI (Table 17-10).[120] As of 2013, however,[121] CLSI changed the recommended schedule for performing routine daily QC from 20 to 30 consecutive days of testing to a new 3 × 5 day QC plan before implementing to a weekly QC testing schedule provided the results of daily tests are within the recommended limits for a particular drug/organism (i.e., drug/bug) combination and test method (Table 17-11). In the initial phase of a 3 × 5 day QC plan, 3 replicates are tested for 5 days (15 results), and testing is passed if 0 to 1/15 results are out of range and a weekly QC schedule can then be used. However, if 2 to 3/15 results are out of range during the initial phase of testing, then a second phase of daily QC testing should be done using another three replicates tested for 5 days (15 results). Daily QC is passed if 2 to 3/30 results in the second test phase are out of range. The advantages of implementing a 3 × 5 day QC plan compared to the previously recommended 20- to 30-day consecutive test plan daily QC testing is more efficient and completed in a shorter period of time, and QC problems may be more rapidly identified. Weekly QC of antibiotic susceptibility testing for each drug/organism combination should be done whenever a new test system is implemented, whenever a new drug is tested, and whenever certain test variables are modified as outlined in Tables 3C and 4F in CLSI M100-S23.[121] To date, this change to QC test frequency has not been published in CLIA regulations and therefore has not been adopted by laboratory accrediting agencies (i.e., CMS, CAP) in the United States. As of 2013,[121] CLSI also changed the frequency of testing a known negative (susceptible) and positive (resistant) strain for disks, agar plates used for agar dilution or single wells or tubes used in broth dilution methods from routine for both control

strains to only having to test a positive strain with each new batch/lot/shipment of test materials. Table 17-12 outlines the frequency of QC when modifications are made to antimicrobial test systems for both a 20- to 30-day and a 3 × 5 day QC plan. CLSI has also outlined recommendation for troubleshooting problems with QC testing (Box 17-3), and appropriate corrective actions to take when QC parameters are not met (Table 17-13).

1105

TABLE 17-9 Quality Control Strains for Antibiotic Susceptibility Testing (AST)

Type of Test	Purpose	Strain[a]
Disk diffusion	• General testing; susceptible strain for VAN screen agar • Monitoring batches of Müeller–Hinton agar for inhibitory compounds to sulfa drugs, TMP, or SXT	• *Staphylococcus aureus* (ATCC 25923) • *Enterococcus faecalis* (ATCC 29212 or ATCC 33186)
Microbroth dilution	• General testing • Used in conjunction with *S. aureus* (ATCC 29213) to control OXA salt agar screening tests • Reference laboratory testing of isolates	• *Staphylococcus aureus* (ATCC 29213) • *Staphylococcus aureus* (ATCC 43300) • *Helicobacter pylori* (ATCC 43504)
Disk diffusion or microbroth dilution	• General testing; VAN susceptibility and high-dose aminoglycoside (HDA) synergy • General testing and quality control including β-lactams • Control of β-lactamase inhibitors; used in conjunction with *E. coli* (ATCC 25922) for β-lactam/β-lactamase inhibitor combinations • Control of extended-spectrum β-lactamase tests • General testing • General testing	• *E. faecalis* (ATCC 29212) (VAN S and HDA S) + *E. faecalis* (ATCC51299) (VAN R and HDA R) • *Escherichia coli* (ATCC 25922) • *Escherichia coli* (ATCC 35218) • *Klebsiella pneumoniae* (ATCC 700603) • *Pseudomonas aeruginosa* (ATCC 27853) • *Haemophilus influenzae* (ATCC 49247) (AMP R and β-lactamase negative) + *H. influenzae* (ATCC 49766) (AMP S and more reproducible for some β-lactams

	• General testing	that ATCC 49247) • *Streptococcus pneumoniae* (ATCC 49619)
Agar dilution and disk diffusion	• General testing	• *Neisseria gonorrhoeae* (ATCC 49226)

TABLE 17-10 Performance and Frequency of 20 to 30 Daily Quality Control Plan for Antimicrobial Susceptibility Testing

Type of Test	Approach	Frequency	Initial Validation Testing	Criteria for Corrective Action	Comments
Disk diffusion or dilution	Daily QC	Daily	None	>1 result in 20 consecutive tests out of control	Conversion to weekly testing if <2 of 20 or <4 of 30 consecutive tests for each drug is out of control
Disk diffusion or dilution	Weekly	Weekly or with each change in reagent components or method	Test all control strains for 20–30 consecutive test days; conversion to weekly testing when results meet the criteria outlined for daily QC	Any result out of control	New antimicrobial agents must be validated. Weekly testing is appropriate only for routinely tested drugs. Infrequently tested agents must be tested on the day of use.
Agar screen tests	Daily	Daily	None	>1 result in 10 consecutive tests out of control	Daily testing must be done if the screening is performed less frequently than weekly or the agent being tested is labile (e.g., OXA screen test for *S. aureus*).
Agar screen tests	Weekly	Weekly or with each change in reagent components or method	Test all control strains for 20–30 consecutive test days; conversion to weekly testing when results meet the criteria outlined for daily QC or disk diffusion or dilution tests.	Any result out of control	New antimicrobial agents must be validated. Weekly testing is appropriate only for routinely tested drugs. Infrequently tested agents must be tested on the day of use.

Quality Assurance and Proficiency Testing. Laboratories should monitor errors in antibiotic susceptibility testing and categorize them as very major, major or minor. Erroneous results may be detected prior to reporting, either by an astute technologist or clinical microbiologist, or by the artificial intelligence rules built into an automated system that flag results that need verification. Comparison of erroneous result or those that are unexpected for a particular organism may alert the microbiologist to a potential problem with the identification and/or susceptibility results. Some of these clues are summarized in Table 17-7. Inadvertent testing of mixed cultures is a frequent cause of mistakes; inclusion of a "purity" plate with the susceptibility test is essential, but apparent purity of the tested isolate is not an absolute guarantee of purity.

All errors in either the testing, interpretation or reporting of antibiotic susceptibility results should be monitored as a major quality indicator of the entire complex process. All laboratories should aim to have an absolute minimum number of errors, but all errors should be investigated to identify and correct the root cause so that there is no recurrence. Technologists should be highly trained and skilled at not only performing the test procedures, but also identification of circumstances wherein a test should be repeated due to suspected erroneous results. Laboratory policy and procedure should also clearly identify specific antibiotic resistance profiles for major pathogens that require additional or confirmatory testing prior to reporting as outlined later in the chapter.

Laboratories performing antibiotic susceptibility testing must also participate in a proficiency testing program such as that offered by the College of American Pathologists (CAP), mandated by federal law, which improves performance and provides useful aggregate data for evaluating the status of susceptibility testing on a national basis.[464] Targeted proficiency programs have also been implemented successfully.[608]

Antimicrobial Susceptibility Test Procedures

Diffusion Susceptibility Methods

Disk Diffusion Susceptibility Test. Disk diffusion susceptibility tests became standardized in the United States based on the work of Bauer, Kirby, and coworkers (Chart 17-1).[118,121,122] This method is still widely used because of its ease of use and lower cost compared to other methods. Unlike dilution methods, an MIC value is not derived, but the diameter of the zone of drug inhibition is compared with the MIC values of the same strain to predict the category of susceptibility. Disk diffusion testing should be performed strictly according to the standard methods outlined by CLSI.[118,121,122] If the test is properly performed, the edges of the inhibitory zones should be clear and easy to measure.

Method Description. The basic principle of the standardized disk diffusion susceptibility test is illustrated in Figure 17-12. All disk diffusion methods rely on diffusion of drug released from an impregnated disk through agar. A detailed theoretical description of the principles of zone formation during this method has been previously described, and only a brief outline is given herein.[28,296] Disks are a standard 6 mm wide and are manufactured to contain a known amount of the drug being tested. CLSI recommends that disks be spaced on the agar plate so that there is 24 mm measured from the center of one disk to another in order to ensure no overlap in their inhibition zones. There should be a maximum of 15 minutes between inoculation of the agar with bacteria and application of the drug disk because diffusion starts shortly after its placement on the surface of the media. As soon as the antimicrobial agent-impregnated disk comes in contact with the moist agar surface, water is absorbed into the filter paper and the antimicrobial agent diffuses into the surrounding medium. The rate of extraction of the antimicrobial agent out of the disk is greater than its outward diffusion into the medium, so that the concentration immediately adjacent to the disk may exceed that in the disk itself. As the distance from the disk increases, however, there is a logarithmic reduction in the antimicrobial agent concentration. If the plate has been previously inoculated with a bacterial suspension, simultaneous growth of bacteria occurs on the surface of the agar. When a critical cell mass of bacteria is reached, the inhibitory activity of the antimicrobial agent is overcome and bacterial growth occurs. The time required to reach the critical cell mass (critical time; 4 to 10 hours for commonly tested bacteria) is characteristic of each species but is influenced by the composition of the medium and temperature of incubation. The lateral extent of antimicrobial diffusion before the critical time is reached will be affected by the depth of the agar because diffusion occurs in three dimensions. The points at which the critical cell mass is reached appear as a sharp circle with a margin of bacterial growth, with the middle of the disk forming the center of the circle if the test has been performed properly (Fig. 17-12). The concentration of diffused antimicrobial agent at this interface of growing and inhibited bacteria is known as the critical concentration and approximates the MIC obtained in dilution tests (See

Methods Using Liquid Media below). Although direct calculation of the inhibitory concentration is not done in practice, the MIC can actually be calculated with reasonable accuracy if the characteristics of antimicrobial diffusion and bacterial growth are known.[28]

1107

TABLE 17-12 Frequency of Quality Control When Modifications Are Made to Antimicrobial Susceptibility Test Systems

Required QC Frequency	Disks	Media (Prepared Agar Plates)	Inoculum Preparation	Measuring Zones	Instruments/Software (e.g., Automated Zone Reader)
1 Day	Use new shipment or lot number or new manufacturer	Use new shipment or lot number			Repair of instrument that affects AST results. Depending on the extent of repair (e.g., critical component such as the photographic device), additional testing may be appropriate for 5 days
5 Days		Use new manufacturer	Convert inoculum preparation/standardization to use of a device that has its own QC protocol (e.g., convert from visual adjustment of turbidity to use of a photometric device for which QC procedure is provided)		Software update that affects AST results. Monitoring all drugs, not just those implicated in software modification
15-Replicate QCP or 20–30 day QCP	Addition of new antimicrobial agent to existing system		Convert inoculum preparation/standardization to a method that depends on user technique (e.g., convert from visual adjustment of turbidity to another method that is not based on a photometric device)	Change method of measuring zones (e.g., convert from manual zone measurements to automated zone reader). In-house verification studies should also be done

BOX 17-3

Corrective Action for Antibiotic Susceptibility Tests That Are Out of Control

Source of Error

Obvious (e.g., wrong control strain, wrong temperature, contamination):

- Retest on day of QC failure until result is in control, then proceed as for an unknown error.

OR
Unknown:

- Possible explanations for the QC failure are summarized in Table 17-12.
- After implementing changes (i.e., new reagents) that could be problematic, proceed with validation.
- Test the failed antibiotic for five consecutive days.
- Proceed with additional testing if the results are out of control.
- Continue daily testing until the problem is resolved.
- Proceed with weekly testing once the results are in control.
- Suppress reporting of any antibiotics that are out of control until the problem is resolved.

TABLE 17-13 Troubleshooting Quality Control Problems in Antimicrobial Susceptibility Testing[a]

Observation	Potential Problem(s)	Corrective Actions[b]
MICs too large or zone sizes too small (isolates too resistant)	1. Inoculum too high 2. Deterioration of antimicrobial agent 3. Change in QC strain 4. Agar too deep 5. Incorrect reading of results	1. Check and adjust inoculums if necessary 2. Check potency of disks or powder; try new lot 3. Test new stock of QC strain 4. Check depth of agar 5. Repeat with multiple observers
MICs too small or zone sizes too large (isolates too susceptible)	1. Inoculum too low 2. Antimicrobial agent too potent 3. Change in QC strain 4. Agar too thin 5. Incorrect reading of results	1. Check and adjust inoculum if necessary 2. Check potency of disks or powder; try new lots 3. Test new stock of QC strain 4. Check depth of agar 5. Repeat with multiple observers
Results for		

Pseudomonas and aminoglycosides out of control	Cation content incorrect	Use cation-supplemented broth or try different lot of agar
Aminoglycosides and macrolides are resistant; tetracycline too susceptible	Medium too acid	Check pH of media
Aminoglycosides and macrolides are resistant; tetracycline too resistant	Medium too alkaline	Check pH of media
Trimethoprim MICs too large or zone sizes too small; results difficult to read	Excess thymidine in medium	Test medium with *Enterococcus feaecalis* (ATCC 29212); add thymidine phosphorylase or lysed horse blood
General	*QC Strain:* Use of wrong QC strain, improper storage, inadequate maintenance (e.g., use of the same working culture for >1 month), contamination, no viability, changes in the organism (e.g., mutation, loss of plasmid)	Use new QC strain and check all test conditions
	Testing Supplies: Improper storage or shipping conditions, contamination, inadequate volume of broth in tubes or wells, use of damaged (e.g., cracked, leaking) panels, plates, cards, tubes, use of expired materials (i.e., disks)	Use new reagents and supplies and check all test conditions
	Testing Process: Use of wrong incubation temperature or conditions, inoculums suspensions incorrectly prepared or adjusted, inoculum prepared from a plate incubated for the incorrect length of time, inoculums prepared from differential or selective media containing anti-infective agents or other growth-inhibiting compounds, use of wrong	Check all test conditions and the reading and recording of test results

	reagents, ancillary supplies, incorrect reading or interpretation of test results, transcription error	
	Equipment: Not functioning properly or out of calibration (i.e., pipettes)	Check the QC on all equipment and perform maintenance as required; replace if continues to malfunction

[a] Adapted from M100-S23 Table 4G[121].

[b] All results that are out of control will require retesting and withholding of results until QC is back in control (see Tables 17-10 and 17-11).

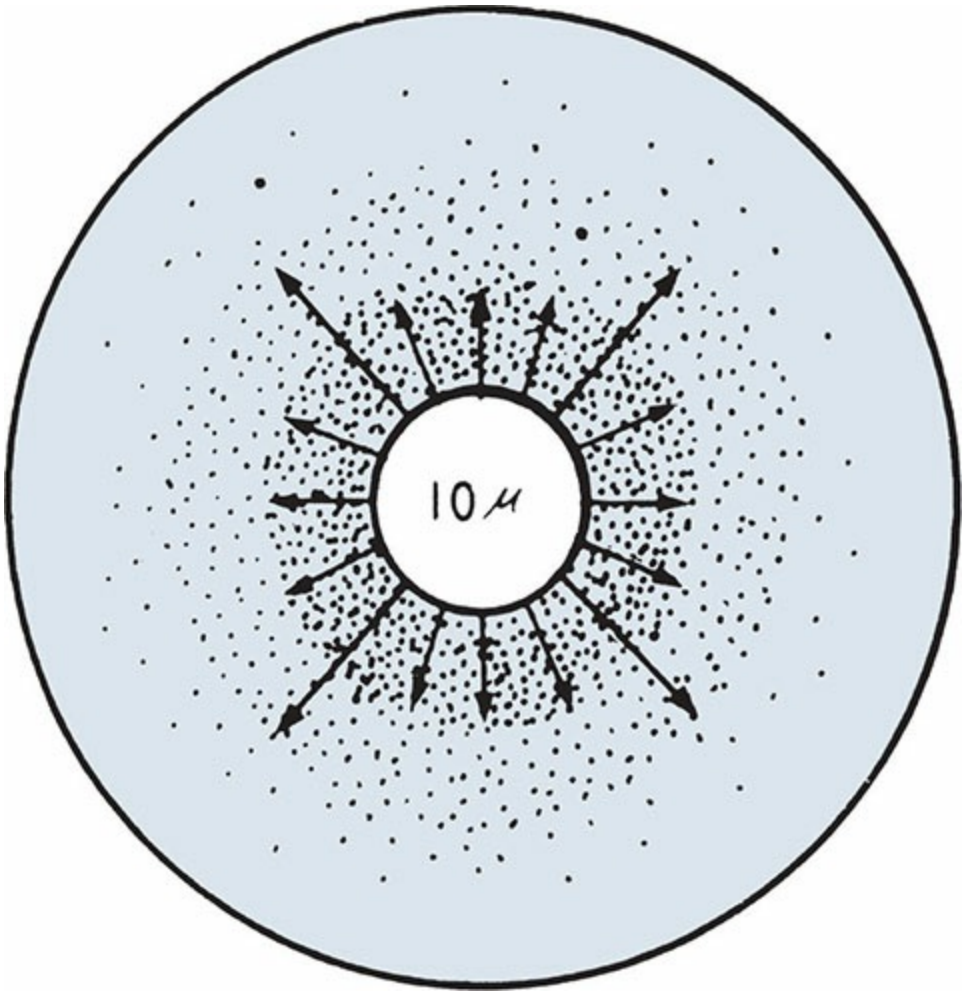
1109

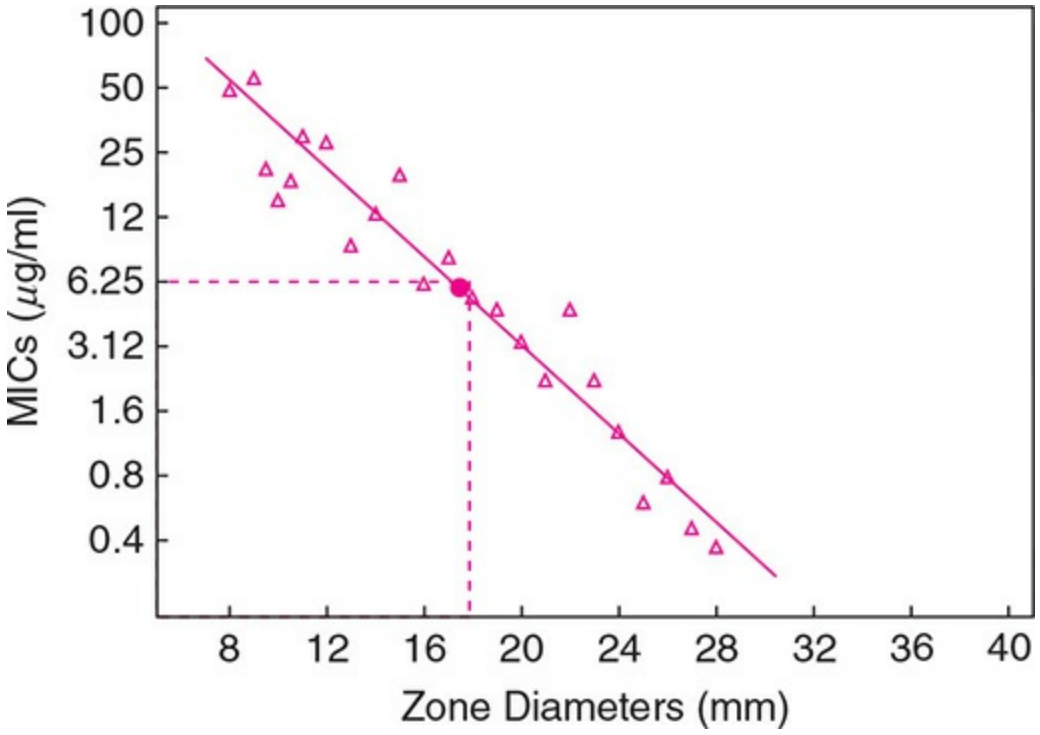


■ **FIGURE 17-12** The principle of antibiotic diffusion in agar. The concentration of antibiotic decreases as the distance from the disk increases.

Interpretation of Results. The zone size observed in a disk diffusion test is compared to the interpretive standards provided by the CLSI.[118,121,652] Zone diameter sizes derived from testing a wide range of strains are correlated with the known MICs of the species tested to assign interpretive breakpoint criteria for susceptible, intermediate and resistance zone sizes. A prototype of a regression curve providing such a correlation is illustrated in Figure 17-13. Multiple strains have been tested against a single antimicrobial agent both by the disk diffusion technique and by a dilution method. Each triangle represents the results of both tests for a single strain. A regression line has been drawn through the many individual points. Once the regression line is established, an approximate MIC result can be inferred from any zone diameter. In this example, a zone size of 18 mm corresponds to an MIC of 6.25 μg/mL; the breakpoint of the broth dilution test illustrated in Figure 17-14.

The interpretive guidelines for the disk diffusion test permit the user to make

approximations of the MIC for each of the antimicrobial agents listed, with zone diameters as determined by the disk diffusion technique. Thus, an antimicrobial agent that produces a zone diameter greater than 18 mm would theoretically have an MIC less than 6.25 µg/mL, and the organism would be considered susceptible. In contrast, a strain producing a zone size less than 18 mm would be considered resistant. In actual practice, regression curves are not that clearly defined, and a 2- to 4-mm zone may be established where it is not possible to determine whether the organism is susceptible or resistant. Isolates that produce an inhibitory zone in this range are characterized as intermediate in susceptibility. In studies conducted late in the 1950s, Bauer, Perry, and Kirby first demonstrated that bacterial strains tested against a given antimicrobial agent tend to fall into either the resistant or susceptible categories; only a small percentage (5% or less) fall into the intermediate range.[31]

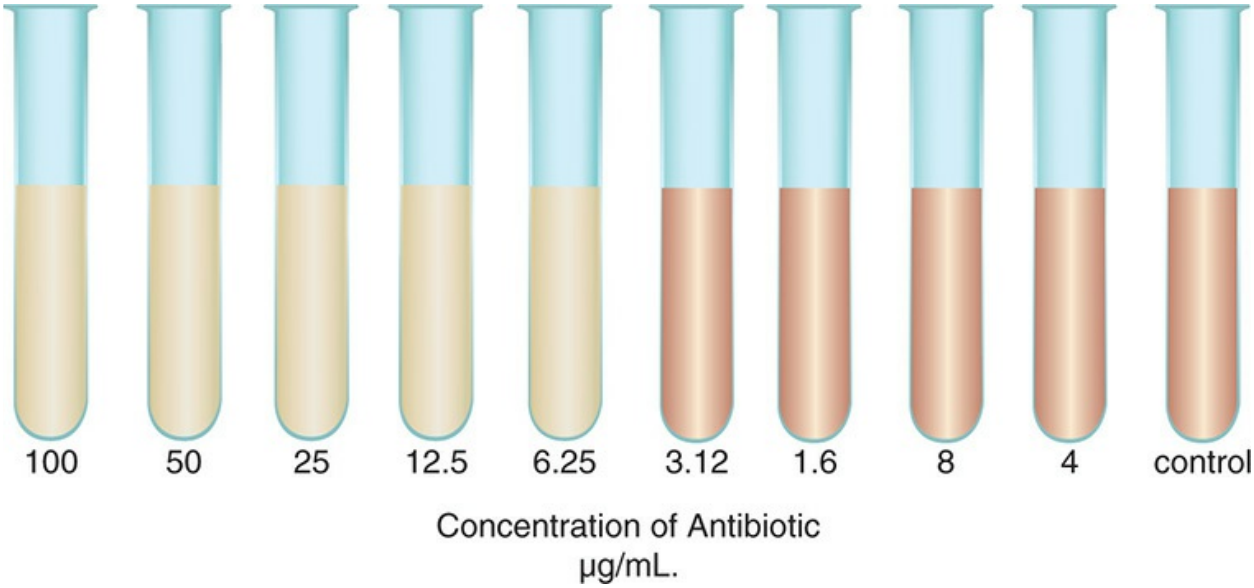


■ **FIGURE 17-13** Prototype regression curve comparing MICs in micrograms per milliliter with zone size in millimeters. Each triangle represents the MIC (*vertical axis*) and inhibitory zone (*horizontal axis*) of a single isolate.

Situations in which the technologist must learn to interpret unclear results correctly are listed in Box 17-4 and illustrated in Figures 17-15 through 17-18.

Quality Control. The objectives of performing QC for disk diffusion tests are to monitor the performance of the medium and disks, and the accuracy of the test

procedure using standard reference bacterial strains. Operator competence in performing the test procedure including the reading of the zone diameter and its interpretation are also being evaluated. Controls should be routinely tested using the methods and frequency of testing set out by the CLSI.[118,121,122] QC should be performed each time a new lot of disks or agar is used. The CLSI has also established limits on zone sizes that are acceptable for the QC strains[118,121,122]; these limits provide a means by which to measure the accuracy of testing. Reference strains recommended by the CLSI for QC of disk diffusion tests for aerobic bacteria include *E. coli* ATCC 25923, *E. faecalis* ATCC 29212, *P. aeruginosa* ATCC 27853, *S. aureus* ATCC 25923, and *E. coli* ATCC 35218. The latter *E. coli* strain is used as a control only for β-lactamase inhibitor combinations containing clavulanic acid, sulbactam, or tazobactam. Table 17-14 provides an example of a chart for recording the results of weekly disk diffusion QC using one of the standard control test organisms, *E. coli* ATCC 25922.



■ **FIGURE 17-14** Broth dilution susceptibility test. The MIC for the test illustrated here is 6.25 µg/mL.

BOX 17-4

Troubleshooting the Reading of Disk Diffusion Tests

- The diameter is read as the widest part of the outer margin of the circular zone of inhibition:
  - Diameter should not include pinpoint colonies or hazy growth.
  - *Proteus* spp. and other motile organisms may swarm when growing on agar surfaces, resulting in hazy growth within the zone which should be ignored; read the outer margin (Fig. 17-15).
  - Check the purity of the culture and perform separate susceptibility testing on the pinpoint colonies in the zone of inhibition; do not ignore these colonies in determining the MIC as they may represent a more resistant subpopulation (Fig. 17-16).
  - Ignore growth inhibition at the outer margin when reading sulfonamide disk results; the clear zone of <80% inhibition should be read as the zone diameter.
  - Overlapping zones may occur when disks are not correctly placed on the agar; the test must be repeated with more careful placement of the disks so the outer margins of the zone can be read correctly (Fig. 17-17).
  - Tests need to be repeated if the plate is not properly streaked resulting in irregular zone margins (Fig. 17-18).
  - When testing β-hemolytic bacteria, assess the zone of inhibition and ignore the hemolysis.

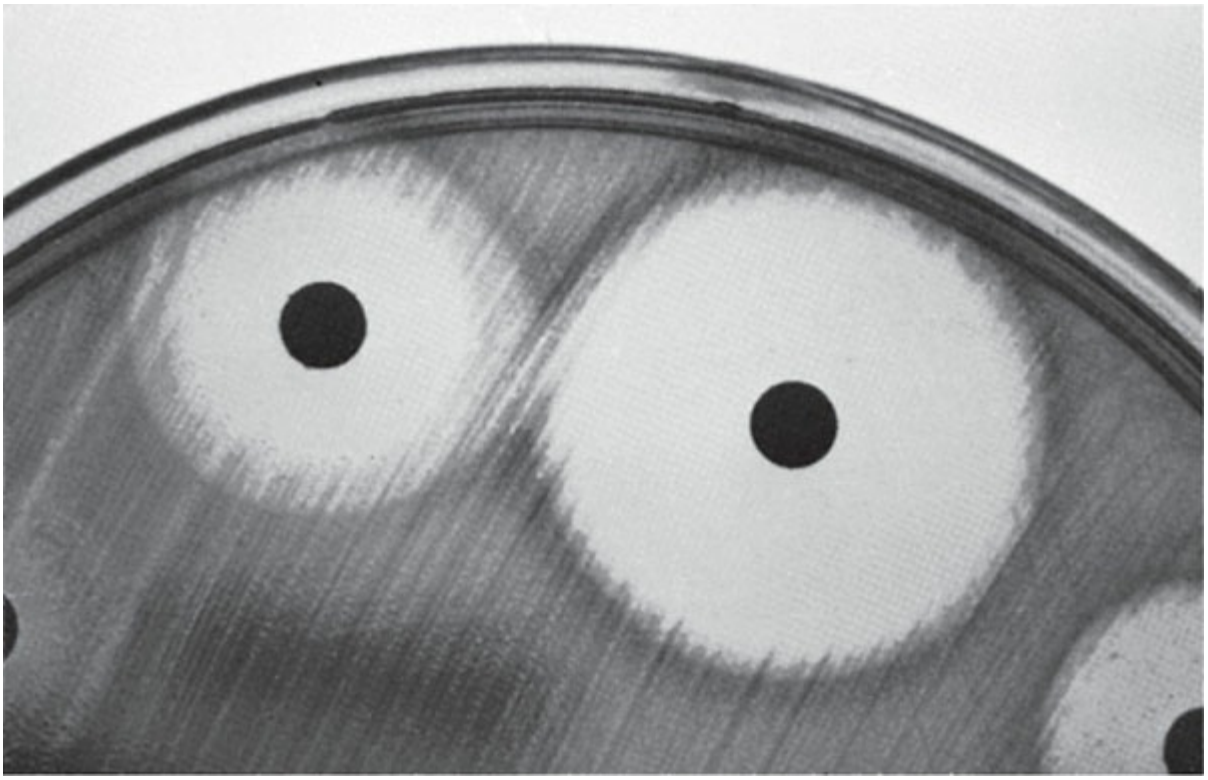


FIGURE 17-15 Photograph of an antibiotic susceptibility plate using a species of

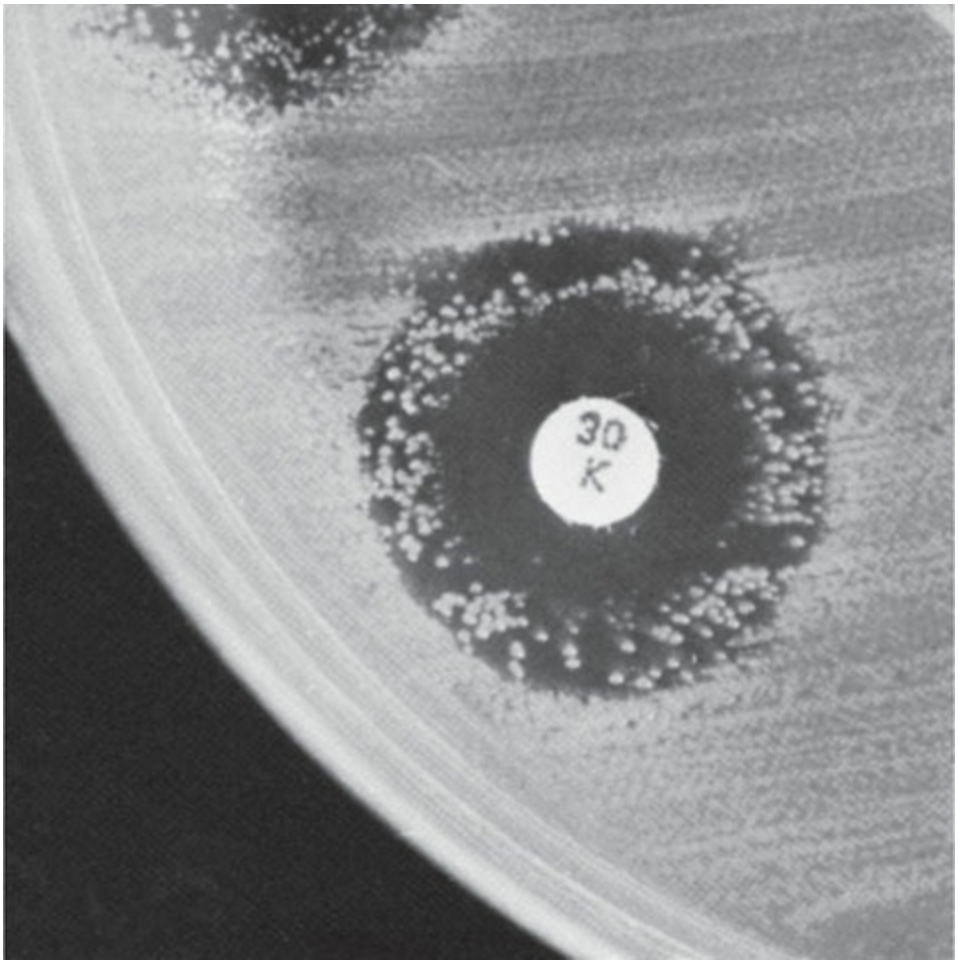
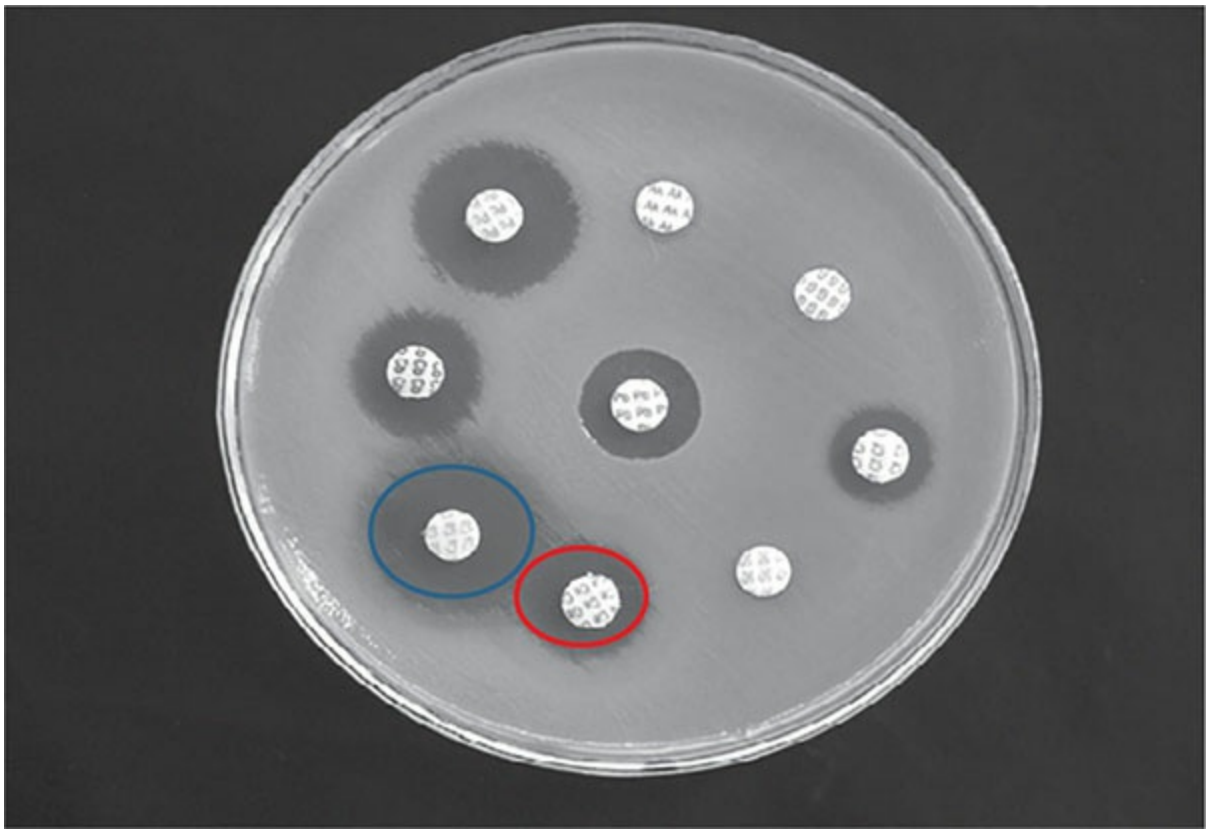
Proteus as the test organism. Note the swarming into the zone of inhibition at the peripheral margins. The second outer zone of growth inhibition should be used when measuring the width of the zone.

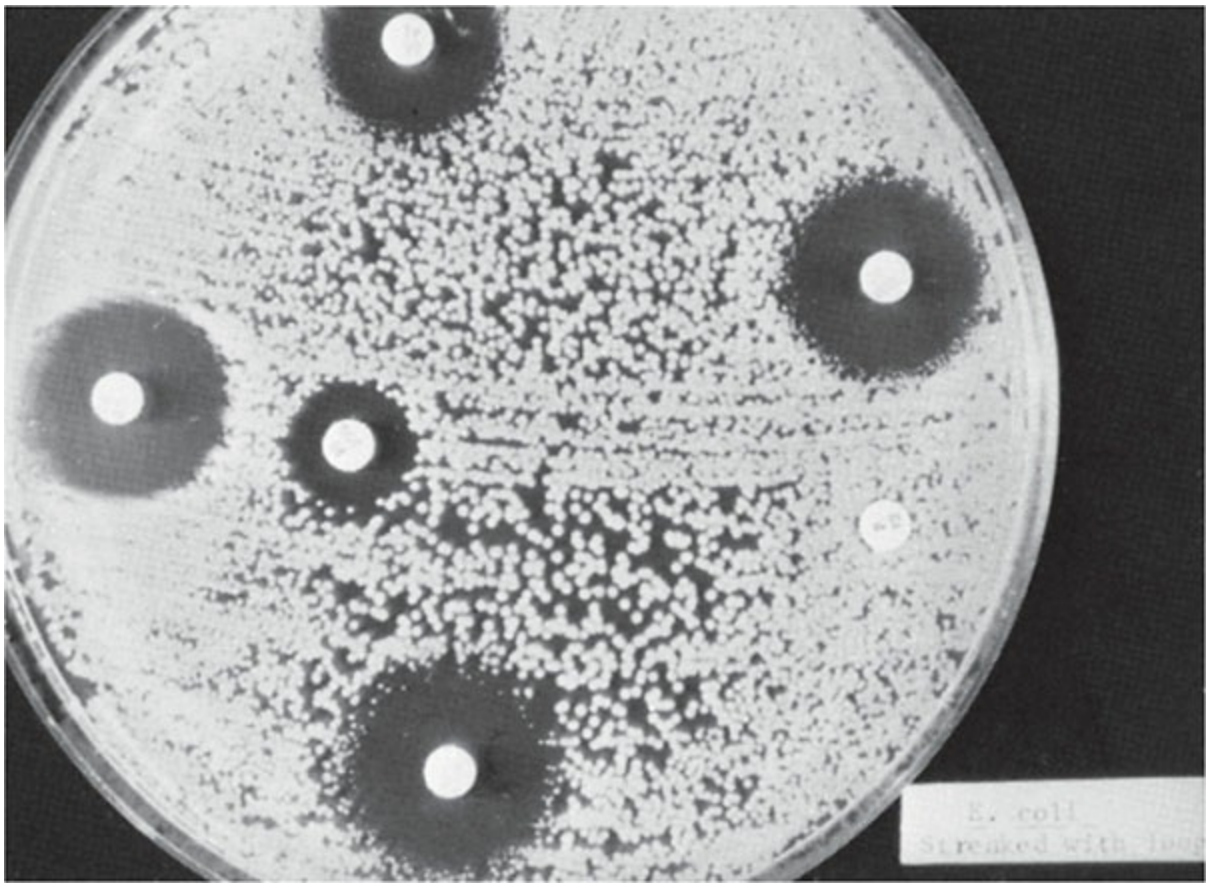


■ **FIGURE 17-16** An antibiotic susceptibility plate in which colonies resistant to kanamycin are growing within the zone of inhibition: biochemical tests must be performed to determine if the resistant strain is a mutant of the organisms being tested or represents a second species growing in mixed culture.



■ **FIGURE 17-17** Improper disk placement: demonstrates the difficulty in measuring diameters when there is overlapping adjacent zones of inhibition, or zones that extend beyond the outer margin of the agar. Oval or elliptical zones occur, and it is difficult to decide where to measure the zone diameter. Test should be repeated with correct disk spacing.

1111



■ **FIGURE 17-18** A poorly streaked antimicrobial susceptibility plate showing uneven growth. The zone margins are indistinct, compromising accurate measurement.

Limitations. The Bauer–Kirby test,[31] as modified by the CLSI, has been accepted in the United States as the standard technique for performing disk diffusion susceptibility tests, and will provide accurate information, provided it is used according to published guidelines.[118,121,122] The test should be applied only to bacterial species that have been thoroughly evaluated. Bacteria that grow slowly, need special nutrients, or require CO_2 or anaerobic conditions for growth should not be tested, unless the validity of the procedure has been documented.[114,115]

Gradient Diffusion Susceptibility Test. Gradient diffusion susceptibility testing or the epsilometer test (Etest) was developed by AB Biodisk in Sweden (Chart 17-3). Although the Etest has now been acquired by bioMérieux, it is still marketed by the same name. The Etest consists of antimicrobial agent-impregnated strips that are placed on the surface of agar, and exploits the same principles as the disk diffusion test, but MIC values are generated by applying a gradient of the antibiotic to be tested along the strip. The antibiotic gradient in the strip is made by applying 15 different

concentrations of antibiotics in repeated arrays on an increasing number of small dots (www.biomerieux-diagnostics.com). Placement of the strip on the inoculation media causes the antibiotic to diffuse into the surrounding medium in a high amount from one end of the strip to a low concentration at the other end. The MIC is read off the linear scale printed on the upper side of the strip where the zone of growth inhibition intersects with the edge of the strip (Fig. 17-19). If the strips are placed on the agar upside down (impregnated side not in contact with the agar), erroneous determinations of the MIC will likely result.[231] The manufacturer indicates, however, that an upside-down strip can be repositioned without problems if the mistake is recognized immediately.

The same factors that influence the disk diffusion susceptibility test also apply to the E test. Diffusion of antimicrobial agents begins immediately after placement of the strip, which cannot, therefore, be moved once the impregnated surface has touched the agar. A plate that is poorly streaked may produce an irregular zone of inhibition at the MIC point. Swarming of *Proteus* spp. and mutant colonies within the zone of inhibition may be challenges with the Etest, as with disk diffusion.

The Etest has been evaluated against a very broad range of bacteria since its advent, and this method produces results similar to those of conventional MIC tests (agar or broth dilution methods).[84,96,509,613] However, despite the simplicity of setting up an Etest compared to other methods, the expense of individual drug strips make this method less attractive for testing multiple antimicrobial agents against organisms that grow well in one of the dilution or disk diffusion procedures. The Etest is invaluable for testing highly selected antimicrobial agents against fastidious organisms that do not grow well in the other tests such as *Streptococcus pneumoniae*[604] or viridans streptococci,[398] for confirming an MIC result for a particular bug/drug combination initially tested by another method[613] and for the detection or confirmation of specific types of antibiotic resistance (i.e., ESBLs, MBLs, VISA/VRSA) as outlined below (see Detection of Special Types of Antibiotic Resistance).[518,573,598]

Laboratories should follow all of the principles and practices of QC for Etest outlined earlier in the chapter for disk diffusion testing. In addition to the general issues common to all susceptibility tests, specific suggestions for troubleshooting the Etest are summarized in Box 17-5. Table 17-15 provides an example of a weekly QC chart for performing gradient diffusion (Etest) testing for *S. pneumoniae* (ATCC 49619).

Dilution Susceptibility Testing

Agar Dilution Susceptibility Test. The agar dilution procedure is the reference method for testing using solid medium. This method has been successfully adapted for routine use in large laboratories by testing only selected concentrations of antimicrobial agent. Although a brief description of the method is outlined, agar dilution testing is

mainly performed by reference laboratories. A standardized suspension of bacteria is inoculated onto a series of agar plates, each containing a different concentration of antimicrobial agent, encompassing the therapeutic range of the drug.[135] For example, if the therapeutic range for a given antimicrobial agent is 2 to 12 µg/mL, a series of agar plates containing 1, 4, 8, 16, and 32 µg/mL of antimicrobial agent might be used to determine the susceptibility of the organism being tested. If the organism grows on the first three plates but not in the plate containing 16 µg/mL of antimicrobial agent, then an MIC value of 16 µg/mL is established.

■ **FIGURE 17-19** Oxacillin Etest—*S. pneumonia*. MIC = 0.47 µg/mL (S). (Courtesy of Calgary Laboratory Services.)

To facilitate testing of a large number of isolates, an instrument known as the Steers replicator is used to inoculated large agar dilution plates with 32-26 wells cut into the agar. These wells are tooled in such a manner that when the seed plate is properly aligned within the guide at the base of the replicator, each of the inoculating pins on the movable instrument head fits exactly into the wells. Each well in the seed plate provides a receptacle into which different bacterial suspensions can be placed. Inoculated agar dilution plates are incubated at 35°C for 18 hours. Agar dilution plates ready for interpretation are shown in Figure 17-20. Note that microorganisms that are susceptible to the concentration of antimicrobial agent contained in any given agar plate do not produce a circle of growth at the inoculum site, whereas those that are resistant appear as circular colonies. The agar plates are marked with a grid so that each microorganism can be identified by a number and the results entered on the worksheet.

Macrodilution Broth Susceptibility Test. The macrodilution broth susceptibility test was among the first to be developed by Fleming, and still serves as a reference method.[196] Serial dilutions of antimicrobial agent are made initially in liquid medium, after which a standardized bacterial suspension is added. Figure 17-14 shows a schematic representation of a broth microdilution test with 10 test tubes that contain CAMHB typically in a volume of 1 to 2 mL. Quantities of antimicrobial agent are serially diluted in nine of these tubes from a high concentration of 100 µg/mL down to

0.4 µg/mL. Tube number 10 serves as a growth control and is free of antimicrobial agent. Each of the 10 tubes is inoculated with a calibrated suspension of the microorganism to be tested and incubated at 35°C for 18 hours. At the end of the incubation period, the tubes are visually examined for turbidity; the five tubes to the left are clear and the five to the right appear cloudy (Fig. 17-14). Cloudiness indicates that bacterial growth has not been inhibited by the concentration of antimicrobial agent contained in the medium. The breakpoint of growth inhibition is between tubes 5 and 6, or between 6.25 and 3.12 µg/mL of antimicrobial agent. This breakpoint represents the MIC (i.e., the **MIC** lies somewhere between 6.25 and 3.12 µg/mL); defined as the lowest concentration of antimicrobial agent in micrograms per milliliter that prevents the **in vitro** growth of bacteria. However, by convention, the **MIC** is interpreted as the concentration of the antimicrobial agent contained in the first tube in the series that inhibits visible growth. Therefore, in this example, the **MIC** is 6.25 µg/mL.

BOX 17-5

Troubleshooting the Reading of Etest Assays

- The MIC equals the point of intersection where the ellipse intersects the scale on the strip:
  - Zone of inhibition includes pinpoint colonies and hazy growth within the zone of inhibition.
  - Check the purity of the culture when there are pinpoint colonies in the zone of inhibition; do not ignore these colonies in determining the MIC.
  - Tilt the plate or use a magnifying glass to visualize pinpoint colonies and hazes, especially for enterococci, pneumococci, and *Stenotrophomonas* spp. Include a haze as growth when determining inhibition, but ignore the swarming of *Proteus* spp.
  - When testing β-hemolytic bacteria, assess the zone of inhibition and ignore the hemolysis.
  - If a paradoxical effect (inhibition at low MIC and regrowth at higher MICs), read the MIC as the zone of final, complete inhibition.
  - Bacteriostatic drugs, such as trimethoprim–sulfamethoxazole, may produce growth with a diffuse, fuzzy edge; read the MIC at 80% inhibition (as for the disk diffusion test).
  - When testing combinations of β-lactams and β-lactamase inhibitors, the inhibitor may have intrinsic activity, producing an extended ellipse at the lowest MICs. Extrapolate the upper ellipse of inhibition to determine the MIC.
  - A "dip" effect at the lowest MIC may be seen when inducible macrolide resistance is present, producing an ellipse with an elongated nipple at the end. Extrapolate the curvature of the primary ellipse to determine the MIC.

- Ignore a thin line of growth along the lower portion of the strip, a phenomenon caused by organisms growing in a tunnel of water along the strip.
- If the zone of inhibition intersects the strip between two markings, read the higher value. Similarly, if the zone intersects the strip slightly differently on the two sides, read the higher value.
- If the MIC produced by the strip is between numbers in the classic twofold-dilution scheme (on which all standard recommendations are based), round the "answer" up to the next twofold dilution. For instance, an MIC of 1.5 μg/mL would be reported as 2.0 μg/mL.

■ **FIGURE 17-20** Agar dilution antimicrobial susceptibility plates that have been inoculated with several species of bacteria from a Steers replicator. Sensitive organisms are inhibited by the concentration of antibiotic contained in the plate, and no growth is evident at the points of inoculation; resistant organisms appear as distinct colonies of bacterial growth.

1115

Because of the large increase in the number of antibiotics that have to be simultaneously tested against clinical pathogens, the broth macrodilution procedure is no longer performed in clinical laboratories. Microbroth dilution testing is done instead which is an adaptation of the macrobroth method performed in a much smaller volume of liquid media as described below.

Microbroth Dilution Susceptibility Test. The performance of the microbroth dilution procedure is similar in principle to the macrobroth method, except that the susceptibility of microorganisms to antimicrobial agents is determined in a series of microtube wells that are molded into a plastic plate (Chart 17-2).[210,296] The development of the microdilution method allows a large number of bacteria to be tested simply and inexpensively against a panel of antimicrobial agents.

Method Description. Broth microdilution has been widely used for both clinical and investigational purposes, and is the international reference method used for establishing MICs by EUCAST (www.EUCAST.org/clinical-breakpoints) and CLSI.[117,121,122] Microbroth dilution tests are referred to as the microdilution technique

because the final volume of liquid media is only 50 μL. MHB has been the most widely used and evaluated liquid medium for dilution susceptibility testing and has been designated the international reference method by EUCAST (www.EUCAST.org) and CLSI.[117,121,122] Each plate may contain 80, 96 or more microwells, depending on the number and concentration of antimicrobial agents that are to be included in the susceptibility test panel. Commercial broth microdilution panels (Pasco systems, MicroScan panels, Sensititre, TREK plates) that contain standard horizontal serial dilutions of different antibiotics in the plate microwells, and the automation of plate incubation and reading (MicroScan system, Sensititre system), allow clinical laboratories to readily determine the MICs for a large number of drugs against a pathogen in a timely fashion.

The antimicrobial agent-containing plates must be frozen at −20°C or lower until used. Frozen prepared plates can be obtained from several commercial sources. Storage of large numbers of frozen microplates may be difficult in some laboratories. In this case, plates that contain lyophilized antimicrobial agent solutions may be purchased. Rehydration of the wells adds another step to the procedure, but the extended shelf life of the freeze-dried plates is valuable, especially for laboratories in which small numbers of panel tests are performed. Both the frozen and lyophilized broth dilution systems have performed well in comparison to the reference methods.[226,474,604,685] Few laboratories have production facilities to make their own plates for patient testing, and in-house plates have been shown to be less reliable and reproducible across laboratories than that of the commercial systems.[209] Some of the commercial systems have not performed well, however, in certain special situations, as discussed below.

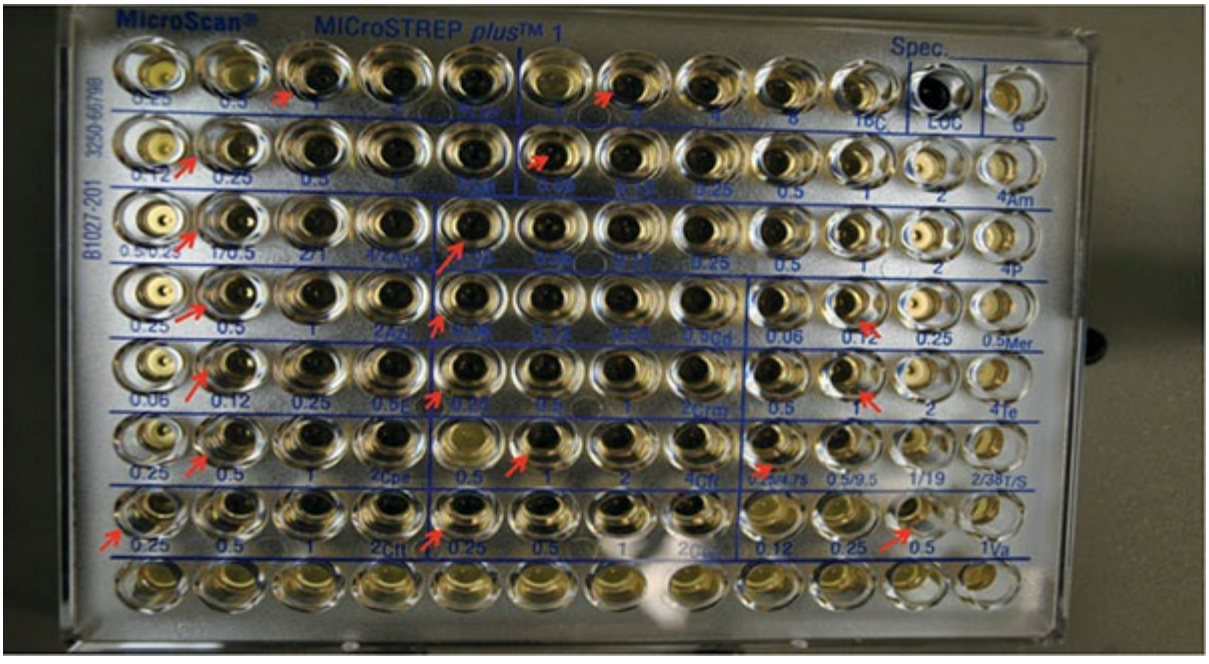
Interpretation of Results. The growth control wells are examined for organism viability and inoculum purity before reading the MICs for the clinical isolate. End points of broth microdilution tests are usually easily defined (Fig. 17-21). Examination of the microplate is facilitated by use of a viewing mirror. Occasionally, skipped wells occur where growth is inhibited in a well that is adjacent to wells with uninhibited growth. If a single well is skipped and the interpretation of the result is not affected, the skipped well may be ignored. The problem should, however, be investigated and the test repeated if multiple wells are skipped, the skipped well occurs at a dilution that is critical for determining susceptibility of the isolate or multiple isolates demonstrate the phenomenon.

The interpretive guidelines outlined by the CLSI should be reported along with or in place of the actual MIC values.[117,121,122] Separate guidelines for interpreting dilution susceptibility test results for fastidious bacteria have been published by the CLSI.[114]

Quality Control. The objectives of performing QC for dilution tests are the same as for disk diffusion tests. International standards have been developed for acceptable performance of susceptibility testing devices including broth microdilution

panels.[121,122] A key principle of the QC of broth dilution tests is the use of reference bacterial strains that are genetically stable and have well-defined MICs that are in the middle range of the expected MICs of each antimicrobial agent to be tested. A dilution series should include at least two concentration increments above and below the previously established MIC for the reference organisms. CLSI has established QC limits for dilution susceptibility tests[117,121,122]; an unacceptable QC result is one that falls outside these published limits. Reference strains recommended by the CLSI for QC of dilution tests for aerobic bacteria include *E. coli* ATCC 25922, *E. faecalis* ATCC 29212, *P. aeruginosa* ATCC 27853, and *S. aureus* ATCC 29213. The β-lactamase-producing strain *E. coli* ATCC 35218 is only recommended for penicillin-β-lactamase inhibitor combinations. Box 17-6 outlines common possible problems that occur with dilution susceptibility testing as well as their explanations.

Quality control tests for dilution susceptibility tests should be performed daily until the QC plan outlined in Table 17-10 (20- to 30-day plan) and Table 17-11 (3- × 5-day plan) is passed.[121] Weekly QC testing may be implemented provided no more than 3/30 consecutive test results for each reference drug–organism combination falls within acceptable limits. However, if a single MIC occurs outside the acceptable range, then daily testing is reinstated unless an obvious source of error is identified and fixed (i.e., incorrect test conditions, wrong inoculum, contamination). In addition, each new batch and lot of commercial plates needs to undergo QC tests before being put into clinical use. Table 17-16 provides an example of a chart for recording the results of daily/weekly QC for a microbroth dilution panel (MicroScan) using one of the standard control test organisms, such as *P. aeruginosa* (ATCC 27853).



■ **FIGURE 17-21** Commercial microdilution panel testing of *S. pneumoniae*. Red arrows indicate the wells where the MIC breakpoint for each drug would be read. (Courtesy of Calgary Laboratory Services.)

1116

BOX 17-6

Troubleshooting Broth Microdilution Assays

- MIC is read as the lowest dilution where growth is inhibited in the well:
  1. When MICs are lower than expected—the inoculum may be too light. Repeat using McFarland 0.5 turbidity standard or standardizing device. Check steps in inoculum preparation and inoculation procedure.
  2. When MICs are either higher or lower than expected—the composition of the cation-adjusted Müeller–Hinton broth may not be optimal. Check the pH and calcium concentration of in-house prepared media. Use an alternative commercial lot of media, or an alternative lot of commercial panels.
  3. When MICs are higher than expected—the inoculum may be too heavy. Repeat using McFarland 0.5 turbidity standard or standardizing device. Check steps in inoculum preparation and inoculation procedure.
  4. When there are skipped wells—may be caused by several problems:
     a. Check for contamination.
     b. Panel may have been inadequately inoculated or the inoculum may have been inadequately mixed.
     c. Drug concentration in the wells may be inaccurate.
     d. Volume of broth in the wells may be inaccurate.
  5. When several MICs too high or too low—may indicate a possible reading/transcription error. Recheck all of the readings and repeat testing using an alternative lot.

Automated Systems

Commercial automated systems for antimicrobial susceptibility testing have been widely used since the 1990s. Automated systems allow for more rapid test turnaround time, and the ability to produce a large number of results with less labor than manual methods. Automated results are highly reproducible, and the development of expert computer systems allow for the on-board interpretation of results using expert rules built into the system, and the ability to retain and analyze a large amount of

susceptibility data. Although most large laboratories have purchased an automated system, the high capital cost on the instrumentation and required consumables compared to manual methods have curtailed their implementation in some smaller facilities. These systems also do not have the capability to test all of the types of encountered pathogens, and problems have been documented using strains that have unusual resistance phenotypes or types of resistance that are difficult to detect.[296] The major systems have generally performed well in comparisons against reference methods, although laboratories need to be aware of the limitations of their particular automated system, and perform manual and/or molecular confirmation of specific types of resistance flagged by the system (see Detection of Specific Types of Antibiotic Resistance Phenotypes below). This section provides a brief overview of the current automated system approved for use by the FDA in the United States. Readers are referred to Section 5.17 of the Clinical Microbiology Procedures Handbook for a more detailed review of the evaluation of commercial automated susceptibility systems.[407]

Vitek 2. The Vitek 2 system (bioMérieux) has been in use in the United States since 2000 (Fig. 17-22). The standard instrument contains 64 wells for cards that have one to six concentrations for 9 to 20 antimicrobial compounds. The larger Vitek 2XL instrument has a 120-card capacity. The system also runs gram-positive and gram-negative identification panels at the same time that susceptibility testing is being performed. Although the initial bacterial inoculum and dilution of the organisms to be tested must be done manually, all other steps are automated. Vitek 2 takes an average setup time of 1.5 minutes per isolate.[407] Each Smart Carrier Station has a barcode reader, and holds up to 15 cards. A memory chip in the cassette captures and transfers scanned data to the reader-incubator unit. Robotics of the instrument move the loaded cassette through successive stations for barcode reading, test dilution preparation, and card inoculation and sealing before placement of the card on the 6-card carousel for incubation. Each card is read by an optical station every 15 minutes, and the amount of light transmitted is inversely proportional to the amount of growth achieved. Vitek 2 uses computer-assisted analysis of growth in plastic cards to calculate a MIC. In some instances the calculation of the MIC depends on the bacterial identification. The additional accuracy provided by the computer-driven correlation of growth pattern and identification is counter balanced by the uncertainty about the susceptibility result if the identification is not yet known or cannot be provided with adequate certainty by the system. The Vitek 2 Advanced Expert System analyzes MIC patterns and detects phenotypes for most organisms tested. The Vitek 2 Observa information management system allows susceptibility results to be stored so that it can be analyzed and formatted into user-defined reports including the generation of cumulative reports.

■ **FIGURE 17-22** Vitek 2 automated susceptibility system www.biomerieux-diagnostics/VITEK-2.

Ligozzi and colleagues reported that the time required for Vitek 2 susceptibility results for gram-positive cocci ranged from 6 to 17 hours depending on the species.[343] *S. aureus* results took 8 hours, while results for coagulase-negative staphylococci took longer at 11 hours. Group B *Streptococcus* results took 9 hours as did enterococci, but *S. pneumoniae* took slightly longer at 9 hours. Vitek 2 also generates rapid susceptibility results for *Enterobacteriaceae* in from 3.3 to 17.5 hours; isolates from blood cultures compared well with manual methods.[348]

MicroScan Walkaway SI. The Microscan Walkaway (Dade Behring) has been on the market the longest of the automated instruments, and has been used in the United States since the early 1990s (Fig. 17-23). All of the panels used on the instrument are conventional 96-well microdilution trays including MIC panels that have a broad range of antimicrobials and combination panels that include wells for identification and susceptibility testing. Breakpoint combo panels are also available that provide a limited range of dilutions that determine whether an isolate is susceptible, intermediate, or resistant to a compound, as well as identification wells. Both frozen and lyophilized panel formats are available on the conventional MicroScan and rapid Walkaway systems. The Walkaway instrument is available in two sizes that will accommodate either 40 or 96 panels. The MicroScan uses broth microdilution to determine the MIC. After inoculation and overnight incubation (i.e., 4.5 to 15 hours), the conventional MicroScan system reads panels turbometrically (conventional MicroScan system) while the Walkaway instrument uses a fluorescence detection system that will provide same-day identification and susceptibility testing for some organisms.

■ **FIGURE 17-23** MicroScan walkaway plus automated ID and antibiotic susceptibility system (www.healthcare.siemens.com/microbiology-testing/microscan-systems/walaway-plus-system)

The Walkaway system is primarily a semiautomated plate incubator-reader attached to a computer and printer. The initial inoculum preparation is done manually, and then a manual device (RENOK) is used to rehydrate and inoculate panels. The newer SI version of the Walkaway instrument has also automated the addition of reagents to the identification wells. Robotics within the instrument moves the plates under a central photometer (MicroScan) or fluorometer (Walkaway) for reading. The data management system LabPro interprets the results, generates reports and stores data for analysis and the generation of epidemiologic reports. An expert system LabPro Alert may also be purchased that contains algorithms for expert rules-based interpretation and reporting.

Although the Walkaway system has comparable clinical performance to other automated systems, panel testing using this instrument is more labor intensive than a fully automated system. Due to the number of panels that need to be tested, more biohazardous waste is generated by the MicroScan than either the Vitek 2 or BD

Phoenix instruments.

BD Phoenix. The BD Phoenix system (Becton Dickenson Diagnostics, Baltimore MD) has been in use in the United States since 2004 (Fig. 17-24). The instrument has the largest capacity of any automated system (i.e., 100 panels), other than the Vitek 2XL. The system provides direct rather than calculated MICs and a wide range of antimicrobials can be tested. Each plastic tray has 126 wells divided between the identification side (51 wells) and the susceptibility side

(85 wells) that contain 16 to 22 antimicrobials. A mean time of 3 minutes per isolate has been reported for the BD PHOENIX setup time.[407] A redox indicator (blue) is added to the bacterial inoculum during preparation, and the suspension is poured into the susceptibility side of the panel and sealed. Individual bar codes are used to identify each test panel. The instrument reads panels every 20 minutes. Turbidity is measured as a growth indicator, and a colorimetric change (to pink) is the redox indicator. BD Phoenix has expert software (BCXpert) and data management software (BD EpiCenter) to interpret MIC values according to CLSI guidelines and reporting rules. Data is stored in the instrument and analyzed to generate epidemiologic reports.

■ **FIGURE 17-24** BD phoenix automated ID and antibiotic susceptibility system (www.bd.com/ds/productcenter/is-phoenix.asp)

The BD PHOENIX system had a somewhat faster overall reporting time for most common types of bacteria than Vitek 2 in one study, but a longer time was required to generate results for *Enterobacteriaceae* than Vitek 2.[407]

Limitations. Automated systems have their individual limitations, particularly with the reporting of unusual resistance phenotypes (See Detection of Specific Antibiotic Resistance Phenotypes below). QC of automated susceptibility results has been difficult and largely remains unstandardized. Standard reference strains should be tested on the instrument after routine maintenance is performed. Laboratories should also validate new products with new or improved test capabilities (i.e., the ability to detect specific types of resistance phenotypes), and validation should also be done with each new software upgrade to the system including the addition of new expert reporting rules.

Choice of Test

A detailed summary of the susceptibility methods recommended by the CLSI for selected organisms is outlined in Table 17-17. Although disk diffusion testing is widely used, particularly in smaller laboratories or laboratories in resource limited settings, some antibiotics cannot be reliably tested against some organisms as outlined in CLSI guidelines,[118,121,122] and below in the section on detection of antibiotic resistance in important pathogens. Antibiotic susceptibility testing using dilution tests provides more quantitative information, and may be applied to a wider range of isolates than the diffusion test. For evaluation of susceptibility tests, and comparison between methods, most investigators use the following definitions for determining the levels of error:

- Very major error: characterization of a resistant isolate as susceptible
- Major error: characterization of a susceptible isolate as resistant
- Minor error: characterization of a susceptible or resistant isolate as intermediate, or characterization of an intermediate isolate as susceptible or resistant

Detection of Specific Types of Antibiotic Resistance

β-Lactamase Testing

Several methods have been used to rapidly and reliably to detect the presence of many

β-lactamases. β-Lactamase testing is based on the detection of the end products of β-lactam ring hydrolysis which are visualized using a chromogenic substrate. Although three different reactions methods have been used including the iodometric, acidimetric, and chromogenic cephalosporin methods, the latter has been widely adopted because of its ease of use and sensitivity for the bacterial species for which the test is recommended. A detailed description of each of these methods has been previously published.[39]

The chromogenic cephalosporin test, is performed by smearing a loopful of a colony onto a nitrocefin disk (Cefinase; BD Diagnostic Systems, Sparks, MD), which is then placed in a closed Petri dish to prevent rapid desiccation. Organisms that containβ-lactamase will change the color of the disk from yellow to red (Fig. 17-25). The reaction usually occurs within 30 seconds, but tests are read finally after 15 minutes.

A positive test is correlated with resistance to specific β-lactam drugs for some bacterial species including (1) *H. influenzae* (amoxicillin, ampicillin), (2) *M. catarrhalis* (amoxicillin, ampicillin, and penicillin), (3) *N. gonorrhoeae* (amoxicillin, ampicillin, and penicillin), (4) *Staphylococcus* spp. (amoxicillin, ampicillin, penicillin, mezlocillin or cloxacillin, and ticarcillin or piperacillin), and (5) *Enterococcus* spp. (ampicillin, amoxicillin, penicillin, piperacillin). However, special precautions must be taken to ensure that β-lactamase production in *Staphylococcus* spp. has been induced prior to testing as outlined below. For other organisms, β-lactamase production does not entirely correlate with resistance to β-lactam drugs that may be used for treatment, and the tests described below should not be used for aerobic gram-negative bacteria including *Enterobacteriaceae* or *P. aeruginosa*.

Surveillance in the United States shows that 30% to 40% of clinical isolates of *Haemophilus influenzae* will be resistant to ampicillin/amoxicillin because of β-lactamase production, and the highest rates of this type of resistance occur in nontypeable strains.[280] A more recent study of pediatric clinical isolates found that ~40% of nontypeable *H. influenzae* isolates from serious infections also produce β-lactamases.[236] A β-lactamase test should be done on all clinically significant isolates to rapidly detect resistance to ampicillin or amoxicillin. However, β-lactamase nonproducing, ampicillin/amoxicillin-resistant (BLNAR) strains that have altered PBP3 can only be detected by a diffusion or dilution susceptibility test.[275] *H. influenzae* recovered from sterile sites/sources that are producing clinically significant infections should undergo full susceptibility testing as outlined later in the chapter.

Most clinically significant isolates of *M. catarrhalis* will demonstrate β-lactamase production. CLSI continues to recommend that laboratories perform a β-lactamase test on all isolates, but full susceptibility testing should be done on isolates from invasive infections.[121,122] Recent surveillance of respiratory tract isolates from several geographic locations have shown the *M. catarrhalis* has developed increased

resistance to second-generation cephalosporin (cefaclor, cefprozil, cefuroxime), tetracyclines, macrolides, and trimethoprim–sulfamethoxazole.[462,538,649]

Staphylococci may require induction in order to ensure the accuracy of detecting β-lactamase production. β-Lactamase production by in *Staphylococcus* spp. is responsible for most of the resistance to penicillin G and related compounds, but the cephalosporins or the penicillinase-resistant penicillins, such as methicillin and nafcillin, are not inactivated by these penicillinases unless produced in large amounts. A staphylococcal β-lactamase test should not be reported as negative unless the test has been performed on the isolate after exposure to an inducing agent (i.e., oxacillin or cefoxitin). Microdilution MIC tests using penicillin may also fail to detect staphylococci that are penicillin-resistant due to the presence of a β-lactamase because only a small amount of the enzyme is typically produced by the relatively small inoculum used in this test. However, the presence of a β-lactamase can be inferred if the MIC of a staphylococcal strain to penicillin is greater than 0.25 μg/mL. *Staphylococcus* spp. isolates with penicillin MICs less than 0.03 μg/mL are considered susceptible. Isolates for which the MIC falls between these limits (0.06 or 0.12 μg/mL) should be tested for the presence of β-lactamase before the results are reported. Use of bacterial growth from a well that contains a penicillin-class drug or from the edge of a zone of inhibition around a disk that contains a penicillin compound may induce activity and enhance detection of the enzyme. The results from the testing of penicillin can be extrapolated to ampicillin.

1120

TABLE 17-17 Summary of Antimicrobial Susceptibility Test Methods for Selected Organisms

Organism	Method	Test Conditions (Medium/Inoculum/Incubation)	Comments
Staphylococcus spp.	Broth microdilution	CAMHB or MHA/DCS/35°C ambient air for 16–20 hours	Use molecular testing for *mecA* gene; confirm VAN I/R strains
	Agar dilution (Reference test)	CAMHB or MHA plus 2% NaCl for OXA, MET or NF/DCS/35°C ambient air for 24 hours	
	OXA–salt agar screen	MHA with 4% NaCl/DCS/35°C ambient air for 24 hours	Chromagar used by many laboratories
	Disk diffusion	MHA/DCS/35°C ambient air X 16–20 hours; 24 hours for OXA, MET or NF	Confirm VAN I/R by an MIC method; low-level resistance not well detected
	Gradient diffusion (Etest)	MHA or MHA with 2% NaCl for OXA, MET, or NF/DCS in broth/35°C ambient air X 16–20 hours; 24 hours for OXA, MET, or NF	Incubate for 48 hours to detect OXA resistant CONS
Enterococcus spp.	Broth microdilution; agar dilution	CAMHB; MHA/Growth method or DCS/35°C ambient air for 16–20 hours; 24 hours for VAN	Confirm VAN R strains; perform β-lactamase test
	Disk diffusion	MHA/Growth method or DCS/35°C ambient air for 16–20 hours; 24 hours for VAN	
	Gradient diffusion (Etest)	MHA/Growth method or DCS/35°C ambient air for 16–20 hours; 24 hours for VAN	
Enterococcus spp. HLAR	Broth microdilution; agar dilution	BHI broth or agar; GM 500 µg or STR 1000 µg/mL (broth) or 2000 µg/mL (agar)/growth method or DCS (standard microdilution inoculum); 10 µL spotted on agar surface/35°C ambient air for 24 hours; reincubate STR an additional 24 hours if susceptible	Perform on invasive isolates only
	Disk diffusion	MHA/120 µg disk GM or 300 µg disk STR/growth method or DCS/35°C ambient air for 16–20 hours	Confirm HLAR results with an MIC method
	Gradient diffusion	MHA; GM and STR high-dose strips/suspension in broth to 0.5–1.0 McFarland standard/35°C ambient air for 48 hours	
Enterococcus spp. VAN resistance	Agar dilution	MHA; VAN 6 µg/mL/growth method or DCS; standard microdilution inoculum; 1–10 µL spotted on agar surface	Chromagar used by many laboratories
Streptococcus pneumoniae	Broth microdilution	CAMHB with 2%–5% (v/v) lysed horse blood/DCS/35°C ambient air for 20–24 hours	OXA disk screen for PEN susceptibility may be used as a preliminary test
	Disk diffusion	MHA with 5% sheep blood/DCS/35°C in 5% CO_2 for 20–24 hours	Disk diffusion not reliable for some antimicrobial agents; MIC test recommended for CNS isolates
	Gradient diffusion	MHA with 5% sheep blood/DCS in broth/35°C in 5% CO_2 for 20–24 hours	Use a 1.0 McFarland inoculum if the bacterial lawn is sparse
Other *Streptococcus* spp.	Broth microdilution	CAMHB with 2%–5% (v/v) lysed horse blood/DCS/35°C ambient air for 20–24 hours	
	Agar dilution	MHA with 5% v/v sheep blood/DCS/35°C ambient air for 20–24 hours/CO_2 if necessary for growth	Use lysed horse blood if testing a sulphonamide
	Gradient diffusion	MHA with 5% sheep blood/DCS in broth/35°C in 5% CO_2 for 20–24 hours	Use a 1.0 MacFarland inoculum for mucoid strains
Listeria spp.	Broth microdilution	CMHB plus 2%–5 % lysed horse blood/DCS/35°C ambient air for 16–20 hours	For AMP and PEN ≤2 µg/mL (susceptible); resistant strains not characterized
Haemophilus spp.	Broth microdilution	HTM broth/DCS/35°C in 5% CO_2 for 20–24 hours	
	Disk diffusion	HTM broth/DCS/35°C in 5% CO_2 for 20–24 hours	
	Gradient diffusion	HTM or MHA with 1% hemoglobin and 1% Isovitalex (BBL) if validated against CLSI/DCS in broth/35°C ambient air for 24 hours	

Neisseria gonorrhoeae	Agar dilution	GC agar base with 1% defined growth supplement (see text)/ DCS/35°C in 5% CO_2 for 20–24 hours	Perform β-lactamase test
	Disk diffusion	GC agar base with 1% defined growth supplement (see text)/ DCS/35°C in 5% CO_2 for 20–24 hours	Cysteine-free medium not required; perform β-lactamase test
	Gradient diffusion	GC agar base with 1% defined growth supplement (see text)/ DCS/35°C in 5% CO_2 for 20–24 hours	
Neisseria meningitidis	Broth microdilution	CAMHB plus 2%–5% (v/v) lysed horse blood/DCS/35°C ambient air for 16–20 hours	
	Agar dilution	MHA plus 5% (v/v) sheep blood/DCS/35°C ambient air for 16–20 hours	Use 2%–5% (v/v) lysed horse blood instead of sheep blood if sulphonamides are tested
	Gradient diffusion	MHA plus 5% sheep blood or MHA plus 1% hemoglobin and 1% Isolvitalex (BBL)/DCS in broth/35°C in 5% CO2 for 18–24 hours	
Vibrio cholerae	Broth microdilution; agar dilution	CAMHB; MHA/growth method or DCS/35°C ambient air for 16–20 hours	
	Disk diffusion	MHA/growth method of DCS/35°C ambient air for 16–18 hours

■ **FIGURE 17-25** Positive β-lactamase nitrocefin test for *S. aureus*. (Courtesy of Calgary Laboratory Services.)

First-generation cephalosporins and penicillinase-resistant penicillins (methicillin, nafcillin, oxacillin, dicloxacillin, etc.) have a modified β-lactam ring that resists enzymatic digestion by staphylococcal β-lactamases. These antibiotics can, however,

be inactivated in vitro by a strain that produces a large quantity of penicillinase. These *S. aureus* strains usually exhibit borderline resistance to oxacillin (MIC, 4 μg/mL) (called BORSAs), but retain susceptibility to other commonly used antimicrobial agents.[291] In contrast, MRSA strains that are resistant to oxacillin by means of altered penicillin-binding proteins usually have an oxacillin MIC ≥ 4 μg/mL, and are typically multi-resistant to other classes of antimicrobial agents, as discussed below. The clinical significance of BORSA strains has been restricted to superficial skin and soft tissue infections. Kernodle and colleagues described a group of such strains of *Staphylococcus aureus* of a certain phage type that produced clinically significant wound infections.[313]

High-level resistance to penicillin in enterococci can also be detected by the nitrocefin test. A positive nitrocefin test indicates resistance to all penicillinase-labile penicillins (i.e., ampicillin, amoxicillin, piperacillin). The β-lactamase, which resembles that of staphylococci, is carried on a plasmid,[409] but the enterococcal and staphylococcal plasmids themselves

are not homologous.[651] Strains of *Enterococcus faecalis* that produce β-lactamase that also exhibit high-level resistance to aminoglycosides have become epidemic in some institutions.[17,527] If the nitrocefin disk test is not performed on isolates, resistance to β-lactam antibiotics may not be recognized. In a survey of New Jersey laboratories by Tenover and colleagues, a β-lactamase-producing strain of *E. faecalis* was recognized as resistant to penicillin by only 66% of 76 participants and to ampicillin by only a few (8%) laboratories. Only 3 of the 76 laboratories recognized that the strain produced β-lactamase, emphasizing the importance of performing a β-lactamase test on enterococci, especially if they have been isolated from sterile sites.[611] A combination of piperacillin and tazobactam is effective against β-lactamase-producing enterococci,[438] and this agent may provide synergy with gentamicin provided the enterococcal strain does not demonstrate high-level resistance to aminoglycosides as discussed below.

Detection of Resistance in Gram-Positive Bacteria

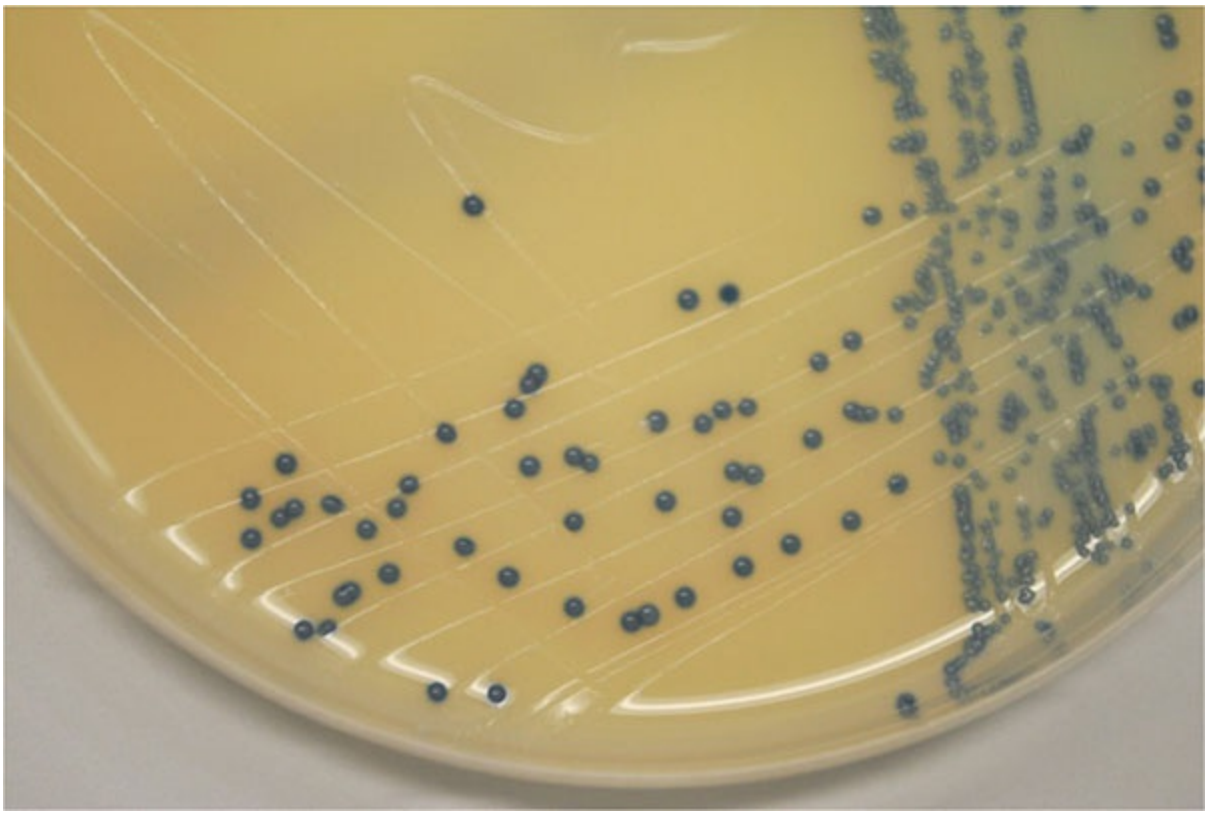
Staphylococci

Methicillin (Oxacillin)-Resistant Staphylococci

Phenotypic Detection. *Staphylococcus* infections are the most common cause of

nosocomial infections worldwide. *Staphylococcus* spp. resistant to semisynthetic penicillins (i.e., methicillin, nafcillin, oxacillin, and cloxacillin) have become a serious threat in both nosocomial and ambulatory healthcare settings.[317,374,688] Worldwide, the rates of MRSA in clinical isolates range from a low of <1% to 3% in the Netherlands and Denmark, to the mid-level of ~20% to 30% for countries such as Germany and Canada, to a high of 50% to 60% in Japan and the United States.[557,579,581] Because most MRSA surveillance data is accrued for nosocomial isolates, the true incidence of ambulatory community-acquired MRSA infections in most jurisdictions is not known.

Because of the global problems being encountered within acute-care facilities due to both hospital-acquired and community-acquired MRSA, many countries have implemented targeted or universal screening of patients on admission. Although MRSA isolates readily grow on routine nonselective media, chromogenic agar has been widely adopted in clinical laboratories to rapidly screen for the presence of MRSA in surveillance and clinical specimens. Several chromagar formulations are available that contain chromogenic substrates and various inhibitors that combine primary growth and selective detection of MRSA, including MRSA ID (bioMérieux), MRSA Select (BioRad), CHROMagar MRSA (BD Diagnostics), and Denim Blue (Oxoid) (Fig. 17-26).[195,414] However, some chromogenic agars will not grow all strains of MRSA, but a cefoxitin disk may be placed onto chromogenic or nonselective media as an alternate method for enhancing detection of MRSA by growth around the disk.[247] Few studies have, however, compared the performance of chromagar with either secondary susceptibility testing of the isolates or detection of the *mec*A gene. Flayhart and colleagues found that the CHROMagar MRSA recovered 95.2% of MRSA isolates and have a specificity of 99.7% compared to a sensitivity and specificity of 94.4% and 96.7% for oxacillin broth microdilution MIC; 94.3% and 96.7% for oxacillin screen agar; 93.7% and 98.5% for PBP2′ latex agglutination; 95% and 98.1% for cefoxitin disk diffusion; and 95.1% and 98.1% for *mec*A polymerase chain reaction (PCR).[195] Healthcare jurisdictions with high rates of MRSA have also implemented rapid commercial real-time PCR assays in place of culture-based methods because of their greater sensitivity and much more rapid turnaround time (see Detection of the *mec*A Gene below).



■ **FIGURE 17-26** MRSA colonies growing on denim blue agar (Oxoid). (Courtesy of Calgary Laboratory Services.)

CLSI defines oxacillin resistance in *S. aureus* as an MIC ≥ 4 μg/mL,[121,122] and all strains meeting this definition are characterized as "MRSA" even though methicillin is no longer used either to test strains in the laboratory or as a therapeutic agent. Although several other resistance mechanisms may result in MRSA (i.e., high level of β-lactamase production (BORSA) or production of modified PBPs (MOD-PBP) with decreased drug affinity), the vast majority of clinical strains that exhibit this type of resistance have acquired the *mec*A gene that encodes for PBP2a which has decreased affinity for binding the compound (See Mechanisms of Resistance).[146,239,628] MRSA strains with a *mec*A gene may either be homogenous or heterogenous in their expression of this resistance phenotype. Accurate detection of heterogenous strains is particularly challenging because some cells will test susceptible while others will be resistant (i.e., typically only 1×10^4 to 1×10^8 cells in a population will express the *mec*A gene).[238] Staphylococci carrying a *mec*A gene with heterogenous expression, may therefore either be missed using the established MIC breakpoint alone because they can have borderline MICs between 2 to 4 μg/mL, or be confused with strains that have borderline resistance due to another mechanism (i.e., BORSA if the β-lactamase test is also positive). Table 17-18 outlines several scenarios that may be encountered in

the clinical laboratory when screening *S. aureus* for oxacillin resistance. MRSA strains carrying the *mec*A gene are also usually multidrug-resistant to one or more classes of other antimicrobial agents. The overall antibiogram profile of a clinical isolate should, therefore, also be used as another important clue that points to this type of resistance mechanism. In most of these cases, however, molecular detection of the *mec*A gene is the most expedient way to determine whether one is truly dealing with a *mec*A-positive strain, because errors in the identification and reporting could have potentially serious clinical and epidemiologic outcomes.

1123

TABLE 17-18 Possible *S. aureus* Oxacillin Resistance Phenotypes

Scenario	Vitek Oxacillin Results	Cefoxitin (30 µg) Disk Screen Results	Resistance Profile to Other Drugs
1	Resistant	Resistant	Multidrug resistant[a]
2	Sensitive	Sensitive	Multidrug resistant[a]
3	Resistant	Resistant	R to β-lactams[b] but S to all other drugs
4	Sensitive Resistant	Resistant Sensitive	Discrepant results between oxacillin and cefoxitin screen

[a] Resistant to two of gentamicin, tetracycline, clindamycin, or erythromycin.
[b] Resistant to penicillin, oxacillin, and cefazolin.

Antibiotic susceptibility testing for reliable detection of MRSA should be done using an MIC method. Broth microdilution is the reference method for detection of oxacillin resistance in *S. aureus*, and in most strains reliably demonstrate the breakpoints recommended by CLSI.[121,122] As of 2013,[121] CLSI has eliminated the use of oxacillin disk testing for *Staphylococcus* spp. Cefoxitin has been shown to be a more sensitive surrogate than oxacillin for detection of MRSA because of its more reliable induction of the *mec*A gene.[121,122,525,559,592] A large multilaboratory study involving the Centers for Disease Control and Prevention (CDC) also investigated whether a cefoxitin broth microdilution MIC breakpoint would correlate with the presence of the *mec*A gene in staphylococci.[70] Using breakpoints of ≤4 µg/mL for *mec*A-negative and ≥6 or 8 µg/mL for *mec*A-positive isolates, sensitivity and specificity compared to the presence of the *mec*A gene for *S. aureus* at 18 hours of incubation were 99.7% to 100% for three CAMHBs. For coagulase-negative staphylococci isolates at 24 hours of incubation, breakpoints of ≤2 µg/mL for *mec*A-negative and ≥4 µg/mL for *mec*A-positive strains gave sensitivities and specificities of 94% to 99% and 69% to 80%, respectively. Routine disk diffusion procedures may be used to perform the cefoxitin disk (30 µg) test on *S. aureus* isolates, and a zone diameter of ≥20 mm is interpreted as susceptible

to oxacillin, while one that is ≤19 mm is interpreted as resistant. A broth microdilution screen using the CLSI cefoxitin breakpoints for *S. aureus* would therefore provide an alternate method that is highly reliable for detection of MRSA.[121,122] This method, however, appears to be less reliable for some species of coagulase-negative staphylococci.

MHA supplemented with 2% sodium chloride and 6 µg of oxacillin, methicillin, or nafcillin per mL is the agar screen method recommended by CLSI.[121,122] Colonies are grown overnight on nonselective agar and transferred to tryptic soy broth to make a 0.5 McFarland suspension. The plate is then inoculated in one quadrant or an area 10 to 15 mm in diameter using either a cotton swab or 1-µL loop. Resistance to oxacillin is indicated if there is growth of more than one colony of the plate after incubation a full 24 hours at 35°C. QC of oxacillin screen plates is done using *S. aureus* ATCC 29213 (susceptible strain) and *S. aureus* ATCC 43300 (resistant strain).

Standardizing testing for coagulase-negative staphylococci has proven to be more of a challenge because of the variability between the many species contained under this umbrella term. Broth microdilution breakpoints for diagnosis of oxacillin resistance in coagulase-negative staphylococci were lowered by CLSI in 1999 due to concerns that *mec*A-positive strains were not being reliable detected (Table 17-19). Although these revised breakpoint criteria improved detection in certain species (i.e., *S. epidermidis*, *S. haemolyticus,* and *S. hominis*), they had less specificity for other species (i.e., *S. saprophyticus* and *S. lugdenensis*) so that disk and MIC methods indicated resistance but the strains did not carry an *mecA* gene.[191,224] In 2005, CLSI recommended that the disk and MIC oxacillin breakpoints for *S. aureus* be used to interpret resistance in *S. lugdenensis*.[119] Similar to *S. aureus*, the cefoxitin-30-µg disk test has replaced the oxacillin-1-µg disk test for accurate detection of *S. lugdenensis* and other coagulase-negative staphylococci that are *mec*A-positive.[121,122] The recommended breakpoints for the cefoxitin-30-µg disk test for *S. lugdenensis* are the same as *S. aureus*, but the zone diameters are higher for all other species of coagulase-negative staphylococci with ≤24 mm being susceptible and ≥25 mm being resistant (Table 17-20).

TABLE 17-19 CLSI Breakpoints (MIC µg/mL) for *Staphylococcus* spp.

Antibiotic	Species	S	I	R
Oxacillin	*S. aureus*	≤2	—	≥4[a]
Oxacillin	*S. lugdenensis*	≤2	—	≥4
Oxacillin	Other CONS	≤0.25	—	≥0.5
Vancomycin	*S. aureus*	≤2	4–8[b]	≥16
Vancomycin	*S. lugdenensis*	≤4	8–16	≥32
Vancomycin	Other CONS	≤4	8–16	≥32

[a] Report as MRSA—send isolates with MIC >4 µg/mL to a reference laboratory.
[b] hVISA/VRSA—send isolates with MIC >8 µg/mL to a reference laboratory.
S, susceptible; I, intermediate; R, resistant.

Detection of the *mecA* Gene. The gold standard for confirmation of phenotypic oxacillin resistance in clinical strains of staphylococci is detection of the *mec*A gene using either a commercial latex agglutination test and/or molecular detection methods. Table 17-18 outlines four scenarios that will be routinely encountered clinically when performing oxacillin resistance testing of *S. aureus* that warrant such confirmation.

1124

TABLE 17-20 CLSI Zone Diameter Breakpoints for Cefoxitin 30 µg Screen

Species	S	I	R
S. aureus	≥22 mm	—	≤21 mm[b]
S. lugdenensis	≥22 mm	—	≤21 mm
Other CONS	≥25 mm	—	≤24 mm

[a] Adapted from reference 122.
[b] Report as MRSA.
S, susceptible; I, intermediate; R, resistant, CONS, coagulase-negative staphylococci.

A latex agglutination test that rapidly detected PBP 2′ as an indicator of MRSA was originally developed in Japan.[417] Several commercial latex agglutination methods that can be rapidly performed on a high number of strains are available, but only the MRSA-Screen test (Deika-Seiken Co. Ltd., Tokyo, Japan) and the PBP 2′ test (Oxoid Ltd, Basingstoke, United Kingdom) are approved for use by the FDA in the United States. Both of these tests use latex agglutination to detect the presence of altered PBP 2a (PBP 2) as evidence for the presence of the *mec*A gene. A slide latex agglutination test may also differentiate MRSA from *S. aureus* isolates with borderline oxacillin resistance.[361] The MRSA-Screen test should only be used to test *S. aureus* for which it has been extensively evaluated and shown to have a high sensitivity and specificity for accurate detection of the *mec*A gene encoded resistance.[593] The MRSA-Screen test has, however, not performed as well in directly testing coagulase-negative isolates, and the procedure has required an increased inoculum or incubation time or, in some cases, induction with either oxacillin or cefoxitin for accurate detection to occur.[677] Coagulase-negative staphylococci including *S. lugdenensis* are tested using organism growth around either a oxacillin-1-μg or cefoxitin-30-μg disk. The Oxoid PBP 2′ test can be used for all staphylococcal isolates, but again, induction with cefoxitin or oxacillin should be performed when testing coagulase-negative staphylococci. Few comparative clinical evaluations of the Oxoid PBP 2′ test have so far been done.

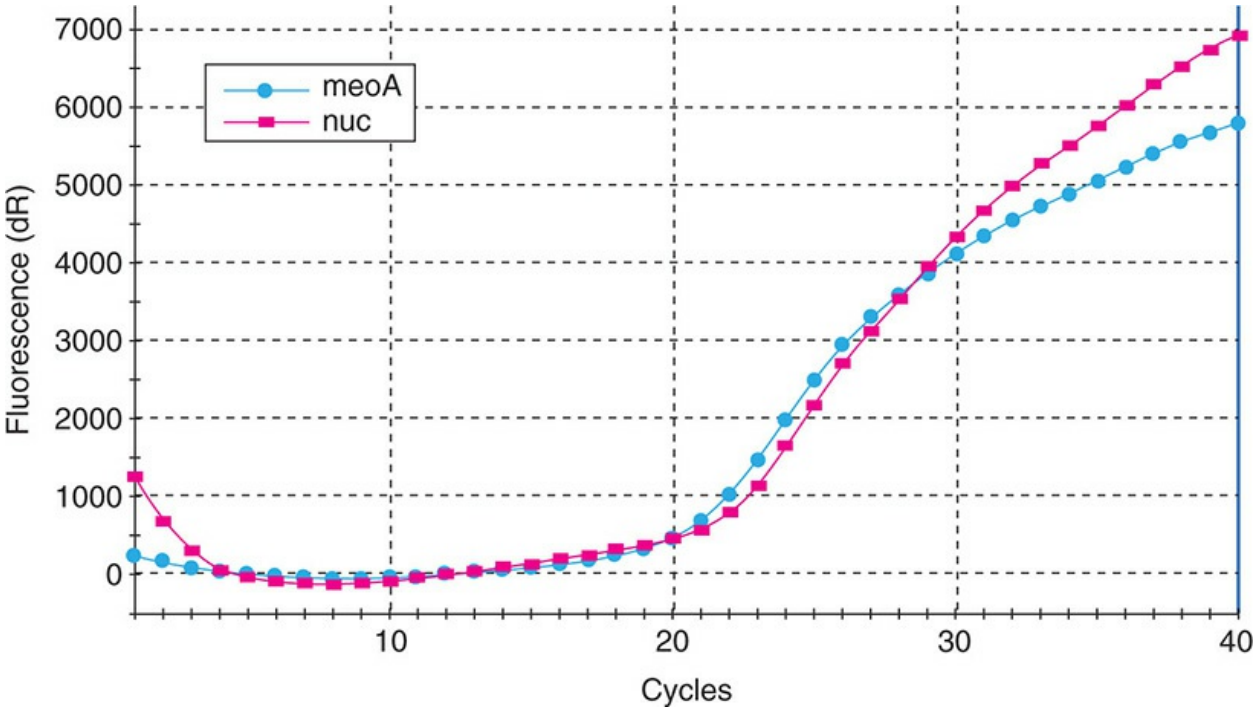
Many larger clinical microbiology laboratories have been using in-house PCR tests to confirm the presence of the *mec*A gene. In-house PCR tests for *mec*A detection have also included the *nuc* and *coa* genes as a specific marker that allows simultaneous identification of *S. aureus*.[75] A quadriplex assay has been developed that will simultaneously distinguish *S. aureus* from coagulase-negative staphylococci using

the 16S rRNA and *nuc* gene markers, that also detect both methicillin (*mec*A) and mupirocin (*mup*A) resistance.[687] Other PCR MRSA detection assays have also used other staphylococcal gene markers (i.e., *femA*, *femB*, *sa*442, and *orfX*), and of these, the open reading frame (*orfX*) where the staphylococcal cassette chromosome *mec* (SCCmec) integrates with the *S. aureus* chromosome has been commercially exploited to develop several rapid detection assays as outlined below.[95] Figure 17-27 shows real-time PCR detection of the *nuc* and *mec*A genes in a *S. aureus* blood culture isolate that demonstrated a Rule 1 phenotypic resistance profile according to Table 17-18.[178] This isolate was confirmed to be *S. aureus* due to the presence of the *nuc* gene, and MRSA due to the presence of the *mec*A gene.

Recent commercial development of rapid test platforms has, however, made real-time PCR detection of the *mec*A gene available to most facilities. Readers are referred to several excellent recent reviews for a detailed discussion of all of the rapid molecular tests currently available for detection of MRSA, but only a brief discussion is provided herein of the two commercial assays currently in use in the United States.[27,95,442,579] The BD GeneOhm MRSA assay (formerly IDI-MRSA assay) (BD GeneOhm, San Diego, CA) was the first commercial real-time PCR assay to be approved by the US FDA for detection of MRSA from nasal surveillance swabs. This multiplex assay uses molecular beacons directed toward multiple targets within SCC*mec* and *orfX* genes to simultaneously identify and detect resistance and differentiate

1125

methicillin-sensitive *S. aureus* from MRSA isolate and *mec*A carrying strains of coagulase-negative staphylococci.[95] The BD GeneOhm assay was initially evaluated by Huletsky and colleagues at IDI,[267] and many subsequent clinical evaluations have shown similar results. The overall ranges for reported sensitivity, specificity, PPV, and NPV were 84.3% to 100%, 93.5% to 99%, 61.1% to 94%, and 97% to 99.7%, respectively.[95,144,186,363,449,568] The high false-positivity rate for this test (i.e., up to 5%) occurs because some *mec*A-negative *S. aureus* continues to carry a fragment of the SCC*mec* element near the insertion site.[95,554] However, this assay has shown reliable detection of a variety of SCC*mec* genotypes in a large number of well-characterized strains from the United States and Taiwan.[59]



■ **FIGURE 17-27** Real-time PCR to detect *mec*A gene in *S. aureus*. (Courtesy of Calgary Laboratory Services.)

The second test to receive US FDA approval was the GeneXpert MRSA assay (Cepheid Diagnostics, Inc., Sunnyvale, CA).[27] This assay also targets SCC*mec* insertion site. The overall ranges for assay performance published by the company for sensitivity, specificity, PPV, and NPV were 86.3% to 96.5%, 90.4% to 94.9%, 80.5% to 90.4%, and 96.6% to 99.7%, respectively.[95] Although some recent clinical evaluations of the GeneXpert assay report even better performance,[13,259,337] studies found a high false-negative rate (7.7% to 12.9%), again due to *S. aureus* isolates that harbor a SCC*mec* element that is *mec*A-negative.[12,554] The GeneXpert MRSA assay is easy to perform on a rapid, fully automated random-access platform that requires minimal specimen processing and provides results in 1.5 to 2 hours. Brenwald and colleagues found that the GeneXpert MRSA assay had a similar performance when performed as a point of care test on the ward compared to the laboratory, but results were available>10 hours quicker at the bedside.[67]

Because of the lack of homology between the nucleotide sequence of the *mec*C gene compared to that of *mec*A, *S. aureus* strains carrying a *mec*C determinant may be difficult for diagnostic laboratories to detect using *mec*A-based in-house or commercial PCR assays. Latex agglutination assay that detects PBP2a will also not detect *S. aureus* strains that have a *mec*C gene because of their altered PBP structure. Skov and colleagues, however, demonstrated that cefoxitin used with EUCAST methodology

reliably detected *mec*C-positive *S. aureus* isolates.[559] Newer version of the commercial real-time PCR MRSA detection assays will need to use primers designed to detect both the *mec*A and *mec*C genes as this type of resistance may be more widespread than currently documented. One such assay has been released on the BD Max system (BD, Sparks, MD).

Reporting. There is clinical evidence that isolates of *S. aureus* that are resistant to oxacillin do not respond in vivo to cephalosporin therapy; the same approach has recently been suggested for *S. epidermidis*. As of 2013,[121] CLSI has eliminated breakpoints for all β-lactam drugs for *Staphylococcus* spp. except for penicillin, oxacillin/cefoxitin, and has added ceftaroline, a cephem with anti-MRSA activity that should be selectively tested and reported for MRSA isolates. This decision was based on the fact that breakpoints had never been extensively evaluated for many β-lactam drugs for *Staphylococcus* spp., and the results of penicillin and oxacillin can be used to predict susceptibility to penicillinase-labile penicillin drugs and penicillinase-stable penicillins respectively. Table 17-21 outlines the current CLSI recommendations for reporting β-lactam results for *Staphylococcus* spp. based on testing penicillin and oxacillin/cefoxitin alone. Laboratories should also have protocols in place for performing extended susceptibility testing on other antibiotics for multidrug-resistant isolates. This protocol should include criteria for referral of multidrug-resistant isolates to a reference laboratory for confirmatory susceptibility testing and molecular genotyping. Infection Prevention and Control and/or public health agencies should be immediately notified of patients who are suspected or confirmed to have MRSA detected either from surveillance or clinical samples.

TABLE 17-21 Prediction of Susceptibility of *S. aureus* to β-Lactams Based on Penicillin/Oxacillin Test Results

Penicillin	Oxacillin (Cefoxitin)	Predicts
S	S	*Susceptible to:* • All penicillins • β-Lactam/β-lactamase inhibitor combinations • Cephems • Carbapenems
R	S	*Resistant to:* • Penicillinase-labile penicillins *Susceptible to:* • Penicillinase-stable penicillins • β-Lactam/β-lactamase inhibitor combinations

		• Cephems • Carbapenems
R	R	*Resistant to:* • All β-lactams except cephems with anti-MRSA activity (e.g., ceftaroline)

Adapted from reference 122.

Decreased Vancomycin Susceptibility in Staphylococci. Increased use of vancomycin has most likely resulted in the rapidly evolving problem of decreased susceptibility of staphylococci to this agent. Currently, the incidence of decreased vancomycin susceptibility in *S. aureus* remains low in some countries such as the United States (<1%),[556] and nonexistent in others.[393] Howden and colleagues have recently published an excellent review on this topic.[264]Although this problem has been found in *Staphylococcus* spp. other than *S. aureus*, the emergence of VISA, and more recently VRSA are of utmost concern because of the potential for nosocomial transmission of these strains, and increased mortality would undoubtedly result.[97,556,665] Invasive infections due to *S. aureus* are common, and few drugs are currently available to effectively treat infection due to VISA/VRSA/VRSA.[325,556,660] Glycopeptide-intermediate (GISA) or –resistance (GRSA) are also terms used for these types of *S. aureus* because these strains also exhibit resistance to other glycopeptide antibiotics such as teicoplanin.[605]

MRSA with decreased vancomycin susceptibility was first reported by Hiramatsu and colleagues in 1997.[254] The resistance mechanism heterogeneously expressed on initial

testing by broth microdilution gave an MIC that was susceptible, but a subgroup of cells tested intermediate according to CLSI criteria with an MIC of 4 to 8 mg/L. Similar to oxacillin resistance in staphylococci, decreased susceptibility to vancomycin may be expressed homogeneously or strains may be heteroresistant (i.e., designated as hVISA/VRSA).[264] VRSA strains in contrast that have acquired a *van*A gene from enterococci continuously express high-level resistance (i.e., MICs ≥ 32 μg/mL).[612]

Phenotypic Detection. Detection of hVISA/VRSA strains has been especially problematic, and an ideal method that is highly sensitive and easy to perform has yet to be developed. Table 17-22 summarizes the performance of methods that have been

used to detect hVISA/VRSA. The reference method for hVISA/VRSA detection is the population analysis profile—area under the curve calculation (PAP-AUC), which involves population analysis to determine the percentage of bacteria is resistant at each of a series of MIC levels.[264] A standard inoculum of an overnight broth culture is plated onto brain heart infusion (BHI) agar plates containing increasing concentrations of vancomycin from 0.5 to 4 μg/mL. Plate counts are graphed to calculate the proportion of cells that are vancomycin-resistant at each dilution. Wootton and colleagues showed that a PAP–AUC concentration ratio between 0.9 and 1.3 is indicative of hVISA/VRSA while a ratio <0.9 is susceptible.[669] The PAP–AUC method even in its more efficient forms is too labor intensive to be routinely performed in a clinical laboratory on a large number of isolates.

Broth microdilution remains the recommended clinical method for detection of hVISA/VRSA. CLSI lowered its breakpoint in 2007 for the vancomycin-intermediate range to 4 to 8 μg/mL because of vancomycin failure to treat serious hVISA/VRSA infections caused by strains with an MIC = 4 μg/mL.[121,122] *S. aur*eus that have an MIC ≤ 4 μg/mL are considered susceptible while those with an MIC ≥ 16 μg/mL are resistant. EUCAST does not define an intermediate range for *S. aureus* but the vancomycin resistance breakpoint was decreased in 2009 to an MIC > 2 μg/mL which is at the upper range for the MIC distribution for wild-type strains (www.eucast.org/clinical-breakpoints). *S. aureus* isolates that have an elevated vancomycin MIC (i.e., ≥8 μg/mL) should be sent to a reference laboratory for confirmatory testing. Laboratories that do not routinely perform broth microdilution as their main susceptibility method may elect to use this method to confirm hVISA/VRSA in clinical isolates with an elevated vancomycin MIC result using another method as outlined below. Alternatively, some laboratories perform broth microdilution on all invasive *S. aureus* but use another susceptibility method to test noninvasive isolates (i.e., superficial wounds).

TABLE 17-22 Ability of Different Methods to Detect Vancomycin Susceptibility in *S. aureus*

Vancomycin MIC (mg/L)	MIC Method	Disk Diffusion Method[a]	Vancomycin Agar Screen
≤2 (S)	Yes	No	Yes
4 (I)	Yes	No	Variable
8 (I)	Yes	No	Yes
16 (R)	Yes	No	Yes
≥32 (R)	Yes	Yes	Yes

[a] Isolates that have a zone diameter of ≥7 mm should be retested using an MIC method.
Adapted from reference 122.

Although coagulase-negative staphylococci have been reported with decreased susceptibility to vancomycin, so far no *van*A gene positive strains have been found. Broth microdilution vancomycin breakpoints for coagulase-negative staphylococci remain higher than *S. aureus*; susceptible is defined as an MIC ≤ 4 μg/mL, intermediate is defined as an MIC of 8 to 16 μg/mL, and resistant is defined as an MIC ≥ 32 μg/mL.[121,122] Coagulase-negative staphylococcal isolates with an elevated vancomycin MIC ≥ 32 μg/mL should be sent to a reference laboratory for further confirmatory testing.

Other screening methods that have been used to detect hVISA/VRSA include a BHI agar screening plate containing either 5 or 6 μg/mL of vancomycin similar to the original method used by Hiramatsu,[254,273] and also currently used to screen for vancomycin resistance in enterococci as discussed below. A 10-μL drop on a 0.5 MacFarland isolate suspension is used to spot a 10 to 15 mm diameter of a BHI plate. More than one colony or light growth on the plate after 24 hours of incubation is considered positive and presumptive evidence for the presence of VISA/VRSA or VRSA. However, confirmatory testing should be done using an MIC method, either broth microdilution or an Etest.

Vancomycin Etest strips have been used alone or in combination with a teicoplanin strip (i.e., macro Etest or MET).[393,517] However, Etest glycopeptides resistance detection (GRD) strips have recently been developed to detect hVISA/VRSA. Etest GRD strips have had limited clinical evaluation to date, but a recent comparison of

Etest GRD and the curve (PAP–AUC) analysis showed less than optimal performance.[517] Etest methods are known to produce higher vancomycin MIC results than broth microdilution and so "false resistance" may be reported using these methods if confirmatory tests are not done. *S. aureus* isolates with an elevated Etest MIC ≥ 8 μg/mL should be referred to a reference laboratory for confirmatory testing (i.e., CDC in the United States).

Disk diffusion tests are unreliable and will not distinguish VISA/VRSA from wild-type strains and should not be used. For this reason, CLSI has recently eliminated vancomycin disk screening criteria for VISA/VRSA.[122] Laboratories using automated susceptibility systems will also miss detecting hVISA/VRSA unless additional confirmatory testing is done on *S. aureus* strains with elevated vancomycin MIC ≥ 2 mg/L.[587] Similarly, *S. aureus* strains with vancomycin MICs between 1.5 and 2 μg/mL according to the MET Etest method should have a broth microdilution test performed.

Reporting. Isolation of hVISA/VRSA is considered to be an urgent clinical, infection control and public health issue. Because hVISA/VRSA isolates are often multidrug-resistant, extended susceptibility testing for alternate therapeutic drugs should be routinely performed and reported on invasive strains including linezolid, daptomycin, fluoroquinolones, rifampin, tigecycline, and ceftaroline. Laboratories

should have protocols in place for performing extended susceptibility testing on other antibiotics for multidrug-resistant isolates, or immediately refer the isolate to a reference laboratory where such testing can be done. Criteria for referral of multidrug-resistant isolates to a reference laboratory for confirmatory susceptibility testing and molecular genotyping should be included in the laboratory protocol. Infection Prevention and Control and/or the public health agencies should be immediately notified of patients who are suspected or confirmed to have hVISA/VRSA detected either from surveillance or clinical samples.

Inducible Clindamycin Resistance. Resistance to macrolides among staphylococci is mediated either by active efflux of antibiotics from the bacterial cells (***msrA***) or by modification of ribosomal targets (usually *ermA* or *ermC*).[344]Ribosomal modification may be expressed constitutively or it may be inducible.[135] Resistance to erythromycin is more easily detected than resistance to clindamycin. Strains that are susceptible to erythromycin are reliably susceptible to clindamycin, but the opposite is not necessarily true.

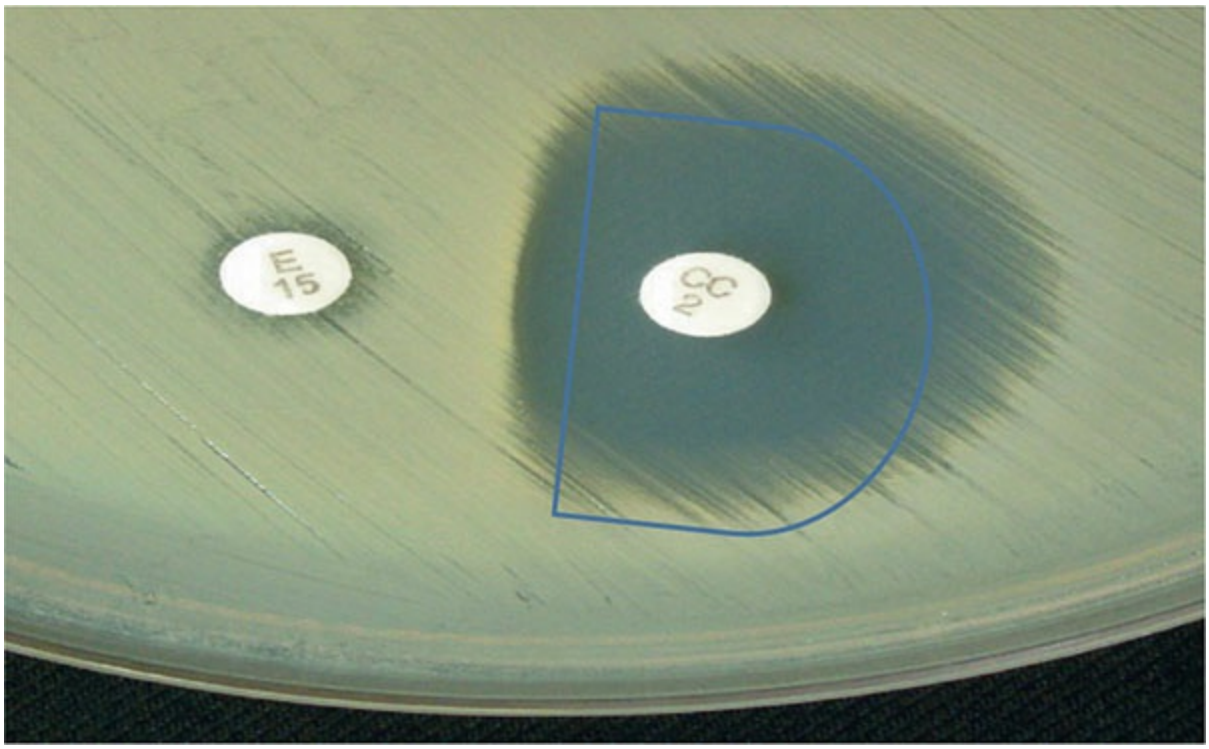
Strains of staphylococci that express constitutive resistance to erythromycin and clindamycin present little difficulty, because they will be detected as resistant in vitro. When resistance is inducible, however, there may be a dissociation occurring between

the erythromycin and clindamycin susceptibility results (Table 17-23). Resistance to 14-membered and 15-membered macrolides, such as erythromycin, is more readily induced than is resistance to 16-membered macrolides and lincosamides, such as clindamycin. There is evidence that inducible resistance to clindamycin is clinically significant in not only staphylococci, but also β-hemolytic streptococci and *S. pneumoniae*.[300,341,390] CLSI recommends that an induction test be performed before reporting clindamycin as susceptible in *S. aureus* isolates that demonstrate discrepant susceptibility to erythromycin and clindamycin (i.e., erythromycin is resistant but clindamycin is susceptible).[121,122] For other staphylococci, β-hemolytic streptococci and *S. pneumoniae*, a clindamycin induction test should be done if requested.[121,122] The D-zone double-disk test for inducible resistance to clindamycin is based on the principle that erythromycin is a potent inducer of the *erm* gene (i.e., MLS_B type).[192,295] If disks containing erythromycin (15 µg) and clindamycin (2 µg) are placed in proximity (i.e., 15 to 26 mm) and resistance is induced by erythromycin, the zone of inhibition around the clindamycin disk will be distorted. The resultant flattening of the zone of inhibition produces a D-shape and is indicative of inducible resistance to clindamycin (Fig. 17-28). Alternatively, a broth microdilution test where 1 µg/mL of erythromycin and 0.5 µg/mL of clindamycin are placed in the same well can be used to detect inducible clindamycin resistance in β-hemolytic streptococci and *S. pneumoniae*.[55,121,122] This pattern indicates inducible resistance, and clindamycin should then be reported as resistant.

TABLE 17-23 Phenotypic Macrolide/Lincosamide Resistance Profiles

Mechanism	Resistance Gene	Erythromycin	Clindamycin
Efflux	*msrA*	R	S D-ZONE Test (–)
Ribosome alteration	*ermA* or *ermC*	R	S→R (inducible) D-ZONE Test (+)
Ribosome alteration	*ermA* or *ermC*	R	R (constitutive) D-ZONE Test (–)

*msr*A, macrolide streptogramin (type B) resistance; *erm*, erythromycin ribosome methylase (MLS_B) resistance.



■ **FIGURE 17-28** D-zone test for Clindamycin inducibility. (Courtesy of Calgary Laboratory Services.)

Reporting. Isolates that have a positive D-zone test, or those that show induction in the broth microdilution test should be reported as resistant to clindamycin. A comment should be added to the report stating "This isolate is presumed to be clindamycin resistant based on detection of inducible clindamycin resistance.[121,122] In the absence of inducible resistance (i.e., negative D-zone test), the isolate may be reported as clindamycin susceptible based on the in vitro susceptibility result. Laboratories should also have protocols in place for performing extended susceptibility testing on other antibiotics for multidrug-resistant isolates. This protocol should include criteria for referral of multidrug-resistant isolates to a reference laboratory for confirmatory susceptibility testing and molecular genotyping. Infection Prevention and Control and/or public health agencies should be immediately notified of patients who are suspected or confirmed to have MRSA detected either from surveillance or clinical samples.

Enterococci

The mainstay of antimicrobial therapy of serious invasive enterococcal infections for decades has been combined therapy with a cell wall agent, either a β-lactam or

vancomycin and an aminoglycoside agent.[17,520] Although enterococci are often tolerant to the actions of β-lactams and are inherently resistant to aminoglycosides (i.e., MICs range of 8 to 256 μg/mL), reliable synergistic bactericidal activity results from combination therapy because the cell wall agent allows the aminoglycoside to be taken up into the cell where it acts on its ribosomal target. However, this approach has been

seriously undermined in the last 50 years, initially by the development of resistance to penicillin but more recently due to the increasing incidence of VRE,[98] and the development of high-level aminoglycoside resistance so that synergy to kill enterococci can no longer be readily achieved.[17] The subject has been recently reviewed by several authors.[216,258,657] More recently, resistance has also been detected in newer agents including linezolid and daptomycin dubbed the "antibiotics of last resort," especially in strains of *E. faecium*.[15,18,197]

Several other factors have coalesced to bring about the current situation of having to routinely treat serious multidrug-resistant enterococcal infections in hospitals worldwide.[17,15,250,658] Enterococci were mostly *E. faecalis* in US hospitals in the late 1970s.*E. faecium* has since become the predominant *Enterococcus* spp. isolated in hospitalized patients, and is now second only to *S. aureus* as a cause of nosocomial infection.[17] *E. faecium* is much more commonly resistant to ampicillin and vancomycin than *E. faecalis*.[250] This "enterococcal species displacement" has primarily occurred because of the increased use of vancomycin and other broad-spectrum antibiotics such as the third-generation cephalosporins, coupled with suboptimal infection control measures.[17,198] There is also evidence for transmission of multidrug-resistant *Enterococcus* strains from humans, animals, and the environment.[142,166,657]

β-Lactam Resistance

Many strains of enterococci, particularly *Enterococcus faecium*, are intrinsically resistant to β-lactam antibiotics because they possess binding proteins with low affinity for these drugs. In general, ampicillin is more effective than penicillin in vitro and is the preferred agent for susceptible enterococci. The cephalosporins are uniformly ineffective against enterococci and should not be tested. The detection of β-lactamase production in *Enterococcus* spp. is outlined above under β-Lactamase Testing.

High-Level Aminoglycoside Resistance

Acquired high-level aminoglycoside resistance (HLR) results in MICs in enterococci that are well above the normal concentration tested in the clinical laboratory (e.g., ≥2,000 μg/mL for streptomycin and ≥500 μg/mL for gentamicin). Detection of HLR of enterococci to aminoglycosides is important because these strains are not inhibited synergistically by combination therapy with β-lactam antibiotics.[404] Although labor-intensive time-kill studies were used to predict synergy between an aminoglycoside and a cell wall agent, several screening methods are now used in the clinical laboratory. *E. faecium,* however, is inherently resistant to synergy between tobramycin, netilmicin, kanamycin, or amikacin and a cell wall agent, and in vitro testing need not be done. Synergy testing is only done to detect HLR for either gentamicin and/or streptomycin in *E. faecium* or *E. faecalis*.[408] Commonly used methods for detection of HLR in enterococci are briefly described below.

Many clinical laboratories use an automated broth microdilution system to screen for HLR. Concentrations of 1,000 mg/L of streptomycin and 500 mg/L of gentamicin are used as recommended breakpoints.[121,122,590] Alternatively, a broth microdilution panel (Pasco, MicroScan) using BHI media supplemented with similar antibiotic concentrations in two aminoglycoside synergy wells may be used.[595] The same standard inoculum is used as a routine gram-positive MIC panel (i.e., 5×10^5 CFU/mL). After a minimum of 24 hours' incubation, any growth is considered resistant. Plates may have to be reincubated for an additional 24 hours if there is no growth for streptomycin after the initial incubation period.

Agar dilution plates are also made using BHI media supplemented with the same amount of gentamicin (500 μg) but twice the amount of streptomycin (2,000 μg) as used for HLR microdilution tests.[117,121,122] Agar dilution plates for HLR testing can be purchased from a commercial supplier. A 0.5 MacFarland isolate suspension is prepared and 10 μl is spotted to provide a final inoculum of 10^6 CFU per spot. Plates should be incubated a full 24 hours in ambient air before reading, and streptomycin plates should be reincubated for another 24 hours if there is no growth after the initial incubation. Growth of a single colony on agar dilution plates indicates resistance. Standard disk diffusion testing is performed using antibiotic disks with high concentrations of gentamicin (120 μg) or streptomycin (300 μg).[408] Resistance is defined by a zone diameter ≤6 mm (no zone), and susceptibility by a zone of <10 mm. Strains with zone diameters of 7 to 9 mm should be tested by agar dilution or microdilution methods because a few HLR enterococcal strains have only moderately elevated MICs.[408] Several comparative method evaluation of HLR testing in *Enterococcus* spp. found virtually complete agreement among high-potency disks, commercially available microdilution panels, and a commercial agar dilution "synergy" plate.[408,590,595]

Decreased Susceptibility to Vancomycin

Dilution susceptibility methods may be used to reliably detect VRE (*van*A or *van*B phenotypes) or intrinsic low-level vancomycin resistance (MICs 2 to 32 µg/mL) associated with *E. gallinarum* or *E. casseliflavus* (*van*C phenotype). *E. faecium* or *E. faecalis* that carry a *van*A gene typically have a high vancomycin MIC ≥ 64 µg/mL and teicoplanin MIC ≥ 16 µg/mL, while strains that carry a *van*B gene have a lower vancomycin MICs between 16 to 512 µg/mL, and remain susceptible to teicoplanin (Table 17-24). Historically, many laboratories used the vancomycin agar dilution screen

test to detect VRE.[588] Agar plates contain BHI media supplemented with 6 µg of vancomycin per mL. A 0.5 MacFarland isolate suspension is used to spot a 10 to 15 mm diameter area on the plate providing a final inoculum of 10^5 to 10^6 per spot. The presence of more than one colony or a haze of growth indicates resistance. BHI vancomycin screen plates may also grow *Enterococcus* spp. that carries a *van*C gene but these can be easily identified by phenotypic methods. *E. casseliflavus* typically grow as yellow pigmented colonies, both *E. casseliflavus* and *E. gallinarum* ferment 1% methyl-α-D-glucopyranoside (MGP), and most strains are motile. Commercial vancomycin agar dilution screening plates that contain 6 µg/mL of drug may be purchased from several suppliers.

TABLE 17-24 CLSI Breakpoints (MIC µg/mL) for *Enterococcus* spp.

Antibiotic	Susceptible	Intermediate	Resistant
Penicillin or ampicillin	≤8	—	≥16
Vancomycin	≤4	8–16[a]	≥32[b]
Teicoplanin	≤8	16	≥32[b]

[a] VRE with decreased susceptibility—VanB genotype if teicoplanin (S).
[b] VRE with high-level resistance—VanA genotype if teicoplanin (R).
S, susceptible; I, intermediate; R, resistant.
Adapted from reference 122.

Automated systems may also be used to detect glycopeptides resistance in enterococci, but laboratories should be aware of reported detection problems.[277,636] Recent versions of all of the automated microdilution systems (i.e., Vitek 2, BD Phoenix, and MicroScan) have improved their ability to detect VRE, including low-level intrinsic resistance, but that was not always the case.[176,572] The Vitek Legacy and MicroScan systems initially had problems detecting moderate (*van*B) and low-level (*van*C) resistance in enterococci. Tenover and colleagues evaluated 10 commercial systems for detection of VRE using a broth microdilution method as the standard for testing 50 reference strains.[610] Although an agar dilution screening test accurately detected VRE, increased numbers of minor errors occurred with the disk diffusion test, very major errors were produced by the Vitek Legacy system (10.3%) and the MicroScan Rapid system (20.7%), and the later system also produced some major errors (13.3%). Recent studies also show that automated systems may have problems detecting specific VRE strains. Abele-Horn and colleagues recently performed a clinical validation of Vitek 2 version 4.01 software and found that the system was able to identify 114(94.2%) of enterococcal strains correctly to the species level and classified 119(98.3%) correctly to the glycopeptides resistance genotype level (i.e., VanA, VanB, or VanC genotypes).[3] Six *E. faecium* strains carrying a *van*A gene, and one *E. casseliflavus* strain (i.e., *van*C gene) were identified with low discrimination and required additional testing. One VanA strain was misclassified as the VanB type because the system did not detect resistance to teicoplanin, and one glycopeptide-susceptible *E. faecium* was misclassified as the VanA type (i.e., resistant to both vancomycin and teicoplanin). Raponi and colleagues also recently compared the ability of Vitek 2, Phoenix, Etest, broth microdilution, and disk diffusion tests to detect glycopeptides and linezolid resistance in 30 clinical isolates of *E. faecium*.[505] All of the strains had undergone molecular testing to detect the presence of the *van*A and *van*B resistance genes and the 23S RNA G2576T mutation conferring resistance to linezolid. Resistance rates to teicoplanin ranged from 3% for Vitek 2 to 57.6% for the Phoenix test, and those to vancomycin ranged from 56.7% for Vitek 2 to 86.7% for the Phoenix test. Only 2/25 strains known to carry the *van*A gene were definitively recognized as the VanA phenotype. Only one strain had the G2576T mutation and did not carry the *van*A gene; disk diffusion, broth microdilution and the Vitek 2 system showed resistance (MIC > 8 μg/mL) but both Phoenix and Etest gave susceptible results (MIC ≤ 4 μg/mL). These studies highlight that more evaluations need to be done of automated dilution susceptibility system against a broader range of molecularly characterized VRE strains.

Disk diffusion tests are not as reliable as dilution assays, and should be performed strictly according to standard methods to minimize errors.[118] Disk diffusion tests should be incubated for a full 24 hours and read under transmitted light. VRE strains carrying a *van*B gene may be missed unless the inhibition zone is inspected carefully

for a diffuse edge. Performance of Etest strips has been shown by some studies to be equivalent to agar dilution and broth microdilution testing.[610] However, in a recent study, Etest failed to detect four *E. faecium* isolates that had been confirmed to carry the *van*B gene.[506] Grabsch and colleagues also found that a vancomycin Etest performed on either standard MHA or BHI agar repeatedly failed to detect a *van*B2-containing *E. faecium* (MIC ≤ 4 μg/mL) during a nosocomial outbreak.[223] Etest results improved when either MHA or BHI agar was supplemented with 1 g/L oxgall and plates were incubated a full 48 hours before reading. More studies are needed to evaluate this media to improve early detection of VRE strains with a low-level resistance phenotype in laboratories where *van*B detection by PCR is not possible.

Reporting. The results of penicillin and/or ampicillin, vancomycin and the screen for HLR to gentamicin and streptomycin should be reported for all *E. faecium* and *E. faecalis* isolates recovered from serious invasive infections. Laboratories should also have protocols in place for performing extended susceptibility testing on other antibiotics (i.e., daptomycin, linezolid) for invasive multidrug-resistant isolates. This protocol should include criteria for referral of multidrug-resistant isolates to a reference laboratory for confirmatory susceptibility testing and molecular genotyping. Infection Prevention and Control and/or public health agencies should be immediately notified of patients who are suspected or confirmed to have VRE detected either from surveillance or clinical samples.

Molecular Detection of Vancomycin Resistance Genes. Molecular testing of enterococci is required to detect a vancomycin gene, and to distinguish the type of gene(s) that are present. Aside from the more common vancomycin resistance genotypes discussed above (i.e., *van*A, *van*B and *van*C), several other vancomycin gene clusters have been reported (i.e., *van*D, *van*E, *van*G, *van*L, and *van*M).[2,58,154,672] The latter genes have been rarely described in clinical isolates, and discovered when routine phenotyping identified the strain as vancomycin-resistant, but molecular testing showed that neither *van*A nor *van*B gene clusters were present. Newer vancomycin gene clusters will likely continue to be found as other studies have documented a high prevalence of glycopeptides resistance genes (i.e., *van*B, *van*D, and *van*G) in human fecal flora that are not associated with enterococci.[164] In a subsequent study, these investigators identified *van*D and *van*G-like gene clusters in a *Ruminococcus* **spp**.[165] Clinical isolates of *Clostridium clostridioforme* and *Atopobium minutum* carrying a *van*B cluster have also been recently found.[376] Other gram-positive bacteria in the human bowel flora, particularly anaerobes, may represent a large pool of vancomycin resistance genes.

Several laboratory developed multiplex methods using PCR and real-time PCR have been developed to primarily detect the *van*A and *van*B gene clusters that are of utmost clinical importance (Fig. 17-29).[179,443,461] Molecular detection of the *van*C1,*van*C2, and *van*C3 genes can also definitively identify *E. gallinarum* as well as to distinguish *E. casseliflavus* from *E. flavescens*.[111] Specific molecular assays can also be done to detect other vancomycin genes.

Recent commercial development of rapid test platforms has, however, made real-time PCR detection of the *van*A/B genes directly from clinical specimens (i.e., rectal swabs and stool specimens) available to most facilities. Initial clinical evaluations of the two assays that have received FDA approval in the United States are briefly described herein. The BD GeneOhm VanR assay (BD GeneOhm, San Diego, CA) is a real-time PCR assay that amplifies specific targets of the *van*A and/or *van*B genes. The VanR assay is performed using the SmartCycler (Cepheid, Sunnyvale, CA). Stamper and colleagues compared the performance of the VanR assay with selective culture using bile esculin azide agar with 6 μg/mL vancomycin (BEAV), and BEAV broth with 8 μg/mL of vancomycin for detection of VRE from rectal swabs and stool specimens.[569] Overall, the VanR assay had a sensitivity of 96.6% and specificity of 87%, and several false-positive tests occurred with the *van*B portion of the assay. Although the sensitivity of the assay for rectal swabs (98.3%) was higher than stool specimens (95.4%), the specificity was similar for both specimen types. When used only to detect *van*A resistance, the VanR assay had sensitivity, specificity, PPV, and NPV of 94.4%, 96.4%, 91.3%, and 97.7%, respectively. Similar performance for the VanR assay was also reported recently in a study that tested 1,786 samples including a set of 50 reference strains known to be of the *van*A-G genotypes.[659] Although the overall sensitivity was 93.1%, the lower specificity (87%) was mainly due to false-positive *van*B results.

The GeneXpert *van*A/*van*B assay (Cepheid Diagnostics, Inc., Sunnyvale, CA) is also a real-time PCR assay that detects both the *van*A and *van*B genes. An evaluation of this test on 804 rectal swab specimens compared to enriched culture[54] demonstrated that although the molecular assay had a high sensitivity and NPV (100%), it had a lower specificity (85.4%) and PPV (8.7%) because of false-positive tests, especially for the *van*B gene. Another more recent evaluation compared direct and broth-enriched culture methods for detection of VRE to the *van*A/*van*B assay, and reported sensitivity, specificity, PPV, and NPV of 96.4%, 93%, 92%, and 96.9%, respectively.[375] The GeneXpert assay for VRE is easy to perform on a rapid, fully automated random-access platform that requires minimal specimen processing and provides results in 1.5 to 2 hours.

Laboratories that do not have the ability to perform molecular testing may consider implementing a chromogenic agar-based culture method to detect VRE directly from

rectal swabs or stool specimens (Fig. 17-30). Two chromogenic media (Chromagar VRE and chromID VRE) were compared for the direct detection of VRE from stool specimens after an overnight enrichment step and 48 hours of incubation of the plates.[456] Both of these media had a high sensitivity (98.2%) and comparable specificity of 96.5% and 97.5%, respectively. BBL CHROMagar VanRE (CVRE) (BD Diagnostic Systems, Baltimore, MD) was also recently compared with BEAV plates to screen for VRE colonization, and had sensitivity, specificity, PPV, and NPC of 98.6%, 99.1%, 95.9%, and 99.7%, respectively.[306] CVRE agar also showed improved performance for detecting VRE in a study of 517 surveillance swabs when compared to BEAV plates, and had sensitivity, specificity, PPV, and NPV of 99.1%, 94.8%, 84.2%, and 99.7%, respectively.[570] Another chromagar formulation (Spectra VRE, Remel, Lenexa, KS) was also much more sensitive (98.2%) and specific (99.3%) compared to BEAV in testing rectal swabs.[460] Currently, only one study has compared PCR-based screening for VRE against a chromogenic agar-based culture method which tested a total of 8,815 rectal swab specimens.[548] VRE were isolated from 8.4% of the samples while PCR detected VRE from 8.9% of the samples. Overall, the PCR has sensitivity, specificity, PPV, and NPV of 98.2%, 99.6%, 95.7%, and 99.8%, respectively, but no *van*B-positive specimens were included in this study.

Enterococcal Resistance to Newer Agents

Linezolid and daptomycin are newer agents that have increasingly been used to treat serious invasive infections due to MRSA and VRE. Laboratories should have protocol for extended testing of these antibiotics for isolates from serious invasive infections, or upon clinical request. If susceptibility of these drugs cannot be done in-house, the isolate should be immediately sent to a reference laboratory for confirmation and additional susceptibility testing. Although resistance to linezolid remains rare in both MRSA and VRE, laboratories should be prepared to recognize these strains because not surprisingly, an increased risk of acquiring a strain resistant to linezolid was associated with the use of the antibiotic and with the duration of therapy.[542] Linezolid breakpoints have been published for both disk diffusion (30 µg) and microdilution methods. However, when using a linezolid disk (30 µg) method, disk diffusion zones should be examined using transmitted light. If a clear zone is not found or the isolate is resistant, an MIC method should be used to perform repeat testing. Linezolid Etest strips also are in agreement with broth microdilution results for MRSA and VRE isolates, but the MIC results may be slightly higher.

A similar situation exists for daptomycin where few strains of either *S. aureus* or VRE have yet to be reported with resistance, but when they do arise, the patient has often been exposed to this agent, sometimes for a prolonged treatment period. Daptomycin is increasingly being used to treat serious invasive infections such as bacteremia and endocarditis due to MRSA or VRE provided the patient does not have

pneumonia because surfactant inactivates this compound. As recently reviewed, in vitro susceptibility testing of daptomycin requires the presence of standardized levels of total calcium (50 µg/mL, using calcium chloride salts).[320] Disk diffusion testing is unreliable for this reason and should not be used for daptomycin susceptibility testing for either *Staphylococcus* spp. or *Enterococcus* spp. Daptomycin Etest strips may be used along with calcium-supplemented MHA where the calcium concentration has been adjusted to the proper level. The in vitro activity of daptomycin in the Etest strip is dependent on the fixed amount of calcium (40 µg/mL) that is present in the strip, as well as the calcium in the agar. One of the largest evaluations of 1,800 *S. aureus* isolates including MRSA showed that the essential agreement of the Daptomycin Etest and microdilution testing was 82.4% but Etest MICS were 0.5 to 1 $\log_2$ dilution higher.[537] Daptomycin Etest MICs agreement rates have been even more variable (66.7% to 100%).[292,320]

Streptococci

Streptococcus pneumoniae

Decreased Susceptibility to Penicillin. Penicillin has been the standard treatment for pneumococcal infections for decades, and susceptibility testing was not indicated because strains remained susceptible. However, highly penicillin-resistant strains of *S. pneumoniae* have recently emerged, and increasingly, serious invasive infections are being reported due to multidrug-resistant clones that have been transmitted worldwide. Recent surveillance studies in the United States show that *S. pneumoniae* strains with multidrug resistance (i.e., resistant to two or more antimicrobial classes including β-lactams, macrolides, tetracycline, and trimethoprim/sulfamethoxazole, but rarely fluoroquinolones) are widespread; overall 20% of the isolates tested were multidrug-resistant, while the prevalence of isolates with intermediate-penicillin resistance (MIC 0.1 to 1 µg/mL) was 17.9% versus penicillin resistance (MIC ≥ 2 µg/mL) was 14.6%.[516]

Serotyping date for pneumococci causing invasive and noninvasive disease in 2008 to 2009 and 2010 to 2011 for more than 43 centers in the United States compared with data from preconjugate vaccine (PCV7) (1999 to 2000) and postconjugate vaccine (2004 to 2005) periods, show that the prevalence of PCV and pneumococcal serotypes decreased from 64% of invasive and 50% of noninvasive isolates in 1999 to 2000 to 3.8% and 4.2%, respectively, in 2004 to 2005.[516] Although the use of 7-valent pneumococcal conjugate vaccine (PVP7) dramatically decreased the incidence of invasive pneumococcal disease (IPD) in both children and adults, IPD continues to occur in individuals at the extremes of age (<2 years or ≥65 years), and those with

comorbidities and/or immunodeficiency because the vaccine only provides limited

1132

protection against the more than 90 *S. pneumoniae* serotypes known to cause human disease.[326,599] In addition, specific *S. pneumoniae* serotypes (i.e., 19A, 3, 6C, and 7F) have emerged in the United States and worldwide that may have heightened virulence and increased antimicrobial resistance not encompassed in the pneumococcal conjugate vaccine (PVP7) administered to children prior to 2010.[227,290,345,655] From 1998 to 2005, the incidence of pediatric IPD caused by 19A in the United States increased from 0.8 cases/100,000 population to 2.5 cases/100,000 population, which directly coincided with an increase of IPD caused by penicillin-resistant 19A strains (i.e., from 6.7% to 35%) belonging to a rapidly emerging international clone (clonal complex 320).[599] Since 2010, when 13-valent pneumococcal vaccine (PCV13) was introduced in the United States, the increase in serotype 19A ceased, and the prevalence of other predominant serotypes included in PCV13 (3, 6C, 7F) have also remained constant between 2008 to 2009 and 2010 to 2011.[599] Other factors that have been shown to enhance the selection of resistant pneumococcal strains include the spread of a few international clones, and the frequency with which oral antibiotics are used in the community.[349]

The mechanism of pneumococcal resistance to penicillin by the alteration of PBPs is described in the section entitled Mechanisms of Antimicrobial Resistance. *Streptococcus pneumoniae* does not produce β-lactamases. Penicillin resistance occurs with a variety of serogroups and among diverse strains that can be differentiated by molecular typing,[515] but relatively few clones are the dominant source of multiply resistant strains.[671] Pneumococci that are resistant to penicillin also have decreased susceptibility to other β-lactam antibiotics.[74] Some β-lactams (i.e., carbapenems, cefotaxime, ceftriaxone, and cefpirome) are more active in vitro than penicillin against penicillin-resistant pneumococci, while other drugs (i.e., ampicillin, cefdinir, cefuroxime, cefoperazone, azlocillin, mezlocillin, piperacillin, cephalothin, and cefamandole) demonstrated slightly less activity. Oxacillin, cefixime, ceftizoxime, cefetamet, cefaclor, ceftazidime, cefoxitin, cefonicid, and latamoxef show very poor activity against penicillin-resistant *S. pneumoniae* strains. The mechanism for resistance to these other β-lactam antibiotics is also an alteration in penicillin-binding proteins.[406] The results of penicillin susceptibility testing, however, cannot be used to predict the susceptibility of other β-lactam antibiotics, because strains with mosaic PBP genes can have low penicillin MICs (<1 μg/mL) and high cefotaxime MICs (2 to 32 μg/mL), or low penicillin MICs (1 to 2 μg/mL) but higher amoxicillin MICs (4 to 8 μg/mL).[163,385]

Resistance to penicillin and other classes of antimicrobial agents in *S. pneumoniae* has serious clinical consequences for adequately treating serious infections, including community-acquired pneumonia, empyema, meningitis, and other invasive infections.[290,599] Vancomycin must be prescribed for suspected or confirmed cases of IPD with meningitis due to high-level penicillin-resistant strains, and multidrug resistance in *S. pneumoniae* has also resulted in a dramatic increase in the use of levofloxacin for community-acquired pneumonia.

Phenotypic Detection of Penicillin Resistance. Disk diffusion remains the primary screening method used by most laboratories for detecting penicillin resistance in *S. pneumoniae*.[591] This method is highly sensitive for *S. pneumoniae* but it does not differentiate strains that have intermediate resistance from strains that are resistant based on determination of the MIC according to the source of the isolate and the formulation of penicillin being used (Table 17-25). The disk diffusion procedure recommended by the CLSI for detection of resistance to penicillin incorporates a 1-µg disk of oxacillin.[118,121,122] Swenson and colleagues found that oxacillin was a better predictor of penicillin susceptibility than was methicillin.[591] Strains that have a zone diameter ≤19 mm should be not be reported as nonsusceptible to penicillin before confirmation by an MIC method.[121,122] Dilution or gradient diffusion MIC testing must be routinely performed on invasive *S. pneumoniae* isolates from sterile fluids, tissues, and blood sources. Although CLSI has published an agar dilution method using MHA with 5% blood, this method produced lower MICs compared to broth microdilution in a recent evaluation.[686] Broth microdilution testing is considered to be the reference MIC method for testing *S. pneumoniae*. Several commercial systems produce microdilution panels for MIC testing of *S. pneumoniae* (e.g., PASCO Strep Plus, Trek Sensititre). Trek Sensititre panels have performed well with only minor errors for penicillin, ceftriaxone, and meropenem in recent evaluations against a bank of *S. pneumoniae* strains that consisted of a selection of strains that span the CLSI criteria.[686] Earlier evaluations also have shown that other manufacturers' microdilution panels give reliable results, except when testing trimethoprim/sulfamethoxazole.[226,398] The major advantage of this approach is that the MICs of an isolate against many drugs can be established.

Due to the fastidious nature of *S. pneumoniae*, isolates should be grown on MHA supplemented with 5% sheep blood to ensure adequate growth when performing Etest. Plates may also be incubated in CO_2 if necessary for growth of the strain. QC of these tests should include known resistant pneumococcal strains in addition to standard control organisms. Figure 17-19 shows the Etest results for penicillin for a highly resistant strain from CSF. Etest has been shown to be a reliable method overall for testing *S. pneumoniae* for penicillin and extended-spectrum cephalosporin resistance but low minor error rates with penicillin (9.5%) and cefotaxime (5.4%) may occur.[297]

Hashemi and colleagues have noted that the Etest produces higher MIC results than does the microdilution test,[242] but reports of false resistance have not subsequently appeared.

TABLE 17-25 CLSI Breakpoints (MIC μg/mL) for *S. pneumoniae*

Antibiotic	Source	S	I	R
Penicillin V	Meningitis	≤0.06	—	≥0.12
Penicillin V	Nonmeningitis	≤2	4	≥8
Penicillin (oral penicillin V)	—	≤0.06	0.12–1	≥2
Third-generation cephalosporin(s)	Meningitis	≤0.5	1	≥2
Third-generation cephalosporin(s)	Nonmeningitis	≤1	2	≥4

S, susceptible; I, intermediate; R, resistant.
Adapted from reference 122.

1133

CLSI changed the breakpoints in 2008 for interpretation and reporting of MICs of parenteral penicillin and other commonly used β-lactams for *S. pneumoniae* depending on whether the isolate is recovered from cerebrospinal fluid (i.e., meningitis) or other sources (i.e., nonmeningitis) (Table 17-25). Clinically, the MIC breakpoints for oral versus parenteral penicillin drug formulations also remain different. The rationale for this change was to not over-estimate resistance in *S. pneumoniae* when treating invasive localized infections (i.e., pneumonia, bacteremia) that had not disseminated to cause meningitis.[656] Use of a single set of breakpoints for all invasive *S. pneumoniae* isolates regardless of source (i.e., nonmeningitis and meningitis) was discouraging the effective use of penicillin in cases where the strain demonstrated intermediate but not high-level resistance. Although patients with relatively resistant strains of *S. pneumoniae* causing pneumonia have responded to penicillin treatment, meningitis may not be treated successfully because concentrations of antimicrobial agent are

lower in cerebrospinal fluid.[591] Strains that have an MIC > 4.0 µg/mL are unlikely to respond to penicillin therapy in any clinical situation. The predictable epidemiologic effects of establishing differential MIC breakpoints for parenteral penicillin has been to lower the incidence of penicillin resistance in nonmeningitis isolates of *S. pneumoniae*, but increase the incidence of penicillin resistance in meningitis isolates.[103,274]

Current CLSI guidelines also include new breakpoints based on MIC and PK/PD data for doxycycline, and revised breakpoints for tetracycline.[121,122] This drug is an option for treating community-acquired pneumonia, but some *S. pneumoniae* isolates may be resistant to tetracycline but susceptible to doxycycline.[371]

Decreased Susceptibility to Macrolides and Lincosamides. Resistance of *S. pneumoniae* to macrolides and clindamycin has been increasing for many years, primarily due to selection pressure from oral antimicrobial agent use.[287,290] In *S. pneumoniae* and other viridans streptococci macrolide resistance occurs due efflux out of the cell due to the *mefA* gene,[584] which is constitutively controlled giving a typical phenotype of erythromycin resistant but clindamycin susceptible. *S. pneumoniae* strains are also increasingly encountered that have inducible resistance to clindamycin (i.e., MLSB due to the presence of an *erm* gene).[192] CLSI now recommends that an inducible clindamycin resistance test (i.e., either a D-zone disk test or a broth microdilution test) be done on request for *S. pneumoniae* isolates that have an antibiogram profile of resistance to erythromycin but susceptibility to clindamycin.[121,122]

Reporting. For a nonmeningitis *S. pneumoniae* isolate, if the penicillin MIC is ≤0.06 µg/mL and the β-lactam drug of interest is listed in CLSI M100-S23 and M100-S24 Table 2G, then the laboratory can extrapolate the susceptible penicillin result to other β-lactam agents.[121,122] As for staphylococci, pneumococcal strains that exhibit inducible resistance to clindamycin should be reported as resistant; strains that lack both intrinsic and inducible resistance to clindamycin may be reported as susceptible. Resistance to other macrolides can be inferred from the erythromycin result.[121,122] Therapeutic failure has been reported when a macrolide was used to treat systemic *S. pneumoniae* infection due to a strain that demonstrated in vitro resistance.[279]Doxycycline may be routinely reported on lower respiratory *S. pneumoniae* isolates if the drug is on the test panel, and stakeholders agree it should be reported, or this drug may be selectively tested and reported at the request of the physician.

Other Viridans Group Streptococci

In addition to *S. pneumoniae,* many other viridans group streptococci (VGS) can

cause serious invasive infections, particularly bacteremia and endocarditis. Increased penicillin resistance in VGS was likely transferred from pneumococcal strains.[171]Reduced susceptibility to penicillin among clinical isolates of VGS range from 20% to around 40%.[232,288,679] Similar to pneumococci, VGS with decreased susceptibility to penicillin are usually more susceptible to third- and fourth-generation cephalosporins.[463] Penicillin resistance occurs due to changes in penicillin-binding proteins (i.e., PBP2b and PBP2x).[185] Alterations in PBPs have produced resistance to other β-lactam antibiotics among several of the species, including *S. mitis*, *S. sanguis,* and *S. oralis*.[185] Several recent studies of VGS bacteremia demonstrated the high levels of multidrug resistance (i.e., decreased susceptibility to clindamycin, tetracycline, erythromycin, and ceftriaxone) that are typical of strains with decreased susceptibility to penicillin.[182,232,288,679] In particular, *S. mitis* blood isolates from cancer patients that had a high degree of nonsusceptibility to penicillin (28%) were also resistant to fluoroquinolones and other classes of antibiotics.[171] Prior antibiotic exposure was a significant risk factor for the isolation of nonsusceptible VGS from bloodstream infections.[232,679] In a study of VGS recovered from the normal oropharynx, resistance to erythromycin, tetracycline, and quinupristin-dalfopristin was documented frequently; strains expressed resistance to levofloxacin and moxifloxacin much less commonly.[549] Vancomycin resistance has so far not been found in penicillin-resistant VGS, and remains the drug of choice for invasive infections due to penicillin-resistant strains.

Disk diffusion is unreliable for detection of resistance to penicillin or carbapenems and should not be used to test VGS. Disk diffusion can be used to test susceptibility to other β-lactams and antimicrobial classes.[118] Microdilution panels or Etest should be used to determine the penicillin MIC of invasive isolates of VGS recovered from sterile fluids, tissues and blood.[121,122] In vitro susceptibility results obtained with the Etest have correlated well with agar dilution for penicillin and the cephalosporins, but somewhat less well with some VGS species for vancomycin.[399] Laboratories that only perform disk diffusion testing should have policies and procedures in place for immediate referral of invasive VGS strains with either decreased susceptibility to penicillin or vancomycin to a reference laboratory for confirmatory MIC testing.

β-Hemolytic Streptococci

This section pertains to large colony-forming pyogenic strains of streptococci with group A (*S. pyogenes*) (GAS),

C, or G antigens and strain with group B (*S. agalactiae*) (GBS) antigen. Penicillin and ampicillin remain the drugs of choice for treatment ofβ-hemolytic streptococcal infections. Routine susceptibility testing of penicillin and other β-lactams approved for treatment of pyogenic streptococcal infections need not be performed because nonsusceptible isolates (i.e., penicillin MICs > 0.12 μg/mL and ampicillin MICs > 0.25 μg/mL) have not been reported for GAS and are remain extremely rare for the other β-hemolytic species.[121,122] Because of the life-threatening nature of invasive infections due to β-hemolytic streptococci, however, laboratories should routinely perform antibiotic susceptibility testing on invasive isolates recovered from sterile fluids, tissues, and blood. β-hemolytic streptococci isolates found to have nonsusceptible to β-lactams should be reidentified, retested, and if confirmed, immediately referred for confirmation to a public health laboratory.[99,122]

Resistance to macrolides and clindamycin in β-hemolytic streptococci has increased, particularly for GAS and GBS. Strains that are resistant to erythromycin and susceptible to clindamycin may carry an inducible MLS_B mechanism and have an inducible clindamycin resistance test done according to CLSI methods (i.e., either the double-disk test (D test) or broth microdilution with 1 μg/mL erythromycin and 0.5 μg/mL clindamycin in the same well).[121,122] If neither intrinsic nor inducible resistance is documented, the strain may be reported as susceptible to clindamycin. GAS and GBS isolates with high-level resistance to fluoroquinolones have also been described.[315,513] For patients who are allergic to penicillin, the oral therapeutic choices may become increasingly limited. Vancomycin is the drug of choice for invasive β-hemolytic streptococci infections in patients with penicillin allergy, and no resistance has been reported.

Macrolide and clindamycin resistance in GAS is primarily mediated by an efflux mechanism, but ribosomal methylation (i.e., MLS_B mechanism that is either constitutively expressed or inducible) due to the presence of an *erm* gene is becoming more widespread, and reports of inducible clindamycin resistance in GAS have recently increased.[390,504] During 2002 to 2003, a total of 1,885 GAS strains were obtained from 45 US medical centers (85% were pharyngeal isolates), and the macrolide-resistance phenotype distribution was as follows: MLS_B 56% of isolates (inducible, 47%; constitutive, 9%; and macrolide alone, 44%).[514] The most common mechanism of resistance in GBS is by a ribosomal methylase (*erm*A or *erm*B), but a minority of strains may express resistance through an active efflux mechanism, either alone or in combination with the methylase.[150,493]

Laboratories should perform susceptibility tests on group A streptococci isolated from throat swabs, and group B Streptococci isolated from vaginal-rectal swabs for surveillance screening in near-term pregnant women if there is an indication that the patient is penicillin allergic, and/or when there has been an indication of treatment

failure with a β-lactam. Recent case reports document failure of peri-partum chemoprophylaxis with clindamycin in preventing transmission of GBS from mother to infant.[47] Therapeutic failures for bacterial pharyngitis may also result from inadequate penetration of antibiotic into the crypts of the tonsils and adenoidal tissue, or failure of therapy due to infection with a macrolide-resistant GAS strain.[360] In these clinical situations, antibiotic susceptibility testing for alternative drugs, such as erythromycin, clindamycin, and levofloxacin, is appropriate.

If testing is performed by the disk diffusion procedure, penicillin (10U) or ampicillin (10 μg) disks may be used to predict susceptibility; use of oxacillin disks, as for pneumococci, is not recommended.[121,122] β-hemolytic streptococci that demonstrate a dissociated susceptibility pattern for macrolides and clindamycin (i.e., erythromycin resistant but clindamycin susceptible) should have an inducible clindamycin resistance test performed according to CLSI methods (i.e., D-zone test or broth microdilution with 1 μg/mL erythromycin and 0.5 μg/mL clindamycin in the same well).[121,122]

Reporting. Alternative antibiotics including erythromycin and clindamycin should be reported on GAS isolates from the pharynx if patients have a penicillin allergy. Although all GBS isolated from vaginal-rectal swabs should be tested for susceptibility to erythromycin, according to the new CDC GBS guidelines this drug should no longer be used for peri-partum chemoprophylaxis,[642] and laboratories should not report the results. However, the erythromycin result assists laboratories with the identification of GBS isolates that may have inducible clindamycin resistance, so in vitro susceptibility testing for this drug should be continued. GBS vaginal–rectal swab cultures should have a comment appended to indicate that susceptibility to penicillin and other β-lactam antibiotics can be assumed, but that the laboratory should be consulted for testing of alternate agents (i.e., clindamycin and vancomycin) if the patient has an allergy to penicillin. Clindamycin should be reported as resistant if the inducible resistance test is positive, and a comment may be added stating that the isolate is presumed to be clindamycin resistant based on the detection of inducible clindamycin resistance.[121,122]

Fastidious Gram-Positive Bacteria

Abiotrophia spp. and *Granulicatella* spp., formerly known as nutritionally deficient streptococci, may cause invasive infection, particularly bacteremia and endocarditis. These organisms are very fastidious and may be hard to grow and identify using biochemical methods. Definitive identification can be achieved using partial 16S rRNA gene sequencing. Due to the fastidious nature of these isolates, susceptibility testing may also be difficult unless adequate growth is achieved. CLSI recommends microdilution testing using CAMHB supplemented with 2% to 5% lysed horse blood and 0.0001% (1 µg/mL) pyridoxal hydrochloride with incubation at 35°C in ambient air with incubation at 35°C in CO_2 for a full 24 to 48 hours.[114] Some strains may also grow better on chocolate agar with cysteine supplementation incubated in CO_2 for a full 24 to 48 hours. Laboratories that cannot get adequate growth to perform susceptibility testing, or those that do not perform microdilution tests should refer these organisms to a reference laboratory.

Corynebacterium spp. have variable susceptibility profiles,[190] and are increasingly being recognized as important emerging pathogens. These are an important cause of

invasive prosthetic joints and heart valve infections, as well as, a cause of infections of

central lines and pacemaker leads. *Corynebacterium* spp. are fastidious bacteria that grow best in the presence of blood. Some isolates such as *C. striatum* or *C. jeikeium* are multidrug-resistant so that susceptibility testing should be done on isolates recovered in pure culture from sterile sites, tissues, prosthetic devices, central lines and blood. CLSI recommends testing by microdilution using cation-adjusted MHB supplemented with 2% to 5% lysed horse blood with incubation at 35°C in ambient air for a full 24 to 48 hours.[528]

Listeria monocytogenes is a major food-borne pathogen that can cause diarrhea, bacteremia, and meningitis, particularly in immunodeficient patients. *Listeria* species are inherently resistant to the cephalosporins. CLSI recommends testing invasive *Listeria* isolates for susceptibility to ampicillin and trimethoprim-sulfamethoxazole.[114] Recent clinical antibiotic surveillance, and surveys from the food industry show that *Listeria* remains susceptible to these agents, with the exception of rare isolates that have decreased susceptibility to trimethoprim-sulfamethoxazole.[364,507] Microdilution should be used to test invasive *L. monocytogenes* isolates using CAMHB supplemented with 2% to 5% lysed horse blood with incubation at 35°C in ambient air for a full 24 to 48 hours.[114]

Vancomycin resistance is commonly found in strains of *Leuconostoc*, *Pediococcus*, and *Lactobacillus*.[589] These genera are infrequently pathogens, but on occasion cause bacteremia and septicemia. Resistance to vancomycin may be a useful clue to the correct identification, because streptococci, with which these genera may be confused, are uniformly susceptible to vancomycin. CLSI recommends testing these genera by microdilution using CAMHB supplemented with 2% to 5% lysed horse blood with incubation at 35°C in ambient air (*Leuconostoc*, *Pediococcus*) or CO_2 (*Lactobacillus* spp.) for a full 24 to 48 hours.[114]

Detection of Resistance in Gram-Negative Bacteria

Haemophilus influenzae *and* Haemophilus parainfluenzae

Tristram and colleagues recently reviewed antibiotic resistance in *H. influenzae*.[622] Susceptibility testing should be performed on *Haemophilus influenzae* and other *Haemophilus parainfluenzae* recovered from sterile fluids, tissues and blood. A β-lactamase test should be done as previously described in the chapter. CLSI recommends testing invasive isolates against ampicillin, a third-generation cephalosporin, meropenem, trimethoprim–sulfamethoxazole, and chloramphenicol. Although chloramphenicol is now rarely used, resistance to this antibiotic was infrequent among isolates of *H. influenzae* (0.5%) in a national collaborative study

when it was commonly prescribed for serious invasive infection.[159] Chloramphenicol remains available as an alternate agent that may have to be used to treat serious invasive infections in patients with severe antibiotic allergies, or due to the presence of a multidrug-resistant *H. influenzae* strain. Although *H. influenzae* strains that are BLNAR remain rare in North America, Japan and Europe have experienced emergence of a *H. influenzae* clone that has decreased susceptibility to ampicillin often at a low level (i.e., ampicillin MICs 0.5 to 4 μg/L) because of alteration in PBP3 due to mutations in the *ftsl* gene.[25,379,622]

Additional agents including amoxicillin clavulanate, a second-generation cephalosporin, and a fluoroquinolone may be tested for isolates causing pneumonia. First-generation cephalosporins have poor activity against *Haemophilus influenzae* and need not be tested. Second-generation cephalosporins, such as cefamandole and cefuroxime, are active against *Haemophilus* species in vitro, but decreased susceptibility may occur due to β-lactamase production or alteration of PBP3 as a result of mutations in the *ftsl* gene.[577] Third-generation cephalosporin drugs, such as ceftriaxone, remain uniformly effective against *H. influenzae*.

Disk diffusion should be done using HTM plates incubated at 35°C for 20 to 24 hours. Proper preparation of the inoculum is very important for testing *Haemophilus* species. The alternative direct method of standardizing the bacterial suspension from an overnight culture should be used as outlined in CLSI M02-11.[118] The 0.5 MacFarland suspension contains approximately 1 to 4 × 10^8 CFU/mL. A higher inoculum concentration may lead to false-resistant results with some β-lactam drugs, particularly when β-lactamase-producing strains of *H. influenzae* are being tested.[121,122] Zone diameters should be read as the area showing no obvious, visible growth using the unaided eye. Ignore faint growth at the edge of the zone that can only be seen with magnification. Agonists in the media may cause growth of *Haemophilus* spp. when testing trimethoprim-sulfamethoxazole using disk diffusion. CLSI recommends that slight growth (20% or less of the lawn of growth) be ignored when reading the zone diameter.[121,122]

Microdilution is recommended to determine the MICs for *Haemophilus* spp. Jorgensen and colleagues, however, found a good correlation of the Etest and standardized microdilution tests for *Haemophilus influenzae*.[299] Another study of five different susceptibility testing methods for *H. influenzae* also documented a generally acceptable performance among these commonly used methods.[214] Disk diffusion or Etest, however, may not detect some BLNAR strains of *H. influenzae*, and confirmatory testing should be done using broth microdilution.[40,206,434]

Reporting. **BLNAR** strains of *H. influenzae* should be considered resistant to other β-lactam agents (amoxicillin clavulanate, ampicillin sulbactam, cefaclor, cefamandole,

cefetanet, cefonicid, cefprozil, cefuroxime, loracarbef, and piperacillin–tazobactam) despite in vitro susceptibility of some strains.[121,122] Although chloramphenicol and/or a fluoroquinolone may be tested, the results should only be selectively reported.

Fastidious Gram-Negative Bacteria

HACEK group organisms including *Aggregatibacter* spp. (formerly *Haemophilus aphrophilus*, *Haemophilus paraphrophilus* and *Haemophilus segnis* and *Actinobacillus actinomycetemcomitans*), *Cardiobacterium* spp., *Eikenella* spp., and *Kingella*

1136

spp. may cause invasive infections including bacteremia and endocarditis. HACEK organisms are common pathogens in periodontitis, particularly *Aggregatibacter* spp.[14] *Eikenella corrodens* is also a common pathogen in human and canine bite wound infections. HACEK group species commonly produce β-lactamase, and these strains should be reported as ampicillin resistant.[14] HACEK species are very fastidious and growth is slow on routine media including blood and chocolate agar incubated in CO_2. Due to the fastidious nature of these isolates, susceptibility testing may also be difficult unless adequate growth is achieved. CLSI recommends microdilution testing using CAMHB supplemented with 2% to 5% lysed horse blood with incubation at 35°C in $CO_2$for a full 24 to 48 hours.[114] CLSI breakpoints for the carbapenem drugs are higher for *Aggregatibacter* spp. (MIC ≤ 4 μg/mL is susceptible, 8 μg/mL is intermediate, and ≥16 μg/mL is resistant) than other HACEK species (MIC ≤ 0.5 μg/mL is susceptible, 1μg/mL is intermediate, and ≥2 μg/mL is resistant).[114]

Pasteurella multocida is the most prevalent pathogen in cat-bite infections, and may spread to cause osteomyelitis or bacteremia. *Pasteurella* are fastidious and require blood supplemented media for adequate growth. Penicillin or ceftriaxone are the drugs of choice but alternate agents such as a fluoroquinolone, a tetracycline, a macrolide or trimethoprim-sulfamethoxazole may need to be used in patients with severe penicillin allergy. Disk diffusion testing is done using MHA supplemented with 5% sheep blood incubated at 35°C in ambient air for 24 hours.[114] Microdilution MIC tests are performed using CAMHA with 2.5% to 5% lysed horse blood incubated under similar conditions as the disk diffusion method. Gradient diffusion appears to not be as reliable as other MIC methods.[410]

Moraxella. *Moraxella catarrhalis* is an important cause of respiratory infections, and dissemination may result in bacteremia and seeding of other sites. This organism grows well on blood agar in ambient air. Broth microdilution testing should be done on

invasive isolates. CAMHB is used for microdilution testing, and plates are incubated in ambient air at 35°C for 20 to 24 hours. CLSI only recommends using disk diffusion to test susceptibility to amoxicillin clavulanate, macrolides, tetracycline, and trimethoprim–sulfamethoxazole.[121,122] A microdilution method should be used to test cephalosporin susceptibility.

Neisseria

Neisseria gonorrhoeae. The gonococcus (GC) has a propensity to rapidly develop antibiotic resistance. Treatment options for *N. gonorrhoeae* infections are becoming extremely limited worldwide because of the successive spread of gonococcal strains, which are resistant to sulfonamides, tetracyclines, penicillins, fluoroquinolones, and more recently cephalosporins.[256] Penicillinase-producing gonococci (PPNG) strains were detected initially in Asia in the mid-1970s,[421,502] but they rapidly became widespread.[104] This β-lactamase resembles the TEM enzyme found in enteric bacilli and Haemophilus influenzae. All GC isolates should therefore be tested for β-lactamase production as described earlier in the chapter. GC strains appeared shortly after which were β-lactamase-negative but penicillin-resistant due to altered PBPs, and these strains have since produced epidemic as well as sporadic infection.[169,188] A decade later, GC strains with high-level plasmid-mediated tetracycline resistance were reported in the United States.[318] In the mid-1980s fluoroquinolones became the drugs of choice for treating GC infections. But as of April 2007, the CDC in the United States removed fluoroquinolones as recommended agents for GC infections because of the high incidence of surveillance strains (13.3%) found to be resistant.[105] Azithromycin-resistant strains of GC have been increasingly reported in certain parts of South East Asia,[329] and the first isolate was also recently reported in the United States.[308]

Sexually transmitted disease treatment guidelines published by the CDC in 2010 recommended the use of oral cefixime or IM ceftriaxone for treatment of uncomplicated genital or rectal GC infections because even multidrug-resistant strains remained universally susceptible.[670] However, cephalosporin resistance has been rapidly increasing worldwide, including in the United States.[102] GC isolates with increased cefixime MICs (≥0.25 mg/L) dramatically increased from 0.1% in 2006 to 17% in 2011, mainly in the western states (from 0.2% to 3.6%) and among men who have sex with men (0.2% to 4.7%).[102] The proportion of GC strains having increased ceftriaxone MIC (≥0.125 mg/L) also increased (0.05% to 0.50%) in the same time period with the same geographic and epidemiologic pattern. The genetic basis of reduced cephalosporin susceptibility in these strains is due to a combination of several chromosomal gene mutations in *pen*A that encodes an altered mosaic PBP2, *pen*B

which results in decreased entry of the drug through the PorB1b OM channel, and *mtr*R, a repressor of the Mtr CDE-encoded pump.[346,630] Clinical cure rates are lower (85% to 95%) for infections due to GC strains with decreased susceptibility to cephalosporins compared to susceptible strains (i.e., >95%). Because of increasing reports of cefixime treatment failures associated with infection due to GC strains with elevated cefixime MICs,[6] the CDC no longer recommends using oral cephalosporins for treatment except for situation where an IM injection cannot be given.[106] Combination therapy with ceftriaxone 250 mg IM and either azithromycin 1 g orally as a single dose or doxycycline 100 mg orally twice daily for 7 days should currently be used to treat uncomplicated GC. This regimen not only treats GC but also *Chlamydia trachomatis*. Penicillin allergic patients should receive an increased dose (2-gm) of azithromycin or spectinomycin, if the GC strain is confirmed to be susceptible. A test of cure should also be done for treatment failure where symptoms persist, and/or a positive GC culture is obtained ≥72 hours, and/or a positive NAAT is obtained ≥7 days after completing therapy.[106]

Culture and susceptibility test of *N. gonorrhoeae* should be done in cases of treatment failure. Antibiotic susceptibility testing of GC using either disk diffusion or agar dilution methods has been reviewed by Doern and Jones.[158] Disk diffusion tests are performed on GC agar base supplemented with 1% of the defined growth supplement. Cysteine-free medium is not required for disk testing; enriched chocolate agar is not recommended.[118,121,122] Susceptibility plates for testing *N. gonorrhoeae* must be incubated at 36°C±1°C (not to exceed 37°C) in 5% CO_2 for 20 to 24 hours. A zone diameter of ≤26 mm for a penicillin (10 U) disk indicates resistance, while a zone size ≤ 19 mm is indicative of β-lactamase

production. But β-lactamase detection using the nitrocefin method is preferred for assessing this mechanism of resistance. CLSI has also developed interpretive criteria for disk diffusion susceptibility testing of GC isolates against tetracycline, fluoroquinolones, and spectinomycin.[118,121,122] Plasmid-mediated tetracycline resistance is indicated by a zone diameter of ≤19 mm around a 30-mg tetracycline disk; such strains should be evaluated by a dilution test. CLSI has defined susceptible breakpoints for parenteral third-generation cephalosporins (i.e., ceftriaxone, cefotaxime, ceftazidime) and oral cephems (e.g., cefixime). However, GC strains that demonstrated decreased susceptibility to cephalosporins (i.e., smaller zone size than susceptible) should have repeat testing using agar dilution.

Table 17-26 outlines the CLSI MIC interpretive criteria for testing *N. gonorrhoeae*. Agar dilution tests are performed using GC agar supplemented after autoclaving with a

1% defined growth supplement (1.1 g L-cysteine, 0.03 g guanine HCl, 3 mg thiamine HCl, 13 mg para-aminobenzoic acid [PABA], 0.01 g vitamin B_{12}, 0.1 g cocarboxylase, 0.25 g NAD, 1.0 g adenine, 10 g L-glutamine, 100 g glucose, 0.02 g ferric nitrate in 1 L H_2O). Cysteine must be omitted if carbapenems or clavulanate are to be tested.[114] The Etest has shown good correlation with agar dilution techniques for non–β-lactamase-producing strains,[637] but resistance may not be detected in strains that produce β-lactamase,[682] emphasizing the necessity for performing a test for β-lactamase production in all strains.

Reporting. Patients with GC infection are empirically treated in the United States based on management guidelines for sexually transmitted diseases published by the CDC.[670] Updates to the CDC treatment guidelines are based on surveillance data from antibiotic susceptibility testing of locally recovered GC isolates. Clinical laboratories should refer GC isolates, particularly those that demonstrate decreased susceptibility to one or more major classes of antimicrobial agents to a public health laboratory for confirmatory testing. Any GC isolate from treatment failures should also be referred to a reference laboratory.

Neisseria meningitidis. *N. meningitidis* causes invasive meningococcal disease, and is an important cause of bacteremia and meningitis. Although effective vaccines are available for serotypes A, C, Y, and W-135, vaccination is given only to select groups, and not all serotypes are included as immunogens (i.e., serotype B). Prompt, effective management is paramount for invasive meningococcal infections, which may have a high mortality despite appropriate antibiotic treatment. Because of its universal susceptibility, penicillin has been the drug of choice for invasive *N. meningitidis* infections, but relative resistance is increasingly being reported worldwide although its clinical relevance remains controversial.[38,73,222] However, *N. meningitidis* strains that demonstrate decreased susceptibility to penicillin remain susceptible to third-generation cephalosporins which are the drugs of choice for treatment of bacterial meningitis. The incidence of decreased susceptibility to penicillin (MIC ≥ 0.125μg/mL) in these recent surveillance studies from Brazil, Europe, and Canada ranged from 13% to 21.5%. Brown and colleagues found that patients with higher mortality from invasive meningococcal disease had infection with serotype B or C strains, while serotype Y and W-135 strains accounted for most of the decreased susceptibility to penicillin.[73] Alterations in the structure of PBP2 encoded by the *pen*A gene account for most of the decreased penicillin susceptibility in *N. meningitidis*. Penicillin nonsusceptible strains of *N. meningitidis* have been shown to have mosaic *pen*A genes, and the variable structure has come about through transfer from commensal *Neisseria* species.[616] Modification of PBP2 caused changes in the peptidoglycan structure of the bacterial cell wall which results in decreased binding affinity for penicillin. Several investigators have shown that these changes result in less sensitivity to penicillin

overtime with a gradual increase in the MIC, rather than a rapid conversion to resistance.[38,616] Plasmid-mediated transfer of β-lactamase to *Neisseria meningitidis* has also been documented, but these strains remain rare.[157] Laboratories need to be able to accurately assess the MICs for penicillin, ampicillin and third-generation cephalosporins such as ceftriaxone and cefotaxime on invasive meningococcal isolates.[121,122,639] In addition, antibiotic testing of chloramphenicol may be indicated for treatment on invasive meningococcal disease in patients with a severe penicillin allergy, or if high-level penicillin resistance emerges in *N. meningitidis* that precludes our ability to use β-lactam drugs for therapy.

TABLE 17-26 CLSI Breakpoints (MIC μg/mL) for *N. gonorrhoeae*

Antimicrobial	S	I	R
Penicillin	≤0.06	0.12–1	≥2
Tetracycline	≤0.25	0.5–1	≥2
Cefixime	≤0.25	—	—
Ceftriaxone	≤0.25	—	—
Ciprofloxacin	≤0.06	0.12–0.5	≥1
Spectinomycin	≤32	64	≥128

S, susceptible; I, intermediate; R, resistant.

Perform all antibiotic susceptibility testing of *N. meningitidis* in a biologic safety level-2 or preferably, -3 cabinet (BSC-3) using level-3 practices including person protective equipment. Generated aerosols and exposure of laboratory staff outside the BSC-3 has an increased risk of laboratory staff-acquired *N. meningitidis* infection that is associated with a case fatality rate of 50%.[121,122] Disk diffusion is unreliable for testing penicillin or ampicillin susceptibility in *N. meningitidis*; MIC tests should be used for this organism.[294] Disk diffusion zone diameters to establish susceptibility versus nonsusceptibility have been published by CLSI for third-generation cephalosporin drugs and meropenem.[121,122] The CLSI reference method for

susceptibility testing of *N. meningitidis* is microdilution using CAMHB supplemented with lysed horse blood (2.5% to 5%). However, most clinical laboratories rely on either agar dilution using MHA supplemented with 5% sheep blood, or performing antibiotic Etest using the same media.[639] One study evaluated the use of agar dilution and Etest using several media formulations (MHA; MHA supplemented with 5% sheep blood; and

MHA supplemented with chocolated blood) using standardized methodology among national and regional reference laboratories in 14 countries.[640] Overall agreement in each antibiotic/method/medium combination defined as the percentage of laboratories with a result within one dilution of the modal result was 90.6% for agar dilution and Etest. However, agreement among this reference laboratory pool ranged from 98.2% to 69.7%, with only six laboratories demonstrating agreement higher than 90%, while it was more than 80% for the other 11 laboratories. Most concerning was the ability of these reference laboratories to detect decreased penicillin resistance in *N. meningitidis* ranged from 100% to 18.2%, indicating that even with standardized methodology, laboratories may encounter difficulty performing accurate susceptibility testing on this critical organism.

Laboratories also need to be able to accurately test antimicrobial agents used for prophylaxis of contacts of patients with invasive meningococcal disease, including azithromycin, a fluoroquinolone, rifampin, trimethoprim–sulfamethoxazole, and minocycline. CLSI has published MIC breakpoints and corresponding zone diameters for this purpose, but specific guidelines for susceptibility testing for clinical treatment purposes have not been defined. Jorgensen and colleagues recently performed susceptibility testing on a collection of 442 meningococcal clinical isolates from 15 countries to 16 antimicrobial agents as an essential first step in defining susceptibility testing breakpoints specific for *N. meningitidis*.[293] Elevated penicillin and ampicillin MICs among this isolate collection were 14.3% and 8.6%, respectively; none of the isolates produced β-lactamase. Among drugs used for prophylaxis, resistance to trimethoprim–sulfamethoxazole (21%) was the highest, but resistance to all of the other compounds was rare or not found. Burgess and colleagues then used PK-PD modeling and the MICs for 15 antimicrobial agents derived from their prior testing of the above large international culture collection (i.e., 442 clinical isolates) to develop antimicrobial breakpoints for *N. meningitidis*.[82] The PK-PD breakpoint was defined as the MIC at which the calculated target attainment was ≥95% for both serum and CSF, and the reported values were the first human studies to specifically define parameters for this organism.

Reporting. Invasive meningococcal isolates recovered from sterile fluids such as CSF,

tissues, or blood should routinely be tested against penicillin and/or ampicillin, third-generation cephalosporins (ceftriaxone or cefotaxime), rifampin, and ciprofloxacin (or other fluoroquinolone).[121,122] In addition, meropenem and chloramphenicol may be tested and reported upon request by the Infectious Disease service or other clinicians in specific clinical situations. Isolation of *N. meningitidis* should be immediately reported to both Infection Control and Prevention and public health so that contact tracing and antibiotic prophylaxis can be administered to prevent secondary cases.

Enterobacteriaceae

β-Lactamases. This section describes the currently used methods for detecting β-lactamases in *E. coli*, *Klebsiella* spp., and other genera of the family *Enterobacteriaceae*. The currently recommended CLSI MIC breakpoints and zone diameters (as of M100-S20, 2010) were established to predict susceptible and resistant interpretations for detection of extended-spectrum β-lactamases, AmpC enzymes, or carbapenemase-type enzymes, and identification of a specific β-lactamase-resistance mechanism (e.g., CTX-M-type ESBL, *Klebsiella pneumoniae* carbapenemase (KPC), New Delhi metallo-β-lactamase [NDM], etc.) as required for clinical care. However, tracking of such strains within a care facility of specific geographic region or globally requires further work to identify the specific mechanism(s) at work in *Enterobacteriaceae* confirmed to have multidrug resistance to β-lactams and other classes of antimicrobials. These enzymes are carried on plasmids that often mediate resistance to other antimicrobial agents, such as aminoglycosides, tetracycline, and sulfonamides, so the appearance of unusual resistance patterns can also serve as a clue that the extended-spectrum enzymes are present.[450] Molecular methods are briefly described for detection of specific types of β-lactamases commonly encountered in *Enterobacteriaceae*.

Extended-Spectrum β-Lactamases. Extended-spectrum β-lactamases (ESBLs) have primarily been detected in either *Klebsiella pneumoniae* or *Escherichia coli*. Although ESBLs occur in other *Enterobacteriaceae*, such as *Enterobacter* spp. and *Citrobacter* spp., detection is more difficult because other types of β-lactamases, especially AmpC enzymes, are commonly present in these genera.[281,450] The CLSI has recently revised the MIC breakpoints and corresponding zone diameters for cephalosporins including cefazolin, cefotaxime, ceftazidime, ceftizoxime, and ceftriaxone and aztreonam in 2010. EUCAST also revised their criteria in 2010, but the breakpoints and corresponding zone diameters are somewhat different. These new breakpoints were established after review of the pharmacokinetic/pharmacodynamic (PK-PD) properties of these drugs, limited clinical data, and the current MIC distribution of clinically relevant *Enterobacteriaceae* species, including ESBL producers. If laboratories have implemented the new MIC breakpoints shown in Table

17-27 or the revised zone diameters for disk testing of these drugs, then confirmatory testing is no longer required before reporting susceptibility results for *Enterobacteriaceae*. The revised breakpoints for these compounds have been based on specific drug dosage regimens outlined by CLSI in Table 2A of the M100-S20-22 document.[120] These drug dosages are required to achieve plasma drug levels in adults with normal renal and hepatic function, and laboratories using these criteria should provide this information to important stakeholders (i.e., infectious diseases physicians, pharmacists, infection control practitioners, and their respective committees).

TABLE 17-27 CLSI Previous (M100-S19) and Revised (M100-S20) Breakpoints (MIC µg/mL) *Enterobacteriaceae* for Cephalosporins and Aztreonam

	Previous (M100–S19)			*Revised (M100–S20)*		
Antimicrobial	**S**	**I**	**R**	**S**	**I**	**R**
Cefazolin	≤8	16	≥32	≤2	4	≥8
Cefotaxime	≤8	16–32	≥64	≤1	2	≥4
Ceftriaxone	≤8	16–32	≥64	≤1	2	≥4
Ceftazidime	≤8	16	≥32	≤4	8	≥16
Ceftizoxime	≤8	16–32	≥64	≤1	2	≥4

1139

A recent study compared the revised CLSI breakpoints with those of EUCAST for ESBL detection in 236 well-characterized clinical isolates including 118 ESBL producers using modified double-disk testing (DDT) with cefpodoxime, ceftriaxone, cefepime, cefotaxime EUCAST (5 µg/disk), ceftazidime EUCAST (10 µg/disk), cefotaxime CLSI (20 µg disk), and ceftazidime CLSI (30 µg disk).[483] Antibiotic synergy was also recorded from the modified DDTs between clavulanic acid disk, and

both the EUCAST and CLSI cephalosporin disks. Overall, the sensitivity (99.2%) for both the EUCAST and CLSI cefotaxime breakpoints were similar. The EUCAST nonsusceptible breakpoint for ceftazidime did not detect 27 ESBL producers, but the CLSI also missed 41 of them. The EUCAST cefpodoxime resistant breakpoint was more sensitive than that of CLSI (100% vs. 98.3%). A modified DDT using clavulanate and cefipime had the highest overall sensitivity (96.6%) of all of the combinations tested, and this disk combination also had excellent sensitivity (100%) and specificity (97.4%) in isolates that also produced an AmpC enzyme.

Reporting. Use of the revised CLSI MIC breakpoints and zone diameters for cephalosporins and aztreonam allows laboratories to report the result for each β-lactam agent; it is no longer necessary to change susceptible results for penicillins, cephalosporins, or aztreonam to resistant results as occurs using the "old" breakpoints and to perform the secondary ESBL-confirmation testing described below. Laboratory stakeholders need to know that the revised MIC breakpoints for *Enterobacteriaceae* will enhance detection of resistance regardless of the mechanism of resistance. Because some ESBLs hydrolyze some cephalosporins but not others, laboratories will likely be reporting discrepant susceptibility test results for isolates that produce this type of enzyme (i.e., an **ESBL**-producing *E. coli* may have a resistant **MIC** for cefotaxime but may be susceptible to other third-generation drugs). When the laboratory implements the revised breakpoints, stakeholders may initially request testing of specific isolates to determine the mechanism of β-lactam resistance.

A rate-limiting step for many laboratories in readily adopting these breakpoint changes has been the delay in automated susceptibility test system accommodating these lowered cutoffs for specific cephalosporins and aztreonam. Despite the CLSI revising existing breakpoints, the FDA in the United States must review the data to determine the clinical affects these changes may have on the indication for use of these agents, and patient safety. Until the FDA approves the breakpoint changes for these drugs, the commercial manufacturers of automated systems cannot proceed to change their systems. Currently the FDA has not approved these changes, the automated susceptibility systems have not been changed and many laboratories continue to screen for ESBL-producing *E. coli* and *Klebsiella* spp. using the "previous" CLSI breakpoints (Table 17-27), and subsequently perform ESBL-confirmation testing as outlined below.

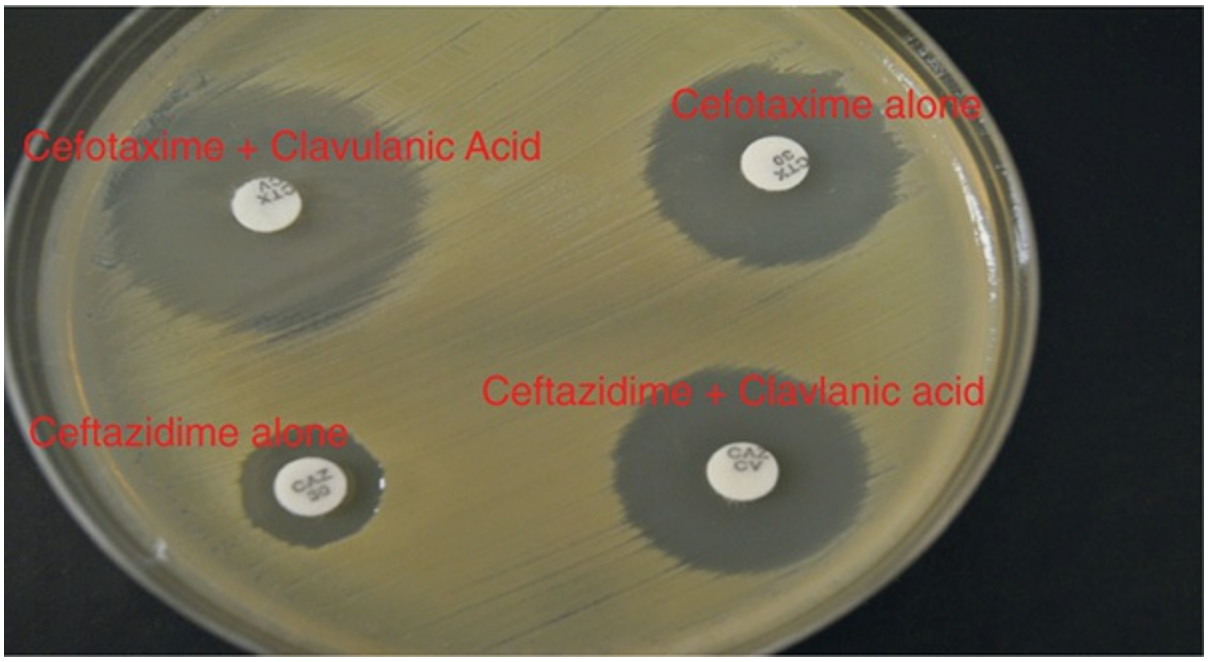
Laboratories that have not yet implemented the revised breakpoints changes for select cephalosporins or aztreonam must continue to perform confirmatory testing on isolates suspected of being ESBL producers according to the CLSI recommended screening test. Routine disk diffusion and MIC tests using the "previous" breakpoints outlined in Table 17-27 may not always identify isolates that produce ESBLs. The previous CLSI recommendations for ESBLs screening for *Klebsiella* spp., *Escherichia coli* and *Proteus mirabilis* are summarized in Table 17-28. ESBL-producing isolates typically demonstrate high-level resistance to one or more of the

screening drugs (e.g., aztreonam, cefotaxime, cefpodoxime, ceftriaxone, ceftazidime), but retain susceptibility to cephamycins (i.e., cefoxitin or cefotetan). However, no single screening antibiotic detects all types of ESBLs, so the use of multiple screening compounds increases the sensitivity of screening. Cefpodoxime is most likely to detect ESBL production, but even with revised breakpoints this indicator may have a lower specificity for *E. coli*.[609]

Phenotypic confirmation of the presence of an ESBL relies on the fact that these enzymes are inhibited by the inhibitor compound clavulanic acid. All of the currently available phenotypic tests summarized in Table 17-28 are based on enhanced activity of the β-lactam (cefotaxime, ceftazidime) when tested with clavulanic acid compared to testing of the β-lactam alone. Before commercial detection tests became available, laboratories relied on combination testing of β-lactams/clavulanic acid either using the DDT or broth microdilution methods recommended by CLSI (Figs. 17-31 and 17-32). These methods may be used to detect ESBLs in *Klebsiella oxytoca*, *K. pneumoniae*, *E. coli,* and *P. mirabilis,* but have not been validated for other *Enterobacteriaceae* species. Another modified DDT procedure has been described that reliably detect ESBLs in other genera of *Enterobacteriaceae*, but routine use of this method in the clinical laboratory can be exacting, particularly the challenging interpretation.

TABLE 17-28 Confirmatory Tests for ESBL-Producing *Enterobacteriaceae*

Method	Comments	Reading and Interpretation	Illustration
Double-disk test (DDT)	Placement of the disks is critical; separation by 20 mm and 30 mm may be necessary	Increase of inhibition zone facing disk that contains β-lactamase inhibitor (clavulanic acid) by ≥5 mm	Figure 17-31
Microdilution	Commercial panel with wells that contain cefotaxime and ceftazidime with and without clavulanic acid	Decrease in the MIC of ≥8-fold (three doubling dilutions)	Figure 17-32
Etest ESBL	Strip contains β-lactam on one end and β-lactam + clavulanic acid on the other	Reduction in the MIC by ≥8 fold in the presence of β-lactamase inhibitor	Figure 17-33
Vitek 2, BD Phoenix, MicroScan ESBL	Automated detection of ESBL	Decrease in the calculated MIC in the presence of β-lactamase inhibitor	Figures 17-22, 17-23, 17-24
Multiplex PCR	Differentiates the type of ESBL present (i.e., TEM, SHV, CTX-M, etc.)	Positive for one or more enzymes	Figure 17-34



■ **FIGURE 17-31** Confirmatory double-disk test for *K. Pneumoniae* producing an ESBL (CTX-M 15 type). (Courtesy of Calgary Laboratory Services.)

The DDT is performed using disks with and without 10 μg of clavulanic acid (Fig. 17-31). The DDT is considered positive for an ESBL production if the zone diameter of either β-lactam increases by ≥5 mm in the presence of clavulanic acid. The types of drug substrates used, the drug concentrations in the disks, and the placement of the disks on the media may all affect the performance of the DDT. All DDT should include the recommended QC strain ESBL-producing *K. pneumoniae* ATCC 700623; the accepted zone diameter ranges for this isolate are provided by CLSI. For broth microdilution testing, the same two third-generation cephalosporins are tested alone and with 4 μg clavulanic acid. A ≥ eightfold decrease (three doubling dilutions) in the MIC with combination testing of the β-lactam/clavulanic acid per well compared to β-lactam testing alone is indicative of an ESBL.

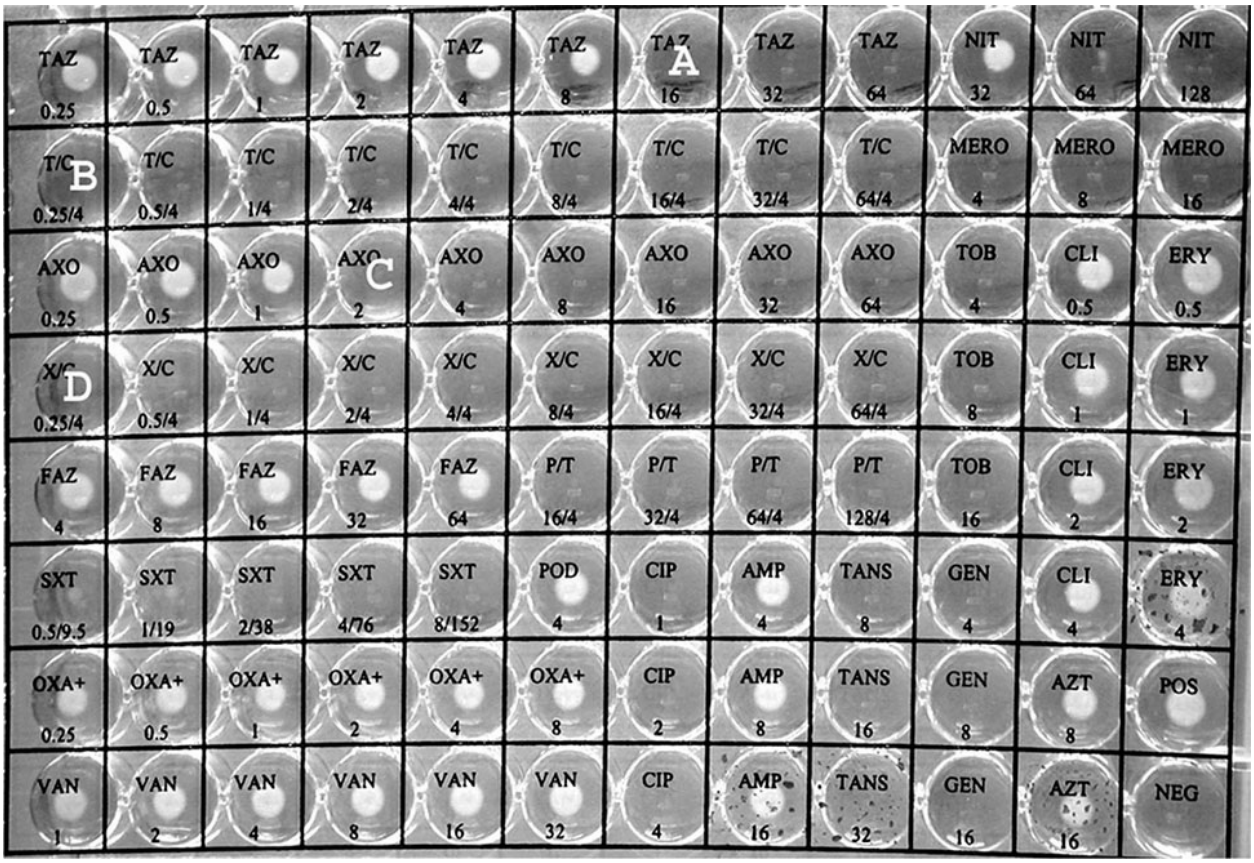
A modified DDT has been developed that will simultaneously detect all types of β-lactamase (i.e., ESBLs, AmpC enzymes, and cephalosporinase overproduction) in *Enterobacteriaceae*, and may improve detection of an ESBL in strains where multiple enzymes are operative.[173,473] The sensitivity of the MDDT has been enhanced by decreasing the distance between the disks of cephalosporins and clavulanate. The addition of a cefepime (fourth-generation cephalosporin) disk that is more slowly inactivated by cephalosporinases than by ESBL improves the detection of synergy with clavulanate when there is also overproduction of a cephalosporinase.[309,580] Resistance to cefoxitin (cephamycin) indicates the presence of an AmpC enzyme.[281]

Commercial disc kits are also available that simultaneously detect the presence of

ESBLs and AmpC enzymes in *Enterobacteriaceae*. Donaldson and colleagues compared

1141

the Vitek 2 AST N-054 card with the MASTdiscs ID ESBL (MAST Group Inc., Bootle, UK) detection disc diffusion test for detecting ESBL production in 137 well-characterized clinical *E. coli* isolates.[167] The MAST disc test correctly detected ESBL in 135 *E. coli* isolates (98.5%; 95% CI, 94.5 to 99.9)] whereas the Vitek card only detected ESBL in 93 (67.9%; 95%CI, 59.7 to 75.1). The MASTdiscs ID AmpC and ESBL 4 disc detection method has recently been compared with a double-disk synergy test for detection of ESBL production in 241 rectal swabs.[339] Of the 41 rectal swabs confirmed positive for ESBL production, the MASTdisc test detected 20(49%) versus 12(29%) by the double-disk synergy test (p = 0.013) after only 24 hours of incubation. The MASTdisc test also confirmed significantly more rectal swabs as negative for ESBL production (183[88%] vs. 158[76%] [$p < 0.001$]), and had a much lower rate of inconclusive results (46[18%] vs. 79[32%]) after 24 hours of incubation. A combination four disc test for simultaneous detection of ESBL and AmpC enzyme production in *Enterobacteriaceae* can also be purchased from Rosco Diagnostica, Tasstrup, DK (www.rosco.dk). Although in-house or commercial modified double-disk synergy tests are not routinely performed in the clinical laboratory, they can assist with differentiation of the enzymatic resistance mechanisms operative when molecular testing is not available.

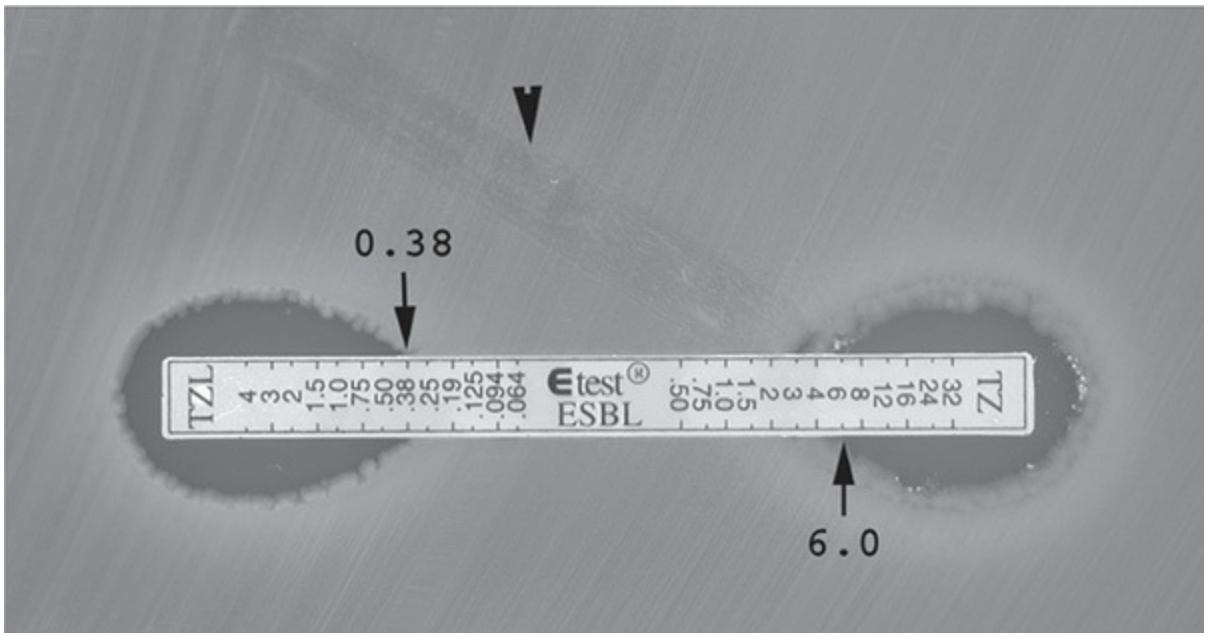


■ **FIGURE 17-32** MIC test for ESBL production in an isolate of *Escherichia coli*. The MIC of this isolate for ceftazidime is 16 μg/mL **(A)**; when combined with clavulanic acid, the MIC is ≤0.25 μg/mL **(B)**. The MIC of the isolate for ceftriaxone is 2 μg/mL **(C)**; in the presence of clavulanic acid, the MIC is ≤0.25 μg/mL **(D)**. Thus, in each case, there is a >fourfold reduction of the MIC in the presence of clavulanic acid, demonstrating the presence of an ESBL.

Nordmann and colleagues have also developed a rapid biochemical test, the ESBL NDP, for detection of ESBLs in *Enterobacteriaceae*.[431] This biochemical test is based on the in vitro detection of a cephalosporin (cefotaxime) hydrolysis that is inhibited by the addition of the β-lactamase inhibitor tazobactam. ESBL activity is evidenced by a color change (red to yellow) of a pH indicator (red phenol) due to carboxyl-acid formation resulting from cefotaxime hydrolysis that is blocked by addition of tazobactam (positive test). Evaluation of the ESBL NDP test for detection of ESBL production in cultured strains (215 ESBL producers and 40 ESBL nonproducers) showed that the test had a sensitivity and specificity of 92.6% and 100%, respectively. A few ESBL producers (n = 16) that remained susceptible to cefotaxime were not detected. Its sensitivity for detection of CTX-M producers was 100%. The ESBL NDP test can be performed in less than 1 hour, and is cost-effective compared to

conventional detection methods for ESBL production which remain time-consuming and take 24 to 48 hours before a result can be reported. The ESBL NDP test is being commercialized and will be available from bioMérieux (www.bioMérieux.com).

Although many laboratories rely on the testing and reporting of the presence of an ESBL from their automated system (e.g., Vitek 2, BD PHOENIX, etc.) or by using an Etest ESBL strip gradient diffusion test (Fig. 17-33), commercial detection has not been widely validated against other methods. Although earlier assessments of commercial methods indicated they were reliable for ESBL detection,[350,565] more recent data are not as favorable. A multicenter evaluation of all of the currently recommended ESBL-confirmation methods was recently reported from the Netherlands.[475] Twenty laboratories submitted 443 *Enterobacteriaceae* with a positive ESBL screen test (i.e., cefotaxime and/or ceftazidime MIC > 1 μg/mL) as well as the results of their confirmatory test (74% *E. coli*, 12% *E. cloacae*, 8% *K. pneumoniae*, 3% *P. mirabilis*, 2% *K. oxytoca*). All isolates used in this study had ESBL genes detected as the reference method. Overall, accurate detection of ESBLs by local laboratories using a phenotypic method was 88% with a PPV of 70%. However, the PPV varied depending on the method used (Vitek 2 69%, BD Phoenix 68%, DDT 92%) and species (95% *K. pneumoniae* vs. 27% *K. oxytoca*). Overall, combination DDT testing for ESBL confirmation was also more specific than Etest ESBL strips (91% vs. 61%), but the PPV for the DDT was poor for certain species (*P. mirabilis* 33% and *K. oxytoca* 38%, although the NPV for these isolates was 100%). ESBL confirmatory tests were also only read and interpreted correctly 93% of the time. These data suggest that ESBL confirmatory testing, regardless of the method used can be an exacting procedure that requires enhanced education of technologists to improve their interpretation. Overall, the DDT had the best performance for the most common species (*E. coli* and *K. pneumoniae*), but the low PPV of automated systems and Etest ESBL strips indicates that the only definitive way to detect all types of ESBLs in *Enterobacteriaceae* is molecular detection of the gene encoding the enzyme(s) present in a given isolate.

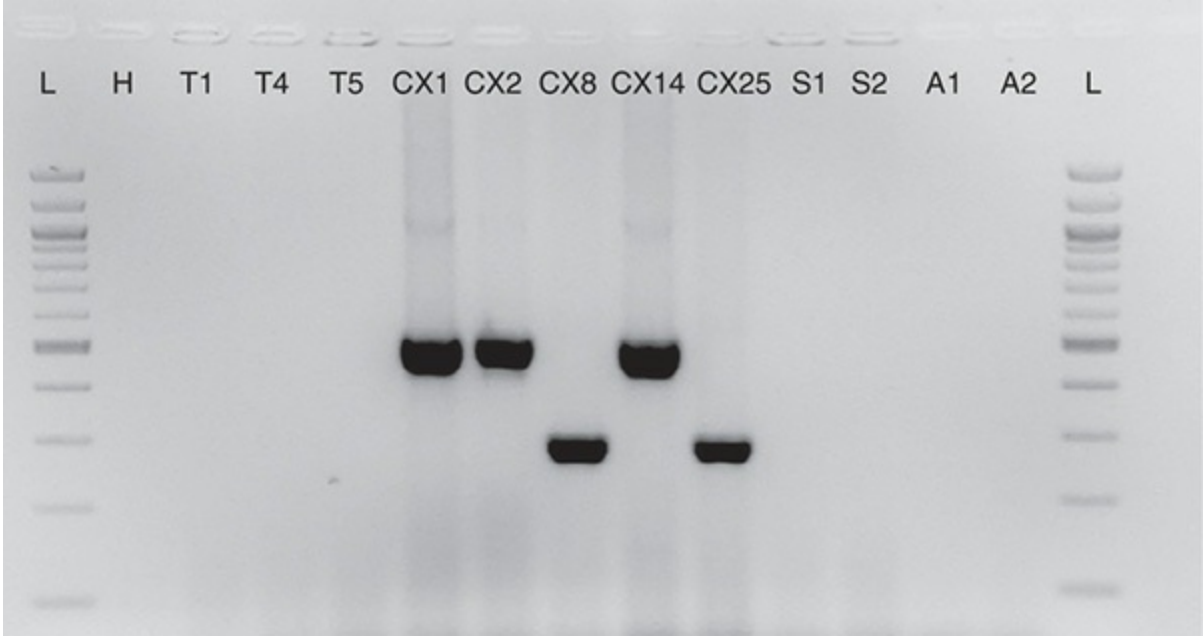


■ **FIGURE 17-33** Etest strip for demonstration of ESBL production in an isolate of *Klebsiella pneumoniae*. The MIC of the isolate for ceftazidime (TZ) is 6 μg/mL. (Note that the zone of inhibition intersects the strip closer to 4 μg/mL on the lower side, but the intersection is at 6 μg/mL on the upper side; the higher value is recorded.) At the other end of the strip, the MIC of the isolate for ceftazidime in the presence of clavulanic acid is 0.38 μg/mL. The reduction of the MIC is > fourfold, indicating the presence of an ESBL enzyme in the strain. Note the impression on the lawn of bacteria of the strip *(arrowhead)*, which was initially dropped upside down on the plate; because the side that was impregnated with antibiotic did not touch the agar, it was acceptable to reposition the strip and continue the test.

Reporting. ESBL-producing isolates of *E. coli*, *Klebsiella* spp., and *P. mirabilis* should be reported resistant to penicillins, except for the β-lactam/β-inhibitor combinations (amoxicillin/clavulanate and piperacillin/tazobactam), and for all cephalosporins, except for the cephamycins (cefoxitin and cefotetan). Laboratories will also encounter *Enterobacteriaceae* isolates that have a positive ESBL screen but a negative confirmatory test. Laboratories should have policies and procedures in place for referral of multidrug-resistant strains to a reference laboratory for molecular detection of β-lactamase genes because of the limitations of existing phenotypic methods (i.e., not all types of ESBLs will be detected and an AmpC enzyme is likely present). Other mechanisms of resistance such as the presence of another type of β-lactamase not inhibited by clavulanic acid (i.e., AmpC enzyme of TEM or SHV enzymes), or altered porins may also be present and effecting the results of the ESBL confirmatory test.

Molecular ESBL Detection. Many investigators have developed and evaluated primers to detect TEM, SHV, OXA, CTX-M, and GES enzymes in gram-negative bacteria.[471,609] Both conventional PCR as well as real-time PCR assays have been developed using primers for one or more ESBL enzymes, and several novel multiplex formats have recently been used including microarrays to simultaneously detect a large panel of β-lactamases.[126,143,338] Figure 17-34 shows a typical multiplex PCR results for detection of CTX-M-type ESBLs in *E. coli*. Although CLSI no longer recommends confirmatory testing for detection of ESBLs, both phenotypic and molecular tests may be required in order to deploy appropriate Infection Control measures and to define a nosocomial outbreak.[455,664] Polsfuss and colleagues recently published a diagnostic approach that combines ESBL screening with subsequent confirmation both by phenotypic and multiplex PCR for detection of CTX-M-type and multiplex PCR and sequencing for TEM and SHV ESBLs before reporting an isolate as "ESBL positive."[481] This article contains a comprehensive diagnostic flow chart that laboratories may wish to consult when having to confirm ESBL as the mechanism of resistance.

AmpC β-Lactamase Detection. Although AmpC detection may be important for clinical and epidemiologic purposes, there are currently no recommended assays for reliable detection of these enzymes published in antimicrobial susceptibility testing guidelines (CLSI or EUCAST). Inducible chromosomal AmpC enzymes occur in *Enterobacteriaceae* within the "SPICE" group of genera including *Serratia marcescens*, indole-positive *Proteus mirabilis*, *Citrobacter freundii,* and *Enterobacter cloacae*.[281] This enzyme confers broad resistance to β-lactams including β-lactam/β-lactamase inhibitor combinations such as piperacillin/tazobactam. More recently, multidrug resistance determinants have moved onto plasmids in other genera, including *Klebsiella* spp., *E. coli,* and *Salmonella* spp. and *P. mirabilis*.[281] Strains that carry an AmpC enzyme, which also have mutations in their porin structure, may also be resistant to carbapenems.[571] Isolates carrying a plasmid-mediated AmpC enzyme, however, are typically resistant to cephamycins such as cefoxitin or cefotetan (MIC ≥ 32 μg/mL), which is a clue to their presence.[281,472] However, second-generation cephalosporin resistance is not a definitive test because other resistance mechanisms may be operative (i.e., altered or lost porin structure).



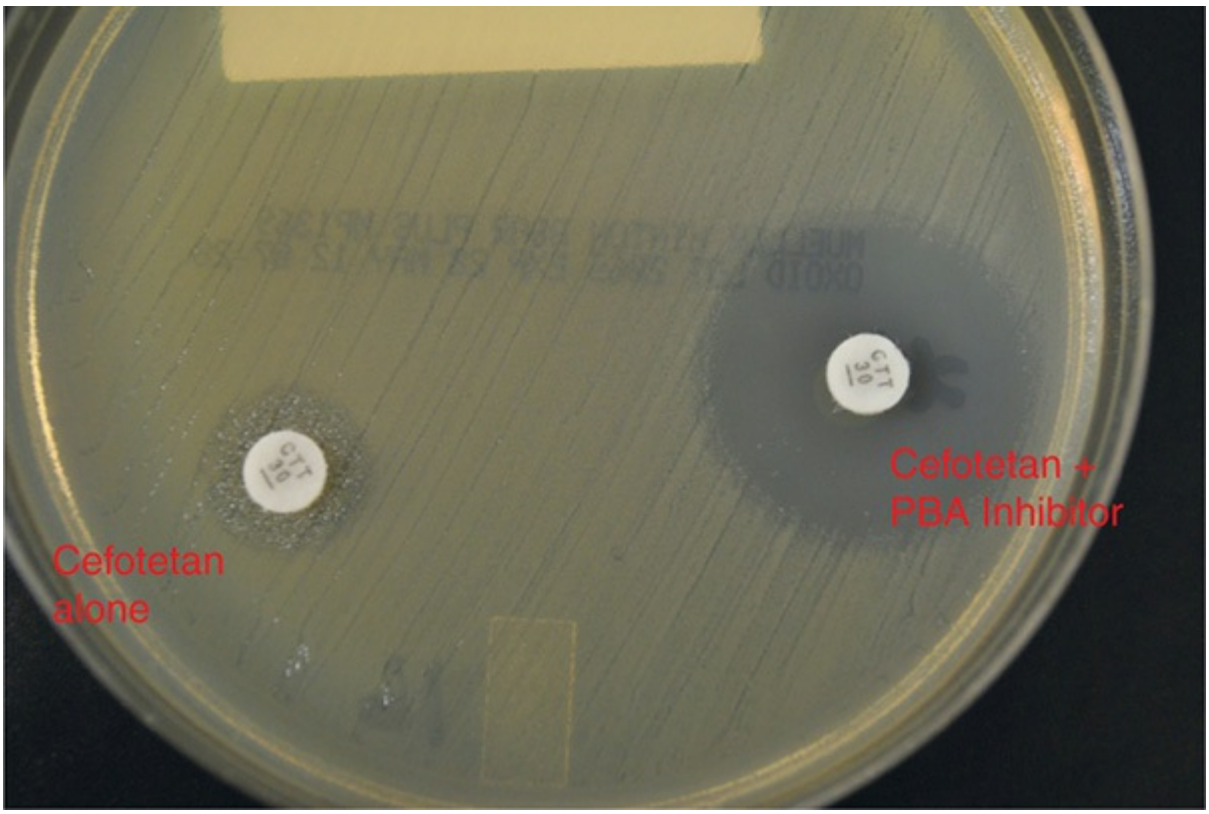
■ **FIGURE 17-34** Multiplex PCR for detection of the ESBL type in *E. coli*. *H*; *H20*, *T1*; *TEM-3*, *T4*; *TEM-10*, *T5*; *TEM-50*, *CX1*; *CTX-M-1*, *CX2*; *CTX-M-2*, *CX8*; *CTX-M-8*, *CX14*; *CTX-M-14*, *CX25*; *CTX-M-25*, *S1*; *SHV-2*, *S2*; *SHV-7*, *A1*; *NMC-A*, *A2*; *KPC-1*. (Courtesy of Calgary Laboratory Services.)

Gram-negative isolates producing a high amount of AmpC enzyme will give a positive result in ESBL screening tests but fail to confirm. Readers are referred to an excellent review by Jacoby of all of the methods used for detection of AmpC enzymes,[281]only a brief description of those used clinically are outlined. Diagnostic tests for AmpC detection have been developed that use an enzyme inhibitor (e.g., 48-1220, LN-2-128, EDTA, cloxacillin, and various boronic acid derivatives),[45] but only 3-amino-phenylboronic acid (PBA) is commercially available. A caveat of using inhibitor-based methods to detect AmpC enzymes is that false-positive results may occur due to KPC enzymes.[45] Yagi and colleagues developed a DDT method that incorporates 300 µg-PBA into disks containing ceftazidime or cefotaxime.[674] Similar to the ESBL DDT test described above, a ≥5 mm increase of the zone of inhibition around the β-lactam/boronic acid disks compared to disk with the drug alone reliably detected the AmpC-types present but not strains with ESBLs or carbapenemases. Pitout and colleagues recently described a modification of the DDT method using cefotetan disks containing PBA to detect plasmid-mediated AmpC enzymes in *Klebsiella* spp., *E. coli*, *Salmonella* spp. and *P. mirabilis*.[472] This study tested 126 control strains and 29,840 nonrepeat clinical isolates that were initially screened using cefoxitin resistance followed by confirmation with the cefotetan DDT. A total of 623 (2%) of the isolates were found resistant on the screen test and 332(52%) were AmpC

positive. Cloxacillin (200 μg) may also be used as the AmpC inhibitor in a double-disk test using cefotetan disks (30 μg).[600] Several commercial methods are also available including a DDT and 4-disc tests for simultaneous AmpC and ESBL enzyme detection (MASTdiscs ID, MAST Group Ltd., Bootle, UK, and Rosco Diagnostics, Denmark), and Etest AmpC strips (contain cefotetan on one end and cefotetan–cloxacillin on the other). A double-disk synergy test that uses cefpodoxime disks alone and supplemented with PBA as the AmpC enzyme inhibitor is shown in Figure 17-35. The AmpC Etest strip contains a concentration gradient of cefotetan on one-half of the strip and cefotetan

1143

with cloxacillin on the other half of the strip; MIC ratios of ≥8 between cefotetan alone and cefotetan with cloxacillin are considered indicative of the presence of an AmpC enzyme. A recent evaluation of the AmpC Etest compared to two DDT methods showed that all three confirmatory tests were able to detect >90% of the strains that were AmpC producers that had been molecularly characterized.[459]



■ **FIGURE 17-35** AmpC enzyme confirmation in *E. coli* using a double-disk test. (Courtesy of Calgary Laboratory Services.)

Molecular detection methods are currently the "gold standard" for definitive detection and characterization of AmpC enzymes. Because of the plethora of AmpC enzymes carried by gram-negative bacteria, and the fact that phenotypic tests cannot distinguish between plasmid-mediated and/or chromosomal gene determinants, multiplex PCR is used to detect plasmid-mediated resistance. A multiplex PCR using six primer pairs has been shown to reliably detect most plasmid-mediate AmpC enzymes, except for CFE-1 β-lactamase.[457] However, a seventh set of primers may be used to detect the CFE-1 enzyme.[416] Polsfuss and colleagues have recently published a comprehensive diagnostic approach for reliable detection of AmpC enzyme producing *Enterobacteriaceae* that includes an initial screen for cefoxitin resistance followed by confirmatory testing using a DDT that include cefotetan/cloxacillin with subsequent multiplex PCR for plasmid-mediated AmpCs and/or AmpC gene promoter sequencing to detect chromosomal promoter mutations.[482] However, this extent of molecular analysis may not be feasible for many clinical laboratories, but commercial development of an automated microarray assay would enable reliable detection and tracking of AmpC-resistant determinants for epidemiologic purposes.

Reporting. Susceptibility reports should be based on the revised **CLSI** breakpoints for cephalosporins and aztreonam; it is no longer necessary to change results for β-lactams to resistant when a susceptible in vitro result is obtained on using the recommended susceptibility test methods. However, *Enterobacteriaceae* confirmed to carry an AmpC enzyme by phenotypic and/or molecular methods should have the penicillins and all cephalosporins except for fourth-generation agents (i.e., cefepime) reported as resistant including, and β-lactam/β-lactam inhibitors combination drugs.

Carbapenemase Detection (*Enterobacteriaceae*). *Enterobacteriaceae* that produce carbapenemases are becoming an increasing problem worldwide. Specific β-lactamase enzymes in molecular classes A, B, and D have carbapenemase activity as shown in Tables 17-29 and 17-30. *Enterobacteriaceae* carrying KPC (*K. pneumoniae*), SME (*S. marcescens*), NDM (*E. coli*, *Klebsiella* spp.), and the OXA enzymes which are widely distributed in many species are all clinically important. Detection of carbapenemase resistance according to CLSI relies on the revised MIC breakpoints and corresponding zone diameter sizes initially published in 2010. Table 17-30 compares the "previous" and revised CLSI MIC breakpoints for carbapenem drugs for *Enterobacteriaceae*. These new breakpoints were established after review of the pharmacokinetic/pharmacodynamic (PK-PD) properties of these drugs, limited clinical data, and the current MIC distribution of clinically relevant *Enterobacteriaceae* species including carbapenemase producers. Revised CLSI carbapenem breakpoints and disk diffusion zone diameters have been set to detect most carbapenemase producers in the *Enterobacteriaceae*. If carbapenem resistance is detected (i.e., meropenem MIC ≥ 1.0 μg/mL) then CLSI no longer recommends doing a phenotypic

confirmation test (CLSI M100-20-22).[120] If laboratories continue to use the "previous" CLSI carbapenem MIC breakpoints (Table 17-31) then a phenotypic confirmation test needs to be done before reporting the isolate as resistant to carbapenems (CLSI M100-S20-22). A Modified Hodge

Test (MHT) may be used to confirm the presence of class A carbapenemases (i.e., KPCs) as described by CLSI in M100-S22 Table 2A. Pasteran and colleagues described modifications to the MHT method by incorporating boronic acid (inhibits class A carbapenemases and AmpC enzymes) and oxacillin (inhibitor of AmpC enzymes) that had a high sensitivity (>90%) and specificity (100%) for distinguishing class A carbapenemases (KPC, GES, SME, IMI, and NMC-A) from other classes of β-lactamases (ESBLs, AmpC enzymes and MBLs).[448] The results of a positive MHT are shown in Figure 17-36. However, CLSI M100-S22 Table 2A indicates that it is important to recognize that not all carbapenemase-producing *Enterobacteriaceae* isolates will have a positive test, and MHT-positive tests may be encountered in isolates with carbapenem resistance mechanisms other than carbapenemase production (Table 17-32). There are currently no CLSI-validated phenotypic tests to confirm the presence of a metallo-β-lactamase in *Enterobacteriaceae*. *Enterobacteriaceae* isolates that demonstrate carbapenem resistance should be referred to a reference laboratory for confirmatory testing.

TABLE 17-29 Molecular Classification of β-Lactamases in Gram-Negative Bacteria

Class	Active Site	Examples
A	Serine Inhibitor susceptible β-lactamases	TEM-1, SHV-1, KPCs, OXY, and most ESBLs including CTX-M types
B	Zinc Metallo-β-lactamases	Metalloenzymes; VIM, IMP, SPM, NDM, GIM, SIM
C	Inhibitor-resistant β-lactamases	AmpC enzymes
D	Oxacillin-active β-lactamases that may be inhibitor susceptible	OXA (including rare ESBL phenotypes), PSE

Adapted from reference 122.

TABLE 17-30 β-Lactamases With Carbapenemase Activity

β-Lactamase Class[a]	Gram-Negative Bacteria Where Enzyme Detected	Examples
A	*K. pneumoniae* *Enterobacteriaceae*	KPC, SME, NMC-A, IMI, PER, GES, SFO, SFC, IBC
B	*Enterobacteriaceae* *P. aeruginosa* *A. baumannii*	Metallo-β-lactamases (MBLs) inhibited by EDTA (IMP, VIM, NDM), SPM, SIM, GIM
D	*Enterobacteriaceae* *A. baumannii*	OXA, PSE

[a] No class C enzymes have carbapenemase activity.

The recommended phenotypic confirmation tests for detection of class A, B, and D

carbapenemases in *Enterobacteriaceae* and their potential for false-positive tests due to the presence of other β-lactamases is outlined in Table 17-32. Cohen, Stuart, and colleagues have recently published guidelines for phenotypic screening and confirmation of carbapenemases in *Enterobacteriaceae*.[127] Besides the MHT test, various combination DDT assays are used that rely on testing of carbapenem susceptibility alone and in the presence of a specific carbapenemase inhibitor. Several different types of DDT assays have been developed for detection of MBLs that use meropenem disks (10 μg) supplemented with dipicolonic acid (DPA) as the enzyme inhibitor, or imipenim disks (10 μg) supplemented with EDTA as the enzyme inhibitor (Fig. 17-37). Other DDT assays have been developed to detect class A carbapenemases that use meropenem disks (10 μg) supplemented with boronic acid, and meropenem disks (10 μg) supplemented with oxacillin to help distinguish the presence of an AmpC enzyme.[218] The Carba NP TEST II identifies carbapenemase production in *Enterobacteriaceae* and *Pseudomonas* spp., and differentiates between classes A, B, and D enzymes.[168] This test is based on the detection of acidification that occurs with imipenem hydrolysis, coupled with tazobactam and EDTA as inhibitors. The Carba NP II test can be rapidly performed and has a reported sensitivity and specificity of 100%,[168] but it is not yet commercially available. Agar-based screening methods have also been described that perform well for detection of MBL and KPC-type enzymes where carbapenem disks are placed on inhibitor (EDTA, PBA, and cloxacillin) impregnated MHA; this method also distinguishes other types of β-lactamases.[42] Due to the limitations of phenotypic tests and the high diversity of genes encoding carbapenemases,[498] molecular analysis is considered the "gold standard" detection method. Genotypic confirmation is performed using multiplex PCR detection for carbapenemases, and sequencing of carbapenemase genes.[432,586] A commercial real-time PCR assays has been developed by Cepheid (Xpert MDRO) for the rapid, accurate screening of patients for the presence of enteric bacteria that carry a bla_{KPC}, bla_{NDM} and bla_{VIM} carbapenem resistance gene.[606] Evaluation of the Xpert MDRO assay compared to broth enrichment culture and sequencing of the target genes showed highly reliable detection of KPC and VIM enzymes from clinical samples, and similar performance for detection of the NDM enzyme in contrived stool samples.

Reporting. *Enterobacteriaceae* should be reported as resistant to carbapenems based on the revised CLSI MIC breakpoints and corresponding disk diffusion zone diameters. *Enterobacteriaceae* isolates that demonstrate carbapenem resistance should be referred to a reference laboratory for confirmatory testing. Laboratories should have policies and procedures for extended susceptibility testing of alternate drug therapy (tigecycline, colistin) for multidrug-resistant strains, and/or immediate referral to a reference laboratory where such testing can be urgently done.

Detection of Fluoroquinolone Resistance in *Salmonella* spp. Salmonellosis is one of the main causes of bacterial enterocolitis transmitted through the fecal-oral route by ingestion of contaminated food or water. Nontyphoidal salmonella are estimated to cause approximately a million cases of bacterial enterocolitis per annum, and invasive cases are not infrequent, especially among infants <1 year of age, the elderly and those with immunosuppression (i.e., HIV, transplant recipients etc.).[139,367] Enteric fever is a serious illness with bacteremia caused by *Salmonella enterica* serovars Typhi and Paratyphi, which mainly occurs in underdeveloped countries with poor standards of hygiene and sanitation, but it is also a common cause of fever in the returned traveler in developed countries.[7,447] Antimicrobial treatment of salmonellosis is essential in these types of patients, but recently increased antimicrobial resistance to key therapeutic agents has been documented in *S.* Typhi and nontyphoidal salmonellae.[138,558] The WHO guidelines (2003) currently recommend the fluoroquinolones as the treatment of choice for uncomplicated enteric fever in adults (www.who.org). The reduced fluoroquinolone susceptibility (MICs of 0.12 to 1 μg/mL) of *S.* Typhi and extraintestinal *Salmonella* infections is a concern because the clinical response rates to ciprofloxacin are poor for these strains.[138]Most fluoroquinolone resistance in *Salmonella* was due to several single base pair mutations

in the DNA gyrase (*gyr*A) gene.[52] A recent study in 13 European countries of *Salmonella* and *E. coli* isolates from animals, humans, food, and the environment, however, showed that plasmid-mediated fluoroquinolone resistance genes (PMQR) were found in 59% of the *Salmonella* isolates.[641]

Previous methods recommended by the CLSI may not be optimal for detection of *Salmonella* strains that are fluoroquinolone resistant due to acquisition of a PMQR, particularly strains that have acquired aac(6′)-1B-cr determinants. Nalidixic acid testing has been used to screen for fluoroquinolone resistance in *Salmonella*, and is a reliable method for isolates that have decreased susceptibility because of one or more gyrase (*gyr*A, *gyr*B) mutations. But an MIC test should be done on *S.* Typhi and extraintestinal *Salmonella* isolates in order to enhance detection on strains carrying a plasmid-encoded fluoroquinolone resistance gene.[121,122]

CLSI currently recommends that susceptibility testing should be done for typhoidal *Salmonella* (*S.* Typhi and *Salmonella* Paratyphi A–C) and on isolates from extraintestinal and intestinal sources.[121,122] But routine susceptibility testing is not indicated for nontyphoidal *Salmonella* spp. isolated from intestinal sources because enterocolitis is a self-limited illness in healthy children and adults. Table 17-33 outlines the revised CLSI guidelines for fluoroquinolone testing of *Enterobacteriaceae* using either disk diffusion or an MIC method. The CLSI MIC breakpoints for *Enterobacteriaceae* susceptibility to fluoroquinolones other than *S.* Typhi and extraintestinal *Salmonella* spp. remain unchanged. However, CLSI has lowered the MIC breakpoints and corresponding zone diameters for fluoroquinolone (ciprofloxacin, levofloxacin, and ofloxacin) testing *S.* Typhi and extraintestinal *Salmonella* spp. in order to enhance detection of strains that may have acquired PMQR.[268] The revised ciprofloxacin breakpoints should also be used to test corresponding enteric *Salmonella* isolates recovered from patients with enteric fever or invasive salmonellosis. However, of the commercial antibiotic susceptibility testing systems, only Etest has incorporated the new CLSI fluoroquinolone breakpoints. CLSI, therefore, recommends the continued use of nalidixic acid to test for reduced fluoroquinolone susceptibility in *Salmonella* until laboratories can implement the MIC interpretive criteria for ciprofloxacin, levofloxacin, and ofloxacin resistance.[121,122]

TABLE 17-33 Revised CLSI Ciprofloxacin Zone Diameter and MIC Criteria Breakpoints for *Enterobacteriaceae* and *Salmonella typhi* and Extraintestinal *Salmonella* spp.

Antimicrobial	Disk Diffusion			MIC		
	S	I	R	S	I	R
***Enterobacteriaceae* and *Salmonella* spp.**						
Nalidixic acid	≥19	14–18	≤13	≤16	–	≥32
Ciprofloxacin	≥21	16–20	≤15	≤1	2	≥4
Levofloxacin	≥17	14–16	≤13	≤2	4	≥8
Extraintestinal *Salmonella* spp.						
Ciprofloxacin[a]	≥31	21–30	≤20	≤0.06	0.12–0.5	≥1

[a] *S. typhi* and extraintestinal *Salmonella* spp. should be tested against ciprofloxacin using the revised criteria. Nalidixic acid may not detect all mechanisms of fluoroquinolone resistance, and isolates that test resistant to nalidixic acid may be associated with treatment failure or delayed response in fluoroquinolone treated patients with extraintestinal infection.
S, susceptible; I, intermediate; R, resistant. Adapted from references 121 and 122.

1146

Reporting. Fecal isolates of *Salmonella* and *Shigella* spp. that are tested should only have ampicillin, a fluoroquinolone, and trimethoprim–sulfamethoxazole routinely reported. Extraintestinal isolates should also have a third-generation cephalosporin tested and reported, and chloramphenicol may also be tested and reported, if requested.[121,122] CLSI also recommends that laboratories continuing to screen for fluoroquinolone resistance using nalidixic acid alone should put a comment on their report that indicates that nalidixic acid-resistant strains may be associated with clinical failure or delayed response to fluoroquinolone-treatment in patients with extraintestinal salmonellosis.[121,122] First- and second-generation cephalosporins, cephamycins, and aminoglycosides are not clinically effective against *Salmonella* spp. and should not be reported although they may appear susceptible on in vitro tests. Multidrug-resistant *Salmonella* strains should immediately be referred to a public health or other reference laboratory for serotyping and extended antibiotic susceptibility testing using an MIC method.

Gram-Negative Nonfermenters

P. aeruginosa and other pseudomonads, along with *Stenotrophomonas maltophilia*, *Burkholderia cepacia* complex, and *Acinetobacter baumannii,* are the most

commonly isolated gram-negative nonfermenters worldwide. Members of this gram-negative nonfermenter group represent a unique and important threat because they are ubiquitous in the healthcare environment, cause opportunistic infections in patients who are critically ill and/or immunocompromised, and are frequently multidrug-resistant (i.e., resistant to ≥3 antibiotic classes).[307,357,386] Cystic fibrosis patients are also commonly colonized with *P. aeruginosa*, and/or less frequently *B. cepacia* complex, and multidrug-resistant strains result in a higher failure rate of initial therapy for exacerbations of infection, as well as decreased survival.[289,446] This section briefly describes the laboratory challenges of detecting recently emerging resistance problems in this nonfermenter group.

P. aeruginosa *(Other Pseudomonads)*

P. aeruginosa strains that are pan-resistant to multiple classes of antibiotics have recently developed due to several mutations that upregulate AmpC β-lactamase and efflux, decrease bacterial cell wall permeability through alterations or loss of porins, and alter the gyrase enzyme target to convey fluoroquinolone resistance.[355] However, *P. aeruginosa* clones have also disseminated to many parts of the world that have acquired plasmid-mediated resistance to several drug classes carried on an integrin gene cassette that encodes metallo-β-lactamases and multiple aminoglycoside modifying enzymes (e.g., MBL-producing *P. aeruginosa*).[130,316,330] As shown in Tables 17-29 and 17-30, class B MBL-β-lactamases are carbapenemases (i.e., IMP, VIM, GIM, SIM, SPM enzyme types) that have zinc at the active site, and these enzymes can be inhibited by EDTA.[647] In some locations, hospital outbreaks have occurred with high mortality in the affected patients due to the limited choices that remain for treatment of MBL-producing-*P. aeruginosa* infections.[445] Laboratories need to be able to reliably detect MBL-producing *P. aeruginosa* isolates so that appropriate antibiotic therapy and infection control measures can be promptly deployed.

CLSI (M100-S22) guidelines recently revised the *P. aeruginosa* MIC breakpoints for piperacillin and ticarcillin with or without a β-lactamase inhibitor to be the same as those for *Enterobacteriaceae* except for slight differences in the corresponding disk diffusion zone diameters.[120] Tam and colleagues recently studied mortality due to *P. aeruginosa* bacteremia due to isolates that had reduced susceptibility to piperacillin/tazobactam (PTZ) (MIC, 32 to 64 μg/mL) but reported as susceptible based on the "previous" CLSI breakpoints (Table 17-34); seven patients received empiric therapy with this drug.[597] Thirty-day mortality was 85.5% in the group treated with PTZ and 22.2% in the control groups who had received other drug therapy (p=0.004). Decreased susceptibility to PTZ and empirical use of this drug also remained the main risk factor for mortality in multivariate analysis after adjusted

differences in age and APACHE II score between the two groups. These investigators recommended that the old CLSI breakpoints for PTZ susceptibility for *P. aeruginosa* were too high, because strains with intermediate-level resistance were being interpreted as susceptible. CLSI originally set the breakpoints for ticarcillin, piperacillin, and their respective β-lactamase inhibitor combination drugs higher for *P. aeruginosa* than those recommended for *Enterobacteriaceae* because of the FDA drug label indications that they should be used in combination with an aminoglycoside. However, the revised CLSI breakpoints are for use of these drugs alone in a dosage regimen of at least 3 g every 6 hours.[120]

Detection of MBL-Producing *P.* aeruginosa. The CLSI has also revised the *P. aeruginosa* MIC breakpoints and corresponding zone diameters for susceptibility testing of carbapenems (doripenem, imipenem and meropenem) in 2012.[56,120]These new breakpoints were established after review of the PK/PD properties of these drugs, limited clinical data, and the current MIC distribution of clinically relevant *P. aeruginosa* species including MBL-β-lactamase producers. If laboratories have implemented the new MIC breakpoints shown in Table 17-34 or the revised zone diameters for disk testing of these drugs, confirmatory testing is no longer required before reporting carbapenem susceptibility results for *P. aeruginosa*. The revised breakpoints for these compounds have been based on specific drug dosage regimens outlined by CLSI in M100 S20-22, Table 2B-1.[120] These drug dosages are required to achieve plasma drug exposures in adults with normal renal and hepatic function, and laboratories using these criteria should provide this information to important stakeholders (i.e., infectious diseases physicians, pharmacists, infection control practitioners, and their respective committees).

1147

TABLE 17-34 CLSI Previous (M100-S21) and Revised (M100-S22) Breakpoints (MIC μg/mL) for *P. aeruginosa* β-Lactam/β-Lactamase Inhibitors and Carbapenems

Antimicrobial	Previous (M100–S21)			Revised (M100–S22)		
	S	I	R	S	I	R
Doripenem[a]	NA	NA	NA	≤2	4	≥8
Imipenem[b]	≤4	8	≥16	≤2	4	≥8
Meropenem[b]	≤4	8	≥16	≤2	4	≥8
Piperacillin	≤64	–	≥128	≤16	32–64	≥128
Piperacillin/tazobactam	≤64/4	–	≥128/4	≤16/4	32/4–64/4	≥128/4
Ticarcillin	≤64	–	≥128	≤16	32–64	≥128
Ticarcillin/clavulanate	≤64/2	–	≥128/2	≤16/2	32/4–64/4	≥128/2

[a] Doripenem interpretive criteria for *P. aeruginosa* are based on a dosage regimen of 500 mg every 8 hour.
[b] Imipenem and Meropenem interpretive criteria for *P. aeruginosa* are based on high dose, frequent therapy (1 g every 6–8 hours).
S, susceptible; I, intermediate; R, resistant.
Adapted from CLSI M100-S21 (2011) and M100-S22 (2012)[120].

Although an MHT similar to the confirmation test described previously for detection of class B carbapenemases (i.e., KPCs) by CLSI in M100-S22 Table 2A (Fig. 17-36) may be done,[120] it performs poorly for confirmation of the presence of a MBL. Pasteran and colleagues described modifications to the MHT method by incorporating boronic acid (inhibits class A carbapenemases and AmpC enzymes) and oxacillin (inhibitor of AmpC enzymes) that had a high sensitivity (>90%) and specificity (100%) for distinguishing class A carbapenemases (KPC, GES, SME, IMI, and NMC-A) for other classes of β-lactamases (ESBLs, AmpC enzymes, and MBLs).[448] An MHT-positive test, however, may be encountered in *P. aeruginosa* isolates because of the presence of carbapenem resistance mechanisms other than carbapenemase production (Table 17-32). There are currently no CLSI-validated phenotypic tests to confirm the presence of a metallo-β-lactamase in *P. aeruginosa*. Isolates that demonstrate carbapenem resistance should be referred to a reference laboratory for confirmatory testing.

The recommended phenotypic confirmation tests for detection of class A, B, and D carbapenemases in *Enterobacteriaceae* and gram-negative nonfermenters, and their potential for false-positive tests due to the presence of other β-lactamases is outlined in Table 17-32. Besides the MHT test, various combination DDT assays are used that rely on testing of carbapenem susceptibility alone and in the presence of a specific carbapenemase inhibitor. Several different types of DDT assays have been developed for detection of MBLs, but the use of meropenem disks (10 μg) or imipenim disks (10

μg) supplemented with EDTA as the enzyme inhibitor appears to work well (Fig. 17-38).[207] The Carba NP TEST II identifies carbapenemase production in *Enterobacteriaceae* and *Pseudomonas* spp., and differentiates between classes A, B and D enzymes.[168] This test is based on the detection of acidification that occurs with imipenem hydrolysis, coupled with tazobactam and EDTA as inhibitors. The Carba NP II test can be rapidly performed and has a reported sensitivity and specificity of 100%,[168] but it is not yet commercially available. Agar-based screening methods have also been described that perform well for detection of MBL where carbapenem disks are placed on inhibitor (EDTA, PBA, cloxacillin) impregnated MHA; this method also distinguishes other types of β-lactamases.[42] An MBL Etest may also be used that has imipenem on one end of the strip and imipenem plus EDTA on the other (Fig. 17-39). However, due to the limitations of phenotypic tests and the high diversity of genes encoding carbapenemases, molecular analysis is considered the "gold standard" detection method. Genotypic confirmation is performed using multiplex PCR detection for carbapenemases, and sequencing of carbapenemase genes (Fig. 17-40).[177] A commercial real-time PCR assays has been developed by Cepheid (Xpert MDRO) for the rapid, accurate screening of patients for the presence of carbapenemases (i.e., KPC or NDM enzymes) in enteric bacteria as well as a VIM enzyme (i.e., metallo-β-lactamase) in *P. aeruginosa*.[606] Evaluation of the Xpert MDRO assay compared to broth enrichment culture and sequencing of the target genes showed highly reliable detection of VIM enzymes from clinical samples.

Reporting. *P. aeruginosa* should be reported as resistant to carbapenems based on the revised CLSI MIC breakpoints and corresponding disk diffusion zone diameters. Isolates that demonstrate carbapenem resistance should be referred to a reference laboratory for confirmatory testing. Laboratories should have policies and procedures in place for extended susceptibility testing of alternate drug therapy (tigecycline, colistin) for multidrug-resistant strains, and/or immediate referral to a reference laboratory where such testing can be promptly performed.

Acinetobacter baumannii

Acinetobacter baumannii is an opportunistic pathogen that has emerged as a major cause of nosocomial pneumonia, particularly ventilator-associated pneumonia in ICU patients, bacteremia and burn wound sepsis.[312] This organism also has a propensity for transmission resulting in nosocomial outbreaks because of its resistance to desiccation and inherent resistance to disinfectants.[50,411] *A. baumannii* has transformed from being susceptible to most antibiotics three decades ago, to the current global situation where some strains are now pan-resistant to almost all available agents including carbapenems, colistin, and tigecycline. Carbapenem and pan-resistant *A. baumannii* is a major threat to patient care in many hospitals, as mortality is understandably higher for serious infections due to these strains.[312]

A. baumannii are almost universally resistant to oxyimino-cephalosporins, primarily

because of an intrinsic chromosomal AmpC β-lactamase, although a large outbreak due to ESBL-producing strains (VEB-1 type) has been reported from France.[411] Although the AmpC enzyme is only constitutively expressed at a low level, insertion of an upstream ISAab1 promoter sequence from the β-lactamase gene can result in over expression.[627] Classical TEM-1 penicillinases are also widespread in *Acinetobacter* spp.[358] All *A. baumannii* isolates also carry the gene for OXA-51-like enzymes, and intrinsic molecular class D carbapenemase, which has low-level expression, so that these strains appear susceptible to carbapenems. However, high-level carbapenemase resistance can be "switched" on by a similar mechanism as that described above for AmpC enzymes. Some clones of *A. baumannii* have been transferred from casualties coming back to hospitals in both the United Kingdom and the United States that are now endemic.[123,662] Several other virulent *A. baumannii* clones carrying other OXA carbapenemases have arisen in at least three clusters (OXA-23-like, OXA-(24)-40-like, and OXA-58) and have now widely disseminated in different parts of the world.[124,479,668] Of concern is a more recent report of NDM-1-producing *A. baumannii* isolated from a patient repatriated to the Czech Republic from Egypt.[265] Although treatment for carbapenemase-resistant *A. baumannii* is limited, colistin and tigecycline have been used.[312] Colistin is, however, the drug of choice for carbapenemase-producing *A. baumannii* infections because tigecycline achieves suboptimal serum levels and resistance may develop on therapy. Tigecycline-resistant *A. baumannii* (typed as OXA-23 epidemic clone) has recently been recovered in the United Kingdom from a patient on therapy; resistance was mediated by an Ade-ABC-mediated efflux

1149

mechanism.[263] Colistin-resistant *A. baumannii* isolates have also been reported initially from the Czech Republic in 1999, but have since widely spread.[92] Colistin resistance in *A. baumannii* may be difficult to accurately detect in the clinical laboratory because heteroresistance is common.

Laboratories can use either microdilution or disk diffusion to perform susceptibility testing of *A. baumannii*. The considerable differences that existed in susceptibility to carbapenem drugs based on whether one is using the EUCAST (www.eucast.org) or CLSI guidelines have been eliminated. CLSI now recommends carbapenem drug zone diameters for *A. baumannii*, and lowered MIC breakpoints for *A. baumannii* that are very similar or identical to those used by EUCAST (Table 17-35).[121,122] Similar phenotypic confirmation methods can be used to detect an MBL-type carbapenemase in *A. baumannii* as described earlier for *P. aeruginosa* including a MHT and a DDT using meropenem and imipenem disks with and without EDTA. Currently, there are no

CLSI-validated methods to reliably detect the presence of an OXA-type carbapenemase in *A. baumannii*. Detection of OXA-type enzymes relies on molecular detection of the bla_{OXA} determinant and sequencing of the gene.[668]

Susceptibility Testing of Cystic Fibrosis Isolates

Cystic fibrosis (CF) patients have chronic pulmonary colonization with a complex microbial flora that is composed of various gram-negative nonfermenters including *P. aeruginosa*, *Stenotrophomonas maltophilia*, *Burkholderia cepacia* complex,*Achromobacter xyloxidans,* and other bacterial species. Many of these co-colonizers are also inherently resistant to antibiotics,[22,71] and in the case of *P. aeruginosa*, resistance increases after repeat exposure to broad-spectrum antibiotics during exacerbations.[180] *S. anginosus* group may also be an important emerging pathogen in some CF patients.[555] During pulmonary sampling, particularly during exacerbations, most patients have one or more morphotypes of *P. aeruginosa* isolated from lower respiratory specimens (i.e., sputa and bronchoalveolar lavages). Much effort and laboratory resource goes into isolating and performing susceptibility testing on individual CF lung isolates but this is far from being a precise science. CLSI breakpoints that were developed for parenteral antibiotic therapy for example, may not accurately predict susceptibility of *P. aeruginosa* to the same agents given by inhalation.[401] Although CLSI recommended methods and guidelines should be used to interpret the results of individual isolate testing, these results may not accurately predict clinical outcome in CF patients for several reasons outlined below.[272]

The complex microbial community inhabiting the lungs of CF patients mainly exists within biofilms, and not as planktonic forms. Studies of *P. aeruginosa* biofilms in the respiratory tract of CF patients clearly show that aggressive antibiotic therapy restrains, but doses not eradicate infection from the inflammatory conductive zone.[44] Methods have been developed for biofilm susceptibility testing (BST) that were recently evaluated in a multi-centered randomized trial that assessed the clinical outcomes of an antibiotic regimen based on the results of the BST compared to conventional susceptibility testing.[402] Study groups showed no significant difference in mean decreases in bacterial density in sputa or mean increases in forced expiratory volume in 1 sec (FEV1), but only a small number of patients were enrolled. Larger numbers of patients need to be assessed in an adequately powered clinical trial before discounting the predictive value of BST methods in this unique clinical situation.

Because *P. aeruginosa* and other gram-negative nonfermenters are also frequently multidrug-resistant, most CF patients are empirically treated with combination antibiotic therapy administers both in parenteral formulation and via inhalation into the lungs. Specialized laboratories have, therefore, developed methods to perform multiple

combination bactericidal synergy tests (MCBT) on CF isolates in order to determine which combination regimen may provide synergistic or additive activity. Only one randomized, double-blinded, controlled trial has, however, been recently completed to assess the clinical outcomes of CF patients treated with antibiotic therapy based on conventional versus MCBT susceptibility testing.[1] Antibiotic therapy directed by MCBT did not result in improved clinical or bacteriologic outcomes compared to conventional susceptibility methods.

Most clinical laboratories that perform routine susceptibility testing on CF pulmonary isolates do so using conventional methods. Conventional susceptibility tests of CF *P. aeruginosa* isolates is particularly challenging because they have a highly mucoid phenotype, and often grow insufficiently to determine a valid result unless incubation is extended for a full 48 hours. When the disk diffusion test was compared to an agar dilution method, poor correlation was observed when mucoid strains were tested against some antibiotics although the interpretive category agreed well between the two methods.[84] For these reasons, disk diffusion testing is not recommended for susceptibility testing.

1150

Although the Etest (AB Biodisk, Solna, Sweden) correlated well with the microdilution method in one study for both for mucoid and nonmucoid isolates, although a small number of very major errors occurred.[84] A recent study compared both the CLSI disk diffusion method and the Etest to broth microdilution for testing a large cohort of isolates from CF patient and non-CF patients.[62] An unacceptable rate of very major and major errors was found for various antimicrobials tested against both CF and non-CF isolates using either the disk diffusion method or Etest.

TABLE 17-35 Comparison of Old and Current CLSI Versus EUCAST Breakpoints (MIC μg/mL) for *Acinetobacter* spp.

	Old			*Current*			*EUCAST*		
Antimicrobial	**S≤**	**I**	**R≥**	**S≤**	**I**	**R≥**	**S≤**	**I**	**R>**
Doripenem	–	–	–	2	4	8	1	–	4
Imipenem	4	8	16	2	4	8	2	–	8
Meropenem	4	8	16	2	4	8	2	–	8

S, susceptible; I, intermediate; R, resistant.
Adapted from references 121 and 122.

Broth microdilution or agar dilution should be used for testing CF isolates, although multiple methods may need to be compared when major discrepancies occur in the susceptibility profile of an isolate from a patient from one visit to the next. Reference methods may also not be reliable for every CF patient isolate. Although broth microdilution compared well with a reference agar dilution technique for *Pseudomonas aeruginosa*, discordant results were found significantly more frequently in isolates from patients with CF than in other patients.[539] Vitek 2 nonfermenting gram-negative cards and version 4.02 software was recently validated for routine clinical use for susceptibility testing of nonfermenting gram-negative rods from patients with CF.[440] The overall essential and categorical agreement of Vitek 2 susceptibility testing was 97.6% and 92.9%, respectively. Direct comparison of the BD Phoenix system with the MicroScan Walkaway system for susceptibility testing of nonfermentative gram-negative bacteria showed an overall agreement of 89.1%, and although there were no very major errors, the rate of major and minor errors was 0.5% and 7.7%, respectively.[561]

Both *B. cepacia* complex species and *S. maltophilia* have inherent high-level resistance to several major classes of antimicrobials. *B. cepacia* complex species are intrinsically resistant to aminoglycosides and polymyxins. Active efflux also mediates resistance to fluoroquinolones, chloramphenicol and trimethoprim, and the presence of inducible β-lactamases in concert with altered PBPs confers resistance to most β-lactams.[22,484] CLSI MIC breakpoints are therefore only available for minocycline, ceftazidime, meropenem, and trimethoprim–sulfamethoxazole. *S. maltophilia* is intrinsically resistant to β-lactam agents due to the presence of two β-lactamases, one of which is a metallo-enzyme (L1) that confers resistance to imipenim. Broad resistance to aminoglycosides and fluoroquinolones also occurs due to decreased permeability through the OM.[71] CLSI MIC criteria are therefore only available for trimethoprim–sulfamethoxazole, minocycline, ceftazidime, ticarcillin clavulanate, and fluoroquinolones. Although many laboratories have not routinely performed susceptibility testing on CF *B. cepacia* or *S. maltophilia* isolates other than TMP-SMX as the drug of choice, increasing resistance to this agent dictates the need for broader testing.[22,617] All of the CLSI recommended antibiotics should be tested and reported on either of these organisms when isolated from CF patients with pulmonary exacerbations. *S. maltophilia* isolates from CF patients with hypersensitivity to TMP-SMX or those found to be resistant to this agent should also be tested against tigecycline and colistin.[187,403] Colistin may need to be tested against *S. maltophilia* using agar dilution as broth microdilution and Etest have high rates of major error.[403] Few agents are left that effectively treat *B. cepacia* complex infections due to TMP-SMX-resistant strains, but β-lactams alone or in combination may be the most effective regimens.[22]

Bacterial Agents of Bioterrorism

Although CLSI has published guidelines for susceptibility testing of potential bacterial agents of bioterrorism (i.e., *Bacillus anthracis*, *Yersinia pestis*, *Francisella tularensis*, *Burkholderia mallei*, *Burkholderia pseudomallei,* and *Brucella* spp.) public health should be immediately notified as soon as these isolates are presumptively identified, and confirmation of their identification and susceptibility testing is only available in reference or public health laboratories.[114] Wherever there is a potential for aerosolization to occur when working with these organisms in the clinical laboratory, one should work in a BSL-3 cabinet and use BSL-3 containment practices including personal protective equipment.

Antibiotic Susceptibility Reporting

The timely and effective communication of antimicrobial results is a critical stage in the susceptibility testing process. Box 17-7 outlines some of the clinical principles that should govern the development of laboratory policy and procedure for the testing and selective reporting of antimicrobial agents from clinical specimens from all sites/sources. These general guidelines can be applied to implementing detailed reporting protocols for specific pathogens isolated from different sites/sources, and the cascading or selective reporting of agents within a given antibiotic class based on the susceptibility profile of the isolate. Laboratories play a critical role in directing the appropriate use of antibiotics. Major time and effort should be go into the development of clinically relevant policies and procedures that ensure that appropriate effective guidance is provided by the laboratory in all clinical situations. This section outlines the formatting, selective reporting and generation of reporting comments that will assist in development of such procedures.

Formatting Antibiotic Susceptibility Reports

Antibiotic susceptibility results should be reported in a standardized format. Smaller laboratories that manually report results should use a standardized form, transcription format and ink color that can be legibly read when the report is faxed and printed. Most laboratories use a laboratory information system for generating susceptibility reports. Decisions need to be made about the format for the susceptibility reports at the time the LIS is implemented. Although most systems allow both the quantitative results (i.e., zone diameter or MIC value) and the interpretive result of susceptible (S), intermediate (I), and resistant (R) to be reported, most stakeholders only need to know the interpretive result to select appropriate therapy. The quantitative result should

never be reported without an interpretation because most clinicians are not familiar with CLSI interpretive guidelines, and do not have time to look up and interpret the quantitative values for each drug on each isolate. In most cases, the preferred report format is to only report the interpretative results (S, I, or R) for each drug for each pathogen isolated from a given specimen. However, the laboratory should be able to provide the quantitative results upon request to clinicians, particularly the Infectious Diseases service.

1151

BOX 17-7

Guidelines for Antibiotic Reporting

- CLSI designated Group A (Primary test and report) agents should be routinely tested and reported.
- Antibiotic susceptibility reports **should include** an interpretation for each drug of S, I, or R.
- Antibiotics **should not be reported** to which the patient is allergic.
- Specific antibiotics **should not be reported** in neonates, infants, and young children who are potentially toxic (i.e., trimethoprim-sulfamethoxazole, chloramphenicol, fluoroquinolones).
- Antibiotics that do not cross the blood–brain barrier **should not be reported** on isolates from cerebrospinal fluid samples.
- CLSI designated Group U (only for treatment of urinary tract infections) **should not be reported** on isolates recovered from any other source except urine.
- Policies and procedures for cascade reporting of antibiotics within each drug class should be implemented and based on these factors:
  - Site/source of the infection
  - Resistance profile of the isolate
  - Available antibiotic formulary and recommended utilization guidelines
- Isolate testing of extended antibiotic panels for CLSI designated Group B and C agents should routinely be performed in the following situations:
  - Patient is allergic to one or more Group A drugs;
  - Group A drugs are not in your formulary; or
  - Isolate is multiple resistant to one or more Group A agents and/or MDR strain (≥3 antibiotic classes).
  - Upon clinical request
- Policies and procedures for either in-house testing or immediate referral to a reference laboratory should be implemented for confirmation of the isolate identification, and resistance mechanism in MDR isolates.

The report should also clearly label the antibiotic susceptibility results with the pathogen identification so there is no clinical confusion as to which results align with which isolate. The report should be formatted in such a way that the antibiotics and interpretive results are aligned for different types of pathogens isolated from a polymicrobial sample. Laboratories should also validate that the report format stays integral when sent across an electronic interface between the LIS and a hospital or of physician-office information system. Antimicrobial reporting format error or clinical confusion in reading a complex susceptibility report may be a major source of inappropriate antibiotic prescription.

Clinically Relevant Antibiotic Reporting

Antibiotic susceptibility results should only be tested and reported on the organisms considered to be pathogens. In most clinical situations, the reporting of an isolate with a susceptibility result indicates to the clinician that the laboratory considers the isolate to be clinically relevant, and treatment may be required. Reporting of antibiotics on commensal bacteria may therefore lead to inappropriate antibiotic prescription.

Automated broth microdilution methods allow the laboratory to test many more antibiotics than appropriate for routine reporting. The CLSI guidelines should be used to direct the reporting of appropriate agents based on the organism and the site/source of infection (Tables 17-7 and 17-8).[114,121,122] Antibiotics not recommended for reporting on specific organisms should not be automatically reported even though an in vitro result was generated by an automated system or panel (Table 17-7). Tables 17-7 and 17-21 also outline situation where a surrogate antibiotic may be used to predict susceptibility to alternate agents within a drug class (i.e., β-lactams). A few examples of inappropriate antibiotic reporting of this type are provided. Although TMP-SMX is included in many test panels for gram-negative nonfermenters, this agent should not be reported on *P. aeruginosa*. *Enterobacteriaceae* known to carry an AmpC β-lactamase should have ampicillin results suppressed regardless of the in vitro susceptibility result. TMP-SMX and clindamycin should also not be reported on enterococci. Antibiotic susceptibility reports in total, or in part should be audited by clinical microbiologists and/or medical staff and pharmacy to ensure that laboratory antibiotic reporting policies are being followed.

Only antimicrobial agents appropriate for the site/source of infection should be included in a susceptibility report. This means that a substantially different antibiotic panel of drugs will be tested and potentially reported for invasive isolates from sterile fluids, tissues and blood cultures than for localized infections. Mainly potent parenteral antibiotics will be reported on isolates from invasive infections because the use of an oral agent would be clinically inappropriate for initial therapy. Oral drugs that have

been designated as Group U by CLSI for use against localized urinary tract

1152

infection should only reported on isolates from urine cultures. Drugs that are active only in the urinary tract should not be reported on isolates from other sites. Antimicrobial agents that do not penetrate into the site of infection should not be reported for organisms isolated from that site. Tigecycline, for example, does not penetrate well into the urinary tract and should not be reported on urine culture isolates. Daptomycin does not work well in the lung due to inactivation by surfactant, and this drug should not be reported on MRSA isolated from lower respiratory specimens. Similarly, first- and second-generation cephalosporins do not cross the blood–brain barrier and should not be reported on *Streptococcus pneumoniae* isolated from CSF; in this clinical situation, CLSI recommends testing and reporting penicillin, cefotaxime, ceftriaxone, meropenem, and vancomycin.[121,122]

There are also some general principles that should be medically followed in selectively reporting antibiotics in specific patient circumstances (Box 17-7). Antibiotic reporting should be tailored to drugs appropriate for the patient. If the laboratory is provided with a clinical history of antibiotic allergy to a specific agent or agents, then reporting of these drugs should be suppressed for that individual. For example, penicillin should not be reported on β-hemolytic streptococci isolated from a patient with a reported penicillin allergy. Some drugs such as fluoroquinolones should also not be prescribed in infants and young children, and routine reporting of these agents should be suppressed. Finally, many drugs may be teratogenic or toxic in pregnant women, especially in the first trimester.[415] Laboratories may decide to suppress reporting of these agents when an indication of pregnancy and/or gestation is provided.

Selective Reporting of Antibiotics

Laboratories should only test and report antibiotics that are locally available on formulary in consultation with members of the medical staff and pharmacy. Laboratories should then work in consultation with local medical experts such as infectious diseases physicians and pharmacists to decide which antibiotic susceptibility results to routinely report for a given isolate and site/source of infection, and which to suppress. The purpose of selective antibiotic reporting is to preserve the clinical utility of broad-spectrum or newer agents when an isolate is susceptible to narrower spectrum agents. Some laboratories may also elect to report the cost per dose either on each susceptibility report, or as part of a local guide to antibiotic therapy. In general, antibiotics that have been available for a longer period of time are less expensive, and selective reporting is also cost-effective. Aside from the antibiotic susceptibility rules provided and flagged by automated broth microdilution systems, laboratories can also

build additional rules either into the artificial intelligence software of the instrument or the LIS, to assist with tailoring antibiotic reporting to conform to local policies.

Table 17-36 shows a selective antibiotic reporting policy for *S. aureus* isolated from a blood culture or central nervous system (CNS) site. In the case of a fully susceptible strain, the report would only include the primary agents listed. However, for an MRSA isolate, extended reporting of newer agents such as linezolid and daptomycin may also be released. Table 17-37 shows a selective antibiotic reporting policy works for *Enterobacteriaceae* isolated from a nonurine site/source. In the case of a fully susceptible strain, the report would only include the primary agents listed. However, for more resistant strains, secondary drugs would also be reported, and in the case of a multidrug- or pan-resistant strain, the report would also include most select agents depending on the site/source of infection. Selective testing and reporting policies must be constantly reviewed and clinically updated as new antibiotic resistance trends evolve, or the local formulary is changed.

TABLE 17-36 Selective Reporting of Antimicrobial Agents for an *S. aureus* Isolate From a Blood or Central Nervous System Culture

Antibiotics	Primary	Secondary	Selective	Comments
Penicillin	X		X	If S, then do not report without performing a β-lactamase test. May only be reported if requested by the physician.
Oxacillin	X			OXA result may be based on Cefoxitin result. If R, then Cefazolin is R. Report additional secondary and selective agents.
Cefazolin	X			Test and report on all isolates. Report as S if OXA is S.
Vancomycin	X		X	Test on all isolates. May only report on MSSA isolates from β-lactam allergic patients and MRSA isolates.
Trimethoprim–sulfamethoxazole		X		Do not report on CNS isolates
Tetracycline		X	X	Do not report on CNS isolates. Report only on MRSA isolates from blood cultures. Do not report on children, pregnant women.
Linezolid			X	Test and report on MRSA isolates
Daptomycin			X	Test on MRSA isolates. Report only on request of the infectious diseases physicians.
Ceftaroline			X	Test and report on MRSA isolates. Report only on request of the infectious diseases physicians.

TABLE 17-37 Selective Antibiotic Reporting for *Enterobacteriaceae* Nonurine Isolates

Antibiotics	Primary	Secondary	Selective	Comments
Ampicillin	X			If I/R, then test AMX/CLA.
Amoxicillin clavulanate		X		If AMP I/R, then test. Report selectively by site. Do not report on CNS isolates.
Piperacillin–tazobactam		X		If AMP I/R, then test. Report selectively by site. Do not report on CNS isolates.
Cefazolin	X			If I/R, then report AMP I/R. Do not report on CNS sites.
Gentamicin	X			If I/R, then test Tobramycin.
Tobramycin		X		If I/R, then test Amikacin.
Cefoxitin	X			Test to screen for AmpC β-lactamase. Do not report.
Ceftriaxone	X			If I/R for *E. coli, Klebsiella,* or *P. mirabilis,* then may be ESBL-producer.
Ceftazidime	X			If I/R for *E. coli, Klebsiella,* or *P. mirabilis,* then may be ESBL-producer.
Trimethoprim-sulfamethoxazole	X			Do not report on CNS sites.
Meropenem	X			If I/R, then may be a carbapenemase-producer.
Ciprofloxacin	X			Report on blood only. Do not report on children.
Colistin			X	Test and report on MDR isolates.
Tigecycline			X	Test and report on MDR isolates. Do not report on blood isolates.

Cumulative Antibiogram Reporting

Most clinical decisions about initial antibiotic prescription are made empirically, because the decision cannot await isolation and testing of a bacterium. To improve the adequacy of empiric prescription pending a detailed susceptibility report, knowledge of local susceptibility patterns is essential. Cumulative antibiotic susceptibility reports for various locations should be compiled and published on an annual basis but interim updates may also be provided for critical care units. Although national surveillance databases track important resistance trends in major pathogenic bacterial species,[101] their results may not accurately reflect what is happening locally, particularly in ambulatory practice.[230]

The CLSI has published recommendations for the methodology and format of compiling cumulative antibiotic susceptibility summaries (i.e., antibiogram).[112,252] Recommendations for the preparation and use of cumulative antibiogram are summarized in Table 17-38. Several additional factors worth noting are summarized in Box 17-8. If a local website or shared access to an electronic file is available, posting of the spreadsheet is a convenient way to provide general access. It may be possible to download the information into personal data assistants (PDAs). Examples of CLSI M39-A2 compliant antibiograms are shown from a large tertiary acute-care hospital (Fig. 17-41) versus all ambulatory care locations (Fig. 17-42) for a large Canadian regional health authority (www.calgarylabservices.com). It may also be useful to provide a hard and electronic copy to clinicians; a useful format is a pocket card that can be carried by the physician and/or downloaded onto an electronic device for easy access.

Antibiotic Stewardship

Antibiotic stewardship is the prudent and efficacious use of these agents by healthcare professionals including the use of the most appropriate antibiotic given in the correct dose and route, administered for a long enough duration to treat infection in an individual patient. Inappropriate antibiotic use including overuse or misuse (e.g., suboptimal dose) is a major factor contributing to the rapid rise in drug resistance and healthcare costs, and suboptimal patient outcomes.[101,131,372] Antibiotics are also not without risk, and patients may experience adverse drug-related complications and/or the development of *C. difficile*-mediated antibiotic diarrhea. Antibiotic stewardship program committees (ASPs) function as a specialized multidisciplinary subcommittee of Pharmacy & Therapeutics (P&T) programs within hospitals, whose aim is to determine antibiotic formulary, to improve clinical outcomes, and to reduce costs by minimizing the inappropriate use of antibiotics. The Infectious Disease Society of America (IDSA) recently published guidelines for the development of a hospital-based ASP.[153] Core membership of the multidisciplinary ASP committee should include as a minimum, an infectious diseases physician and a clinical pharmacist with infectious diseases training who should direct the program. Ideally, a clinical microbiologist, an information system specialist, and infection control practitioner and a hospital epidemiologist should also be recruited. Collaboration of the ASP committee members with infection control and the P&T committee is essential. Hospital administration must also support and collaborate with the ASP so that the necessary resources can be put in place to implement various elements of the program. Similar to infection control programs, the ASP should function within the hospital under the auspices of a quality assurance program within the areas of patient safety and risk management. Specific expectations should be set for the ASP, including both clinical and economic outcomes, and the necessary infrastructure must be put in place to prospectively measure antimicrobial use and to monitor quality outcomes. Creation of relational laboratory and healthcare system databases allows the evaluation of process interventions and outcome measurements as a routine quality indicator. Without access to an electronic medical record, compilation and evaluation of program outcomes is less feasible.

1154

TABLE 17-38 CLSI M39-A3 Recommendations for Cumulative Antibiogram Preparation and Use

Recommendations	Comments

Use CLSI M39-A2 to compile antibiogram	Published guideline should be used because data will be used to guide initial empiric therapy.
Analyze and present data at least annually	Small isolate sample size may not provide an accurate antibiogram profile.
Include diagnostic, not surveillance isolates	Surveillance isolates may skew the data (i.e., tend to be more resistant).
Include results only for drugs that are routinely tested	If some drugs included in the cumulative antibiogram are only tested on selected isolates, the data will be skewed.
Include the first isolate per patient in the period analyzed, irrespective of the body site from which the specimen was obtained or the AST pattern	If repeat isolates are not eliminated from the analysis, the percentage susceptible will in most cases be lower than if repeat isolates are eliminated.
Calculate the percentage susceptible. Do not include the percentage of isolates with intermediate susceptibility	The percentage susceptible for a specific drug–pathogen combination will be impacted by culturing practices, patient populations, specimen collection practices, and laboratory antimicrobial susceptibility testing policies. Because the data will be used to guide initial empiric therapy, only drugs that are susceptible should be chosen.
For *Streptococcus pneumoniae*, calculate and list both the percentage susceptible and the percentage of isolates with intermediate susceptibility for penicillin; calculate and list the percentage susceptible for cefotaxime or ceftriaxone using both the meningitis and nonmeningitis breakpoints	Assists with empiric antibiotic therapy based on site/source of infection; CLSI M100 S23 breakpoints differ for penicillin, cefotaxime, or ceftriaxone based on diagnosis.278
For viridians streptococci, calculate and list both the percentage susceptible and the percentage of isolates with intermediate susceptibility for penicillin	In addition to the percent S to penicillin (e.g., 80%), include the percent I in a footnote (e.g., "For the 20% of nonsusceptible isolates, 15% were intermediate [MIC 0.25–2 μg/mL] and 5% were resistant [MIC 4 μg/mL] to penicillin").
For *Staphylococcus aureus*, calculate and list the percentage susceptible for all isolates, as well as for the subset of MRSA	Many MRSA isolates will have lower percent S to non–β-lactam antistaphylococcal agents than MSSA isolates.

Adapted from CLSI M39-A3 and reference 252.

BOX 17-8

Guidelines for Compiling a Cumulative Antibiotic Susceptibility Report

- Duplicate results should clearly be excluded; only the first isolate of a particular bacterium from a particular patient in a given time period (e.g., 1 year) be included in the analysis, regardless of other characteristics of the isolates.
- If possible, outbreak isolates that are clonally related should be excluded in order to not bias the antibiogram profile of a particular pathogen.
- Group A and B agents for each organism should be included; exclude selectively tested drugs.
- Differentiate the cumulative antibiogram profile for important isolates by invasive versus localized body sites and/or specimens sources for all locations and patient groups.
- Compile antibiogram profiles for different facility locations (i.e., ICU vs. other hospital wards), and different regional locations (i.e., different hospitals vs. ambulatory care) if there is a sufficient number of isolates to do so.
- Analyze isolate data separately for the elderly (i.e., long-term-care facilities), and hospitalized adults and pediatric patients to determine difference in resistance trends for these patient groups.
- A concise format should be used that is easy for clinicians and other stakeholders to access and read (i.e., electronic reporting is preferred).
- Data should be updated at regular intervals; a cumulative antibiogram should be published annually, or more frequently for ICUs.

♦ Susceptibility testing not routinely performed. Results based on all GAS isolated from adult throat cultures at CLS where susceptibility testing was indicated for treatment purposes.
◊ Stenotrophomonas maltophilia results represent the whole Calgary in-patient population.
Note: Percent susceptible for each organism/antimicrobial combination was generated by including the first isolate of that organism recovered from a given patient. Only those species with at least 30 isolates are included in the antibiograms.
Note: Please refer to the Community antibiogram for any isolate not listed.

■ **FIGURE 17-41** Cumulative antibiogram for a large tertiary care hospital. (Courtesy of Calgary Laboratory Services.)

Table 17-39 outlines several elements of an effective ASP that should be implemented in whole or in part depending on local policy, needs, and resources.[153] However, the optimal strategies for the prevention and control of antimicrobial resistance within a hospital have not been fully established as yet because few randomized, controlled trials have been done for various interventions. As a minimum, as ASP should actively monitor rate of resistance for key organisms (i.e., MRSA, VRE, multidrug-resistant gram-negatives), implement strategies to minimize inappropriate drug use and work closely with infection control to minimize the secondary spread to resistance. Most physicians do not receive adequate training in the diagnosis of infectious diseases and the prescription of antibiotics. Education is, therefore, one of the most essential components to an ASP.

The clinical microbiology laboratory plays a critical support role to both the hospital infection control and antimicrobial stewardship programs. As discussed earlier in the chapter, the timely and accurate identification of key bacterial pathogens and clinically important antibiotic resistance profiles are central to the effective delivery of both of these quality assurance programs. Generation of local antibiogram(s) with pathogen-specific susceptibility data is also critical to the development of appropriate treatment

recommendation for empirical therapy of various types of infection. Genotyping of important antibiotic-resistant strains to track clonal spread is also a key function of the laboratory. Although not required for routine patient care, the molecular characterization of specific mechanisms of resistance in important pathogens is a key requirement for effective surveillance and the investigation of outbreaks. For example, molecular typing of all MRSA isolates within a healthcare jurisdiction can determine whether the strains are hospital-acquired or community-acquired, or community-acquired but endemic in a given facility due to secondary spread.[149] Likewise, epidemiologic investigation of the spread of ESBL-producing *E. coli* in a large regional health authority identified travel to Asia as one of the major causes for the introduction and spread of this agent as a cause of urinary tract infections.[470]

† Synergy with cell wall active antibiotics predicted from susceptibility to 500 mg/L gentamicin.
* These organisms usually produce inducible ß-lactamase which cause failure of 3rd generation ß-lactam therapy, despite *in vitro* susceptibility
# Susceptibility testing not routinely performed.
¥ Isolated from urine. Not speciated.
♦ Pneumococcus Penicillin and Ceftriaxone susceptibilities based on meningitis breakpoints.
≈ Refer to Hospital In-patient antibiograms
Note: Percent susceptible for each organism/antimicrobial combination was generated by including the first isolate of that organism recovered from a given patient. Only those species with at least 30 isolates are included in the antibiograms.

■ **FIGURE 17-42** Cumulative antibiogram for community care locations in a large Regional Health Authority. (Courtesy of Calgary Laboratory Services.)

Clinical microbiologists should be part of an effective ASP program and ensure that laboratory procedures are in place to provide the various types of support outlined. In particular, antibiotic susceptibility testing and reporting procedures should be reviewed annually, and updated guidelines published by CLSI should be promptly implemented in order to accurately detect emerging types of resistance.

Future Perspectives

Newer technology may increasingly be used to rapidly detect specific types of resistance in key bacterial pathogens. Recently, it has been demonstrated that carbapenemase activity could be rapidly (4 hours) detected in *Enterobacteriaceae*, *P. aeruginosa,* and *A. baumannii* by MALDI-TOF spectrometry.[81,266,311] This assay has many several advantages over other conventional techniques for detection of carbapenem resistance, such as phenotypic methods and PCR, because it was able to detect low-level carbapenemase activity at a low cost even when the type of enzyme in a particular strain was unknown. MALDI-TOF could potentially be used to detect resistance due to other types of enzymes in key bacterial pathogens.

Molecular detection of several resistance determinants using a Luminex xMAP (Luminex, Texas) microarray assay is also feasible although the rate-limiting step is identification of all of the possible genes involved in various types of resistance. A Luminex assay has been used to detect fluoroquinolone resistance in *Campylobacter jejuni* and *Salmonella* spp.[26,564] Other commercial molecular multiplex PCR systems have more recently become available for the rapid simultaneous identification of major gram-positive and gram-negative organisms along with key antibiotic resistance genes. The Verigene Gram-positive Blood Culture Test (Nanosphere Inc., Northbrook, Ill) has recently been FDA-cleared for the rapid identification of pathogens from blood cultures (i.e., ~2.5 hours), and includes detection of the *mec*A and *van*A/B genes (www.nanosphere.us/product/gram-positive-blood-cultures).[582,663] Minimal hand-on time is required for sample preparation, inoculation of the test cartridge and loading the cartridge into the Verigene reader and processor SP instrument. Recent evaluations of this assay show a high degree of overall accuracy compared to routine blood culture methods for rapid pathogen identification, and use of this assay may have allowed appropriate antibiotic treatment to be started earlier for AROs. The Biofire FilmArray is an FDA-cleared multiplex PCR test that integrates sample preparation, amplification, detection, and analysis in one system (www.filmarray.com/the-panels). The FilmArray blood culture identification panel currently tests for a total of 27 targets including 24 pathogens and three antibiotic resistance genes associated with bloodstream infections. This rapid identification test can identify the most commonly detected bacterial pathogens and two *Candida* species in a positive blood culture in approximately an

hour with a limited amount of hands-on time. Few evaluations comparing the FilmArray BCID with routine blood cultures or other molecular methods have so far been reported in the literature.[8,46]

TABLE 17-39 Key Elements of an Effective Antimicrobial Stewardship Program

Elements	Strategies	Comments
Monitoring antimicrobial resistance	Prospective audit of agent use and feedback to the prescriber	Results in reduced inappropriate use of antimicrobials. Monitoring should be done routinely in institutions using formulary restrictions to determine if prescribing shift to alternative agents is resulting in increased resistance.
Pharmacy interventions	Formulary restriction and preauthorization requirements for specific agents	Results in significant reductions in antimicrobial use and costs. May be beneficial to a multifaceted response to a nosocomial outbreak. Long-term benefit on controlling antimicrobial resistance is not established.
	Antibiotic order forms	Results in decreased antimicrobial consumption through the use of automatic stop orders requiring physician adjustment. Can also facilitate implementation of practice guidelines.
	Dose optimization	Adjustment of dosing based on patient characteristics, causative organisms and site of infection, and PK/PD drug characteristics is essential.
	Conversion from parenteral to oral therapy	Systematic plan for step-down to oral therapy, when the condition of the patient allows; this can decrease the length of hospital stay and healthcare costs. Institutional practice guidelines facilitate implementation.
	Education is essential to	

Fostering appropriate antibiotic use	influence prescribing behavior and enhances the acceptance of other strategies	Education without active intervention is only marginally effective in changing behavior.
	Development and implementation of multidisciplinary practice guidelines and clinical pathways	Guidelines and clinical pathways that incorporate local microbiology and resistance patterns can improve antimicrobial utilization. Guideline implementation is facilitated by education and feedback on antimicrobial use.
Microbiology laboratory	• Provides patient-specific culture and susceptibility data • Provides cumulative antibiotic susceptibility data (i.e., antibiogram)	Optimizes patient management and assists infection control in the effective surveillance of resistance. Assists physicians with initial empiric antibiotic choice and assists infection control in the effective surveillance of resistance.
Infection control program	Collaboration with an effective infection control program	Prevents the secondary spread of resistance.

Adapted from reference 112.

Newer technology are allowing the cycle time from collection of a clinical sample to reporting or clinically relevant identification and antibiotic susceptibility results to be significantly reduced compared to routine culture and phenotypic identification and antimicrobial susceptibility test methods. Reduction in the microbiology test cycle, particularly for patients with serious invasive infections (i.e., bacteremia), may ultimately result in improved clinical outcomes because appropriate antibiotic therapy is started as early as possible, and subsequently healthcare costs may be reduced because of decreased length of stay.

Introduction

Mycoplasmas and ureaplasmas are organisms that differ from other bacteria in that they lack a rigid cell wall. Individual cells are bound only by a trilaminar unit membrane. In addition, the amount of genetic material comprising the genome of these organisms is quite small (approximately 500 kb). These organisms have limited biosynthetic capabilities, and consequently, the cultivation of mycoplasmas and ureaplasmas requires an enriched medium that contains precursors for nucleic acid and protein (inclusion of basal peptone and yeast extract), and lipid biosynthesis (serum is usually included). In fact, one of the principal criteria used in the taxonomic classification of these organisms is the requirement for the complex lipid cholesterol in the growth medium by certain mycoplasma and mycoplasma-like organisms.[472,505] All *Mycoplasma* species produce adenosine triphosphate (ATP) by substrate-level phosphorylation effected by phosphoglyceric acid kinase and pyruvate kinase, two

enzymes of the glycolytic pathway from glucose to pyruvate.[392] These two enzymes appear to be the major source of most of the ATP synthesized by organisms in the class *Mollicutes.*

These organisms are much smaller than most bacteria and are able to pass through bacteriologic filters. *M. hominis* (MH) and *Ureaplasma* spp. are coccoid cells, about 0.5 μm in diameter; *M. pneumoniae* appears as spindle-shaped cells, about 1 to 2 μm long and 0.1 to 0.2 μm in diameter.[524] The generation time for these organisms varies from 1 to 1.5 hours for *Ureaplasma* spp. and MH to ~6 hours for *M. pneumoniae*. There are also more fastidious species that have been recently isolated from clinical disease in humans, such as *M. genitalium*, that have a generation time of ~16 hours.[524] The lack of a typical bacterial cell wall containing peptidoglycan renders these organisms insensitive to cell wall active antimicrobial agents, such as penicillins and cephalosporins. Because of

1172

1173

this, the recovery of these organisms from clinical specimens may have significant therapeutic implications.

Mycoplasmas and ureaplasmas have been recovered from humans, animals, birds, insects, and plants, and new species are being continually identified and reported in the taxonomic literature.[505] Some species also have a free-living existence in soil and water. The human mycoplasmas belong to the genus *Mycoplasma* and to the genus *Ureaplasma,* the latter of which contains mycoplasmas that are able to hydrolyze urea. Several species in the genus *Mycoplasma* and two species in the genus *Ureaplasma*, *U. urealyticum* (UU) and *U. parvum,* are found in human clinical specimens. For purposes of simplicity, *Ureaplasma* spp. will be used in this chapter when referring to these genital mycoplasmas rather than to individual species names. MH, *M. genitalium*, and *M. fermentans* will be discussed as separate species, however.

With the exception of *M. pneumoniae*, the role of other mycoplasmas—specifically MH, UU, and *U. parvum*—in human disease has been controversial. *M. pneumoniae* is the well-recognized cause of atypical pneumonia, whereas MH, UU, and *U. parvum* are associated primarily with genital tract colonization and infection in adults and respiratory tract colonization and disease in newborns.[121,435] These species are associated with and implicated as causative agents in a wide variety of pathologic conditions. However, these same species may also be isolated from asymptomatic individuals, suggesting that they may behave principally as opportunistic pathogens.[321,323,324] *M. genitalium* has been isolated from both the genital and

respiratory tracts, and its role as a sexually transmitted agent causing nongonococcal, nonchlamydial urethritis (NGNCU) and other genital tract infections is currently being elucidated.[23,312,509] However, the presence and behavior in the respiratory tract is not clear. Other *Mycoplasma* species are found as part of the normal flora of the mouth, particularly in the gingival areas surrounding the teeth. In the late 1980s, another "new" mycoplasma, termed "*M. incognitus*" at that time, was detected in autopsy specimens from patients with AIDS, suggesting that this organism may be either another opportunistic infection or a sexually transmissible cofactor that influenced disease progression.[290,345] This organism was subsequently identified as a strain of the fastidious mycoplasma, *M. fermentans*. Several other newly described mycoplasmas have been isolated from HIV-infected patients, and these discoveries have spurred a renewed interest in virulence factors of mycoplasmas, as well as in the methods for their detection and identification.[546] In this chapter, the human mycoplasmas will be addressed, with emphasis on the clinical significance of *M. pneumoniae* and the genital mycoplasmas (MH, UU, and *M. genitalium*) and the methods used for the isolation, identification, and susceptibility testing of these bacteria in the clinical laboratory.

Taxonomy of Mycoplasmas and Ureaplasmas

The first published report referring to the genus *Mycoplasma* came in 1898 by the French scientists Nocard and Roux when they described an unusual organism associated with contagious bovine pleuropneumonia.[418] Mycoplasmas involved in human infection were not described until 1942 when Eaton et al. recovered a filterable agent from the sputum of patients with "atypical pneumonia." The term *Eaton agent* was later used when referring to these small organisms that were initially thought to be viral particles. By 1962, the Eaton agent was isolated in cell-free cultures, demonstrating that it was actually a bacterium that did not possess a cell wall and had specific requirements for growth in culture.[418]

Mycoplasmas and ureaplasmas are classified in the class *Mollicutes* (Box 18-1). The name *Mollicutes* means "soft skin," referring to the lack of a rigid bacterial cell wall. Analysis of ribosomal RNA (rRNA) sequences has revealed that the *Mollicutes* are most closely related to gram-positive bacteria, and their closest relatives are the streptococci.[407,418] The class *Mollicutes* contains 4 orders (*Mycoplasmatales*, *Entomoplasmatales*, *Acholeplasmatales,* and *Anaeroplasmatales*; Box 18-1), 5 families, 8 genera, and >150 species, of which about 16 have been isolated from human specimens.[524] The order *Entomoplasmatales* was created to accommodate the families *Entomoplasmataceae* and *Spiroplasmataceae*. The genera *Entomoplasma* and *Mesoplasma* in the family *Entomoplasmataceae* are found in insects and plants.[506]

The genus *Entomoplasma* contains sterol-requiring species that grow optimally at 30°C, whereas the genus *Mesoplasma* contains species that do not require cholesterol but grow best at 30°C in cholesterol- or serum-free media supplemented with Tween 80 (0.04%). The family *Spiroplasmataceae* includes the single genus *Spiroplasma*, which are spiral-shaped *Mollicutes* that require cholesterol for growth and are found in plants and insects. Members of the order *Acholeplasmatales* do not require sterols for growth and are found predominantly in plants, animals, and insects.[16,511] The presence of these organisms in animal tissues is documented by the occurrence of acholeplasmas as contaminants in tissue culture media that are supplemented with animal serum.[16] Two species, *Acholeplasma laidlawii* and *Acholeplasma oculi*, have been isolated from humans.[314,400,536] *A. laidlawii* is immunologically related to both *M. pneumoniae* and *M. genitalium*.[72] Because sterol compounds are not required for growth, acholeplasmas may be cultivated in medium lacking exogenous serum. The order *Anaeroplasmatales* comprises a single family (*Anaeroplasmataceae*) containing two species,*Anaeroplasma* and *Asteroleplasma*.[506] These two species are strictly anaerobic in their metabolism. *Anaeroplasma* species require cholesterol for growth, whereas members of the genus *Asteroleplasma* do not. Both of these species are found in the rumens of cattle and sheep. The family *Mycoplasmataceae* now includes the hemotrophic mycoplasmas that were previously classified in the genus *Eperythrozoon* and the genus *Haemobartonella* (Box 18-1). These organisms parasitize the erythrocyte surfaces of various animals.

Members of the order *Mycoplasmatales* require sterols, such as cholesterol, for cultivation in vitro. The sole family in the order—*Mycoplasmataceae*—contains two genera: *Mycoplasma* and *Ureaplasma*. The genus *Mycoplasma* contains over 100 species that inhabit a wide variety of plants and animals, including mammals, insects, birds, and reptiles, and may exist as commensals, parasites, and/or pathogens.[320,505,517] The *Mycoplasma* species that have been isolated from humans are listed in Box 18-2.*Mycoplasma hominis*, *M. genitalium*, *M. fermentans*, *M. primatum*, *M. spermatophilum*, and *M. penetrans* are isolated primarily from the human genital tract, whereas *M. pneumoniae*, *M. salivarium*, *M. orale*, *M. buccale*, *M. faucium*, and *M. lipophilum* may be recovered from the human respiratory tract. *M. salivarium* is found in the gingival crevices and may play a role in certain types of periodontal disease. *M. orale*, *M. faucium*, *M. buccale*, and *M. lipophilum* are considered part of the normal upper respiratory tract microbiota and are nonpathogenic. *M. genitalium* has garnered much scientific interest in recent years as the etiologic agent of acute and chronic nongonococcal urethritis (NGU) and a host of other genital tract infections.[312,517] *M. fermentans* was first isolated from the human urogenital tract and is postulated to play roles in urethritis, rheumatoid arthritis, and progression of HIV infection. This species is the same as "*M. incognitus*," recovered

from patients with AIDS (see discussion below).[413] *M. penetrans*, a relatively new addition to the genus, has been isolated from the urine of patients with AIDS and, like *M. fermentans*, may act primarily as an opportunistic infectious agent in immunocompromised hosts. The ecologic niche of *M. pirum* in humans is uncertain.

1174

BOX 18-1

Taxonomy of the Phylum *Firmicutes*, Class *Mollicutes*

Order	Family	Genus	Sterols Required for Growth	Habitat	Comments
Mycoplasmatales	*Mycoplasmataceae*	*Mycoplasma*	Yes	Humans, animals	Optimal growth at 35°C–37°C; metabolize glucose or arginine or both
		Ureaplasma	Yes	Humans, animals	Optimal growth at 35°C–37°C; metabolize urea
		"*Eperythrozoon*" (now members of the genus *Mycoplasma*)		Animals, including primates	Noncultivable, cell wall-less, parasitic bacteria found on the membrane surfaces of red blood cells
		"*Haemobartonella*" (now members of the genus *Mycoplasma*)		Animals; the possibility of human infections has been raised.	Noncultivable, cell wall-less, parasitic bacteria found on the membrane surfaces of red blood cells
Entomoplasmatales	*Entomoplasmataceae*	*Entomoplasma*	Yes	Insects, plants	Optimal growth at 30°C
		Mesoplasma	No	Insects, plants	Optimal growth at 30°C; grow in serum-free medium with 0.04% Tween 80
	Spiroplasmataceae	*Spiroplasma*	Yes	Insects, plants	Optimal growth at 30°C–37°C
Acholeplasmatales	*Acholeplasmataceae*	*Acholeplasma*	No	Animals, insects, plants	Optimal growth at 30°C–37°C
Anaeroplasmatales	*Anaeroplasmataceae*	*Anaeroplasma*	Yes	Rumen of cattle, sheep	Anaerobic
		Asteroleplasma	No	Rumen of cattle, sheep	Anaerobic

BOX 18-2

Mycoplasmas and Ureaplasmas Isolated From Humans

Species	Common Site(s) of Isolation	Comments (i.e., Other Sites of Isolation, Associated Diseases)
Mycoplasma pneumoniae	Respiratory tract, genital tract (very rare), joint fluid aspirates (very rare)	Pneumonia, bronchitis, bronchiolitis, pharyngitis, croup; meningoencephalitis; rare isolate from genital tract and joint fluid aspirates
Mycoplasma orale	Oropharynx and nasopharynx	No disease association; has been isolated from leukemic bone marrow and lymph nodes
Mycoplasma salivarium	Oropharynx and nasopharynx	No disease association, questionable role in periodontal disease; rare isolates from cervix/vagina and arthritic joints
Mycoplasma buccale	Oropharynx and nasopharynx	No disease association
Mycoplasma faucium	Oropharynx and nasopharynx	No disease association
Mycoplasma lipophilum	Oropharynx and nasopharynx	No disease association
Mycoplasma spermatophilum	Cervix, sperm	No disease association
Mycoplasma primatum	Oropharynx and nasopharynx, female urethra	No disease association; recovered from umbilicus site
1175 *Mycoplasma hominis*	Female genitourinary tract, oropharynx	Blood cultures (postpartum septicemia); bacterial vaginosis and other genital tract infections; lung and pleural effusion specimens; organ and tissue transplant infections; surgical wound infections; prostheses-associated infections; neonatal infections; amnionitis
Mycoplasma genitalium	Genitourinary tract, oropharynx	Some cases of nongonococcal, nonchlamydial urethritis; role in respiratory tract infection unknown; presence in joint fluid (rare) probably results from bacteremia

		and seeding of joint spaces
Mycoplasma fermentans	Genitourinary tract, respiratory tract	Peripheral blood lymphocytes and urine in AIDS patients; arthritic joints; bone marrow; possible role in pathogenesis of HIV infection
Mycoplasma penetrans	Genitourinary tract, urine	Urine in patients with AIDS; possible role in HIV pathogenesis; opportunistic infectious agent
Mycoplasma pirum	Blood (rare)	Peripheral blood lymphocytes; a contaminant in tissue culture cells of human origin; previously proposed role in HIV pathogenesis
Ureaplasma urealyticum	Genitourinary tract; oropharynx, lower respiratory tract, placental tissues	Lower respiratory tract, blood (neonatal sepsis); cerebrospinal fluid; surgical sites; possible role in nongonococcal urethritis; genital tract infections; neonatal infections
Ureaplasma parvum	Genitourinary tract	Genital tract infections

As with other bacteria, the human mycoplasmas recovered from clinical material differ in certain phenotypic characteristics that are exploited for their isolation and identification (Table 18-1). *M. pneumoniae* ferments glucose with the production of acidic end products, whereas MH uses arginine with the formation of basic end products. Cultivation of these organisms is dependent on the use of special agar and broth media that are enriched with factors required for mycoplasmal growth in addition to specific growth substrates, such as glucose and arginine. *M. pneumoniae* strains are antigenically homogeneous, with only one recognized serovar with all strains having a similar rRNA composition. The number of different MH serovars is unknown, but heterogeneous rRNA patterns have been demonstrated.[71,563] In addition to certain ultrastructural similarities, both serologic cross-reactivity and genetic homologies have been described between *M. pneumoniae* and *M. genitalium*.[72,280,564]

The genus *Ureaplasma* includes mycoplasmal organisms that are specifically able to hydrolyze urea. The genus currently contains seven species: UU, *U. parvum*, *U. diversum*, *U. gallorale*, *U. felinum*, *U. cati*, and *U.*

canigenitalium.[19,167,168,194,249,438] *Ureaplasma* was formerly known as the "T-strain" mycoplasma because of the small ("T" for "tiny") size of their colonies on solid media.[438] Prior to 1999, 14 serotypes of UU had been described in humans, nonhuman primates, and other animals. These 14 serotypes were defined by reactivity with a panel of polyclonal antisera.[19,405] These serotypes were clustered into two biovars: Biovar 1 was composed of serotypes 1, 3, 6, and 14, and biovar 2 included serotypes 2, 4, 5, and 7 through 13.[166] Members of these two biovars also have differences in other properties, including restriction-fragment-length polymorphisms, whole-cell protein patterns on polyacrylamide gel electrophoresis, and sensitivity to manganese salts.[19,166,399,405,463] Within biovars, analysis of rRNA with nucleic acid probes demonstrated significant nucleotide sequence homology among constituent serotypes. The percentage of DNA–DNA hybridization among serotypes 1, 3, and 6 in biovar 1 was 91% to 92%, whereas that among serotypes 2, 4, 5, 7, and 8 in biovar 2 ranged from 69% to 97%. However, monoclonal antibodies developed against biovar 1 serotypes also reacted on Western immunoblots with clinical biovar 2 isolates, indicating considerable antigenic cross-reactivity within the polyclonally defined serotypes.[64] Polymerase chain reaction (PCR) techniques that detect biovar-specific 16S rRNA were developed and have been used to examine reference strains and clinical isolates to determine relationships between biovars and specific disease entities associated with UU.[406,491] In 1998, UU biovars 1 and 2 were formally classified as *Ureaplasma parvum* and *Ureaplasma urealyticum*, respectively.[248]

1176

TABLE 18-1 Characteristics for the Identification of Human *Mycoplasma* and *Ureaplasma* Species

Site of Isolation Species	Utilization of			Optimal pH	Time to Recovery	Growth in			Serovars
	Glucose	Arginine	Urea			Air	CO_2	Anaerobic	
Respiratory Tract									
Mycoplasma pneumoniae	+	–	–	6.5–7.5	4–21 days	4+	4+	1+	1
Mycoplasma salivarium	–	+	–	6.0–7.0	2–5 days	2+	NA	4+	1
Mycoplasma orale	–	+	–	7.0	4–10 days	2+	NA	4+	1
Genital Tract									
Mycoplasma hominis	–	+	–	5.5–8.0	1–5 days	4+	4+	4+	Unknown
Ureaplasma urealyticum/ U. parvum	–	–	+	5.5–6.5	1–4 days	4+	4+	4+	14
Mycoplasma fermentans	+	+	–	7.0	4–21 days	2+	NA	4+	1
Respiratory/Genital Tracts									
Mycoplasma genitalium	+	–	–	7.0	SLOW	2+	3–4+	1+	Unknown
Acholeplasma laidlawii	+	–	–	6.0–8.0	1–5 days	4+	4+	4+	1

+, positive; –, negative; NA, data not available.

The other *Ureaplasma* species are found exclusively in animals. *U. diversum* (three serovars) is found in the bovine and ovine respiratory and genital tracts; it is the etiologic agent of maternal and fetal infections in these animals, including amnionitis, abortion, low birth weight, and neonatal pneumonia and death.[194] *U. gallorale* (one serovar) is a nonpathogenic species found in the respiratory tract of chickens and other fowl.[19,225,249] Two species—*U. felinum* and *U. cati*—have been recovered from the respiratory tracts of healthy domestic cats.[167] *U. canigenitalium*, the most recently described species, was isolated from oral, nasal, and prepuce cultures of dogs and includes four serovars.[168] In addition to these seven formally described species, genetically and antigenically distinct avian, porcine, simian, bovine, and caprine/ovine ureaplasmas have also been described but have not been assigned definitive species status or epithets.[19,169]

Virulence Factors of Human Mycoplasmas

Mycoplasma and *Ureaplasma* are primarily mucosa-associated bacteria that reside in the respiratory and urogenital tracts of the host in close association with epithelial cells, but are located extracellularly.[195] Potential virulence factors in human pathogenic mycoplasmas have been discovered, and some proposed mechanisms that may explain their pathogenicity have been suggested. These include competition for biochemical precursors, adherence to cells, fusion to cell membranes, cell invasion, and

cytotoxicity.[418] *M. pneumoniae* possesses an attachment organelle, which is a tapered extension at one pole of the cell that has an electron dense core and a terminal "button."[256,432] These structures are part of the mycoplasmal cytoskeleton, which is composed of a network of various proteins. Clustered at the tip of the attachment organelle is a membrane-associated, 169-kDa protein called P1, which is the major cytoadhesin that mediates the adherence of *M. pneumoniae* to host cells.[206,524] Following adherence P1 attachment induces ciliostasis, local inflammation, and tissue destruction that is further mediated by the liberation of peroxides.[524] In addition to P1, other membrane proteins that are associated with cytoadherence include P30, P116, and HMW1-3. Alterations or absence of these proteins renders *M. pneumoniae* avirulent.[418] Because cytoadherence is a necessary first step for infection of susceptible mucosal surfaces, these proteins represent true virulence factors in this organism. Individuals infected with *M. pneumoniae* produce a vigorous antibody response against the P1 adhesin, suggesting that purified adhesin proteins may be useful in serologic tests for diagnosis of *M. pneumoniae* infections.[109,205,206] Cytopathic changes can be related to the local damage following cytoadherence of *M. pneumoniae* proteins. *M. pneumonia*e can penetrate cell membranes and invade host cells. Hydrolytic enzymes and cytolytic metabolites are released directly into the cell once the attachment and invasion has occurred.[409,561]Substantial literature also exists on the induction of multiple cytokines (interleukins, interferon, tumor necrosis factor [TNF], and colony-stimulating factors)

1177

resulting from infection with *M. pneumoniae* and the role of these cytokines in the pathogenesis and mechanisms of mycoplasmal disease.[354,418,560]

Another possible virulence factor, referred to as MPN372, has been identified that could be responsible for airway cellular damage and other sequelae associated with *M. pneumoniae* infections in humans. MPN372 elicits extensive vacuolization and ultimate cell death of mammalian cells, including distinct and progressive patterns of cytopathology in tracheal rings in organ culture that had been infected with virulent *M. pneumoniae*.[228] *M. pneumoniae* evades the host immune response due to survival within host cells, phenotypic plasticity, and molecular mimicry. In addition, *M. pneumoniae* may induce transient depression of T-lymphocyte function and depletion of the host's CD4+ T cells.[418]

Cytoadherence proteins responsible for the initiation of colonization and infection have also been demonstrated in MH. P50 and P100, two surface-localized polypeptides of MH, function in adherence of this species to eukaryotic cells.[178] MH also binds sulfated glycolipids in a time-, temperature-, and dose-dependent manner

that can be inhibited by preincubation of the organisms with high-molecular-weight dextran sulfate.[369] Binding of recombinant P50 protein to HeLa cells is also inhibited by high-molecular-weight dextrans, indicating that P50 cytoadherence protein binds to sulfatides on the host-cell membrane.[244] Sulfated glycolipids and other glycoconjugates are present in high concentrations in the male and female urogenital tracts, and the specific interaction of MH with these molecules may help explain the urogenital tissue tropism of MH. The P100 cytoadherence lipoprotein of MH also possesses a substrate-binding domain for peptide transport across the cell membrane.[179] MH strains also possess another surface-exposed, adherence-associated protein called Vaa (variable adherence-associated) antigen, which is encoded by six distinct *vaa* gene types.[43,44] Expression of these genes can be switched on and off; this ability has been postulated to promote spread of the organisms from one cell to another.[569]

UU also produces a variety of virulence-associated factors. Isolates of UU produce three phospholipase enzymes (A1, A2, and C) that are localized in the plasma membrane.[103] These enzymes hydrolyze phospholipids, with the release of arachidonic acid. Because UU is associated with amnionitis and perinatal morbidity and mortality (i.e., spontaneous abortions, prematurity, stillbirth), it has been postulated that infection of the female genital tract may initiate a sequence of pathologic events related to phospholipase production.[121] Release of arachidonic acids from amniotic membranes may lead to production of prostaglandins, which can trigger premature labor.[29] UU has also been shown to induce the production of inflammatory cytokines (i.e., TNF-α, interleukin-6 [IL-6]) in both human and rat macrophage cell lines, and to stimulate the release of nitric oxide by cultured alveolar macrophage.[274,276] The extensive release of these cytokines may contribute to the inflammatory response and to the pathology of chronic lung disease seen in very low-birth-weight premature infants. UU has also been demonstrated to induce apoptosis in human lung epithelial cells and macrophages; cell death was abrogated by anti-TNF-α monoclonal antibodies.[275]These data suggest that UU lung infection in these neonates may be involved in the chronic impairment of lung tissues both directly and indirectly by the production of inflammatory cytokines that are known to play roles in chronic lung disease of premature infants.[251,504] The three phospholipases described above may also contribute to fetal lung disease related to respiratory tract infection with UU.[417] Both MH and UU also produce immunoglobulin A (IgA) proteases, which may facilitate mucosal invasion by hydrolyzing mucosal IgA.[229]

M. fermentans, *M. penetrans*, and *M. pirum* have been associated with disease in both healthy individuals and patients with AIDS. These organisms have been implicated as opportunistic agents or cofactors that contribute to the pathology and

pathogenesis of HIV-related disease.[345] The mechanisms involved in these postulated roles include specific activation of the cellular immune system, production of superantigens that stimulate the release of various immunomodulating lymphokines and cytokines, and the generation of free radicals that contribute to oxidative stress observed in HIV infection. All of these "AIDS-associated" mycoplasmas use glucose and hydrolyze arginine. Mycoplasmal arginine deaminase may cause depletion of arginine in infected macrophages. Arginine is a precursor for a molecule that is directly involved in macrophage-mediated cytotoxicity; therefore, depletion of arginine by mycoplasmal infection may result in diminished macrophage cytotoxicity. Mycoplasmas also release into the growth medium nucleases that degrade host-cell nucleic acids to generate precursors for synthesis of their own nucleic acids. *M. fermentans*, *M. penetrans*, and *M. pirum* are also able to invade cells and survive as intracellular pathogens.[84]The association of these organisms with intracellular locations in lymphocytes and macrophages helps explain the recovery of these organisms, especially *M. fermentans* from the blood of patients with and without AIDS.

Clinical Significance of the Human Mycoplasmas

Mycoplasma pneumoniae

M. pneumoniae is a frequent respiratory pathogen in children, as well as in adults. It infects the upper and lower respiratory tracts and is one of the many causes of the pneumonic process called atypical pneumonia; other causes of atypical pneumonia include several viruses (e.g., influenza, respiratory syncytial virus, adenoviruses), fungi (e.g., *Pneumocystis jirovecii*), and bacteria (e.g., *Chlamydophila pneumoniae*, *Legionella pneumophila*).[42,132,450] *M. pneumoniae* is transmitted from person to person by airborne transfer of droplets containing the organisms, with transmission facilitated by coughing or sneezing. About 20% of community-acquired pneumonias that require hospitalization are caused by *M. pneumoniae*; however, these cases represent only 3% to 10% of all *M. pneumoniae* infections, since tracheobronchitis or minor upper respiratory tract infections, not pneumonia, develop in most infected individuals, or else they remain asymptomatic.[132,418,453,455,524] The incubation period is 1 to 3 weeks, but symptoms can occur in as little as 4 days after infection.[418] In a report from Seattle, WA, in 1977, the rates of infection with *M. pneumoniae* varied from 2% in endemic years to 35% in epidemic years, with epidemics occurring

every 4 to 7 years. Children aged 5 to 9 years developed more pneumonia than did

adolescents aged 15 to 19 years.[137] In closed populations (e.g., summer camps, military bases, schools, and college dormitories), *M. pneumoniae* may result in outbreaks of pneumonia. Upper respiratory tract infections tend to develop in children younger than 3 years of age, whereas tracheobronchitis or pneumonia more often develops in older children and adults. Interestingly, studies in pediatric populations have not demonstrated a role for *M. pneumoniae* in acute myringitis or otitis media with effusion.[252,459] Most infections caused by *M. pneumoniae* are relatively mild and include pharyngitis, tracheobronchitis, bronchiolitis, and croup; up to one-fifth of infections are actually asymptomatic.[132]

Disease is generally not seasonal and may occur year-round, but the incidence of overt disease is usually highest in late fall and winter, when young people are going back to school. A study in China, however, found the incidence to be highest in the summer as compared with *C. pneumoniae,* which did not have a seasonal occurrence.[63]

The presenting symptoms of mild *M. pneumoniae* illness are sore throat, coughing, and wheezing and hence, infection can be mistaken for asthma. Fulminant respiratory infections are uncommon, but severe infections requiring hospitalization may develop in elderly and immunocompromised patients, and death may result from some of these infections.[316,383,418] For a more recent historical review of *M. pneumoniae* and its relevance in clinical disease, see Cunha.[82]

After exposure in susceptible hosts, the organism attaches to epithelial cells in the respiratory tract and multiplies. Organisms may be recovered in culture during the incubation period and for several weeks during and after clinical illness, even in the presence of specific antibodies. Following a 2- to 3-week incubation period, the clinical presentation of mycoplasmal pneumonia is usually insidious, rather than abrupt, with the gradual onset of constitutional and pneumonic symptoms that mimic influenza. Fevers of 101°F to 102°F will develop over a few days in most patients, with chills, malaise, headache, sore throat, nasal congestion, and a dry, nonproductive cough appearing early in the clinical course. The leukocyte count is often normal or only slightly elevated. In 5% to 10% of patients, progressive lower respiratory tract symptoms develop; the sputum becomes more mucoid or mucopurulent and blood may be noted in the sputum. Occasionally, Gram-stained smears of sputum at this point usually show few to moderate polymorphonuclear leukocytes and no organisms. With the onset of pneumonic symptoms, patients may feel as if they have a severe cold or the "flu," yet will continue to function relatively normally, hence the application of the term *walking pneumonia* to this disease. On chest examination, localized rhonchi and scattered rales are usually detected, and findings on chest roentgenograms are consistent with a diffuse bronchopneumonia, generally involving multiple lobes of the lung without consolidation. With *M. pneumoniae* pneumonia, chest roentgenogram patterns vary widely and may show peribronchial pneumonic

infiltrates, atelectasis, nodules, and hilar lymphadenopathy. Radiologic findings usually appear more extensive than the physical examination of the patient would suggest. Pleural effusions are relatively rare with mycoplasmal pneumonia, occurring in up to 20% of patients.[379] Other pleuropulmonary complications, such as pneumothorax and lung abscess, are also uncommon. However, there was a report of a 10-year-old with a 15-day history of fever and cough, who did not respond to amoxicillin and ceftriaxone for presumed pneumococcal disease, who showed a rapid response when treated with clarithromycin; serologic evidence suggested *M. pneumoniae* infection with lung abscess.[268] A few other patients with lung abscesses have been reported, and like this patient in whom macrolide therapy was delayed, the *M. pneumoniae* disease progressed.

M. pneumoniae pneumonia is generally self-limited, with resolution of most constitutional symptoms in 3 to 10 days without antimicrobial therapy. Abnormalities on chest films generally resolve more slowly, and complete resolution may take anywhere from 10 days to 6 weeks. Recurrences and relapses of pneumonia despite appropriate antimicrobial therapy may also occur. Using serologic methods and molecular detection techniques, several studies have now shown that *M. pneumoniae* may play a significant role in acute and chronic asthma in children and adults, exacerbations of chronic obstructive pulmonary disease particularly among older adults, and adult respiratory distress syndrome.[34,131,255,332,524,552] Data also suggest that *M. pneumoniae* may be implicated in acute chest syndrome, a pneumonia-like disease that manifests in patients with sickle cell disease.[360]

Respiratory infections with *M. pneumoniae* are associated with a wide range of extrapulmonary manifestations, including neurologic, cardiac, dermatologic, musculoskeletal, hematologic, and gastrointestinal symptoms.[156,502,532] As many as 25% of patients with *M. pneumoniae* infection may experience dermatologic complications. Most commonly, erythema multiforme major (Stevens–Johnson syndrome) is seen, presenting as vesicular lesions in mucocutaneous areas of the body[272,412,418]; various types of cutaneous macular, morbilliform, and vesicular eruptions; bullous erythema multiforme; and erythema nodosum.[66,272,428] In one instance, a patient with *M. pneumoniae* urticarial vasculitis was mistaken for adult Stills' disease in the United Kingdom but fortunate for the patient, once appropriate treatment was given, the patient did recover.[110] The mechanism of skin and mucosal disease is unknown but postulated to be due to immune complex vascular injury or autoimmune mechanisms.[418]In adults and pediatric patients with mucositis, *M. pneumoniae* infection should be included in the differential diagnosis.[130]

Cardiovascular manifestations may occur in as many as 10% of patients and include conduction defects, cardiac arrhythmia, pericarditis, tamponade, and congestive heart failure.[236,335,419] Myopericarditis has been described in a child who presented with

fever, lethargy, oliguria, and dyspnea.[376]

Central nervous system (CNS) manifestations are the most common extrapulmonary complications of *M. pneumoniae* infections. In patients with serologically confirmed infections that require hospitalization, as many as 10% may develop neurologic complications, most commonly encephalitis and meningoencephalitis, followed by polyradiculitis and aseptic meningitis.[156,418] *M. pneumoniae* is a major cause of encephalitis in children, especially those <10 years, often resulting in the need for intensive care management. A study in children with acute encephalitis documented *M. pneumoniae* infection in 31% of the patients, with *M. pneumoniae* being the probable cause of the encephalitis in at least 7% of

the patients, based on PCR cerebrospinal fluid (CSF) results and positive serologic tests.[36,537] Acute transverse myelitis also occurs because of *M. pneumoniae* infections, including those associated with Guillain–Barré syndrome; this is most common in individuals <35 years old.[156,418,447,500] The pathogenesis of CNS complications is not completely understood. It may be due to direct invasion of the bacteria, especially in patients with an early onset of encephalitis, as suggested by the presence of PCR-positive findings of *M. pneumoniae* in the CSF.[269,354,503] It is likely, however, that postinfectious neurologic syndromes probably occur via an autoimmune mechanism induced by the mycoplasmal infection, and/or via thromboembolic events leading to microangiopathy, cerebral vasculitis, and demyelination in perivascular areas in the CNS.[31,35,156,354,386,503] Severe CNS complications of the latter type have been associated with strokes following acute *M. pneumoniae* infection.[372,454]

Urologic and hepatobiliary complications are manifested as acute nephritis and cholestatic hepatitis, respectively.[155,448] Hemolytic uremic syndrome (HUS) has been described in a one-year-old boy as a complication of *M. pneumoniae* respiratory illness.[144] An article from China has described an increased seroprevalence of and infection with *M. pneumoniae* in patients with hepatitis C who were receiving hemodialysis.[260]

Ocular complications reported in association with *M. pneumoniae* infection include optic disk swelling, optic nerve atrophy, optic papillitis, retinal exudation, hemorrhage, and bilateral uveitis.[340,415,547] Various types of hematologic complications have also been reported (i.e., hemolytic anemia secondary to the formation of cold agglutinins, intravascular coagulopathy, neutropenia, thrombocytopenia, paroxysmal cold hemoglobinuria), which may result from the generation of specific antibodies and autoantibodies directed against lung, tissue, cardiolipin, and muscle tissues.[62,65,92]

Humoral and cellular immunodeficiency states also predispose individuals to more serious disease with *M. pneumoniae,* as well as other mycoplasmas.[132,375,408] Individuals with hypogammaglobulinemia may suffer repeated bouts of *M. pneumoniae* pneumonia and have difficulty eliminating the organism from the respiratory tract despite adequate therapy. *M. pneumoniae* organisms persist in most individuals with respiratory tract infection for a few months after infection, whereas they may persist for years in a patient with hypogammoglobulinemia.[524] These patients often have severe upper and lower respiratory tract symptoms with few or no infiltrates observed on chest radiography, and have significant complications, including rashes, joint pain, septic arthritis, and osteomyelitis.[224,263,485,489] *M. pneumoniae* may also cause severe disease in patients with conditions that abrogate cellular immunity, including HIV infection and sickle cell disease.[217,243,360,375] A PCR assay of bronchoalveolar specimens was found positive of *M. pneumoniae* in a 10-year-old renal transplant patient who had chronic respiratory symptoms and a new mass lesion in the upper lobe of his lung. The young child responded well to macrolide therapy.[430]

Although arthralgias are a common manifestation of mycoplasmal infection, definitive arthritis, with positive cultures from joint fluids, has been reported, but is considered very uncommon.[61,88] Joint infections, however, have been associated with many of the *Mycoplasma* spp., including *M. pneumoniae. M. pneumoniae* and *M. salivarium* have been found in synovial fluid of patients with arthritis in a UK study, but not in fluid that developed after traumatic injury. *M. fermentans* has likewise been found in cellular infiltrates of inflamed joints.[223] In addition, more recently, PCR and sequencing have led to the finding of *M. pneumoniae* in periprosthetic joint infections.[161] With better laboratory assays for detection of *Mycoplasma* spp., the detection of *M. pneumoniae* in these clinical situations may increase.

Fulminant, disseminated *M. pneumoniae* infection with multisystem involvement is rare, but it has been reported. Kountouras and colleagues reported on a previously healthy 50-year-old man who presented with progressive respiratory distress, aseptic meningitis, cholestatic hepatitis, renal failure, and disseminated intravascular coagulation.[253] *M. pneumoniae* infection was diagnosed serologically; the patient was treated with erythromycin and experienced an uneventful recovery. Takiguchi and colleagues reported on a previously healthy 64-year-old woman in whom progressive respiratory distress developed, with widespread bilateral alveolar infiltrates on chest radiographs.[467] Acute respiratory distress syndrome and disseminated intravascular coagulation then developed. *M. pneumoniae* infection was diagnosed serologically. Despite intensive antimicrobial and corticosteroid therapy, mechanical ventilation, hemodialysis, and plasma exchanges, the patient died of multiple-organ system failure. Similarly, Koletsky and Weinstein reported a 30-year-old woman who developed rapidly fatal, disseminated *M. pneumoniae* infection during which severe respiratory

disease, pneumonia, cardiovascular collapse, and renal failure developed after a 9-day clinical course.[246] Unfortunately, the patient died within 24 hours of admission to the hospital. On autopsy, the organism was recovered from the lungs, kidneys, and brain. Histopathologic examination revealed bilateral consolidated pneumonia and disseminated intravascular coagulation.

M. pneumoniae may occasionally be isolated from unusual extrapulmonary sites other than those listed above. Goulet and coworkers isolated *M. pneumoniae* from urogenital tract specimens of 22 female patients over a 2-year period.[145] In addition, the organism was recovered from the urethra of one of three male sexual partners of a woman who harbored the organism in her genital tract. *M. pneumoniae* has also been isolated from a tubo-ovarian abscess.[495] An association with Kawasaki's disease has been reported in four Italian children in which serology confirmed *M. pneumoniae* infection; however, there was no other evidence of a causal relationship.[520]

Mycoplasma hominis *and* Ureaplasma urealyticum

Both MH and UU may be isolated from the genital tract of asymptomatic men and women.[321,323,324] Publications in 1972 and 1986 by McCormack and colleagues demonstrated that rates of colonization with MH and UU in men varied from 0% to 13% and 3% to 56%, respectively.[321,322] The same authors reported data in women that vaginal colonization rates for MH and UU range from 0% to 31% and 8.5% to 77.5%, respectively, depending on age, race, sexual experience, and socioeconomic status.[321,322,324] Rates of genital

tract colonization in both men and women are related to sexual activity, and individuals with multiple sexual partners are more likely to be colonized. Therefore, the epidemiology of organism acquisition suggests that these mycoplasmas are likely sexually transmitted. Additional evidence for sexual acquisition is suggested by much lower isolation rates among women who use barrier contraceptives.[324] Given these data, it is clear that these organisms are exceedingly prevalent, particularly in the lower genital tracts of sexually active women.

Over the past several years, both UU and MH have been implicated in a variety of clinical conditions primarily related to lower genital tract colonization and infection, upper genital tract infections in women, and, rarely, upper genital tract infection and prostatitis in men.[121,170,209,381] Both organisms have been postulated to play roles in early and late endometritis, chorioamnionitis, and premature rupture of membranes.[106,121,151] The presence of UU in the genital tract, in particular, has been

associated statistically with prematurity, low-birth-weight infants, and infertility.[124,151,170,230] Controlled studies on the pathogenicity of the genital mycoplasmas are complicated because both organisms are highly prevalent in sexually active asymptomatic adults. To further confound issues of etiology, genital mycoplasmas are often recovered in culture along with other recognized genital tract pathogens, such as *Chlamydia trachomatis* and *Neisseria gonorrhoeae*.[330] These associations make it difficult to determine whether a pathologic condition is attributable solely to the presence of the genital mycoplasmas. An excellent example of this dilemma is the clinical condition of bacterial vaginosis. MH is often isolated from women with this infection.[182,234,259] However, bacterial vaginosis is now known to result from a complex interaction among aerobic and anaerobic bacteria. The roles of genital mycoplasmas in this condition have not been elucidated or defined, and a causal relationship between MH and bacterial vaginosis has not been proven. Studies on the pathogenicity of the genital mycoplasmas are further confounded by recovery of the organisms during or after the administration of antimicrobial agents for other genital tract pathogens.[79] Antimicrobial therapy for these other organisms may act to select for mycoplasmas that are resistant to the agents being used (e.g., penicillins and cephalosporins). After their recovery from a genital culture or a site of infection, it becomes difficult to ascribe an etiologic role for the organisms in the context of previous or ongoing antibiotic administration.

MH and UU have been isolated from blood cultures of women with postpartum fever.[94,121,123,261,325,353] About 10% of women with fever postpartum or post abortion will have either MH or UU isolated from blood cultures.[524] In some cases, these bacteria may be isolated with other genital tract microorganisms, again confounding the etiologic role of the genital mycoplasmas. Postpartum bacteremia results from the ascension of the microorganisms from the vagina into the endometrium, where the organisms cause endometritis. Infection of the placental membranes and amniotic fluid with mycoplasmas most frequently occurs in colonized women with premature rupture of the fetal membranes and preterm or prolonged labor.[136] From these sites, the organisms enter the bloodstream during and after labor and delivery, or after a cesarean section. UU bacteremia has also been documented as a complication in women undergoing hysterectomy.[90]

Isolation of mycoplasmas, especially UU, from the lower genital tracts of pregnant women is associated with several adverse outcomes of pregnancy, including the delivery of low-birth-weight infants. In a study conducted by Kass and coworkers, women whose genital tracts were colonized with UU and who demonstrated a fourfold or greater antibody response to the organism showed a 30% rate of low-birth-weight infants, whereas only 7.3% of colonized women who did not generate this antibody response had low-birth-weight infants.[230] Furthermore, this antibody response was

serotype-specific, suggesting that the additional rate of low birth weight was related to recent infection with a new serotype of UU that differed from the serotype or serotypes already present in the vagina. A study that examined the relationship between the two UU biovars and pregnancy outcomes found that the *urealyticum* biovar was associated with more adverse outcomes with regard to birth weight, gestational age, and preterm delivery than the *U. parvum* biovar.[1] Therapeutic trials with tetracycline or erythromycin have resulted in decreased rates of low-birth-weight infants, implying that eradication of mycoplasmas (or other susceptible organisms) from the genital tract may have a direct, beneficial effect on certain adverse outcomes of pregnancy.[230,486] Review articles concerning the association of mycoplasmas and adverse outcomes during pregnancy are recommended for those interested in additional reading.[262,487]

Amniotic infections with UU may be demonstrated in asymptomatic women with intact fetal membranes, and these infections are frequently associated with adverse pregnancy outcomes.[57,152,193,565] UU is capable of initiating an intense inflammatory tissue response, with no associated symptoms; the serologic evidence of an antibody response to these organisms and simultaneous recovery of ureaplasmas from the blood of these patients appears to confirm the possibility of silent amniotic infections.[57,138] Gray and associates studied two groups of asymptomatic pregnant women who were matched for maternal age, gestational age, and indications for amniocentesis.[152] Transabdominal amniocentesis specimens were cultured for mycoplasmas. Among the 86 women in the *Ureaplasma*-negative group, there was a 1.2% incidence of spontaneous second trimester abortion and a prematurity rate of 9.3%, for an overall adverse outcome rate of 10.5%. However, the rate of adverse outcomes (six spontaneous abortions and two premature deliveries) among the eight *Ureaplasma*-positive women was 100%, representing an 8.6-fold greater risk of adverse outcome. One of the premature deliveries survived but with the complication of hyaline membrane disease. Histologic examination of placental tissues from the eight infected women revealed chorioamnionitis in all of them, and all seven lung tissue specimens from the infants showed pneumonia. Four of five placentas and three of five fetal lung tissue specimens that were cultured grew UU.[152] Horowitz and colleagues also showed that 50% of six women with midtrimester amniotic cultures for UU that were positive had adverse pregnancy outcomes, as compared with 12% of 123 women with negative amniotic fluid cultures.[193] In another study that examined endocervical colonization with and serologic responses to UU, Horowitz and colleagues found that cervical colonization, when

associated with increased titers to UU, identified a population of women who were at risk for complications of pregnancy.[191,192] Eschenbach reviewed the evidence relative to the contribution of UU to adverse outcomes of pregnancy and concluded that, although the presence of UU in the lower genital tract was not associated with premature birth, the presence of the organism in the chorioamnion was strongly associated with histologic evidence of chorioamnionitis and weakly associated with premature birth as an outcome.[124] Although it has been well established that healthy women who are colonized with MH in the genital tract usually deliver healthy colonized infants, MH has also occasionally been associated with chorioamnionitis, abortion, stillbirth, and intrauterine fetal death.[331]

In some cases, placental infection with ureaplasmas has been shown to contribute a priori to subsequent endometritis, premature rupture of membranes, and premature labor. Colonization of the placenta permits infection of the endometrium, from which the organisms can gain access to the bloodstream. The recovery of UU and MH from endometrial tissue sometime after delivery has established that mycoplasmas and ureaplasmas could be the probable causes of early- and late-onset endometritis in some cases. Postpartum endometritis is a major complication of pregnancy and occurs more frequently after cesarean section than after vaginal delivery. In one study, endometritis occurred in 28% of women with UU present in the chorioamnion at cesarean delivery, compared with only 8.4% if the culture was negative and 8.8% if only bacteria other than UU were present.[15] These workers concluded that chorioamniotic colonization with UU in women with intact membranes being delivered by cesarean section was an independent predictor of subsequent endometritis. A subsequent randomized clinical trial of extended-spectrum antimicrobial prophylaxis using agents active against UU in women undergoing cesarean delivery was found to reduce the frequency of postdelivery endometritis.[14] Although it has been suggested by some studies, a definite causal relation between genital mycoplasmas and pelvic inflammatory disease (PID; salpingitis) has not been unequivocally demonstrated.[121,279,435,462]

Because of the high colonization rates of genital mycoplasmas in both men and women, these organisms have also been evaluated for relationships with involuntary infertility. Although some studies suggest a possible role for these organisms in this condition, there is no definitive proof indicating that these organisms cause either male or female infertility.[471] MH was found in 1.3%, UU in 20%, *N. gonorrhoeae* in 0.4%, and *C. trachomatis* in 2.2% of 230 women undergoing infertility evaluations in the United States.[202] In a 2002 study of 50 infertile women and 46 fertile women, MH was isolated from the genital tracts of 8% of the infertile women and was not isolated from any of the controls.[128] UU was isolated from 56% of the infertile women and from 39% of the control women; this difference was not statistically significant, but

the authors suggested that an association between infertility and UU may exist. In a study of 92 asymptomatic male partners of infertile couples, 12 (13%) men had UU in their ejaculates. Again, these workers suggested that UU may play a role in infertility in the absence of other conditions.[273] In vitro, UU has been shown to adhere to sperm cells, resulting in significant reductions in sperm motility and causing alterations in cell membranes, which could suggest an in vivo role for UU in infertility.[364] However, another study found no difference in sperm quality in men with and without positive cultures for MH or UU, as assessed by sperm density, vitality, motility, and morphology.[13] More recently, an Italian study of unselected men attending an infertility clinic showed an elevated prevalence of UU and MH infection and demonstrated that the presence of these microorganisms was associated with a higher percentage of patients with abnormal sperm parameters. Of the 250 infertile men, 16% had cultures positive for UU and 4% had cultures that contained MH.[414]

UU may play a role in spontaneous abortion through its ability to cause chorioamnionitis, but like the other conditions described above, definitive proof has not been obtained. Joste and associates cultured and examined the histopathology of specimens from 42 first-trimester spontaneous abortions, 21 first-trimester elective abortions, and 32 third-trimester, preterm deliveries, 11 of which were culture-positive for UU.[226] Specimens from 26% of the first-trimester spontaneous abortions grew ureaplasmas, whereas none of the 21 elective abortion specimens contained UU. Histologic evidence of chorioamnionitis did not correlate with culture positivity for the spontaneous abortion specimens, but did correlate with positive UU cultures for the 11 third-trimester, preterm deliveries. These workers postulated that early changes caused by UU infection other than histologically evident chorioamnionitis may be responsible for the pathogenesis of spontaneous abortions related to ureaplasmal infection.[226] A study conducted from 1989 to 1994 in Belgium noted a strong association between bacterial vaginosis and miscarriage.[107] After multivariate analysis, MH and UU, but no other microorganisms, remained significantly associated with increased risk of miscarriage. In contrast, another study published in 2004 found no association between first-trimester miscarriages and the presence of mycoplasmas or ureaplasmas in expelled placental specimens.[319]

Urinary tract infections caused by mycoplasmas have also been reported in pregnant women. Determination of the significance of mycoplasmas in clean-catch urine specimens from women is difficult, owing to the likely contamination of the specimen from organisms colonizing the vagina and the distal urethra. Savige and coworkers collected suprapubic bladder aspirates for culture from 72 healthy pregnant women and 51 women with preeclampsia.[425] UU was isolated from the urine of 7% of the healthy women and from 20% of those with preeclampsia. In a subsequent study of bacteriuria in 340 pregnant women, the presence of UU in the urine during the first

trimester correlated with the development of preeclampsia during the third trimester of pregnancy.[141] Among the 21 women in whom preeclampsia developed, 29% had ureaplasmas present in urine during the first trimester, compared with only 10% of the patients in whom preeclampsia did not develop. Therefore, the development of preeclampsia was three times more likely in women who had ureaplasmas in the urine at the start of pregnancy than in women who were culture-negative. Although the mechanisms involved in the pathogenesis of preeclampsia are unclear, it is suggested that ureaplasmas, similar to other bacteria involved in bacteriuria, may also contribute to adverse pregnancy outcome. In another study of mycoplasmas in 48 women with symptoms

of chronic urinary tract infection, 23 (48%) had positive cultures (22 UU and 1 MH).[393] Cultures from all the women became negative after targeted therapy, and 91% of the infected women experienced alleviation of their chronic symptoms. These investigators concluded that, following exclusion of common agents of urologic infections, anatomic abnormalities, and neurologic dysfunctions, culture for mycoplasmas and subsequent targeted antimycoplasmal chemotherapy is warranted before other diagnostic procedures are entertained.[393] A study from Greece examined 153 nonpregnant women with chronic voiding symptoms and found that 52% of the women had UU isolated from urethral, vaginal or urine specimens and 3.3% of women had both MH and UU isolated. After therapy for the supposed MH/UU infections, 92% of the women cleared their MH/UU cultures and all had significant improvement in symptoms posttherapy.[18]

Genital mycoplasmas have been associated with NGNCU. *C. trachomatis* is well established as the etiologic agent responsible for 30% to 50% of acute urethritis not attributable to *N. gonorrhoeae*. A significant association has also been made between NGNCU and *Mycoplasma genitalium*, which may account for 15% to 25% of cases of acute NGNCU.[96,97,186] Although several studies have been done, the role of UU in male urethritis is not entirely clear. Although earlier data suggested that UU is the cause of some NGNCU, it is not known what proportion of infections is due to the organism; even if the organism is present in the urethras of symptomatic men, its role as the causative agent has not been established. Studies of symptomatic men treated with antibiotics having differential activity between *C. trachomatis* and UU, and cultures performed on men with persistent symptoms of urethritis following antigonococcal and antichlamydial therapies suggest that some patients with NGU are caused by UU.[79,476] Use of highly sensitive molecular approaches along with serologic responses has already provided more complete information regarding the role of UU in

NGU. A study conducted by Horner and colleagues found that UU was not associated with acute NGNCU in multivariate analysis, but was associated with chronic NGNCU, which was defined for the study as urethritis occurring 30 to 92 days after commencement of treatment.[187,188] These workers concluded that ureaplasmas were a probable cause of chronic NGNCU that occurs after treatment. A 2004 study conducted in Japan reported a significant association between UU and NGNCU and suggested that the presence of *U. parvum* in the urethra may reflect colonization and not infection.[99]Other recent studies using sensitive molecular techniques have established that UU is associated with some cases of NGNCU and that *U. parvum* is seen more often in asymptomatic infections, although some patients with *U. parvum* may be symptomatic.[395,567] The relationship of MH and NGNCU is much less defined in men and has not been found to be involved in women with urethral syndrome.[524]

The role of MH and UU as an etiology of chronic prostatitis has been investigated by many researchers. Using classical techniques for localizing infections to the prostate, several investigators have documented UU as being responsible for a small proportion of cases of chronic prostatitis.[365,366,381,449] In a 2002 study from Croatia, UU was the sole agent isolated from the prostatic fluids of 2.54% of 276 patients with chronic prostatic infection.[449] In a study from Japan, UU was recovered from prostatic fluid secretions of 18 of 143 patients with prostatitis.[366] Targeted anti-*Ureaplasma* treatment eradicated the organisms and resolved symptoms, suggesting that UU was the causative agent in these patients. UU is rare as a cause of epididymitis; a single patient infection has been reported wherein the organisms were isolated from an epididymal aspirate in association with a significant rise in the specific antibody titer.[209] In a PCR-based Russian study in 2011, men with chronic prostatitis were found to harbor MH at a rate three times higher than those with benign prostatic hyperplasia, and there was no evidence of the organism in men without prostate disease. In addition, the study found higher titers of antibody against MH and increased prostate-specific antigen (PSA) levels in patients who were positive for MH. The authors felt that MH might potentially be used as a marker of early prostate disease and as a target for its improved prevention and treatment.[21]

Infants born to mothers who are colonized with genital mycoplasmas are also frequently colonized. In survey studies, 18% to 45% of neonates delivered to colonized mothers were also colonized with MH, with positive cultures being obtained from the throat, the genital tract, or the urine.[106,121] The rate of vertical transmission of UU ranges from 18% to 55% among full-term infants and from 29% to 55% among preterm infants.[416] Colonization usually decreases after about 3 months of birth; in addition, less than 10% of older children and non–sexually experienced adults are

found to be colonized.[524] Syrogiannopoulos and associates cultured the throat, eyes, and vaginas of 193 full-term infants born to women colonized vaginally with UU.[465] Of these, 107 (55%) had UU present in at least one of the sites cultured. Colonization may persist in these babies for prolonged periods with no ill effects to the child. In the latter study, 68%, 33%, and 37% of the infants who had colonization at birth in the throat, eyes, and vagina, respectively, still had colonization on follow-up at 3 months of age. Among the children who had colonization in the respiratory tract, there was no increased incidence of respiratory tract illnesses when compared with children who did not have colonization in this area. In a study performed in Israel, 24% of 99 preterm infants were colonized with mycoplasmas; UU was isolated from 21 infants and MH was isolated from three infants.[204] In this study, the colonization rate was inversely correlated with gestational age, with 80% of infants younger than 28 weeks of gestation having colonization, as opposed to 17.9% of infants at 28 to 36 weeks of gestation.[204] Of the 27 infants requiring ventilatory assistance in this study, 22% had UU isolated from lower respiratory tract secretions. Ureaplasmas can invade the amnionic sac and induce an inflammatory response, resulting in chorioamnionitis, preterm labor, and neonatal lung injury. The ability of UU and MH to cause pneumonia, bacteremia, and meningitis in newborns can no longer be questioned.[537a] Future investigations to prevent prematurity should be directed toward identification and localization of specific microorganisms combined with targeted antibiotic trials to determine whether such interventions can improve long-term infant outcomes.[537a]

Several studies have suggested that UU is associated with chronic lung disease, bronchopulmonary dysplasia, persistent pulmonary hypertension, and systemic infection in premature infants.[32,56,58] Prospective studies and animal model

1183

studies have now shown a significant relation between UU respiratory tract infection and the development of chronic lung disease of the newborn.[80,410] Cassell and others found that the recovery of UU from the tracheas of infants weighing less than 1,000 g, who also required ventilatory assistance, was associated with the development of bronchopulmonary dysplasia and associated conditions (e.g., hyaline membrane disease, patent ductus arteriosus, and pneumonia).[56] A subsequent study by Crouse and associates showed that low-birth-weight infants with respiratory distress who had UU recovered from tracheal cultures were more likely to show dysplasia and evidence of pneumonia on chest radiography than those without UU.[80] Nasopharyngeal or tracheal colonization of preterm infants with UU is also associated with an elevated peripheral white blood cell count.[367] Sanchez and Regan found that, among infants colonized with ureaplasmas in the respiratory tract, chronic lung disease requiring

mechanical ventilatory assistance developed in 30%, whereas respiratory tract illness developed in only 8% of noncolonized neonates.[417] Bloodstream infection with UU has been documented in newborn infants, and these infections are often associated with coexisting respiratory tract infections.[32,49,528] These systemic infections are associated with urinary tract infection, preterm or prolonged membrane rupture, preterm labor, chorioamnionitis, low birth weight, and the presence of congenital anomalies and perinatal asphyxia in the newborn.[528] The pathogenesis of this syndrome in the neonate has been supported by animal models and reflects both the nature of these bacteria as opportunistic agents and the immunocompromised status of the premature infant.[531] Studies with neonatal lung fibroblast cultures have demonstrated induction of cytokine release from these cells by infection with UU in vitro, suggesting a role for cytokines in the pathogenesis of bronchopulmonary dysplasia in prematurity.[457]Serologic studies indicate that the neonate or fetus systemically infected with UU generates serovar-specific anti-*Ureaplasma* IgM and IgG responses, providing additional evidence for the pathogenic potential of these organisms.[398]

Several reports and studies have also shown that both UU and MH may be recovered infrequently from the CNS as a cause of silent or clinically symptomatic meningitis in the newborn period.[518] Several cases of MH CNS infections in the neonate have been described; most of these occurred in premature infants for whom prolonged rupture of membranes had been documented, although cases have also been described in full-term infants.[11,326,531,550] In a prospective study of 100 preterm infants, Waites and coworkers isolated UU from the CSF of eight babies and MH from the CSF of five babies.[529] Among the babies with UU infection, six had intraventricular hemorrhage, three had hydrocephalus, and three died. None of the infants with MH infections died, and only one had neurologic signs of meningitis. Gilbert and Drew, however, reported a case of meningitis in a premature infant caused by MH that had a chronic course, with the development of intraventricular hemorrhage.[140] In all of these infants, eradication of the organisms with antimicrobial therapy proved difficult. In a study of 318 predominantly full-term infants with signs of suspected sepsis or meningitis born to primarily low-risk women, MH was isolated from the CSF of nine infants and UU was recovered from the CSF of five infants.[528] Of these 14 infected infants, 12 recovered without therapy and 2 died. Of these two infants, one with MH died of *Haemophilus influenzae* sepsis, whereas the other, infected with UU, had intraventricular hemorrhage. This study suggested that mycoplasmas are more common in neonatal CNS infections than had been appreciated previously. A case of MH meningitis subsequent to neurosurgery in an adult has been described, detected using PCR of the CSF, since culture, and other nonmolecular

techniques were not sufficient for the diagnosis.[264] Although CNS infections with MH usually resolve spontaneously, ureaplasmas apparently can elicit an inflammatory response that is associated with intraventricular hemorrhage.[176]

In addition to CNS infections, mycoplasmas, particularly MH, have also been isolated from other extragenital infections in both children and adults. Perinatally acquired MH has been recovered from subcutaneous scalp abscesses at the site of forceps or monitor injuries, conjunctival infections, and submandibular lymph nodes in the newborn.[47,143,396] MH was also isolated in multiple blood cultures from a 10-month-old child who had suffered severe burns.[87] In adults, MH has been cultured from patients with a wide variety of infections, including bacteremia, postoperative and posthysterectomy wound infections, hematomas, septic arthritis, aspiration-associated empyema, septic thrombophlebitis, peritonitis, periorbital abscesses, intra-abdominal and retroperitoneal abscesses, and brain abscesses.[48,75,137,177,242,271,309,317,327,340,341,380,402] MH bacteremia and postoperative sternal wound infection have occurred in patients following cardiothoracic surgery.[347,352,451] In another report of a MH sternal wound infection, UU was also recovered.[390] MH prosthetic valve endocarditis has been reported, and both MH and UU have been isolated from pericardial tissues or fluids of patients with pericardial effusions.[40,135,236]

Patients with these infections had histories of recent cardiac surgery (e.g., coronary artery bypass surgery, aortic valve replacement, heart transplantation secondary to idiopathic dilated cardiomyopathy) or were immunocompromised (e.g., systemic lupus erythematosus, chronic obstructive pulmonary disease).[236] MH was also isolated from a surgical wound infection following insertion of a silicone breast prosthesis.[420]

MH and UU can behave as opportunistic infectious agents in those with underlying diseases or conditions, such as hypogammaglobulinemia, Hodgkin's disease, systemic lupus erythematosus, renal transplantation, heart disease, leukemia, lymphoma, rheumatoid arthritis, and severe trauma.[75,227,306,339,342,370,378,480,497] There is a patient with perihepatitis associated with a perinephric abscess due to MH that occurred 4 months postrenal transplantation.[53] In an otherwise immunocompetent Australian patient, a parapharyngeal abscess was identified following an acute Epstein–Barr virus infection.[235] MH and UU septic arthritis have been reported in patients with hypogammaglobulinemia, hematologic malignancies, massive trauma, postpartum bacteremia, lupus erythematosus, and common variable immunodeficiency; this clinical entity likely occurs following hematologic seeding of the joint spaces.[51,75,225,497] In 1994, Kane and associates reported the first patient with a respiratory tract infection with diffuse alveolar hemorrhage caused by MH; the patient was a bone marrow transplant recipient.[227] MH has been isolated from postoperative

perihepatic

1184

hematomas that developed in the abdomen of liver transplant recipient a month after the transplant surgery.[208] Both MH and UU were isolated from a retroperitoneal hematoma 12 days after liver transplantation in a 45-year-old woman with fulminant hepatic failure.[160] Infections of prosthetic joints by MH have also occurred, and MH wound infections following open reduction of fractured mandibles and after cesarean sections have been reported as well.[451] A dual infection with antibiotic-resistant MH and *U. parvum* progressed from septic arthritis to a fatal disseminated infection in an immunocompromised patient in Germany.[307] Infections in the head, neck, and chest areas and in tissue contiguous with the genital tract may reflect the presence of these organisms in the adjacent respiratory and urogenital tracts, respectively.[341,402] For example, Kayser and Bhend reported a 45-year-old woman with paraspinal and intervertebral soft tissue infection that developed 16 days after she underwent an abdominal hysterectomy.[233]

MH has also been isolated from the urine of patients with HIV infection. In a study by Chirgwin and colleagues at the State University of New York in Brooklyn, MH was isolated from 18% of the urine specimens obtained from 180 HIV-positive individuals and from 21% of urine specimens from 38 HIV-negative individuals.[68] In this study, an additional 30 glucose-using mycoplasmas were recovered only from the HIV-positive individuals.[68] Growth inhibition with species-specific antisera allowed for the identification of 18 of these isolates: 14 were identified as *M. fermentans* and 4 were identified as *M. pirum*. The remaining 12 isolates were nonviable on subculture.

Mycoplasma genitalium

In 1981, Tully and coworkers isolated a previously undescribed and unusually fastidious mycoplasma from urethral specimens of 2 of 13 homosexual men with NGNCU.[509] Although several subsequent attempts to isolate this new organism failed, several isolates of the same organism were recovered from urogenital specimens in China.[304] In 1983, this new species was named *M. genitalium*.[510] Ultrastructural analysis of these isolates indicated that the new organism shared several characteristics with *M. pneumoniae*. These characteristics included the tapering flask-like shape of the individual cells and the presence of a specialized apical structure that facilitated the adherence of the organisms to tissue cells, erythrocytes, and inert material such as plastic and glass.[510] *M. genitalium* possesses a species-specific, 140-kDa protein called P140 that is a structural and functional counterpart of the 170-kDa P1

cytoadhesin protein of *M. pneumoniae*.[346] Nonadherent variants of *M. genitalium* have an altered P140 adhesin or have lost the membrane-associated adhesin molecule.[334] *M. genitalium* and *M. pneumoniae* contain a 43-kDa cross-reactive protein that is also detectable on isolates of *Acholeplasma laidlawii*.[72] These shared antigenic epitopes are likely to be responsible for the serologic cross-reactions observed with *M. genitalium* in most tests for *M. pneumoniae* antibodies, including complement fixation (CF), indirect immunofluorescence assays, and metabolic inhibition and growth inhibition tests using heterologous antisera.[85,86,280] DNA hybridization studies have shown that the two organisms have 6.5% to 8.1% nucleotide sequence homology, the latter probably reflecting those genes that code for the antigenically cross-reactive proteins.[280,564] Other gene sequences are indeed unique for the two species, providing evidence that *M. pneumoniae* and *M. genitalium* are distinct species.[510] There have been many studies since the 1990s implicating *M. genitalium* with male and female reproductive tract syndromes. Since the organisms are very difficult to culture in routine laboratories, and serology is not often useful for diagnosis, dependence on PCR and other molecular methods for enhanced detection is necessary for research and diagnosis.[312] In a study by Taylor-Robinson and colleagues, rises in antibody titers to *M. genitalium* were detected in 4 of 14 patients with NGU and in 2 of 17 patients without urethritis, but only 1 of the 4 patients who seroconverted had a positive culture.[478] Failure to isolate the organisms in studies on urethritis probably reflected the lack of adequate techniques for reliable culture of this fastidious species. To circumvent the inherent problems of culture, other investigators have used species-specific nucleic acid probes prepared from genomic DNA of *M. genitalium* with or without simultaneous PCR.[185] These workers have detected the organism in 14% of men with gonococcal urethritis, 10% of men with chlamydial urethritis, 14% to 28% of men with NGU, and 13% to 23% of men with NGNCU. One study, in addition, detected *M. genitalium* DNA in 27% of 37 men with recurrent or persistent urethritis. However, the organism was also detected in 6% to 12% of men who had no genitourinary tract symptoms in these studies. The presence of this organism in the male urogenital tract was independent of the presence of *Chlamydia trachomatis* in many of these studies, although others have suggested an increased incidence with *C. trachomatis* infection.[206,207,216,218,219]Using PCR techniques, one of the above research groups failed to detect *M. fermentans*, *M. penetrans*, or *M. pirum* in urethral specimens from patients with NGNCU.[95] These workers concluded that *M. genitalium* was the etiologic agent in many cases of NGNCU; this was also supported by the clinical response of the infected men to treatment with doxycycline.[186]

Several studies using molecular techniques have now established the incidence of

M. genitalium as the cause of acute NGU and NGNCU. It is estimated that between 18.4% and 45.5% of all cases of NGNCU in men are due to this organism, and that persistence of the organisms in the urethra after antimicrobial therapy is associated with persistent or recurrent NGU.[97,212,310,333,484,501] Molecular approaches for the detection of *M. genitalium* include conventional and real-time PCR assays that amplify the *M. genitalium*-specific adhesin (MgPa) gene or species-specific regions of the 16S rRNA gene.[100,119,215,566] The use of real-time PCR assays for detection of *M. genitalium* in first-voided urine specimens has resulted in quantitative results, showing that the organism loads of *M. genitalium* in these specimens of symptomatic men are much higher than those seen in asymptomatic men. Organism loads in men with *M. genitalium*-positive NGU were suppressed during levofloxacin therapy, and the patients became asymptomatic. Following treatment, symptoms often resolved, but the organisms remained detectable in the urethra. The reappearance of symptoms was associated with an increase in organism load in patients in whom treatment failed. These studies have suggested that antimicrobial therapy that results in the elimination of the organisms from

the genital tract is required for the management of *M. genitalium*-associated urethritis to prevent subsequent recurrence of NGNCU.[100]

Blanchard et al. recently published on the evolution of *M. genitalium* and reported that *M. genitalium*, MH, and *Ureaplasma parvum* share a core genome of ~250 protein-encoding genes that correspond to their basic cellular metabolism, but also show a striking difference in their energy-generating pathways. They concluded that *M. genitalium* is a sexually transmitted organism associated with NGU in men and several inflammatory reproductive tract syndromes in women, such as cervicitis, PID, and infertility.[37] A review of 34 studied by Manhart et al. in a 2011 Centers for Disease Control and Prevention (CDC) publication "Sexually Transmitted Guidelines," which included >7,100 men between 1993 and 2011 using PCR as method of detection, concluded that *M. genitalium* can indeed cause acute urethritis. Twenty-eight of the 34 studies were from resource-rich countries, including the United States, and four were from China and Africa. Across all studies, 13% of men with NGU were positive for *M. genitalium* (incidence range of 5% to 42%), and in 11 studies that included NGNCU data, 25% were positive with a range of 10% to 38%.[312] Taylor-Robinson et al. have described the proposed pathogenesis of *M. genitalium* in a review paper.[486] A human endocervical epithelial cell model system has been used to demonstrate that *M. genitalium* infection can activate cellular host defense and inflammation pathways.[329]

A few studies have addressed the detection and significance of *M. genitalium* in the female genital tract.[22,481] In a study performed in a sexually transmitted disease (STD) clinic in London, *M. genitalium* was detected by PCR in genital tract specimens from 18% of 57 female patients.[374] Another study, done in Copenhagen, reported finding of *M. genitalium* in endocervical specimens from 5 of 74 women.[219] Neither of these studies addressed the association of these isolates with the presence of disease. Although definitive evidence on the pathogenicity of *M. genitalium* in the female genital tract is lacking, indirect evidence suggests that it may also be involved in both lower and upper genital tract infection. A study conducted in Japan found *M. genitalium* in 7.8% of 64 women with purulent cervicitis, and studies conducted in the United States found that, once gonococcal and chlamydial infections were excluded, patients with purulent cervicitis were more than three times as likely to have *M. genitalium* in the cervix than those without purulent cervicitis.[313,514] In a study comparing the prevalence of *M. genitalium, C. trachomatis, N. gonorrhoeae,* and *T. vaginalis* in adolescent girls, using transcription mediation amplification, *M. genitalium* was detected in 22% of the girls as compared with 24% *C. trachomatis* and had a lower prevalence compared with the other two agents. There was no association of *M. genitalium* with vaginal or cervical symptoms; however, there was a higher incidence of *M. genitalium* when *C. trachomatis* was present and there was a history of recent sexual contact.[198] Similarly, Casin and colleagues examined 170 women with genital tract symptoms attending a STD clinic in Paris and found no correlation between mucopurulent cervicitis and the presence of *M. genitalium*, despite the fact that 38% of the women had positive PCR results for *M. genitalium* at one or more genital sites (usually vaginal).[55] A more recent study of 261 women in New Zealand also showed no correlation between clinical symptoms of cervicitis and detection of *M. genitalium* in endocervical swabs (8.4% prevalence), by which they concluded that presentation of cervicitis should not necessarily elicit a screen for *M. genitalium*.[368] Although there is continued controversy regarding the association of *M. genitalium* and clinical genital disease in women, a recent study reviewed epidemiologic evidence in over 27,000 women with a range of prevalence of *M. genitalium* from 2% to 7% and demonstrated strong correlations between the presence of *M. genitalium* and lower genital tract infections (urethritis, cervicitis, and vaginal discharge), as well as convincing evidence for upper genital tract inflammation (i.e., PID and infertility).[328] The CDC publication referenced above also reviewed data concerning cervicitis and urethritis. In the 14 studies of cervicitis, 57% found an association, whereas 43% did not. However, they did find that the studies that used only clinical criteria for decisions about the diagnosis were less likely to find an association with *M. genitalium* as compared with studies that defined cervicitis as ≥30 leukocytes per high-power field. The conclusion of the CDC group was that there was

existing evidence to support the hypothesis that *M. genitalium* may cause cervicitis, although data are conflicting at this point. Only a few studies addressed female urethritis. In these studies, *M. genitalium* was found in 4% to 9% of women with urethritis. Their conclusion was that *M. genitalium* may cause female urethritis, but data are presently too limited to draw any definite conclusions.[312]

Evidence also exists for *M. genitalium* being involved in endometritis and acute PID. Serologic studies have documented elevated antibody titers to *M. genitalium* in some women with PID that was not attributable to *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, or MH; experimental studies in chimpanzees have demonstrated the ability of *M. genitalium* to cause upper and lower genital tract disease in this animal model.[344,479] Serologic studies also suggest that *M. genitalium* infection may be an independent risk factor in the pathogenesis of an inflammatory process that may lead to scarring of the uterine tissues, resulting in infertility.[73] A study in Nairobi, Kenya, that examined 115 women who presented with persistent pelvic pain found that 16% of 58 women with histologically confirmed endometritis were PCR-positive for *M. genitalium* in the cervix, the endometrium, or both locations.[76] In another study conducted in London, 13% of 45 women with PID had PCR-based evidence of *M. genitalium* in the endocervix, compared with none of the control patients.[446] A US study showed that 682 women with suspected endometritis and PID were treated with cefoxitin and doxycycline; those positive by PCR for *M. genitalium* had a higher risk of short-term failure and were more likely to develop recurrent pelvic pain and PID, as well as infertility, and decreased pregnancy and live births. The authors suggest that the recommended antimicrobial regimen is not adequate for patients with *M. genitalium* endometritis.[159] The association of *M. genitalium* and PID and subsequent reproductive sequelae, independent of *C. trachomatis* and *N. gonorrhoeae* infection, has been affirmed in a review article that examined studies in which PCR detection methods were used.[158] The Manhart CDC publication reviewed nine studies that examined the association with PID by serology or PCR, but in many of the studies, the absence of a negative control group was a limitation. Their conclusion

was that the data provide some support for a relationship, but at the present time, data remain conflicting.[312] Taylor-Robinson (2011) has implicated *M. genitalium* as a potential cause of adverse outcomes in pregnancy and felt that if it was detected, then the patient should be treated due to its pathogenic potential.[486] The Manhart review, however, on the basis of five published studies, suggested that *M. genitalium* was not common in women who have preterm births, at least in resource-rich countries, and

the data from resource-poor countries are conflicting. In this same review, there was no sufficient evidence from few studies that addressed ectopic pregnancies that implicated *M. genitalium.*[312]

In 1988, Baseman and coworkers recovered *M. genitalium* along with *M. pneumoniae* from 4 of 16 frozen specimens collected from the upper respiratory tracts of military recruits during an *M. pneumoniae* vaccine trial in 1974 and 1975.[23] The role of *M. genitalium* in respiratory tract disease is not clear, but it has been suggested that the association with *M. pneumoniae* may result in a synergistic infection that causes more severe pneumonia or may contribute to the pathogenesis of extrapulmonary complications of *M. pneumoniae* infection.[212] The presence of *M. genitalium* in the respiratory tract, with or without *M. pneumoniae*, and the immunologic cross-reactivity between the two organisms may not only complicate the infectious process in coinfected individuals, but may also affect the immunologic response to infection. Such interactions, consequently, may interfere with the interpretation of serologic tests that are frequently used to diagnose *M. pneumoniae* infections. The use of species-specific PCR assays for *M. pneumoniae* and *M. genitalium* may provide a solution to clinical and diagnostic problems by circumventing the need to cultivate these agents and clarifying the cross-reactive immune responses that occur with these organisms.[200]

Besides the respiratory and genital tracts, *M. genitalium* has also been recovered from joint fluid aspirates of patients with arthritis. *M. genitalium* was detected by PCR analysis in the knee joint of a 25-year-old man with Reiter's syndrome and has been detected in the knee joint of a 58-year-old man with seronegative rheumatoid arthritis.[482] Both *M. pneumoniae* and *M. genitalium* were detected in a specimen of knee joint fluid from a patient with hypogammaglobulinemia and polyarthritis following a bout of mycoplasmal pneumonia.[507]

M. genitalium has also been associated with HIV infection, although not to the extent that other species, such as *M. fermentans* and *M. penetrans,* have been associated. Montagnier and Blanchard detected *M. genitalium* in the blood of a patient with AIDS in 1993 by PCR.[345] However, a 1996 search for the presence of six *Mycoplasma* species in peripheral blood mononuclear cells (PBMCs) of 154 HIV-seropositive patients, 40 HIV-seronegative STD clinic patients, and 40 HIV-seronegative blood donors failed to detect *M. genitalium* by PCR in any of them.[254] Another search for mycoplasmas in the urine of 15 HIV-seropositive children conducted in 1999 found only a single specimen positive for *M. genitalium* in 1 of 9 HIV-infected children classified as having severe HIV disease.[199] *M. genitalium* has also been detected by PCR in urethral and rectal specimens from homosexual men with and without NGNCU.[483] An Australian study of the prevalence of genital mycoplasmas in women attending STD clinic using a PCR method of detection found

M. genitalium in only 4% of 527 women, as compared with prevalences of 17%, 14%, and 52% for MH, UU, and *U. parvum*, respectively; in this study, *M. genitalium* was significantly associated with women who were HIV-positive and women who presented with symptoms of cervicitis, as compared with the other mycoplasmas. These authors recommended routine screening for *M. genitalium* in women who are HIV-positive and/or present with cervicitis symptoms.[305]

Mycoplasma fermentans

M. fermentans is a fastidious human *Mycoplasma* species that has been recognized as a tissue culture contaminant for many years.[515] The increased usage of human-derived lymphocytes and macrophages in immunologic and viral research was likely responsible for recognition of this agent as a tissue culture contaminant. *M. fermentans* has been detected by PCR in salivary samples of healthy individuals and has also been detected in the genitourinary and respiratory tracts of humans.[67,439] In a PCR-based study conducted in London, *M. fermentans* was sought in throat swabs and urine specimens from healthy university students and from patients with congenital immunodeficiencies.[7] Twenty-seven percent of the students who submitted throat and urine specimens had *M. fermentans* in at least one of these specimens. *M. fermentans* was detected in one throat swab and three urine specimens from the 19 patients with congenital immunodeficiencies tested. A hamster model has demonstrated the ability of two different strains of *M. fermentans* and a strain of *M. pneumoniae* to cause interstitial pneumonitis, suggesting the pathogenic potential for *M. fermentans* for respiratory disease and perhaps other chronic infections in humans.[559]

In 1986, interest in *M. fermentans* as a human pathogen was stimulated when Lo and coworkers at the Armed Forces Institute of Pathology (AFIP) and the National Institutes of Health (NIH) reported the isolation of a novel mycoplasma, provisionally named *M. incognitus,* from Kaposi's sarcoma (KS) tissues of patients with AIDS.[281,290,291] Using immunohistochemical techniques employing monoclonal antibodies against this new agent, Lo and coworkers detected *M. incognitus* antigens in thymus, liver, spleen, lymph nodes and brain tissues of patients with AIDS, and in placental tissues delivered by pregnant women with AIDS.[284] The histopathology of the infected tissues showed a range of responses; in some tissues, no histologic changes were observed, whereas in others fulminant necrosis with inflammation was noted. Intraperitoneal inoculation of four silver leaf monkeys with this agent resulted in a wasting syndrome and death within 7 to 9 months.[294,296] These same workers also reported on six patients, from six different geographic areas, who presented with an acute flu-like illness and a syndrome of persistent fevers, lymphadenopathy, diarrhea, and multiple-organ failure, resulting in death within 1 to 7 weeks. Autopsies revealed fulminant necrosis of lymph node, lungs, liver, adrenal gland, heart, and brain tissues.

Immunohistochemical techniques and electron microscopy revealed mycoplasmal antigens in the areas of necrosis, and a labeled, specific DNA probe detected the genetic material of the agent in the infected tissues.[283] None of these patients were infected with HIV-1 or HIV-2. Nucleic acid hybridization profiles, restriction

1187

endonuclease mapping, and antigenic analyses indicated that *M. incognitus* was not a new mycoplasma, but rather a strain of *M. fermentans*, a fastidious, "nonpathogenic" mycoplasma found in the genital tract.[54,413]

The "incognitus" strain of *M. fermentans* was subsequently found to be associated with other histopathology in patients with AIDS. Bauer and colleagues examined kidney tissues of 15 patients with AIDS with light microscopic evidence of AIDS-associated nephropathy.[24] Tissues from these patients showed immunofluorescence reactions with *M. fermentans* incognitus strain-specific monoclonal antibodies in glomerular endothelial and epithelial cells, glomerular basement membranes, tubular epithelial cells and casts, and mononuclear interstitial cells. Mycoplasmal structures were also seen by immunoelectron microscopy in kidney tissues of these patients. Renal tissues from patients with AIDS without renal involvement and from non–HIV-infected patients with and without nephropathy did not reveal any organisms on histopathologic examination.[24] Ainsworth and associates also reported a patient with HIV-associated nephropathy in whom *M. fermentans* was detected in renal tissues by PCR when nephropathy first became clinically apparent; 18 months later, as the disease progressed and renal function deteriorated, PCR detected *M. fermentans* in the patient's urine, throat, and peripheral blood.[8] *M. fermentans* DNA was also detected in lymph node specimens from 4 of 7 patients with AIDS.[423] Lo and colleagues reported fulminant adult respiratory distress syndrome associated with *M. fermentans* in three patients without AIDS; immunohistochemical and electron microscopic studies revealed evidence of the organisms in the lungs and liver of these patients.[295] Disseminated *M. fermentans* infection has also been documented in HIV-positive patients with non-Hodgkin's lymphoma.[5]

Others also reported on the association of the *M. fermentans* incognitus strain with ultimately fatal disease in patients without AIDS. Macon and colleagues described a 35-year-old homosexual man with KS and T-cell lymphoma with a peripheral CD4 cell count of 43 per cubic millimeter.[308] Fatal *Pneumocystis* pneumonia and disseminated cryptococcal infection subsequently developed. Multiple enzyme immunoassays (EIAs) and Western immunoblots for HIV-1, HIV-2, human T-cell lymphotropic virus (HTLV)-I, and HTLV-II antibodies were negative, as were retroviral cultures and reverse transcription-PCR studies. Systemic *M. fermentans* infection was documented

by immunohistochemical and PCR methods in premortem and postmortem tissue specimens. Beecham and coworkers reported a similar instance, wherein a previously healthy 28-year-old nonimmunocompromised man presented with a 7-day history of fever, abdominal pain, diarrhea, rash, and shortness of breath. *M. fermentans* was detected in a bone marrow biopsy specimens by PCR and electron microscopy.[27] In another report of a previously healthy HIV-seronegative man with AIDS-like symptoms of fever, malaise, weight loss, diarrhea, and extensive liver and spleen necrosis, treatment with doxycycline (300 mg/day, orally for 6 weeks) resulted in resolution of the symptoms and full recovery.[282] These studies suggested that *M. fermentans*, or a specific strain of this species, may be a systemic pathogen in non–HIV-infected patients.

Using PCR technology, Dawson and associates detected *M. fermentans* in 23% of 43 urine sediment specimens from patients with AIDS-associated nephropathy.[89] Some of these urines were culture-positive for MH and/or UU. None of 50 urine sediment specimens from 50 HIV-negative, healthy patients were culture- or PCR-positive for *M. fermentans*, although 23 specimens grew UU and one specimen grew MH.[89] Katseni and coworkers examined blood, throat, and urine specimens from 117 HIV-positive patients and 73 HIV-seronegative patients attending an STD clinic in London.[231] *M. fermentans* was detected by PCR in 10% of peripheral blood mononuclear specimens, 23% of throat specimens, and 8% of urine specimens from the HIV-positive patients. Among the 73 HIV-seronegative patients, *M. fermentans* was detected in PBMCs, throat, and urine specimens of 9%, 20%, and 6%, respectively. Hawkins and colleagues at the NIH detected *M. fermentans* DNA sequences in 11% of blood specimens from 55 HIV-seropositive patients, but detected none in 26 HIV-seronegative, low-risk individuals.[172] In France, Bebear and coworkers performed culture and PCR on throat, endocervical, urethral, urine, and PBMC specimens from 105 HIV-positive individuals.[25] Although culture and PCR assays for *M. pneumoniae* and *M. genitalium* were negative, *M. fermentans* was detected by PCR in a least one specimen site in 26.7% of the 105 patients. The presence of *M. fermentans* in these patients was not associated with the stage of HIV disease, the viral load, or the CD4 count.

M. fermentans is able to actively invade cultured cells, a property not previously associated with *Mycoplasma* species. Although an *M. fermentans* reference strain and the incognitus strain were able to invade HeLa cells, *M. fermentans* incognitus strains were more invasive when tested in tracheal explant cell cultures. Incognitus strain organisms could be observed intracellularly, whereas the reference strain was observed adhering to only between cells.[456,488] Intranasal infection of rats and subsequent explant cultures of the tracheal tissues of these animals also revealed an intracellular localization of these organisms within the cultured cells.[456] *M. fermentans* incognitus

strain and the other *M. fermentans* strains cause ciliostasis and cytopathology in tracheal explant cultures, but the extent and severity of the cytopathology varied considerably from strain to strain. Studies in animals also indicated that immunosuppression may allow *M. fermentans* to grow and flourish. Intravenous administration of *M. fermentans* incognitus strain killed BALB/c nude mice, but did not kill immunocompetent BALB/c mice.[477]

Although some investigators have noted differences between the *M. fermentans* incognitus strain and other *M. fermentans* strains, others have noted no differences. Sasaki and coworkers compared the original incognitus strain with three other reference and clinical isolates of *M. fermentans*. Restriction-fragment-length polymorphism analysis of the DNA from these strains showed similar patterns on gel and immunoblot profiles of cellular proteins, indicating a high degree of antigenic homogeneity among the four strains examined. Exposure of PBMCs to these mycoplasmas resulted in significant increases in the production of IL-1β, IL-6, and TNF-α; these increases were observed after exposure to all four *M. fermentans* strains and were not restricted to the incognitus strain. Lastly, exposure of HIV-infected PBMCs to any of the *M. fermentans* strains resulted in a 1.8- to 4.3-fold enhancement of reverse transcriptase activity and a 3.3- to 7.0-fold increase in the production of p24 antigen in the

culture. These workers concluded that the incognitus strain of *M. fermentans* was not unique when compared with other *M. fermentans* strains.[422]

Several investigators are currently examining the role of *M. fermentans* and other mycoplasmas as cofactors affecting progression of HIV-associated disease.[6,190] In vitro studies on HIV-infected CEM cells (a CD4-enriched T-lymphoblastoid tumor cell line) showed that treatment of the cells with tetracycline analogs or fluoroquinolones was able to inhibit the production of virus-induced cytopathic effects without inhibiting the replication and production of progeny virus.[266,363] Subsequent studies have indeed shown that *M. fermentans* acts synergistically with HIV-1 in lymphoblastoid and promonocytic cells to produce cell death; this ability has also been demonstrated to occur with other *Mycoplasma* species, including *M. penetrans*, *M. pirum*, and *M. arginini*.[267,292] Phillips and associates showed that mycoplasmal attachment to HIV-infected lymphocytes was associated with sites of viral budding, leading these investigators to surmise that attachment of mycoplasmas may trigger or enhance production of progeny virus by infected cells.[387] Several mechanisms have been proposed whereby mycoplasmas such as *M. fermentans* may act as cofactors or immunomodulators in the production of HIV-associated disease.[345] Lymphocyte

activation stimulates the replication of HIV, and *Mycoplasma* species, including *M. fermentans* and *M. penetrans*, have the capacity to behave as polyclonal activators of both B and T lymphocytes.[127,203,460] *M. fermentans* is able to induce the production of lymphokines (i.e., TNF-α, IL-1, and IL-6) in various cell types (i.e., monocytes, macrophages, astrocytes, and glial cells) in vitro.[133,350,351] Muhlradt and Frisch isolated and partially purified a substance, which they termed mycoplasma-derived high-molecular-weight material (MDHM), that was membrane associated, contained lipid, and existed in an aggregated form when purified.[349] The presence of MDHM in nanogram per milliliter amounts activates macrophages to release nitric oxide, IL-6, and TNF. Another group identified a 48-kDa, hydrophobic, membrane-associated *M. fermentans* antigen distinct from MDHM that also stimulates the secretion of both TNF and IL-1 from cultured monocytes.[250] *M. fermentans* may also produce superantigens that bind directly to the major histocompatibility complex (MHC) proteins, thereby stimulating T-lymphocyte activation. Another *M. fermentans*-derived lipoprotein called the macrophage-activating lipopeptide 2 (MALP-2) has also been shown to induce the release of pro-inflammatory cytokines, chemokines, and nitric oxide by mouse peritoneal macrophages.[232] *M. fermentans* also enhances concanavalin A-induced apoptosis of T cells.[441] Some investigators have proposed that the production of peroxides and free radicals by mycoplasmas or the production of enzymes that inactivate the normal intracellular catalase may induce HIV gene expression and activate viral replication. Peroxides and other reactive oxygen species induce HIV gene expression in vitro by transactivation of viral promoter regions and contribute to programmed cell death.[265] *M. fermentans* incognitus strain is able to fuse with both T cells and peripheral blood lymphocytes.[105] The delivery of mycoplasmal components into these cells may directly affect normal lymphocyte functions. In addition, the fusion of mycoplasmal and lymphocyte membranes may significantly change the structure or orientation of various receptors on the lymphocyte surface, thereby altering the binding, induction, or production of various lymphokines. These fundamental alterations in lymphocyte structure and function may influence attachment, integration, and gene expression of HIV. Both *M. fermentans* and *M. penetrans* also possess membrane-associated phospholipase C, which can induce an inflammatory response, cause membrane damage to host cells, and activate the arachidonic acid cascade.[440]

M. fermentans may also play a role in genital tract infections. In 1989, *M. fermentans* was detected in the placental tissues of two women with AIDS.[284] Blanchard and coworkers used culture and PCR methods to examine the presence of both *M. genitalium* and *M. fermentans* in the genital tracts of sexually active adults and in the amniotic fluids of women with intact fetal membrane who were undergoing cesarean deliveries.[38] *M. genitalium* was detected by PCR, but not by culture in 11%

of 94 men and 87 women with clinical symptoms of NGU or cervicitis, but was not detected by either method in any of 232 amniotic fluid specimens. Conversely, *M. fermentans* was not detected by either method in any of the urogenital specimens, but was detected by PCR in 4 of 232 amniotic fluid specimens, suggesting that the organism may be transmitted transplacentally. Interestingly, 2 of the 4 patients with positive PCR results for *M. fermentans* had histologic evidence of chorioamnionitis, implying that *M. fermentans* may also be a genital tract pathogen.[38]

M. fermentans has also been implicated in rheumatoid arthritis and other rheumatic disorders.[189,222] In a 1996 study conducted in London, *M. fermentans* was detected by PCR in synovial fluid specimens from 21% of 38 patients with rheumatoid arthritis, 20% of 10 patients with spondyloarthropathy, 20% of 5 patients with psoriatic arthritis, and 13% of 31 patients with unclassified arthritic condtions.[427] Genotypic characterization of isolates from synovia of patients with arthritis revealed no unique characteristics; some were related to the *M. fermentans* American Type Culture Collection (ATCC) type strain, while others were related to strains isolated from tissue cultures as contaminants.[426] *M. fermentans*, *M. salivarium*, or both were detected by PCR in synovial fluid specimens from aspirates from the temporomandibular joint of patients with destructive osteoarthritis of the jaw.[544] This condition is thought to result from the action of proteases and cytokines on the articular cartilage of this joint. Watanabe and coworkers suggested that mycoplasmas present in the temporomandibular joints damage the synovium and cartilage by their enzymatic activities plus the recognized ability of mycoplasmas to stimulate release of cytokines from immune effector cells.[544] In a 2000 study, *M. fermentans* was detected by PCR in the synovial fluid of 88% of 26 rheumatoid arthritis patients. Seven of 8 patients with a variety of other inflammatory arthritides were also positive for *M. fermentans*.[189] A study published in 2001 also found *M. fermentans* DNA in synovial fluids of 17% of 35 patients with rheumatoid arthritis, 25% of 44 patients with undifferentiated seronegative arthritis, and 17% of 24 patients with psoriatic arthritis.[142] More recently, *M. fermentans* was found by culture or PCR in 23% of blood samples taken from 87 patients with rheumatoid arthritis, and in the same study, there was a higher incidence of IgG and IgM antibodies to an antigen of *M. fermentans* in these arthritic patients than in healthy controls.[139]

1189

M. fermentans infection, like many other organisms, has been investigated for its relationship to chronic fatigue syndrome (CFS). Using PCR-based assays for *M. fermentans*, MH, and *M. penetrans*, Choppa and colleagues examined PBMCs from 100 patients with CFS.[70] *M. fermentans*, MH, and *M. penetrans* were detected in the

PBMCs of 32%, 9%, and 6% of the 100 patients with CFS, respectively, whereas they were detected in 8%, 3%, and 2% of healthy controls, respectively. A subsequent study by the same research group detected *M. fermentans* in PBMCs of 36% of 50 patients with typical CFS as defined by the CDC, 32% of 50 patients with atypical CFS, and in 8% of 50 healthy control subjects.[521] Nasralla, Haier, and Nicolson used PCR methods to detect *M. fermentans*, *M, pneumoniae*, *M. penetrans*, and MH in blood specimens of 91 patients with CFS and/or fibromyalgia syndromes.[355] Among the 91 subjects, 59%, 48%, 31%, and 20% were positive for *M. pneumoniae*, *M. fermentans*, MH, and *M. penetrans*, respectively. Of the 91 subjects, 53% had molecular evidence of bloodstream infection with multiple *Mycoplasma* species. In a survey of 261 patients with CFS and 36 healthy volunteers, bloodstream infection by at least one *Mycoplasma* species was detected by a forensic PCR test in 68.6% of the patients with CFS and in 5.6% of healthy volunteers.[361] MH was detected in 36.8%, followed by *M. fermentans* and *M. pneumoniae* in 25.7% and 25.7%, respectively. Infection with multiple *Mycoplasma* species was detected in 17% of the patients with CFS. Although these studies show that high rates of infection with *Mycoplasma* species are found in patients with CFS, there is no definitive evidence that these mycoplasmas are the causative agents of CFS. The development of sensitive assays and improvements in culture techniques for these organisms will hopefully enable natural history and treatment studies to be undertaken.

M. fermentans was also postulated to play a role in the illness observed among veterans of Operation Desert Storm. A serologic survey study was conducted among Persian Gulf War veterans and nondeployed servicemen using both prewar and postwar serum specimens. *M. fermentans* infections were documented to have occurred in this military population both before and after service in the war, but these infections were independent of deployment to the Persian Gulf, indicating that epidemiologic and serologic data did not support a role for *M. fermentans* in the illness seen in Gulf War vetereans.[153] A similar study conducted by the AFIP also concluded that there was no serologic evidence for an association between *M. fermentans* infection and the "Gulf War illness."[289]

Even with its relatively short but fascinating epidemiologic history and the intensity of investigations by several research groups, the role of *M. fermentans* in HIV pathogenesis, STDs, rheumatoid arthritis, CFS, and other conditions is not known. Although molecular methods facilitate the detection of specific gene sequences of the organisms, the lack of reliable culture techniques complicates studies that may include various treatment methods. *M. fermentans* has been recovered in culture from joint fluid specimens, but it is often not known whether molecular assays are detecting viable or nonviable organisms. Molecular studies have shown that *M. fermentans* is genotypically heterogeneous, as evidenced by the presence of insertion sequence-like elements at various locations in the DNA, resulting in interstrain and intrastrain

variation.[391] In studies in which the organism has been successfully grown in SP-4 medium, biochemical testing has delineated four phenotypic clusters based on the utilization of arginine, glucose, fructose, and *N*-acetyl-glucosamine.[373] Systematic phenotypic and genotypic analysis of *M. fermentans* isolates from a variety of clinical specimens and conditions may help to define the pathogenicity and pathogenesis of *M. fermentans* infections and the role of this organism in various clinical settings.

Mycoplasma penetrans

In 1991, Lo and colleagues at the AFIP in Washington, DC, reported the isolation of a new *Mycoplasma* species from the urogenital tracts of homosexual men with HIV infection.[287] This organism exhibited unique morphologic characteristics, including a flask-shaped cell body composed of two compartments: one containing loosely packed, coarse granules consistent with ribosomal structures and the other tapered, smaller compartment containing densely packed fine granules.[286] This organism fermented glucose and hydrolyzed arginine, but not urea, required cholesterol for growth, and could be cultivated in SP-4 medium. It was also able to adhere to and actively invade mammalian cells.[285] Intracellular organisms were observed to be inside membrane-bound vesicles, with subsequent cell disruption and necrosis. This new species was given the name *Mycoplasma penetrans*.[286,424] Two separate studies investigating the prevalence of genital mycoplasmas in Nigerian men and women have shown *M. penetrans* in low numbers as compared with other genital mycoplasmas. *M. penetrans* was cultured from three vaginal specimens. In this study, 81% of the isolated *Mycoplasma* spp. were MH and 13% *M. fermentans,* as compared with 6% *M. penetrans*. One isolate of *M. penetrans* was isolated from semen samples in men seeking help with infertility; in this study, 24% of the *Mycoplasma* spp. were MH, 10% *M. fermentans*, and 5% *M. penetrans*.[3,4]

Seroepidemiologic studies have documented a high frequency of antibodies against *M. penetrans* in HIV-infected individuals.[93,149,512,540] Wang and associates found that 35.4% of serum samples from 444 HIV-1-infected patients were positive for antibodies against *M. penetrans*.[540] Among 234 men with AIDS, 41.5% were seropositive; in comparison, 20.3% of 118 asymptomatic HIV-1-infected individuals were also seropositive. Only one of 384 HIV-negative blood donors had antibodies against *M. penetrans*. Interestingly, 40% of 85 serum samples archived from patients with "GRID" (gay-related immunodeficiency), a term used in the early 1980s to describe AIDS, were also positive for anti-*M. penetrans* antibodies. Among 336 serum specimens from STD clinics in southern California, Brooklyn, and Milwaukee, only three were positive for *M. penetrans* antibodies. None of the 178 serum specimens obtained from HIV-1-seronegative individuals with other diseases or immunologic

disorders (e.g., patients on dialysis, or patients with systemic lupus erythematosus, rheumatoid arthritis, multiple sclerosis, leukemia, lymphoma, or other cancers) were positive for antibodies against *M. penetrans*.[540] Additional seroepidemiologic studies by the same research group found high rates of mycoplasmal antibodies in both symptomatic and asymptomatic HIV-1-positive homosexual men, but only 1% of 308

specimens from intravenous drug users and only 0.6% of 165 specimens from patients with hemophilia with or without HIV-1 infection, suggesting that *M. penetrans* may be sexually transmitted.[541] Grau and coauthors reported very similar findings on the presence of *M. penetrans* antibodies in a study conducted in France.[149] These workers found that positive *M. penetrans* serology was associated with both HIV-1 infection and with high-risk sexual practices among homosexual men; the seroprevalence in these patients increased with progression of AIDS-related disease. During the early 1990s, some researchers reported an epidemiologic relationship between the presence of *M. penetrans* antibodies and the development of KS. Lo and colleagues examined *M. penetrans* seroprevalence in a cohort of 33 HIV-seropositive and 31 HIV-seronegative homosexual men who were enrolled in an AIDS natural history study in New York City in 1984.[288] Testing of archived serum specimens from 1984 to 1985 revealed that 45.5% of the HIV-positive men and 22.5% of the HIV-negative men had antibodies against *M. penetrans*, suggesting that *M. penetrans* was circulating as a probable sexually transmissible agent early in the AIDS epidemic and was not necessarily associated with HIV infection. Over the subsequent 8 years, KS developed in nine men; seven of which had *M. penetrans* antibodies. Baseline seropositivity to *M. penetrans* was statistically associated with the subsequent development of KS, and among the HIV-positive men, KS was more likely to occur among men who had positive baseline serologies for *M. penetrans*. These workers concluded that *M. penetrans* infection may act as a cofactor with HIV in the subsequent development of KS.[81,288,541] However, others have found no association between *M. penetrans* infection and KS, which is now known to be associated with human herpesvirus type 8 infection.[149]

The use of sensitive molecular techniques for direct detection of *M. penetrans* has shown that this organism may be involved in chronic infections of cells and/or tissues other than blood mononuclear cells. Kovacic and colleagues used specific PCR assays for *M. pneumoniae*, *M. fermentans*, *M. genitalium*, *M. pirum*, *M. penetrans*, and MH to investigate the presence of these organisms in PBMCs from subjects infected or not infected with HIV-1.[254] Only *M. fermentans* was detected in 5.8% of 154 HIV-seropositive and 11.1% of HIV-seronegative patients. These investigators suggested

that the urogenital tract is the probable ecologic niche of this organism, since it was originally isolated from urine specimens and has been detected by PCR in urine specimens from patients who are seropositive for *M. penetrans* antibodies.[149,286,287] *M. penetrans* bacteremia has also been reported in non–HIV-infected patients with antiphospholipid syndrome.[558]

The exact role of *M. penetrans* in the pathogenesis of HIV infection is not known. Most work has centered on its putative role as a cofactor in HIV-associated disease progression. Sasaki and colleagues at the Institut Pasteur demonstrated that *M. penetrans* was able to activate human T lymphocytes to undergo blastogenesis followed by cell proliferation and expression of cell surface markers of activation.[421] These phenomena were observed with lymphocytes from healthy donors and from both symptomatic and asymptomatic HIV-infected patients. Characterization of the lymphocytes activated by exposure to *M. penetrans* showed that lymphocytes expressing either CD4 or CD8 underwent blastogenesis as a result of this expression. Activation activity was associated exclusively with cells of *M. penetrans* and not with culture supernatants. In cultured lymphoid cells, infection with *M. penetrans* stimulates the release of TNF-α and enhances replication of coinfecting HIV-1.[203] Longitudinal serologic studies have also demonstrated higher HIV viral loads and more rapid declines in CD4 cell counts in patients with persistently high or increasing anti-*M. penetrans* antibody titers, suggesting an association between active *M. penetrans* infection and progression of HIV disease.[150]

M. penetrans has been shown to bind human serum IgA and secretory IgA, but not IgG. The authors of this research suggested that this binding might afford a defense mechanism to *M. penetrans* in avoiding clearance by IgA antibodies as they establish infection.[348]

Mycoplasma pirum

Although originally described in 1985, *M. pirum* has attracted some attention recently because it is another of the AIDS-associated mycoplasmas, along with *M. fermentans* and *M. penetrans*. Before this association, *M. pirum* had been isolated only from cell cultures as a presumed contaminant, but the cell lines from which it was isolated were of human origin; it is now thought that these mycoplasmas may have been in the cultured tissues naturally.[102] *M. pirum* has been isolated from PBMCs of a patient with HIV infection and has been detected by PCR in blood mononuclear cells of HIV-seropositive individuals.[147] Similar to *M. fermentans*, HIV-associated cytopathic effects in vitro are also enhanced by the presence of *M. pirum*, leading to the suggestion that, similar to *M. fermentans*, *M. pirum* may act as a cofactor in the pathogenesis of HIV-related conditions.[345]

M. pirum is closely related to *M. penetrans* and *M. pneumoniae*, and, similar to these two other mycoplasmas, has a flask-shaped morphology and a "tip" by which the organism is able to attach to glass or plastic. The P1-like adhesin protein of *M. pirum* and the gene coding for it have been characterized.[494] Following attachment, *M. pirum* is able to actively invade cells, as are *M. fermentans* and *M. penetrans*.[475] Research is underway to further define the interaction of *M. pirum* and other mycoplasmas with human cells and to investigate the role of these organisms, if any, in the pathogenesis of HIV-associated disease.

Mycoplasma primatum

M. primatum is a common inhabitant of the oral and urogenital tracts of cercopithecine monkeys, and was first isolated from these animals in 1971.[101] The strains isolated from monkey tissues in 1971 were found to be similar to unclassified mycoplasmas that had been isolated from an infected umbilicus and from the vagina of a human patient in 1955.[411] Reexamination of the monkey isolates and the unclassified human isolates found them to be all the same. This mycoplasma used arginine, required serum or cholesterol for growth, and was negative for glucose fermentation, urease, hemolysis, hemadsorption activity, and tetrazolium reduction. These human/primate isolates were given the name *M. primatum*. To date, this mycoplasma has not been associated with infections or clinical disease.

1191

Mycoplasma salivarium

M. salivarium is most often isolated from the respiratory tract and resides in dental plaque and gingival sulci.[122] It has been most often associated with periodontitis, but has been isolated from joints and other sterile sites in patients with hypo- or agammaglobulinemia and has been found in a submasseteric abscess in an elderly woman.[154,452] Two patients with cerebral abscess in which *M. salivarium* was felt to have a causal role were reported from Denmark in 2011. Both were men, 53 and 39 years old, and presented with signs and symptoms of CNS disease; CT scans revealed an abscess in parietal-occipital and temporal lobe, respectively. The 53-year-old man had prior tuberculosis, poor dentition, and prior alcohol abuse. He presented with 3 weeks of dyspnea, headache, and impaired extremity coordination. The 39-year-old man had no known prior conditions. The aspirate from these abscesses disclosed the presence of *M. salivarium* by both culture and PCR; the abscesses also contained combination of oral aerobes and anaerobes. A combination of penicillin, metronidazole, and moxifloxacin was used in each case. The older patient fared better

than the younger, who had neurologic deficits and associated problems up to 6 months after treatment.[371]

Mycoplasma spermatophilum

M. spermatophilum is a newly described anaerobic *Mycoplasma* species that has been isolated from five sperm specimens and from a single endocervical specimen obtained from six patients who were attending an infertility clinic.[181] In culture, this obligate anaerobic species grows best at 35°C to 37°C and produces a hemolysin that lyses guinea pig, sheep, and human erythrocytes. Colonies have the typical fried-egg appearance on agar media. This species requires sterols for growth and does not use glucose or hydrolyze either arginine or urea; it is not yet recognized as a human pathogen.

Human Infections Due to Mycoplasmas *of Animal Origin*

M. arginini is one of the few mycoplasmas found in a number of animal hosts, including sheep and goats (respiratory and ocular tissues), cattle (respiratory tract, blood, udder, eyes, urogenital tract), and felines (respiratory tract). These animals may or may not exhibit pathologic symptoms, and the role of this organism in animal diseases is still unknown. Yechouran and colleagues reported a 64-year-old man with stage IVB non-Hodgkin's lymphoma who developed pneumonia complicated by fatal septicemia caused by *M. arginine.* This patient had hypogammaglobulinemia and had been receiving prednisone.[562] Before his admission to the hospital, he had worked in a slaughterhouse, where he slaughtered sheep, cows, and chickens. *M. arginini* grew from three blood cultures: a bronchial brush specimen, a bronchoalveolar lavage (BAL) specimen, and the tip of a Swan–Ganz catheter. Susceptibility testing of the isolate using a broth dilution procedure found that it was susceptible to tetracycline, doxycycline, and ciprofloxacin, but resistant to erythromycin and streptomycin. This susceptibility pattern has also been found in *M. arginini* isolates recovered from animals. The authors of this case report suggested that the patient acquired his infection by inhalation of contaminated aerosols in the slaughterhouse setting. *M. arginini* has also been isolated along with *U urealyticum* from an otherwise healthy 23-year-old Hungarian man with eosinophilic fasciitis presenting with generalized sclerodermiform skin lesions that progressed over 19 months. Blood was cultured for the *M. arginini*, and a species-specific PCR was positive from the skin biopsy. No comments about animal contact were given.[444]

Armstrong and colleagues reported a pulmonary infection caused by *M. canis* in a woman who was receiving antineoplastic therapy for metastatic carcinoma of the cervix.[17] The same organism was isolated from the respiratory tract of other family members and from the family dog, all of whom had upper respiratory tract infections

at the same time. Bonilla and colleagues also reported a case of septic arthritis of the left hip and right knee due to *M. canis* in a woman with common variable immunodeficiency.[45] This patient had a history of exposure to cats. Despite surgical debridement and treatment with doxycycline, widespread chronic osteomyelitis of the hip developed, necessitating hip arthroplasty.

Hemotrophic Mycoplasma *Species*

Haemobartonella and *Eperythrozoon* species are mycoplasma-like bacteria that adhere to and grow on the surfaces of red blood cells of several vertebrate species.[258] Until recently, these organisms were classified in the order *Rickettsiales*, since they resemble the rickettsiae with respect to their size, staining properties, and transmission from animal to animal by arthropod vectors. On the red blood cell surface, these bacteria appear as small, blue-to-purple, coccoid, rod- or ring-shaped structures when stained by the Wright–Giemsa method or by acridine orange.[41] Phenotypically *Eperythrozoon* species form ring-shaped structures on the surface of red cells and may often appear unattached to red cells and free in the plasma. *Haemobartonella* species, in contrast, do not form ring-shaped structures and are rarely seen in the free unattached state. The arbitrariness of the phenotypic differentiation of these two species has been recognized for some time and has led to their recent reclassification (see below). These bacteria are noncultivable using standard bacteriologic media and are maintained in research laboratories by serial passage in their animal hosts. Infections in animals caused by *Eperythrozoon* and *Haemobartonella* species are usually asymptomatic and may persist in a latent form for years; it is thought that the organisms are cleared from the circulation by the spleen.[311] Because of predisposing factors that are not completely understood (i.e., stress, etc.), large numbers of organisms may reappear in the bloodstream. In some animals, a subtle, chronic anemia develops or an overt, severe, and often fatal hemolytic anemia may develop.[336,337] For example, the well-studied feline hemotrophic mycoplasmas ordinarily do not cause disease in naturally infected animals, but may cause anemia in feline leukemia virus (FeLV)–infected cats and may accelerate the development of FeLV-induced myeloproliferative diseases.[464] Hemotrophic mycoplasmas are transmitted from animal to animal by various blood-feeding arthropods, including lice, ticks, flies, fleas, and mosquitoes.

1192

As they were discovered, the various species of *Haemobartonella* and *Eperythrozoon* were named after the host that they primarily infected, although the host ranges of the various species were really not known. As of the mid-1990s, the

recognized species of *Haemobartonella* and *Eperythrozoon* were *H. canis* (canines), *H. felis* (cats), *H. muris* (rodents), *E. coccoides* (mice), *E. ovis* (sheep), *E. suis* (swine), *E. parvum* (pigs), and *E. wenyonii* (cattle). In 1997, the 16S rRNA gene sequences of *H. felis*, *H. muris*, *E. suis*, and *E. wenyonii* were investigated. This demonstrated that these bacteria were not phylogenetically related to the rickettsiae, but were most closely related to members of the genus *Mycoplasma*.[359,403] In 2001, these four species organisms were removed from the order *Rickettsiales*, family *Anaplasmataceae*, and were given "candidatus" status in the genus *Mycoplasma* as "*Candidatus* Mycoplasma haemofelis," "*Candidatus* Mycoplasma haemomuris," "*Candidatus* Mycoplasma haemosuis," and "*Candidatus* Mycoplasma wenyonii."[221,357,469] "Candidatus" status is usually reserved for new, incompletely described taxa. Because of this, the Judicial Commission of the International Committee on the Systematics of the Prokaryotes ruled that, by changing validly published organism names to the taxonomically demoted "candidatus" status, the original names would lose standing because there would be no new or replacement names to add to the Approved List of Bacterial Names. As a result, all the species that had been renamed under "candidatus" status were revised by eliminating the "candidatus" status and renaming them as new species in the genus *Mycoplasma*.[358] At the same time this opinion was published, three additional "*Candidatus*" species —"*Candidatus* Mycoplasma haemodidelphidis," "*Candidatus* Mycoplasma haemolamae," and "*Candidatus* Mycoplasma haemominutum"—were described as hemotrophic bacteria from naturally infected opossums, alpacas, and cats, respectively.[338]As a result, the former *Eperythrozoon* and *Haemobartonella* species are now classified in the genus *Mycoplasma* as *M. haemofelis* (cats), *M. haemomuris* (mice), *M. haemosuis* (pigs), *M. wenyonii* (cattle), *M. ovis* (sheep and goats), *M. haemolamae* (lamas),*M. haemocanis* (canines), *M. haemodidelphidis* (opossums), and "*Candidatus M. haemominutum*."[356,357,470] Together, these hemophilic mycoplasmas have been given the trivial name "hemoplasmas."

Culture of Human Mycoplasmas From Clinical Specimens

General Considerations

Human mycoplasmas can be divided into three groups on the basis of the utilization of three substrates: glucose, arginine, and urea (Table 18-1). Depending on the species of *Mycoplasma* that is being sought, an enriched peptone basal medium, containing yeast extract and serum, is supplemented with one of these three substrates and a pH

indicator (usually phenol red) is added. *M. pneumoniae* metabolizes glucose to produce lactic acid, resulting in a shift to an acidic pH. MH metabolizes arginine with the production of ammonia and a shift in pH from neutral to alkaline. Similarly, UU produces urease enzymes that hydrolyze urea to ammonia, which also results in an alkaline pH shift. *M. fermentans* produces acid from glucose and also metabolizes arginine.

Specimens for the isolation of mycoplasmas, particularly the more rapidly growing genital mycoplasmas, are routinely inoculated onto both solid agar media and into some type of selective/differential broth enrichment media. Many broth media formulations used for isolation of mycoplasmas are diphasic, with medium containing agar in the butt of a tube overlaid with broth of similar composition. Media for isolation of mycoplasmas also contain antibiotics (e.g., ampicillin, penicillin, polymyxin B, and amphotericin) to inhibit contaminant bacteria and fungi.

Human mycoplasmas differ in their optimal pH for growth and in the atmospheric conditions that are required for successful recovery from clinical specimens (Table 18-1). Media for the isolation of *M. pneumoniae* are buffered at an initial pH of about 7.8, whereas the growth medium for MH is buffered initially at a neutral pH (7.0). UU grows optimally in an environment with a slightly acid pH, so a primary isolation medium for this species is buffered at about pH 6.0. The optimal temperature for mycoplasmal growth is 35°C to 37°C. *M. pneumoniae* and MH grow well in air or in an atmosphere of 95% nitrogen and 5% carbon dioxide. UU tends to be capnophilic, with optimal growth occurring in an atmosphere of 10% to 20% carbon dioxide and 80% to 90% nitrogen. An agar medium inoculated directly with specimens or subcultures from broths should be incubated under the appropriate conditions described in the foregoing; a broth medium can always be incubated under aerobic conditions.

Broth media are generally inoculated with 0.1 to 0.2 mL of the specimen contained in a transport fluid. Agar plates are inoculated with a similar amount, and the inoculum is spread over the surface of the agar with a sterile bent glass rod. Agar plates are sealed with air-permeable cellophane tape to prevent desiccation of the agar. Media for isolation of *M. pneumoniae* should be incubated for up to 4 weeks before a final culture report is made. Cultures for genital mycoplasmas should be incubated for 7 to 8 days; most positive broth cultures will be detected after 5 days of incubation. Diphasic media are compared with co-incubated tubes of the same media inoculated with sterile transport medium and with tubes inoculated with control mycoplasma strains to detect subtle differences in color or turbidity. Cultures should be inspected daily for subtle changes because the organisms die rapidly once growth occurs and the substrates are utilized. If a potentially positive culture is detected visually in diphasic medium, the broth is subcultured onto a solid agar medium, such as SP-4 agar or A7 differential agar (see discussion below).

Identification of the mycoplasmas requires the recognition of typical colonies on

solid media directly inoculated with the specimen or with a loopful of broth medium from a presumptively positive diphasic broth medium. Colonies on agar media can be directly examined under 30× to 100× magnification with peripherally incident light to ascertain morphology and growth characteristics. Supravital dyes, such as Dienes' stain, can be used to further characterize colonies and to differentiate them from artifacts. Various identification tests may be performed directly on solid medium, such as the hemadsorption test for presumptive identification of

M. pneumoniae, or the utilization of substrates such as arginine or urea, plus a phenol red indicator, may be incorporated into the agar to provide a direct assessment of substrate utilization and, therefore, a presumptive identification. Media for culture of respiratory and genital mycoplasmas and identification procedures for *M. pneumoniae* and UU are detailed in Charts 18-1 to 18-6.

Specimen Collection

M. pneumoniae may be recovered from both upper and lower respiratory tract specimens, including throat swabs, nasopharyngeal swabs, throat washings, sputum, tracheal and transtracheal aspirate, bronchoscopy, BAL, and lung tissue specimens. The organism may be recovered from these specimens throughout the course of the illness and for some time after symptomatic recovery. Mycoplasmas are very susceptible to heat and drying out, so culture media should be inoculated as soon after collection as possible or transport media should be used to preserve their viability if there are anticipated delays in processing. Culture media dispensed into small vials or purchased transport tubes may be used for transport of swab specimens; other specimens (e.g., sputum, tissue, washings) may be transported quickly to the laboratory in sterile screw-capped containers. Specimens should always be homogenized; however, Sputolysin or other chemical treatments for sputum liquefaction can be toxic to mycoplasmas and should be avoided.

Genital mycoplasmas may be isolated from a variety of specimens. These include urethral, vaginal, and cervical swab specimens; prostatic secretions; semen; urine; blood; miscellaneous body fluids (CSF, amniotic fluid, respiratory tract secretions, synovial fluid, pericardial fluid); and tissues (e.g., endometrial washings and biopsies, placental or amniotic tissues, fetal or abortus tissues, fallopian tube biopsies, uterine biopsies, wound biopsies, rectal tissues). Swab specimens should be obtained using Dacron, calcium alginate, or polyester swabs, with either plastic or aluminum shafts. Swabs with wooden shafts should not be used because the wood may be toxic. Contact of the swab surfaces with antiseptic solutions, creams, jellies, or lubricants should be avoided. Swab specimens should not be allowed to dry and should be

placed immediately into a transport or culture medium after collection. Other body fluids and tissue biopsy specimens should be submitted in sterile containers. Saline should not be used to moisten tissue specimens, for it may cause lysis of the organisms. In the laboratory, tissue specimens should be minced in sterile transport medium to produce a 10% (w/v) suspension and serially diluted 10- and 100-fold. This is necessary to prevent inhibition of mycoplasmal growth by organic materials such as hemoglobin, toxic phospholipids, antibodies, or complement that may be present in the tissue specimen. These dilutions are then used to inoculate growth media.

Blood specimens can be cultured for mycoplasmas by inoculation of growth media at a ratio of one part blood to nine parts broth (1:10 dilution). Optimally, at least 10 mL of blood from adult patients should be cultured. Ideally, the growth medium should not contain sodium polyanethol sulfonate (SPS), which inhibits the growth of *Mycoplasma* species, but should be a medium specifically formulated for mycoplasmas (see below). Inoculated broth media should be subcultured blindly, since the automated, continuously monitored blood culture instruments may not be able to detect the growth of mycoplasmas.[524,525]

Transport Media

Mycoplasmas are very susceptible to adverse environmental conditions, so specimens should be placed into appropriate transport or growth media as soon after collection as possible. A variety of transport media may be used for genital mycoplasma cultures. These include trypticase soy broth with 0.5% bovine serum albumin, 2SP broth (10% heat-inactivated fetal calf serum with 0.2 M sucrose in 0.02 M phosphate buffer, pH 7.2), or various types of mycoplasmal growth media (e.g., SP-4, Shepard's 10B broth). Antibiotics and antifungal agents (penicillin, 100,000 units/mL; polymyxin B, 5,000 mg/mL; amphotericin B, 2 mg/mL, final concentrations) are generally added to decrease contamination by other bacteria and fungi. Specimens should be transported to the laboratory immediately and may be held up to 24 hours at 4°C before inoculation of growth media. If culture is delayed beyond this time, the specimen should be frozen at –70°C. Prior to culture, these specimens should be thawed rapidly in a 37°C water bath. Urine specimens for culture should be centrifuged and the sediment diluted 1:1 with transport medium before freezing. The protein stabilizers in the transport medium prevent loss of organism viability that may occur if urine specimens are frozen without this protective measure.

Media for Culture of Mycoplasmas

Several types of broth and agar media have been described in the literature for the cultivation of *M. pneumoniae* and the genital mycoplasmas.[524] All have a source of

serum, as well as glucose, arginine, and/or urea, and a pH indicator is also included for media designed to detect genital mycoplasmas. SP-4 broth and Hayflick's broth or agar are excellent for growth of *M. pneumoniae*, MH, and other slow-growing strains of *Mycoplasma* spp.[508,524] Shephard's 10B broth and A8 agar are good for MH and *Ureaplasma* spp.[524] For *M. pneumoniae,* a biphasic medium is often recommended rather than broth or agar alone. One such medium recommended by the CDC for isolation of *M. pneumoniae* is methylene blue-glucose diphasic medium. This medium contains PPLO (pleuropneumonia-like organism) broth and agar, yeast extract, and serum supplements, as well as glucose, methylene blue, and phenol red. The methylene blue in the medium inhibits the growth of other human mycoplasmas that may be found in the respiratory tract, making the medium selective for *M. pneumoniae*. During growth of *M. pneumoniae*, the medium becomes more acidic and the phenol red turns color from salmon to yellow. At the same time, the organisms reduce the methylene blue and turn it from blue to colorless. Therefore, the color of the broth phase changes from purple to green or yellow-green, while the agar phase turns from a purple color to a yellow or yellow-orange. This medium can be used in conjunction with mycoplasmal glucose agar medium. Colonies recovered either directly on this medium or from subcultures of positive broths are then subjected to

inspection and identification procedures. The components and formulas for *M. pneumoniae* isolation medium are presented in Chart 18-4.

In a comparative study conducted by Tully and coworkers, diphasic SP-4 medium recovered *M. pneumoniae* from 69 of 200 specimens that were negative when cultured by other "standard" methods.[508] As with the methylene blue-glucose diphasic medium, growth is detected by the change of the phenol red indicator from red to yellow, indicating the production of acid from glucose. SP-4 agar and broth media can be used for isolation of MH, if arginine is added instead of glucose.

Because MH and UU metabolize different substrates and differ in the pH for optimal growth, many laboratories use two types of agar medium for the cultivation of mycoplasmas. In addition, diphasic broth and agar formulations of each medium type can be inoculated for optimal recovery of mycoplasmas. Media used to isolate MH should be buffered at a neutral pH (7.0). Some formulations may also contain arginine as the growth substrate, with both medium turbidity and a shift in the color of the phenol red indicator into the alkaline range being used to detect organism growth. Media used to isolate UU are buffered at a lower pH (5.5 to 6.0) and contain urea as the growth substrate. The latter media are also made more selective for UU by the inclusion of lincomycin because ureaplasmas are resistant to this drug and MH strains are susceptible. Medium formulations for isolation of genital mycoplasmas are found

in Chart 18-5.

Several other media have been described in the literature for the isolation and identification of genital mycoplasmas. Broth media include the U-9 urease medium described by Shepard and Lunceford, bromthymol blue broth, S-2 Boston broth, and the SP-4 medium used for recovery of the respiratory tract mycoplasmas that is supplemented with arginine and urea.[434,436,437,443,524,555] S-2 Boston broth is a single medium that contains an enriched base medium, horse serum, yeast extract, phenol red indicator, L-cysteine, urea, and penicillin. Growth of UU is detected by the appearance of a pink color in the medium, whereas growth of MH is detected by a pale salmon-pink to orange color or by the appearance of slight turbidity. Shepard's A7 differential agar medium and various modifications (e.g., A7B and A8) are particularly useful because both MH and UU grow well on these formulations and can be easily differentiated from one another by colony morphology and by the direct detection of urease formation by the latter species (see discussion below).[434,436,437] As described below, presumptive identification of MH and definitive identification of UU can usually be attained with these media, without the need for additional tests or reagents.

Isolation and Identification of Mycoplasma pneumoniae

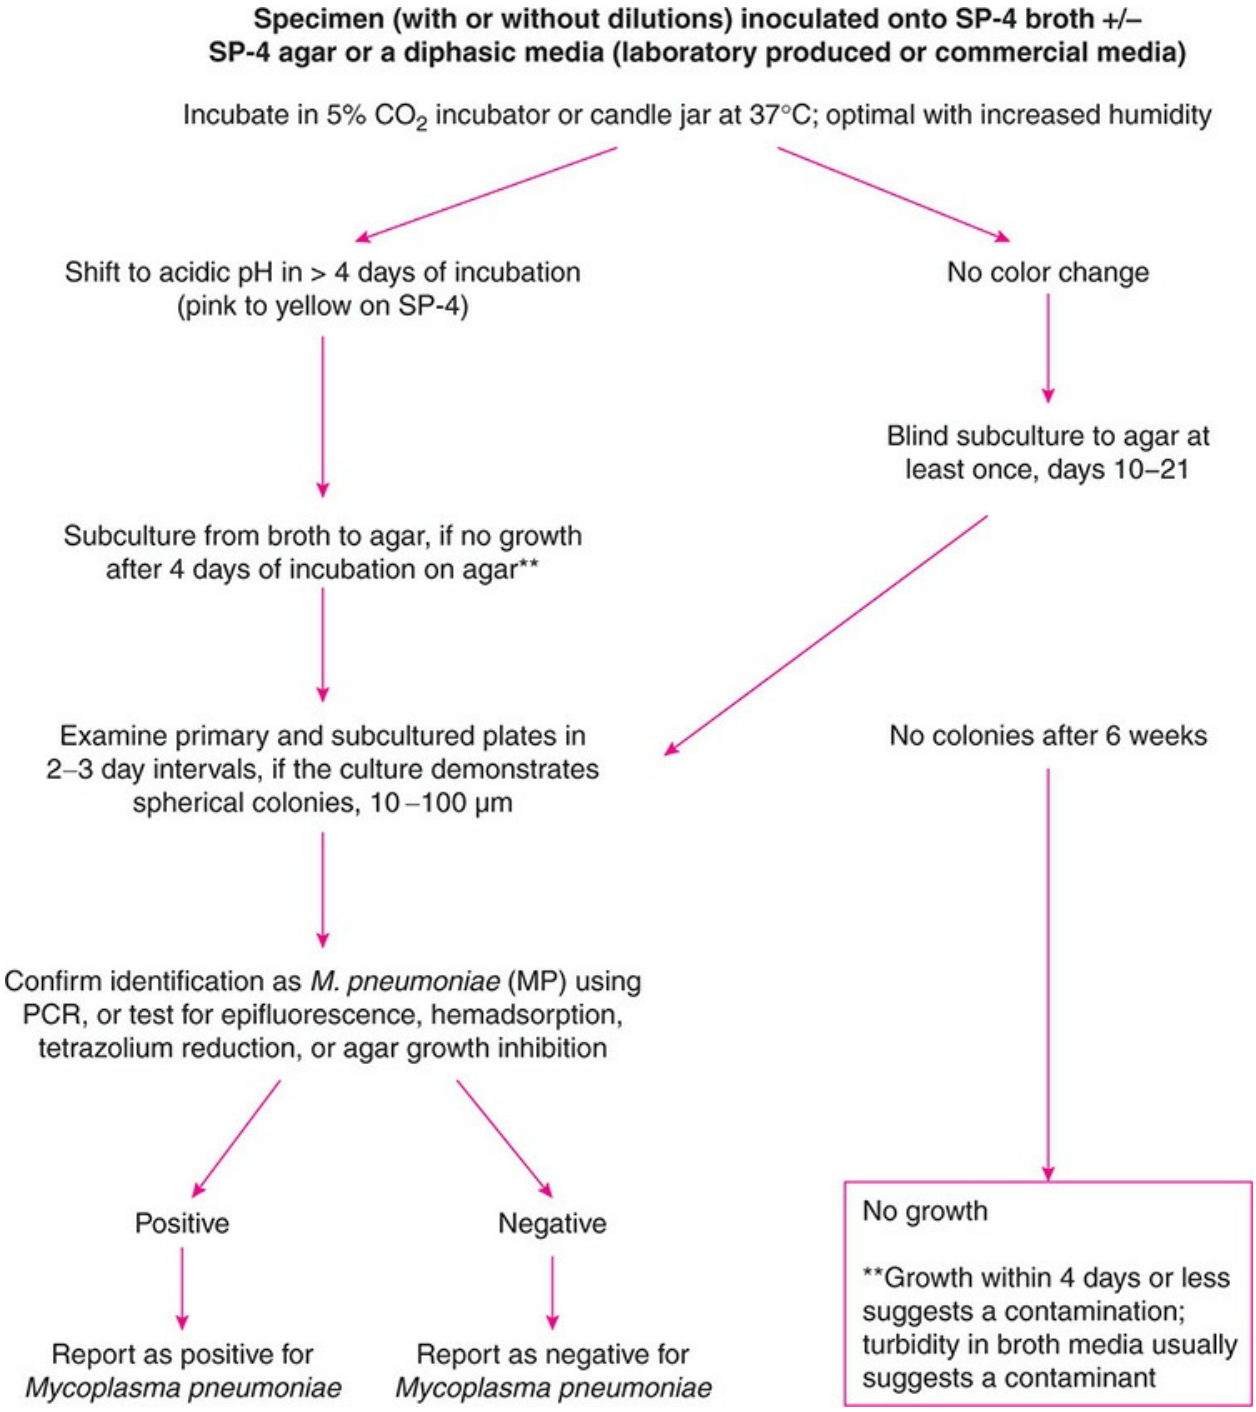
In general, the growth of *M. pneumoniae* from clinical specimens is detected by the ability of these organisms to produce acid from glucose.[91] Methylene blue-glucose diphasic medium, inoculated with 0.2 mL of specimen, is incubated at 35°C. Tubes are inspected daily for color changes and turbidity for up to 4 weeks. The development of gross turbidity and an acid or alkaline shift of the indicator in <5 days is generally due to bacterial contamination. As soon as color changes in the medium are apparent, the broth must be subcultured to appropriate agar medium (e.g., SP-4 agar) and incubated in air for 5 to 7 days. Inspection of the agar surface under the low power of the microscope will reveal small colonies of the organisms. In the absence of obvious color change in diphasic media, a blind subculture to agar media should be performed after 1 and 3 weeks of incubation. A general scheme for the isolation of *M. pneumoniae* is shown in Figure 18-1.

Glycolytic, spherical colonies that grow on SP-4 agar, for example, from a respiratory tract specimen between 4 and 20 days can be presumptively considered to be *M. pneumoniae*. *M. genitalium* may resemble the colonies of *M. pneumoniae,* but would require more than 20 days for growth, and *Acholeplasma* spp. may mimic the glycolytic activity of *M. pneumoniae* on SP-4 agar, but will grow in less than 4 days and the colonies will have a "fried-egg" appearance, which is not typical of *M. pneumoniae*. To confirm colonies suspected to be *M. pneumoniae,* PCR sequencing or epifluorescence techniques can be performed, if these are available.[524] Colonies may also be identified as *M. pneumoniae* specifically using a hemadsorption assay

(Chart 18-2), tetrazolium reduction test (Chart 18-6), or by using specific antibodies to inhibit growth of the organism.[91,524] The hemadsorption assay is accomplished by flooding the SP-4 with 5% washed guinea pig erythrocytes, incubating 30 minutes, and washing with sterile saline 2 to 3 times; colonies on the agar surface are then examined microscopically for the adherence of the erythrocytes. If positive, *M. pneumoniae* is confirmed; *M. genitalium*, although also positive, is much more fastidious and would not be present in the 4 to 20 days in which *M. pneumoniae* colonies will appear.[524] The tetrazolium reduction test exploits the unique ability of *M. pneumoniae* to reduce the colorless compound triphenyl tetrazolium to the red compound formazan. To perform, the agar surface is flooded with triphenyl tetrazolium, incubated at 35°C for 1 hour during which time the colonies, if *M. pneumoniae*, will appear reddish; with longer incubation, colonies may turn purple to black. The tetrazolium test can be performed even after the colonies are tested with the hemadsorption procedure.[524] Methods for performing these tests can be found in references 91 and 524; use of these tests is usually limited to reference laboratories.

Although considered to be the reference procedure, the growth inhibition test for identification of *M. pneumoniae* requires specific antibodies, is the most time-consuming procedure, and hence is not often utilized as a confirmatory test. A broth culture of the organism presumed to be *M. pneumoniae* is diluted 1:50 and 1:500 and spread on the agar surfaces to which are then added strips of filter paper that have been impregnated with anti-*M. pneumoniae* antibodies. After incubation, inhibition of growth around the paper strips would indicate the presence of *M. pneumoniae*. Normal animal serum should be used as negative control.[524] All of these confirmatory tests can be useful, but since culture for *M. pneumoniae* is considered less sensitive than molecular techniques for detection, it is doubtful whether they would ever be employed widely in routine clinical laboratories.[433]

1195



■ **FIGURE 18-1** Protocol for isolation of *Mycoplasma pneumoniae* from respiratory tract specimens.

Noncultural Detection of Mycoplasma *pneumoniae*

Because of the slow growth of *M. pneumoniae*, non–growth-dependent, direct detection methods continue to be developed. These have included antigen capture

assays, direct immunofluorescence, immunoblot analysis, and nucleic acid probe methods.[245,300,315,524] In general, most of these tests lack sufficient sensitivity to be clinically useful and have been largely replaced by nucleic acid amplification-based molecular techniques. They will not be further discussed in this chapter.

Prior to the development of amplification-based methods, a direct, radiolabeled DNA probe was developed for the diagnosis of mycoplasmal respiratory tract infections. The *M. pneumoniae* DNA probe (Gen-Probe, San Diego, CA) hybridized with the 16S rRNA of the organism and used a ^{125}I radioactive label to generate a detection signal. Tilton and coworkers compared the DNA probe with culture and found that the probe had a sensitivity of 100% and a specificity of 98% when compared with culture.[498] Dular and associates reported that the probe had both a sensitivity and a specificity of 89% compared with culture.[115] In both reports, the authors stressed the practical aspects of the probe as a rapid, sensitive, and timely approach to diagnosis, because probe results are available in about 2 hours, whereas culture requires several weeks. Despite these advantages, the Gen-Probe test was withdrawn from the market in 1992.

Several molecular methods, including nested and seminested PCR, multiplex PCR assays, nucleic acid sequence–based amplification (NASBA), Qb-replicase, and real-time PCR, have been developed since 1989 for the detection of *M. pneumoniae* in a variety of specimen types.[300,516] Specimen types include sputum, throat swabs, nasopharyngeal and tracheal aspirates, BALs, transthoracic needle aspirates, fixed lung tissues, and open lung biopsies. Major gene targets for these assays have included the P1 adhesin gene, species-specific 16S rRNA, the mycoplasmal ATPase operon genes, and the *tuf* gene, which codes for elongation factor 2, a factor

that functions in protein synthesis at the ribosome-mRNA level.[50,184,247,299–301,303,499,542,548,549] Early on, several investigators designed species-specific probes for *M. pneumoniae* based on *M. pneumoniae*-specific 16S rRNA sequences and found that amplification and subsequent probe detection of these sequences in clinical specimens was more sensitive than culture.[300,499,519] By using PCR technology, Narita and coworkers detected *M. pneumoniae*-specific DNA in 4 of 6 CSF specimens and in 3 of 4 serum specimens from patients with clinically and serologically confirmed *M. pneumoniae* CNS infection.[356a] A CDC study of community outbreaks of *M. pneumoniae* respiratory infections analyzed results of PCR and serologic assays and concluded that neither approach alone is sufficient, but they should both be used to enhance recovery of *M. pneumoniae* especially in absence of other pathogens.[496]

In addition to single assays for the detection of *M. pneumoniae*, multiplex assays

that can detect *M. pneumoniae, Chlamydophila pneumoniae*, and, in some, *Legionella pneumophila* are being developed to provide a comprehensive and sensitive approach to the diagnosis of the most common causes of atypical bacterial pneumonia.[77,297,548] Nilsson et al. compared a PCR for detection of *M. pneumoniae* in the oropharynx with serologic assays and found the PCR to be more sensitive, especially in the early stages of infection. DNA did remain in the specimens for quite a while after being detected as would be expected. In the same study, asymptomatic carriage of *M. pneumoniae* as detected by PCR was low even when testing was done during an outbreak.[362]Use of two PCR assays in the BAL of 50 hospitalized patients in a study in Italy was concordant for detection of *C. pneumoniae* 100% of the time and 98% for *M. pneumoniae*. The positive results agreed with clinical suspicion of community-acquired infection in many cases, and in acute infection, the molecular tests were in total agreement with the finding of IgM-specific antibodies for either or both pathogens.[389] Table 18-2 provides information on PCR assays that have been developed and corresponding evaluations. Review articles comparing methods for diagnosis of *M. pneumoniae* are also available.[298,299,522,524,535] In most instances, culture is less sensitive than PCR, but serologic methods (discussed below) still play a role in conjunction with molecular methods for optimal detection of *M. pneumoniae* infections.[108]

Isolation and Identification of the Genital Mycoplasmas

Mycoplasmas that may be recovered from the genital tract include MH, *M. genitalium*, *M. fermentans*, and UU. MH and UU are easily cultivated and usually grow within 1 to 5 days, whereas *M. genitalium* and *M. fermentans* grow much more slowly and are more difficult to detect in culture. Furthermore, culture systems that are in current use for the recovery of genital mycoplasmas may not support optimal growth of these species. Because of these considerations, genital mycoplasmas other than MH and UU are generally not cultured routinely in genital tract specimens.

M. genitalium is exceedingly difficult to recover using culture-based methods. Jensen and colleagues reported the successful isolation of *M. genitalium* from genital tract specimens.[216] From 11 specimens, 9 were successfully propagated in Vero cell cultures from PCR-positive urethral specimens from patients with urethritis. Growth in Vero cell culture was monitored by PCR. Of these nine isolates, six were adapted by serial passage to growth in Friis medium, a complex growth medium containing Hanks' balanced salts solution, brain–heart infusion broth, "homemade" yeast extract, and up to 20% (v/v) horse serum. These six isolates required from 1 to 19 serial passages in Vero cell cultures before they could be adapted to growth in broth, and from 2 to 6 passages in broth before visible colonies were produced on an agar medium similar in formulation to the broth. In this report, the authors note that, although the

development of a medium able to support the growth of *M. genitalium* represented a major breakthrough, PCR methods were essential for initial detection and for monitoring the cultures for growth. Molecular techniques that are highly sensitive and specific have been developed for detection of *M. genitalium* in genital tract specimens and first-pass urine specimens and should become more widely available in the future.[100,118–120,214,215,458,538,566–568]

For culture of MH and UU, appropriate specimens received in transport media are inoculated onto both broth and agar media. For the diagnosis of mycoplasmal infections of the lower urinary tract infections, urethral swabs may be optimal over urine or vaginal swabs.[197] In a study in women with symptoms of cervicitis, vaginal swabs were preferred over endocervical swabs for isolation of *M. genitalium*.[343] The correct specimen type is essential for optimal recovery. In general, about 0.2 mL of the specimen should be streaked onto agar media and placed in broth media. Broths may be incubated aerobically at 35°C, but plates should be incubated in a CO_2 incubator or a candle jar. UU and MH may also be recovered under anaerobic conditions. Plated media should be inspected daily under 40× magnification using oblique light to observe the "fried-egg" colonies of MH or the small, dense colonies of UU. In M broth, MH produces a slight turbidity in addition to a change in color. In U broth, UU will tend to produce a slight color change early in incubation with no distinct or obvious turbidity. In both cases, subcultures must be performed at these times to ensure recovery of viable bacteria because there is a rapid decrease in viability of the organisms once the pH has been elevated by substrate utilization and depletion. As with the primary culture plates, subcultures plates should be inspected daily. Most isolates of MH and UU will grow within 5 to 7 days. If growth is not detected on primary plates or broth subcultures after this time, the culture can be reported as negative for genital mycoplasmas. It is advisable to freeze aliquots of positive broths at –70°C in the event that problems are encountered with viability on direct agar cultures or subcultures. The general scheme for isolation of genital mycoplasmas is presented in Figure 18-2.

Identification of genital mycoplasmas is generally quite easy and straightforward. MH colonies grow in 1 to 5 days, have the typical fried-egg colonial morphology, and are usually 50 to 300 fm in diameter. Colonies may be stained with the Dienes' stain (Chart 18-1) to aid visualization (Image Plate 18-1B). Further identification procedures are not necessary because rapidly growing, arginine-positive organisms exhibiting the typical colony morphology are invariably MH. The small colonies of UU may be difficult to distinguish from various artifacts, such as mammalian cells and cellular debris or materials present in serum. Because of these problems, suspect UU colonies must be confirmed. This is done by exploiting the ability of UU to hydrolyze urea. If the U agar medium, which contains urea and phenol red, is used, then the suspect *Ureaplasma* colonies will be surrounded by a red halo.

TABLE 18-2 Molecular Methods for Detection of *M. pneumoniae*

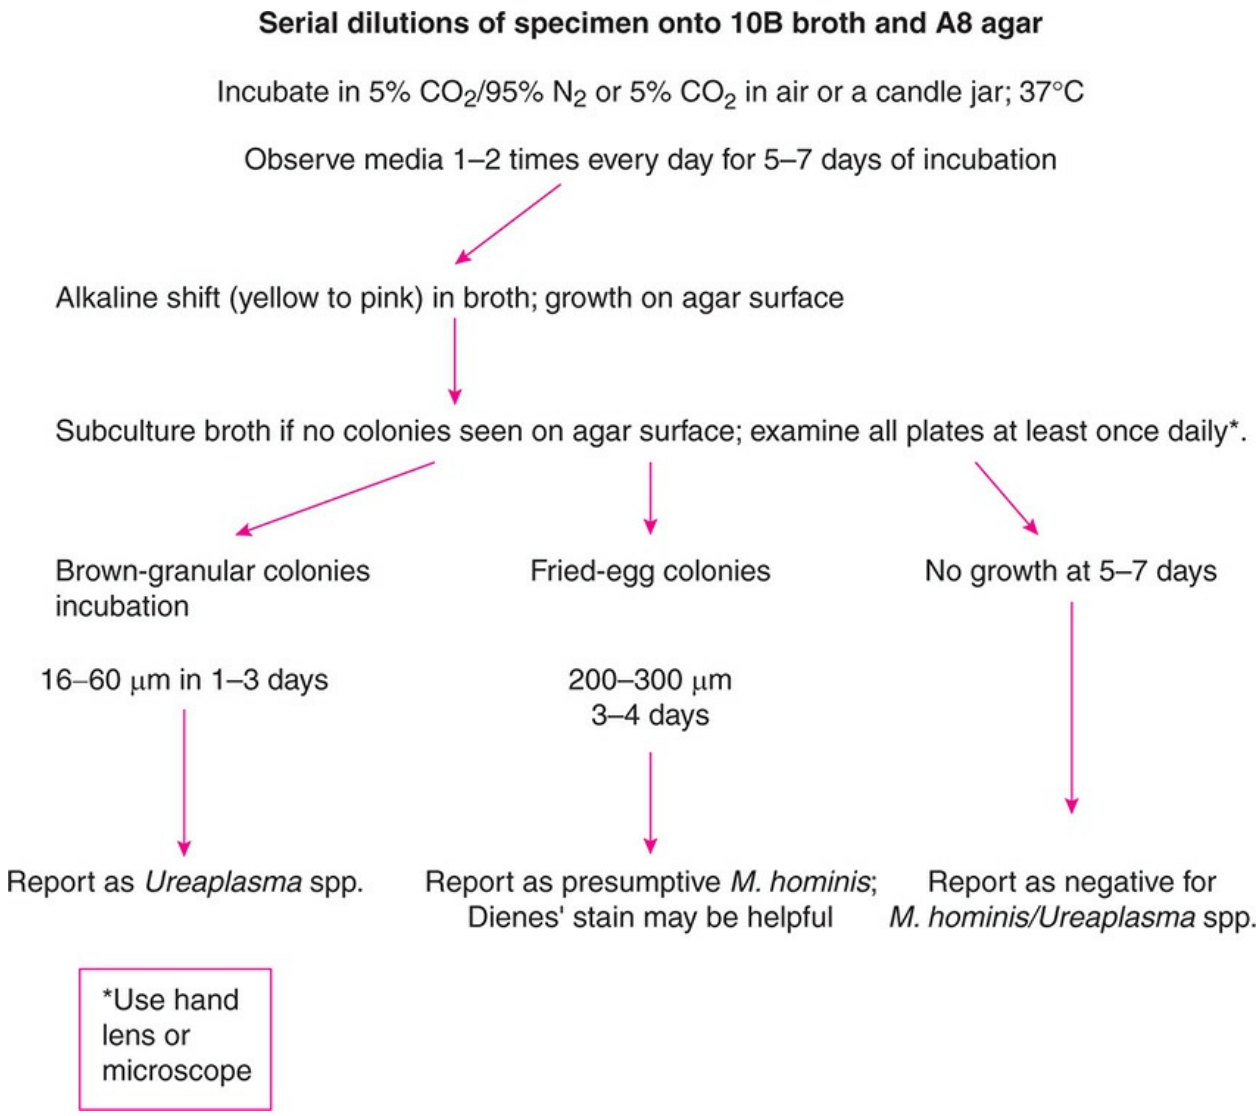
Name of PCR or Type	Targeted Organisms	Method/Specimens	Results	Reference
Pro-Pneumo-1	*M. pneumoniae* *C. pneumoniae*	Prodesse real time-PCR	146 samples; 100% sensitive and 98% specific for *M. pneumoniae* vs. culture	180
Scorpion-based real time-PCR	*M. pneumoniae*	Real time-PCR and unimolecular probe	388 specimens; compared better than conventional PCR when both were compared with serology	104
Real time-PCR	*M. pneumoniae* *C. pneumoniae*	Molecular Beacons; throat and nasopharyngeal (NP) samples	100% sensitive and 98% specific for *M. pneumoniae* in 120 throat and nasopharyngeal specimens compared with conventional PCR	157
Comparison of simplex NASBA, multiplex NASBA, and conventional PCR	M. *pneumoniae* *C. pneumoniae* *L. pneumophila*	NASBA	251 respiratory specimens; for *M. pneumoniae*, the sensitivity was 78% for conventional PCR vs. 100% for simplex or multiplex NASBA	297
NucliSens EasyMag/EasyQ (NASBA, bioMérieux) vs. MagNA Pure/real time-PCR (Roche)	*M. pneumoniae* *C. pneumoniae*	NASBA vs. Roche real time-PCR	The sensitivity and specificity for *M. pneumonia* were equivalent, whereas the NASBA system demonstrated a higher sensitivity for *C. pneumonia*.	33
Microfluidic real time-PCR (Advanced Liquid Logic, NC)	*M. pneumoniae*	Hydrolysis (i.e., TaqMan) probes and primers; nasopharyngeal swabs	The microfluidic real time-PCR method was equivalent to conventional real time-PCR; considered less expensive and more convenient	553
PneumoBacter ACE Detection Assay (Seeplex Pneumo-Bacter; Seegene) vs. ProbeTec ET Atypical Pneumonia Assay (APA; Becton Dickinson)	*M. pneumoniae* *C. pneumoniae* *L. pneumophila*	Sputum and NP swabs compared	100% Agreement for CP and LP in PneumoBacter and APA Both assays demonstrated a 95% sensitivity and 100% specificity in sputum specimens, but only a 38% sensitivity and 94% specificity for nasopharyngeal specimens.	69
Colorimetric loop-mediated isothermal amplification assay (LAMP, China)	*M. pneumoniae*	Isolates and clinical samples	100% sensitivity and specificity in analytical studies; the LAMP assay performed well compared with the conventional PCR for the detection of *M. pneumonia* in clinical specimens.	570

Suspect UU colonies may also be confirmed with the manganous chloride–urea test (Chart 18-3). In this test, an agar plate containing colonial growth is flooded with an aqueous solution of urea (1%) and 0.8% (w/v) manganous chloride. Hydrolysis of urea by urease liberates hydroxyl groups from water, and these hydroxyl moieties oxidize manganous chloride to insoluble manganese oxide, which, in turn, causes the deposition of a golden brown precipitate in the colonies within a few minutes.

Shepard's A7 differential agar media and modifications thereof, A7B and A8 agars, have the urea and the urea-hydrolysis-detection reagent incorporated in the medium, so flooding the plate with manganous chloride is not required.[434,436,437] A7 agar contains manganous sulfate as the precipitating agent along with penicillin (1,000 U/mL) and amphotericin B (2.5 mg/mL). A7B differential agar is identical to A7 agar, except that the polyamine putrescine dihydrochloride (10 mM) is added to enhance the

Ureaplasma growth and development of the precipitate in the colonies. A8 differential agar incorporates calcium chloride (1 mM) as the divalent cation indicator for the detection of ammonia formation from urea, as well as colistin (7.5 mg/mL), ampicillin (1 mg/mL), and amphotericin B (2.5 mg/mL). On all three medium formulations (i.e., A7, A7B, and A8 differential agars), MH appears with the characteristic fried-egg morphology after 1 to 3 days. UU colonies appear within 1 to 3 days and are 15 to 50 mm in diameter (depending on crowding). UU colonies on A7 and A7B agars are dark brown due to the accumulation of manganese oxide in the colony, whereas colonies on A8 differential agar are gold to light brown (Image Plate 18-1B). Several comparative evaluations of A7, A7B, and A8 media indicate that they are probably the agar media of choice for culture of genital mycoplasmas and, when used with an appropriate broth medium (e.g., bromthymol blue broth, Boston broth), give the highest yield of positive cultures.[388,555] Because the growth characteristics of UU on these media are unique, further testing is not necessary. Both A7 and A8 differential agars are commercially available from Remel Laboratories (Thermoscientific).

1198



■ **FIGURE 18-2** Protocol for isolation of *Mycoplasma hominis* and *Ureaplasma urealyticum* from genital specimens.

Definitive identification of MH may be made by growth inhibition using specific antisera. An indirect immunoperoxidase method has also been published for the identification of mycoplasmas.[201] This method produces results comparable with those of the antiserum growth inhibition procedure. Similar procedures, using both immunofluorescence and immunoperoxidase techniques, have been developed for use in mycoplasmal studies in animals, where different *Mycoplasma* species that have similar tissue tropisms may be present in mixed culture.[30]

Noncultural Detection of the Genital Mycoplasmas

Nonculture methods have also been examined for their ability to detect genital

mycoplasmas. Hirai and colleagues developed an indirect fluorescence antibody (IFA) test for direct identification of MH in vaginal specimens.[183] The staining of Vero cells that were infected with other *Mycoplasma* species, including *M. orale*, *M. salivarium*, and *M. fermentans*, demonstrated that the IFA procedure was specific for MH. The IFA test was compared with culture on vaginal specimens collected from 193 healthy women. Among 22 culture-positive specimens, 17 were positive with the IFA test. Interestingly, 48 of 171 specimens that were negative by culture were positive with the IFA test, suggesting that the IFA method was more sensitive than culture. These workers also demonstrated that the location of granular aggregates that were observed on vaginal epithelial cells stained with the Papanicolaou stain frequently corresponded to the areas of the smears that stained with the MH-specific IFA reagents.[183]

Probe technology was initially exploited for detection of *M. genitalium* in urogenital specimens because this organism is very difficult to recover in culture. There are recognized antigenic cross-reactivity between *M. genitalium* and *M. pneumoniae* and similarities in certain nucleotide sequences between these organisms. Therefore, nucleic acid probes for *M. genitalium* had to be constructed to exclude nucleotide sequences that are shared with *M. pneumoniae* in order to prevent false-positive results.[564]Such carefully constructed DNA probes were used along with gene amplification techniques and PCR to detect *M. pneumoniae*- and *M. genitalium*-specific nucleotide sequences directly in clinical specimens.[219] In one study, 10 of 150 genital specimens recovered from eight patients (three men and five women) were positive for *M. genitalium*.[219] These results were verified by Southern blot hybridization tests because cultures were not performed.

Molecular assays have also been developed for detection and specific identification of MH and UU in genital tract specimens, amniotic fluids, and respiratory tract specimens from newborns.[302,458,568] PCR assays for MH have used MH-specific 16S rRNA sequences as the target for amplification

1199

and detection, whereas similar assays for UU have used organism-specific 16S rRNA sequences, the multiple banded (MB) antigen gene sequences or urease gene sequences.[39,207,491] Some of these tests are able to detect as few as one colony-forming unit (CFU) in specimens from the adult urogenital tract and amniotic fluids, and endotracheal aspirates from newborn infants. Teng and coworkers examined 50 clinical specimens (8 urethral swab specimens, 8 urine specimens, 12 endocervical swab specimens, 8 prostatic fluid specimens, and 14 semen specimens) by both culture and PCR.[490] Cultures were positive for five specimens, and an additional four specimens produced appropriate pH changes in broth but did not grow on subculture

to agar medium ("doubtful" positives). PCR was positive for all five culture-positive specimens, all four doubtful-positive specimens, plus three specimens (one prostatic fluid and two endocervical specimens) that were culture-negative. A broad-range PCR was used to detect MH in a patient with culture-negative, late-onset prosthetic valve endocarditis; targeted antimicrobials against MH were successful in curing the patient.[210] A PCR-based reverse line blot assay that can simultaneously detect 14 uropathogens from urine specimens has been reported to be sensitive, specific, user-friendly, and inexpensive. It includes targets for MH, UU, *U parvum*, and *M. genitalium*.[330] A genus-specific PCR for MH, *M. genitalium,* and UU was found more sensitive than culture in 210 patients with suspected genital mycoplasmal infections. Forty percent of patients were positive for one or more genital mycoplasmas in culture versus 57% via PCR. In addition, 11% of samples were found to be coinfected with *Mycoplasma* spp. and UU by PCR.[12] Scientists in France compared a quantitative real-time PCR targeting the *yidC* gene, encoding a membrane protein translocase, with quantitative culture of MH in 153 urogenital specimens. The clinical sensitivity of the PCR was higher than culture (45 positive by culture vs. 55 by PCR), the analytical specificity was 100%, and PCR limit of detection was 7 copies/ μL. The quantitation in those 45 samples that were positive in both culture and PCR correlated well.[129] A Bio-Rad PCR assay demonstrated excellent sensitivity and specificity for simultaneous detection of *C. trachomatis, N. gonorrhoeae,* and *M. genitalium* in urogenital specimens of 658 symptomatic and asymptomatic men and women as compared to a hydrolysis probe real-time PCR assay for detection of *C. trachomatis*, culture of *N. gonorrhoeae,* and a laboratory-developed PCR assay for the detection of *M. genitalium*.[270] A real-time PCR assay for detection of *M. genitalium* has also been described, which in addition to identification of macrolide resistance markers.[213] PCR methods have been used to detect a unique DNA sequence in *M. fermentans* that appears repetitively in the genome of the organism, whereas those for detection of MH, *M. penetrans*, and *M. pirum* detect unique nucleotide sequences within the 16S rRNA of these species.[147,148,539] Although serologic and genetic methods suggest that *M. fermentans* represents a homogeneous organism group, AIDS-associated strains, cell culture isolates, and other clinical isolates of *M. fermentans* can be differentiated from one another by pyrolysis mass spectrometry.[165] All isolates of *M. fermentans* have been detected by amplification of a conserved 206 base pair region of the IS1550 insertion sequence. Amplification of the macrophage-activating lipopeptide gene (*malp*) can also identify all strains of *M. fermentans* and provides another option for identification.[2]

Commercial Mycoplasma *Culture Systems*

The Mycotrim RS and Mycotrim Triphasic flask systems (Irvine Scientific, Irvine, CA) are commercially available systems that have been used extensively for the cultivation of *M. pneumoniae* and the genital mycoplasmas, respectively. The Mycotrim RS system consists of a bottle containing a layer of enriched glucose agar medium containing phenol red indicator on one side and a broth of similar composition. Thirty minutes before inoculation with the specimen, disks are saturated with antibiotics and thallous acetate, then these are added to the flasks to allow time for the antimicrobials to elute from the disk and diffuse into the agar. A pipette is used to add liquid specimens and to "streak" the agar surface. Swab specimens are rolled over the agar surface. The flask is incubated agar side up for 2 weeks at 35°C to 37°C. Reinoculation of the agar is performed after 3 days by manipulating the bottle so that the broth washes over part of the agar phase. Growth is first indicated by a change in the indicator from red to yellow-orange without noticeable turbidity. Definitive identification is made by placing the flask on the stage of a light microscope agar side up and inspecting the surface of the agar for mycoplasmal colonies. This may be done with or without the addition of a vital stain such as Dienes' stain.

Mycotrim GU broth contains arginine, urea, and phenol red indicator. This broth is inoculated with 0.1 mL of the specimen and is incubated aerobically at 35°C. The medium is observed for changes in the color of the indicator to a more alkaline pH; subculture to solid media, such as A7 or A8 differential agar; and subsequent incubation allows the recovery and identification of both MH and UU.

The Mycotrim Triphasic flask (formerly called the Mycotrim GU system) system is a diphasic system that contains modified A8 differential agar with calcium chloride in a tissue culture flask and a broth medium containing arginine, urea, and phenol red indicator. Before inoculation, antibiotic impregnated disks are added and antibiotics are allowed to elute from the disks and diffuse into the agar phase. The flask is inoculated with 0.10 mL of the specimen, and the broth–specimen mixture is washed over the agar phase. The flask is incubated at 35°C aerobically. Subculture of the agar is achieved by allowing the broth to wash over part of the agar phase after 24 hours of incubation. With the appearance of a color change in the phenol red indicator from yellow to orange or orange-red, the agar phase is examined under the microscope for the typical fried-egg colonies of MH or the small, brown calcium oxide–stained colonies of UU. Cultures are inspected daily and incubated for 7 days.

Early studies found good correlation of the Mycotrim GU system compared to conventional culture methods using arginine broth, urea broth, glucose agar, and A7B differential agar.[46,388,551] In laboratories doing a modest amount of mycoplasmal work, it appears that the Mycotrim GU broth combined with a differential agar medium and the Mycotrim Triphasic flask system are fairly comparable, although

the components for the "conventional" procedure may be less expensive. Another commercially available system for the recovery, identification, and susceptibility testing of MH and UU is MYCOFAST US (Wescor, Utah) and MYCOFAST EvolutioN 3 (Elitech Microbiology, Signes, France). This commercial kit has a special transport medium for specimens and plastic tray for inoculation of the specimens into media containing urea and arginine, which are metabolized if the genital mycoplasmas are present. There are enumeration wells for each organism and wells which contain antibiotics that are used for differentiation of the two organisms. Surveillance studies have used this media successfully in the laboratory for sensitive detection of MH and UU.[414]

Isolation of Mycoplasmas on Routine Culture Media

In general, *M. pneumoniae* and UU are more fastidious in their growth requirements than MH. This latter species is the one that is most frequently recovered from sites other than the genital tract, such as blood, wounds, and joint fluids. Therefore, MH may occasionally be isolated on routine bacteriologic culture media. The clinical microbiologist must be able to recognize these organisms under these less-than-optimal conditions. MH is able to grow on enriched media such as Columbia CNA agar and chocolate agar; the organism grows less well on tryptic soy–based blood agar.[377] The organisms will grow best under anaerobic conditions, with less rapid growth in an aerobic, CO_2-enriched environment. Mycoplasmal growth may not be apparent until after prolonged incubation (i.e., 72 to 96 hours), depending on the conditions of incubation and the numbers of organisms present. Colonies of MH are extremely small and may be detected only as a "film" or "speckling" of the agar surface when examined by strong, incident, reflected light. Examination of this type of growth is facilitated by using a dissecting microscope. The colonies are difficult to pick up with a loop and will not stain with the Gram's stain.

Suspected mycoplasmal colonies from routine agar medium can be subcultured by cutting out a block of the blood agar and rubbing the side with the growth across the surface of a mycoplasmal growth medium such as A7 differential agar. Another block should be aseptically removed and immersed in a broth medium such as H broth or Boston broth. Both broth and agar subcultures are then incubated and processed as described in the foregoing. Inspection of colony morphology, along with the growth rate and assessment of optimal incubation conditions for growth, will allow presumptive identification of the species.

MH may also be occasionally recovered from blood cultures, particularly in women with postpartum fever. If MH bacteremia is suspected, blood should optimally be inoculated at the bedside of the patient into an SPS-free medium. Incubation of the cultures should be prolonged, and blind subcultures to appropriate agar and broth mycoplasmal isolation medium, in addition to CNA agar, should be made at frequent

intervals. Blood for recovery of mycoplasmas should be inoculated directly into the mycoplasmal culture medium. The blood should be diluted 1:10 with growth medium; therefore, culture of a substantial blood volume may require multiple vials of culture media.

Serologic Tests for Diagnosis of *Mycoplasma pneumoniae* Infections

Because of the limited availability of culture, the technical difficulties inherent in the culture techniques, and the amount of time required for culture results to become available, the diagnosis of *M. pneumoniae* infection is often made by a combination of clinical, molecular, and serologic findings. Diagnosis on clinical grounds alone is difficult because many other pneumonic processes, particularly those caused by viruses, can present similarly. In addition, persistence of *M. pneumoniae* in the respiratory tract for variable periods after resolution of the disease process complicates the interpretation of positive growth-based and molecular detection methods. Because *M. pneumoniae* has lipid and protein antigens that promote the development of antibodies usually within 1 week of infection, serologic assays have been used for diagnosis.[522] In most instances, acute and convalescent titers are most beneficial, with single assay results not always providing accurate correlation to present infection. The most widely used serologic test for diagnosis of *M. pneumoniae* infection had been the CF test, but due to cross-reactivities with other organisms, including *M. genitalium*, and the inability to differentiate among antibody classes, it has been largely replaced by alternative methods.

Serologic test methods using indirect immunofluorescence, particle agglutination, and EIA approaches are currently available commercially. Table 18-3 lists a number of commercially available assays using these formats and, where available, references about their methodology and/or evaluation. The *M. pneumoniae* Antibody Test System (Zeus Scientific, Branchburg, NJ) uses indirect immunofluorescence for the separate detection of *M. pneumoniae*-specific IgG and IgM. In one evaluation of this assay, IFA for *M. pneumoniae*-specific IgM was compared with PCR, culture, and CF for diagnosis of mycoplasmal infection.[108] Based on the positivity of culture and CF as the criteria for a positive diagnosis of infection, the sensitivity of the IgM IFA test was 78% and the specificity was 92%. The predictive value of a positive IgM IFA in this study was only 57%. In another evaluation that used consensus results defining true positives as those yielding positive results in two or more EIA or CF assays in conjunction with clinical findings, the IgM IFA had a sensitivity and specificity of 89% and 99%, respectively.[10]

EIAs for the detection of *M. pneumoniae*-specific antibodies have become the most widely used in clinical and reference laboratories. There have been a number of evaluations performed, and readers are encouraged to review these when considering use of one of the assays.[28,468,493,524,534] Microtiter EIA kits that are available include the *Mycoplasma pneumoniae* IgG/IgM antibody test system (Remel Thermoscientific), ImmunoWELL *Mycoplasma pneumoniae* IgM EIA (GenBio, San Diego, CA), the Zeus *Mycoplasma* IgM EIA (Zeus Scientific, Inc.), the Platelia IgM and IgG *Mycoplasma* EIA (Bio-Rad), the ETI-*M. pneumoniae* IgM/IgG assay (Savyon Diagnostics, Israel), and others listed in Table 18-3.

Some assays detect IgM and IgG separately, whereas others detect these simultaneously. The EPI-MP products of Savyon Diagnostics offer assays for IgM, IgG, and IgA separately. Two assays, the Meridian ImmunoCard and Remel MP IgG/IgM antibody test system, offer a membrane-based format for EIA. The other EIA assays utilize a 96 well microtiter plate (e.g., GenBio ImmunoWELL) or breakaway strips (e.g., Savyon EPI-MP and Platelai). All of the EIA assays vary in the type of antigen used in the solid phase. Antigens used in these assays include solubilized and purified ultrasonicates from *M. pneumoniae* cultures (e.g., Platelia), purified *M. pneumoniae* glycolipids (e.g., ImmunoWELL assay), or purified membrane protein antigens that include the immunodominant *M. pneumoniae* cytadhesin P1 (e.g., the ETI assays) as the predominant antigen in the solid phase. The specificity of IgM testing by EIA is improved when an IgM capture method is used. In a comparative evaluation of several IgM assays, a specificity of 100% was noted only for the Platelia IgM EIA, which uses IgM capture (i.e., the solid phase is coated with anti-IgM antibodies), whereas assays that used IgG absorption or other IgG removal methods for IgM detection had specificities ranging from 90% (i.e., the ImmunoWELL IgM) to as low as 25% (ETI-*M. pneumoniae* IgM).[384] In general, the IgM assays are more sensitive and specific when testing sera from children, since adults may not generate a significant IgM response.[442,543] In addition, since adult populations tend to include individuals who have residual specific anti-*M. pneumoniae* IgG from past or subclinical infections, testing of paired sera collected 1 to 3 weeks apart is important for documenting a fourfold or greater rise in antibody titer and thereby determining acute infections in adults.[513] A recent study in Belgium evaluated 10 serologic assays that measured IgA, IgM, and/or IgG in 120 patients who were serologically positive for *M. pneumoniae* or positive for other agents of interstitial pneumonia. The IgG assays performed poorly; overall interassay performance was not good among the assays. The authors suggested that improvements were needed in these serologic assays, especially in regard to IgG determinations.[52]

TABLE 18-3 Serologic Assays for Detection of *M. pneumoniae*

Name	Format	Immunoglobulin Detected	Antigen	Manufacturer	Reference
M. pneumoniae (MP) antibody test system	Indirect immunofluorescence assay (IFA)	IgM and IgG separately	Antigenic substrate or colonies on slide	Zeus Scientific, Inc. (Branchburg, NJ)	3, 524, 534
Serodia Myco II gelatin agglutination test	Particle agglutination	IgM and IgG simultaneously		Fujirebio & Fujirebio America; distributed in Japan and outside of Japan by Bayer (Europe, Canada, Australia)	20, 27, 524
SEROFAST	Particle agglutination	IgM and IgG simultaneously		International Microbiology	524
ETI-MP IgM or IgG	EIA, 96 well microtiter format	IgM, IgG, and IgA separately	MP P1 protein	Savyon Diagnostics Ltd., Israel	28, 468, 524
ImmunoCard	Membrane-based EIA	IgM only	MP antigen	Meridian Diagnostics, Cincinnati	10, 28, 318, 468, 493, 524, 534
M. pneumoniae IgG/IgM antibody test system	Membrane-based EIA	IgM and IgG simultaneously	MP cytadhesin protein	Remel Thermoscientific	468, 493, 524, 534
Mycoplasma IgG and IgM ELISA test system	Breakway strip EIA	IgM and IgG separately	Inactivated *M. pneumoniae*	Zeus Scientific, Inc. (Branchburg, NJ)	468, 524, 534
GenBio ImmunoWELL *M. pneumoniae* IgM and IgG	EIA, 96 well microtiter format	IgM and IgG separately	MP glycolipid antigen	Alexon-Trend, Inc. (Ramsey, MN)	28, 468, 493, 524, 534
Platelia IgG and IgM	EIA, breakaway strip	IgG and IgM separately	MP culture ultrasonicate	Bio-Rad	28, 524

These do not represent all commercial assays available for serologic testing of *M. pneumoniae* antibodies, but represent the ones most commonly mentioned in texts and for which there are evaluations available.

One of the advantages of the membrane-bound EIA assays is a quicker time to result, which are usually available in minutes versus hours that might be needed for the microtiter formats. Evaluations of the Remel *M. pneumoniae* IgG/IgM antibody test system, for example, disclosed a 5-minute EIA for simultaneous, qualitative detection of antibodies against *M. pneumoniae*. Thacker and Talkington evaluated this test with 50 paired serum samples and found that the Remel test detected antibodies in three specimens with CF titers of 32 and was positive for all but one specimen with CF titers of 64 or higher.[443] Another evaluation of this system reported a sensitivity of 91% and a specificity of 91%, with corresponding positive and negative predictive values of 87% and 93%, respectively.[126] The Meridian ImmunoCard *Mycoplasma*

IgM assay (Meridian Biosciences, Cincinnati, OH) is a 10-minute, qualitative, membrane-based EIA in which test serum is allowed to react with *M. pneumoniae* antigen extracts impregnated into filter paper. This assay does not require IgM separation or IgG removal from the serum prior to test performance. Evaluations of

this assay suggest that the ImmunoCard test is more sensitive than other serologic tests for detecting low levels of IgM antibodies.[10,117,318,468,493] In an evaluation of the assay using specimens from 40 pediatric patients, all acute-phase serum specimens were positive with the ImmunoCard, whereas the CF and particle agglutination tests were positive for 30% and 77.5% of the specimens, respectively.[318] In another comparative evaluation with 64 acute-phase sera from adults, the ImmunoCard detected specific IgM in 46% of the specimens, whereas the CF test, the Remel EIA, and the ImmunoWELL IgM EIA detected antibodies in 38%, 41%, and 23%, respectively.[493] A third evaluation using 145 acute-phase sera from children reported resolved sensitivity, specificity, and positive and negative predictive values of 85%, 97%, 93%, and 93%, respectively, when compared with both the Remel and Zeus IgM microtiter EIAs.[117] The evaluations of the ImmunoCard *Mycoplasma* IgM assay suggest that this rapid test is highly reliable for establishing a diagnosis of recent *M. pneumoniae* infection in both children and adults.[543] A newer immunoblotting method for serologic diagnosis of *M. pneumoniae* was developed in Germany using a new set of antigens, and the results of a study evaluating this assay demonstrated that 92% of PCR-positive patients were positive with this immunoblot method and the specificity was 93% to 100%.[116]

Microparticle agglutination assays have also been marketed for detection of *M. pneumoniae* antibodies. The Serodyne Color Vue IgG/IgM test (Serodyne, Indianapolis, IN) uses latex particles coated with *M. pneumoniae* lipid antigen, whereas the Serodia Myco II test (Fujirebio, Tokyo, Japan) uses similarly sensitized gelatin particles. Thacker and Talkington evaluated the Serodyne 40-minute passive agglutination test and found it less sensitive than the Remel EIA; only 68% of patients with mycoplasmal pneumonia could be serologically diagnosed with this kit, compared with 94% and 96% of patients who were diagnosed by the CF and Remel tests, respectively.[492] Lieberman and colleagues evaluated the Serodia Myco II gelatin agglutination test and found the sensitivity, specificity, and predictive values of positive and negative tests to be 48.1%, 86.9%, 49.3%, and 86.3%, respectively.[277] Inadequate specificity of the Serodia Myco II particle agglutination assay compared with an IgM-specific capture EIA and an IgM IFA has been noted by other researchers as well.[20]

The purification and sequencing of the P1 adhesin of *M. pneumoniae* and the recognition of immunodominant epitopes of P1 and other cell surface molecules may allow the manufacture of synthetic peptides that can be used as specific, chemically defined antigens in future serologic tests for *M. pneumoniae*.[206] Suni and colleagues evaluated a new EIA method (*M. pneumoniae* IgG, IgA, and IgM, Thermolabsystems, Helsinki, Finland) in which the solid-phase antigen is enriched for the P1 cytoadherence protein antigen of *M. pneumoniae*.[461] When compared with the

ImmunoWELL and Platelia EIAs, the sensitivity and specificity of this test were 100% and 96.5% to 100%, respectively. Another group investigated the performance of two novel EIAs in comparison with the CF test. In one assay, the solid phase contained recombinant P1 antigen; in the other assay, the solid phase contained recombinant p116 antigen.[109] Both of these antigens have demonstrable antigenicity and engender the formation of specific antibodies in infected patients.[113,114,196]One of these studies found that the recombinant antigen assays showed good agreement with the CF test, with the recombinant P1 EIA showing the best discrimination between positive and negative specimens.[109] The use of species-specific antigenic epitopes in serologic tests for *M. pneumoniae* infection may help to eliminate false-positive serologic tests resulting from *M. genitalium* respiratory or urogenital tract infection, since these organisms are known to possess cross-reacting antigens.[280]

Serodiagnosis by detection of anti-*M. pneumoniae* IgA levels has also been investigated as a possible method for diagnosis of *M. pneumoniae* infection. Watkins-Riedel and colleagues evaluated a 3-hour IgA EIA method (SeroMP-IgA kit; Savyon Diagnostics, Ashdod, Israel) and compared it with the microparticle agglutination assay (Serodia Myco II; Fujirebio), the CF test, an IgM-specific EIA (SeroMP-IgM kit; Savyon Diagnostics), and the rapid ImmunoCard IgM EIA (Meridian Diagnostics) on acute-phase serum samples from 23 patients with *M. pneumoniae* pneumonia.[545] The IgA assay performed with a sensitivity of 96% to 100% and a specificity of 91% to 100%. Sensitivity of the other assays ranged from 87% to 91%. During the course of this study, the investigators noted that younger patients tended to have higher levels of IgM than adults, whereas the adult patients tended to have higher levels of IgA antibodies. This assay appeared to address two of the recognized shortcomings of *Mycoplasma* serology: the comparatively lower sensitivity and specificity of the CF test and the inconsistent presence of *M. pneumoniae*-specific IgM in infected adult patients. A newer antigen test, utilizing an automated immunofluorescence multiplexed antigen array (InoDiag, France), was compared with standard culture, antigen, or PCR-based tests for diagnosis of six agents of atypical pneumonia including *M. pneumoniae.* Sensitivity was 100% and specificity 98% for IgM detection in the 19 sera from patients ≤30 years old who were positive for *M. pneumoniae* by the Meridian ELISA assay.[146]Other investigators have suggested that in young patients, a single elevated IgM titer could indicate acute infection, although seroconversion was definitely more specific.[384] This InoDiag assay does afford a rapid turnaround time (15 minutes), avoids the specificity issues associated with IFA, and can potentially be used in epidemiologic studies since various cutoff values can be used in populations with different prevalence and incidence.[146]

A nonspecific serologic test that is often used to support the diagnosis of *M. pneumoniae* infection is the production of cold agglutinins. These IgM antibodies react

in the cold with human erythrocyte I antigens. These antibodies are produced within 2 weeks after infection with *M. pneumoniae* and can persist for up to 5 months. The I antigen, which is similar in structure to some antigenic determinants in the glycolipid membrane of *M. pneumoniae*, is inactivated by α-glycosidase, and the binding of cold agglutinins to these cells is inhibited by galactose.[78,211,418,556] Furthermore, when erythrocytes containing the I antigen are subjected to

1203

chloroform–methanol extraction, an antigen is extracted that will fix complement in the presence of anti-*M. pneumoniae* antibodies.[556] As with other serologic tests, a fourfold rise in cold agglutinin titers in the presence of a compatible clinical illness is suggestive of *M. pneumoniae* infection. However, only about 50% to 60% of *M. pneumoniae* infected individuals will be positive for cold agglutinins, and several other conditions can cause increases in cold agglutinins, including infectious mononucleosis, mumps, influenza, rubella, respiratory syncytial virus infections, adenovirus infections, peripheral vascular disease, and psittacosis. Therefore, the specificity of this assay is not optimal.[418]

Serologic Tests for Genital Mycoplasmas

Serologic methods have also been investigated for the diagnosis of MH infections. Lipid-associated membrane proteins (LAMPs) constitute a major group of cell surface proteins that are highly antigenic and are major targets in the immune response against mycoplasmas.[263] LAMPs have been identified in several *Mycoplasma* species, including *M. salivarium*, *M. penetrans*, *M. pirum,* and *M. genitalium.* These antigens have been used in serologic assays for testing patients with various types of infections.[538,540,541] Antibodies to these LAMP antigens appear to be highly species-specific, with no apparent cross-reactions with those of other species. Antibodies against LAMP antigens have also been used to delineate serotypes of MH. In a recent study, the antigenicity and antibody profiles of 14 different MH strains were compared by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) and Western immunoblot.[293] The LAMPs from these 14 strains showed similar SDS-PAGE profiles, and immunoblot analysis showed that these proteins were highly immunogenic when tested against sera from infected patients. These workers also demonstrated that sera from 28 of 31 HIV-positive patients with MH culture-positive urine specimens reacted with each of the 14 different MH isolates on Western immunoblot examination. These studies showed that LAMPs from any isolate of MH

could be used as a target antigen in an EIA test format for detection of antibodies against MH. This LAMP-derived EIA was used to demonstrate that the prevalence of MH-specific antibodies was significantly greater among patients attending STD clinics (67.8% prevalence) than among healthy blood donors (34.4% prevalence) and that MH infection occurred at a much younger age in women than in men. These EIAs for detection of serum antibodies against MH are research-based assays and are not widely available.

Serologic methods have also been evaluated as a way to establish the presence of UU infection. Serologic methods have included EIA techniques, with purified organism sonicates as the solid-phase antigen, or Western immunoblot techniques, wherein antigens were prepared by growing representative UU serovars in culture, lysing the organisms with SDS, separating the antigens by electrophoresis, and transblotting of the antigens onto nitrocellulose paper. One study examined the presence of the UU in amniotic fluids along with the serologic response as documented by EIA in women in their third trimester of pregnancy, who were undergoing amniocentesis for genetic indications, women admitted for preterm labor with intact fetal membranes, and women with preterm rupture of the fetal membranes.[192] Although the prevalence of UU infection was 2.9%, 4.3%, and 17.8%, respectively, in the three groups, the corresponding antibody prevalences were 50%, 86%, and 57%. These workers found that the incidence of adverse pregnancy outcomes—preterm birth, low birth weight, or fetal death—was significantly greater in women who had generated an immune response against UU.[192] Another study by the same group showed that 30% of women with postpartum endometritis had positive EIA serologies for UU, compared with 6% of the control group.[60] A serologic study of women and infants using immunoblots for UU-specific IgM and IgA found that 4.5% of infants born at less than 30 weeks of gestation, less than 1.7% of infants born between 30 and 34 weeks of gestation, and none of the infants born at 35 weeks or greater had detectable IgM- or IgA-specific antibodies; this suggested a possible role for the immune response in pregnancy outcome.[83] Serologic studies such as these may help to clarify the role of the specific immune response to UU in the pathogenesis of infection and to provide information for the development of sensitive and specific serologic tests to augment cultural and molecular diagnostic approaches in the clinical laboratory. As with MH, serologic tests for UU are not widely available and are mainly used in research settings.

Antimicrobial Susceptibility and Treatment of *Mycoplasma* Infections

Treatment of M. pneumoniae *and Genital Mycoplasmas*

Atypical pneumonia cause by *M. pneumoniae* is generally treated with tetracycline or a macrolide, including erythromycin, azithromycin, or clarithromycin. Although the organism may still be present in the upper respiratory tract during and after treatment, clinical manifestations of infection generally improve and infiltrates on chest radiography usually disappear during therapy. Standardized methods for performing in vitro susceptibility tests using agar and broth microdilution including quality control parameters have recently been described in the literature, and a Clinical Laboratory Standards Institute (CLSI) document is available that provides methods for and interpretation of results of susceptibility testing for *M. pneumoniae,* MH, and *Ureaplasma* spp.[74,530,534] Without these standards, testing has been limited to a few reference laboratories. If resistance to the usual drugs for treatment becomes more prevalent and molecular methods continue to increase the detection of mycoplasmal infections, then even more requests for susceptibility testing may be made. Now that susceptibility testing has been standardized, it will be necessary to know where such testing is available.[74,530] Box 18-3 provides an overview of the usual agents to which various mycoplasmas are susceptible and resistant. More specific information about specific treatment for each agent and the disease it may cause can be found in many of the references included in the table and in this chapter section.

1204

BOX 18-3

Usual Susceptibility Patterns of *Mycoplasma* spp. and *Ureaplasma* spp.

Organism	Usually Susceptible	Resistant or Usually Resistant	Comments
M. pneumoniae	Macrolides Fluoroquinolones Tetracyclines	Penicillins Cephalosporins Glycopeptides SXT Rifampin Nalidixic Polymyxins	High-level macrolide resistance has been in many countries[9,26,385,397,524,554,557]
M. hominis	Tetracyclines Fluoroquinolones Clindamycin Chloramphenicol Streptomycin Gentamicin	Penicillins Cephalosporins Glycopeptides Macrolides (intrinsic and induced resistance) SXT Rifampin Nalidixic Polymyxins	Occasional fluoroquinolone resistance with mutations in DNA gyrase/topoisomerases[524]
Ureaplasma spp.	Macrolides Fluoroquinolones Tetracyclines Chloramphenicol Streptomycin Gentamicin	Penicillins Cephalosporins Glycopeptides Clindamycin SXT Rifampin Nalidixic Polymyxins	High-level macrolide resistance rare, but has been detected.[524] Occasional fluoroquinolone resistance with mutations in DNA gyrase/topoisomerases.[112,524]
M. fermentans	Tetracyclines Clindamycin Chloramphenicol Fluoroquinolones	Penicillins Cephalosporins Glycopeptides Macrolides Aminoglycosides SXT Rifampin Nalidixic Polymyxins	There is some variability in the literature about in vitro activity of macrolides and aminoglycosides.
M. genitalium	Macrolides Tetracyclines (but therapeutic failures have occurred with tetracyclines) Clindamycin Fluoroquinolones	Penicillins Cephalosporins Glycopeptides SXT Rifampin Nalidixic Polymyxins	Macrolide resistance may be induced.[524] Occasional fluoroquinolone resistance with mutations in DNA gyrase/topoisomerases.[524]

SXT, Trimethoprim–sulfamethoxazole.
Most of this information unless specifically referenced was taken from references 524 and 534.

All mycoplasmas are innately resistant to β-lactam antibiotics (e.g., penicillins and cephalosporins), glycopeptides (e.g., vancomycin), as well as sulfonamides, trimethoprim, polymyxins, nalidixic acid, and rifampin.[474,524] *M. pneumoniae* strains are usually susceptible to a wide variety of antimicrobial agents, including the quinolones (i.e., ciprofloxacin, levofloxacin, ofloxacin, gemifloxacin, moxifloxacin), clindamycin, lincomycin, tetracycline, doxycycline, minocycline, the macrolides (i.e., erythromycin, azithromycin, and clarithromycin), and

streptomycin.[111,164,237,474,524,526,527]

Resistance to macrolides has been reported in many countries, including the United States.[9,26,397] Most of the resistance has been seen in children. In a study of 49 patients with *M. pneumoniae* pneumonia in 2007 to 2010, the incidence of macrolide resistance was 8.2%. Patients require treatment with tetracycline or fluoroquinolones when there is

1205

resistance to macrolides.[557] Simmons et al. have detected the presence of biofilms in certain strains of *M. pneumoniae* that might confer this macrolide resistance and impair host immune response, consequently preventing effective treatment of the infections.[445] A review article on the pathogenesis and detection of *M. pneumoniae* presents more information on antibiotic resistance in the United States.[523]

Most isolates of MH and UU are susceptible to tetracyclines. MH strains are usually also susceptible to clindamycin and lincomycin, but are innately resistant to erythromycin and other macrolides (i.e., azithromycin). Inducible resistance to macrolides like erythromycin can also occur in MH.[382] UU strains are usually susceptible to erythromycin and azithromycin, but not to clindamycin and lincomycin. The growth of MH and UU is also inhibited by chloramphenicol, streptomycin, and gentamicin, but not by cell wall active agents (e.g., cephalothin, ampicillin, and vancomycin). During the mid- to late 1970s and early 1980s, strains of both species were found that were resistant to tetracycline; these strains contained a genetic antimicrobial resistance determinant (transposon) called *tetM*.[404,524] Strains of UU that are resistant or intermediate in susceptibility to erythromycin and newer macrolides have also been described.[524] Global resistance to many antimicrobial agents has been shown in a recent study of 290 MH isolates and 179 UU isolates in Germany using either an agar dilution or Etest method from 1999 to 2008. Doxycycline remained the most active of the tetracycline agents tested. Although up to 13% of the MH strains were resistant to doxycycline, only 1% to 3% of UU isolates were resistant.[257] Macrolides remain the drug of choice for the treatment of UU non-CNS infections in neonates. Erythromycin is used much less frequently in older children and adults because of availability of newer macrolides, such as azithromycin and clarithromycin. Whether this will become the standard in neonates, replacing erythromycin, is yet to be determined.[533] CNS infections in neonates by these organisms are best treated with tetracycline.[533]Strains of UU are generally less susceptible to the quinolone antibiotics than either *M. pneumoniae* or MH.[239–241] Krausse and colleagues found that ofloxacin was effective against both species, but only 30% of the UU strains were susceptible to

ciprofloxacin as compared with 70% of the MH strains.[257] In general, the mycoplasmas are more susceptible to the newer fluoroquinolones in vitro as compared to older agents, such as ofloxacin.[524]

The treatment of *M. genitalium* infections has not yet been standardized, nor are methods available for susceptibility testing. Macrolides are recommended, especially single-dose azithromycin; tetracyclines are responsible for a large number of therapeutic failures even without any acquired resistance being demonstrated. The antimicrobial susceptibility profile of *M. genitalium* appears to be similar to that of *M. pneumoniae* in that isolates of this species are susceptible to tetracyclines and a variety of macrolides.[473,474] Renaudin and colleagues determined the susceptibilities of seven *M. genitalium* isolates using an agar dilution method and compared them with three *M. pneumoniae* strains.[401] Both species were susceptible to macrolides (i.e., erythromycin, spiramycin, roxithromycin, azithromycin, and clarithromycin), clindamycin, tetracycline, doxycycline, minocycline, and the fluoroquinolones (i.e., ofloxacin, ciprofloxacin, lomefloxacin, sparfloxacin).[98] Acquired resistance to macrolides and fluoroquinolones leading to therapeutic failure has, however, been described.[37,312,466] Despite in vitro susceptibility of *M. genitalium* to the tetracyclines, several studies have shown that tetracycline therapy is often associated with treatment failures. A study by Johannison and colleagues found that 62% of 13 men with *M. genitalium* urethritis who were treated with tetracycline for 10 days still had the organism in the urethra at follow-up.[220] In another study, all of seven men with *M. genitalium* urethritis who were treated with doxycycline still had urethritis on follow-up.[186] In a treatment study comparing tetracyclines and azithromycin, all six patients who had received azithromycin were negative for *M. genitalium* by PCR after treatment, while 63% of 16 patients treated with tetracycline were still PCR-positive for *M. genitalium* after treatment.[125] The presence of the organisms in the urogenital tract with or without attendant symptoms following treatment with these agents may be directly related to the dosage and duration of treatment. According to the treatment guidelines for STDs, azithromycin for treatment of urethritis is administered in a single 1-g dose.[59] Patients with *M. genitalium* urethritis who have been treated with azithromycin according to these recommendation have had partial clinical responses and remained positive for *M. genitalium* by PCR a week after completion of therapy.[134] In a 2012 North Carolina study of NGU in 293 homosexual men, persistence of *M. genitalium* after treatment was seen in 44% of those positive initially as compared to the 12% who persisted after 4 weeks of therapy for *C. trachomatis* infection. Persistence of the *M. genitalium* was found to be 66% in men treated with doxycycline versus 33% of those treated with azithromycin.[431]

With use of a modified broth dilution procedure with SP-4 medium, Hayes and

colleagues determined the antimicrobial susceptibilities of the *M. fermentans* incognitus strain along with reference strains of both *M. fermentans* (i.e., Strain PG18 [ATCC 19989]) and *M. pneumoniae* (ATCC 15531).[173,175] As expected, all three mycoplasmas were resistant to cell wall–active agents (e.g., penicillin, ampicillin). Both the PG18 and the incognitus *M. fermentans* incognitus strains were resistant to erythromycin (mean minimal inhibitory concentrations [MICs] of erythromycin, 31.2 mg/mL and 43.0 mg/mL, respectively), whereas *M. pneumoniae* was susceptible to erythromycin (mean MIC, 0.0073 mg/mL). The *M. fermentans* incognitus strain was susceptible to tetracycline, doxycycline, clindamycin, lincomycin, chloramphenicol, and ciprofloxacin. Both *M. fermentans* strains tested in this study were resistant to the aminoglycosides (i.e., gentamicin, kanamycin, streptomycin, and neomycin), whereas *M. pneumoniae* was susceptible. Aminoglycoside MICs for the incognitus strain of *M. fermentans* were higher than 1,000 mg/mL for all four of these drugs, while the MICs for gentamicin, kanamycin, streptomycin, and neomycin for the PG18 strain were 15.6, 20.8, 18.2, and 52.1 mg/mL, respectively. Subsequent antimicrobial susceptibility testing of 24 additional *M. fermentans* isolates also disclosed that this species is resistant to erythromycin and the aminoglycosides.[173] This subsequent study also documented that only ciprofloxacin and levofloxacin had a significant bactericidal effect.[173]

Using a modified dilution technique with Hayflick's broth, Hannon examined several *M. fermentans* strains isolated

from human infections and from tissue culture cells.[162] These strains were much more susceptible to azithromycin than to either erythromycin or clarithromycin. Clindamycin and several tetracycline congeners also showed good activity against the *M. fermentans* strains, although mycoplasmacidal concentrations were severalfold greater than inhibitory concentrations of antibiotic. This study also demonstrated that *M. fermentans* strains isolated during the 1960s in cell-free media were susceptible to the aminoglycosides, while recent human isolates and strains obtained from tissue culture cells were often resistant to a single or multiple aminoglycoside drugs, with MICs to these agents exceeding 500 mg/mL. Azithromycin was more active against *M. fermentans* strains than either erythromycin or clarithromycin.[162]

In a subsequent study, Hannon examined the aminoglycoside susceptibility of several *M. fermentans* strains, including three AIDS-associated isolates (including one incognitus strain), six recent respiratory tract isolates, one leukemia-associated isolate from 1962, and eight tissue culture isolates.[163] Two of the 3 AIDS-associated isolates and all of the non–AIDS-associated respiratory tract isolates were susceptible to the six

aminoglycoside drugs tested, while the *M. fermentans* incognitus strain and all the recent tissue culture isolates were highly resistant to all six agents, with MICs exceeding 250 mg/mL. The strain isolated from tissue culture of the bone marrow of a patient with leukemia in 1962 was highly resistant to streptomycin (MIC, >250 mg/mL), but susceptible to the other five aminoglycosides. These results were consistent with Hannon's earlier studies, which established that *M. fermentans* incognitus was the only human strain of the nine examined that demonstrated multiple aminoglycoside resistance.[162] Using a macrodilution, metabolic inhibition assay, Poulin and colleagues examined the antimicrobial susceptibilities of several AIDS-associated mycoplasmas, including *M. fermentans* (a stock strain, two clinical isolates from patients with AIDS, and the "incognitus" strain), *M. penetrans* (one strain), and *M. pirum* (one strain).[394] All isolates were susceptible to azithromycin, clarithromycin, clindamycin, doxycycline, ofloxacin, and tetracycline. *M. fermentans* strains and *M. pirum* were resistant to erythromycin, whereas *M. penetrans* was susceptible. Hayes and colleagues tested nine strains of *M. penetrans* by a broth dilution procedure.[174] All were susceptible to azithromycin, chloramphenicol, ciprofloxacin, clindamycin, doxycycline, erythromycin, levofloxacin, lincomycin, and tetracycline, but were resistant to gentamicin and streptomycin.

Methods for Susceptibility Testing of Mycoplasmas

Agar disk diffusion is not an acceptable method for in vitro susceptibility testing of mycoplasmas. Both agar dilution and broth dilution methods for antimicrobial susceptibility testing of mycoplasmas have been described, as well as Etest methods.[74,524]SP-4 or Hayflick's media with pH of 7.3 to 7.4 are recommended for testing MH or *M. pneumoniae*. 10B broth, Bromthymol Blue Broth, or A8 agar can be used for testing *Ureaplasma spp.*; a pH of 6.0 to 6.5 is used for testing UU. For agar dilution, doubling dilutions of antimicrobial agents are incorporated into the agar medium and inoculation is performed using a Steer's replicator to deliver an inoculum of 30 to 300 CFUs per inoculum spot. This inoculum is determined by plating aliquots of 10-fold dilutions of a growing broth culture in triplicate, performing colony counts, and diluting the organism suspension appropriately so that the replicator delivers 30 to 300 CFUs per spot. Plates are incubated in air at 35°C to 37°C for 4 days (UU), 5 days (MH), or 14 days (*M. pneumoniae*). Growth may be enhanced for UU if media is incubated in increased CO_2.[74,524]

For broth microdilution, the antimicrobial agents are solubilized and diluted in microtiter trays with the proper broth medium containing a phenol red indicator to achieve a range of drug concentrations. The inoculum should be prepared from cultures that are in the exponential growth phase, where the numbers of organisms is generally about 10^7 CFU/mL for ureaplasmas and 10^8 to 10^9 CFU/mL for large-

colony mycoplasmas, which are also expressed as color-changing units (CCUs) per milliliter. An inoculum of 10^4 to 10^5 CFU (CCU) of organism is added to each of the microtiter wells containing the antimicrobial dilutions, and then the plates are sealed and incubated aerobically at 35°C to 37°C. The microtiter trays are examined daily until a color change due to a change in pH is detected in the drug-free growth control. The MIC is defined as the lowest concentration of antimicrobial agent at which the metabolism of the organisms is inhibited enough to prevent a change in the color of the medium (due to the pH indicator) at the time that the drug-free control first shows a color change. For UU, growth will usually be present within the control well after 24 hours, while growth of MH usually requires 48 hours. *M. pneumoniae* strains generally require 4 to 8 days of incubation before a change is noted in the control well. With both agar dilution and broth dilution procedures, strains with known susceptibilities and reproducible MICs must be included with the performance of testing, as external controls.[74,524] There are a few commercial products available for susceptibility testing of mycoplasmas, including *Mycoplasma* IST (bioMérieux), *Mycoplasma* SIR (Bio-Rad), MYCOFAST All IN (Unipath, UK), and MYCOKIT-ATB (PBS Orgenics), but these are available only in Europe presently.[524]

In all of these susceptibility procedures, problems that relate to the biologic characteristics of the organisms and to the method itself may be encountered. Biologic problems include the possibility of mixed cultures (e.g., both mycoplasmas and ureaplasmas) and the coexistence of susceptible and resistant populations in the same culture. The latter problem may be detected only in agar dilution-based systems, because colonies growing on antibiotic-containing media can be directly reidentified by urea hydrolysis or by serologic methods. Problems relating to methodology, including the lack of a standard medium for test performance, discrepancies related to the pH required for optimal mycoplasmal growth versus optimal antibiotic activity, the difficulty in standardization of inoculum size, the lack of standardized incubation times and conditions, and the lack of a standardized susceptibility breakpoints, have been greatly overcome with publications of documents such as Cumitech and CLSI 43-A.[74,238,524] Susceptibility testing on mycoplasmas will continue to be performed primarily in reference laboratories and larger institutions with special research interests in the therapy of genital mycoplasmal infections.

Diagnosis and Treatment of Hemotrophic *Mycoplasma* Infections in Animals

Former members of the genera *Eperythrozoon* and *Haemobartonella* cannot be grown in culture, so diagnosis is based on the examination of blood smears stained by Romanowsky-type blood film stains, including Giemsa, May-Grünwald–Giemsa, Wright–Giemsa stains, or by the acridine orange stain.[336,337,469] Because the organisms display a cyclical parasitemia where they may be rapidly cleared from the blood, examination of multiple blood films collected over a 24-hour period increases the likelihood of a positive diagnosis in a clinically compatible host species. Blood films should be prepared immediately after collection using nonanticoagulated blood or blood collected in heparinized tubes; EDTA anticoagulant may cause detachment of the organisms from the red blood cell membrane, making microscopic diagnosis difficult.[336,469] The organisms appear as coccal forms that are 0.5 to 0.8 mm in diameter and adherent to the surfaces of the erythrocytes. They are usually found around the periphery of the erythrocyte and may appear singly or in pairs, clusters, and chains. With the acridine orange fluorescence stain, the organisms appear as bright orange to yellow-green. Molecular and serologic assays for the hemotrophic mycoplasmas have also been developed but are not widely available.[469] All species appear to be susceptible to tetracyclines and resistant to β-lactam antimicrobial agents. Treatment with erythromycin effectively controls acute infection, but treatment does not consistently clear animals of the infection.[336]

Vaccines and Prevention of *Mycoplasma* Infections

There have been attempts to develop inactivated vaccines for the prevention of *M. pneumoniae* infection. A systematic review and meta-analysis of the literature as of 2009 were published by Linchevski et al.[278] They found an efficacy against *M. pneumoniae* infection of 46% or 52% depending on the approach used with little adverse effects recognized. Overall, they reported that the vaccine could reduce rates of pneumonia and *M. pneumoniae* specifically by about 40% and suggested further development of such vaccines especially for high-risk populations.[278] A P1-C DNA vaccine fused with the B subunit of *Escherichia coli* heat-labile enterotoxin demonstrated increased efficacy in protecting mice against *M. pneumoniae* infection.[571]Strategies to create chimeric proteins derived from functional adhesin regions of *Mycoplasma pneumonia* for vaccine development have also shown efficacy in animal models.[171,429]

1220

Test methods and algorithms used for the growth, detection, identification, and susceptibility testing of mycobacteria have changed considerably over the past several decades. Several new techniques have been introduced that are directed toward the detection of *M. tuberculosis* complex (MTBC) directly in clinical specimens by nucleic acid amplification, the more effective recovery of mycobacteria from clinical specimens, the rapid identification of mycobacteria using molecular techniques, and the rapid determination of drug susceptibility profiles. Although the quest for pure research in molecular biology is an integral part of this evolution, the driving force for clinical laboratory personnel is to provide ever more rapid species identification and antimycobacterial drug susceptibility profiles. As molecular-based procedures evolve

from research laboratories into commercial products, some of which have received Food and Drug Administration (FDA) approval, the ability to diagnose tuberculosis and have a preliminary idea of drug susceptibility within days—or incredibly even hours—rather than weeks is now possible. These techniques are discussed in more detail later in this chapter.

Trends in Clinical Tuberculosis

Worldwide Incidence of Tuberculosis

According to the World Health Organization,[371] the global burden of tuberculosis (TB) has been slowly declining over the past several years, but it remains high. In 2012, there were an estimated 8.6 million incident cases of TB worldwide (range, 8.3 million to 9.0 million), of which 0.5 million occurred in children, 2.9 million in women, and 1.1 million in persons infected with HIV. Of those, 450,000 were multidrug-resistant TB (MDR-TB). Fifty-eight percent of the total TB cases occurred in South-East Asia and Western Pacific regions, 28% in the African region, and much smaller proportions elsewhere: 8% in the eastern Mediterranean region, 4% in the European region, and 3% in the region of the Americas. The five countries with the highest number of cases were India, China, South Africa, Indonesia, and Pakistan. The lowest rates were in the United States, Canada, Western Europe, Japan, Australia, and New Zealand. An estimated 1.3 million people died from TB in 2012, of which 320,000 were infected with HIV and 170,000 had MDR-TB.

In 2013, 9,588 new cases of TB were reported in the United States (incidence, 3.0 cases per 100,000 population), a 4.2% decrease from 2012.[43] The rate among foreign-born persons was about 13 times greater than the rate among US-born persons, and rates among non-Hispanic Asians were nearly 26 times greater than among non-Hispanic whites. Over half (51.3%) of the cases occurred in four states: California, Texas, New York, and Florida. Eighty-six cases of MDR-TB were reported in 2012 (the most recent year for which drug susceptibility test results are complete) and 88.4% of these occurred in foreign-born persons.

Persons at Risk for Mycobacterium tuberculosis *Infection and Active Tuberculosis*

Persons at increased risk for *M. tuberculosis* infection are as follows:

- Close contacts of those with known or suspected active TB
- Foreign-born from an area with a high incidence of active TB (e.g., Asia, Africa)
- Persons who visit an area with a high prevalence of active TB

- Residents and employees of congregate settings whose clients are at increased risk for active TB (e.g., correctional facilities, homeless shelters)
- Healthcare workers who care for patients at increased risk for active TB
- Persons who abuse drugs or alcohol

Factors that increase the risk for progression of infection to active TB are as follows:

- HIV infection, which is the strongest known risk factor for progressing to active TB among persons with latent *M. tuberculosis* infection
- Age <5 years
- Immunosuppressive therapy (e.g., tumor necrosis factor-α antagonists, systemic corticosteroids)
- Recent (within the past 2 years) infection with *M. tuberculosis*
- History of untreated or inadequately treated active TB
- Silicosis, diabetes mellitus, chronic renal failure, leukemia, lymphoma, cancer of the head, neck, or lung
- Gastrectomy or jejunoileal bypass
- Weight <90% of the ideal body weight
- Cigarette smoker or abuse of drugs or alcohol

Rapidly Progressive Disease

Recently acquired infections with *M. tuberculosis* do not invariably follow the classic, slowly progressive course of secondary disease. Primary progressive TB or the rapidly spreading miliary type of TB may occur in patients with profound immunosuppression, such as patients with AIDS. Progression of disease in such patients may be measured in terms of weeks, rather than months or years. The rapid replication of mycobacteria at sites of infection leads not only to high concentrations of organisms at these sites, but also to miliary spread and potential treatment failures secondary to the overwhelming burden of mycobacteria and possible emergence of multidrug-resistant strains.

Infection Control and Epidemiologic Measures

Measures should be instituted to ensure that patients with a high index of suspicion for TB are promptly placed in airborne (i.e., respiratory) precautions. Hospital personnel involved in the direct care of patients with TB are at high risk for infection and are required to follow isolation procedures and wear protective clothing and high-filtering masks. Laboratory personnel who handle clinical specimens from patients with TB are also at risk for infection, but may work in a safe manner with these specimens using universal precautions and processing specimens in laminar flow biologic safety hoods.

Ventilation systems in hospitals and in crowded settings, such as in prisons, nursing homes, and urban homeless shelters, where outbreaks of TB have been reported, are under intense scrutiny. Nardell and associates[221] found that

1221

poor air quality contributed to airborne infection in buildings fitted with air duct systems that delivered an inadequate mixture of outside air. Problems will remain in unsuspected settings, however, such as the outbreak of TB among patrons of a local bar, as reported by Kline and coauthors.[163] The index case in this report was a homeless person who was a regular patron of the bar, and who had a long asymptomatic interval before diagnosis. The possibility of heavy alcohol use among this population of patrons may also have contributed to the high rate of infectivity.

The Clinical Laboratory

Optimizing the Detection and Identification of Mycobacteria

The traditional practice of waiting for bacterial colonies to appear on solid agar, determining the species identification using only biochemical tests, and performing drug susceptibility tests only on solid media is too time-consuming. Decisions regarding the procedures and tests that will be performed in the on-site laboratory and which will be sent to a qualified reference laboratory must be determined within each practice care community. In many practice settings, activities of the on-site laboratory may be limited to rapid turnaround procedures, such as screening smears for acid-fast bacilli (AFB) or the inoculation of culture media and provisional assessment of isolates. Other procedures, again to be determined by local healthcare personnel, may be best performed in a reference laboratory. A team of healthcare workers, including clinicians, laboratory specialists, and support personnel, should be established to determine how diagnostic approaches are to be coordinated. Early diagnosis and prompt initiation of appropriate therapy are the major ingredients to ensure the cure of the infected patient, prevent the emergence of resistant strains, and, for TB, interrupt person-to-person transmission.

Laboratory Safety

The inappropriate handling of infectious biologic material such as clinical specimens places laboratory personnel at risk for infection. Any activity with the potential to generate aerosols must be done in a Class I or II biologic safety cabinet (BSC). Liquification and concentration of sputum specimens may be conducted safely on the

open bench if the specimens are first treated in a Class I or II safety cabinet with NaOH (as discussed later in this chapter). Biosafety Level 3 (BSL3) practices are required for laboratories that propagate and manipulate cultures for *M. tuberculosis* or *M. bovis*.

The BSL3 space, which includes the BSC and centrifuge, should have nonpermeable walls and work surfaces, directional airflow (with the lowest air pressure in the laboratory), and a double-door air lock to prevent the backflow of air. Air from the BSL3 space should be vented through high-efficiency particulate air (HEPA) filters directly to the outside. Laboratories and hoods should be equipped with gauges to monitor air pressure.

Because equipment and the worker's arms placed in a BSC may disrupt the laminar airflow and deflect contaminated air out of the cabinet, anyone working in the laminar flow BSC and in the BSL3 space should also wear personal protective equipment, including a respirator. Personnel must be tested each year to ensure that the respirator fits correctly. Disposable gowns should be worn over a scrub suit (street clothes should not be worn into the BSL3 space because they may become contaminated), along with gloves, caps, and shoe protection to complete the protective personal accessories, since accidental splashes may occur. Protective clothing should be removed and placed in a bag for autoclaving when work in the BSL3 is completed.

Each laboratory director must determine the extent to which renovations in the current laboratory space may be required. Renovations may cost many thousands of dollars and may not be cost-effective in certain settings. In such instances, a decision must be considered about whether cultures for mycobacteria would be more effectively performed at another facility, such as a reference laboratory that can comply with the recommended standards.

Specimen Collection

Mycobacteria can be recovered from a variety of clinical specimens, including respiratory specimens (sputum, bronchial washes, bronchoalveolar lavage fluid, and bronchial biopsies); urine, feces, blood, cerebrospinal fluid; tissue biopsies; and deep-needle aspirations of virtually any tissue or organ. Specimens that may contain normal bacterial flora should be processed as soon after collection as possible to minimize the degree of overgrowth with specimen contaminants.

Respiratory Specimens

Sputum samples collected by expectoration or by ultrasonic nebulization are best obtained shortly after the patient awakens in the morning, when mycobacteria are at their highest concentration. Twenty-four-hour collections are discouraged because the

sample containing the highest concentration of mycobacteria will be proportionately diluted by subsequent low-yield samples, and the chances for bacterial and fungal overgrowth during the prolonged collection process are significantly increased.

The irregular and intermittent release of mycobacteria into the bronchial lumen from mucosal ulcers or loculated cavities often results in a variable pattern of recovery from respiratory secretions. Cultures obtained from patients with pulmonary or renal TB, in particular, may be positive one day but negative the next; thus, a minimum of three early-morning sputum specimens should be collected on successive 24-hour periods to maximize the chance of recovery of mycobacteria. All specimens should be transported promptly to the laboratory and refrigerated if processing is delayed.

Blood Cultures

Several approaches may be used for the recovery of mycobacteria from blood cultures. Berlin and associates[21] report on the use of a biphasic system using modified 7H11 oleic acid albumin as the agar phase and brain–heart infusion as the broth phase. Positive cultures for *Mycobacterium avium* complex

(MAC) were obtained as early as 6 to 8 days. However, Agy and coworkers[3] report that only 43.8% of blood cultures from known blood culture–positive patients were recovered using a similar biphasic system. The use of the lysis-centrifugation blood culture system (ISOLATOR; Wampole, Alere, Waltham, MA) has been shown to increase the yield and shorten the time to recovery of mycobacteria from blood cultures.[97,191] The lysis-centrifuge tube contains an anticoagulant and a lysing agent to effect rupture of both erythrocytes and neutrophils. Thus, intracellular mycobacteria are released into the broth milieu, further enriched by the lysis of the red blood cells. Following centrifugation of the tube, the eluate is discarded and the sediment is transferred to appropriate culture media.

The first semiautomated system that could be used for culture of mycobacteria from blood was the BACTEC 460 (Becton Dickinson, Sparks, MD).[3,76,313,344,361] The detection of bottles positive for mycobacteria was based on measuring radioactive $^{14}CO_2$released in the blood culture vial from the metabolism of 1-[^{14}C]-palmitic acid that was included in the broth medium. This system is no longer supported by the manufacturer and, therefore, is not discussed further.

There are several newer commercially available options for the culture of blood for mycobacteria, some of which contain lytic agents to aid in the release of the mycobacteria from phagocytes. These include the VersaTrek (formerly ESP Culture System II, Trek Diagnostic), the BACTEC MYCO/F lytic (BD Diagnostic Systems),

and the MB/BacT bottle (bioMérieux), all of which are discussed further later in this chapter.

Whatever blood culture system is used, the policy of routinely obtaining at least two culture sets may not be cost-effective for patients in whom mycobacteremia is suspected.[311] From a total of 1,047 mycobacterial blood cultures obtained from 273 patients with disseminated MAC, Stone and colleagues[311] found that only 1 of the 2 bottles was positive in only 4 of 98 positive cultures (4%). In 85%, both bottles were negative, and in 11%, both bottles were positive. Thus, as a routine, they recommend obtaining only a single blood culture for the diagnosis of mycobacteremia and ordering a repeat culture only if there is strong clinical evidence of disseminated infection.

Other Specimens

In certain patients with AIDS, the concentration of mycobacteria, particularly MAC, may be sufficiently high in the lower intestinal tract to be recovered in culture. Kiehn and associates[153] have outlined a procedure for processing stool specimens for mycobacterial culture:

- Stool specimens are collected in a clean (not necessarily sterile) container with a tightly fitting lid, as for routine bacterial cultures.
- A direct smear is first prepared from a small quantity of the specimen and stained for AFB.
- If the smears are negative for AFB, the specimen is not processed further.
- If AFB are seen in the smear, 1 g of feces is suspended in 5 mL of Middlebrook 7H9 broth or equivalent and subjected to the same NaOH digestion–decontamination as used for sputum specimens (described below).

One might question the significance of detecting mycobacteria in fecal samples. Conlon and coworkers,[56] in a study of 89 patients with AIDS-related enteropathy in Lusaka, Zambia, found that chronic diarrhea did not correlate with the presence of mycobacteria in stool specimens. In contrast, Chin and colleagues[46] found that the recovery of MAC organisms from stool specimens was predictive of disseminated disease.

Specimens submitted for mycobacterial culture that are normally sterile, such as cerebrospinal fluid, synovial fluid, and other body fluids, need not be decontaminated before culture. Processing can commence with centrifugation, as described below, and aliquots of the sediment transferred to appropriate culture media. Low-volume fluid samples can be added directly to broth and incubated.

A first-morning clean-catch midstream urine sample, at least 40 mL, should be collected in a sterile container on 3 consecutive days. Twenty-four-hour pooled

specimens are not acceptable. Although these specimens can sometimes be processed without decontamination, the need for decontamination should be based on the experience of the individual laboratory. If the need to decontaminate is not clear, the specimen can be refrigerated until the results of routine bacterial cultures are available the following day.

Tissues and needle biopsy material should be placed in a small quantity of 7H9 or 7H11 broth as a holding medium. Depending on the size and nature of the material obtained, the specimen should be ground in a small amount of broth with a mortar and pestle and aliquots of the suspension transferred to appropriate culture media.

There is virtually no indication for obtaining material for mycobacterial culture with a swab because the hydrophobic nature of the lipid-containing cell wall of the bacteria inhibits transfer of the organisms from the swab to the aqueous culture medium. It is optimal to reject such specimens for mycobacterial culture. However, if a swab is received in the laboratory and material for culture cannot be recollected, the tip of the swab should be placed directly on the surface of the culture medium or into a tube containing approximately 5 mL of 7H9 broth and incubated for 6 to 8 weeks.

Laboratory Approach to the Recovery and Identification of Mycobacteria

The conventional laboratory approach to the diagnosis of mycobacterial infections involves the phenotypic characterization of colonies growing on a solid medium followed by a battery of biochemical tests. However, this process is too time-consuming and often does not provide an accurate identification. Currently, using a combination of phenotypic and molecular assays for the rapid identification of mycobacteria is recommended, particularly for the identification of MTBC.

Smears should be prepared from the material submitted and stained with a fluorescent dye (auramine O alone or in combination with rhodamine B). Some laboratories choose to confirm positive results with a carbol fuchsin-based stain (Ziehl–Neelsen or Kinyoun), but this is not required. However, some rapidly growing mycobacteria may not stain with a fluorochrome stain; therefore, if infection with a rapid grower is suspected, staining smears of the specimen with a carbol fuchsin stain should be considered.

1223

Sputum and other contaminated specimens are first treated with *N*-acetyl-L-cysteine–sodium hydroxide (NALC–NaOH), a decontamination–digestion procedure for concentrating any mycobacterial cells that may be present. It is currently

recommended that all sputum digests and other specimens be inoculated to broth culture media in addition to a solid medium (Löwenstein–Jensen [LJ] medium or Middlebrook agar). When mycobacterial growth is detected, a molecular test for identification of MTBC should be done as soon as the concentration of organisms exceeds the threshold of sensitivity for the assay.

Specimen Preparation

The high concentration of lipids in the cell wall of most mycobacteria makes them more resistant to killing by strong acid and alkaline solutions than other bacteria that may be present in the specimen. Consequently, specimens likely to contain a mixed bacterial microbiota are treated with a decontaminating agent to reduce undesirable bacterial overgrowth and to liquefy mucus. After treatment with the decontaminating agent for a carefully controlled period, the acid or alkali used is neutralized and the mixture is centrifuged at high speed to concentrate the mycobacteria.

Digestion and Decontamination

Some decontaminating solutions, such as 6% sodium hydroxide, are so strong that they may kill or seriously injure mycobacteria to the point that they will grow only very slowly, if at all. Decreasing the strength of the acid or alkaline decontamination solution has resulted in improved recovery of mycobacteria by culture, but frequently at the price of overgrowth of the culture with contaminants. Exposure of specimens to strong NaOH, 5% oxalic acid, or other agents must be carefully timed to prevent excessive chemical injury to the mycobacterial cells.

The use of mild decontaminating agents, such as trisodium phosphate (TSP) alone or combined with benzalkonium chloride (Zephiran; Winthrop Laboratories, New York, NY), is popular in some laboratories. Specimens containing a large quantity of *M. tuberculosis* can withstand the action of these agents for as long as overnight, and careful timing of exposure is not required. Specimens treated with TSP–Zephiran should be inoculated onto an egg-based culture medium to neutralize the growth inhibition of the Zephiran. If agar-based media are used, neutralization of the Zephiran can be accomplished by adding lecithin. The standard digestion–decontamination procedure developed by Kubica et al.[172] is shown in Box 19-1.

BOX 19-1

The Standard Digestion–Decontamination Procedure Developed by Kubica et al. at the Centers for Disease Control and Prevention[172]

1. Prepare the acetylcysteine-alkali digestant as follows: Combine 50 mL of 2.94%trisodium citrate-$3H_2O$ (0.1 M) with 50 mL of 4%NaOH. To this solution, add 0.5 g of powdered *N*-acetyl-L-cysteine (NALC) just before use. The NaOH (which becomes a 2%solution after mixing equal parts with the specimen) serves as a decontaminating agent. Occasionally, the concentration of NaOH must be increased to 3% (6%original solution) during warm weather or in treating specimens from patients with large pulmonary cavities associated with persistent bacterial contamination. The NALC is a mucolytic agent without bactericidal activity that liquefies mucus by splitting disulfide bonds. The mycobacteria are released when the mucus is liquefied, rendering them easy to concentrate by high-speed centrifugation.
2. Use 50-mL plastic centrifuge tubes with tightly fitting lids for the processing of all specimens. Add the NALC digestant mixture in a volume equal to that of the specimen. Typically, a volume of 10–15 mL of specimen is used. Tighten the screw cap.
3. Homogenize the mixture with a vortex mixer for 15–20 seconds or until well mixed and allow to stand at room temperature for 15–20 minutes, swirling the tubes periodically. Proper attention should be paid so that this digestion time does not exceed 20 minutes, because "overtreated" specimens result in fewer positive cultures.
4. After the digestion–decontamination step, add phosphate buffer, pH 6.8 (preferred over sterile water), up to the top ring in the tube. Mix well. The phosphate buffer makes strong shifts in pH less likely and also serves to "wash" the specimen, to dilute and neutralize toxic substances, and to reduce the specific gravity of the specimen so that centrifugation is more effective in the sedimentation of organisms.
5. Concentrate the specimen by centrifugation at 2,000 to 3,000 *g* for 15–20 minutes. A refrigerated centrifuge may be used at higher speeds to increase the yield of mycobacteria.
6. After centrifugation, decant all the supernatant carefully into a splash-proof receptacle containing a phenolic disinfectant. Wipe the lip of the tube with a cotton ball soaked with 5%phenol. Add a small quantity of phosphate buffer, pH 6.8 (1–2 mL), and resuspend the sediment with a Pasteur pipette.
7. Prepare smears on clean microscope slides for staining, preferably with a fluorochrome stain. Use either a sterile applicator stick or a flamed, 3-mm diameter bacteriologic loop and smear a portion of the sediment over an area 1 × 2 cm. If the quantity of sediment is very small, delay making smears until after the next step (i.e., the addition of albumin). Add 1 mL of sterile 0.2%bovine albumin.
8. Inoculate the concentrate to appropriate liquid and solid culture media.

Usually, concentrated HCl or concentrated NaOH is used to neutralize the decontaminating agents. Because of the strength of these solutions, a neutral end point is sometimes difficult to achieve. One advantage of the NALC procedure is that the addition of a large volume of phosphate buffer makes strong shifts in pH less likely. The addition of buffer serves to "wash" the specimen, dilutes toxic substances, and decreases the specific gravity of the specimen so that centrifugation is more effective in sedimentation of organisms.

Table 19-1 lists additional agents for decontaminating and concentrating specimens, along with comments about their use.[292,304] Each mycobacteriologist should select the agents to use in their laboratory on the basis of the number and types of specimens received and the time and technical staff available to process the specimens. As listed in Table 19-1, dithiothreitol is also an effective mucolytic agent when used with 2% NaOH. Cetylpyridium chloride has also been recommended for the decontamination of specimens, particularly those mailed from remote sites of collection.[304] The digestion–decontamination procedure is further described in Chart 19-1.

Ratnam and coauthors have described a simplified acetylcysteine–alkaline procedure that combines the decontamination and the concentration steps and the inoculation of the specimen to selective culture media (containing antibiotics, to be described later in this chapter).[262] Specimens are mixed with the NALC–NaOH solution on a vortex mixer and, without any waiting or addition of buffer or water to the digested specimens, the mixture is centrifuged at 3,000 *g* for 15 minutes. The supernatant is decanted, and the sediment is suspended in 1 to 2 mL of phosphate buffer (0.067 M, pH 5.3). The NaOH concentration in the solution may be reduced from the usual 2% to 1.5% if necessary or feasible. This method eliminates two steps: the 15- to 20-minute decontamination time following digestion of specimens and the addition of phosphate buffer or water. It also eliminates the potential for specimens to drip from the cap or run down the outer surface of the tube when diluent is added after vortex mixing and thus reduces the chance for cross-contamination. According to these authors,[262] the greatest killing of mycobacteria occurs during the first few minutes of exposure to the alkali digestion fluid, and as many as 10^4 mycobacteria may be lost, depending on the species. Eliminating the initial digestion step had no adverse effects on the recovery of mycobacteria. In fact, at times, the addition of phosphate buffer or water actually resulted in poorer recovery, owing to a greater dissolution of the particulate matter in the specimens. Alkali tolerance was not a consistent feature among the mycobacterial species and strains tested, with the rapid growers being the most susceptible to a high pH. By reducing or eliminating the standard treatment time of 15 to 20 minutes or by decreasing the concentration of NaOH in the digestant solution from the usual 2% to either 1.5% or 1%, the adverse effects can be easily

overcome.

Because of the emergence of drug-resistant strains of *M. tuberculosis*, rapid laboratory tests to determine drug susceptibility profiles are useful. Many of the new tests for identifying drug resistance profiles are based on nucleic acid amplification procedures. Consequently, it may be necessary to store specimens or digested concentrates for future batch testing or for shipping to a distant reference laboratory. It may be advisable to render such samples noninfectious at early stages of processing to minimize the biohazard to laboratory workers. Williams and associates[358] found that ethanol fixation of sputum sediments containing *M. tuberculosis* served to render the bacteria nonviable, while still preserving the integrity of genomic DNA in a state suitable for testing by polymerase chain reaction (PCR) techniques. In their studies, 0.25 mL of sputum sediments were diluted with 0.583 mL of 100% ethanol to bring the final ethanol concentration to 70%. They recommend storage of the ethanol-treated specimens at 4°C if PCR testing is to be delayed. Zwadyk and

coworkers[381] reviewed several methods for rendering specimens safe for further testing, and introduced the technique of heating the samples at 100°C for 30 minutes in a boiling water bath or a forced-air oven, which both killed and lysed the mycobacteria, releasing short DNA fragments suitable for amplification.

TABLE 19-1 Agents Commonly Used for Decontamination and Concentration of Specimens

Agent	Comments
N-Acetyl-L-cysteine plus 2% NaOH	Mild decontamination solution with mucolytic agent NALC to free mycobacteria entrapped in mucus. Limit exposure to NaOH to 15 minutes.
Dithiothreitol plus 2%NaOH[a]	Very effective mucolytic agent used with 2% NaOH. Trade name of dithiothreitol is Sputolysin. Reagent is more expensive than NALC. Limit exposure to NaOH to 15 minutes.
Trisodium phosphate, 13% plus benzalkonium chloride (Zephiran)	Preferred by laboratories that cannot carefully control time of exposure to decontamination solution. Specimens treated with TSP–Zephiran should be inoculated onto an egg-based culture medium to neutralize the growth inhibition of the Zephiran. If agar-based media are used, neutralization of the Zephiran can be accomplished by adding lecithin.

NaOH, 4%	Traditional decontamination and concentration solution. Time of exposure must be carefully controlled to no more than 15 minutes. NaOH, 4%, effects mucolytic action to promote concentration by centrifugation.
Trisodium phosphate, 13%	Can be used for decontamination of specimens when exposure time can be completely controlled. Not as effective as TSP–Zephiran mixture.
Oxalic acid, 5%	Most useful in processing specimens that contain *Pseudomonas aeruginosa* as a contaminant.
Cetylpyridium chloride, 1%, plus 2% NaCl[b]	Effective as a decontamination solution for sputum specimens mailed from outpatient clinics. Tubercle bacilli have survived 8-day transit without significant loss.

[a] See reference 292.
[b] See reference 304.

Centrifugation

Rickman and Moyer have called attention to the importance of carefully controlling centrifugal force in the recovery of mycobacteria from clinical specimens, particularly in the correlation of positive AFB smears with positive mycobacterial cultures.[266] The focus of their study was to understand the unique physical characteristics conferred on mycobacteria by the high lipid content of the cell wall (up to 30% dry weight). The lipid has the effect of making the specific gravity of the organism very low. If the organism is to be maximally sedimented during the centrifugation of the specimen, the specific gravity of the suspending fluid should be kept as low as possible, and the centrifugal force applied to the specimen should be as high as practical. Improved recovery of mycobacteria by culture occurred as the relative centrifugal force (RCF) was increased from 1,260 to 3,000 *g* (Table 19-2).[266,381] When the RCF was increased to 3,800 *g*, a twofold increase in the correlation of positive smears to positive cultures from 40% to 82% was realized, or more than a threefold increase from the correlation when the RCF was only 1,260 *g*.

Subsequent evaluation for recovery of mycobacteria from sputum samples seeded with known concentrations of organisms following centrifugation has confirmed that the recovery rate increases with centrifugation time and speed.[261] However, the recovery rates in these experimental samples were not significantly lower when using

an RCF of 2,074 *g* for 20 minutes (67% to 71%) compared with the recovery rates at RCFs of 3,005 *g* and 3,895 *g* for 15 minutes (76% to 80%). Acid-fast smear sensitivity for 25,000 specimens processed with an RCF of 3,800 *g* for 20 minutes was 71%. However, sensitivity was still 69%, as determined for an additional 30,000 specimens processed in a similar manner but with an RCF of 2,000 *g*. The authors conclude that the actual rates of recovery of viable mycobacteria from clinical specimens also depends on the method of treatment and individual species and strain differences of mycobacteria for alkali tolerance. Thus, although centrifugation at an RCF of 3,000 *g* for 15 minutes may be optimal for the recovery of mycobacteria from clinical specimens, the chances for recovery will not be substantially compromised in laboratories where lower cost centrifuges attaining only a maximum of 2,074 *g* are available, if the time is increased to 20 minutes. With the centrifugation forces produced at RCFs of 3,000 *g* or higher, glass or plastic centrifuge tubes may collapse and must be placed in sealed cups. Also, considerable heat is generated at high speeds, and refrigerated centrifuges may be required when RCFs exceed 3,000 *g*.

TABLE 19-2 Effect of Increasing Centrifugal Force on Results of Smears and Cultures for Mycobacteria

	Relative Centrifugal Force (g)		
	1260	3000	3800
Positive smears	1.8%	4.5%	9.6%
Positive cultures	7.1%	11.2%	11.6%
Correlation of positive smears/cultures	25%	40%	82%

Adapted from reference 266.

Centrifuges used for the processing of specimens potentially containing mycobacteria should be equipped with 50- or 250-mL centrifuge cups with aerosol-free tops that can be adapted to hold 50-mL centrifuge tubes. Such centrifuges should

not be vented to the outdoors because of the danger of reverse airflow through the vent during windstorms. Precautions should be taken to prevent the spontaneous rupture of fluid surface tension membranes when inoculating broth cultures or liquid specimens. If such a membrane in an inoculation loop breaks, for example, droplet aerosols may be created that can persist in the air for long periods. All such transfers must be performed in a biologic safety hood.

Bone Marrow, Tissue, and Body Fluid Specimens

Bone marrow and tissue biopsies are usually not contaminated with other microorganisms, so they can be homogenized and inoculated directly onto culture media without the use of a decontaminating solution. Draining sinuses or other cutaneous lesions suspected of harboring mycobacteria are best cultured by obtaining a small portion of infected tissue or drainage. Fine-needle biopsies are also being used with increased frequency to obtain material for tissue culture from a variety of subcutaneous and deep visceral lesions. In a study of 390 patients in which needle biopsy specimens were obtained to diagnose suspected tuberculous lymphadenitis, the overall rate of smear positivity was 23.6%, and culture positivity was 35%.[257] Caseating lesions were more likely to produce positive cultures (40%) than noncaseating lesions (9%).

Liquid specimens (e.g., cerebrospinal fluid, pleural fluid, peritoneal fluid, etc.) should be centrifuged, stained for AFB, and inoculated directly to broth and solid culture media. Pleural fluid specimens may be diluted with buffer to lower the specific gravity, thereby improving sedimentation of mycobacteria.

Staining of Acid-Fast Bacilli

The cell walls of mycobacteria, because of their high lipid content, have the unique capability of binding fuchsin dye so that it is not removed (destained) by acid–alcohol. This acid-fast staining reaction of mycobacteria, along with their characteristic size and shape, is a valuable aid in the early detection of infection and in the monitoring of therapy for mycobacterial disease. The presence of AFB in sputum, combined with a history of chronic cough and weight loss plus consistent chest radiographic findings (e.g., upper lobe

infiltrate with or without cavity formation), should be considered TB until proven otherwise.

It has been estimated that when using standard concentrating techniques, approximately 10,000 AFB per milliliter of sputum are required to be detected by

routine microscopy. Patients with extensive disease shed large numbers of mycobacteria, with a good correlation between a positive AFB smear and a positive mycobacterial culture. Many patients have minimal or less-advanced disease, and the correlation of positive smears to positive cultures in this group may be only 25% to 40%.

Smears stained for AFB are also useful in following response to treatment. After antimycobacterial drugs are started, cultures may become negative before the smears, suggesting that the organisms are not viable but still are capable of binding the stain. With continued treatment, more organisms are killed and fewer shed, so assessing the number of organisms in the sputum during treatment can provide an early objective measure of response. Should the number of organisms fail to decrease after therapy is started, the possibility of drug resistance must be considered, and additional specimens for culture and susceptibility studies should be obtained.

Two types of acid-fast stains are commonly used (Table 19-3):

1. Fluorochrome stain: auramine O, with or without a second fluorochrome, rhodamine
2. Carbolfuchsin stains: a mixture of fuchsin with phenol (carbolic acid)
   a. Ziehl–Neelsen (hot stain)
   b. Kinyoun (cold stain)

The carbolfuchsin and auramine O dyes used in these techniques each function by binding to mycolic acids in the mycobacterial cell wall. Smears stained with the carbolfuchsin technique must be scanned with an oil-immersion objective. This limits the total area of a slide that can be viewed in a given unit of time. In contrast to the carbolfuchsin stains, smears stained by the auramine procedure can be scanned with a 25× objective, thereby increasing the field of view and reducing the time needed to scan a given area of the slide. Fluorochrome-stained smears require a strong light source—either a 1200-W mercury vapor burner or a strong blue light with a fluorescein isothiocyanate (FITC) filter.

Fluorochrome-stained bacteria are bright yellow or orange-red against a dark background, allowing the slide to be scanned under lower magnification without losing sensitivity. The sharp contrast between the brightly colored mycobacteria and the dark background offers a distinct advantage in scanning the slide (Image Plate 19-1A). Modifications of the auramine fluorochrome stain include the addition of rhodamine, giving a golden appearance to the cells, or the use of acridine orange as a counterstain, resulting in a red to orange background. False-positive reactions may be due to

fluorescence of nonspecific tissue or cellular debris that can be mistaken for bacilli

with the 25× objective. The 40× objective should be used to confirm any suspicious forms. Dead mycobacterial cells will also stain with rhodamine and auramine, leading to a smear-positive, culture-negative situation. This feature is also important to remember when using acid-fast smears to assess treatment efficacy—the presence of AFB in fluorochrome-stained smears does not necessarily indicate treatment failure. Fluorochrome-stained smears can be stained subsequently with carbolfuchsin; the opposite situation does not apply.

TABLE 19-3 Acid-Fast-Staining Procedure

Ziehl–Neelsen Procedure	Kinyoun Cold Procedure	Auramine Fluorochrome Procedure
Carbolfuchsin: Dissolve 3 g of basic fuchsin in 10 mL of 90%–95%ethanol. Add 90 mL of 5% aqueous solution of phenol.	**Carbolfuchsin:** Dissolve 4 g of basic fuchsin in 20 mL of 90%–95% ethanol and then add 100 mL of a 9% aqueous solution of phenol (9 g of phenol dissolved in 100 mL of distilled water).	**Phenolic auramine:** Dissolve 0.1 g of auramine O in 10 mL of 90%–95% ethanol and then add to a solution of 3 g of phenol in 87 mL of distilled water. Store the stain in a brown bottle.
Acid–alcohol: Add 3 mL of concentrated HCl *slowly* to 97 mL of 90%–95% ethanol, in this order. Solution may get hot!	**Acid–alcohol:** Add 3 mL of concentrated HCl *slowly* to 97 mL of 90%–95% ethanol, in this order. Solution may get hot!	**Acid–alcohol:** Add 0.5 mL of concentrated HCl to 100 mL of 79%alcohol.
Methylene blue counterstain: Dissolve 0.3 g of methylene blue chloride in 100 mL of distilled water.	**Methylene blue counterstain:** Dissolve 0.3 g of methylene blue chloride in 100 mL of distilled water.	**Potassium permanganate:** Dissolve 0.5 g potassium permanganate in 100 mL of distilled water.
Procedure Cover a heat-fixed, dried smear with a small rectangle (2 × 3 cm) of filter paper. Apply 5–7 drops of		

carbolfuchsin stain to thoroughly moistened filter paper.
Heat the stain-covered slide to steaming, but do not allow to dry. Heating may be done by gas burner or over an electric staining rack.
Remove paper with forceps, rinse slide with water, and drain.
Decolorize with acid–alcohol until no more stain appears in the washing (2 minutes).
Counterstain with methylene blue (1–2 minutes).
Rinse, drain, and air dry (1–2 minutes).
Examine with 100× oil-immersion objective. Mycobacteria are stained red and the background is light blue.

Procedure
Cover a heat-fixed, dried smear with a small rectangle (2 × 3 cm) of filter paper.
Apply 5–7 drops of carbolfuchsin stain to thoroughly moisten filter paper. Allow to stand for 5 minutes. Add more stain if paper dries. Do not steam!
Remove paper with forceps, rinse slide with water, and drain.
Decolorize with acid–alcohol until no more stain appears in the washing (2 minutes).
Counterstain with methylene blue (1–2 minutes).
Rinse, drain, and air dry (1–2 minutes).
Examine with 100× oil-immersion objective. Mycobacteria are stained red and the background is light blue.

Procedure
Cover a heat-fixed, dried smear with carbol auramine and allow to stain for 15 minutes. Do not heat or cover with filter paper.
Rinse with water and drain.
Decolorize with acid–alcohol (2 minutes).
Rinse with water and drain.
Flood smear with potassium permanganate for at least 2 and not more than 4 minutes.
Rinse with tap water. Drain.
Examine with 25× objective using a mercury vapor burner and BG-12 filter or a strong blue light.
Mycobacteria are stained yellow-orange against a dark background.

With carbolfuchsin, the AFB stain bright red against either a blue or a green background, depending on the counterstain used (Image Plate 19-1B). Although the Ziehl–Neelsen and the Kinyoun techniques are theoretically the same, it has been the experience of some that the former is more sensitive in detecting lightly staining organisms, particularly some of the rapidly growing mycobacteria. The property of acid-fastness is due to the thick, waxy capsule that surrounds the mycobacterial cells. For aqueous carbolfuchsin to penetrate through the wax, the capsule must be "softened." This is done with heat in the Ziehl–Neelsen procedure, much like the melting of a paraffin film in the hot rays of the sun. Dye that penetrates the heat-softened cell wall binds to the mycolic acids; then, when the bacteria cells cool after the heat is removed, the wax again hardens, protecting the bound dye from the action of the acid–alcohol decolorizer ("acid-fast"). In the Kinyoun, or "cold" technique, a

surface-active agent is used to increase permeability of the dye through the waxy capsule; however, the re-formation of the waxy film may be incomplete, allowing most, if not all, of the bound dye to be extracted by the acid–alcohol decolorizer. Obviously, mycobacterial cells that are endowed with a thin waxy capsule will be more susceptible to decolorization, as may be the situation with many rapidly growing strains. The carbolfuchsin-based procedure is described in Chart 19-2.

One potential drawback of the fluorochrome stains is lower sensitivity for detection of rapid growers. Uribe-Botero et al.,[330] who used Truant's auramine–rhodamine staining of routinely processed bone marrow aspirates and biopsies, describe considerable success in the detection of mycobacteria with this method. In this study, 51 bone marrow specimens from 47 HIV-positive patients were studied and mycobacteria were detected in 72%. If the fluorescent stain was positive, the positive predictive value for culturing mycobacteria was 87%. McCarter and Robinson studied 782 primary sputum smears evaluated blindly by the rhodamine–auramine method both at room temperature and at 37°C, and found that the preparation stained at room temperature detected only 85.7% of the positive smears; 43.3% of the smears had more AFB in the 37°C stained smears, compared with only 13.3% more AFB in the room temperature–stained smears.[199] They concluded that staining at 37°C with this method enhances the detection of AFB. Regarding smears made from cytocentrifugation versus traditional NALC–NaOH concentration, Woods and coworkers[369] found no increase in the detection of AFB in 844 auramine O–stained cytocentrifuged sputum smears when compared with the traditional NALC–NaOH concentration method.

The fluorochrome stain offers the advantage of greater sensitivity compared with the carbolfuchsin method, since a significantly larger area of the smear can be scanned per unit of time with the fluorochrome stain. Some workers use the fluorochrome method for scanning purposes and then confirm their findings by reexamining the preparation after destaining and restaining with the carbolfuchsin method, but as previously stated, this is not required. The introduction of relatively low-cost blue light illuminators has made fluorescence microscopy available to clinical laboratories where the detection and recovery of mycobacteria is offered as a service.[250] In laboratories where expensive illuminators may not be affordable, use of the ultraviolet (UV) ParaLens adapter (Becton Dickinson, Sparks, MD), a lightweight, portable, inexpensive epi-illuminator, offers an alternative possibility. Patterson and associates[232] found a comparable sensitivity and specificity in the detection of fluorescing AFB using the UV ParaLens adapter when compared with Kinyoun-stained smears.

The recommendations of the American Lung Association for reporting mycobacteria seen on acid-fast-stained smears, listed in Table 19-4, are followed by many laboratories to

provide consistency of observations between technologists in a given laboratory and uniformity of reporting from one laboratory to another. A summary of the carbolfuchsin-based and fluorescent techniques for the staining of mycobacteria can be found in Charts 19-2 and 19-3.

TABLE 19-4 Method for Reporting Numbers of Acid-Fast Bacilli Observed in Stained Smears[a]

Number of Bacilli Observed	CDC Method	Report
0	Negative	–
1–2/300 fields	Number seen[b]	±
1–9/100 fields	Average no./100 fields	1+
1–9/10 fields	Average no./10 fields	2+
1–9/field	Average no./field	3+
More than 9/field	More than 9/field	4+

[a] Examination at 800× to 1,000× is assumed. Magnifications less than 800× should be clearly stated. If a microscopist uses a consistent procedure for smear examination, relative comparisons of multiple specimens should be easy for the clinician, regardless of the magnification used. To equate numbers of bacilli observed at less than 800× with those seen under an oil-immersion objective, adjust counts as follows: for magnifications about 650×, divide count by 2; near 450×, divide by 4; near 250×, divide by 10; e.g., if 8 bacilli per 10 fields were seen at 450×, the count at 1,000× would be equivalent to about 2/10 fields (8 ÷ 4).

[b] Counts less than 3/3,000 fields at 800× to 1,000× are not considered positive; another specimen (or repeat smear of same specimen) should be processed if available.

Mycobacterial Culture of Specimens Using Solid

Media

The recovery of mycobacteria from agar culture media was poor when the first attempts were made late in the 19th century. Through experimentation it was found that a culture medium containing whole eggs, potato flour, glycerol, and salts solidified by heating to 85°C to 90°C for 30 to 45 minutes was effective in isolating *M. tuberculosis*. The process of solidifying protein-containing medium by heat is known as inspissation. An inspissated culture medium is more subject to liquefaction from the effects of proteolytic enzymes produced by contaminating bacteria than a medium solidified by the addition of agar. However, it was soon discovered that the use of aniline dyes, such as malachite green or crystal violet, in the inspissated medium helped control contaminating bacteria. The concentration of dye must be carefully controlled; if the concentration is too high, the growth of mycobacteria may also be inhibited along with the contaminating bacteria. Malachite green is the dye most commonly incorporated into nonselective culture media, in varying concentrations (Table 19-5).

Egg-Based Media

Egg-based culture media for the recovery of mycobacteria are listed in Table 19-5. LJ medium is commonly used in many clinical diagnostic laboratories; it is less inhibitory to the growth of mycobacteria than is Petragnani medium, which is used primarily to recover mycobacteria from specimens heavily contaminated with bacteria. Conversely, the American Thoracic Society (ATS) medium, which contains only 0.02 g/100 mL of malachite green, is less inhibitory to the growth of mycobacteria.

Agar-Based Media

During the 1950s, Cohen and Middlebrook developed a series of defined culture media for use in both research and clinical laboratories. These media were prepared from defined salts and organic chemicals; some contained agar, but all were found to require the addition of albumin for optimal growth of mycobacteria. The Middlebrook media that contain agar are transparent and in general allow earlier detection of mycobacterial growth compared with other media. This is partly due to the inclusion of biotin and catalase to stimulate revival of damaged bacilli in clinical specimens. Albumin is also incorporated to bind toxic amounts of oleate and other compounds that might be released from spontaneous hydrolysis of Tween 80. The albumin does not appear to be metabolized by the bacilli.

Middlebrook culture media used today include 7H9 broth and 7H10 and 7H11 agar media, which are used for isolation and susceptibility testing.[367] 7H11 differs from 7H10 only in containing 0.1% casein hydrolysate, an additive that improves the rate

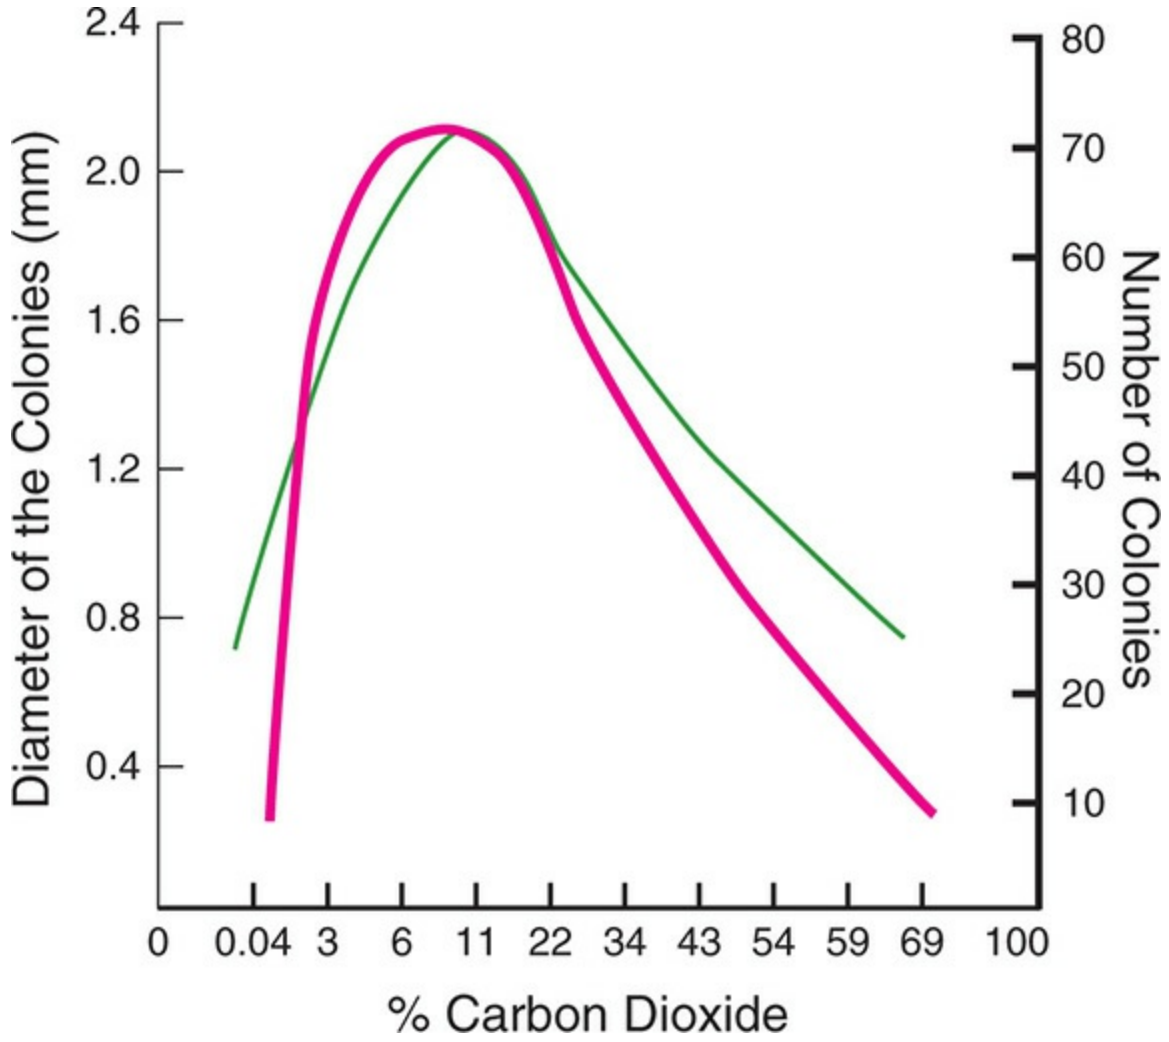
and amount of growth of mycobacteria resistant to isoniazid (INH).[54] Both 7H10 and 7H11 contain malachite green but at one-tenth the quantity usually used in egg-based media, explaining in part the higher incidence of contamination than on egg-based media.

One other advantage of the use of Middlebrook agar is that experienced mycobacteriologists can often make a presumptive identification of *M. tuberculosis* and other groups of mycobacteria within 10 days by examining early microcolonies on the agar and observing certain well-defined morphologic features.[277] Photomicrographs of representative microcolonies are illustrated in Image Plate 19-1C (*M. tuberculosis*) and Image Plate 19-2A and 2B (*M. avium* complex).

Although essentially all culture media yield more growth and larger colonies of mycobacteria when incubated in 5% to 10% CO_2, the Middlebrook media absolutely require capneic incubation for proper performance (Fig. 19-1). Exposure of 7H10 and 7H11 to strong light, or storage of the media at 4°C for more than 4 weeks may result in deterioration and release of formaldehyde, a chemical very inhibitory to mycobacteria.[211]

TABLE 19-5 Nonselective Mycobacterial Isolation Media

Medium	Components	Inhibitory Agent	Medium	Components	Inhibitory Agent
Löwenstein–Jensen	Coagulated whole eggs, defined salts, glycerol, potato flour	Malachite green, 0.0025 g/100 mL	Middlebrook 7H10	Defined salts, vitamins, cofactors, oleic acid, albumin, catalase, glycerol, dextrose	Malachite green, 0.025 g/100 mL
Petragnani	Coagulated whole eggs, egg yolks, whole milk, potato, potato flour, glycerol	Malachite green, 0.052 g/100 mL	Middlebrook 7H11	Defined salts, vitamins, cofactors, oleic acid, albumin, catalase, glycerol, 0.1% casein hydrolysate	Malachite green, 0.0025 g/100 mL
American Thoracic Society medium	Coagulated fresh egg yolks, potato flour, glycerol	Malachite green, 0.02 g/100 mL			



■ **FIGURE 19-1** Effect of CO_2 on the growth (colony size and number of colonies) of *M. tuberculosis* after primary isolation from sputum. (Redrawn from David HL. Bacteriology of the mycobacterioses. DHEW Publication No. [CDC] 76-8316, Atlanta, GA: Centers for Disease Control and Prevention, Mycobacteriology Branch, 1976.)

Selective Media

Culture media containing antimicrobial agents are used to suppress bacterial and fungal contamination, and their use can improve recovery of mycobacteria. Although certain antimicrobial agents are known to reduce contamination, they may also inhibit the growth of mycobacteria. Therefore, the times of exposure must be carefully controlled. Table 19-6 lists the names and components of several selective media.

The selective medium described by Gruft consists of LJ medium with penicillin, nalidixic acid, and RNA.[110] Petran subsequently described a selective medium containing cycloheximide, lincomycin and nalidixic acid to control fungal and bacterial

contaminants.[238] By varying the concentrations of these agents, the medium can be prepared with either LJ or 7H10 base.

Selective 7H11 is a modification of an oleic acid agar medium first described by Mitchison.[213] The medium was originally designed for use with sputum specimens without the use of a decontaminating agent. Mitchison's medium contains carbenicillin, polymyxin, trimethoprim lactate, and amphotericin B. McClatchy suggested reducing the concentration of carbenicillin from 100 mg/mL to 50 mg/mL and using 7H11 medium instead of oleic acid agar.[200] He called this modification selective 7H11, or S7H11. With the use of S7H11 medium with LJ and 7H11, recovery of mycobacteria is improved, particularly when the S7H11 medium is used with the NALC–1% NaOH decontamination procedure.

Incubation Temperature

Different species of mycobacteria show dependence on the temperature of incubation for optimal growth. Species having a propensity for infecting skin (such as the rapidly growing mycobacteria, *M. marinum*, *M. ulcerans,* and *M. haemophilum*) grow best at the temperature of the skin (30°C to 32°C). *M. tuberculosis* grows best at 37°C and poorly or not at all at 30°C or 42°C to 45°C (the body temperature of birds). *Mycobacterium xenopi*, a species not commonly found as a cause of infection in humans, grows best at 42°C and has been implicated as an environmental contaminant in the hot water system of a large hospital.[109]

Optimal recovery of different mycobacterial species depends on the incubation of at least part of the concentrated specimen at a temperature most likely to promote growth of that species. An incubator set at 30°C to 32°C should be used for all specimens from skin or subcutaneous lesions. If a 30°C to 32°C incubator is not available, the specimens can be held in a temperature-monitored, closed box placed in a sheltered area away from warm or cool drafts. The temperature in the box should be between 24°C and 25°C and recorded daily. An incubator maintained at 42°C can be helpful in recovering *M. xenopi*, although this organism will grow at 37°C.

Mycobacteria grow best in an atmosphere of 3% to 11% CO_2. Use of CO_2 is mandatory if Middlebrook 7H11 medium is used. However, if lack of incubator space to maintain cultures is a problem, cultures can be removed from the CO_2 atmosphere after 7 to 10 days, for organisms will be in a log

phase of growth and are less dependent on CO_2. For reasons that are not well understood, mycobacteria do not grow well in candle extinction jars. The CO_2 concentration in incubators should be monitored daily and a record kept of both the

incubator temperature and the CO_2 level.

TABLE 19-6 Selective Mycobacterial Isolation Media

Medium	Components	Inhibitory Agent	Medium	Components	Inhibitory Agent
Gruft modification of Löwenstein–Jensen	Coagulated whole eggs, defined salts, glycerol, potato flour, RNA, 5 mg/100 mL	Malachite green, 0.025 g/100 mL Penicillin, 50 U/mL Nalidixic acid, 35 mg/mL	Middlebrook 7H10	Defined salts, vitamins, cofactors, oleic acid, albumin, catalase, glycerol, glucose	Malachite green, 0.0025 g/100 mL Cycloheximide, 360 μg/mL Lincomycin, 2 μg/mL Nalidixic acid, 20 μg/mL
Löwenstein–Jensen	Coagulated whole eggs, defined salts, glycerol, potato flour	Malachite green, 0.025 g/100 mL Cycloheximide, 400 μg/mL Lincomycin, 2 μg/mL Nalidixic acid, 35 μg/mL	Selective 7H11 (Mitchison's medium)	Defined salts, vitamins, cofactors, oleic acid, albumin, catalase, glycerol, glucose, casein hydrolysate	Carbenicillin, 50 μg/mL Amphotericin B, 10 μg/mL Polymyxin B, 200 U/mL Trimethoprim lactate, 20 μg/mL

Rapid Methods for Establishing a Diagnosis

Smears for Acid-Fast Bacilli

One of the more practical and readily available methods to shorten the time to diagnosis of TB is to increase the RCF applied to clinical specimens to improve the sedimentation of the lipid-laden mycobacterial cells.[266] The improved correlation of positive smears to positive cultures has made the examination of a smear stained for AFB somewhat more reliable as an index of mycobacterial infection. Lipsky, in a review of factors affecting the clinical value of microscopy for AFB, concluded that when the results of all specimens from each patient are considered in total, the acid-fast smear has a high predictive value and remains one of the most rapidly performed tests in the detection of mycobacterial infections.[188]

Broth Culture Systems

For optimal recovery of mycobacteria, inoculation of both a broth system and a solid medium is recommended.[317] Broth systems are more sensitive than solid media, and they allow for more rapid growth. The first broth-based system for growth and detection of mycobacteria was the semiautomated radiometric BACTEC TB460. Many studies have shown that compared to conventional solid culture media, the BACTEC TB460 is more sensitive (i.e., results in recovery of more mycobacteria) and decreases time to detection of growth by several days.[13,35,65,66,82,216,268,290] The BACTEC TB460 also could differentiate MTBC from nontuberculous mycobacteria (NTM) using *p*-nitro-α-acetylamino-β-hydroxy-propiophenone, which inhibits growth

of MTBC organisms.[108] Disadvantages of this system are the use of needles, with the potential to cause cross-contamination,[58,219] and the need to dispose of radioactive material. Because the manufacturer no longer supports the BACTEC TB460, it is not discussed further. Virtually all laboratories that used the BACTEC TB460 have replaced it with one of the fully automated, nonradiometric broth systems described below.

Mycobacteria Growth Indicator Tube Systems. The Mycobacteria Growth Indicator Tube (MGIT) (BD Diagnostic) is a round-bottomed glass tube that contains modified Middlebrook 7H9 broth base. A fluorescent compound is embedded in silicone on the bottom of the tube. The fluorescent compound is sensitive to dissolved oxygen in the broth; that is, the presence of oxygen in the uninoculated medium serves to quench the emission of fluorescent light. As the actively growing mycobacteria consume the dissolved oxygen, the fluorescence is unmasked and can be detected manually by observing the tube under long-wave UV light (Wood's lamp). Growth may also be detected by observing a nonhomogeneous turbidity or small grains or flakes in the culture medium.

The MGIT system can be used to culture all specimen types except blood and urine. For optimal performance, OADC (oleic acid, albumin, dextrose, and catalase) growth supplement and an antibiotic mixture (PANTA: polymyxin B, amphotericin B, nalidixic acid, trimethoprim, and azlocillin) are added to the broth. The antibiotic mixture inhibits the growth of contaminating bacteria. The OADC supplement provides oleic acid, an important metabolic stimulant for mycobacteria; albumin, to bind toxic free fatty acids; dextrose, as an energy source; and catalase, to destroy toxic peroxides that may be present in the medium. After adding the Supplement/PANTA mixture, the tube is inoculated with 0.5 mL of specimen or specimen concentrate; adding more than 0.5 mL of specimen may adversely affect the performance of the tube. The cap is replaced, and the ingredients are mixed by inverting the tube several times. For manual reading, tubes are placed in a 37°C incubator, and are read every other day starting on the second day after inoculation. Tubes are read with a Wood's lamp, placing the tube with the test mixture between a positive (sodium sulfite solution) and a negative (uninoculated MGIT tube) control. UV protective goggles are worn while looking for a bright orange color in the bottom of the positive tubes; an orange reflection is also seen at the meniscus. Positive tubes are stained for AFB, preferably using a carbol fuchsin method. Negative tubes are returned to the incubation rack and again observed at regular intervals for up to 6 weeks.

Hanna and coworkers[117] used the MGIT system to test 193 specimens (44 patients) from various body sites for the presence of *Mycobacterium* species. Sputum concentrations from 32 patients from whom at least one positive acid-fast smear was seen were studied. The MGIT cultures were positive in 31 (MTBC, 25; MAC, 4; and

M. haemophilum, 2) patients. MGIT tubes were positive for an additional three smear-negative patients; the one false-negative MGIT test occurred in a patient with very few AFB seen on smear. The mean time to detection was 10.4 days (range, 4 to 26). The two *M. haemophilum* isolates were recovered by adding an X (hemin) disk to the MGIT tube and incubating at 30°C.

Rather than read the tubes manually, tubes may be placed in an instrument, either the MGIT 960 or 320. Both instruments are nonradiometric, automated systems that use the MGIT tubes and sensors to detect the fluorescence that is visually interpreted in the manual version described above. The system holds 960 (or 320) plastic tubes, which are continuously monitored. The performance characteristics have been shown in several studies to be comparable to those of the BACTEC TB460 and/or other automated systems.[64,117,118,130,183,230,248,272,323,354,355]

MB/BacT ALERT Mycobacteria Detection System. The MB/BacT ALERT is an automated system to detect growth of mycobacteria, similar in design to the BacT/Alert blood culture system. The MB/BacT bottles contain enhanced Middlebrook 7H9 broth in an atmosphere of CO_2, nitrogen and oxygen under vacuum. This bottle therefore provides suitable nutritional and environmental conditions to recover the more commonly encountered *Mycobacterium* species from clinical specimens other than blood. An antibiotic

supplement, containing amphotericin B, azlocillin, nalidixic acid, polymyxin B, trimethoprim and proprietary growth factors, is added to each bottle just before use to enhance the growth of *Mycobacterium* species and curtail the growth of contaminating bacteria that may survive the decontamination and concentration procedure. The bottom of each broth bottle is fitted with a gas-permeable sensor that changes from dark green to bright yellow when CO_2 is produced in the broth by metabolizing mycobacteria. Bottles are placed bottom down within individual cells in the incubation chamber, and reflected light is used to continuously monitor the production of microbial-generated CO_2.

As with the MGIT 960, the performance characteristics of the MB/BacT ALERT are superior to solid media alone[98] and comparable to the BACTEC TB460 and/or other fully automated growth and detection systems.[65,230,246]

VersaTREK (Formerly ESP Culture System II). The VersaTREK System (Thermo Scientific) is an adaptation of their blood culture system. Each culture bottle, when placed in a special drawer in the incubation module, is attached to a sensor, consisting of a plastic housing, a recessed needle, and a hydrophobic membrane. Thus, each

bottle is continuously monitored (every 24 minutes) for any change in gas pressure due to the metabolic activity of microorganisms in the culture bottle. Significant pressure change is signaled based on the rate of consumption of oxygen within the head space of the culture bottle by the metabolizing microorganisms.

The bottles contain a liquid culture medium (VersaTREK Myco Broth), a growth supplement, an antibiotic supplement and cellulose sponges. The sponges provide a growth platform for the mycobacteria, simulating the alveoli of the lungs.

Early studies showed that the ESP MYCO System was an acceptable option for growth and detection of mycobacteria from all specimen types, including blood.[319,368] Later, Williams-Bouyer et al.[359] compared the ESP Culture System II with the BACTEC MGIT 960 and Middlebrook 7H11 and 7H11 selective agar, examining a total of 3,151 specimens. The recovery rates for all mycobacteria were 71.2% for the ESP II, 63.9% for the MGIT 960, and 61.8% for the Middlebrook media. However, with the exclusion of *M. gordonae*, the recovery rates for the remaining mycobacteria were 70.2%, 72.6%, and 66.3%, respectively. These differences were not statistically significant.

For isolates recovered in both automated systems, the mean times to detection of all mycobacteria and members of the *M. tuberculosis* complex, respectively, were 15.8 and 17.4 days for ESP II and 12.5 and 11.9 days for BACTEC MGIT 960 ($P < 0.05$). False-positive signals occurred less frequently with the BACTEC MGIT 960 cultures (23 [0.7%]) compared with the ESP II cultures (84 [2.7%]) ($p < 0.01$).

BACTEC MYCO/F LYTIC. The BACTEC MYCO/F LYTIC blood culture bottle contains a lytic agent to release the mycobacteria that have been phagocytosed by white blood cells. It is incubated and monitored automatically in a manner similar to the other BACTEC blood culture bottles. In addition to growing mycobacteria, the BACTEC MYCO/F LYTIC is a good culture system for bacteria and fungi that may be present in the bloodstream.[93,335] In a direct comparison of many of the commercially available products, Crump et al.[65] evaluated the performance of the BACTEC 13A (BD Diagnostic), BACTEC MYCO/F LYTIC (BD Diagnostic), BacT/ALERT MB (bioMérieux), and ISOLATOR 10 lysis-centrifugation (Wampole Laboratories) systems for detection of mycobacteremia in adults. Of 600 patients tested, 85 (14%) yielded MAC and 9 (2%) yielded other species of mycobacteria. Of 26 complete (three bottles and one tube) and adequately filled (5 ± 1 mL) sets from which MAC was recovered, BACTEC 13A was positive for 19 (73%), BACTEC MYCO/F LYTIC was positive for 21 (81%), BacT/ALERT MB was positive for 22 (85%), and ISOLATOR 10 was positive for 21 (81%). Of the six possible two-way comparisons, the mean times to detection for the recovery of MAC from each bottle in adequately paired sets were 15.3 days for BACTEC 13A versus 12.8 days for MYCO/F LYTIC for 33 of 340 pairs, 14.1 days for BACTEC 13A versus 11.6 days

for BacT/ALERT MB for 38 of 380 pairs, 12.6 days for BACTEC 13A versus 20.0 days for ISOLATOR 10 for 26 of 261 pairs, 12.8 days for BACTEC MYCO/F LYTIC versus 11.0 days for BacT/ALERT MB for 33 of 340 pairs, 13.2 days for BACTEC MYCO/F LYTIC versus 20.4 days for ISOLATOR 10 for 24 of 230 pairs, and 9.9 days for BacT/ALERT MB versus 19.0 days for ISOLATOR 10 for 24 of 257 pairs. There were no significant differences in yields between the systems. However, there were differences in the mean times to detection among the systems. The time to detection was shortest for BacT/ALERT MB, followed by BACTEC MYCO/F LYTIC and BACTEC 13A and then ISOLATOR 10. They found the continuously monitored systems (BACTEC MYCO/F LYTIC and BacT/ALERT MB) to be as sensitive and, on balance, faster for the detection of MAC bacteremia than the standard manual ISOLATOR 10 and radiometric BACTEC 13A systems. Others have also found this method to be superior to traditional methods.[196]

Gas-Liquid and High-Performance Liquid Chromatography

Analysis of cellular long-chain fatty acids by gas-liquid chromatography (GLC) has been used to aid in the characterization of mycobacteria. The pyrolysis gas-liquid method of Reiner, in which long-chain mycolic acids are split into characteristic cleavage products, is largely restricted to research laboratories.[263] Tisdall has developed a GLC procedure for saponifying organisms in methanolic NaOH that permits the correct identification of most mycobacterial species based on chromatogram tracings and colony characteristics.[320] Guerrant and associates[111] have used acid methanolysis for isolating mycolic acid methyl esters from bacterial cells, a method that is not only less time-consuming than saponification techniques but is also more sensitive in detecting small numbers of cells. As little as a 1-mm loopful of organisms can be used, and the total time for analysis is less than 2 hours.

The FDA-cleared commercial system, the MIDI Sherlock Microbial Identification System (Microbial ID, Newark, DE), consisting of an 1100 HPLC and a computer is a rapid and reliable method for the culture confirmation of mycobacteria. The computer system includes a library of 40 cell wall lipid profiles for the most medically important *Mycobacterium*

species, derived from isolates acquired from the American Type Culture Collection (ATCC) and including numerous clinical isolates. The use of negative-ion mass spectrometry to detect tuberculostearic acid in clinical specimens also holds promise for the rapid detection of mycobacteria in such specimens for those equipped with the necessary instruments.[177]

High-performance liquid chromatography utilizing fluorescence detection (HPLC-FL) of mycolic acid 6,7-dimethoxycoumarin esters has been used for the rapid identification of *M. tuberculosis* and *M. avium* directly from fluorochrome-stained, smear-positive sputum specimens and BACTEC 12B cultures with early growth. In a study of 132 sputum specimens positive for *M. tuberculosis* and 48 positive for MAC, HPLC-FL made direct identifications with sensitivities of 56.8% and 33.3%, respectively.[147]When using HPLC-FL to test cultures grown in BACTEC 12B bottles, sensitivities of 99.0% and 94.3% were achieved. The specificity was 100% in both evaluations. Cage also successfully identified to the species level 117 of 126 (93%) mycobacteria grown in BACTEC 12B medium supplemented with oleic acid.[37] Glickman and colleagues[100] describe a computer-based file that contained the patterns of mycolic acids characteristic of 45 species of *Mycobacterium*. By using their system in the evaluation of 1,333 strains representing 24 *Mycobacterium* species, 97% were correctly identified (identification of *M. tuberculosis* was 99.85% accurate; of MAC, 98% accurate). Thus, for those possessing the equipment and using computer-based pattern recognition files, mycobacteria can be identified accurately and rapidly using HPLC-generated chromatographic data. These systems are in direct competition with nucleic acid-based methods for the rapid identification of mycobacteria.

Nucleic Acid Amplification

Nucleic acid amplification tests (NAATs) for direct detection of MTBC in clinical specimens became commercially available in the mid-to-late 1990s.[62] These assays, which are discussed in detail later in this chapter, have added considerable value to mycobacterial testing. Positive results allow earlier diagnosis and treatment of TB, a decreased period of infectiousness and better outcomes; negative results can eliminate unnecessary contact investigations. However, these assays have limitations, so results must be interpreted with caution. Their sensitivity is less than culture, so a negative result does not exclude the diagnosis of TB; false-positive results are possible; and they are an added laboratory cost.

The Centers for Disease Control and Prevention (CDC) has issued the following recommendations on the uses of NAATs for diagnosis of TB. All clinicians and TB control programs should have access to an NAAT for direct detection of MTBC, and these assays should become the standard of practice for patients with suspected TB. An NAAT should be performed on at least one respiratory specimen from each TB suspect, because a single positive result can support the diagnosis of TB, and all specimens with negative results should be tested for inhibitors. The time from specimen collection to NAAT report should be as brief as possible, preferably within 48 hours, and laboratories performing one of these assays should participate in a proficiency testing program.

Identification of Mycobacteria Using Conventional Methods

Although the applications of molecular techniques are currently the standard for the identification of cultured mycobacteria, conventional methods remain useful and are discussed briefly here. Charts 19-1 through 19-15 provide a detailed presentation of the principles, reagents, procedures, and interpretation of various laboratory techniques, including digestion–decontamination methods, and biochemical tests (included in Table 19-7). The use of molecular assays, including nucleic acid probe analysis, is covered separately.

Optimal Temperature for Isolation and Rates of Growth

Each *Mycobacterium* species has an optimal temperature for growth and a range of time for recovery in culture (Table 19-7). The time to recovery varies depending on the type of media used—the average time of recovery of mycobacteria on egg-based media is about 21 days, but ranges from as short as 3 to 5 days to as long as 60 days, depending on the species and the quantity of mycobacteria in the specimen. The time to recovery on solid media is generally shorter by several days when using 7H10 or 7H11 agar if the technique of microscopic observation for microcolonies is used (described below). The use of broth-based culture shortens the times of detection considerably.[66,160,268]

Any standard nonselective culture medium can be used when assessing the time of growth, either in tubed slants or in Petri plates. A well-isolated colony of the test organism is subcultured to 7H9 broth containing Tween 80 and incubated for several days or until the medium is slightly turbid. The broth is diluted 1:100, and isolation streaks are made to the test medium, either in tubed slants or on Petri plates, to obtain isolated colonies. To determine the growth rate accurately, it is necessary to use an inoculum sufficiently diluted to produce individual colonies. An inoculum of large numbers of slow-growing mycobacteria may form a visible colony within a few days and give an erroneous impression of the growth rate. *M. tuberculosis* stock cultures of known growth rates should be used as a control for slow-growing organisms; similarly, stock cultures of *M. fortuitum* can be used as a control comparison for rapidly growing organisms.

Petri plates of 7H10 agar or equivalent are preferred to the use of tubed media because the appearance of developing microcolonies can be studied with a dissecting or low-power microscope. With experience, an assessment of the morphology of these microcolonies can be useful in the exclusion of certain mycobacteria, and potentially the preliminary classification of others. Runyon published guidelines by which the microcolonies of various species of mycobacteria can be distinguished by those who

have gained experience with this approach.[277]

Koneman and associates in the clinical microbiology laboratory at the University of Illinois, Chicago, were able to detect the microcolonies of 29 smear-positive clinical sputum isolates of *Mycobacterium* species growing on 7H10 agar in an average of 6.1 days (range, 3 to 12) compared with average recovery times using standard visual observations of 32.4 days with LJ medium and 27.9 days with 7H11 agar

1233

(personal communication). The average detection time for these 29 isolates was 5.8 days by the BACTEC system, using radiometric 12B bottles. The results of this study indicate that mycobacteria can be detected by observing for microcolonies in the same shortened time period as that achieved with the BACTEC system. The microcolony method also allows an assessment of colony morphology, providing additional information not provided by the BACTEC system, which is helpful in making an early presumptive characterization of an unknown *Mycobacterium* species. If probes are used for identification, this morphologic data could be used to assist in probe selection. In a study that examined the time to detection, the average time to detection of microcolonies of *M. tuberculosis* was 11 days on Middlebrook 7H11 agar, whereas it was 16 days with the MB/BacT bottles and 19.5 days with the LJ medium.[98]

As noted above, some *Mycobacterium* species, such as *M. marinum* and most of the rapidly growing mycobacteria, grow better at temperatures that are slightly less than core body temperature. This may also be associated with the fact the disease produced by these organisms, particularly *M. marinum*, most commonly affects the extremities, which are slightly cooler than core body temperature. Therefore, laboratories should incubate mycobacterial cultures from specimens that may contain these organisms (e.g., skin biopsies from the extremities) at 30°C to 32°C.

Pigment Production

The determination of whether an unknown *Mycobacterium* species isolate is capable of producing colony pigmentation in the dark (scotochromogen) or only after exposure to light (photochromogen) is not very helpful in making a final species identification, but may be useful in narrowing the possibilities (Chart 19-5). *M. tuberculosis* fails to produce pigment, beyond a light buff color, even after exposure to light. The pigment-producing capabilities of other *Mycobacterium* species are listed in Table 19-7 (Image Plate 19-2C–E).

Niacin Accumulation

All mycobacteria produce niacin; however, only *M. tuberculosis*, *M. simiae,* and

occasional strains of *M. africanum*, *M. bovis*, *M. marinum,* and *M. chelonae* lack the enzyme necessary to further convert the niacin to niacin ribonucleotide. Thus, the determination of whether niacin has accumulated in the culture medium is a valuable differential test in identifying these species of mycobacteria, particularly *M. tuberculosis* (Chart 19-10). Reagent-impregnated filter paper strips have been developed that eliminate the need for using cyanogen bromide, a highly toxic substance, as required in the originally described method for performing this test. The development of a yellow color in the test medium incubated with a reagent strip is indicative of niacin accumulation and a positive test (Image Plate 19-1D). It is essential to have sufficient growth on the primary egg-based medium; otherwise, the risk of obtaining false-negative results is increased.

Reduction of Nitrates to Nitrites

Only a few species of mycobacteria, most notably *M. tuberculosis*, produce nitroreductase, which catalyzes the reduction of nitrate to nitrite. The development of a red color on addition of sulfanilic acid and *N*-naphthyl ethylenediamine to an extract of the isolate to be identified is indicative of the presence of nitrite and a positive test (Chart 19-11). The test must be carefully performed using three control cultures—one known to give a strong positive reaction, one a weak reaction, and the last a negative reaction. In addition to supporting the identification of *M. tuberculosis*, the nitrate reduction test is also a key test in the identification of *M. kansasii* and *M. szulgai* (Table 19-7 and Image Plate 19-1E).

Tween 80 Hydrolysis

Tween 80 is the trade name of a detergent that can be useful in identifying mycobacteria that possess a lipase that splits the compound into oleic acid and polyoxyethylated sorbitol. This test is helpful in identifying *M. kansasii*, which can produce a positive result in as quickly as 3 to 6 hours. Two scotochromogens with similar-appearing colonies, *M. gordonae* (positive) and *M. scrofulaceum* (negative), can be differentiated using the Tween 80 hydrolysis test. The Tween 80 hydrolysis reactions for other mycobacteria are listed in Table 19-7; the test procedure is described in detail in Chart 19-14, and a positive reaction is illustrated in Image Plate 19-2G.

Catalase Activity

Most of the mycobacteria produce catalase; however, not all species are capable of producing a positive reaction after heating the culture at 68°C for 20 minutes (heat-stable catalase). Most strains of *M. tuberculosis* and other members of the MTBC do not produce heat-stable catalase, except for certain INH-resistant strains, for which the

results of this test are of particular value as a possible surrogate marker. Catalase activity is assessed semi-quantitatively by measuring the height achieved by the column of bubbles produced when hydrogen peroxide is added to growing colonies in a tube culture (Chart 19-6). To perform this test, tubes of LJ medium must be poured in an upright position to produce a flat rather than a slanted surface. This surface is heavily inoculated with the test organism and incubated for 14 days before adding the hydrogen peroxide reagent. A column higher than 45 mm is considered a positive test (Image Plate 19-2H). A quick assessment of catalase activity can be determined by placing a few drops of hydrogen peroxide on colonies growing on the surface of Middlebrook 7H10 agar and observing for rapid effervescence of bubbles (Image Plate 19-2I).

Arylsulfatase Activity

Determination of the activity of the enzyme arylsulfatase in mycobacteria is helpful in differentiating the rapidly growing mycobacteria from group III nonphotochromogenic mycobacteria (Image Plate 19-2J). Small quantities of this enzyme can also be produced by *M. marinum*, *M. kansasii*, *M. szulgai,* and *M. xenopi*. These slower-growing species, however, do not produce sufficient enzyme to give a consistently positive reaction. The development of a red color in the test medium, indicating a release of free phenolphthalein, is a positive result (Chart 19-4).

1234

TABLE 19-7 Differential Characteristics of Mycobacteria

	Optimal Isolation Temperature (Time for Growth)	Pigmentation Growth in		Niacin Test	Nitrate Reduction	Tween 80 Hydrolysis—10 Days
		Light	Dark			
M. tuberculosis	37°C (12–25 days)	Buff	Buff	+	+	V
M. africanum	37°C (31–42 days)	Buff	Buff	V	V	–
M. bovis	37°C (24–40 days)	Buff	Buff	V	–	–

M. marinum	30°C (5–14 days)	Yellow	Buff	V	–	+
M. simiae	37°C (7–14 days)	Yellow	Buff	+	–	+/–
M. asiaticum	37°C (10–21 days)	Yellow	Buff	–	–	+
M. szulgai	37°C (12–25 days)	Yellow to orange	Yellow—37°C Buff—25°C	–	+	V
M. scrofulaceum	37°C (10 days)	Yellow	Yellow	–	–	–
M. gordonae	37°C (10 days)	Yellow to orange	Yellow	–	–	+
M. thermoresistible	45°C (7 days)	Yellow	Yellow	–	+	+
M. flavescens	37°C (7–10 days)	Yellow	Yellow	–	+	+
M. xenopi	42°C (14–28 days)	Yellow	Yellow	–	–	–
M. avium complex	37°C (10–21 days)	Buff to pale yellow	Buff to pale yellow	–	–	–
M. haemophilum	30°C (14–21 days)	Gray	Gray	–	–	–
M. malmoense	37°C (21–28 days)	Buff	Buff	–	–	+
M. shimoidei	37°C (14–28 days)	Buff	Buff	–	–	+
M. genavense	37°C (14–28 days)	Buff	Buff	–	–	+
M. celatum	37°C (14–28 days)	Buff	Buff to yellow	–	–	–
M. gasti	37°C (10–21 days)	Buff	Buff	–	–	+
M. terrae complex	37°C (10–21 days)	Buff	Buff	–	V	+
M. triviale	37°C (10–21 days)	Buff	Buff	–	+	+
M. fortuitum	32°C (3–5 days)	Buff	Buff	–	+	V
M. chelonae	28°C (3–5 days)	Buff	Buff	V	–	V
M. abscessus	32°C (3–5 days)	Buff	Buff	–	–	V
M. smegmatis	32°C (3–5 days)	yellow	yellow	–	+	+

+, positive; –, negative; V, variable; blank spaces, little or no data.

Urease Activity

Assessment of urease activity is an important test to differentiate *M. scrofulaceum* (positive) from *M. gordonae* (negative). It is also useful in differentiating *M. gastri* (positive) from other members of the group III nonchromogenic mycobacteria (Table 19-7). Determination of whether any given *Mycobacterium* species can produce urease can be performed either by inoculating the organism into distilled water containing a urea-base concentrate or by use of filter paper disks containing urea that are added to distilled water. Details of the urease test as applied to the identification of *Mycobacterium* species are presented in Chart 19-15 (Image Plate 19-2K).

Pyrazinamidase

The test for pyrazinamidase is especially useful in distinguishing weakly niacin-positive *M. bovis* from *M. tuberculosis*, although many other mycobacteria are positive (Table 19-7). Pyrazinamidase is an enzyme that deaminates pyrazinamide

Species	OX	CAT	Growth			Acid produced from:					Polysaccharide from sucrose	Reduction of:		DNase	Tributyrin hydrolysis	Habitat

(PZA) to form pyrazinoic acid, which produces a red band in the culture medium.[345] Details of this test are presented in Chart 19-12, and the end reaction is illustrated in Image Plate 19-2L.

Iron Uptake

The rapidly growing mycobacteria have many similarities. The ability of *M. fortuitum* to take up soluble iron salts from the culture medium and to produce a rusty brown appearance on addition of an aqueous solution of 20% ferric ammonium citrate is a useful characteristic that differentiates this organism from species in the *M. chelonae/M. abscessus* group, which lack this property (Chart 19-9).

Growth Inhibition by Thiophene-2-Carboxylic Acid Hydrazide

Thiophene-2-carboxylic acid hydrazide (T2H) selectively inhibits the growth of *M. bovis*, whereas most other

mycobacteria, including *M. tuberculosis*, can grow in a medium containing this compound. This feature is particularly helpful for differentiating certain strains of *M. bovis* (Chart 19-8 and Image Plate 19-1F). For example, 30% of *M. bovis* BCG (bacille Calmette–Guérin) strains may be weakly niacin-positive, and others may be weak nitrate reducers, at times making differentiation of these strains from *M. tuberculosis* by these key tests somewhat difficult.

Growth in 5% Sodium Chloride

The ability to grow on an egg-based culture medium containing 5% NaCl when incubated at 28°C is a characteristic shared by *M. triviale,* some strains of *M. flavescens, M. fortuitum,* and *M. abscessus* (Table 19-7). Other mycobacteria do not tolerate this increased salt concentration. Slants of LJ medium containing 5% NaCl are commercially available. The test cannot be performed in an agar-based medium (Chart 19-13).[171]

Growth on MacConkey Agar

MacConkey agar, from which the crystal violet has been removed, will support the growth of the rapidly growing mycobacteria. However, most other *Mycobacterium* species cannot grow on this medium. The test procedure is detailed in Chart 19-7.

Classification of Mycobacteria

The recognition that an unknown microorganism is "acid-fast" is usually the first clue that the organism may be a mycobacterium. Acid-fast is a term that is used to describe bacteria that resist decolorization with acidified alcohol once they have been stained with carbolfuchsin. Certain bacterial species, notably *Nocardia* species and *Rhodococcus* species, retain carbolfuchsin only if a less stringent decolorizing agent is used, such as a low-concentration inorganic acid like 1% H_2SO_4 or 1% HCl. These bacteria are termed "partially acid-fast."

In the late 1950s, as species of mycobacteria other than *M. tuberculosis* were being encountered with increasing frequency in medical practices, Runyon proposed the grouping of these "atypical" organisms based on growth rate and pigment production (Box 19-2). The term "atypical," however, really is not appropriate because these organisms are simply different from MTBC. Preferred terms are nontuberculous mycobacteria (NTM) and mycobacteria other than MTBC (MOTT). Advances in our knowledge of the genetics, cell structure, and aberrant phenotypic properties of

previously known and newly discovered species of mycobacteria have advanced our knowledge beyond the neat packaging of species under the classic Runyon system of classification. In addition, certain strains of *M. kansasii*, for example, are either pigmented in the dark or are nonpigmented (qualifying for Runyon group II or group III, respectively). Therefore, a reliance on these phenotypic criteria may be misleading. Therefore, Woods and Washington have suggested a clinically oriented classification of mycobacteria (Box 19-3), refined from an earlier published proposal by Wolinski.[364,370]

BOX 19-2

Runyon's Scheme for Classification of Nontuberculous Mycobacteria

Group I: Photochromogens
Group II: Scotochromogens
Group III: Nonphotochromogens
Group IV: Rapid Growers

Nevertheless, for the traditionally trained mycobacteriologist, separating MTBC from NTM and the preliminary

placing of NTM into 1 of the 4 Runyon groups continues to provide a meaningful initial orientation. The fact that certain strains of the usually photochromogenic *M. kansasii* may be nonpigmented or even scotochromogenic, that some strains of the MAC may be lightly pigmented, and even that *M. szulgai* is scotochromogenic at 37°C but photochromogenic at 25°C (certainly disruptive to the Runyon scheme) does not suggest that past orientations should be totally discarded, but rather that the phenotypic variability of these organisms should be recognized and incorporated into conventional identification schemes.

BOX 19-3

Woods and Washington Classification Scheme, Updated

Species Potentially Pathogenic in Humans
M. avium complex
M. kansasii
Rapid growers: *M. fortuitum* group, *M. chelonae/M. abscessus* group
M. scrofulaceum
M. xenopi
M. szulgai
M. malmoense
M. simiae
M. genavense
M. marinum
M. ulcerans
M. haemophilum
M. celatum
Saprophytic Mycobacteria Rarely Causing Disease in Humans
M. gordonae
M. asiaticum
M. terrae
M. triviale
M. shimoidei
M. gastri
M. nonchromogenicum
M. paratuberculosis
Species With an Intermediate Growth Rate
M. flavescens
Other Rapidly Growing Species
M. thermoresistible
M. neoaurum
M. smegmatis group
M. mucogenicum group
M. mageritense
M. wolinskyi

Laboratory Identification of Mycobacteria and Related Clinical Syndromes

The identification of mycobacteria by traditional methods requires patience, familiarity with the end points of different identification characteristics, and a collection of control strains. Additionally, it is time-consuming and often does not provide an accurate identification to the species level. Not every laboratory needs the ability to identify all mycobacteria to the species level. The number of patients with TB in any given

hospital in the United States is not large, and it may be prudent to use the services of a reference laboratory to provide definitive identifications and susceptibility testing of clinically important isolates recovered in the primary care laboratory. Each laboratory director must determine the extent of services to be provided to meet the needs of the local clinical practice.

Review of Mycobacterium *Species: Laboratory Aspects and Clinical Correlations*

Although a presumptive diagnosis of pulmonary TB can be made based on clinical history, presenting symptoms, physical examination, radiographic evidence of disease and the presence of AFB in the sputum, the definitive diagnosis requires recovery of the causative organisms in culture or demonstration of these organisms by nucleic acid amplification methods. Several NTM are now recognized as important pathogens, each with a different potential for producing disease and sometimes with unique antimycobacterial drug susceptibility profiles that must be determined by laboratory tests. A wide variety of *Mycobacterium* species may be isolated from extrapulmonary sites. Laboratory culture characteristics and the clinical manifestations of select human mycobacterial diseases (Box 19-4 and Table 19-8) are discussed briefly in the following paragraphs and Clinical Correlation Boxes.

Mycobacterium tuberculosis *Complex.* Members of the MTBC are the only mycobacteria of public health importance and, therefore, the major focus of identification in clinical laboratories (Clinical Correlation Box 19-1).

Mycobacterium tuberculosis. Traditionally, it has been taught that classic strains of *M. tuberculosis* can be phenotypically differentiated from *M. bovis*, *M. microti,* and *M. africanum*. However, several parameters, including analysis of antigenic extracts, target epitopes for monoclonal antibodies, and antigenic and DNA-relatedness studies, suggest that *M. tuberculosis*, *M. bovis*, *M. microti,* and *M. africanum* represent a single species and currently are considered under the general term MTBC.

BOX 19-4

Mycobacterium species: Order of Presentation

Mycobacterium tuberculosis complex
Photochromogens
- *M. kansasii*
- *M. marinum*
- *M. simiae*
- *M. asiaticum*

Scotochromogens
- *M. scrofulaceum*
- *M. szulgai* (photochromogen at room temperature)
- *M. xenopi*
- *M. celatum*
- *M. gordonae*

Nonphotochromogens
- *M. avium* complex
- *M. paratuberculosis*
- *M. terrae, M. gastri,* and *M. triviale*
- *M. shimoidei*
- *M. malmoense*
- *M. haemophilum*

Rapid Growers
- *M. fortuitum* group
- *M. chelonae/M. abscessus* group
- Infrequent human pathogens

Other Mycobacteria
- *M. ulcerans*
- *M. genavense*

A few relatively simple tests are needed to identify most isolates of MTBC. The following are phenotypic characteristics by which an identification of *M. tuberculosis* can be made:

1. Formation of nonpigmented, rough, buff colonies after 14 to 28 days of incubation at 37°C on LJ or Middlebrook media (Image Plate 19-1G and H).
2. Appearance of microcolonies after 5 to 10 days incubation on Middlebrook 7H10 or 7H11 agars, with formation of serpentine cords owing to the production of "cording factor" (Image Plate 19-1C and H).
3. Accumulation of niacin (Image Plate 19-1D). *M. simiae*, certain strains of *M. bovis*, and occasional strains of *M. marinum* and *M. chelonae* may also be niacin-positive; therefore, this characteristic must be used in conjunction with the other findings.

TABLE 19-8 Nomenclature of Select Mycobacteria

Legitimate Species Name	Relative Pathogenicity for Humans	Equivalent Runyon Group	Acceptable Common Name	Comments
M. tuberculosis	+++		Human tubercle bacillus	Causes human tuberculosis—highly contagious.
M. bovis	+++		Bovine tubercle bacillus	Causes bovine and human tuberculosis; avirulent strains are used for bacille Calmette-Guérin (BCG) vaccines.
M. ulcerans	+++			Associated with skin infections in tropics.
M. africanum	+++			It is found in northern and central Africa.
M. kansasii	+++	I photochromogen		Rarely nonpigmented or scotochromogenic.
M. marinum	+++	I photochromogen		Causes skin infections, usually associated with water exposure.
M. simiae	++	I photochromogen		Photoreactivity may be unstable; niacin-positive.
M. genavense	++			Requires mycobactin J for growth on solid media. Propensity for causing disseminated disease in patients with AIDS.
M. asiaticum	++	I photochromogen		Similar to *M. simiae* but differs antigenically.
M. scrofulaceum	++	II scotochromogen		May cause cervical lymphadenitis.
M. szulgai	+++	I photochromogen at 25°C II scotochromogen at 37°C		Associated with chronic pulmonary and extrapulmonary disease; distinctive lipid composition of cell walls.
M. xenopi	++	II scotochromogen		Grows slowly; best at 42°C; may contaminate hot water systems.
M. celatum	+	Unclear (see text)		Propensity for causing respiratory infections in patients with AIDS. Closely resembles *M. xenopi*.
M. gordonae	Rare	II scotochromogen	Tap water bacillus	Rarely pathogenic for humans.
M. thermoresistible	0	II scotochromogen		Growth at 52°C. Not proven to be a human pathogen.
M. avium complex	+++	III nonphotochromogen[a]	Battey bacillus	May cause disseminated infection in patients with AIDS.
M. terrae	Rare	III nonphotochromogen	Radish bacillus	May be closely related to *M. triviale*.
M. shimoidei	+			Resembles *M. terrae* complex. Rare cases of pulmonary infections.
M. triviale	0/+	III nonphotochromogen	V bacillus	
M. malmoense	+++	III nonphotochromogen		Slowly growing mycobacterium usually causing pulmonary disease.
M. haemophilum	+++	III nonphotochromogen		Associated with skin lesions usually in immunosuppressed patients.
M. fortuitum group	++	IV rapid grower		Predominantly causes skin infections. It may cause pulmonary disease. May cause nosocomial infection.
M. chelonae	++	IV rapid grower		May cause skin infections, particularly in persons with compromised cell-mediated immunity.
M. abscessus	++	IV rapid grower		Predominantly causes skin infections. May cause pulmonary disease in patients with chronic respiratory disease or cystic fibrosis.

[a]Strains recovered from patients with AIDS may develop a pale yellow pigment with age.

CLINICAL CORRELATION BOX 19-1 *Mycobacterium tuberculosis*

Tuberculosis typically begins in the lungs, where diffuse, finely nodular, or patchy infiltrates may be seen, predominately in the apical portions of the upper lobes, but also spreading to other foci in miliary form or as progressive exudative tuberculosis (Image Plate 19-3A). Cavitary lesions, primarily in the apical portions of the upper lobes are common, and a solitary tuberculoma or "coin lesion" that may be part of an old Ghon complex may be seen (Image Plate 19-3B and C). Disseminated or miliary spread of infection occurs in certain persons, usually those with malnutrition, immunosuppression, or other chronic debilitating diseases. Jereb and coworkers,[143] using restriction-fragment-length polymorphism (RFLP) by PCR, were able to trace the source of an outbreak of *M. tuberculosis* among 10 kidney-transplant recipients in one hospital to a single patient who had posttransplantation exposure in another hospital before transfer. The mean incubation time for the onset of tuberculosis in the newly infected kidney-transplant recipients was 7.5 weeks. This situation illustrates how molecular techniques can be helpful in detecting point sources of tuberculosis so that early isolation can be implemented to prevent nosocomial transmission of disease.

Reactivation, or adult-type, tuberculosis is a slowly progressive inflammatory process in the lungs, characterized by granulomatous inflammation, which may erode into bronchi (Image Plate 19-3D). Large numbers of tubercle bacilli are spread to fresh foci within the lung when a cavity ruptures, and may be expectorated if the cavity breaks into a bronchus, potentially infecting others in close contact. Coughing, weight loss, low-grade fever, dyspnea, and chest pain are the usual clinical signs and symptoms of chronic progressive pulmonary tuberculosis. This is a description of what has been termed secondary- or reactivation-type tuberculosis. In patients with AIDS, the disease is more reminiscent of primary progressive tuberculosis, and is characterized by less focal fibrosis and caseation, and more rapid progression and miliary dissemination to involve virtually any organ in the body.

Tuberculous meningitis is relatively rare in the United States. Patients may present with headaches, change in mentation, or, uncommonly, progress to manifestations of severe meningitis. In most instances, at least 1 of 3 laboratory measurements of cerebrospinal fluid will be altered: an increase in cell count, usually a lymphocytosis; a decrease in glucose levels; or an increase in protein concentrations, although any one of these parameters may be normal. Acid-fast bacilli may be observed in centrifuged specimens in about 40% of patients, a yield that increases with the

number of spinal examinations performed. Pathologically, the meningeal involvement is most pronounced at the base of the brain, where visible changes range from a diffuse opacity to the presence of a thick gelatinous exudate, seen primarily in the areas overlying the pons and adjacent to the optic chiasm (Image Plate 19-3E).

Bacteremia with *M. tuberculosis* is traditionally considered to be rare; however, Bouza and associates,[28] in a study of 285 patients with culture-proved tuberculosis in whom blood cultures were obtained, found that 50 (14%) were bacteremic. Of these, 81% were infected with HIV. In 14 patients, blood was the first specimen from which organisms were recovered. Archibald et al.,[7] when studying 517 patients with possible community-acquired bloodstream infections in sub-Saharan Africa, found that of the 145 patients with a proven bloodstream infection, 81% of which were HIV-infected, the most frequently isolated pathogen was *M. tuberculosis*, at 39%.

The majority of *M. tuberculosis* isolates from untreated patients in the United States are susceptible to the primary antituberculosis drugs and respond to the recommended four-drug treatment. Susceptibility testing of mycobacteria is presented later in this chapter.

4. Reduction of nitrates to nitrites (Image Plate 19-1E).
5. Ability to grow in the presence of T2H (Image Plate 19-1F).
6. Lack of catalase activity.

The typical cell morphology of *M. tuberculosis* as seen in carbol fuschin-stained smears is a thin, slightly curved bacillus that measures 0.3 to 0.6 × 1 to 4 nm, deeply red staining (strongly acid-fast), with a distinct beaded appearance (Image Plate 19-1B). In the preparation of smears from cultures, the individual cells are often difficult to disperse, appearing as irregular aggregates, or lying in parallel strands. Distinctive cording may be seen in preparations from broth cultures, wherein aggregates of the AFB form long, serpentine cords. Mycobacteria may be seen in the Gram's stain as gram-positive, beaded bacilli. The beading represents nonuniform staining of the bacillus. The presence of a *Mycobacterium* species can also be suspected in Gram's stains if poorly or nonstaining bacilli are observed surrounded by a clear halo (Image Plate 19-1I). The crystal violet dye in the Gram's stain reagent does not penetrate the thick, waxy lipid cell wall of the organism, and they may appear as either beaded or almost as a negative image against the counterstained background.

Mycobacterium bovis. *Mycobacterium bovis* (Clinical Correlation Box 19-2) can be differentiated from classic strains of *M. tuberculosis* based on the following:

1. Most strains are niacin-negative.
2. Nitrates are not reduced to nitrites.
3. Pyrazinamidase is not produced.

4. Selective inhibition of growth by T2H; *M. bovis* will not grow in medium containing T2H.

The classic human strains have a very slow growth rate, producing "dysgonic"-appearing colonies on LJ medium. Growth of most strains is better on LJ medium than on Middlebrook 7H11 or equivalents. The medium most favorable for *M. bovis* contains 0.4% pyruvate without glycerol. Typical colonies are buff, low, and small and may appear either smooth or rough on egg-containing medium. On Middlebrook 7H11 agar, colonies are very thin and often show little or no stranding (referred to as "water-droplet-like"). These colonies may also simulate dysgonic forms of organisms in the MAC. The latter, however, are 68°C catalase-positive, do not produce urease, and are pyrazinamidase-positive. If pyruvate has been added to the medium, colonies may show serpentine cords similar to those of eugonic *M. tuberculosis*.

1240

CLINICAL CORRELATION BOX 19-2 *Mycobacterium bovis*

Mycobacterium bovis produces tuberculosis typically in cattle but may also infect other animals, including dogs, cats, swine, rabbits, elk, deer, and possibly, certain birds of prey. Fanning and Edwards traced 446 contacts of humans with domesticated elk in Alberta, Canada, 81 of whom were skin-test-positive for *M. bovis*.[84] Of these, 50 had been in contact with culture-positive animals, including one case of active *M. bovis* pulmonary infection diagnosed by a positive sputum specimen. With DNA fingerprinting assays with IS*6110* as the genetic marker, van Soolingen et al.[334] were able to determine that the strains of *M. bovis* causing human infection in Argentina were transmitted from cattle, whereas the strains causing human disease among persons living in the Netherlands were contracted from animals other than cattle (various wild and zoo animals). In some areas in Scotland and in eastern Europe, where cattle and dairy farming is still the chief livelihood, *M. bovis* still may constitute as many as 39% of all cases of tuberculosis.[357] Human bovine pulmonary tuberculosis closely resembles that caused by *M. tuberculosis*.

During the time that humans physically milked cows much more frequently than today, cutaneous infections of the fingers were common, often with underlying osteomyelitis and osteoarthritis of the digits (Image Plate 19-3F). A common site of recovery of *M. bovis* in clinical laboratories is from urine samples, as the bacille Calmette-Guérin (BCG) strain is used in bladder irrigations as an immunologic stimulant in the treatment of bladder carcinoma. This possibility should be considered when a slow-growing *Mycobacterium* is recovered from urine samples. In some

individuals, the BCG strain being used is not totally attenuated and may cause cystitis.

BCG strains of *M. bovis*, which have been used as a vaccine in highly endemic areas of the world, simulate *M. tuberculosis* by being "eugonic," or more rapidly growing (3 to 4 weeks on LJ medium), having a rough, buff appearance and, in some cases, accumulating niacin. However, these strains remain T2H-sensitive and can be differentiated on that basis. The microscopic morphology of *M. bovis* cells in acid-fast-stained smears is not distinctive.

Photochromogens

Mycobacterium kansasii. *M. kansasii* is an important cause of pulmonary disease that clinically, radiologically and histopathologically resembles TB (Clinical Correlation Box 19-3). Pulmonary disease due to *M. kansasii*, however, does not have the same public health implications as TB and is not transmitted from person to person. Originally known as the "yellow bacillus" following the first description by Buhler and Pollak in 1953, *M. kansasii* is a photochromogen classified within the Runyon group I. Although infections occur throughout the United States, most cases have been reported from the southern states (Texas, Louisiana, and Florida), Midwest (Illinois), and California. Males are infected more frequently than females, with a ratio of approximately 3:1. The disease is uncommon in children. Non-pulmonary disease, such as peritonitis in a patient undergoing continuous ambulatory peritoneal dialysis, is far less common than pulmonary disease, but has been reported.[95]

Laboratory aspects. Typical strains of *M. kansasii* grow at approximately the same rate as or slightly more rapidly than *M. tuberculosis* at 37°C. The distinctive feature is the dependence on light exposure for the production of a visible yellow pigment (Image Plate 19-2C) and the formation of reddish carotene crystals on prolonged incubation. The colonies are typically intermediate between fully rough and fully smooth; however, certain strains are totally one or the other. The microcolonies typically show elevated centers and curving strands of bacilli in the outer, thinner margins that may be confused with the serpentine cording of *M. tuberculosis*. Phenotypic properties, in addition to photochromogenicity, by which the identification of *M. kansasii* can be confirmed include:

1. Rapid hydrolysis of Tween within 3 days
2. Strong reduction of nitrate to nitrite
3. Rapid catalase reaction, including 68°C test
4. Strong pyrazinamidase activity

Less commonly, scotochromogenic or nonchromogenic strains may be encountered, including some strains with low catalase activity. The bacterial cells in acid-fast smear

preparations are characteristically long and broad and distinctly cross-banded or barred (Image Plate 19-2M), presumably from utilization of the lipid in the medium. Although experienced mycobacteriologists may make a presumptive identification based on acid-fast stain, additional testing is required before a definitive identification can be made.

Mycobacterium marinum. In 1926, while investigating infectious diseases in saltwater fish, Aronson discovered a new *Mycobacterium* species, later named *Mycobacterium marinum* ("of the sea").[8,346] The organism has also been called *M. platypoecilus* from infections observed in Mexican platyfish and also as *M. balnei* (a name referring to bath or spas). All are the same organism (Clinical Correlation Box 19-4). Exposure to water is often the clue in the clinical history to the etiologic agent of disease.[87]

1241

CLINICAL CORRELATION BOX 19-3 *Mycobacterium kansasii*

Chronic pulmonary disease simulating classic tuberculosis is the most common manifestation, classically involving the upper lobes. Cavitation with scarring is evident in most patients, and disease is slowly progressive. Extrapulmonary or disseminated infections are less common, although cases of scrofula-like lymphadenitis, sporotrichosis-like cutaneous infections, osteomyelitis, soft tissue infections, and tenosynovitis have been reported. Dillon et al.,[74] in particular, cite the progressive damage to the deep structures of the wrist and hand that can occur in cases of tenosynovitis. Disseminated disease may be seen in the presence of severe immunosuppression and has been reported in patients with AIDS. Jacobson and Isenberg described an AIDS-related infection caused by *M. kansasii* that presented as granulomatous interstitial pneumonitis, but report that only 0.2% of AIDS patients have superimposed *M. kansasii* infections.[138] However, Valainis and coworkers,[332] reporting from Louisiana, a region endemic for *M. kansasii*, in a 60-month review of patients attending two major referral centers in New Orleans, found that 31.9% of HIV-1-infected patients were coinfected with *M. kansasii*. In a retrospective study of 35 patients conducted in Kansas City, the incidence of *M. kansasii* infections in patients with AIDS was three times higher than *M. tuberculosis* infections.[12] Standard therapy for *M. kansasii* infections includes isoniazid, rifampin, and ethambutol, the most important drug of which is rifampin. An alternative, equally effective regimen is rifampin, ethambutol, and clarithromycin.

M. kansasii infections in patients with AIDS usually occur when CD4 lymphocyte counts are fewer than 50/μL, with serious and life-threatening complications in many instances. Levine and Chaisson reviewed 19 patients with *M. kansasii* and HIV

infection, 14 of whom had exclusive pulmonary infection, three had pulmonary and extrapulmonary disease, and two had extrapulmonary involvement exclusively.[184] All patients with pulmonary infection presented with fever and cough of at least 2 weeks' duration. Focal upper lobe infiltrates, diffuse interstitial infiltrates, or thin-walled cavitary lesions, or a combination thereof, were seen on chest radiographs. Other AIDS-related infections caused by *M. kansasii* have been reported.[124,294] In one patient, caseating granulomas were seen in the bowel wall and in the mesenteric lymph nodes, with accumulation of foamy histiocytes resembling Whipple's disease. Giladi and coauthors reported a catheter-associated *M. kansasii* peritonitis in a 62-year-old woman undergoing continuous ambulatory peritoneal dialysis, presumably the first such case report.[337] Tortoli and coworkers[328] found a cluster of *M. kansasii* strains that did not hybridize with the AccuProbe *M. kansasii* culture identification test (Gen-Probe, San Diego, CA) and that were distinctly associated with the HIV status. This suggests that additional tests for identification may be required for AccuProbe-negative strains.

Strains of *M. kansasii* resistant to rifampin have been reported. Wallace and coauthors reported on 36 patients from whom rifampin-resistant *M. kansasii* had been isolated, 90% of whom had previously received therapy with this agent.[340] The majority of patients, however, responded to a four-drug regimen, based on in vitro susceptibility studies, and sputum cultures that converted to negative in 90% of those treated in a mean of 11 weeks.

CLINICAL CORRELATION BOX 19-4 *Mycobacterium marinum*

Typical infections with *M. marinum* involve the skin, usually resulting when traumatized skin comes in contact with inadequately chlorinated freshwater or saltwater (e.g., swimming pools, tropical fish aquariums, water-cooling towers). Fisher has reported cutaneous infections in three lifeguards, citing this infection as a hazard of the trade.[50] Hoyt and associates[129] report several deep-tissue infections and destructive tenosynovitis among fishermen in the Chesapeake Bay area. Several other citations of deep cutaneous infections, usually of the hands, and commonly associated with aquatic activity, such as cleaning of fish, include a patient with tenosynovitis, arthritis and bursitis, and osteomyelitis.[16,50,131]

Sporotrichosis-like lesions, with central spread along the lymphatics emanating from an ulcerated area at the primary site of inoculation, may occur, but more typically, the lesions present as tender, red or blue-red subcutaneous nodules, usually involving the elbow, knee, toe, or finger ("swimming pool granuloma"). Such lesions have been mistaken for rheumatoid nodules.[9]

Antimicrobial therapy is discussed later in this chapter.

1242

Laboratory aspects. *M. marinum*, when recovered from clinical specimens, grows optimally at 30°C to 32°C, but it may grow, perhaps not as well, at 37°C. Subcultures generally grow better at 37°C than the initial culture of the specimen. Colonies appear in 8 to 14 days; those grown in the dark may appear nonpigmented. When exposed to light, a deep yellow pigment develops. Colonies vary between wrinkled and rough to smooth and hemispheric, particularly if grown on 7H10 or 7H11 media (which contains oleic acid and albumin). Microscopically, the cells are relatively long rods with frequent cross-barring.

Photochromogenicity and preference for growth at 30°C to 32°C are initial clues to the identification of *M. marinum*. The following are additional characteristics by which a definitive identification can be made:

1. Some strains may accumulate niacin.
2. Nitrates are not reduced to nitrites.
3. Tween is hydrolyzed.
4. Urease is positive.
5. Pyrazinamidase is produced.
6. Heat-stable catalase is not produced.

Mycobacterium simiae. Weiszfeiler and Karczag named *M. simiae* in 1969,[350] in recognition of the first recovery of the organism 4 years earlier by Karassova and colleagues,[349] from *Macaca* rhesus monkeys imported into Hungary from India (Clinical Correlation Box 19-5). This organism was subsequently found to be identical to a niacin-positive strain of a group III mycobacterium recovered in Cuba by Valdivia and coworkers from patients with pulmonary tuberculosis. They named the organism *M. habana*, which subsequently has been shown to be the same organism as *M. simiae*.

Laboratory aspects. Colonies of *M. simiae* develop within 2 to 3 weeks on egg-based media and are typically smooth. Most strains are photochromogenic. Prolonged exposure to light may be required for isolates that fail to produce pigment. The key identifying biochemical reactions are as follows:

1. Positive niacin accumulation
2. Hydrolysis of Tween (may be slow, requiring more than 10 days)
3. High thermostable catalase activity

Poor reproducibility of test reactions by some strains may make identification using conventional tests somewhat difficult.

Mycobacterium asiaticum. *Mycobacterium asiaticum* is in many ways phenotypically similar to *M. gordonae;* both have high catalase activity, hydrolyze Tween 80, and are negative for urease and nitrate reduction.[346] *M. asiaticum*, however, is a photochromogen, whereas *M. gordonae* is a scotochromogen. *M. asiaticum* is also biochemically similar to *M. simiae,* except it is niacin-negative. *M. asiaticum* has a distinct 16S rRNA profile, justifying a separate species status.[309]

Rare instances of human infection have appeared in the literature. The first indication that this organism could be pathogenic was in a report from Australia by Blacklock.[24] Two of the 5 patients had progressive cavitary pulmonary disease; three had no evidence of progressive pulmonary disease, and the sputum isolates were thought to represent secondary colonization. The first reported pulmonary infection caused by *M. asiaticum* in the United States occurred in a 62-year-old man living in Los Angeles.[316] Four isolates have also been reported from Florida.[102] Dawson and coworkers[69] have reported recovery of *M. asiaticum* from fluid aspirated from an olecranon bursa in a patient with a postsurgery infection. The infection cleared with drainage, regular dressing changes, and immobilization, without the need for antimycobacterial therapy.

Scotochromogens

Mycobacterium scrofulaceum. The species name *scrofulaceum* is derived from *scrofula* ("brood sow"). This mycobacterium was named in 1956 by Prissick and Mason in reference to the most common form of disease by this organism, cervical lymphadenitis in children[253] (Clinical Correlation Box 19-6). *M. scrofulaceum*, however, is not the only mycobacterium that causes cervical lymphadenitis. Gill et al.[96] reviewed the 16 children with this disease; 6 were caused by *M. scrofulaceum*, 4 by *M. tuberculosis*, and 4 by MAC.[96]

Kirschner and associates[162] recovered large quantities of *M. scrofulaceum* from swamp water in several locations in Georgia, West Virginia, and Virginia, indicating that environmental water sources are likely connected with the increased incidence of scrofula infections seen in these regions. High concentrations of organisms were found in warm water with low pH, low dissolved oxygen content, high soluble zinc levels, and high levels of humic and fulvic acids.

Laboratory aspects. Colonies of *M. scrofulaceum* grow slowly (4 to 6 weeks) at various temperatures (25°C, 31°C, and 37°C). They produce colonies that typically are smooth, buttery in consistency, and globoid, with pigmentation ranging from light yellow to deep orange (Image Plate 19-2D). Pigment production is not dependent on light exposure; thus, the organism is included in the scotochromogen group II of

Runyon.

CLINICAL CORRELATION BOX 19-5 *Mycobacterium simiae*

Reports of human infection with *M. simiae* are relatively few. Isolated reports of pulmonary infections have been described in France, Israel, Thailand, and the United States.[185] These authors report a 43-year-old man with AIDS in whom disseminated mycobacterial infection developed. Organisms were recovered from blood, jejunal fluid, and duodenal and rectal biopsies. Although a few other instances of *M. simiae* infections have been reported in patients with AIDS, the association is infrequent and does not serve as a marker.[236] The Israeli experience with *M. simiae* is interesting, in that 399 strains were isolated from 287 persons during the period 1975–1981, primarily among inhabitants of the coastal plain of Tel Aviv.[179] Most of the isolates were commensal organisms related to environmental water sources. A few pulmonary infections occurred among patients from whom multiple isolates were recovered, usually complicating preexisting chronic pulmonary conditions.

Disseminated disease, with renal involvement following pulmonary infection has also been reported.[275]

1243

CLINICAL CORRELATION BOX 19-6 *Mycobacterium scrofulaceum*

Lymphadenitis is the classic presenting symptom of infection with *M. scrofulaceum*, occurring most commonly in children between 18 months and 7 years of age, a time when a barrier break in the oral mucous membrane occurs during teething. The next higher incidence of disease occurs in young adults who are cutting molar teeth. The lymphadenitis is unilateral, involving nodes high in the neck adjacent to the mandible or posteriorly behind the ears (Image Plate 19-3G and H). The nodes often drain from the surface of the skin without complications, except for varying degrees of residual scarring at the sites of surface penetration of sinus tracts. The disease often affects healthy children; pain is usually minimal, and constitutional symptoms are absent. Colonization of the organism in the mouth and throat is presumed to be the site of origin. The high incidence of disease among young children is thought to be related to

disruption of the gums during tooth eruptions, during an age when the immune system is still relatively immature. The local disease is best treated with surgical incision and drainage of the involved nodes.

Key biochemical test reactions include the following:

1. Failure to hydrolyze Tween.
2. Nitrates are not reduced to nitrites.
3. 68°C catalase test is positive.
4. Urease is produced.

Mycobacterium szulgai. *M. szulgai*, officially reported as a species in 1972 by Marks and coworkers,[194] is named after the Polish microbiologist T. Szulg. The unique feature of this species is the temperature-dependent production of pigment. When grown at 37°C, the organism is scotochromogenic, whereas it is photochromogenic when grown at room temperature (25°C). Therefore, to assess the photochromogenicity of an unknown strain of *M. szulgai*, the light-exposed plates must be incubated at room temperature and not at 37°C. The scotogenic pigment produced at the higher temperature will mask any chance to visualize any photogenetic pigment that may be produced (Chart 19-5 and Clinical Correlation Box 19-7).

Laboratory aspects. Growth is relatively rapid, with either smooth or rough colonies developing within 2 weeks at 37°C. Orange pigment may be observed, intensifying with exposure to continuous light. In acid-fast smear preparations, the bacterial cells appear as moderately long bacilli, with some cross-barring, reminiscent of *M. kansasii*.

Key biochemical test reactions for *Mycobacterium szulgai* include the following:

1. Slow hydrolysis of Tween
2. Nitrates reduced to nitrites
3. Positive catalase activity
4. Intolerance to 5% NaCl

Mycobacterium xenopi. *M. xenopi* (*Xenopus*, a genus of frog), was first isolated from an African toad. Hot and cold water taps, including water storage tanks and hot water generators of hospitals, are potential sources for nosocomial infections (Clinical Correlation Box 19-8). Previously considered to be nonpathogenic, *M. xenopi* has been incriminated in several infections.[326] Wolinski reported *M. xenopi* infections of 50 patients, primarily in England, France, Denmark, Australia, and the United States.[364]Birds that frequent the coastal regions in Great Britain constitute an important reservoir.

Laboratory aspects. *Mycobacterium xenopi* colonies are slow-growing, small, erect, and produce characteristic yellow pigment, although occasional strains are nonpigmented. Growth is more rapid at 42°C than 37°C and is absent at 25°C. Although included with the nonphotochromogenic mycobacteria in the past, the brightly pigmented yellow colonies usually found on primary isolation suggest that the organism would be better considered with the scotochromogens. Colonies tend to be rough, and an aerial mycelium may be evident. Examination of young microcolonies on 7H10 agar reveals a distinctive "bird's nest" appearance, with sticklike projections. Branching and filamentous extensions appear in older colonies. Microscopically, acid-fast-stained smears reveal long, filamentous rods that are tapered at both ends, tending to arrange in palisades.

CLINICAL CORRELATION BOX 19-7 *Mycobacterium szulgai*

Maloney and associates[193] presented their experience with three patients with infections caused by *M. szulgai* and reviewed 24 cases previously reported in the literature. Lung infections were present in two-thirds of the cases, with chest radiographs revealing unilateral or bilateral apical disease, with cavitation, simulating *M. tuberculosis*. A patient with a persistent lung infection caused by *M. szulgai* has also been reported.[55] Fever, cough, hemoptysis, and weight loss were common symptoms. Extrapulmonary infections with *M. szulgai* cited in the foregoing review include olecranon bursitis, tenosynovitis, carpal tunnel syndrome, osteomyelitis, and localized cutaneous disease.

CLINICAL CORRELATION BOX 19-8 *Mycobacterium xenopi*

Most human infections caused by *M. xenopi* have been pulmonary, resembling those seen in patients with *M. tuberculosis*, *M. kansasii*, or MAC infections. Radiographic findings include multinodular densities, cavities, and fibrosis. Infections usually occur in patients with preexistent lung disease or predisposing conditions, such as alcoholism, malignancy, and diabetes mellitus. Contreras and coauthors, in reviewing 89 adult patients with pulmonary infections, report that *M. xenopi* was the second most frequent isolate (38% of patients).[57] Similarly, in a review of cultures positive

for nontuberculous mycobacteria, excluding MAC and *M. gordonae*, from 86 patients at the State University of New York Health Sciences Center at Brooklyn, it was demonstrated that *M. xenopi* was the species most commonly isolated (33 patients).[291] The majority of these isolates were recovered from respiratory specimens in patients with AIDS. The recovery of 28 isolates of *M. xenopi* from patients residing in the Ontario province of Canada has also been reported.[299] In 19 patients, the isolate was considered insignificant; 9 isolates were from middle-aged men with other chronic pulmonary diseases. In the province of Ontario, *M. xenopi* has been the second most common nontuberculous mycobacterial pathogen, after MAC.

Intrapulmonary spread usually occurs in patients with AIDS; in patients with disseminated disease, the organisms may also be recovered from bone marrow aspirates.[10] *M. xenopi* infections are uncommonly found in HIV-positive patients. In two instances of HIV-infected men with symptomatic pulmonary infection, night sweats, cough, and pleuritic pain were reported.[139] This organism grew in cultures of multiple respiratory specimens obtained from each patient. Both patients improved with multidrug therapy. A pulmonary infection in a 39-year-old kidney allograft recipient has been reported.[347] Isolated extrapulmonary infections involving bone, lymph node, epididymis, sinus tract, and a prosthetic temporomandibular joint have also been described.[364] Infections of the lumbar spine have been described; one patient was a 77-year-old immunocompetent woman who presented with a paravertebral abscess.[254,258] An outbreak of pulmonary infections in 13 residents of a housing project in Prague have been reported.[301] The point source was thought to be the local water supply, as organisms were recovered from water faucets in five of the flats. Tortoli and coauthors reviewed the microbiologic features of 64 isolates of *M. xenopi* recovered from patients living in Florence, Italy, during a 15-year period.[326] The homogeneity of the biochemical, cultural, and antimicrobial sensitivity patterns of these isolates suggested that there may be an endemic focus in the Florence area.

Key biochemical test reactions for *Mycobacterium xenopi* include the following:

1. Optimal growth at 42°C
2. Yellow scotochromogenic pigment
3. No niacin accumulation
4. Nitrate reduction-negative
5. Catalase produced at 68°C only
6. Arylsulfatase-positive
7. Pyrazinamidase-positive

Mycobacterium celatum. *M. celatum* is the name proposed for this

Mycobacterium species by Butler and coauthors.[36] The most appropriate Runyoun group for *M. celatum* is unclear. The initial isolate was described as nonchromogenic; however, other investigators found that isolates produced a weak yellow pigment in the dark. *M. celatum* most closely resembles *M. xenopi* phenotypically, differing only in its poor growth at 45°C, formation of large colonies on 7H10 agar, and the production of only trace amounts of the fatty acid 2-docanosol. It may cross-react with MTBC when using the acridinium ester–labeled DNA probe, AccuProbe (Gen-Probe, San Diego, CA), a problem that, although addressed, remains unresolved.[36] *M. celatum* has been recovered from respiratory specimens, and less commonly from the blood, stool, and cerebrospinal fluid, obtained from patients residing in diverse geographic locations, including the United States, Finland, and Somalia. It may cause serious disease (pulmonary and disseminated) in patients with AIDS.[247] In the original report by Butler and coauthors, approximately one-third of the isolates were recovered from patients with AIDS.[36] Haase and coworkers[114] report a case of scrofula-like unilateral cervical lymphadenitis in an immunocompetent child.

Mycobacterium gordonae. *Mycobacterium gordonae* rarely causes human infections, but is possibly the mycobacterium that is recovered in clinical laboratories with greatest frequency (Clinical Correlation Box 19-9). It is found particularly in aqueous environments, leading to the alternative designation of *M. aquae,* or the "tap water bacillus."

Laboratory aspects. *Mycobacterium gordonae* is a scotochromogen, and it is readily recognized by the smooth, deeply yellow-orange pigmented colonies that develop after 7 days of incubation at 37°C (Image Plate 19-2E). The organism hydrolyzes Tween 80 and produces heat-stable catalase; it is urease-negative and does not reduce nitrates to nitrites. An organism that may be phenotypically confused with *M. gordonae* is *M. flavescens*, which is a scotochromogen; however, *M. flavescens* possesses urease activity and reduces nitrates to nitrites, two characteristics not demonstrated by *M. gordonae*. *M. flavescens* is a commensal for humans and is not known to cause disease.

Nonphotochromogens

***Mycobacterium avium* Complex.** Strains of *M. avium* and *M. intracellulare*, often referred to as MAC, are widely distributed in water, soil, dust, mammals, and poultry. For humans, these organisms initially were considered of low pathogenicity and an uncommon cause of disease (Clinical Correlation Box 19-10). However, the AIDS epidemic has demonstrated the pathogenicity of these organisms in persons with depleted T-cell immunity.[102]

CLINICAL CORRELATION BOX 19-9 *Mycobacterium gordonae*

Mycobacterium gordonae most often is a contaminant. There should be a careful review of the clinical and histopathologic findings from the patient and, if possible, repeat isolation of the organism from the patient prior to ascribing disease to *M. gordonae*. There have been several isolated reports of infections caused by this organism, which include meningitis secondary to involvement of ventriculoatrial shunts, hepatoperitoneal disease, endocarditis in a prosthetic aortic valve, cutaneous lesions of the hand, and possibly patients with pulmonary involvement.[370] Disseminated disease, soft tissue infections, chronic urinary tract infection, and peritonitis in a patient undergoing peritoneal dialysis have also been described.[140,141,348,378] Wayne and Sramek, however, after reviewing many of the previously reported alleged infections caused by *M. gordonae,* caution that organism descriptions and convincing clinical correlations often are lacking in many of the papers, and that its true pathogenicity remains in question.[346] When recovered from specimens, each isolate must be accurately identified and a careful clinical correlation made to determine the clinical significance for what in most instances will be a contaminant.

CLINICAL CORRELATION BOX 19-10 *Mycobacterium avium* Complex

Conditions predisposing individuals to pulmonary infections with members of the *M. avium* complex (MAC) include chronic obstructive pulmonary disease by whatever primary cause, bronchiectasis, chronic aspiration or recurrent pneumonia, tuberculosis, pneumoconiosis, cystic fibrosis, and bronchogenic carcinoma.[107,149,156] Pulmonary disease also occurs in postmenopausal women without predisposing conditions, the so-called Lady Windermere's syndrome, after Oscar Wilde's Victorian character who had the peculiar habit of suppressing a cough. In immunocompetent patients, pulmonary manifestations of MAC disease are similar to those of *M. tuberculosis*: cough, fatigue, weight loss, low-grade fever, and night sweats. Radiographic findings include solitary nodules or more diffuse infiltrates, but cavitary disease may occur, albeit less frequently than in tuberculosis.

The greatest upsurge of MAC disease during the past decades has been in patients with AIDS. In a review of MAC disease in HIV-positive patients before the widespread use of highly active antiretroviral therapy (HAART), it was found that the disease was

usually dissemination and occurred late in the course of HIV infection.[190] The risk of MAC disease in patients with AIDS with CD4 counts lower than 50 is high (45% within 1 year after diagnosis).[46] When organisms were found in the sputum or gastrointestinal tract, 60% of patients had disseminated disease. Disseminated disease is characterized by intermittent fever, sweats, weakness, anorexia, and weight loss that is relatively rapidly progressive. Abdominal pain or diarrhea with malabsorption was seen in some patients. Significant pulmonary involvement was infrequent, despite recovery of MAC organisms in sputum specimens. Bacteremia occurs in over 90% of patients with disseminated disease, with organisms found within the circulating monocytes; therefore, mycobacterial blood culture is the recommended specimen for culture in these patients. Colony counts as high as 10^6 colony-forming units (CFUs)/mL have been reported, although counts in the range of $^{10^1}$to 10^2 are more common.[365]

In a study of mycobacterial infections in 94 patients with AIDS, significant pulmonary disease occurred in about 25% of patients infected with MAC, in contrast to 83% of patients with *M. tuberculosis* infections who had pulmonary disease.[215] Also, classic tuberculosis preceded the diagnosis of HIV infection in two-thirds of the patients, in contrast with MAC disease, which was a secondary complication of the patient reaching the AIDS stage of disease in all patients studied. Members of the MAC have also been recovered from patients with AIDS and tuberculous meningitis, reiterating the importance of considering a number of coincident pathogens in patients which reach that stage of immunosuppression.[137] The recovery of organisms from the spinal fluid indicated disseminated disease, and prognosis in this group of patients was poor. Disseminated MAC disease, however, has become much less common since the introduction of HAART for HIV infection.

The typical histologic findings in hematoxylin-and-eosin-stained sections of tissue from patients with AIDS who have disseminated MAC disease are aggregates of foamy macrophages filled with acid-fast bacilli, simulating the lepra cells seen in *M. leprae* infections (Image Plates 19-2P and 19-3I and J) or Whipple's disease when there is involvement of the gastrointestinal tract. Patients with histologic evidence of gastrointestinal (and pulmonary) involvement invariably have disseminated disease.[46] Ingestion of contaminated water or food could well be the major mode of transmission. The histology of localized MAC disease in patients without AIDS includes necrotizing inflammation, and/or granulomas with or without caseation necrosis.

MAC organisms also cause a scrofula-like cervical lymphadenitis in children.[159,175] Woods and Washington cite several other MAC infections, including granulomatous synovitis, genitourinary tract disease, cutaneous lesions, osteomyelitis, meningitis, and colonic ulsers.[370]

Members of the MAC can be recovered from many environmental sources, including water estuaries, pools, soil, house dust, plants, and bedding materials. Natural sources of water, including potable water, pose some risk for acquiring human infections.[337] Waters that have moderate salinity (1% to 2% salt) have relatively high acidity (pH 4.5 to 6.5) and are located at lower altitudes are ideal for supporting the propagation of MAC organisms.[31] Human MAC infections may occur from ingestion of contaminated water and food (the intestinal tract is thought to be the primary route of infection in HIV-infected patients) or by inhalation of organisms contained within aqueous aerosols. Wendt and coworkers[352] found MAC organisms in droplet sizes of 0.7 to 3.3 μm above freshwater surfaces, sufficiently small to reach the alveolar spaces, and organisms may become highly concentrated in jet streams emanating from air–seawater interfaces. Although poultry, swine, and other species of birds and animals become infected and excrete organisms in the feces that can remain viable for long periods in soil, animal-to-human transmission is a rare event, and human-to-human transmission has not been documented.[136]

MAC has a worldwide distribution; however, endemic areas have been found in temperate geographic areas, including the United States, Canada, Great Britain, Europe, the Netherlands, and Japan.[136] Members of MAC are the NTM most frequently associated with human disease. When HIV infection was first recognized, the overall increase in the incidence of infections due to MAC paralleled the incidence of AIDS cases. For example, of the 161,073 patients with AIDS reported to the CDC by December 1990, more than 12,000 cases of NTM infections were also reported; in 96% of these, the causative agent was a member of the MAC.[128] HIV infection is the primary risk factor for disseminated infections with this organism[224]; however, the incidence of disseminated MAC infections in HIV-infected patients has diminished dramatically since the introduction of highly active antiretroviral therapy. MAC is also an important cause of chronic pulmonary disease, typically involving three groups of patients: those who have underlying lung damage with apical fibrocavitary lesions, postmenopausal women with bronchiectasis and nodular opacities, and patients with cystic fibrosis.

Laboratory aspects. The members of the MAC may appear as 1 of 3 colony variants: (1) Smooth, opaque, and dome-shaped; (2) Smooth, transparent, and flat; and (3) Rough (Image Plate 19-2N and O). The isolates recovered from patients with AIDS commonly produce the smooth, transparent, flat colony variant, as seen in microcolony observations (Image Plate 19-2A and B). These flat, translucent colony types are thought by some to be more virulent than strains that produce other colony types.[63,280,286,312] Although *M. avium* was originally classified in Runyon group III

(nonchromogens), in the experience of many, some strains recovered from patients with AIDS have varying degrees of yellow pigmentation, intensifying as the colony ages. Doern and associates,[76]however, found that most of their strains were nonpigmented. Stormer and Falkingham have determined that the strains recovered from HIV-positive patients were nonpigmented and were more likely to be resistant to antimicrobial agents compared with pigmented strains.[312]

Microscopic examination of acid-fast smears reveals cells that are typically short and coccobacillary. Early in culture and under certain conditions, long, thin bacilli may be seen. Staining is usually uniform, without beading or banding. Phenotypically, MAC strains are best characterized by a battery of negative reactions (Table 19-7). The organism does produce heat-stable catalase and has the ability to grow on T2H-containing media; otherwise, the biochemical reactions are inert. With the availability of a nucleic acid probe for the culture confirmation of members of the MAC, the delay in obtaining a species identification by conventional methods is no longer warranted. Although it is common to perform the combination probe for MAC, it may occasionally be important to determine whether the causative agent is *M. avium* or *M. intracellulare*, since some suggest that disease with *M. avium* appears to be more severe than that caused by *M. intracellulare*.[375]

Most strains of MAC are resistant to the commonly used antituberculosis drugs. The underlying mechanism of resistance is based on the impermeability of the cell wall.[260] The synthesis of aminoglycoside- and peptide-inactivating enzymes has not been demonstrated, although some strains do produce β-lactamases.[214] The surfactant effect of Tween 80 on the cell wall may potentiate the effect of certain antimicrobial agents; ethambutol also has an effect on cell wall permeability, reflecting how this agent may work synergistically to potentiate the effect of certain other antituberculous drugs.[126] The addition of macrolides to treatment regimens has dramatically improved outcomes for patients with MAC disease.

***Mycobacterium paratuberculosis* and Crohn's Disease.** Hermon-Taylor and coauthors[123] cite the work of a Glasgow surgeon, T.K. Dalziel, who published a detailed description of chronic enteritis in humans and proposed that the disease was caused by the same microorganisms as those responsible for Johne's disease, an ulcerative intestinal condition associated with chronic diarrhea in cattle. Johne's disease had been known since 1895 and was thought to be associated with AFB, which could be seen in the tissues of infected animals but, in these early days, could not be cultured. Not long afterward, however, a slow-growing mycobacterium was finally recovered from the intestinal mucosa of infected animals, initially known simply as Johne's bacillus but later identified as *M. paratuberculosis*.

In 1984, Chiodini and associates,[48] working with Hermon-Taylor and colleagues at St. George's Hospital in London, reported the recovery of an unclassified, extremely

fastidious *Mycobacterium* species from three patients with Crohn's disease. After considerable effort, these workers identified the organism as belonging to the Runyon group III, closely related to *M. avium* and *M. paratuberculosis* complexes. Several additional cases linking *M. paratuberculosis* and Crohn's disease have been cited from the United States, the Netherlands, Australia, and France.[47] Further evidence that the Crohn's disease mycobacterium and *M. paratuberculosis* are the same was provided in yet another publication from the St. George's hospital group, who demonstrated identical DNA restriction digests between these groups of organisms.[201]

Gitnick and coauthors report the recovery of fastidious mycobacteria, including *M. paratuberculosis*, from 5 of 82

1247

surgically resected intestinal specimens from patients, 27 of whom had Crohn's disease.[99] These isolates required between 4 and 8 months for cultivation, which may be one reason why this organism has not been recovered in clinical laboratories. Prantera and coworkers[251] provided indirect evidence of the association of Crohn's disease with *M. paratuberculosis* by demonstrating high serum levels of antimycobacterial antibody that was demonstrated in patients following successful dapsone therapy, a phenomenon similar to that observed after treatment of classic cases of TB. With PCR and a portion of the *M. paratuberculosis* insertion sequence IS*900* as a probe, Sanderson and associates[282] were able to identify *M. paratuberculosis* DNA in 65% of rectal biopsy specimens in patients with Crohn's disease, in comparison with only 4.3% and 12.5% of patients with ulcerative colitis and healthy persons, respectively. Similarly, Fidler and colleagues[86] found that the material obtained from granulomata of Crohn's disease tissues (31 biopsy samples in the study) were much more likely to amplify *M. paratuberculosis*-specific DNA on PCR than non–Crohn's disease tissues (10 biopsies of ulcerative colitis as negative controls). If indeed mycobacteria are the cause of intestinal diseases, new methods for treatment of these conditions, notably Crohn's disease, may be in order. The association has not been proved by Koch's postulates (see Cocito and coauthors for a commentary on paratuberculosis[53]).

Mycobacterium terrae, M. gastri,* and *M. triviale. These mycobacteria are also slow-growing nonphotochromogenic bacteria that, in the past, have not generally been known as pathogens but are rarely encountered in the clinical laboratory (Clinical Correlation Box 19-11). They can be differentiated by the characteristics listed in Table 19-7. *M. triviale* colonies may resemble those of MAC or in some instances may be so rough that they are confused with tubercle bacilli; however, these strains are niacin-negative and can grow in media containing 5% NaCl. *M. triviale* also

hydrolyzes Tween 80 within 5 days, whereas MAC organisms are Tween-negative. *M. gastri* and *M. terrae* are other nonphotochromogenic species that may require biochemical differentiation (Table 19-7). *M. terrae* is also known as the "radish bacillus," since it was initially recovered from radish washings. Colonies of *M. terrae* tend to be smoother than the rough colonies of *M. triviale*.

Mycobacterium shimoidei. In 1988, Imaeda and coworkers,[135] based on DNA homology studies, officially established *M. shimoidei* as a distinct species. Additional clinical infections caused by *M. shimoidei* have been reported since the report of the index case. This organism has been reported as the cause of pulmonary infections in patients living in Australia and in Germany, the latter patient had this infection as a complicating condition of long-standing silicosis.[346] *M. shimoidei* differs phenotypically from members of the *M. terrae* complex by negative catalase and positive β-galactosidase reactions, and from *M. malmoense* by a positive acid phosphatase reaction. However, because β-galactosidase and acid phosphatase reactions are rarely performed in clinical laboratories, species identification based on phenotypic properties is difficult.

Mycobacterium malmoense. In 1977, Schroder and Juhlin recovered a new *Mycobacterium* species from four patients with pulmonary disease.[288] They called the organism *Mycobacterium malmoense*, after the Swedish city Malmo, in which these patients lived. The disease has also been noted to occur in Scotland.[90] The organism has been recovered from patients in the United States: 12 strains by Good and associates in 1980,[103] and from four patients with chronic lung disease by Albers and coworkers, in two of whom progressive disease developed[6] (Clinical Correlation Box 19-12).

Laboratory aspects. This organism typically grows slowly. Some strains are seen as soon as 2 to 3 weeks of incubation at 37°C; however, some strains may require as long as 12 weeks before colonies become visible. This need for prolonged incubation, beyond a period used in most clinical laboratories, may lead to under-detection. Typical colonies of *M. malmoense* are grayish white, smooth, glistening, opaque, and domed. They are colorless, and exposure to light does not produce pigment. On acid-fast smears, the organisms appear coccoid or as short rods without cross-bands.

CLINICAL CORRELATION BOX 19-11 *Mycobacterium terrae* and *Mycobacterium triviale*

M. terrae and *M. triviale*, although previously considered together in a complex, may also be considered separately. These mycobacteria have been incriminated in several

human infections, as cited by Woods and Washington: septic arthritis caused by *M. triviale* in an infant, synovitis and osteomyelitis caused by *M. terrae* in a young man with Fanconi's pancytopenia, and possible disseminated *M. terrae* infection in a young woman with previous miliary tuberculosis.[370] Several instances of pulmonary infection with *M. terrae* have been reported.[173,321] Krishner and coauthors report the presentation of one patient and cite six previously reported cases of respiratory infection.[168] Peters and Morice report the *M. terrae* pulmonary infection in a 64-year-old woman with ovarian carcinoma, which presented as miliary infiltrates on chest radiographs and accompanied by a rash on the extremities.[235] The lung and skin lesions resolved after 6 weeks of therapy with isoniazid, rifampin, and pyrazinamide, despite apparent "resistance" of these drugs, as determined by in vitro susceptibility testing. Petrini and coworkers[240] report a patient with *M. terrae* tenosynovitis of the hand. Both the tendon and tendon sheaths were swollen and chronic inflammation, granuloma formation, and necrosis were seen histologically. Tenosynovitis caused by this organism was also reported in the finger of a middle-aged fisherman who incurred puncture wounds while handling Crappie fins.[167]

1248

CLINICAL CORRELATION BOX 19-12 *Mycobacterium malmoense*

In the past few decades, *M. malmoense* has been reported with increasing frequency as a pulmonary pathogen. Infection typically occurs in patients with underlying lung diseases, often middle-aged men with pneumoconiosis.[379]Radiographic findings generally are indistinguishable from tuberculosis. Jenkins and Tsukamora[142] describe two cases of cervical adenitis, whereas Warren and associates[343] present a patient in the United States with chronic pulmonary disease. Albers and coworkers[6] believe that *M. malmoense* infections may be underreported, as some strains require 8–12 weeks or more of incubation before visible growth occurs, a period longer than cultures are held in most laboratories. A broth culture medium should be used in parallel, which has become the standard for mycobacterial culture, to improve the yield of particularly slow-growing strains.[125] Additional reports include lymphadenitis in a 5-year-old girl, septic cutaneous infection in a patient with hairy-cell leukemia, and several reported infections in HIV-positive patients.[39,51,60,244,360] In one patient, the infection was successfully treated with ethanbutol, cycloserine, and isoniazid, despite

multiresistance in in vitro susceptibility tests.[39] The lack of a clear correlation between in vitro susceptibility tests and clinical response was reported over a decade ago.[13] In the experience of these authors, omission of ethanbutol from the therapeutic regimen, even if it showed resistance in in vitro studies, has led to an unsatisfactory response.

Key biochemical test reactions for *Mycobacterium malmoense* include the following:

1. No accumulation of niacin.
2. Nitrate is not reduced to nitrite.
3. Tween 80 is hydrolyzed.
4. Catalase is produced at 68°C.
5. Pyrazinamidase is positive.

Mycobacterium haemophilum. Sompolinsky and associates[306] first recovered *M. haemophilum* in 1978 from a subcutaneous lesion of an Israeli patient with Hodgkin's disease (Clinical Correlation Box 19-13). As the species name would indicate, *M. haemophilum* requires hemoglobin or hemin for growth. Chocolate agar, 5% sheep blood Colombia agar, Mueller–Hinton agar with Fildes supplement, or LJ medium containing 2% ferric ammonium citrate is suitable for recovery of this organism. McBride and associates[198] report success in the recovery of *M. haemophilum* using a medium containing Casman base, 5% heated sheep blood, and crystal violet. Because of the remote chance for recovery of this organism in most laboratories in the United States, use of an X-factor strip in the area of inoculation on 7H10 agar, as suggested by Vadney and Hawkins, offers a suitable alternative in suspected cases.[331]

Most infections involve the skin and subcutaneous tissue, possibly reflecting the propensity of the organism to grow at lower temperature.[169] Gupta and coworkers[113] reported a patient with AIDS who had osteomyelitis and skin infection, which was successfully treated with minocycline. Kiehn and associates reported four cases in immunocompromised patients, two had AIDS and two were allogeneic bone marrow transplant recipients.[154] Because of the unique requirements for hemin and lower temperature for optimal growth, these authors suggest that *M. haemophilum* should be considered when specimens from immunocompromised patients with unexplained illness fail to grow mycobacteria under routine culture conditions or when AFB are seen on smears.[314]

Laboratory aspects. Optimal growth occurs at 28°C to 32°C; some strains grow at 20°C; little or no growth occurs at 37°C. Growth is stimulated by an incubation

atmosphere of 10% CO_2. Typical colonies may be rough or smooth after 2 to 4 weeks of incubation at 32°C on egg medium or 7H10 agar (supplemented with hemin or on the surface of which an "X-strip" has been placed, as discussed earlier). Pigment does not develop, even after exposure to light. Under the microscope, the cells are short, curved, and strongly acid-fast, without banding or beading. This organism is also

biochemically inert, with the production of pyrazinamidase the only positive reaction among the conventional tests commonly used to identify mycobacteria.

CLINICAL CORRELATION BOX 19-13 *Mycobacterium haemophilum*

Painful subcutaneous nodules, swellings, and/or ulcers that can progress into abscesses and draining fistulas are common clinical presentations of *M. haemophilum*. Rogers and coworkers[271] report instances of disseminated disease in patients with AIDS, in whom the skin lesions were multiple, involving the upper arm, hands, and feet. In a study of 13 patients with *M. haemophilum* infections culled from 7 metropolitan hospitals in New York, clinical manifestations included disseminated cutaneous lesions, bacteremia, and involvement of the bones and joints, lymphatics, and lungs.[89] The authors of this study stress that improper culture techniques may delay or result in a falsely negative culture, resulting in a missed laboratory diagnosis. It is possible that infections may be more common than realized due to these failures to culture the organism.

M. haemophilum has also been isolated from the wrist and ankles at sites of severe tenosynovitis, and from a cutaneous lesion, lymph node, and eye of a man who was the first reported patient with an *M. haemophilum* infection in Canada; the second patient was a 3-year-old Canadian girl with lymphadenitis, who was also included in this report.[192,318] Patients with lymphopenia are at particularly high risk for infections; renal dialysis and corticosteroid therapy have been shown to be predisposing conditions of *M. haemophilum* infection.[105,217]

Rapidly Growing Mycobacteria

***Mycobacterium fortuitum* Group and *M. chelonae/M. abscessus* Group.** The rapidly growing mycobacteria are ubiquitous land and aquatic organisms that

contaminate water supplies, including reagents and wash solutions used in hospitals. Clinical manifestations of infections that these mycobacteria cause are described in Clinical Correlation Box 19-14. The species of rapidly growing mycobacteria that most commonly cause human disease are *M. fortuitum* group (predominantly *M. fortuitum*) and *M. chelonae*/*M. abscessus* group (predominantly *M. chelonae* and *M. abscessus* subsp. *abscessus* [formerly *M. abscessus*]). Species within the *M. fortuitum* group are *M. fortuitum, M. peregrinum, M. senegalense, M. setense, M. septicum, M. porcinum, M. houstonense, M. boenickei, M. brisbanense,* and *M. neworleansense.* Identification to the species level requires molecular techniques, but in most instances has little clinical relevance; it may, however, be useful for epidemiologic investigations. Species in the *M. chelonae/M. abscessus* group are *M. chelonae, M. immunogenum, M. abscessus* subsp. *abscessus, M. abscessus* subsp. *massiliense, M. abscessus* subsp. *bolletii* (formerly *M. massiliense* and *M. bolletii),* and *M. salmoniphilum*. In the past, *M. chelonae/M. abscessus* complex was reported. However, differentiating *M. chelonae* from *M. abscessus* subsp. *abscessus* is recommended because the latter is more resistant to antimicrobial agents.[33,68,283,373]

CLINICAL CORRELATION BOX 19-14 Rapidly Growing Mycobacteria

M. fortuitum group and *M. chelonae/M. abscessus* group are the most clinically important of the rapidly growing mycobacteria (RGM). A wide variety of infections have been associated with these mycobacteria, including infections of the skin and subcutaneous tissue (which are the most common), bone, lung, central nervous system, prosthetic heart valve, and disseminated disease.[34,89,370,297] Wallace and Brown reviewed 100 isolates of *M. chelonae* from skin, soft tissue, and bone over a 10-year period.[339] Cutaneous infection (53%), localized cellulitis or osteomyelitis (35%), and catheter-associated infections (12%) were most commonly found. Underlying risk factors for infections included organ transplantation, rheumatoid arthritis and other autoimmune disorders, and trauma, including invasive medical procedures. Previously, Wallace and coworkers[341] had reviewed 125 human infections caused by RGM. Fifty-nine percent of these cases involved the skin and soft tissues (e.g., postsurgical wound infections, accidental trauma, and needle injections).

Nosocomial outbreaks of *M. fortuitum* skin infections have been associated with exposure to a contaminated ice machine and to contamination of an automated bronchoscope disinfection machine.[91,178] A clinically distinctive cutaneous syndrome associated with infection caused by the then *M. chelonae* complex (*M. abscessus* was not routinely distinguished from *M. chelonae* at that time) in kidney-transplant

recipients, consisting of indolent, tender, nodular lesions, on the extremities has been reported.[59] Sporotrichoid spread of these infections may occur in immunosuppressed patients, and, rarely, cutaneous infection with RGM may represent the extension of disseminated disease.[77,218] Cutaneous infections due to RGM also have been associated with tattoo ink.[252]

Several other clinical entities caused by RGM have been reported. Keratitis has been reported in wearers of both soft and hard contact lenses.[30,151] Most of these infections followed trauma, and topical antibiotic therapy often is not successful; therefore, keratoplasty may be required to effect a cure. It has been suggested that acid-fast smears of corneal scraping be performed on any patient with chronic corneal ulcers.[265] Patients receiving continuous ambulatory peritoneal dialysis are also at risk of acquiring peritonitis caused by RGM.[49,81,164,204,307] Therefore, it is reasonable to perform mycobacterial cultures on patients with peritonitis associated with continuous ambulatory peritoneal dialysis when routine cultures fail to reveal organisms. RGM should be considered when Gram's stain smears prepared from isolates recovered from peritoneal or dialysis fluids show what appears to be poorly characterized diphtheroids or beaded, gram-positive bacilli. Removal of the catheter, drainage of fluid collection, and appropriate use of antimicrobial agents usually result in rapid cure.

RGM may cause pneumonia, with pulmonary infections caused by *M. abscessus* being particularly serious.[341] RGM are ubiquitous in many water sources and may colonize the respiratory tract of patients who have compromised local defense mechanisms, who are debilitated or immunocompromised, or who have long-standing chronic obstructive pulmonary disease. Burns and associates[35] studied an outbreak of positive *M. fortuitum* sputum cultures among 16 patients being treated on an alcoholism rehabilitation ward. Pulsed-field electrophoresis of large genomic DNA restriction enzyme fragments disclosed that the 16 isolates were identical. The point source was found to be a tap connected to the water line supplying the showers being used by these patients; no further cases occurred after the showers were disconnected and decontaminated.

Several reports of catheter-associated infections caused by RGM have been made. Raad and coworkers[255] reviewed 15 infected patients with cancer, 9 were infected with *M. fortuitum*, whereas 6 had contracted *M. chelonae*. Four patients with bacteremia and associated catheter infections recovered after removal of the catheter and prompt institution of antibiotic therapy. Bacteremia recurred in seven patients in whom the catheter was

left in place and who were treated with antibiotics alone. Patients with infections of the catheter tunnel required surgery for cure. Patients with mycobacteremia are at

risk to develop infective endocarditis, particularly if they have a prosthetic valve or valvular abnormalities.

Mycobacterium chelonae infections have also been reported in patients with febrile neutropenia, which is a risk factor for disease.[202]

Other infections caused by the RGM include *M. chelonae* otitis media due to transfer of the organism between patients from contaminated instruments, aortitis following aortic valve replacement, sternal wound infection, endocarditis, cardiac bypass-related infections, hepatitis, synovitis, retroperitoneal abscess complicating a gunshot wound to the flank, and disseminated *M. fortuitum* infection in a patient with AIDS.[133,189,270,287,300,351,370] *Mycobacterium smegmatis* posttraumatic soft tissue infections were reported in a 21-year-old man and a 29-year-old woman who were involved in separate motor vehicle accidents.[223] The former patient presented with a draining left leg lesion and inguinal adenopathy and the latter with a chronically draining subcutaneous area of cellulitis of the posterolateral thigh. The authors also cite 12 cases of *M. smegmatis* infections reported in the literature, dispelling doubt that this organism is nonpathogenic. Finally, Newton and Weiss subsequently reported *M. smegmatis* as a cause of aspiration pneumonia.[222]

The RGM vary in their in vitro susceptibility to antimicrobial agents. For example, most isolates of *M. fortuitum* group are susceptible to trimethoprim/sulfamethoxazole, whereas virtually all *M. chelonae/M. abscessus* group are resistant. Most of the *M. fortuitum* group, *M. smegmatis* group, and *M. mucogenicum* are susceptible to imipenem, most *M. chelonae* are susceptible to tobramycin, and most *M. abscessus* are susceptible to amikacin. Antimicrobial susceptibility testing should be performed on all clinically significant isolates of RGM, following Clinical and Laboratory Standards Institute guidelines.[367]

Laboratory aspects. Mycobacteria are categorized as rapid growers, by definition, if they grow on a solid medium within 7 days after subculture. The young colonies appear smooth and hemispherical, usually with a butyrous or waxy consistency. Colonies of *M. fortuitum* group and *M. chelonae/M. abscessus* group are typically nonpigmented but may appear off-white or faintly cream-colored (Image Plate 19-2Q). *M. fortuitum* may produce branching, filamentous extensions from 1- to 2-day-old colonies on cornmeal–glycerol or Middlebrook 7H11 agar. Some strains produce rougher colonies with short aerial hyphae, best observed under a stereomicroscope. *M. chelonae* lacks these filamentous extensions.

The above mycobacteria often have the capability of growing on MacConkey agar without crystal violet. They also appear as smooth, dome-shaped colonies that may have a slight pink pigmentation (Image Plate 19-2R). Additionally, they may grow on routine 5% sheep blood agar, initially appearing as tiny pinpoint colonies (Image Plate 19-2S). Microbiologists must be alert to this possibility and perform acid-fast stains in

addition to Gram's stains if the correct identification is to be made.

Microscopically, in acid-fast-stained preparations, the bacterial cells are generally pleomorphic, ranging from long, filamentous forms to short, thick rods. Branching typically is absent or rudimentary; at times the cells may appear beaded or swollen, with nonstaining ovoid bodies present at one end. Some strains of *M. fortuitum* may grow within 48 hours on routine 5% sheep blood agar. The bacterial cells appear as short, slender, filamentous, faintly staining gram-positive bacilli (Image Plate 19-2T).

Silcox and associates[297] have identified the following characteristics for an isolate to belong to the rapidly growing mycobacteria:

1. Acid-fast
2. Lack of pigment production
3. Growth on solid media in less than 7 days at its optimal temperature
4. Evidence of arylsulfatase activity at 3 days
5. Growth at 28°C on special MacConkey agar (devoid of crystal violet)

Accurate identification of rapidly growing mycobacteria, however, requires molecular methods (described later in this chapter).

Infrequent Human Pathogens. Rapidly growing mycobacteria that infrequently or rarely cause human disease are *M. mucogenicum* group (*M. mucogenicum, M. auagnense,* and *M. phocaicum*), *M. mageritense, M. wolinskyi*, the early-pigmented rapidly growing mycobacteria (*M. neoaurum, M. canariasense,* and *M. cosmeticum*), and the pigmented rapidly growing mycobacteria *M. smegmatis, M. goodie,* and *M. thermoresistible,* the latter of which has the unique ability to grow at 52°C. The infrequency of reports describing disease caused by *M. thermoresistible* in humans indicates that exposure is either minimal or the organism is of very low virulence. Weitzman and coauthors reported an infection by *M. thermoresistible* in an immunocompromised woman with fever, cough, and weight loss.[351] Cavitary pulmonary disease was seen on radiographs. The organisms were recovered from sputum and a bronchoscopy specimen. Histologic examination of a lung biopsy revealed numerous microabscesses and granulomas with Langhans giant cells. Wolfe and Moore reported a breast infection in a woman following augmentation mammoplasty.[363]

Other Mycobacteria

Mycobacterium ulcerans. Most cases of *M. ulcerans* infections have been reported from Central and West Africa, Malaysia, New Guinea, Guyana, Mexico, and Australia (Clinical Correlation Box 19-15). The name "Bairnsdale ulcer" has been used for the cutaneous lesions of *M. ulcerans* infections, named after the Australian town where the organism was first recognized by Alsop and Searls in the 1930s.[256] Most human

infections occur in the tropical regions following rain forest disturbance.[120] It is postulated that the mycobacteria are carried from the soil into draining lacustrine systems, where they multiply over a period of months or years. Humans become infected by contacting organisms from these contaminated estuaries.

1251

CLINICAL CORRELATION BOX 19-15 *Mycobacterium ulcerans*

Infection with *M. ulcerans,* termed Buruli ulcer, typically presents as a "boil" or lump under the skin on the lower extremities, which usually develops at the site of previous trauma. This, then develops into a shallow, nonhealing ulcer, with a necrotic base within a few weeks. Lesions are generally painless, unless they become secondarily infected with bacteria. Some lesions may be quite severe, with avascular coagulation necrosis extending deep into the subcutaneous fat.[134] Satellite nodules that ulcerate may also develop.

Disease has been reported from at least 33 countries. These are located in Africa, South America, and the Western Pacific. Although Delaporte et al.[72] reported one of the first *M. ulcerans* infections in a patient with AIDS, it is not a marker for that disease. Buruli ulcer is one of the 17 neglected tropical diseases. This infection is progressive and causes significant morbidity, disability, and disfigurement. Up to 80% of patients are thought to be curable, if treated with the appropriate antimicrobial agents. Up-to-date information about Buruli ulcer is available from the World Health Organization at http://www.who.int/topics/mycobacterium_ulcerans/en/.

Laboratory aspects. *M. ulcerans* grows optimally at 33°C and not at all at 37°C. Rough, lightly buff or nonpigmented, convex to flat colonies, with irregular outline, often simulating those of *M. tuberculosis*, develop after 6 to 12 weeks. Microscopically, the acid-fast cells are moderately long and rod-shaped, without banding or beading. *M. ulcerans* is biochemically inert, showing only heat-stable catalase activity among the several tests usually used to identify mycobacteria.

Mycobacterium genavense. *M. genavense* is an uncommonly recovered, slow-growing, nonpigmented, NTM that causes infection in patients with AIDS. The organism was first recognized by Boettger and associates[27] by finding a unique pattern using DNA extracted from mycobacteria growing in BACTEC 13A blood culture media. Amplified gene fragments were sequenced directly, and electrophoretic profiles were determined in 0.8% agarose gel stained with ethidium bromide. The authors

studied 16 isolates that had a unique DNA sequence profile and officially designated the organism *M. genavense* after the 28-year-old patient with AIDS, who was living in Geneva, from whom the first isolate was recovered. Subsequently, Coyle and associates,[61] using assays for sequencing of the gene for 16S rRNA that had been extracted from unidentified mycobacterial isolates of 15 blood cultures obtained from seven patients with AIDS, also confirmed the identity of *M. genavense* as a separate species. The sequence pattern was most closely related to *M. simiae*; however, the clinical presentation (fever, weight loss, diarrhea, hepatosplenomegaly, and anemia), response to therapy, and autopsy findings more closely resemble infections with MAC.[22] Histopathologically, *M. genavense* in HIV-positive patients produces lesions characterized by masses of foamy histiocytes and ill-defined granulomas, the development of which depends on the immunologic reactivity of the host.[197] In one autopsy series, the small intestine, spleen, liver, and lymph nodes were most commonly involved; the lungs, myocardium, and kidney were spared, a distribution similar to that seen in patients with disseminated disease caused by a member of the MAC.

Although the initial isolates were identified in specimens obtained from patients with AIDS in Switzerland, disseminated infections caused by *M. genavense* have been described from elsewhere in Europe, North America, and Australia.[27,234] This geographic distribution may reflect more the awareness by health workers of this new species rather than select areas of endemicity. *M. genavense* may be underrecognized because it grows only in broth culture media or on a solid medium to which mycobactin J (which is not available in most clinical laboratories) has been added, and it requires prolonged incubation.

The Detection and Identification of Mycobacteria by Molecular Methods

In the past several years, most clinical mycobacteriology laboratories have discontinued the time-consuming and tedious task of performing biochemical tests to make a species identification of mycobacteria recovered in culture. More and more often, nonculture methods based on molecular biology are being used in clinical laboratories for the identification of *Mycobacterium* species isolates recovered in culture. For example, the use of nucleic acid probe assays has virtually replaced conventional biochemical testing in the identification of MTBC, MAC, *M. kansasii,* and *M. gordonae*.[82,78,152,180,220,206,264,284,327]

There are four major applications for molecular techniques that are available for use in clinical laboratories:

1. Culture confirmation of isolates recovered from clinical specimens using DNA probes.
2. The identification of mycobacteria through DNA sequencing or other molecular techniques.
3. The direct detection of MTBC in respiratory and extrapulmonary specimens using nucleic acid amplification assays.
4. DNA fingerprinting and strain typing of *Mycobacterium* species.

The medical literature relative to molecular diagnostics as applied to the identification of the mycobacteria is vast. Although the molecular tools used in different

mycobacteriology laboratories vary, virtually all modern mycobacteriology laboratories use molecular diagnostics to some extent. Study of these techniques also provides a fundamental understanding of the basic biology of mycobacteria and helps to determine the best role for newer techniques when they are introduced into the clinical laboratory. The detection and characterization of mycobacteria by molecular methods may be separated into nonamplification- and amplification-based methods. After amplification, the product(s) of amplification may be analyzed by DNA sequencing to acquire identification information or by other techniques or typing. The salient features of these applications are described below.

Signal Amplification Methods

Nucleic Acid Probes. Nucleic acid probes were the first nucleic acid-based technology to be used routinely in the clinical microbiology laboratory for the identification of mycobacteria in positive cultures. These nonisotopic probes were pioneered and brought to market by Gen-Probe (now Hologic, San Diego, CA). The accuracy, sensitivity, and specificity of these probes are very high when used to identify mycobacteria in culture.[78,104,152,180,206,220,284] Nucleic acid probes are available for the identification of MTBC, MAC, *M. kansasii,* and *M. gordonae*. Separate probes are also available for *M. avium* and *M. intracellulare,* if the differentiation of these mycobacteria is desired.

In brief, this technology uses acridine ester-labeled single-stranded DNA probes that hybridize with the ribosomal RNA (rRNA), which is released from the test bacterium through the action of a lysing agent, heat, and sonification. Ribosomal RNA is a useful genetic target for the identification of microorganisms, since it often contains signature sequences and is present in the cells and culture in high quantities secondary to the growth of the organism (i.e., biologic amplification). The DNA probe and rRNA hybridize according to traditional Watson and Crick base-pairing for a stable DNA–

RNA complex. After the inactivation of the unhybridized probe, a signal-generating step is performed and light is produced and recorded by an instrument. The light produced is proportional to the amount of probe present, and a predetermined threshold is used to determine positivity. The 2 hours required for the probe-based determination of the species for which genetic probes are available represents a significant advance compared with identification by traditional methods.[206,284] The commercial kits have an extended shelf-life, which also extends the usefulness to a large number of laboratories.

One advantage recognized early was the use of these probes on positive broth cultures, which recover mycobacteria more rapidly than solid media in most instances.[82,152,237,264] In an effort to decrease the time of detection even further, Forbes and coworkers[88] applied PCR amplification to detect *M. tuberculosis* recovered in BACTEC 12B broth cultures. By using PCR, positive BACTEC 12B vials could be assayed when the growth index (GI) reached 10, shortening the time of incubation required for the GI to reach 100 or more. The use of PCR in this study resulted in a mean time to detection of *M. tuberculosis* of 9 days, compared with 14 days using nucleic acid probes from growth of BACTEC 12B subcultures on solid media. The observation of cord formation in acid-fast stains performed on broth from signal-positive cultures can be used as a guide to immediately select the MTBC probe assay.[148]

Nucleic Acid Amplification Methods

Commercially Available Applications. The burden of organisms in rare instances is large enough in the clinical specimen to achieve detection with a chemiluminescent genetic probe. However, in most instances, this method is too insensitive for direct use on clinical specimens. A nucleic acid amplification–based assay is recommended if identification of mycobacteria is to be attempted directly from the clinical specimens. In the late 1990s, two commercially available nucleic acid amplification assays for the detection of MTBC received approval by the FDA for use on respiratory specimens. These tests, the Amplicor *M. tuberculosis* PCR assay (Roche Diagnostics, Indianapolis, IN) and the Amplified *Mycobacterium tuberculosis* Direct test (AMTD), which uses transcription-mediated amplification, had both been approved for use with smear-positive specimens, whereas only the latter was been approved for use on smear-negative respiratory specimens. This represented the culmination of several developmental studies and field trials over several years, leading to products that are standardized and designed in such a way that problems of contamination with extraneous DNA and inhibition of amplification reactions by endogenous inhibitors are minimized. Nucleic acid amplification assays perform well on smear-positive specimens, but not unexpectedly the sensitivity is lower with smear-negative

respiratory specimens, when compared with culture.[20,25,67,73,132,228,241,242,281,303,338]

It is beyond the scope of this textbook to review all the published works of other researchers in the evolution of AMTD and PCR applications to direct testing of specimens for mycobacteria, but there are many. Some of the studies for each of these FDA-approved technologies are described in the following paragraphs.

One of the early field trial studies of the Gen-Probe AMTD test (now Hologic, San Diego, CA) was published by Jonas and coauthors in 1993.[146] In a study of 758 processed sputum sediments, 119 (16%) of which were positive for *M. tuberculosis*, the Gen-Probe assay performed with a sensitivity, specificity, positive and negative predictive value of 82%, 99%, 97%, and 96%, respectively, which were comparable with the results derived from culture and better than from smear analysis.

Miller and coworkers[209] performed a retrospective evaluation of three separate respiratory specimens from each of 250 patients using the AMTD, comparing the results with those of microscopy, culture, and patient chart review. Of these patients, 198 (from whom 594 specimens were collected) were negative for *M. tuberculosis* by culture and clinical criteria, whereas 52 were positive (156 specimens). The overall specificity of the AMTD was 98.5%. Of the 156 specimens obtained from the patients with TB, organisms were recovered from 142 (91%), acid-fast microscopy was positive for 105 (67.3%), and the AMTD was positive for 142 (91%). When all three specimens from each patient were tested, AMTD detected all 52 patients that were positive for TB.

In a study of 938 respiratory specimens, Pfyffer and associates[242] found that the AMTD test performed with a

sensitivity of 93.9%, a specificity of 97.6%, a positive predictive value of 80.7%, and a negative predictive value of 99.3% after resolution of discrepant results by chart review. These authors concluded that the AMTD was highly sensitive and specific for detecting MTBC organisms within a few hours. The results of another study, however, were less encouraging.[25] Of 617 respiratory tract specimens, 590 were culture- and AMTD-negative. Twenty-one cultures (3.4%) yielded *M. tuberculosis*; of these, 15 (71.4%) were detected by AMTD and 6 were missed. *M. tuberculosis* did not grow in culture from six AMTD-positive specimens (28.6%) obtained from three patients under treatment for TB. Thus, the sensitivity, specificity, and negative and positive predictive values for AMTD were 71.4%, 99%, 99%, and 71.4%, respectively. The test was judged to be easy to perform and highly specific by these authors, but lacking in sensitivity. They suggested that inclusion of an internal amplification control may be helpful.

Vuorinen and associates[338] conducted studies that compared the performance of the Gen-Probe product with the Roche Amplicor *M. tuberculosis* Test (Roche Molecular Diagnostics, Indianapolis, IN), prior to FDA approval of the latter assay in the United States. These authors tested 256 respiratory specimens obtained from 243 patients for the presence of MTBC with both the AMTD and PCR Roche Amplicor *Mycobacterium tuberculosis* Test (Amplicor PCR). When compared with the results of culture performed in parallel, the sensitivities of staining, AMTD, and Amplicor PCR were 80.8%, 84.6%, and 84.6%, respectively. The specificities for these three tests were 99.1%, 98.7%, and 99.1%, respectively. The conclusions of these authors were that both nucleic acid amplification methods were rapid, sensitive, and specific for the detection of *M. tuberculosis* in respiratory specimens.

The following are brief summaries of a few other studies of the PCR Roche Amplicor *Mycobacterium tuberculosis* Test. Ichiyama and associates,[132] in a parallel study of 422 sputum samples obtained from 170 patients with mycobacterial infections, also found that the AMTD system and the Amplicor *Mycobacterium* system performed equally well, with 98.7% agreement. D'Amato and colleagues[67] tested the Roche Amplicor test on 985 specimens from 372 patients. The sensitivity, specificity, and positive and negative predictive values compared with culture and clinical diagnosis were 66.7%, 99.6%, 91.7%, and 97.7%, respectively, comparable with culture results. The authors cite the great advantage of having test results available approximately 6.5 hours after the specimen arrives in the laboratory. Wobeser and coworkers[362] found that the Amplicor PCR assay performed with sensitivity, specificity, and positive and negative predictive values of 79%, 99%, 93%, and 98%, respectively, in a study of 1,480 clinical specimens obtained from 1,155 patients. In smear-positive specimens, the sensitivity was 98%, versus 59% for smear-negative specimens. The sensitivity and specificity of specimens demonstrating a positive GI on the BACTEC 460 system were 98% and 100%, respectively. Delacourt and associates,[71] in a study of 68 children with various stages of tuberculosis, found that PCR was positive in 83.3% of 199 specimens obtained from children with active disease, but also in 38.9% of children without symptoms.

In 2012, a third nucleic acid amplification assay—the Xpert MTB/RIF assay (Cepheid, Sunnyvale, CA)—was cleared by the FDA for use in the United States. The assay has two components: (1) a plastic cartridge that contains liquid sample processing and PCR buffers and lyophilized real-time PCR reagents and (2) the GeneXpert instrument, which performs sample processing and real-time PCR in a hands-free manner. This assay simultaneously detects *M. tuberculosis* and rifampin resistance by PCR amplification of the 81-bp fragment of the *M. tuberculosis rpoB* gene and subsequent probing for mutations associated with rifampin resistance. The internal control is a hemi-nested molecular beacon assay to detect *Bacillus globigii* DNA. Approved specimen types are raw sputum and concentrated sediments prepared

from sputum. Total hands-on time is less than 5 minutes per specimen, and results are available in less than 2 hours. The sensitivity versus culture when testing sputum specimens was 98% to 100% for AFB smear-positive samples and 69% to 72% for smear-negative samples.[26,121,380] Specificity of the assay in these two studies was 100%.

An additional amplification assay for MTBC—the *M. tuberculosis* BD ProbeTec (BD Diagnostic)—is available for use outside the United States; it is not FDA-approved. This assay, which uses strand displacement amplification, has been used for direct detection of MTBC in respiratory specimens, as well as in positive cultures.[15,18,342] Barrett et al.[15] studied the direct respiratory specimens of 205 patients who had a high probability of having TB. Of the 109 patients with culture-proven TB, 101 were positive by the BD ProbeTec assay, yielding a sensitivity of 92.7%. There were three false-positive reactions reported in this study from patients with NTM, giving a specificity of 96%.

The use of commercial products does not preclude users from encountering problems in implementation and use of the test. Manufacturer's recommendations must be closely followed and quality control standards must be rigidly enforced. These tests are not a replacement for culture. There are still instances in which MTBC is recovered from culture but not detected by molecular methods. Furthermore, complete molecular profiling for all the determinants of resistance is not yet available, so phenotypic susceptibility testing must be performed. Culture methods must be run in parallel for each specimen received, the clinical aspects of each case must be closely monitored, and communication between the laboratory and primary care physicians must be maintained throughout. With all of these provisions in place, the ability to diagnose new cases of TB early has a major impact on therapy and infection control, limiting person-to-person transfer of disease.

Laboratory-Developed PCR Assays, Including Real-Time PCR. In addition to FDA-approved assays, numerous laboratory-developed (formerly termed "home-brew") nucleic acid amplification assays have been developed. These applications, although not approved for use by the FDA, may be important diagnostic tools in the hands of the skilled user. The potential for shortening to hours, rather than days and weeks, the detection and identification of MTBC and perhaps other *Mycobacterium* species directly in a variety of clinical specimens make these assays attractive. The cost of laboratory-developed amplification assays is often considerably less than comparable commercially available products, but the appropriate validation of the assay resides with the user of the test.

Nolte et al.[226] developed one of the earliest PCR assays for the rapid diagnosis of pulmonary TB; in this paper the authors described important background information that would be of interest to those who wish to learn more about developing and setting up a PCR assay. Some of the potential problems that must be addressed with nucleic acid–based amplification assays are inhibition of amplification and the reproducibility of the assay. These were addressed in a multi-laboratory study reported by Noordhoek and coauthors.[227] They circulated 200 sputum, saliva, and water samples containing known numbers of *M. bovis* BCG cells along with negative controls for PCR analysis, among seven laboratories that used the IS*6110* insertion sequence as the target for DNA amplification. Each laboratory used its own protocol for pretreatment, DNA extraction, and detection of the amplification product. High levels of false-positive PCR results were found among the participating laboratories, ranging from 3%to 20%, with an extreme of 77% in one laboratory. This relatively poor performance resulted from lack of monitoring of each step of the procedure and underscores the necessity for careful quality control during all stages of the assay. In addition, inhibition of amplification and the erroneous reporting of false-negative results may be a problem with PCR. For this reason, the use of an internal amplification control, or the documentation and monitoring of the false-negative rate of an assay, is required for laboratory accreditation by the College of American Pathologists for laboratories that use these tests.

Real-time nucleic acid amplification is a more rapid method of performing PCR or other methods of amplification, wherein amplification and detection occur in the same reaction vessel. This vessel is closed, which significantly decreases the chance of amplicon contamination of the laboratory. Several assays have been designed for the rapid detection of *M. tuberculosis*, using most of the available formats.

Assays have been described using the LightCycler system (Roche Diagnostics, Indianapolis, IN). Some of these are specific for *M. tuberculosis* using a single set of fluorescence resonance energy transfer (FRET) probes.[166,208] Miller et al.[208] examined 135 AFB-positive specimens, of which 105 grew *M. tuberculosis*. Both the LightCycler assay and the Amplicor *M. tuberculosis* PCR test to which it was compared detected 103 of 105, yielding a sensitivity of 98.1%, each. They also studied 232 BacT/Alert MP culture bottles of respiratory specimens, 114 of which were positive for *M. tuberculosis*. All the positive cultures were detected by the LightCycler assay.

Shrestha et al.[295] took another approach and designed a broad-range PCR to detect all mycobacteria, but to differentiate *M. tuberculosis* from NTM based on postamplification melt-curve analysis. After amplification is complete, melt curves may be generated with some types of real-time amplification assays. Assays that use FRET probes produce very distinct melt curves that distinguish even a single nucleotide difference in the probe hybridization sites. Shrestha et al. used this feature to

differentiate *M. tuberculosis* from NTM using both 186 cultured isolates and 50 clinical specimens that were culture-positive for *M. tuberculosis*. Both the LightCycler assay and the Amplicor *M. tuberculosis* PCR test to which it was compared detected 48 of 50 specimens.

The results of real-time PCR assays are innately quantitative, and when used with standards the definitive amount of an organism present may be determined. Kramme and associates[165] describe a real-time PCR assay, wherein not only the presence of the organism is detected, but an indication of the amount of organism present could be determined. Similarly, Rondini et al.[274] have developed a hydrolysis probe–based assay (i.e., a Taqman assay) for the detection of another important cutaneous mycobacterial pathogen, *M. ulcerans*.

Postamplification Analysis

Reverse Hybridization/Line Probe Assays. Reverse hybridization is similar in many ways to the traditional Southern blot, wherein the amplicon-probe hybridization reaction occurs on a nitrocellulose or similar substrate. In this technology, the target sequences are first amplified by PCR using biotinylated primers. The multiple probes are immobilized on a nitrocellulose strip, and the amplified product is applied to the strip, which is the reverse of a Southern blot. Lines form at the site of amplicon-probe hybridization. When this pattern is compared with a key, one can interpret the results of this reaction (Fig. 19-2). The advantage over traditional Southern blotting is that numerous probes are assayed simultaneously and radioisotopes are not used.

■ **FIGURE 19-2** The INNO-LiPA MYCOBACTERIA V2 (Innogenetics, Gent, Belgium) reverse hybridization assay is demonstrated. This strip contains a conjugate control line, and hybridization probes to determine the presence of mycobacteria at the genus level and identification information for 16 different species. (The photograph is from the company package insert.)

1255

Reverse hybridization technology is commercially available as line probe assays for the rapid identification of mycobacteria. These assays perform best using colonies on a solid medium or broth from a positive liquid culture, although direct testing of AFB smear-positive specimens is possible. The first-version reverse hybridization assay examined was the LiPA Mycobacteria assay (Innogenetics). This assay used a broad-range PCR directed against the 16S to 23S spacer region and probes for MTBC, MAC, and the following mycobacterial species: *M. avium, M. intracellulare*, *M. kansasii*, *M. chelonae* group, *M. gordonae*, *M. xenopi,* and *M. scrofulaceum*. Miller et al.[210] studied 60 clinical isolates of mycobacteria from 59 patients using this product and found no discrepancies with routine laboratory identification with the majority of the isolates, although some were not identified to the species level. Of the isolates tested, 26 were MTBC, 9 *M. avium*, 3 MAC, 3 *M. kansasii*, 4 *M. gordonae,* and 5 *M. chelonae* group isolates. Three patient samples had positive reactions for MAC and were subsequently determined to have *M. intracellulare* by PCR–restriction-fragment-length polymorphism (RFLP) analysis. Seven additional mycobacterial species were identified only to the genus level (*Mycobacterium* spp.); six of these were *M. fortuitum*, and one was *M. szulgai*. Several other groups have examined this product with similar results, and during these studies they demonstrated minor problems that led to the development of a new, improved version.[315,324,325] PCR followed by reverse hybridization has also been used on direct clinical specimens, with excellent results from smear-positive specimens.[145] The newer version, the INNO-LiPA Mycobacteria v2, has expanded the number of identifiable mycobacterial species to 16. Tortoli et al.[324] tested 197 mycobacteria belonging to 81 taxa with this product and found 100% specificity and sensitivity for 20 out of 23 probes. The probes specific for *M. fortuitum* complex, for the MAC–scrofulaceum group, and for *M. intracellulare* type 2 demonstrated cross-reactivity with several mycobacteria that are rarely isolated from clinical specimens. The overall sensitivity was 100% and the overall specificity was 94.4%.

Reverse hybridization assays have also been shown to be useful for the detection of the genetic determinants of resistance to various antituberculosis agents.[4,42,70,144,293,305] As with species identification, detection of the genetic

determinants of resistance has also been achieved directly from the clinical specimen.[144] Although performance is good, especially for rifampin, sensitivity and specificity are less than 100%, so susceptibility testing using a phenotypic method still must be done.

DNA Sequencing. DNA sequencing for the analysis of an amplified product is now a common method of postamplification analysis. Although useful, this technology is more complicated than simple probe hybridization and often requires the user to have experience with sequence alignment and editing software, and genetic databases. Analysis of these variable regions interspersed between conserved regions that serve as broad-range primer hybridization sites becomes a powerful tool for microorganism identification.[29,94,101,106,176,259,289,372]

Traditional DNA sequencing, also known as Sanger sequencing, was once used solely in research laboratories, but it has also become commonplace in many molecular pathology and molecular microbiology laboratories. These methods have been used successfully for the identification of bacteria, mycobacteria, nocardia, and fungi. The genes that encode for the ribosomal subunits of these organisms are the most commonly used genetic targets of sequence-based identification.

This technology is revolutionizing the laboratory identification of slow-growing microorganisms such as mycobacteria and nocardia.[52,115,150,203,233,239] One of the most useful regions of the 16S gene complex for the identification of mycobacteria involves the hypervariable A region. This has been used to achieve rapid and accurate sequenced-based identification of the most common clinically relevant mycobacteria.[75,119] It has also been used to help identify and differentiate more difficult to characterize isolates.[308] This region has also been used successfully for the identification of most clinically relevant mycobacteria using pyrosequencing.[14]

MicroSeq (Applied Biosystems, Inc. [ABI], Foster City, CA) is a commercially available system for the identification of microorganisms by DNA sequencing. After cultivation, a PCR is performed using the primers provided. The sequence is then determined through ABI capillary-based sequencing, and the product is submitted as a query to a genetic database that is maintained and updated by the manufacturer. Hall et al.[115] examined this database using 59 ATCC strains and 328 clinical isolates. Sequence-based identification correctly identified, based on what is called a distance score of <1%, 98.3% (58 of 59) of the ATCC strains to the correct group or complex and 90.1% (219 of 243) of the clinical isolates. Of the remaining isolates that had distance scores of >1%, 41.1% (35 of 85) were identified to the appropriate species, complex or group level, whereas 15.3% (13 of 85) were identified to the species level. Most significantly, they report a turnaround time for mycobacteria identification of less than 24 hours, which is phenomenal when one considers the time to identification of

traditional phenotypic methods.

The *rpoB, hsp,* and *tuf* genes have also been used successfully as the genetic targets for sequence-based identification for a variety of bacteria.[79,80,150,174,229,231,267] The *rpoB* gene, which encodes for DNA-dependent RNA polymerase, has been used by several groups for the identification of mycobacteria.[157,158,181,329] Sequencing this genetic target is popular, since it not only provides identification information, but also provides information regarding the susceptibility of the isolate to rifampin.[305,336]

Microarray Analysis. Microarrays, devices commonly referred to as gene chips, have been used extensively for research. These have also been used for the identification of mycobacteria and the detection of the genetic determinants of resistance. Troesch et al.[329] describe the use of a microarray that examined two genetic regions, the 16S rDNA and the *rpoB* gene. They examined 70 mycobacteria representing 27 different species and 15 rifampin-resistant isolates of *M. tuberculosis* with this microarray and were able to identify 26 of 27 species and all of the resistant mutants. Microarrays hold great promise, but they are expensive, and currently remain a research tool.

1256

Strain Typing and DNA Fingerprinting. The advent of molecular techniques permits strain-specific analysis of *M. tuberculosis* isolates for purposes of epidemiologic studies. The insertion sequence, IS*6110*, was specifically identified as the target of a DNA probe to be used in fingerprint analysis.[40,41] The IS*6110* was conserved in all of the *M. tuberculosis* strains studied and was present in high copy numbers. The specific fingerprint technique described involved digestion of the genomic DNA with the restriction endonuclease *Bam*HI, followed by separation of the fragments by agarose gel electrophoresis, transferring the DNA fragments to a nylon membrane and hybridizing the membrane with cloned DNA segments representing two different portions of IS*6110*.

Several workers have used the insertion sequence IS*6110* as the target for conducting epidemiologic studies. Yang and associates[377] compared the fingerprinting patterns of 68 mycobacterial isolates obtained from HIV-seropositive patients with TB in the Dar es Salaam region of Tanzania, with 66 isolates recovered from HIV-negative patients living in the same region. They observed 101 fingerprint patterns among this group of patients, with the level of diversity equal between the two. Of these isolates, 8.8% showed resistance to at least one drug, again, with no tendency to cluster within either of the groups. In a study of the IS*6110* fingerprint patterns of *M. tuberculosis* recovered from 64 patients living in French Polynesia, 11 separate clusters were identified.[322] Clustering of strains with identical patterns were identified among family

groups, indicating that active transmission plays as significant a role as reactivation disease in French Polynesia. Similarly, in a subsequent study, a high degree of likeness was found in IS*6110* fingerprint patterns among closely related individuals.[376] One of the prevalent IS*6110*-defined clusters in Greenland accounted for 91% of 245 cases of TB in Denmark collected during the same period. These cases were traced to a group of immigrants from Greenland living in a small, defined geographic region in Denmark.

van Soolingen and associates[334] detected 43 different IS*6110* fingerprint patterns of 153 *M. bovis* strains originating from cattle and humans in the Netherlands and Argentina, various animals in Dutch zoos, in a wild park in Saudi Arabia, and from diseased seals and cats in Argentina. Strains presenting only a single band were characteristic for the strains recovered from cattle. Of the 20 human isolates from Argentina, 18 showed a single band, similar to that seen in the cattle strains, strongly suggesting bovine-to-human transmission. The fingerprint patterns of human *M. bovis* isolates from the Netherlands were diffuse, except for similar patterns in five patients, all living in Amsterdam and three of whom were from the same family. Cave and coworkers[40] found that the IS*6110* fragment-length polymorphism patterns among 6 *M. bovis* isolates from 1 patient and 42 *M. tuberculosis* repeat isolates from 18 patients remained stable over a period of 8 months to 4.5 years and were not altered by changes in drug resistance profiles. These studies illustrate the usefulness of restriction endonuclease analyses in epidemiologic studies of human and animal TB.

Several other DNA repetitive elements have been used as markers by a large number of researchers for the strain typing of *M. tuberculosis* and other *Mycobacterium* species. Hermans and coworkers[122] discovered a complex-specific mycobacterial DNA insert that hybridized specifically with DNA of MTBC strains. A nonrepetitive 158-bp fragment of this sequence was amplified with PCR and used for the selective detection of mycobacteria from the MTBC directly in pleural fluid, bronchial washings, and biopsies, to a lower limit of sensitivity of 20 bacterial cells (about 10^3 cells in a sputum sample). Wiid and associates[356] used oligonucleotide GTG5 as a marker for the identification of *M. tuberculosis* strains, which they found useful in cases in which certain *M. tuberculosis* strains have few or no insertion elements such as IS*6110*. Friedman and colleagues[92] used PCR amplification of DNA segments located between two copies of repetitive elements IS*6110* and the polymorphic GC-rich repetitive sequence. A PCR-amplified 439-bp segment of the 65-kDa heat-shock protein (HSP) gene was used to develop RFLP patterns of several rapidly growing *Mycobacterium* species, including *M. fortuitum*, *M. chelonae*, *M. smegmatis,* and *M. mucogenicum*.[310] The repetitive insertion sequence element IS*1245* was used in a study of human and animal isolates of *M. avium*.[112] In another study, the repetitive insertion sequences IS*1311* and IS*900* were used as DNA probes in assessing the RFLP of 75 clinical isolates of *M. avium*.[273] Two markers, one of

which encodes for a 40-kDa protein (p40) and the insertion sequence IS*901*–IS*902,* have been used as molecular markers in the typing of 184 field strains of MAC.[5]

Pulsed-field electrophoretic separation of restriction fragments generated by digestion of chromosomal DNA was used in the typing of 16 strains of *M. haemophilum*, 12 of which showed similar patterns, including 6 from the same hospital.[374] This technique has also been used to identify patients who were infected with more than one strain of MAC.[302] Random amplified polymorphic DNA (RAPD; also referred to as arbitrary primer PCR) has been used in the study of several primers to determine which are most discriminatory in providing reproducible fingerprints in the strain typing of *M. tuberculosis*.[187] This technique has also been used to type strains of *M. tuberculosis*, with a PCR-amplified region separating the genes coding for 16S and 23S rRNA serving as the marker.[1] These authors present molecular typing by RAPD as being more rapid and less technically demanding than most other molecular-typing methods. Also, smaller quantities of purified DNA are required than for other methods, allowing earlier analysis of young primary isolates of *M. tuberculosis*.

Kirschner and colleagues[161] have developed libraries of restriction-fragment profiles of 16S rRNA subunits extracted from several *Mycobacterium* species that were previously characterized by biochemical tests or nucleic acid probes. The specific restriction endonuclease profile of an unknown *Mycobacterium* species can be easily compared with the library profile, providing a rapid nonculture means for making an accurate identification. Similarly, Avaniss-Aghajani and associates[11] developed a method for identifying mycobacterial isolates directly from water and clinical specimens. PCR was first used to amplify a portion of the small-subunit rRNA (SSU) from 13 different species of mycobacteria, using a 5′ PCR primer that carried a fluorescent label to allow detection of the amplified product. The PCR product was digested with restriction endonucleases, and the sizes of the labeled restriction fragments were determined by an automated DNA sequencer. A library of 5′ restriction fragment lengths produced by five restriction endonucleases has

been developed that can categorize 20 *Mycobacterium* species. Each *Mycobacterium* species has a unique 5′ restriction-fragment length for each specific endonuclease, selections from which can be used to make identifications of unknown species. Advantages of this technique over rapid PCR methods include lower cost and the ability to characterize several *Mycobacterium* species and to detect more than one *Mycobacterium* species in the same sample.

Strain-typing methods have also been used in the detection of drug-resistant strains

of *M. tuberculosis*. In separate studies, Whelen and coworkers[353] and Felmlee and associates[85] used unique methods to detect mutations in the beta subunit of *M. tuberculosis* RNA polymerase (*rpoB*) to detect mutations most frequently associated with rifampin resistance. Plikaytis and coworkers,[249] in the study of an outbreak of MDR-TB in New York City, used a multiplex PCR assay targeting a direct repeat of IS*6110* with a 556-bp intervening sequence (NTF-1), to identify patients who were infected with what they designated the multidrug-resistant "W" strains of *M. tuberculosis*. Their assay correctly identified all 48 strain W isolates of *M. tuberculosis*, among a total of 193 strains studied. These studies indicate the degree of sophistication achieved by molecular techniques and the practical applications for which they are being used.

Susceptibility Testing

Mycobacterium tuberculosis *Complex*

The need for prompt and accurate susceptibility testing of MTBC is essential due to the emergence of multidrug-resistant strains. Susceptibility testing should be performed on the first isolate of MTBC recovered from every patient and should be repeated after 3 months of appropriate therapy if cultures remain positive. Initial testing should include all primary drugs: INH at the critical concentration, rifampin, ethambutol, and PZA.

The reference method for susceptibility testing of MTBC to INH, rifampin, and ethambutol is agar proportion. Recommended concentrations in Middlebrook 7H10 agar are as follows: INH, 0.2 µg/mL; rifampin, 1.0 µg/mL; and ethambutol, 5.0 µg/mL. Agar proportion, however, cannot be used to test PZA. Moreover, agar proportion is not a rapid method; results are reported after incubation for 3 weeks, if growth is sufficient. To ensure the earliest possible detection of resistance, a broth method with a short incubation time is recommended.[367] The CDC suggests that mycobacteriology laboratories strive to report results of first-line testing within 15 to 30 days of receipt of the specimen in the laboratory.[317] Ideally, susceptibility results for the primary drugs should be available within 7 to 14 days after isolation of MTBC. Second-line drugs (Table 19-9) should be tested if an isolate is resistant to rifampin or any two of the primary agents. Isolates with monoresistance to INH also should be tested for susceptibility to second-line drugs if the planned treatment regimen includes a fluoroquinolone.[367]

The frequency of drug-resistant mutants in a culture of tubercle bacilli has been estimated to be about $1:10^5$ bacteria for INH and $1:10^6$ for streptomycin. If two drugs

(i.e., INH and streptomycin) are taken together, the incidence of resistance is $1:10^{11}$, which is the sum of the two taken separately. Knowledge of the incidence of mutants becomes important because it has been determined that patients with an open pulmonary cavity may have a total bacillary population of 10^7 to 10^9 bacteria. Therefore, if these patients are treated with a single antituberculosis agent, their cultures may soon show the emergence of an isolate that is resistant to that agent, and thus treatment fails. Consequently, patients with TB must always initially be treated with the four primary drugs listed above. The failure of patients to adhere to this regimen may lead to the emergence of a specific drug-resistant tubercle bacillus (Fig. 19-3). After following a group of patients coinfected with *M. tuberculosis* and HIV, Nolan found that lack of compliance with antituberculosis drug therapy was the primary reason for treatment failure.[225] Lack of compliance may also contribute to therapeutic failure and the emergence of drug resistance.

TABLE 19-9 Second-Line Antituberculous Drugs and the Recommended Concentrations in Middlebrook 7H10 Agar

Drug	Concentration (μg/mL)
Isoniazid	1.0
Ethambutol	10.0
Amikacin	4.0
Capreomycin	10.0
Ethionamide	5.0
Kanamycin	5.0
Levofloxacin	1.0
Moxifloxacin	0.5
Ofloxacin	2.0
p-Aminosalicylic acid	2.0
Rifabutin	0.5

Streptomycin	2.0 and 10.0

A second principle of MTBC susceptibility testing is based on the in vitro correlation between the clinical response therapy and the result of in vitro susceptibility testing. If more than 1% of the tubercle bacilli present are resistant to a drug in vitro, therapy with that drug is not clinically useful. Therefore, methods for drug susceptibility testing of mycobacteria must be capable of determining the proportion of bacilli susceptible and resistant to a given drug or yield results that are equivalent when methods are compared. When using agar proportion, the inoculum should be adjusted so that the number of spontaneously resistant mutants will not mislead the laboratory worker to interpret the culture as resistant. By the same token, there must be a sufficient number of colonies on the plate so that the incidence of drug resistance in the range of 1% can be determined. This is best accomplished when 100 to 300 colony-forming units (CFUs) are present on each quadrant of a four-quadrant Petri plate. To determine the incidence of resistance, it may be necessary to inoculate two sets of susceptibility test plates, the second set with a 100-fold dilution of the inoculum used for the first set.

■ **FIGURE 19-3** Emergence of mycobacterial antimicrobial resistance with one- and two-drug therapy. **A.** The patient is treated with only isoniazid (INH). Although the small number of streptomycin-resistant mutants are inhibited by the INH, the INH-resistant mutants are refractory and, in time, make up the majority of the population. This represents drug failure. **B.** The patient is treated with both streptomycin and INH. The streptomycin-resistant mutants are inhibited by the INH, and the INH-resistant mutants are inhibited by streptomycin. Thus, neither of these mutant strains can overgrow and the drug therapy is successful. (Redrawn from Crofton J. Some principles in the chemotherapy of bacterial infections. BMJ 1969;2:209–212.)

Agar proportion is performed in plastic Petri dishes divided into four quadrants. Plates can be purchased or prepared in-house. Five milliliters of agar medium are placed into each quadrant, the first with no antimycobacterial agent to act as a growth control, and the other three with varying concentrations of the drug to be tested. Either 7H10 or 7H11 agar as the base is acceptable.[367] Paper disks containing specified amounts of antituberculous drugs are placed in the individual quadrants, and drug-free agar medium is dispensed into each quadrant. Alternatively, agar medium may be prepared with liquid drug. A reference strain of *M. tuberculosis*, H37Rv (ATCC 27294), which is susceptible to all primary and second-line antituberculous drugs, is recommended for quality control of both agar proportion and the preferred broth susceptibility test methods.

The first broth-based antimicrobial susceptibility testing for MTBC was the BACTEC 460 instrument fitted with a "TB hood." The basis of this broth test is the radiometric detection of ^{14}C, released from 7H12 liquid medium containing 1-[^{14}C] palmitic acid by the metabolizing bacteria.[268,205,366,296,207] The BACTEC 460 instrument revolutionized susceptibility testing of MTBC, but it is no longer supported by the manufacturer and, therefore, is not discussed further.

In 2002, the fully automated, nonradiometric MGIT 960 system (described earlier in this chapter) was approved by the FDA for susceptibility testing of MTBC to INH, rifampin, ethambutol, PZA, and the secondary drug streptomycin. Many studies have shown that the performance of the MGIT system for testing primary drugs is comparable to that of both the radiometric BACTEC 460 and the agar proportion method, and the time to results is similar to that for the BACTEC 460.[2,17,127,170,243,278,285]Although the MGIT 960 is not FDA-approved for testing second-line agents other than streptomycin, several investigators have validated its performance for this purpose.[170,127,186,269,279]

The MGIT system uses a two-tier testing protocol: INH, rifampin, and ethambutol are in the first-tier, and PZA is tested separately. The inoculum may be prepared from either a liquid or a solid medium. To ensure accuracy and reproducibility of results, it

is critical that the manufacturer's guidelines be strictly followed. An MGIT drug susceptibility testing set includes a drug-free growth control tube and drug-containing tubes. When the GI of the growth control reaches 400 within 4 to 13 days, the system flags the completion of the testing and interprets results as follows: An isolate is called resistant to a drug when the GI of the drug-containing tube is >100; it is called susceptible when the GI is ≤100. The test is invalid if the GI of the growth control reaches 400 in <4 days or >13 days; this indicates that the inoculum is either too heavy or contains contaminants, or it is too light.

Testing PZA in the MGIT system differs slightly from testing the other three primary drugs. Inoculum preparation and interpretation of results are the same, but the broth in the MGIT PZA tube has a reduced pH, the tube has a separate supplement, and the PZA growth control tube is inoculated with a 1:10 dilution of the inoculum to PZA-containing tube. The performance of the MGIT system for testing PZA appears to be inferior to that of the other primary drugs.[44,45] There appears to be a problem with false resistance, which, based on data from one study, might be corrected by reducing the inoculum from 0.5 to 0.25 mL.[245] Some investigators have suggested that a combination of culture-based testing and *pncA* sequencing might be the most reliable approach to assessing PZA susceptibility or resistance.[298]

VersaTREK, a fully automated, continuously monitoring system described earlier in this chapter for growth and detection of mycobacteria, also is FDA-approved for testing susceptibility of MTBC to all primary drugs. As with the MGIT system, the inoculum can be prepared from either broth (VersaTREK Myco or 7H9) or a solid medium (LJ or 7H10/7H11). Inoculated drug-containing and drug-free control bottles are placed in the instrument, which automatically monitors growth every 24 hours. A susceptibility test is valid when growth in a control bottle is detected 3 to 10 days after inoculation. Drug-containing bottles are monitored for 3 days after the control bottle is positive. An isolate is resistant to a drug if growth in the drug-containing bottle is detected ≤3 days after detection of growth in the control

1259

bottle. An isolate is susceptible if there is no growth in the drug-containing bottle or if growth is detected >3 days after that of the control bottle. Studies have shown good agreement among the VersaTREK Myco system, BACTEC 460, MGIT 960, and agar proportion.[19,83,276]

Another broth-based method for susceptibility testing of MTBC is the TREK Sensititre MYCOTB MIC 96-well plate, which includes both first-line (except PZA) and second-line drugs. At the time of this writing, this test is not cleared by the FDA and, therefore, is for research use only. The inoculum is prepared from colonies grown on a solid medium, and results are available 10 to 21 days after the plate is inoculated.

Performance of this method compared to agar proportion is satisfactory to excellent, with categorical agreement of 94% to 100% in one study and 80% to 99% in another.[116,182] This method has the advantage of testing both first- and second-line agents simultaneously, and it does not require an instrument for interpretation of results. However, it does not include PZA, which is a major drawback, and the turnaround time is longer than automated broth systems.

Given the importance of rapid identification of drug-resistant TB, several molecular methods for detection of mutations associated with resistance have been developed. These methods can be used to test positive cultures (broth or colonies) or AFB smear-positive specimens. However, drug resistance can be caused by mutations other than those detected by these methods; therefore, failure to detect a mutation does not necessarily equate to a phenotypic result of susceptible.

Molecular methods can be divided into those that are probe-based (e.g., Cepheid's GeneXpert MTB/RIF assay using molecular beacons and HAIN's MTBDR*plus* and MTBDR*sl* assays using line probes) and those that are sequence-based (e.g., Sanger sequencing and pyrosequencing). Probe-based methods detect the presence or absence of mutations, whereas methods based on sequencing provide sequences of either wild-type isolates or mutants. Mutations are not always associated with drug resistance; therefore, detection of a mutation by a probe-based method may not in all cases equate with phenotypic resistance. Additionally, because not all mechanisms of resistance are known, failure to detect a mutation does not unequivocally exclude resistance. Therefore, although molecular-based methods provide useful information quickly, all are adjuncts to, not replacements for, phenotypic drug susceptibility testing.

The GeneXpert MTB/RIF assay was described earlier in this chapter. Detection of rifampin resistance is determined when the presence of a mutation(s) in the 81-bp rifampin resistance determining region of the *rpoB* gene is detected. The performance of this assay for detection of *M. tuberculosis* in clinical specimens was previously discussed. With regard to detecting rifampin resistance in *M. tuberculosis*, Zeka et al.[380] reported total agreement with agar proportion for 89 of the 429 specimens that were culture-positive for *M. tuberculosis*: 88 were susceptible, 1 was resistant. Marlowe et al.[195] tested 217 specimens, of which 130 were culture-positive for *M.tuberculosis*. All 130 were rifampin-susceptible by broth microdilution, but 3 were initially resistant by GeneXpert. The liquid culture of the three with discrepant results was retested by GeneXpert: two were susceptible and one remained resistant.

The HAIN probe assays, which use reverse hybridization to detect mutations, are not FDA-cleared for diagnostic use in the United States but have been used in several countries outside the United States. Both MTBDR*plus* and MTBDR*sl* assays include both wild-type probes and probes for several commonly encountered mutations. The absence of a wild-type band indicates that a mutation is present. The simultaneous presence of a mutant band indicates that a specific mutation is present in the

specimen/isolate. The absence of both a wild-type band and a mutant band indicates the presence of a mutation but does not provide information regarding the identification of the mutation. The performance of these assays varies depending on the drug, being best with rifampin and the quinolones. For both assays, specificity (the drug is susceptible by both the line probe assay and phenotypic drug susceptibility testing) is ≥95% and with the exception of rifampin, is greater than sensitivity (drug resistant by both the line probe assay and phenotypic drug susceptibility testing).[155,212,333]

Investigators at the CDC evaluated DNA sequencing for detection of first- and second-line drug resistance in 314 isolates of *M. tuberculosis*.[38] Phenotypic testing was done by agar proportion, except for PZA, which was tested by the BACTEC 460 or MGIT 960. Genetic loci examined were drug resistance determining regions of *rpoB, embB,* and *gyrA*, promoters of *inhA* and *eis*, regions of *katG* and *rrs* with established mutations, and complete open reading frames of *tlyA* and *pncA*. Specificities for first-line drugs were 86% for *pncA* (PZA), 93% for *embB* (ethambutol), 94% for *rpoB* (rifampin), and 100% for *katG, inhA,* and *katG* + *inhA* (INH). Sensitivities were 97% (*rpoB*), 91% (*katG* + *inhA*), 85% (*pncA*), and 79% (*embB*). Sensitivity and specificity for second-line drugs were 82% and 98% for ciprofloxacin and ofloxacin (*gyrA*), 86.5% and 96% for kanamycin (*rrs* or *eis*), 90% and 99% for amikacin (*rrs*), and 61% and 87% for capremycin (*rrs* and/or *tlyA*).

Nontuberculous Mycobacteria

For susceptibility testing of NTM, the Clinical and Laboratory Standards Institute (CLSI) recommends testing clinically significant isolates by broth microdilution, using cation-adjusted Mueller–Hinton broth with 5% OADC or OAD, and provides guidelines for MAC, *M. kansasii* (which also apply to other slowly growing, nonfastidious NTM), *M. marinum,* and the rapidly growing mycobacteria.[367] The general recommendations are described in the following paragraphs, but the CLSI M24 document[367] should be consulted for specific details. Both the minimum inhibitory concentration (MIC) and an interpretation should be reported. Quality control testing should be performed on each new batch of 96-well test plates and once weekly or each time testing is performed, if less than weekly, thereafter.

For susceptibility testing of MAC, the only primary drug recommended at the time of this writing is clarithromycin. However, data published by Brown-Elliott and colleagues[32] support initial testing of amikacin as well. Secondary agents, which may be useful in select patients, are moxifloxacin and linezolid. Although ethambutol, rifampin, rifabutin, and streptomycin are useful clinically, there is no correlation between in vitro susceptibility testing results and clinical

outcome of patients with MAC who are treated with these drugs. Therefore, susceptibility test results should not be reported for these agents. The translucent colony variants should be selected for testing if possible, because they are thought to be more virulent and more resistant to antimicrobial agents. Trays should be incubated in ambient air at 35°C to 37°C and examined at day 7. If growth is insufficient, trays are reincubated and examined again at days 10 to 14. The endpoint is visible turbidity. The recommended quality control strain is *M. avium* ATCC 700898, with an acceptable alternative being *M. marinum* ATCC 927. Susceptibility testing should be repeated if cultures remain positive after 3 months of therapy for patients with disseminated disease and after 6 months for patients with chronic pulmonary disease.

Standard therapy for *M. kansasii* pulmonary disease consists of rifampin, INH, and ethambutol, of which rifampin is essential for a successful outcome. An alternative, equally effective regimen is rifampin, ethambutol, and clarithromycin. CLSI recommends that all initial isolates of *M. kansasii* be tested for susceptibility to rifampin or, if the alternative regimen is planned, to rifampin and clarithromycin.[367] Testing susceptibility of *M. kansasii* to INH is not recommended because in vitro results do not correlate with clinical outcome and, therefore, could cause a false impression of resistance. Microdilution trays are incubated at 35°C to 37°C in ambient air for 7 to 14 days. Acceptable QC strains are *M. kansasii* ATCC 12478, *M. marinum* ATCC 927, and *Enterococcus faecalis* ATCC 29212. *M. kansasii* clinical isolates that are resistant to rifampin (MIC ≥1 μg/mL) should be tested for susceptibility to rifabutin, ethambutol, clarithromycin (if not initially tested as a primary drug), amikacin, ciprofloxacin, trimethoprim–sulfamethoxazole, linezolid, and moxifloxacin. Testing streptomycin also should be considered; however, breakpoints for susceptibility and resistance have not been established, so only the MIC should be reported.

Routine susceptibility testing of *M. marinum* is not recommended, because isolates are consistently susceptible to rifampin, ethambutol, doxycycline/minocycline, trimethoprim–sulfamethoxazole, and clarithromycin. However, if a patient does not respond to appropriate therapy after several months and remains culture-positive, susceptibility testing should be considered. Microdilution trays are incubated at 28°C to 30°C for 7 days. Drugs to test are rifampin, clarithromycin, amikacin, doxycycline or minocycline, ciprofloxacin, moxifloxacin, and trimethoprim–sulfamethoxazole.

Treatment of skin and soft tissue infections caused by rapidly growing mycobacteria should include clarithromycin, if the isolate is susceptible, and at least one additional agent, selected based on results of susceptibility testing. Antimicrobial agents that should be tested are amikacin, cefoxitin (up to 256 μg/mL), ciprofloxacin, clarithromycin, doxycycline or minocycline, imipenem, linezolid, moxifloxacin,

trimethoprim–sulfamethoxazole, and tobramycin.[367] Tobramycin is used to treat *M. chelonae* infections, but not infections due to *M. abscessus* or *M. fortuitum* group. Microdilution trays are incubated at 28°C to 30°C in ambient air for 72 hours. If growth is insufficient at that time, trays are examined again on days 4 and 5. This is the final read for all drugs except clarithromycin. To ensure detection of inducible macrolide resistance, clarithromycin wells are read at days 7 to 10 and again at day 14, unless the isolate is resistant at an earlier read. The MIC is the lowest concentration of an antibiotic that completely inhibits visible growth, except for trimethoprim-sulfamethoxazole, to which the rapidly growing mycobacteria exhibit trailing. For this drug, the MIC is read at about 80% inhibition of growth. The recommended QC strain is *M. peregrinum* ATCC 700686, although *Staphylococcus aureus* ATCC 29213, *Pseudomonas aeruginosa* ATCC 17853, and *E. faecalis* ATCC 29212 are acceptable alternatives.

Although broth microdilution is considered the standard method for testing rapidly growing mycobacteria, the Etest (bioMerieux) may be a viable option. Biehle and associates[23] performed Etests for 100 clinical strains of rapidly growing mycobacteria against six drugs: amikacin, cefoxitin, ciprofloxacin, clarithromycin, doxycycline, and imipenem. These authors found 85% agreement between the Etest results and agar dilution MICs within 1 $\log_2$ and a 97% agreement at 2 $\log_2$ dilutions. The rates of major and minor errors were 2.2% and 11.7%, respectively; there were no very major errors (defined by the authors as disagreement of 3 $\log_2$ dilutions or more). Interlaboratory agreement between Etest MICs determined in two separate laboratories was 81% within 1 $\log_2$ dilution and 92% within 2 $\log_2$ dilutions. These data suggest that Etest may be a reasonable alternative method for determining the susceptibility of rapidly growing mycobacteria, but additional studies testing all drugs recommended by CLSI and comparing results to broth microdilution are needed.

Spirochaetes

Human pathogens within the class *Spirochaetes* cause a significant burden of illness worldwide, but laboratory confirmation of infection may be difficult because some organisms have been cultured only in vivo, and some remain noncultivatable in the clinical laboratory. Although laboratory diagnosis of spirochetal infections has

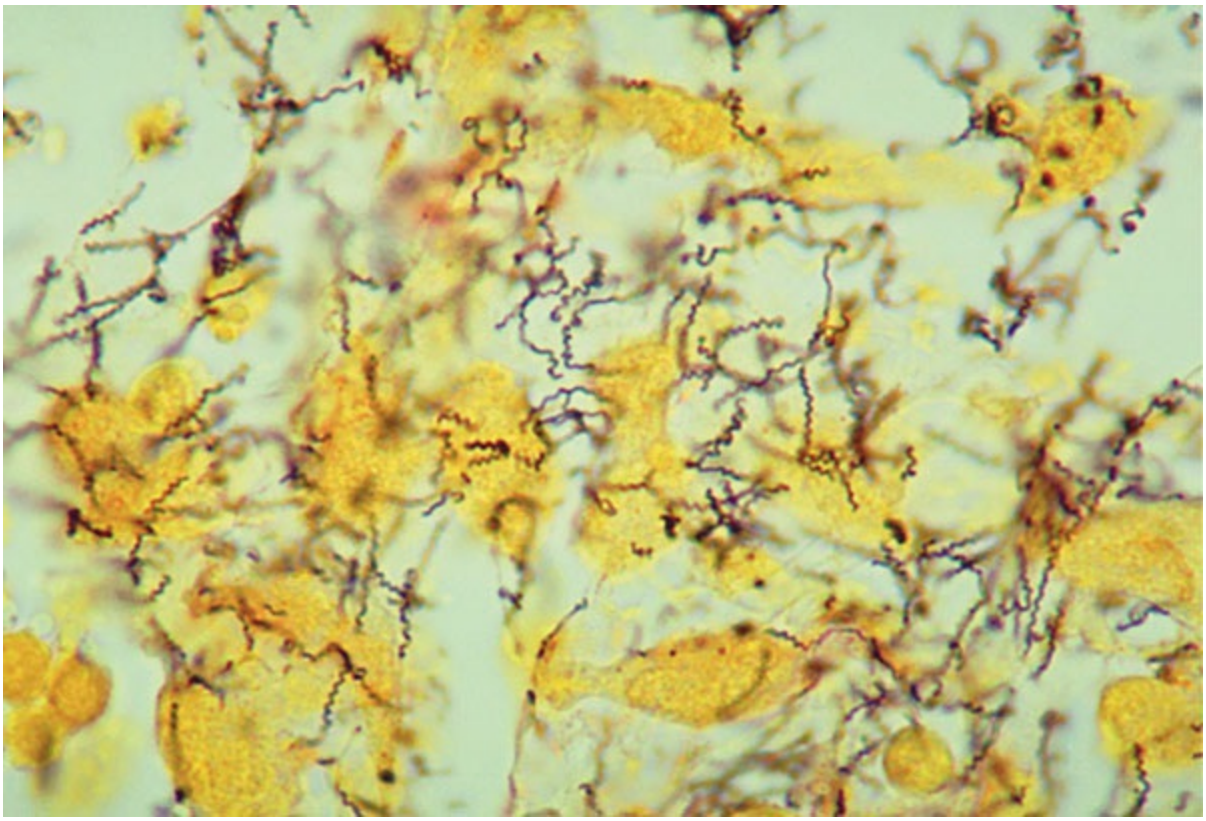
historically relied on host serologic tests, molecular methods are increasingly being developed to improve the sensitivity of detection. The focus of this chapter is the clinical manifestations and laboratory diagnosis of *Treponema*, *Borrelia*, *Leptospira,* and *Spirillum* infections. *Treponema pallidum* subspecies *pallidum,* the causative agent of syphilis, has for centuries been a major sexually transmitted infection (STI) and has staged a dramatic comeback in the later part of the 20th century, in part due to coinfection with HIV.[128,215,514] Conversely, *Borrelia burgdorferi* sensu lato, the causative agent of Lyme disease, was discovered only 25 years ago, but has subsequently become the most common spirochetal infection in the United States,[75,80] and many parts of Europe where the *Ixodes* tick vectors reside and play a key role in animal-to-human spirochete transmission.[440,441] Tick-borne relapsing fever (TBRF) caused by *Borrelia* spp., leptospirosis caused by *Leptospira* spp., and rat-bite fever (RBF) caused by *Spirillum minus* are also classic zoonotic diseases acquired through contact with animal reservoirs due mainly to occupational exposure.[36,125,157]

Taxonomy

Spirochaetes (spirochetes) belong to a distinctive group of long gram-negative bacteria that are helically coiled, resulting in spiral-shaped cells that measure 0.1 to 3.0 µm in diameter by 5 to 120 µm in length (Fig. 20-1).[345] Spirochetes are chemoheterotrophic and motile via a unique mechanism.[87,345] They are extremely motile via endoflagella that give these organisms their characteristic corkscrew and oscillating movement. Spirochetes have axial filaments that are flagella-like organelles enclosed within an outer sheath, which spirally wrap around the cell wall of the bacteria and facilitate their rapid rotational corkscrew motility even in high-viscosity liquids.[177,231,345] Axial filaments are attached to the cell wall by insertion disks located at the end of cells.[231,345]

1269

1270



■ **FIGURE 20-1** *T. pallidum* spirochetes. (Courtesy of www.Glown.com.)

The number of axial filaments and insertion disks along with phenotypic metabolic characteristics are used to broadly differentiate genera within the family *Spirochaetaceae*.[345] *Treponema* are slender organisms with tight coils (6 to 10 axial filaments attached by a single insertion disk), *Borrelia* appear thicker with fewer and looser coils (30 to 40 axial filaments attached by two insertion disks), and *Leptospira* closely resemble *Borrelia* except they have hooked ends (two axial filaments attached by 3 to 5 insertion disks).[320,345] The genus *Spirillum*, however, has an external flagellum for motility.

The classification of the bacteria within the *Spirochaetes* phylum is shown in Table 20-1. All of the human pathogens within the *Treponema*, *Borrelia,* and *Leptospira* genera are classified in the *Spirochaetales* order, and further within the *Spirochaetaceae* and *Leptospiraceae* families.[345] *Brevinema andersonii* infects short-tailed shrews (*Blarina brevicauda*) and white-footed mice (*Peromyces leucopus*),[108] while *Cristispira* has been found in a variety of aquatic organisms including freshwater mollusks.[346]*Spirochaeta* are free-living spirochetes found in aquatic or marine environments.[345] *S. plicatilis* has been found in deep-sea sediments, while *Spirochaeta americana* is a haloalkaliphilic and obligately anaerobic bacteria that

thrives in bleach-like alkaline, salty, deep waters of California's Mono Lake.[197,346] Some *Brachyspira* spp. (*Serpulina*)within the *Brachyspiraceae* family are important causes of diarrheal illness in humans, animals, and birds.[345] *B. aalborgi* affects only humans and high primates.[49,196,424] *B. pilosicoli* causes intestinal spirochetosis and diarrhea in pigs, and may be transmitted to man through the fecal–oral route.[424] Most cases of colonic spirochetosis occur in the developing world, and human colonic spirochetosis due to either *B. pilosicoli* or *B. aalborgi* manifests as diarrhea, rectal bleeding, and abdominal cramps.[424,475] *B. hyodysenteriae* causes dysentery in swine, whereas *B. alvinipulli* is an enteropathogen in chickens.[424] The type species of *Leptonema* is *L. illini*, which was separated from the *Leptospira* genus because of its unique structure and DNA base composition.[345,346] The pathogenicity of *L. illini* remains unknown.

Additional novel spirochete species may be found that have pathogenic potential in animals and humans. Several novel spirochetes have recently been isolated from mosquitoes and black flies in the Czech Republic, and 16S rRNA gene sequencing shows that they differ from *B. burdorferi*

1271

sensu lato as well as other described members of the *Spirochaetales* order.[420] Many other "noncultivatable" spirochetes remain to be discovered and classified. The phylogenetic diversity and pathogenicity of spirochetes will continue to evolve as investigators study the microbiotome of the gastrointestinal tracts of mammals, birds, and insects, and aquatic and marine environments.

TABLE 20-1 Classification of Spirochetes

Organism	Geographic Location	Disease
Order *Spirochaetales*		
Family *Spirochaetaceae*		
Genus I. *Spirochaeta*		
Genus IV. *Treponema*		
T. pallidum subspecies *pallidum*	Worldwide	Syphilis, congenital syphilis, neurosyphilis

T. pallidum subspecies *pertenue*	Tropical Asia, Africa, South and Central America	Yaws
T. pallidum subspecies *endemicum*	Africa, SE Asia, Middle East, Yugoslavia	Endemic nonvenereal syphilis
T. carateum	Central and South America	Pinta
T. denticola and other "*T. pallidum*-like oral spirochetes"	Worldwide	Necrotizing gingivitis, odontogenic infection
Genus V. *Borrelia*		
Borrelia burgdorferi/afzelii	North America, Europe	Lyme disease, erythema chronicum migrans, neuroborreliosis
Borrelia hermsii/duttoni/parkeri	Worldwide	Tick-borne relapsing fever
Borrelia recurrentis	South America, Europe, Africa, Asia	Louse-borne relapsing fever
Family *Leptospiraceae*		
Genus I. *Leptospira*		
Leptospira interrogans	Worldwide	Leptospirosis

Adapted from reference 345.

Treponema

Table 20-2 describes the four major pathogens in the genus *Treponema*.[345,346] Although none of the *Treponema pallidum* subspecies are genetically related, they produce very distinct diseases. None have been cultivated indefinitely in vitro. *T. pallidum* subspecies *pallidum* (hereafter called *T. pallidum*) is the main "venereal" pathogen among the spirochetes that is transmitted by sexual contact. *Treponema pallidum* subspecies *pertenue* (hereafter called *T. pertenue*) is not sexually transmitted and causes a cutaneous disease called yaws that differs in most aspects from syphilis.[226] The entire genome of the Nichols strain *T. pallidum* (isolated in 1912) was initially sequenced in 1998,[155] but recent sequencing of the complete genome and

annotation of the Chicago strain of *T. pallidum* (isolated in 1951) that has been extensively used in syphilis research show important differences among strains.[162] Alignment of the *T. pertenue* genome with that of *T. pallidum* shows almost complete genome homology between these two spirochetes.[179] A difference of only one nucleotide in the gene coding for a 19-kDa protein was reported by one study, but the immunoreactivity of this protein was identical in the two subspecies.[321,322] Endemic syphilis (bejel) is caused by *T. pallidum* subspecies *endemicum* (hereafter called *T. endemicum*); and *T. pallidum* subspecies *carateum* (hereafter called *T. carateum*) is responsible for pinta.[15,226] These important *Treponema* subspecies have yet to be completely sequenced.

Spirochetes are also an important part of the human oral flora; *Treponema denticola*, *Treponema pectinovorum*, *Treponema socranskii,* and *Treponema vincentii* are the only four species that have been cultivated, but a large variety of other oral spirochetes are microbiota and likely important opportunistic pathogens in periodontal disease.[95,112] The human oral microbiome project has recently shown that ~8% of the total diversity is made up 49 taxa of oral treponemes within the *Spirochaetes*: 11 named species, 3 taxa that are cultivated but unnamed, and 35 taxa that have not yet been cultivated or named.[112] As the type species, *T. denticola* has been shown to attach to human gingival fibroblasts, basement membrane proteins, and other substrates, resulting in cytotoxicity and cell death.[85] Along with other oral anaerobes, *T. denticola* may disseminate from the oral cavity and seed atherosclerotic plaques.[70]

Syphilis

Treponema pallidum

T. pallidum, the cause of venereal syphilis, has been infamous for 500 years, although the origin of this infection remains uncertain.[107,303,384] The disease did not appear prominently in Europe until the 16th century. Fornaciari and colleagues[153] studied a Renaissance mummy that contained structures identified by immunofluorescence and electron microscopy as *T. pallidum.* Some investigators believe that Columbus and his sailors brought the disease back from the New World (the Caribbean and South America),[385] whereas others believe that urbanization spread endemic syphilis in Europe.[107,384,472] A pandemic designated as the "Great Pox" (variola virus produced the "Small Pox") occurred in Europe shortly after Columbus returned from America, but it also occurred simultaneously with the increased movement of armies and people

in Europe.[472] Bone changes attributed to syphilis have been described in New World skeletons,[385] but similar lesions have also been reported from pre-Columbus skeletons from the Old World. Recent phylogenetic studies of available *Treponema* sequence data appear to support the import of syphilis from the New World.[179] More interesting is the question of how limited divergence between *Treponema* species and subspecies results in the differences in disease pathogenesis. A genome-wide microarray analysis and whole-genome restriction mapping of *T. pallidum* (Nichols strain) compared with *T. paraluiscuniculi* (strain Cuniculi A) showed that this closely related spirochete that causes venereal spirochetosis in rabbits has limited sequence differences that occur primarily in the *tpr* genes or nearby genes.[171] It is

possible that evolution of genes within the *tpr* locus is primarily responsible for the differences in disease manifestations and host susceptibility.[171,231,461]

TABLE 20-2 Transmission of Spirochetes

Organism	Transmission
T. pallidum	Sexually transmitted infection Vertical transmission from mother to infant Blood transfusion (human only)
T. pertenue	Direct skin contact (human only)
T. carateum	Direct skin contact (human only)
T. endemicum	Direct mucosal contact (human only) Contaminated eating or drinking vessels
B. recurrentis	Human host, human louse vector (*Pediculus humanus humanus*)
B. hermsii/duttonii/parkeri	Rodents, primates, human host; tick vector (*Ornithodoros, Rhipicephalus*)
B. burgdorferi/afzelii	Rodent, deer host; tick vector (*Ixodes*)
L. interrogans	Rat hosts; contaminated water

Epidemiology. Treponemes are inoculated and penetrate into the body through a skin

or mucous membrane defect. Syphilis may therefore be transmitted by sexual contact,[378] direct inoculation into the vascular system by shared needles or transfusions,[84] direct cutaneous contact with infectious lesions, or transplacental transfer of spirochetes (Table 20-2).[231] However, sexual contact with an infected person in an early stage of syphilis (stage I or II) is the most common mechanism of disease spread.[77,185] Men are usually diagnosed during the primary stage, whereas the primary lesion is often not detected in women, who are diagnosed during the early latent phase unless they are screened for another reason (e.g., pregnancy).[240] On average, one-third of patients become infected from sexual contact with an infected person, but the risk varies and may be higher.[231,393] Congenital syphilis (CS) is acquired by transmission of treponemes to the infant via the placenta.[74,256,296] Screening used by modern blood transfusion services has made the transmission of syphilis via this route extremely rare. Experimental studies in human volunteers have documented that the ID_{50} for *T. pallidum* (the number of organisms needed to infect 50% of those exposed) is as few as 57 organisms.[273] Shortly after inoculation, the spirochetes disseminate throughout the body, where they may eventually cause disease. The incubation period varies from 3 to 90 days, with a mean of 3 weeks.[231]

Syphilis Prevalence, Risk Groups, and HIV Coinfection. Despite the introduction of effective therapy for *T. pallidum* and prevention programs, the sexual spread of syphilis continues to be a problem,[382] and rates in the United States have increased.[71] Although epidemiologic data from the United States are presented herein, similar trends in increasing primary and secondary syphilis (P&S) cases, particularly among men who have sex with men (MSM), have occurred in many other jurisdictions.[214,239,431,470,503] Figure 20-2 shows the overall prevalence of P&S and late syphilis cases reported to the Centers for Disease Control and Prevention (CDC), Atlanta, GA, from 1941 when surveillance began until 2012.[71] Prior to the introduction of penicillin therapy in 1941, the rate of syphilis was ~350 to 400 cases per 100,000 persons in the United States.[71] Although effective therapy, contact tracing programs, and treatment of contacts of infected cases subsequently decreased and stabilized the syphilis rates for several decades, the aim to eradicate syphilis was never realized.[389] A syphilis epidemic occurred from 1981 to 1989 in the United States when the incidence of P&S syphilis cases among heterosexuals and minority populations grew from 13.7 to 18.4 cases per 100,000 persons, an increase of 34%.[379] During the 1990s, the rate of P&S syphilis cases then declined again due to implementation of effective control measures among all racial and ethnic groups.[71] Since 2001, the syphilis rate has begun to increase again, mainly due to spread among MSM who use

unsafe sexual practices.[41,56,71,89] The syphilis rate between 2008 and 2012 has increased among all racial and ethnic groups except American Indians/Alaska natives (Fig. 20-3).[71] Overall, the rate of P&S cases for blacks in 2012 was 6.1 times higher than those for whites, with 16.4 cases/100,000 occurring in blacks and 2.7 cases/100,000 occurring in whites.[71] The highest rates in 2012 occurred in black men aged 20 to 24 years (96.7/100,000), followed by black men aged 25 to 29 years (89.2/100,000).[71]Trends in syphilis rates in young black men are concerning because of the high HIV incidence in this population.[79] Similar trends occurred for black women aged 20 to 24 years of age; this group had the highest incidence among women with 19.1 cases/100,000 women.[71] In 2012, rates were 17 times higher for black women aged 20 to 24 years than white women in this same age group.[71]

From 2008 to 2012, the rate of P&S syphilis increased 40.9% among Hispanics (from 2.4 to 2.9 cases/100,000), 17.8% among American Indians/Alaska natives (from 2.9 to

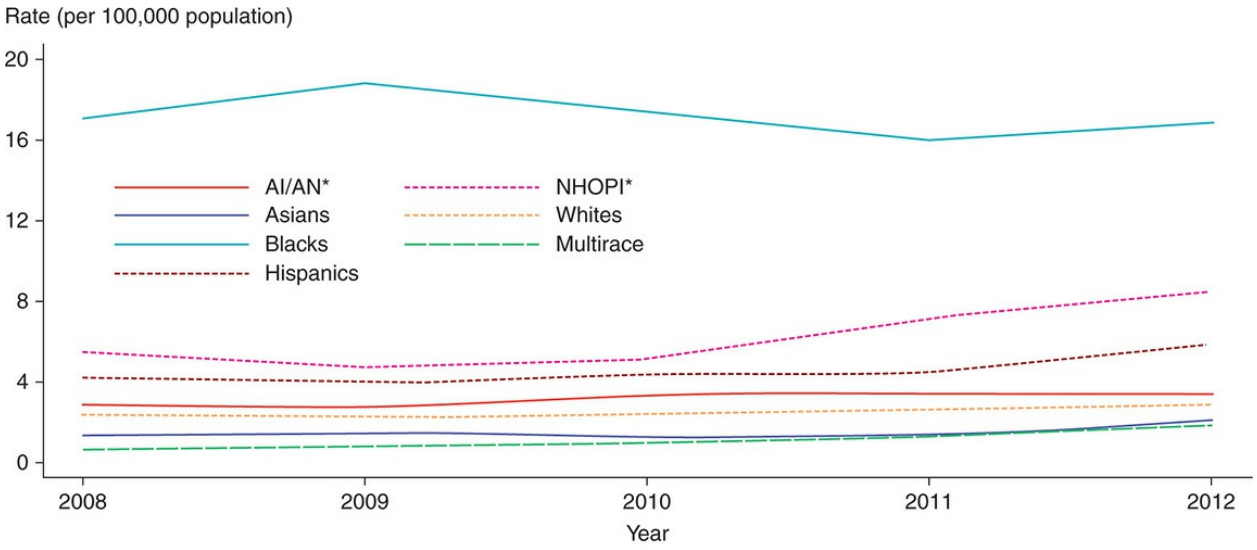
1273



*AI/AN = American Indians/Alaska Natives; NHOPI = Native Hawaiian and Other Pacific Islanders.

■ **FIGURE 20-3** Distribution of syphilis cases by ethnicity, United States (1994–2012). (Adapted with permission from reference 71.)

3.4 cases/100,000), 21.4% among whites (2.4 to 2.9/100,000), and 55% among Asians (from 1.4 to 2.1/100,000).[71] The rates decreased within this time period by 0.7% for blacks (from 17.1 to 16.9 cases/100,000).[71]

CS rates rose by 18% during the period from 2006 to 2008. This was followed by a period of decline wherein the rate of CS decreased by 25% from 2009 to 2012 (i.e., a decrease from 10.4 to 7.8 cases/100,000).[71] The highest rates of CS continue to occur in the South, but these rates have declined from 16.7/100,000 in 2008 to 12.7/100,000 in 2012.[71] Significantly, there has been a substantial decrease in CS rates in Puerto Rico; in 2008 there were 17.5 cases/100,000, whereas in 2012 this rate declined to only 2.2 cases/100,000.[71] Overall rates of syphilis contraction by women of childbearing age must be controlled in order to abate this upward trend in CS. Early access to prenatal care for women of all races/ethnicity is required in order for syphilis screening to contribute to the prevention of maternal fetal transmission.

Several other factors besides age and race/ethnicity have been clearly associated with higher rates of syphilis transmission in the United States and elsewhere. *T. pallidum* and HIV interact in several ways.[470,513,514] It has been suggested that genital ulcers of a variety of etiologies facilitate the acquisition of HIV.[439,471] In healthy individuals, serologic tests are uniformly reactive during the secondary phase of syphilis, but immunosuppression due to HIV infection may affect the serologic response to syphilis.[514] Biologic false-positive reactions in nontreponemal tests are also more common in HIV-infected patients, particularly those with hepatitis C virus (HCV)

coinfection.[16,417] Haas and colleagues[175] evaluated the sensitivity of treponemal tests as a marker of prior syphilis in a cohort of 109 homosexual men with HIV infection who had a documented history of treated syphilis. Individuals receiving antiretroviral therapy maintained reactivity to treponemal tests, but 7% of the symptomatic men who had subclinical HIV infection and 38% of those with HIV disease lost reactivity to these antigens.[175] Other confirmatory tests besides the FTA-ABS may have to be used to diagnose syphilis in HIV-infected individuals when the initial test is negative.[136]Although physicians should be aware of the potential for unusual serologic responses in HIV-infected patients, the interpretation of nontreponemal and treponemal serologic test for syphilis is the same as those who do not have HIV infection.[71]

Patients who are infected with HIV are more likely to present with secondary syphilis and with persistent chancres than non–HIV-infected patients.[513,514] Some experts have documented that the HIV epidemic has been accompanied by an increased risk of developing neurosyphilis.[152,468] A correlation between abnormal cerebrospinal fluid (CSF) findings consistent with neurosyphilis and advanced HIV disease has also been reported.[277,279] Unsuccessful treatment of syphilis in patients infected with HIV has been reported by several investigators.[161,166,198]

Prevention and Control. Traditional epidemiologic approaches used to control syphilis include reporting of all cases to public health who then does contact tracing and partner notification. Active treatment of all laboratory confirmed cases and follow-up as outlined above is also critical to stop ongoing transmission. Traditional epidemiologic techniques alone, however, are proving inadequate,[69] and electronic communication tools are increasingly being used to communicate with and educate persons at risk of acquiring disease as well as to enhance partner notification within sexual networks.[220,221,291] Syphilis should also be tested for in all patients diagnosed with HIV or another STI.[71]Molecular epidemiology should also enhance contact tracing and identification of transmission clusters. In several reported applications of molecular epidemiology, however, numerous genetic subtypes have been identified in a geographic area.[278,281]

Elimination of CS requires additional strategies to reduce mother-to-child transmission. Adverse pregnancy outcomes due to syphilis can be averted by early identification of maternal infections through antenatal screening programs,

and the prompt treatment of women who test positive.[256] Although the United States

and almost all other countries have existing policies recommending universal syphilis screening during pregnancy, significant barriers exist within many healthcare jurisdictions that limit effective screening and treatment.[71,516] This is particularly true for some of the most high-risk patients including those in lower socioeconomic classes, injection drug users, and some racial-ethnic groups.[71] These women often have limited access to early antenatal clinical services, not only in resource-poor countries,[230,476] but also in developed nations where universal healthcare coverage is not provided. Treatment may also be delayed when laboratory results are not relayed in a timely fashion, or when pregnant women have to travel to another clinic location for syphilis-specific treatment.[304] Although epidemiologic data is collected on maternal syphilis screening and CS cases, access to healthcare services and the provision and timing of treatment should also be included in order to identify deficiencies in existing programs.

Clinical Disease and Treatment. Syphilis is known as "the great imitator" because the varied and complex clinical manifestations of this illness can mimic many other diseases.[349] Sir William Osler, one of the founders of modern medicine stated in 1891, "Know syphilis in all its manifestations and relations, and all other things clinical will be added into you." Although untreated syphilis is a chronic progressive systemic infection, somewhat arbitrary overlapping clinical stages are defined that are used to guide assessment, treatment, and follow-up (Table 20-3).

Early Disease (Stages I and II)

Primary syphilis (Stage I). The first sign of syphilis is the development of a primary ulcerated lesion called a chancre at the site of inoculation, which results from an intense inflammatory response. A localized erythematous, painless, indurated papule initially develops, and then evolves within days with necrosis of the skin surface into a typical chancre.[86,421] The typical chancre is a painless ulcer with minimal exudates that has a clean, smooth base with a well-circumscribed raised, firm edge. Secondarily infected lesions, however, will have surrounding erythema, and be painful and purulent. Patients suspected of having syphilis should have a thorough examination of all skin and mucosal surfaces for a primary chancre. A solitary chancre is usually located on the genitalia in otherwise healthy men (i.e., most commonly the glans, the coronal sulcus, and the foreskin of the penis) and women (i.e., the labia, fourchette, and perineum).[10,86,421] Extra-genital lesions occur in <2% of cases, and are mainly found in the oral cavity and on the lip, but other locations have been described (i.e., digits, limbs, trunk, nipples, and eyelids).[8,365] MSM may present with multiple ulcers and symptoms of anorectal infection, including rectal pain and nodular popular lesions surrounding the peri-anal area.[363,382,514] A diagnosis of syphilis may be delayed, particularly in women who have a vaginal or endocervical lesion, MSM with atypical anal lesions, or those with nonerosive ulcers.[302,421,437] The chancre base

contains spirochetes that can be visualized after scraping the lesion and making a smear by darkfield microscopy or direct immunofluorescence.[195,235] Firm, rubbery, painless bilateral regional lymphadenopathy may also occur simultaneously with the development of the primary chancre, but this is not always the case. The chancre heals in 3 to 6 weeks (range, 1 to 12).

Secondary syphilis (Stage II). Approximately one-half of untreated patients with primary syphilis will develop symptoms of the second stage within 6 to 8 weeks after the appearance of a chancre, whereas the other half enter directly into the latent phase. HIV coinfected patients may present with symptoms that overlap the primary and secondary phases of the disease.[215] The secondary stage is the most florid part of the disease and is the result of hematogenous dissemination of *T. pallidum*. Most patients present with a widespread rash,

which may be macular, maculopapular, papulosquamous, or pustular, but not vesicular.[236] HIV-positive patients often have a more severe secondary course with extensive pustular, granulomatous, or nodular variations.[236,514] The rash in syphilis characteristically involves the trunk, face, extremities, and the palms of the hands and soles of the feet. Palmoplantar exanthems may become hyperkeratotic (clavi syphilitici) while lesions around the hairline form a crown-like pattern called corona veneris.[236] In moist intertriginous areas, broad, moist, gray-white plaques called condylomata lata may be found, which are teeming with infectious spirochetes, and can be visualized by scraping the lesions and making smears for darkfield microscopy or direct immunofluorescence.[195,235] Similarly, infectious lesions called mucous patches are found on mucous membranes. There may be loss of hair or thinning of the eyebrows.

TABLE 20-3 Definition of the Stages of Syphilis

Stage	Duration	Manifestation
Incubation period	3 weeks (9–90 days)	
Primary syphilis (stage I)	6 weeks	Chancre formation at the site of inoculation, regional infection
		Various skin eruptions, mucous membrane lesions, generalized

Secondary syphilis (stage II)	Months	lymphadenopathy, organ involvement, hematogenous dissemination
Early latent	<1 year (CDC), <2 years (WHO)	Seropositivity, asymptomatic phase
Late latent	>1 year (CDC), >2 years (WHO)	Seropositivity, asymptomatic phase
Tertiary syphilis	Years (1–50)	Late benign syphilis (granulomatous nodules, psoriasitiform plaques, gummas, tubero-serpiginous syphilis). Gummatous involvement of various organs, cardiovascular syphilis, neurologic involvement.
Neurosyphilis	Years	
Early (in stage II of latent syphilis)		Acute syphilitic meningitis, meningovascular syphilis (symptomatic or asymptomatic), gummatous neurosyphilis
Late (in tertiary syphilis, sometimes referred to as "metasyphilis")		Late parenchymatous neurosyphilis (tabes dorsalis, general paresis)

WHO, World Health Organization.
Adapted from Syphilis—Physician's Pocket Guide, Centers for Disease Control and Prevention (CDC).

Systemic symptoms include fever, malaise, sore throat, headache, myalgias, and a generalized lymphadenopathy. Virtually any organ may be involved in secondary syphilis, but the most common involvement occurs in the eyes (uveitis), ear (sudden deafness), certain visceral organs (hepatitis, nephritis), and the central nervous system (meningitis).[421] Although infection of the central nervous system (CNS) occurs at any stage of syphilis, this is most common during the secondary phase.[390] Aseptic meningitis presents with headache and meningismus. Spirochetes have been cultured from the CSF, however, without any evidence of inflammation and without clinical

disease.[264] Secondary syphilis typically resolves spontaneously after 4 to 12 weeks, but relapse may occur in untreated patients within a year after the initial presentation. HIV coinfected patients may relapse despite treatment.[39]

Latent and Late Disease (Stage III)

Latent syphilis. After the primary/secondary stages, the disease becomes latent, and is characterized by the presence of positive syphilis serology and an absence of symptoms. Patients in whom the primary and/or secondary manifestations of syphilis went unnoticed and untreated may continue to be asymptomatically infected until symptoms of the tertiary stage develop. This period has been arbitrarily divided into early- and late-latency stages by public health agencies. The CDC defines early latency as a duration of infection up to 1 year, while infection of >1 year is considered to be late latency when the patient is no longer considered to be contagious.[71] Although the World Health Organization (WHO) considers 2 years to be the dividing line between the early and late latent periods of syphilis, these distinctions are often not clinically possible and both latency phases are similarly treated. Neurosyphilis must be excluded in patients with latent infection, and a lumbar puncture should be done in patients who present with neurologic, ophthalmologic, or otologic symptoms, particular those with HIV coinfection.[71,470,514]

Late syphilis (Stage III). Approximately one-third of untreated patients will progress to late-stage or tertiary syphilis. This stage of the disease is rarely seen in the developed world, but cases are increasingly being diagnosed worldwide due to HIV coinfection.[470,514] The three different forms of tertiary syphilis are late "benign" syphilis, cardiovascular syphilis, and neurosyphilis.

Late "benign" syphilis. This manifestation occurs in one-half of syphilis cases. Most patients present with various skin lesions, but the formation of nonspecific granulomatous lesions called gummata occurs in ~15% of untreated patients. The formation of the granuloma indicates a fully active cellular immune response. Gummata may destroy surrounding tissue as it enlarges[377]; clinically, they are destructive mass lesions that can occur in virtually any organ and may be mistaken initially for carcinomas.

Cardiovascular Syphilis. Syphilitic aortitis occurs in approximately 1% of untreated cases. It is caused by inflammation in the small vessels that supply the aorta (syphilitic endarteritis) and primarily affects the ascending aorta.[421] Two complications may result: an aortic aneurysm and dilatation of the aortic ring causing insufficiency and regurgitation of blood through the aortic valve. Aortic aneurysms may grow to such a size that they erode through the sternum and are visualized under the skin of the chest.

Neurosyphilis. The interval between primary disease and neurologic complication is 5 to 10 years for meningovascular syphilis, 15 to 20 years for general paresis, and

25 to 30 years for tabes dorsalis. Late neurovascular syphilis may be symptomatic or asymptomatic.[390] Asymptomatic disease is characterized by CSF abnormalities in the absence of symptoms. Pleocytosis, elevated protein levels, or depressed glucose levels are often found in the CSF. A positive CSF serologic test, classically the Venereal Disease Research Laboratory (VDRL) assay, defines the disease, although spirochetes may rarely be demonstrated by culture or molecular methods.[235,274,276] Symptomatic infection is either meningovascular or parenchymatous, but there is considerable overlap in the categories. Meningovascular syphilis resembles the aseptic meningitis of the secondary stage. Any cranial nerve may be affected by the inflammation, and deafness or visual impairment may result. Parenchymatous disease may involve the neurons of either the cerebrum or the spinal cord. Cerebral involvement is manifested as a wide variety of neuropsychiatric disturbances, including physical changes, such as paralysis, and psychiatric problems, such as delusions of grandeur ("general paresis of the insane"). The posterior columns (sensory tracts) of the spinal cord are preferentially affected, causing severe pains and inability to perceive sensory impulses from the extremities. The disease, called tabes dorsalis, includes a peculiar "slapping" gait and deformed knees (Charcot's joints), which are caused by the lack of proprioception and the feedback loop that allows for appropriate use of force during ambulation.

Patients with HIV coinfection may have an increased risk for neurologic complication even in the early stages of syphilis,[470,477,514] and also may have higher rates of serologic treatment failure with currently recommended regimens.[470] Persons coinfected with HIV and syphilis manifest clinical and CSF abnormalities consistent with neurosyphilis with a CD4 count of ≤350 cells/mL and/or an rapid plasma reagin (RPR) titer of ≥1:32.[514]

Treatment. Comprehensive guidelines for the treatment of STIs including syphilis have recently been published by the CDC.[71] Parenterally administered penicillin G is the preferred agent for treating all stages of syphilis. Syphilis regimens used to treat non–HIV-infected patients are also effective in preventing neurosyphilis in HIV-infected patients.[71] Benzathine penicillin administered by IM injection is the recommended drug preparation for treatment of

both adults and children diagnosed with syphilis regardless of their HIV infection status who do not have CNS involvement. Adults confirmed to have primary or secondary syphilis should be treated with benzathine penicillin G 2.4 million units IM as a single dose, while infants and children should receive a dose of 50,000 units/kg IM in a single dose, but the total amount given should not exceed the adult dose (i.e., 2.4

million units).[71] Although latent syphilis is not transmitted sexually, patients should still be treated with this stage of disease to prevent complications. Adults with early latent syphilis should be treated with benzathine penicillin G 2.4 million units IM as a single dose, while infants and children should receive 50,000 units/kg IM as a single dose, but the total amount given should not exceed the adult dose (i.e., 2.4 million units).[71] Adults with late latent syphilis of unknown duration should be treated with higher doses of benzathine penicillin G 7.2 million units total, administered as 3 doses of 2.4 million units IM each at 1-week intervals. Similarly, children at this stage should receive three weekly doses of 50,000 units/kg IM each, up to the adult dose (a total of 150,000 units/kg up to the adult total dose of 7.2 million units).[71]

If patients have clinical evidence of neurologic involvement (e.g., cognitive involvement, motor or sensory deficits, ophthalmic or auditory symptoms, cranial nerve palsies and symptoms of signs of meningitis) or syphilitic eye disease (e.g., uveitis, neuroretinitis, and optic neuritis), a CSF examination should be performed. All patients with neurosyphilis and/or syphilitic eye disease should be treated with aqueous crystalline penicillin G 18 to 24 million unit per day administered as 3 to 4 million units IV every 4 hours or continuous infusion, for a duration of 10 to 14 days.[71]

Patients with primary and secondary disease with a severe allergy to penicillin may be treated with an alternative regimen.[71] The effectiveness of alternatives to penicillin in the treatment of latent syphilis is not well documented. Nonpregnant patients diagnosed in the early latent stage of disease should respond to the alternative antibiotic regimens recommended for the earlier stages of syphilis, but they should be closely followed both clinically and serologically after the treatment course is completed. Patients with late latent syphilis must be treated with penicillin after undergoing desensitization.[71] Pregnant patients should also be desensitized and treated with the penicillin regimen appropriate for their stage of infection.

Congenital Syphilis. CS occurs when fetal *T. pallidum* infection is acquired from a mother with untreated or inadequately treated syphilis. Because most infants at risk for CS can be easily identified by a positive serologic test in the mother,[493] it is tragic that CS rates have steadily increased since 1983 along with those in the general population.[71,74,120] Transplacental infection is most likely to occur during the primary or secondary stages of syphilis (Image Plate 20-1A), but spirochetes may infect the fetus at any time during pregnancy. The estimated rates of vertical transmission in untreated women are 70% to 100% for primary syphilis, 67% for secondary syphilis, and 40% to 83% for early latent syphilis.[35] Mothers with late latent syphilis may also transmit infection, but the rate is low (10%).[35] Infection may also be transmitted at the time of delivery in women who have active genital lesions, if there is a short interval (<4 weeks) between treatment and delivery.[35,71]Symptoms and signs of early CS can occur at any time during the first 2 years but seldom later than 3 to 4 months after

birth. Early CS cases include stillbirth due to in utero spirochete infection.[493] In some areas, CS is the most common cause of nonimmune hydrops, a disease of the placenta that causes fetal death.[28] Although the likelihood of clinical disease increases as the pregnancy progresses, more than half of all infected infants are asymptomatic at birth, and the signs in symptomatic infants may be nonspecific. The most common clinical presentation of early CS include premature and low birth weight infants (10% to 40%), hepatomegaly and/or splenomegaly (33% to 100%), a skin rash that may resemble the lesions of secondary syphilis (40%) and deformed tibias (saber shins) or teeth (mulberry molars) (75% to 100%) with associated radiologic changes, among other findings.[254,497] Pseudoparalysis, respiratory distress, bleeding, anemia and fever may occur in early CS.[149,497] Late CS may occur if the diagnosis of syphilis is missed in the neonatal and early childhood period. Late CS cases present after 2 years of age, and the clinical symptoms mainly affect the bones, teeth and nervous system.[208,294,497] CS may be prevented by clinically screening all pregnant women for syphilis infection. In high-risk populations, maternal and neonatal sera should undergo serologic testing for antibodies to *T. pallidum* at delivery. Cord blood is inferior to neonatal sera.[90]

Treatment. Interpretation of reactive serologic tests for syphilis in infants may be difficult because of the transplacental transfer of maternal nontreponemal and treponemal IgG antibodies to the fetus. Infants at risk of contracting CS should be treated even if a definitive laboratory diagnosis cannot be made due to limitations of the available tests (see Laboratory Diagnosis of Treponemal Diseases—CS section). Treatment decisions are therefore made on the basis of several factors, including: (1) diagnosis of syphilis in the mother, (2) adequacy of maternal treatment, (3) presence of clinical, laboratory, or imaging evidence of CS at delivery, and (4) comparison of maternal (at delivery) and infant nontreponemal serologic titers using the same test done by the same laboratory. Treatment regimens using different preparations of penicillin based on a combination of these factors have been clearly outlined by the CDC guideline document,[71] and a detailed description of the various clinical scenarios, their recommended evaluation, and treatment is beyond the scope of this chapter.

Antibody Response, Serologic Profile, and Immunity. *T. pallidum* has been called the stealth organism because its outer membrane contains few proteins, such that there are few cell surface antigen targets recognized by host immune cells or antibodies. Serum IgM and IgG antibody responses to *T. pallidum* have been the focus of several animal and human studies.[263] Certain membrane lipoproteins (e.g., TpN47, TpN17, and TpN15) primarily mediate the inflammatory effects of *T. pallidum* infection.[231,263] TpN47 is highly immunogenic and activates endothelial cells, and TpN17 and TpN15 induce antibody responses.[30] Several recombinant antigens

including Tp0453, Tp92 and Gpd proteins also showed equivalent serum antibody responses for *T. pallidum* infection.[483] Both antitreponemal IgM and IgG antibodies may be detected as early as 3 days after the onset of the chancre in primary syphilis.[23] Early antibody

1277

responses are directed toward TpN47 and some flagella proteins, followed by TpN15 and TpN17.[231] Antitreponemal IgG3 specific responses are increased in secondary syphilis, and immune-complex may be formed by coupling of IgG1 or IgG3 antibodies and *T. pallidum* antigens.[29]

Common patterns of serologic reactivity with production of IgM and IgG antibodies are seen in patients with syphilis.[23,231] Anti-IgM treponemal antibody production starts ~14 days after exposure before a chancre appears, with titers steadily increasing until 10 to 12 weeks, after which they gradually decline. Production of anti-IgG treponemal and nontreponemal antibody production starts ~14 days after IgM production and the appearance of a chancre but the IgG antibodies persist for years after the time of infection, regardless of treatment. By the time a patient has untreated latent syphilis, there is a markedly reduced IgM but strong IgG response. Patients in an even later stage of disease have a further reduction in IgM (i.e., faint or absent), and more variability in the number of IgG reactive antigens compared to those with early latent syphilis.[23]

The cellular immune system plays an important role in resistance to repeat *T. pallidum* infection. There is firm evidence in humans that immunity to *T. pallidum* is partial or delayed in development.[231] Adolescents who had congenital syphilis and volunteers who previously had natural syphilis have been re-infected. The likelihood that reinfection will occur decreases with increasing time after primary infection.[231] A period of partial resistance develops, in which reinfection may occur without the presence of a chancre. By the late stage, the patient is completely immune to reinfection. The likelihood that reinfection will occur decreases with increasing time after primary infection.[231] A period of partial resistance develops, in which reinfection may occur without the presence of a chancre. By the late stage, the patient is completely immune to reinfection.

Endemic Treponemosis

The treponemal diseases endemic to the tropics include yaws, pinta, and bejel caused by the different *Treponema* spp. (Table 20-1). All of these diseases have prominent

cutaneous manifestations, occur primarily in children, and are spread through lack of clothing, poor hygiene, crowded conditions, and poor access to health care. Epidemiologic and clinical features of these interesting conditions are reviewed in detail elsewhere and only briefly described herein.[15,226]

Treponema pertenue

Yaws is caused by *T. pertenue* and is the most prevalent nonvenereal treponematosis (Table 20-1).[15] It is endemic in tropical regions that have heavy rainfall and annual temperatures at or above 27°C (80°F), including central Africa and parts of the Indian subcontinent, South America, and southeast Asia. Yaws is a chronic disease that most commonly affects children younger than 15 years of age. Treponemes are inoculated by contact with open skin lesions, most commonly excoriations or bites.[15,138,226]There are primary, secondary and tertiary stages of the disease (Table 20-2). Primary yaws begins with a sentinel lesion (pruritic but nontender ulcer with a honey-brown crust) that develops 2 to 4 weeks after inoculation, usually on the buttocks or lower extremities. Secondary yaws begins several weeks to months afterwards, and the skin and bones are primarily affected.[15,138] Multiple cutaneous "daughter yaws" lesions develop near orifices such as the mouth and nose, but then spread diffusely, and ulcerate secreting infectious treponemes. Central resolution in these lesions mimics fungal infection and is therefore called "tinea yaws." A "crablike gait" may develop due to the formation of hyperkeratotic plaques on the palms and soles, and "pianic onychia" results from hyperkeratotic macules and papules within the nail folds.[138] Periostitis and osteitis cause severe pain in the hands, feet, and limbs. Periosteal thickening can be palpated and plain radiography demonstrated the early bone changes.[138]Tertiary yaws develops in 10% of patients 5 to 10 years after inoculation. The results of long-standing skin infection are destructive and deforming. Diffuse subcutaneous gummatous nodules cause large necrotic skin ulcers which heal by scarring and contracture.[15] Destructive osteitis results in saddle nose deformity, a rhinopharyngitis called gangosa, or bowing of the tibia or saber shins.[138,226] Periarticular sites are the most common locations for bone gummata, and a unique aspect of tertiary yaws is the development of gondou due to exostosis of the paranasal maxilla.[138] CNS disease is seldom attributed to endemic treponemes although late yaws may be associated with optic atrophy.[299] Benzathine penicillin is curative, although it may take months for the lesions to regress. Antibodies to *T. pertenue* are indistinguishable from antibodies to *T. pallidum*.

Treponema endemicum

Endemic syphilis is caused by *T. endemicum* (see Table 20-1).[15] The Arab Bedouins

called this disease bejel. This treponemal disease is geographically isolated in the dry, arid climates of the Arabian peninsula and the Sahel (southern border of the Sahara desert) and southern Africa, and it has not been eradicated due to poor hygiene in rural areas.[138,226] Bejel runs in families and primarily effects children 2 to 15 years of age. Several serologic surveys show that seropositivity ranges from 7.5% up to 27% in children in these regions.[138] Bejel mimics venereal syphilis in both clinical presentation and course. The primary skin lesions develop as painless, tiny papules or ulcers within the oral and nasopharyngeal mucosa. Spirochetes are transmitted through direct oral contact or with oral contact with contaminated food, cups, or kitchen utensils (Table 20-2). Bejel is not diagnosed until 3 to 6 months after exposure during the secondary stage because the primary oral lesions are not visible. A diffuse, nonpruritic maculopapular, papulosquamous, or annular skin rash then develops, and new lesions also develop within the oral and nasopharyngeal cavities that often move down to cause laryngitis.[138,226] Osteitis and periosteitis are also prominent signs of secondary bejel. The latent phase occurs within 6 to 9 months and is much shorter than that of yaws. Tertiary bejel starts as early as 6 months after the initial symptoms resolve, and is characterized by gummatous skin nodules that progress to form depigmented, noncontracted scars with dark margins. Nasopharyngeal destruction occurs through necrosis, and secondary infection with scarring of mucosal

gummata, and gangosa may ensue.[138,226] Bejel seldom produces the marked bony changes characteristic of tertiary yaws, but bone gummata may be seen on plain radiographs, and most patients have arthralgias and bone pain from periosteitis. Improved nutrition and earlier access to effective antibiotic treatment may attenuate the course of bejel so that leg pain due to periosteitis may be the only manifestation.[138]

Benzathine penicillin is the therapy of choice. Correction of poor sanitation and hygiene may be preventive. Patients with endemic syphilis produce antibodies that cross-react with *T. pallidum*.

Treponema carateum

T. carateum, the etiologic agent of pinta, is probably the oldest of the human treponemes.[15] Pinta is the least severe of the nonvenereal treponematoses, and causes only ulcerative or papulosquamous skin lesions that often depigment.[138,226] This disease occurs only in the western hemisphere, and remains endemic in remote regions of Mexico (states of Oaxaca, Guerrero, Michoacan, and Chiapas), and central and South America (primarily the western Amazon region of Brazil) (Table 20-1). No

recent pinta serologic survey data is available in these regions. Pinta like the other endemic treponematoses largely affects children less than 15 years of age.[138,226] Treponemes are most likely transmitted by direct skin-to-skin contact (Table 20-2). A primary sentinel skin lesion develops within 1 to 8 weeks after inoculation. A small number of papules or erythematous macules expand and coalesce into a scaling nonpruritic, nonulcerative plaque surrounded by a red halo.[138] The sentinel lesion is found on the exposed lower limbs and is rich in treponemes. Between 3 and 5 years after inoculation, a secondary skin rash occurs with diffuse, scattered lesions similar to the primary lesion called pintids.[138] Pintids development then waxes and wanes for 2 to 4 years when lesions may change color, and form larger coalescing lesions that lead to extensive depigmentation. After another 3 to 10 years, generalized pigmentary skin changes resembling vitiligo develop over bony prominences.[138] Spirochetes may be seen in histopathologic sections of skin biopsies of late hypopigmented skin, but these late-stage lesions are not infectious.

Benzathine penicillin is the therapy of choice. Pinta has no long-term systemic health effects, but the cosmetic disability is considerable. Antisera from patients with pinta cross-react with specific antigens of *T. pallidum*.[281]

Laboratory Diagnosis of Treponemal Disease

Traditional approaches to the laboratory diagnosis of syphilis have been extensively reviewed by Larsen and colleagues,[235] but more recently clinical laboratories have changed the screening algorithm, using newer highly sensitive commercial treponemal enzyme immunoassays (EIAs), immunochemiluminescence, and rapid immunochromatographic assays as the initial test.[81] This section outlines the current tests available for diagnosing syphilis, the ability of various test methods to detect infection throughout the various stages of the disease, the use and outcomes of implementing a reverse sequence testing algorithm, and the use of molecular tests.

Culture. Prior to the development of serologic assays, culture was the gold standard test for diagnosis of syphilis, but is now only performed as an investigative tool (Table 20-4). Testicular tissue from rabbits was initially used by Noguchi (1911)[319] for cultivating 10 different strains of *T. pallidum* in pure culture (i.e., rabbit infectivity test [RIT]). Much later, Fieldsteel and colleagues[146] also propagated the virulent Nichols strain of *T. pallidum* in tissue culture monolayer of cottontail rabbit epithelial cells growing under an atmosphere of 1.5% oxygen. The RIT had been used to diagnose in utero fetal infection by inoculation of rabbits with amniotic fluid.[311] Molecular detection methods have now supplanted the use of the RIT, but one recent study found that polymerase chain reaction (PCR) was less sensitive for detection of *T.*

pallidum in neonatal samples due to PCR inhibitors in clinical specimens.[194]

Microscopy. The diagnosis of early primary syphilis has traditionally relied on direct detection of spirochetes in the exudates of active skin lesions (i.e., primary chancre) using darkfield microscopy (DFM) or direct histologic examination of tissue (Chart 20-1). Visualization of spirochetes (i.e., spiral organisms with pointed ends that have rapid corkscrew motility) by DFM in material scraped from the surface of a chancre is diagnostic of primary infection. DFM has a lower limit of resolution than bright-field microscopy (0.1 µm vs. 0.2 µm) so that the spirochetes, if present, may be easily visualized as luminous spiral-shaped organisms against a dark background (Fig. 20-4). Examination of oral or rectal lesions is not recommended because of the frequent presence of saprophytic spirochetes at these sites. Cutaneous and

visceral lesions of secondary syphilis may also contain large numbers of spirochetes, which can be demonstrated by DFM of scrapings or imprints. DFM has also been used to detect fetal infection by finding spirochetes in amniotic fluid, but the specimen must be fresh and promptly examined.[194] Because of transport requirements, DFM testing is not feasible and thus not widely available in clinical laboratories. Specimens must be immediately examined after collection in order to visualize viable motile spirochetes, and up to three sequentially collected specimens should be examined before providing a negative result. Some STI clinics, however, continue to perform onsite DFM examination as a means to detect patients in the early phases of syphilis.

T. pallidum is difficult to stain using routine laboratory stains, but a direct fluorescent antibody (DFA) stain using monoclonal antibodies improves the detection of spirochetes in early skin lesions (Image Plate 20-1B).[204,235] Overall, DFM and DFA staining have a sensitivity of 74% to 86% and 73% to 100% and a specificity of 85% to 100% and 89% to 100%, respectively.[235] To perform the direct fluorescent antibody test for *T. pallidum* (DFA-TP), material from a lesion or tissue is collected as described for the darkfield examination, except that the material is allowed to dry on the slide (Chart 20-1). Alternatively, the dried smears or the exudates itself may be sent to a reference laboratory, the latter of which is collected in capillary tubes, then

sealed and stored at 4°C for transportation. The direct immunofluorescence method has also been effective for diagnosis of *T. pertenue* as well as for *T. pallidum*.[351]

Hook and colleagues[195] used polyclonal *T. pallidum* antibodies and demonstrated fluorescent treponemes in 30 patients with primary syphilis, 29 of whom also had positive darkfield examinations. More recently, Cummings and colleagues[100] compared DFM and monoclonal DFA staining to an early solid-phase enzyme-linked immunosorbent assay for detection of *T. pallidum* in lesion exudates from 188 patients, 64 (34%) of whom had lesions of early syphilis diagnosed by one of more of these methods. While DFM and the early EIA were positive in 55(85.9%) and 52(81.3%) and of the 64 patients, respectively, the DFA demonstrated the presence of *T. pallidum* in 59(92.2%) of the patients. A DFA test may give false-positive reactions even using a highly specific monoclonal antibody when testing oral lesions because oral spirochetes which cross-react with *T. pallidum* antigens are described in cases of necrotizing gingivitis.[376]

Diagnosis of the early stages of syphilis may be difficult in patients coinfected with HIV or other immunosuppressed patients because antibody titers may be so low as to be undetectable, yielding false-negative serologic tests. Syphilis may be diagnosed by biopsy of skin lesions, but characteristic morphologic features are often not present.[134,207,423] Spirochetes in formalin-fixed tissue have traditionally been detected by one of several silver impregnation stains, such as the Steiner, Warthin–Starry, or Dieterle procedures (Image Plate 20-1A).[482] Silver stains are sometimes difficult to interpret because of intense background staining.[193] Detection of spirochetes on histopathology in the appropriate clinical situation is presumptive but nonspecific evidence of syphilis. Immunohistochemistry with application of a fluorescein antibody provides improved specificity as well as sensitivity. Ito and colleagues[204] have demonstrated *T. pallidum* in formalin-fixed tissues using either polyclonal antisera or monoclonal antibodies after treatment with ammonium hydroxide or trypsin to open antigenic sites. More recently, PCR and real-time PCR have been used to improve detection of *T. pallidum* in tissue biopsies.[31]

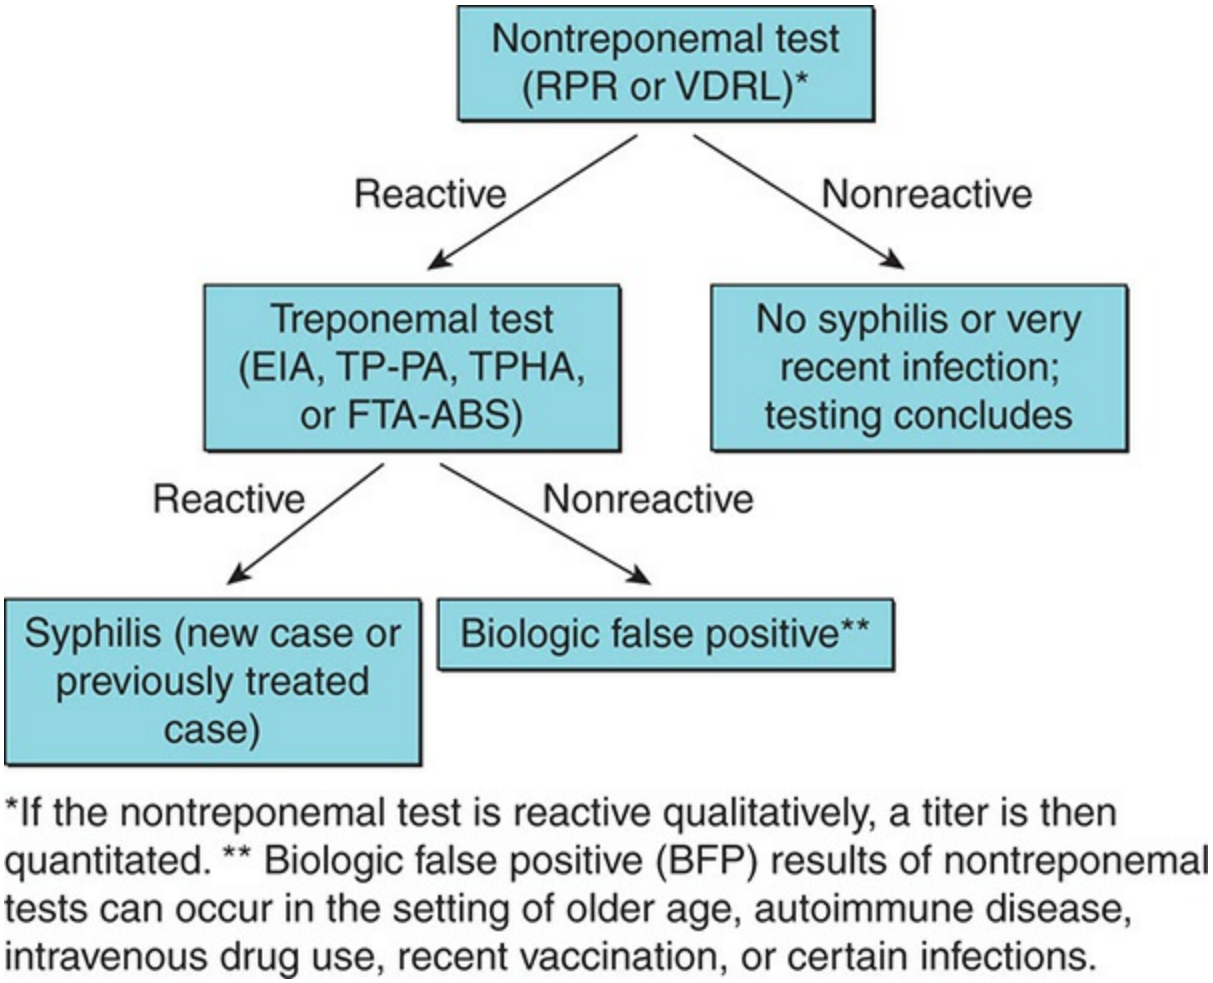
Serology. Most cases of syphilis are confirmed by serology, followed by confirmation using either a second serologic test or another method including Western blot, or more recently a rapid immunochromatography assay or real-time PCR. The serologic tests for syphilis include nontreponemal and treponemal tests including newer commercially available enzyme EIAs, which have distinctive characteristics that make them useful for different purposes. The overall performance of the different tests for diagnosis of syphilis depending on the stage of disease is summarized in Table 20-5.[412] The US Public Health Service has published standardized procedures for performance of nontreponemal and traditional treponemal tests,[235] and the manufacturer's instructions

should be followed when performing a commercial syphilis assay.

Nontreponemal Tests. Nontreponemal antibodies directed against a tissue lipid called cardiolipin begin to be produced by the later stage of primary syphilis when the chancre appears (i.e., 21 days after inoculation), but seroconversion may occur up to 6 weeks after infection.[235] The association was recognized early in this century, and formed the basis for development of a variety of complement fixation tests.[227] Binding of cardiolipin and other host lipids to the spirochete may convert them into immunogens.[344] There are currently three tests available in the United States that use a synthetic form of cardiolipin that is complexed with lecithins and cholesterol as the antigen and rely on flocculation on reaction with IgM and IgG antibodies including: (1) VDRL, (2) RPR, (3) and the toluidine red unheated serum test (TRUST).[68,235] All of these nontreponemal tests are manually performed because none are suitable for the current methods of automation. Nontreponemal tests have been used to initially screen patients for syphilis, but they are now more commonly used as secondary confirmation tests in the newer test algorithms (Fig. 20-5) (see Reverse Testing Algorithm).

The VDRL test was the first nontreponemal test introduced for testing sera, and it remains the only syphilis serologic test that can be performed on CSF that is accepted universally for the diagnosis of neurosyphilis. Plasma and cord blood should not be used because borderline reactions may be obtained.[235] The VDRL assay is somewhat difficult to perform because of the precision required to prepare the antigen. The cessation of manufacture of the bottles required for preparation of VDRL antigen also prompted a search for an acceptable alternative.[358] Examples of VDRL reactions are shown in Figure 20-6. The procedure is summarized in Chart 20-2.

1280



*If the nontreponemal test is reactive qualitatively, a titer is then quantitated. ** Biologic false positive (BFP) results of nontreponemal tests can occur in the setting of older age, autoimmune disease, intravenous drug use, recent vaccination, or certain infections.

■ **FIGURE 20-5** Prior conventional syphilis testing algorithm.

The RPR test is a flocculation test adapted to a card format (Fig. 20-7). The procedure is described in Chart 20-3. The visibility of the flocculation is enhanced by incorporation of charcoal particles. The RPR test is performed on sera samples, but it has not been validated for testing on CSF. Again, plasma and cord blood should not be used because of the risk of borderline reactions.[235] Due to the simplicity of the RPR test, most laboratories perform this assay as their primary nontreponemal screening test. The TRUST assay is performed in the same way as the RPR card test, but the antigen is based on the one used in the VDRL. In addition, ethylenediaminetetraacetic acid (EDTA), choline chloride, and toluidine red toner are added in order to produce a visible flocculation reaction.[352] This assay also has similar performance characteristics to the RPR test (Table 20-5).

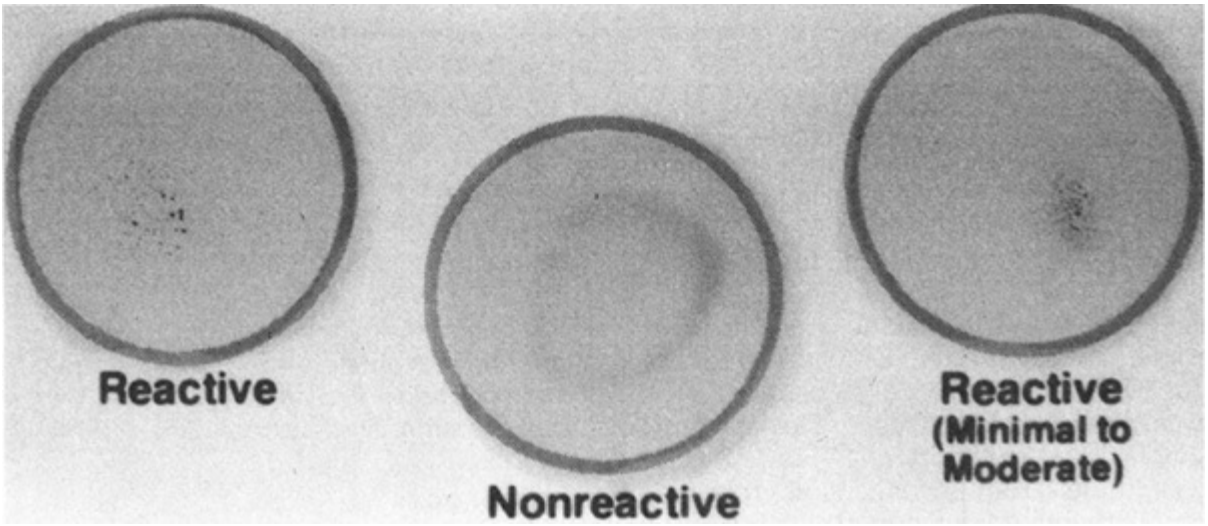
■ **FIGURE 20-6** VDRL test: The reactions in this test are evaluated microscopically. **A.** Nonreactive serum. The particles of VDRL antigen are uniform and freely dispersed without clumping. **B.** Reactive serum: The VDRL antigen particles are strongly agglutinated by this

syphilitic serum. The individual particles have aggregated into sheaves and large clumps ×100. (Courtesy of Burton Wilcke, PhD and Mary Celotti.)



■ **FIGURE 20-7** RPR card test: The reactions in this test are read with the naked eye, using incandescent light illumination. This control card contains Reactive (R), Weakly reactive (W), and Nonreactive (N) sera. The modified VDRL antigen is made visible by complexing with charcoal particles. The charcoal-antigen particles are evenly dispersed and finely distributed in the nonreactive serum and are grossly clumped. The serum with minimal-to-moderate activity produces small aggregates and clumps of charcoal-VDRL antigen particles.

The nontreponemal tests are affected by antimicrobial therapy and thus quantitative titers at baseline allow monitoring of the response to treatment.[235,23] The results of any positive test should be titered to an end-point dilution. In addition, serum from patients with large amounts of antibody may produce a prozone phenomenon resulting in a false-negative result. When a prozone occurs, the large relative concentrations of antibody to antigen prevent precipitation or flocculation from occurring. The prozone results are often marked by a "rough" appearance to the flocculated antigen. Any serum that produces this rough appearance should be titered. Serum should also be diluted and retested if it is strongly suspected on clinical grounds that a patient with negative test results has syphilis. In the general population the frequency of prozone reactions is sufficiently low that routine dilution of serum is not cost-effective.[132]

Treatment failure should also be considered if the nontreponemal antibody titer does not fall progressively as expected after an antibiotic course is given. There should be at least a fourfold decrease in antibody titer by 3 months after antitreponemal therapy. In patients who are treated in the late stages of syphilis or who are reinfected, titers that

decline very slowly or remain stable may develop. Some of these "chronic persisters" may maintain positive nontreponemal tests for life.

The nontreponemal tests have a sensitivity of 70% to 99%, depending on the stage of disease (Table 20-5).[412] Nontreponemal tests may not be positive in early syphilis, and serology should be repeated 7 days, 1 month, and 3 months after a negative result is obtained in a patient suspected of having syphilis. During the secondary phase, the sensitivity of the VDRL or RPR approaches 100%. Late syphilis, especially if treated, can also not be diagnosed using a nontreponemal test because the titer of antibody will eventually decline to undetectable levels (Tables 20-5 and 20-6).[368,412]

The lack of specificity (98%; range = 93% to 99%) of the nontreponemal tests limits their use as screening tests, particularly in low-prevalence populations (Table 20-5). Biologic false-positive reactions occur not only in patients who have other treponemal infections, but also in patients with other inflammatory conditions, including viral infections where antibody may be transiently produced, as well as pregnancy, advanced age, cancer, and autoimmune diseases (Table 20-7).[368] Biologic false-positive reactions have also been reported in intravenous drug users, a population at increased risk for contracting syphilis,[188,218] and HIV and hepatitis C seropositive patients.[16,514] A positive nontreponemal test requires confirmation by a treponemal test because of this limitation. Treponemal tests, however, may also be falsely-negative, in patients with immunosuppression or HIV coinfection.[215]

TABLE 20-6 Interpretation of Serologic Tests for Syphilis

Nontreponemal Tests	Treponemal Tests	Likely Interpretation
Positive	Positive	Syphilis, yaws, or pinta
Positive	Negative	False-positive (no syphilis)
Negative	Positive	Primary or latent syphilis; previously treated or untreated syphilis, yaws, or pinta
Negative	Negative	No syphilis, incubating syphilis

Adapted from reference 368.

TABLE 20-7 Causes of False-Positive Serologic Tests for Syphilis

Nontreponemal Tests	Treponemal Tests
Elderly	Elderly
Drug addiction/IVDU	Drug addiction/IVDU
Immunizations	Immunizations
Immunoglobulin abnormalities	Immunoglobulin abnormalities (Hyperglobulinemia)
Pregnancy	Pregnancy
Systemic infection: Bacterial endocarditis, brucellosis, chancroid, chickenpox, hepatitis, infectious mononucleosis, leprosy, lymphogranuloma venereum, measles, mumps, pinta, pneumococcal pneumonia, rickettsial disease, tuberculosis, viral pneumonia, yaws	Systemic infection: Brucellosis, genital herpes, infectious mononucleosis, leptospirosis, leprosy, Lyme disease, malaria, pinta, relapsing fever, yaws
Other inflammatory conditions: Idiopathic thrombocytopenic purpura, malignancy, polyarteritis nodosa, rheumatoid arthritis, systemic lupus erythematosis, thyroiditis, ulcerative colitis, vasculitis	Other inflammatory conditions: Cirrhosis, scleroderma, systemic lupus erythematosis, thyroiditis

Treponemal Tests. Treponemal tests detect antibodies directed against surface antigens of *T. pallidum*, and antibody titers correlate poorly with disease activity or stage. Once positive, these tests remain reactive for years, regardless of treatment status (Tables 20-5 and 20-6). Treponemal tests, therefore, cannot be used to monitor the response to therapy, or to detect relapse or reinfection in previously treated patients. Treponemal tests may also be cross-reactive in patients with endemic treponemoses (yaws and pinta) and thus cannot be used to distinguish patients with syphilis from these other types of spirochete infection (Table 20-6). Traditional treponemal tests (FTA-ABS or TPPA) have mainly been used to confirm nontreponemal test reactivity, or as diagnostic tests in patients with late syphilis who have a negative nontreponemal test. More recently, however, highly sensitive

treponemal immunoassays have become available in several formats that are increasingly being used to screen low-prevalence populations for syphilis.

The first treponemal assay developed was the *T. pallidum* immobilization (TPI) test, in which the motility of live, virulent treponemes was inhibited by the presence of a specific antibody.[295] Due to the technical problems with this assay and its expense, other test formats have been progressively developed in the past 60 years. Tests formats that are currently available for the detection of specific *T. pallidum* antigens include earlier enzyme and particle immunoassays, newer commercial EIAs including some that are immunochemiluminescence assays that incorporate recombinant antigens, and rapid immunochromatographic assays that are being used in resource-limited settings.[129,130,139,176,412] This section briefly describes the principles behind each of these types of tests, including their performance and limitations.

Traditional Treponemal Tests. Earlier treponemal tests have been used for several decades to confirm the diagnosis of syphilis in patients with reactive nontreponemal test results, but these assays are now mainly used as reference tests since the implementation of highly sensitive EIAs to screen for syphilis (Fig. 20-5; see Reverse Sequence Testing Algorithm). The four treponemal tests that have been in use in the United States include the fluorescent treponemal antibody absorption assay (FTA-ABS), the *T. pallidum* particle agglutination (TPPA) (Fujirebio Inc., Japan), the microhemagglutination assay for *T. pallidum* (MHA-TP) (Fujirebio Inc., Japan), and the *T. pallidum* hemagglutination assay (TPHA).[235] The MHA-TP uses sensitized sheep erythrocytes coated with *T. pallidum* (Nichols strain), which agglutinate with antitreponemal IgM and IgG antibodies. The TPHA is a microhemagglutination assay for IgM and IgG antibodies. The MHA-TP assay and TPHA are less sensitive than the other treponemal tests for diagnosis of early syphilis (Table 20-5), and all equivocal reactions required confirmation by another treponemal test (i.e., FTA-ABS).[462] The MHA-TP and TPHA have, therefore, been replaced by more sensitive treponemal assays. Treponemal tests remain reactive for life except for patients who are diagnosed and receive therapy with primary syphilis,[235] and thus cannot be used to monitor the effects of therapy.

The FTA-ABS test is a qualitative indirect immunofluorescence test that requires pretreatment of sera samples with an absorbent to remove nonspecific antibodies (Chart 20-4). The assay uses fixed *T. palladium* to bind fluorescent IgM and IgG antibodies. Darkfield illumination was originally used, but the double-staining procedure which also applies rhodamine-conjugated IgG antitreponemal antibody as a contrasting counterstain improves location of spirochetes. The performances of the FTA-ABS traditional and double-staining procedures are comparable.[375] The FTA-ABS test is more sensitive than the MHA-TP or TPHA and the nontreponemal tests for detection of antibodies in early syphilis, but all of these tests are better at detecting patients in the later stages of syphilis (Table 20-5). The FTA-ABS test approaches a

sensitivity of 100% during the secondary stage.

1283

The FTA-ABS test has a high specificity which can be increased by absorption of the test sera with a nonpathogenic spirochete, the Reiter strain of *T. phagedenis.*[22,202] It has been estimated that 1% of the normal population will have a false-positive FTA-ABS test. Although false-positive FTA-ABS results are uncommon, patients with systemic lupus erythematosus or other connective-tissue diseases, and other infections may produce an unusual beaded staining reaction.[229] Cross-reactions can also occur with other pathogenic treponemes.[22] False-positive reactions may occur even with this very specific test if the FTA-ABS test is used to screen low-prevalence populations for syphilis.

Because the TPPA is less expensive and less complex to perform than the FTA-ABS test, it is one of the more commonly used traditional treponemal tests. The TPPA assay is a quantitative agglutination assay for the detection of antibodies to *T. pallidum* in sera or plasma. The TPPA uses the same treponemal antigen as the MHA-TP but instead uses colored gel particles sensitized with *T. pallidum* antigen instead of erythrocytes, thereby eliminating false-positive reactions in plasma samples.[235] The TPPA is as sensitive as the FTA-ABS test in primary syphilis but cannot be used to monitor therapy (Table 20-5).

Enzyme immunoassays. Investigators have been developing highly sensitive and specific enzyme immunoassays for syphilis since the 1970s.[485] The initial commercial EIA for syphilis, detected IgG antitreponemal antibodies using a microtiter plate with wild-type *T. pallidum* antigens coated in the wells.[508] This early EIA assay had a sensitivity of 98.4% and a specificity of 99.3% compared to the FTA-ABS and TPPA reference tests. The treponemal antigens, antibody targets and documented performance of several currently available commercial treponemal-based EIA tests, as well as an estimated range of positive predictive values based on the prevalence of syphilis in the US population are shown in Table 20-8.[412] Commercial syphilis EIA assays now mainly use one or more recombinant treponemal antigens (Tp15, Tp17 and/or Tp47) although some tests still use wild-type antigens. EIA tests that use wild-type antigens or only one recombinant antigen may be less sensitive, but this has not been verified using a large number of samples. For example, an immune-capture EIA (ICE Syphilis; Abbott Murex) which uses recombinant TpN15, TpN17, and TpN47 antigens had higher sensitivity than the CAPTIA SelectSyph-G (Centocor) that uses wild-type antigens (99% vs. 91.4%; $p<0.01$).[509]

These assays have been increasingly adopted as the major syphilis screening tests used by clinical laboratories because EIAs have comparable performance to traditional

treponemal tests (FTA-ABS and TPPA), but they are performed on automated systems that allows a higher volume of tests to be reported using less technologist time. Most EIA assays detect both IgG and IgM antibodies against one or more *T. pallidum* antigens, and are therefore unable to distinguish treated from untreated syphilis infections. Although many evaluations have been reported on the performance of individual EIA compared to reference tests, these studies have used different reference methods and testing algorithms, making it difficult to directly compare these assays. Only a small number of studies have been reported that evaluated several different EIAs using either wild type of recombinant *T. pallidum* antigens for detection of IgG and IgM antitreponemal antibodies using the same patient population. Cole and colleagues[92] compared 15 serologic assays (10 commercial EIAs vs. four TPHA and one TPPA kit) for the detection of syphilis using the same specimen panel that included 114 serum and plasma samples from patients with syphilis (40 with primary, 43 with secondary, 19 early latent stage, and 12 late latent stage infections) and 249 specimens from unselected blood donors. The sensitivity of the ten EIAs (Trepanostika TP Recombinant, bioMérieux; Syphilis EIA II, Newmarket Laboratories; Abbott Murex ICE Syphilis; Enzygost Syphilis, Dade Behring; Diesse Enzywell Syphilis; Biokit Bioelisa Syphilis 3.0; Bio-Rad Syphilis Total, Omega Pathozyme Syphilis; Mercia Syphilis, Microgen Bioproducts; Trinity Biotech CAPTIA Syphilis) and five TPHA/TPPA kits ranged from 93.9% to 99.1%, and overall, the EIAs had the highest sensitivity for detection of early syphilis cases. Only the Trinity Biotech EIA and three TPHA assays failed to detect specimens from the untreated secondary syphilis category. All specimens from all other syphilis diseases stages were detected by all other assays. All of the kits gave a final specificity of 100% except for the Abbott murex ICE Syphilis and the Biokit TPHA kits, which were repeatedly reactive with a few specimens that were negative according to supplemental tests.

Binnicker and colleagues[37] recently compared the performance of seven treponemal assays (BioPlex 2200 Syphilis IgG, Bio-Rad; Zeus Scientific FTA-ABS; Serodia TP particle agglutination [Fujirebio Diagnostics]; Trep-Sure EIA [Phoenix Biotech]; Trep-Chek EIA [Phoenix Biotech]; Trep-ID EIA [Phoenix Biotech] and Treponema ViraBlot IgG [Viramed Biotech]) using 303 serum samples submitted to a reference laboratory for the detection of syphilis. All of the samples in this study were also tested using an RPR assay and a treponemal IgM Western blot assay (Viramed VirBlot). Compared to a "consensus of the test panel" (defined as 4/7 treponemal tests in agreement) as the gold standard, the seven evaluated assays had comparable performance, with agreement ranging from 95.7% (95% CI, 92.7% to 97.5%) for the Trep-Sure EIA up to 99.3% (97.5% to 99.9%) for the Trep-ID EIA. Despite the overall performance of these assays, all of them gave discordant results. For example, when FTA-ABS results were compared to the consensus of the panel, three discordant samples were found with FTA-ABS positive, panel-negative results.[37] One of these

samples was also positive by the Trep-Sure assay but negative for all other tests including the RPR and IgM assays and was interpreted as probably false-positive FTA-ABS results.[37] Discrepant test results in this study could not be correlated to the clinical presentation or treatment history because no clinical data were submitted with these samples.

Although most commercial syphilis EIA assays have comparable performance, laboratories should validate individual assays to determine their limitations including the potential for false-positive and false-negative results in the population to be tested. Serum samples that test positive by the treponemal immunoassay but negative by the RPR assay should be analyzed with a second treponemal test that is different from the initial test used (see Laboratory Testing Algorithm).

Immunochemoluminescence assays. Two commercial immunochemoluminescence assays are currently available on high-throughput automated systems (Table 20-8). These assays use paramagnetic microparticles that are coated with

TABLE 20-8 Treponemal Antigens, Antibody Targets, and Performance of Several Treponemal-Based Tests and Their Estimated Positive Predictive Values Based on Syphilis Prevalence Ranging From 0.7% to 4.0% in the US Population

recombinant *T. pallidum* antigens that detect labeled anti-human IgG and IgM monoclonal antibodies. The LIASON assay (Diasorin) uses the TpN17 antigen while the Architect Syphilis Chemiluminescence Assay (CLIA, Abbott) includes Tp15, Tp17 and Tp47 recombinant antigens. These assays provide high sensitivity for detection of early syphilis but like other treponemal tests cannot distinguish recent, remote or previously treated spirochete infections. Young and colleagues recently tested 129 sera

from serologically characterized cases of untreated syphilis and 1,107 sera submitted for routine

1285

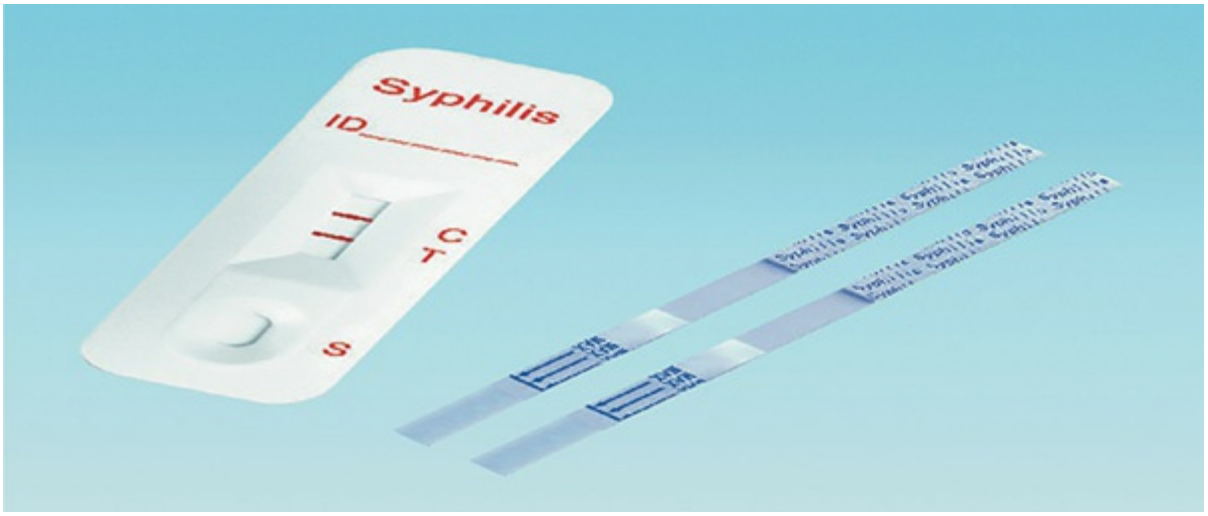
syphilis testing. The Architect Syphilis assay and the TPPA were in total agreement for all untreated infections with sensitivity of 98.4%, which was significantly higher than that of the Murex immunocapture EIA (ICE), the IgM immunoassay or the VDRL test.[510] Furthermore, the difference in sensitivity between the Architect syphilis assay and the Murex ICE assay was due to increased detection of primary stage syphilis cases (97.5% vs. 77.2%, $p<0.001$), but the specificity was higher for the Murex ICE (99.9%) versus the Architect assay (99.1%) ($p = 0.016$).[510] Knight and colleagues[224] recently showed similar performance characteristics for the LIASON assay compared with the CAPTIA Syphilis-G EIA using a testing algorithm that also included the RPR and TPPA assays. As a screening test, the LIASON compared with the EIA showed levels of agreement within the test algorithm, respectively, of 94.1% and 100% for 51 samples from patients with primary or secondary syphilis, 93.2% and 98.7% for 999 samples sent to the laboratory for routine syphilis testing, 84.5% and 94.0% for 200 samples from human immunodeficiency virus-positive patients, 98.0% and 100% for 200 samples from pregnant patients, and 94.3% and 98.3% for 992 samples from apparently healthy adults.[224] As a confirmatory test, the LIASON showed 99% agreement for 204 RPR-positive samples with the EIA. After resolution with further TPPA testing, and the discard of one inadequate sample, there was 100% agreement for the remaining 203 samples. For the total group of 2,645 samples, the overall relative sensitivity was 95.8% and the relative specificity was 99.1%.[224]

Both of the CLIA assays demonstrate excellent sensitivity as a screening test for syphilis among various patient populations, including specific populations with reportedly increased rates of false-positive nontreponemal test results. However, due to their somewhat lower specificity compared to some EIA assays (Table 20-8), a small increase in confirmatory tests may be required to exclude false-positive results in some patient populations.

Rapid tests. Commercial rapid point of care tests for syphilis are promising for syphilis screening, and are increasingly being used in resource-limited settings where other treponemal syphilis assays may not be readily available onsite. Rapid syphilis assays are available either as agglutination tests using latex particles coated with treponemal antigens or as immunochromatographic strips (ICS) where a colored line indicates a positive reaction (Fig. 20-8). These assays have been developed to meet the ASSURED (Affordable, Sensitive, Specific, User-friendly, Rapid/robust, Equipment-free, and Delivered) criteria set out by the WHO for resource-limited settings. Most rapid tests can be stored at room temperature, are simple to perform in

that they require minimal training and no equipment, and the results can be read visually in less than 30 minutes. Another advantage of this format is the test can be performed with whole blood, serum, or plasma.

More than 20 rapid tests for syphilis detection are currently commercially available but none have yet been approved for use in North America. The WHO, the CDC, and other public health agencies have evaluated several rapid tests, mostly of the ICS format. Bronzan and colleagues[48] evaluated onsite rapid antenatal syphilis screening in South Africa using an ICS compared to an onsite RPR and offsite RPR and TPHA tests and found 79/1250 (6.4%) of women had syphilis according to the reference laboratory. The onsite ICS resulted in the highest number of pregnant women correctly diagnosed and treated for syphilis (89.4% vs. 63.9% for onsite RPR and 60.8% for offsite RPR/TPHA). The onsite RPR had a low sensitivity (71.4%) for high-titer syphilis, and the offsite approach resulted in the lowest client return rates for treatment. In a further study, these investigators also showed that onsite antenatal screening using an ICS was also cost-effective.[38]



■ **FIGURE 20-8** TP Syphilis Test Card—Positive Syphilis Rapid Test (Boson; LumiQuick, USA). This rapid anti-TP test employs chromatographic lateral flow test device in a cassette format. Colloidal gold conjugated recombinant antigens (Au–Ag) corresponding to TP antigens (P47, P45, P17, P15) are dry-immobilized at the end of nitrocellulose membrane strip. TP antigens are bond at the Test Zone (T) and rabbit anti-TP antibodies are bond at the Control Zone (C). When the sample is added, it migrates by capillary diffusion rehydrating the gold conjugate. If present in sample, TP antibodies (anti-TP) will bind with the gold conjugated antigens forming particles. These particles will continue to migrate along the strip until the Test Zone (T) where they are captured by TP antigens generating a visible red line. If there are no anti-TP antibodies in sample, no red line is formed in the Test Zone (T). The gold conjugate will continue to migrate alone until

it is captured in the Control Zone (C) by the rabbit anti-TP aggregating in a red line, which indicates the validity of the test. The presence of two color bands "C" and "T" within the results window indicates a positive reaction, while a single band "C" is negative.

Although limited systematic analysis of rapid tests in clinical settings has been done, clinical evaluations and in vitro laboratory research suggests that rapid treponemal tests have similar sensitivities and specificities to traditional nontreponemal tests (RPR). A large meta-analysis on syphilis testing using ICS tests to detect *T. pallidum* antibody was recently reported, because this test format has been evaluated in more clinical settings than other types of devices.[476] Tucker and colleagues[476] obtained clinical data from more than 22,000 whole blood, plasma, or fingerstick ICS tests done at STI clinics and antenatal clinics during 15 separate studies. ICS syphilis tests have a high sensitivity (median 0.86, interquartile range 0.75 to 0.94) and a higher specificity (0.99, 0.98 to 0.99) compared to the RPR nontreponemal screening test.[476]

More recently, several rapid immunochromatographic tests have been developed that simultaneously detect both nontreponemal and treponemal antibodies. The CDC recently evaluated an immunochromatographic device made by Chembio Diagnostics Systems Inc. (Medford, NY).[67] The device contains two nitrocellulose membrane strips perpendicular to each other contained within a plastic cassette that allow independent delivery of the sample (one strip) and the conjugate detecting reagents (second strip) consisting of colloidal gold particles conjugated to protein A and anti-human

1286

IgM antibody (Fig. 20-9). This assay has been used by the CDC to test 1,601 banked serum samples, and the results compared to the RPR and TPPA assays.[67] Compared with the RPR test, the rapid dual test had a reactive concordance of 98.4% when RPR titers of sera were ≥1:2 and the nonreactive concordance was 98.6%. Compared to the TPPA assay, the reactive and nonreactive concordances of the treponemal line were 96.5% and 95.5%, respectively.

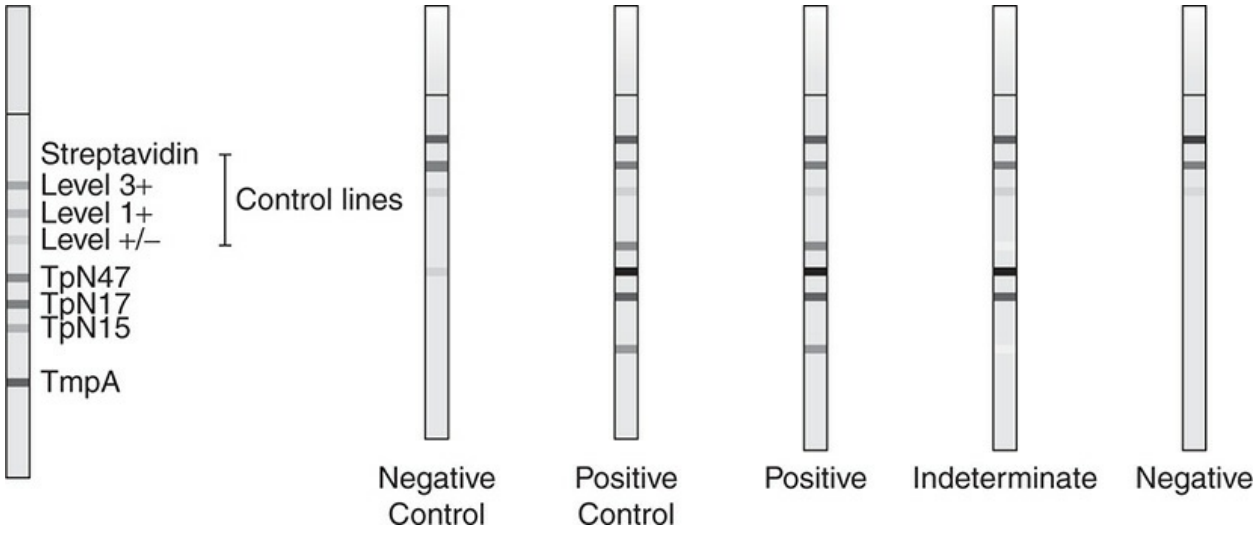
■ **FIGURE 20-9** Rapid Syphilis Test—Chembio's Dual Path Platform Technology. The recombinant *T. pallidum* antigen (T1) and synthetic nontreponemal antigen (T2) are bound to the membrane's solid phase, while a third line serves as a procedural control. Hydration of the conjugate reagents in the second well causes migration along the second strip to the test area where antibodies to treponemal and nontreponemal antigens are detected and visually read in the cassette window as red/magenta-colored lines within 15 minutes.

These data and the results of other evaluations of rapid tests suggest that these assays could be used for the serologic diagnosis of syphilis in primary healthcare clinics or resource-poor settings to improve rate of treatment where patients are unlikely to return for their laboratory results.[476] More research is needed to evaluate ICS and other rapid syphilis tests among patients with primary syphilis and patients infected with HIV before deploying these rapid tests widely in syphilis screening programs worldwide.[476]

Immunoblots. Immunoblots have also been used primarily as a confirmatory test for syphilis.[63] An advantage of this technology is that purified antigen can be used as the substrate, and the pattern of reactivity of sera can be used to determine positivity. If the criteria for determining positive immunoblot tests are not standardized, however, the variation in interpretation among laboratories can cause diagnostic problems. Western blot (immunoblot) assays for the detection of antibodies to *T. pallidum* were originally developed using the whole-cell organism (*T. pallidum* Nichols strain) as the antigen,[114,324,388] and detected the major surface antigens of *T. pallidum* (TpN15,

TpN17, TpN44.5, and TpN47). The sensitivity of one early immunoblotting assay for detection of IgM antibodies in 14 symptomatic neonates was 92%, whereas only 83% of 12 asymptomatic neonates who were later proved to be infected were detected by Western blotting.[388]

Commercial immunoblot assays have subsequently become available as confirmatory assays for *T. pallidum* antibodies that have comparable performance as a single multi-parameter test compared to confirmation using a combination of serologic assays. The INNO-LIA Syphilis Kit (Innogenetics NV, Ghent, Belgium) is a line immunoassay (LIA) that uses three immunodominant membrane proteins (TpN15, TpN17, and TpN47) derived from *T. pallidum* (Nichols strain) and one synthetic peptide (TmpA) derived from transmembrane protein A.[130,176,232] In addition to the syphilis antigens, control lines are used for a semiquantitative evaluation of the results and to verify that the reagents and sample have been added. Figure 20-10 shows the layout of the INNO-LIA syphilis kit strip. The interpretation algorithm of this immunoblot assay has been optimized for visual reading using a set of known negative and positive samples. Several representative INNO-LIA syphilis kit reactivity patterns are shown in Figure 20-10. Briefly, a sample is *T. pallidum* antibody-negative if no band or an isolated band with a minimum intensity equal to 0.5 is present. If multiple bands with a minimum intensity equal to 0.5 are visible, the sample if considered positive. A sample is considered indeterminate if a single band is visible with a minimum intensity equal to 1. Ebel and colleagues[130] reported a sensitivity of 99.6% (95% confidence interval [CI], 98.5% to 99.9%) and a specificity of 99.5% (95% CI, 98.1% to 99.9%) for this immunoblot assay compared to the consensus result (i.e., results of classical serologic assays and the clinical history). Six of seven indeterminate samples in this study using classical serologic assays tested positive using the INNO-LIA syphilis kit. In another evaluation using 289 seronegative sera, 219 seropositive sera, and 23 sera that were indeterminate based on serologic testing, the INNO-LIA assay had a sensitivity and specificity of 100% (219 of 219) and 99.3% (286 of 288), respectively, and gave a significantly higher number of correct results than either the FTA-ABS (IgG) or TPHA assays.[176]



■ **FIGURE 20-10** Syphilis INNO-LIA immunoblot reaction. (Adapted from INNOGENETICS and references 176, 232.)

1287

Other immunoblot and Western blot assays have been recently evaluated for the detection of *T. pallidum* antibodies. Two IgG immunoblot assays (Treponema ViraBlot test kit IgG [Viralab, Inc., Oceanside, CA] and the *Treponema pallidum* IgG line immunoblot [Genzyme ViroTech, GmbH, Russelsheim, Germany]) and one IgG Western blot assay (*T. pallidum* IgG Marblot strip test system [MarDx Diagnostics, Inc., Calsbad, CA]) were compared with the RPR, FTA-ABS, and the TPPA test results for 200 samples submitted to a reference laboratory that receives a high percentage of inconclusive FTA-ABS samples from primary screening laboratories.[492] The agreement levels of the Viramed, Virotech, and MarDx assays were 97.0%, 96.4%, and 99.4%, and the agreements of samples inconclusive by FTA-ABS and resolved by TPPA were 91.7%, 83.3%, and 69.4%, respectively. The performance of the two Western blot assays (IgG Western blot assay [*T. pallidum* IgG Marblot strip test system (MarDx Diagnostics, Inc., Carlsbad, CA)] and the INNO-LIA Syphilis) has also been compared with the Murex ICE Syphilis EIA and the FTA-ABS and TPPA tests for the serologic diagnosis of syphilis in 135 patients attending a social hygiene clinic (39 in primary, 20 in secondary, 19 in early latent, and 58 in latent of unknown duration) in Hong Kong.[232] The LIA assay had an overall sensitivity of 94.1% (95% CI, 88.7% to 97%), whereas the MarDx assay was 65.2% (95% CI, 56.8% to 72.7%), but both Western blot assays had a specificity of 100%. The LIA assay had a positive agreement with the consensus results of the other assays (EIA, FTA-ABS, and TPPA) of 98.5% (95% CI, 94.5% to 99.6%), whereas the MarDx assay was significantly lower at 68.2%(95% CI, 59.8% to 75.6%). Therefore, Western blot and

immunoblot assays offer additional accurate treponemal tests that can confirm the currently recommended tests in the syphilis algorithm, but some assays may be better than others at confirming the results of other types of treponemal assays. The ViraBlot immunoblot assay and the INNO-LIA Syphilis Western blot assay currently have the best performance as confirmatory tests. However, the number and quality of immunoblot and Western blot tests will likely expand as our understanding of the nature of the immunologic response to other protein antigens of *T. pallidum* increases.[231,438]

Congenital Syphilis. An excellent review of diagnostic tests for CS in newborns provides an overview of the current use and performance of various tests, including the use of newer EIA, immunoblot and PCR assays.[190] Serologic diagnosis of CS remains difficult because laboratory test results may be indeterminate in the neonatal period due to the presence of maternal antibody (IgG), so that no single test can be used to make the diagnosis. Nontreponemal tests have limited application for diagnosing CS due to the very low sensitivity (4% to 13%) of an infant's serum VRDL/RPR titer being at least fourfold (two or more dilutions) above that of the mother's serum at birth.[443] However, if the VDRL/RPR tests become nonreactive before 6 months of age in an infant who has not received treatment, the diagnosis of CS is excluded.[190] Neurosyphilis may also be confirmed in infants with symptomatic CS by the presence of CSF abnormalities, including pleocytosis, an elevated protein level, and a reactive CSF VDRL.[294]

The detection of specific antitreponemal IgM remains the most sensitive initial test for diagnosis of CS.[348] Unlike IgG antibodies that cross the placenta and enter the fetal circulation, immunoglobulins of the M class do not cross the placenta so that the detection of specific antitreponemal IgM antibodies in a neonate indicates intrauterine infection.[9] Herremans and colleagues[190] summarize the reported performance of different types of IgM assays in newborns at risk or with clinical or asymptomatic CS and healthy newborns. Three different methods are currently used to detect treponemal-specific IgM in neonates in order to diagnose syphilis including: (1) 19S FTA-ABS, (2) IgM immunoblots, and (3) IgM EIAs. Because antibody reactivity to some *T. pallidum* antigens may occur in normal sera, the 19S IgM FTA-ABS test includes fractionation of serum (separation of the maternal IgG fraction for the fetal 19S IgM fraction) to obtain IgM specificity, prior to performing the FTA-ABS test.[217,459] The sensitivity of the 19S FTA-ABS test in clinical CS cases is 72% to 77% with a specificity of 100%. Rosen and Richardson demonstrated good performance with a research assay, but encountered problems when commercial reagents were used.[383] A few at-risk asymptomatic children tested false-positive for IgM using this assay.[383] False-positive reactions occur if antiglobulins, such as

rheumatoid factors or anti-idiotype antibodies, are present in fetal sera. False-negative reaction may also occur due to excessive amounts of IgG antibody blocking the antigenic sites. The 19S FTA-ABS test has, therefore, improved specificity; so it can be used as a confirmatory procedure, but its lower sensitivity compared to the FTA-ABS assay prevents its use as a screening test.

Several IgM EIAs have been evaluated for the diagnosis of CS. The sensitivity (88% to 100%) and specificity (100%) of these assays are high, and positive IgM tests are detected in 3% to 7% of asymptomatic patients at risk for CS.[190] The CAPTIA Syphilis-M EIA (Trinity Biotech) detects only IgM antitreponemal antibodies, and has been cleared by the Food and Drug Administration (FDA) for the diagnosis of CS, and may also be used for the diagnosis of primary syphilis because of its high sensitivity.[241,502] Although few studies have been done comparing commercial IgM EIAs with IgM immunoblots, the later assay may be slightly more sensitive for diagnosing CS. Overall, 21/25 (84%) of infants with a positive IgM immunoblot were also positive by the IgM EIA, and two of the false-negative EIA test occurred in patients with only single antigen bands on the immunoblot.[189] Another study of 97 mother–baby pairs showed that 18 were positive using an IgM immunoblot (7 infants had CS), while the IgM EIA was only positive in 14 infants (5 infants had CS, while 2 were false-positive and had a negative immunoblot).[371] In this study, the nontreponemal test (RPR) was also shown to be inferior to an IgM treponemal test for diagnosing CS.[371]

The 47-kDa protein is one of the major immunogens in CS that stimulate neonatal IgM antibody production that may also be detected in fetal blood.[388] Sanchez and colleagues[388] used Western blot analysis to identify a 47-kDa antigen that was not seen in control patients and was correlated with intrauterine infection. IgM immunoblot reactions are reported as positive in infants when one or more of the 47-, 45-, 30-, and 15/17-kDa reactive bands are present.[190] In CSF, any IgM-reactive band in the 47 and 15.5 ranges are considered positive.[294] The IgM immunoblot is very effective in

confirming CS in symptomatic infants with sensitivity between 83% and 100% and a specificity of 100%.[189,190] In asymptomatic infants at risk for CS, 4% to 22% may have a reactive IgM immunoblot, but the specificity remains high.[190] The sensitivity of immunoblot for detection of IgM antibodies in 14 symptomatic neonates was 92%, whereas 83% of 12 asymptomatic neonates who were later proved to be infected were detected by Western blotting.[293] Twenty-seven of 30 (90%) uninfected infants were correctly characterized.[293] Dobson and colleagues[114] demonstrated reactivity to 47-

and 37-kDa protein antigens in the serum of congenitally infected infants. Although rheumatoid factor could theoretically cause problems in the immunoblot assay, removing rheumatoid factor from the sera did not affect the results.

Sequential testing remains an important part of the laboratory monitoring of CS. If the infant or mother is IgM seroreactive at birth, treatment should be started and follow-up tests arranged for 1, 2, 3, 6, and 12 months after birth to assess the response to treatment. Given appropriate therapy, the serologic tests (VDRL/RPR and IgM) in symptomatic infants decline within 3 months and disappear by 6 months. Treponemal tests are less effective at monitoring the response to therapy because the infant may have persistent maternal IgG until 15 months of age.[190] However, infants with persistently reactive treponemal test at 18 months of age may have CS if the VDRL-RPR is still reactive, and they should be reevaluated.

Molecular Methods. Molecular techniques have increasingly been applied to the direct detection of spirochetes in tissues and fluids. Investigators have concentrated their attention on intrauterine and CNS infection, because serologic techniques are not adequate for these important clinical problems.[172,323] DNA probes have not been sufficiently sensitive, so efforts have been focused on amplification techniques, such as PCR.

T. pallidum has successfully been detected by PCR targeting different gene regions in clinical specimens.[83,172] The *T. pallidum* gene encoding a 47-kDa protein has been used as the target region for most PCR studies, but the DNA polymerase I gene may be a more sensitive target.[255]

The detection of *T. pallidum* by PCR in amniotic fluids, neonatal sera, and CSF has been shown to be a moderately sensitive alternate method (76% to 86%), with a specificity of 100% for diagnosing CS compared with the RIT.[172] Although PCR should be more sensitive than the RIT, the presence of inhibitors in clinical specimens may yield false-negative tests, especially in CSF. Treponemal DNA in spinal fluid appears stable, so negative results are probably not from deterioration of nucleic acids in the specimens.[487] PCR detection of *T. pallidum* has helped confirm a diagnosis of CS in infants born to mothers with syphilis.[294] In this study, spirochetes were detected in the CSF of 17 of 76 infants with no prior antibiotic exposure by rabbit infectivity testing.[294] Most of these infants (16/17) had an abnormal clinical examination and/or abnormal laboratory or radiographs suggestive of CS. Overall, a positive result on IgM immunoblotting or PCR of serum, blood or CSF were the best predictors of CNS infection.

PCR has also been used to detect *T. pallidum* in formalin-fixed, paraffin-embedded tissues. Genest and colleagues[159] developed a PCR assay to detect the 47-kDa treponemal membrane antigen and evaluated the performance of this assay using 49 formalin-fixed, paraffin-embedded placentas (38 from mothers with positive syphilis

serology and 11 with negative serology) against histopathology and Steiner staining. PCR was significantly associated with placental histopathologic results diagnostic of CS and the detection of spirochetes by the Steiner stain, but also detected a few additional patients with negative histology. Behrhof and colleagues[31] developed a semi-nested PCR assay targeting the DNA polymerase I gene and compared this approach with immunohistochemistry and silver staining (Dieterle) for detecting *T. pallidum* in 36 skin biopsy specimens from patient with a clinical and/or serologic diagnosis of syphilis. Twenty skin biopsy specimens contained *T. palladium*: 17 were positive by immunohistochemistry, 14 were PCR-positive and only 9 were detected by the Dieterle stain. PCR was highly dependent on the quality of the tissue specimen and the integrity of the DNA, but was positive in all cases except one when poor quality specimens were excluded, including three cases negative by the other methods.

A few studies have been reported that compared syphilis PCR assays with serology results. Bruisten and colleagues[53] used a basic membrane protein (bmp) gene target in a gel-based nested PCR method, and compared the results against RPR, TPHA, and FTA-ABS results in a cohort of 364 STI clinic patients in the Netherlands. The PCR assay had a correlation of 96% with the other methods but only 12 patients were detected by PCR, 7 patients were detected by serology, and only 3 patients were detected by both PCR and serology. Palmer and colleagues[340] used a gel-based PCR assay to detect the *T. pallidum* 47-kDa integral membrane lipoprotein gene in 98 STI clinic patients in the United Kingdom and compared the results with serology (RPR, TPPA/TPHA, and EIA IgM and IgG). Although the PCR had a sensitivity of 94.7% and specificity of 98.6% for the detection of primary syphilis, the sensitivity decreased to 80% compared with serology for detection of secondary cases most likely because of sampling error or insensitivity of the PCR assay.[340] More recently, investigators have focused on developing reliable real-time PCR assays to detect *T. pallidum* in a variety of clinical specimens. Leslie and colleagues[242] developed a real-time PCR assay targeting the *pol* A gene of *T. pallidum* (TpPCR) with an analytic sensitivity of 1.75 target copies per reaction. TpPCr results were compared with serology for 301 patients and the TpPCR assay showed 95% agreement, with a sensitivity of 80.39% and a specificity of 98.40% but discrepancy occurred for 14 patients (10 had positive serology but negative PCR reactions; 4 had negative serology but positive PCR reactions). Again, the insensitivity of the PCR assay was attributed to incorrect timing or site of sampling. A real-time PCR assay targeting the 47-kDa gene of *T. pallidum* was used to diagnose syphilis in a cohort of 74 patients with and without HIV infection who were at different stages of syphilis (primary [n = 26], secondary [n = 40], and latent) by testing various blood samples, lesion swabs, and/or urine and CSF samples.[158] Overall, the sensitivity of the PCR (regardless of samples type) was 65% during primary and 53% during secondary, but no latent cases were detected. No difference was found in either serology or PCR results among HIV-infected patients.

The performance of a real-time PCR targeting the *polA* gene of *T. pallidum* was recently compared to the diagnosis of syphilis made by the STI clinic (including a DFM result) for 716 patients with primary

1289

and 133 patients with secondary syphilis.[191] For patients with primary syphilis, the PCR assay had a sensitivity of 72.8%, specificity of 95.5%, and a positive predictive value of 89.2% and a negative predictive value of 95%. However for those with secondary syphilis, the sensitivity of the real-time PCR assay was much lower (43%) compared to skin or mucosal findings plus an RPR titer ≥1:8.[191]

Multiplex real-time PCR assays or microarrays may be the best approach for comprehensive diagnosis of the presence of *T. pallidum* and other pathogens known to cause genital ulcer disease. Suntoke and colleagues[465] developed two duplex real-time PCR assays for detection of *Haemophilus ducreyi* (causative agent of chancroid), *T. pallidum*, and herpes simplex 1 and 2 and used them to detect these pathogens in ulcer swabs taken from 100 people with symptoms in rural Uganda. Of the 100 swabs analyzed from 43 HIV-positive and 57 HIV-negative patients, 71% were positive for one or more STI pathogens by real-time PCR (61% for HSV-2, 5% for *T. pallidum*, 3% for HSV-1, 1% for *H. ducreyi,* and 1% for dual *H. ducreyi*/HSV-2). A real-time PCR test targeting the 47-kDa membrane gene of *T. pallidum* was multiplex with an existing HSV1/2 real-time PCR assay and used to test 692 samples from patients attending genitourinary clinics in Glasgow.[404] Of the 692 samples, 139 were positive for HSV1, 136 for HSV2, 15 for syphilis, and 1 for both syphilis and HSV1. All syphilis PCR-positive cases were confirmed by a second PCR assay, and this method was more sensitive than both DFM and serologic testing for the diagnosis of primary syphilis and unexpected cases of syphilis where HSV was clinically suspected to be the cause of the genital ulcer disease. Multiplex detection of *T. pallidum* and HIV has also been done using a visual DNA microarray-based on gold label silver stain and coupled with multiplex asymmetric PCR.[467] This visual gene detection technique accurately detected HIV and *T. pallidum* in 169 clinical samples compared to EIA and fluorescence quantitative real-time PCR.[467]

Based on the early success of these in-house molecular detection approaches, multiplex detection assays that can simultaneously detect *T. pallidum* and other important STI pathogens will likely be developed (e.g., Luminex microbead-based assay) and commercialized for the reliable, rapid, and efficient diagnosis of syphilis and coinfections in at-risk patients.

Reverse Testing Algorithm. The traditional laboratory based approach to screening patients for syphilis has been to first test with a nontreponemal assay (VDRL or RPR),

and then to secondarily use a treponemal test because of its perceived higher specificity to confirm positive VDRL or RPR results, or to test patients with a negative nontreponemal test where there is a high clinical suspicion of infection. But the perceived "greater" specificity of some treponemal tests is entirely an artifact of their use as confirmatory tests after performance of a nontreponemal test.[180] When the tests are compared head to head as the initial serologic procedure, the VDRL nontreponemal test is actually as specific as or more specific than the treponemal FTA-ABS test.[234]

Due to the commercial availability of highly sensitive automated syphilis EIA IgG and IgM assays, there has recently been an increasing clinical laboratory implementation of a reverse sequence algorithm for syphilis testing that reverse the order of use of nontreponemal and treponemal tests. The clinical advantages of this approach are that test results can be available the same day, and that specific antitreponemal antibodies are detected earlier in the course of the infection thereby enhancing the detection of primary syphilis cases. Testing stops in the new test algorithm if the treponemal EIA test is nonreactive, but a reactive treponemal EIA test leads to testing with a nontreponemal test with titer quantification, and to other tests if the VDRL/RPR is not reactive. All of the new algorithms produce a combination of results (i.e., reactive treponemal EIA but nonreactive VDRL/RPR) that were not produced by the traditional test approach. A recent investigation by the CDC of the use of the newer syphilis screening algorithm investigated highlighted discrepancies in laboratory testing and reporting practices that can further complicate interpretation of the results combinations that may be produced depending on the disease stage and treatment history (Fig. 20-11).[81] The investigators reviewed data on 116,822 specimens tested during 2005 to 2006 at four New York City laboratories using syphilis testing algorithms that started with a treponemal EIA.[81] A total of 6,548 (6%) specimens were reactive to a treponemal EIA test and most (99%) had secondary testing using an RPR test, while further testing was not done on nonreactive samples (94%).[81] Forty-four percent of the 6,548 samples were confirmed positive by the RPR test, and the remaining samples were nonreactive.[81] Patients with a positive result in both tests (EIA + RPR) had either a new or old case of syphilis depending on the RPR titer as follows: (a) RPR titer had not increased fourfold, no further treatment is required, and (b) RPR titer showed a fourfold rise, retreatment is required. Patients with positive EIA results but a negative RPR had early syphilis, old or previously treated syphilis, or a false-positive EIA test. False-positive treponemal EIA tests can be resolved by performing a different treponemal test (TPPA, FTA-ABS) or an immunoblot with a high sensitivity (i.e., INNO-LIA).[81] Although only 69% of the 3,664 samples (EIA + but RPR −) were tested with a second treponemal test, 83% of the 2,528 tested by a second treponemal method were positive.[81] Importantly, these

patients should be staged and treated unless previous syphilis treatment can be documented. The 17% of patients who had discrepant results between the initial reactive EIA and second treponemal test may be considered false-positive EIA results by the laboratory, but these patients should be clinically reviewed to determine whether a third treponemal test should be used to resolve the discrepancy.

Only two studies have evaluated the cost-effectiveness to the newer algorithm approach for syphilis screening. A cohort decision-analysis has been used to estimate the expected costs and effects including follow-ups and overtreatment of a traditional (Nontreponemal-first) versus newer (treponemal-first) syphilis test algorithm in the US healthcare system.[333] For a cohort of 200,000 patients (1,000 current infections and 10,000 previous infections), the net costs were $1.6M (treponemal-first) and $1.4M (nontreponemal-first). The treponemal-first approach resulted in treatment of 118 more cases (986 vs. 868), and a significant increase in the number of patients who were overtreated (964 vs. 38) or had to be followed-up (11,450 vs. 3,756). The estimated cost-effectiveness ratios were $1,671 (Treponemal-first) and $1,621 (Nontreponemal-first) per case treated. A Canadian cost-effectiveness analysis compared the traditional testing approach (Nontreponemal-first) for syphilis screening

1290

compared to the newer algorithm which uses an initial treponemal EIA and the INNO-LIA syphilis immunoblot (EIA + IL) for confirmatory testing of reactive EIA results.[91] The incremental cost-effectiveness ratio was $461 CDN per additional correct diagnosis (less costly and more effective) using the EIA + IL algorithm compared with RPR + TPPA/FTA-ABS for screening and diagnosis of syphilis.[91]

Borrelia

Taxonomy

The genus *Borrelia* is currently made up of 37 species, and several of them are pathogenic for humans and domestic animals (Table 20-9). *Borrelia* spp. are helical bacteria that measure 0.2 to 0.5 µm in diameter and 8 to 20 µm in length with 3 to 10

loose coils.[27] Most have 15 to 30 periplasmic flagella but isolates of *B. burgdorferi* have only 7 to 11 (see Image Plates 20-1C, D, and F). *B. burgdorferi* and other species that have been cultivated in vitro are microaerophilic (Table 20-9). The bacteria stain well with Giemsa, but on Gram's stain these organisms are neither gram-negative nor gram-positive.[27,40] *Borrelia* spp. that are human pathogens are transmitted by insect vectors, either lice or ticks (Table 20-2). The relapsing fever borreliae differ from the Lyme disease borreliae in their arthropod vectors.[27] Soft-bodied ticks in the family *Argasidae* (genus *Ornithodoros*), or lice (*Pediculus humanus*) are the biologic vectors of relapsing fever borreliae, whereas Lyme disease borreliae are restricted to hard-bodied ticks of the family *Ixodidae*. Louse-borne relapsing fever (LBRF) is caused by *B. recurrentis,* TBRF by a variety of species, and Lyme disease by *B. burgdorferi* and related species. Borrelial spirochetes also cause infection in animals, particularly rodents, but some species have yet to be associated with a disease process.[27]

Borrelia spp. have unique genomes consisting of a small linear chromosome (~1,000 kb) and both linear and circular plasmids, which have very low G+C (~30%) content. Genomic data from sequencing the *rrs* (16S rRNA gene) and *flagellin* genes show the phylogenetic classification and taxonomy of relapsing fever *Borrelia* spp. (see Pathosystems Resource Integration Center website at www.patricbrc.org).[156,367] Three main clusters are found in the *Borrelia* genus including: (1) Lyme *Borrelia* complex (agents of Lyme disease), (2) New World TBRF *Borrelia*, and (3) Old World *Borrelia* that includes the louse-borne *B. recurrentis*.

Lyme Disease

Lyme disease was clinically recognized as a multisystem inflammatory disorder of the skin, joints, heart, and CNS in the United States in the 1970s,[451] although there had been a long

preceding history of European investigations that is summarized in Box 20-1.[445,446] Investigators at Yale University reported that an epidemic of arthritis had been occurring in residents of several surrounding Connecticut communities since at least 1972 following the investigation of several cases of unusual arthritis in children.[451] Lyme arthritis was almost always preceded by a very distinctive skin rash, an erythematous papule that developed into a rapidly expanding annular lesion consistent with erythema chronicum migrans (EM),[450] which had been previously described in

Europe, particularly from Scandinavian countries. Although a tick bite was only reported in one of the early Connecticut cases, the nature of the primary skin lesion, and the fact that the initial cases occurred in the summer and early fall suggested an arthropod vector. Several reviews of Lyme disease have recently been published,[142,275,312,444] and the relevant web sites for clinical information have been summarized by Sood.[433,434]

TABLE 20-9 Characteristics of Pathogenic *Borrelia burgdorferi* Sensu Lato Genomospecies

Species	Growth	Vector(s)	Disease	Location
B. burgdorferi sensu stricto genomospecies[a]	Microaerophilic	Ixodidae (Hard-bodied ticks)	Lyme disease	
B. burgdorferi	Microaerophilic	*Ixodes scapularis*	Lyme disease	United States
B. burgdorferi	Microaerophilic	*I. pacificus*	Lyme disease	United States
B. burgdorferi	Microaerophilic	*I. ricinus*	Lyme disease	Europe
B. garinii	Microaerophilic	*I. ricinus, I. persulcatus*	Lyme disease	Eurasia
B. afzelii	Microaerophilic	*I. ricinus, I. persulcatus*	Lyme disease	Eurasia
B. valaisiana	Microaerophilic	*I. ricinus*	Lyme disease	Eurasia
B. lusitaniae	Microaerophilic	*I. ricinus*	Lyme disease	Europe (Portugal), North Africa, Asia
B. bissettii	Microaerophilic	*I. scapularis, I. pacificus*	Lyme disease	United States and Europe
B. spielmanii	Microaerophilic	*I. ricinus*	Lyme disease	Europe
B. japonica	Microaerophilic	*I. ovatus*	Lyme disease	Japan
B. tanukii	Microaerophilic	*I. tanukii, I. ovatus*	Lyme disease	Japan
B. turdae	Microaerophilic	*I. tardus*	Lyme disease	Japan
B. sinica	Microaerophilic	*I. ovatus*	Lyme disease	China
B. andersonii	Microaerophilic	*I. dentatus*	Lyme disease	United States

BOX 20-1

European Investigations of Lyme Disease

1921–1923	Afzelius in Sweden and Lipschütz in Austria described erythema chronicum migrans. Later, the chronic atrophic skin lesion described by Herxheimer in 1902 was recognized as part of the same process.
1944	Bannwarth described a chronic radiculitis, sometimes preceded by erythema, accompanied by chronic lymphocytic meningitis, and cranial or peripheral neuritis. Later, the disease was associated with ticks.
	Lennhoff described the presence of spirochetes in the lesion of erythema

1948	chronicum migrans.
1951	Hollström described the successful treatment of erythema chronicum migrans with penicillin.

Borrelia burgdorferi *sensu lato*

B. burgdorferi is the longest and narrowest of the borreliae. Molecular analysis showed that this spirochete is related to other *Borrelia* species,[391] but shares almost no homology with species of *Treponema* and *Leptospira.*[203,210] Several genospecies are recognized as definite human pathogens within the *B. burgdorferi* complex (*B. burgdorferi* sensu lato): *B. burgdorferi* sensu stricto is global in distribution, while the other pathogenic species *B. garinii, B. afzelii,* and rarely *B. spielmanii* have also been isolated in Europe,[110,441] Asia,[181] and other parts of the world.[25] *B. garinii* is more commonly isolated from CSF,[331] and appears to be associated with neuroborreliosis,[117] whereas *B. afzelii* is most often associated with arthritis and chronic skin disease—acrodermatitis chronica atrophicans (ACA).[117,446,460,480] A significant number of *I. ricinus* ticks in Europe are infected with more than one member of the *B. burgdorferi* complex.[369,370,435] Strains found

in the United States are relatively homogeneous and conform to the definition of *B. burgdorferi* sensu stricto.[257] The immunologic homogeneity of most American strains was demonstrated by analysis of borreliacidal antibodies in vitro.[260] Among strains of *B. burgdorferi* sensu stricto, however, some investigators have noted greater variation in strains from the United States than in those from Europe.[11,12] A potentially significant finding for studies of genetic homogeneity is the documentation of greater variation in *B. burgdorferi* when amplification products from skin lesions were compared to isolated spirochetes from the same lesions, suggesting that current culture techniques may select for certain genetic types.[258]

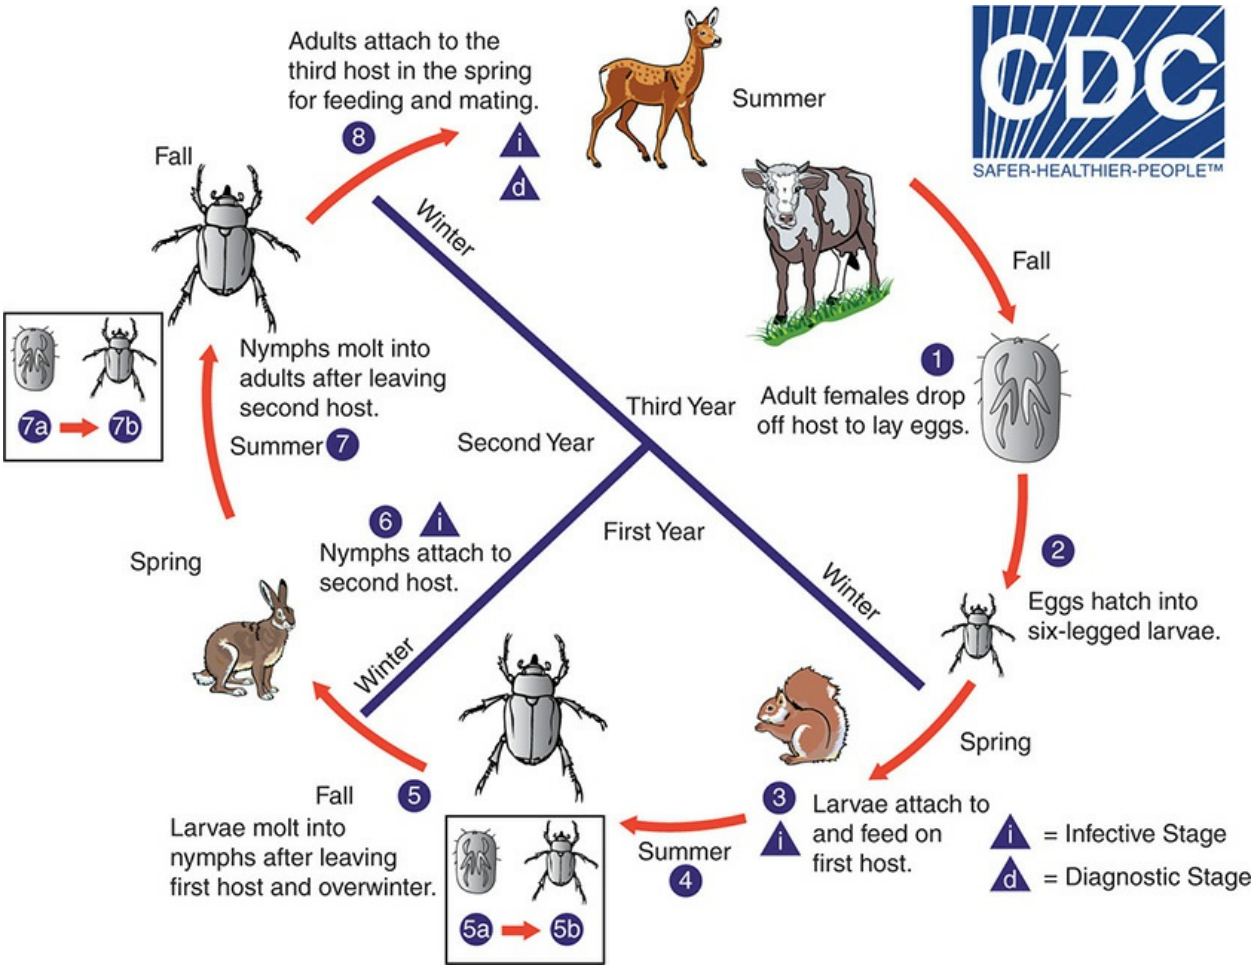
An increasing number of other genomic species have been documented within the *B. burgdorferi* sensu lato complex,[354,441] but the extent of their association with human disease is not yet clear. Evidence of involvement in human disease exists for *B. lusitaniae* and *B. valaisiana*, which have been shown to cause a few cases of Lyme borreliosis (LB) in Europe, Asia, and North Africa.[102,164] In addition, a human disease

that resembles Lyme disease has been associated with a noncultivable spirochete, named *B. lonestari,* so named because it is found in *Amblyomma americanum,* the "lone star tick."[206,396] This species may be responsible for many of the cases of Lyme disease found in the southeastern United States.[19,163,484]

Life Cycle. *B. burgdorferi* is transmitted from infected Ixodes ticks to humans, but the life cycle also involves several other animal species (Fig. 20-12).[200] The tick most often acquires the *Borrelia* spirochetes when feeding on an infected host during its larval stage.[354] The cycle of both *B. burgdorferi*[442] and *Babesia microti*[436] in nature is maintained by a number of small rodents, notably the white-footed mouse (*Peromyscus leucopus*) in North America, and the wood mouse (*Apodemus sylvaticus*), yellow-necked mouse (*Apodemus flavicolis*), and bank vole (*Clethrionomys glareolus)* in Europe,[12,354] all of which maintains an asymptomatic parasitemia or spirochetemia. Birds have also been identified on both sides of the Atlantic as being reservoirs for *B. burgdorferi* sensu lato.[354] White-tailed deer are important for the survival of the tick. Although deer are not directly involved in transmission of the infection, reduction of deer populations diminishes the number of vector ticks, after which the incidence of infection decreases.[200,442] Although interaction of ticks with mice and deer usually occurs in rural areas, Lyme disease may also be acquired in cities in endemic areas.[58]

Ixodid ticks develop in three distinct stages over a life span of 2 years. Ticks feed in late summer as larvae and the next year as nymphs (early spring) and adults (late summer).[354,355] A blood meal is required for the molts from larva to nymph and nymph to adult, as well as for oviposition (laying eggs) by the adult female. The most effective tick stage for transmission is the nymph, which is prevalent during the late spring and early summer, when most cases of human disease occur. Transmission of nymphs is also dependent on their small size, which allows them to escape detection

for longer times than adult ticks. The larval and nymphal stages are so small that many patients do not recall having been bitten. In order to transmit the infection, however, a tick has to have fed on an infected rodent. *B. burgdorferi* is not transmitted vertically from parent to offspring, so the larval stages of ticks that have not fed on an infected host are not infected and cannot transmit the infection. Because adult male ticks rarely feed on humans since they do not require a blood meal, transmission of infection via this route is unlikely to occur.



■ **FIGURE 20-12** Life cycle of *Ixodes* ticks, United States.

Pathogenesis. The causative spirochete for Lyme disease was discovered in 1982,[60] and described as a new species and named as *Borrelia burgdorferi* in 1984 after the main investigator.[61,211,391] Burgdorfer and colleagues[60] isolated a spirochete from the implicated tick vector, demonstrated that the spirochetes produced cutaneous lesions in rabbits, and that the serum of patients with Lyme arthritis contained antibodies to the spirochete. Steere and colleagues[448]were then able to isolate this spirochete from blood, skin lesions, or CSF of infected patients as well as from ticks. Shortly thereafter, spirochetes were isolated from the lesions of EM and those with Bannwarth's syndrome (i.e., chronic lymphocytic meningitis and polyradiculitis) in Europe.[32,361]

Lyme disease, however, has most likely been around for a much longer period. Retrospective examination of *Ixodes ricinus* ticks that had been preserved in Hungarian and Austrian museums in 1884 and 1888, respectively, has documented the presence of DNA from a member of the *B. burgdorferi* complex.[287] Similarly, *OspA*

sequences from *B. burgdorferi* have been demonstrated by molecular techniques in white-footed mice that had been trapped in Massachusetts in 1894.[280] American and European foci of Lyme disease have, therefore, been independently present for at least a 100 years.

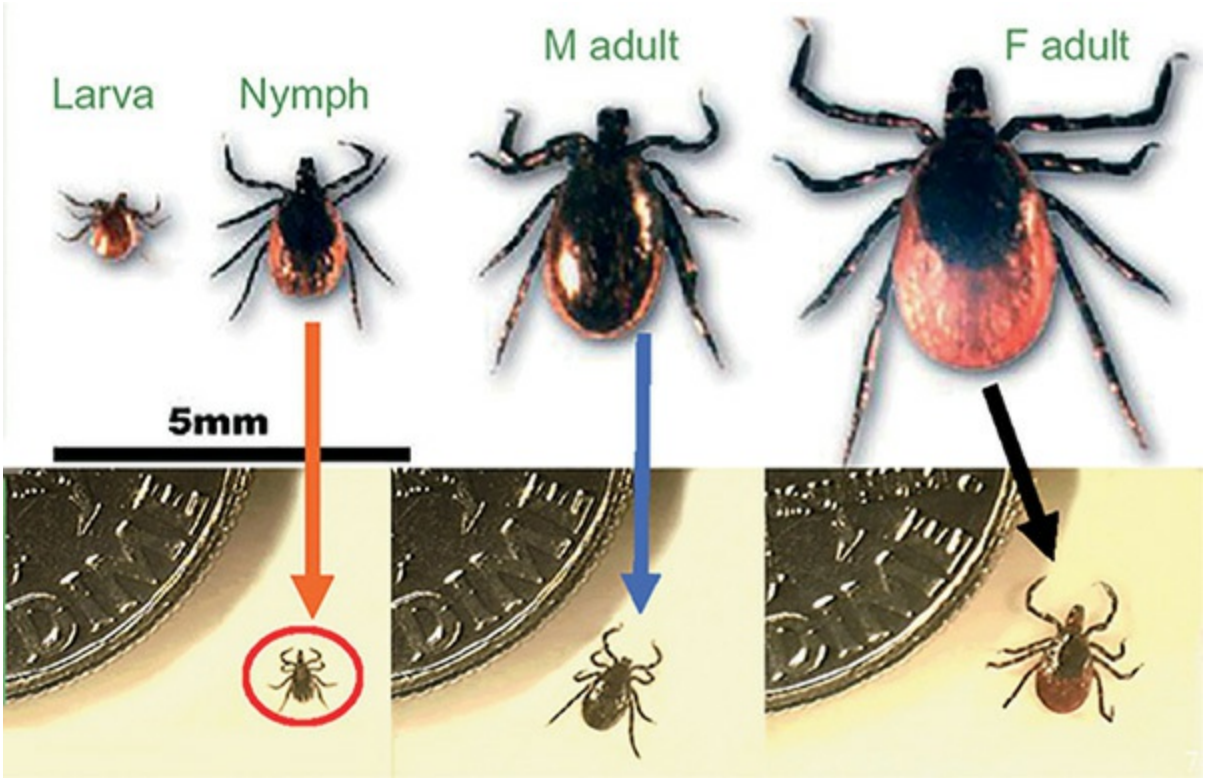
Complete sequencing of the genome of *B. burgdorferi* has provided insight into the pathogenesis of Lyme disease.[154] A large part of the genome encodes lipoproteins, of which the outer surface proteins are the most studied. Outer surface proteins A and C are particularly important in the biology of Lyme disease. The outer membrane antigenic composition changes dramatically when infected Ixodes ticks engorge. Animal studies have shown that OspA and OspB have an important role in persistence of the spirochete within the tick.[313,337,504] *OspA* is expressed predominantly in the midgut of ticks, where it is responsible for adherence to epithelium via a tick receptor, designated as the tick receptor for OspA (TROSPA).[338] High levels of TROSPA enable the spirochete to persist in the tick gut between blood meals. After the tick takes a blood meal, the spirochetes migrate through the hemocele to the salivary glands. In the process the expression of *OspA* is downregulated and there is a dramatic increase in the amount of OspC produced.[337,339] Although cell-mediated and humoral immunity is mounted against multiple antigens, the predominant early antibody response is directed against OspC. Increased expression of the *salp* 15 gene encoding for a 15-kDa feeding-induced salivary gland protein protects the spirochete from antibody-mediated killing.[394] Salp15 inhibits activation of T-lymphocytes by binding to the CD4 co-receptor,[14] inhibits complement-mediated killing of *B. burgdorferi*,[395]and facilitates binding to OspC. OspC is also an important determinant of clinical disease as certain variants are only found in ticks, while others have been associated with limited or localized disease or produce more severe, disseminated infections.[410,411] Lin and colleagues[252] found that the predominant isolates of *B. burgdorferi* sensu stricto in the southeastern United States contain OspC variants that are not associated with invasive disease, which may explain the relative paucity of well-documented cases of classical Lyme disease in this region.

Epidemiology. The distribution of Lyme disease worldwide correlates with the vector range of the Ixodes ticks in various geographic locations. *Ixodes scapularis*, *I. ricinus,* and *I. persulcatus* are the most important vectors of LB worldwide.[200,354,435] In the Northeast and North Central regions of the United States, the vector is usually *I. scapularis* (Image Plate 20-1E), whereas *I. pacificus* carries the spirochetes in the Northwest.[449] These species share many characteristics and are also known as black-legged ticks or deer ticks. There has been controversy over the nomenclature of the black-legged ticks found in the eastern United States, but *I. dammini* is considered by most investigators to be synonymous with *I. scapularis*.[330,436] Eastern deer ticks (*I.*

scapularis and other ticks within the *I. ricinus* complex) may be multiply infected with *B. burgdorferi* and other pathogens including *Babesia microti* and the more recently recognized agent of human granulocytic anaplasmosis (HGA),*Anaplasma phagocytophilum.* As a result, these other tick-transmitted infections share a similar distribution with LB.[58] Not surprisingly, coinfection with various combinations of *B. microti, A. phagocytophilum,* and *B. burgdorferi* also occurs at rates as high as 39% of cases.[13] In the eastern United States, babesiosis and LB most commonly occur together and account for ~80% of all diagnosed coinfections.[13] In Connecticut and Wisconsin, coinfection with HGA and LB occurs much less commonly in only 3% to 15% of patients.[13] In Europe, *I. ricinus* is the most common vector, whereas *I. persulcatus* is the main arthropod host in Eurasia and parts of Asia.[66,99,354,435] A clinical illness that resembles Lyme arthritis has been reported in Australia,[386] but despite ticks (*I. holocyclus* and *I. cornuatus*) being present which cause paralysis in dogs and other mammals,[432] none of the Ixodes tick species that carry *B. burgdorferi* sensu lato complex have been identified despite extensive testing of ticks by culture and PCR.[386]

Other environmental factors also influence the development of human disease in a particular geographic region. Although an enzootic cycle of *B. burgdorferi* infection in *I. spinipalpus* ticks and wood rats exists in northern Colorado, Lyme disease is nonendemic in this area.[289] Remoteness of this area may result in a lack of contact between humans and this species of ticks as a likely explanation for the absence of human infection. Lyme disease is also present in the Pacific Northwest,[52] where the vector is *I. pacificus*, but cases occur much less often than in North Central and Northeastern states. Difference in the life cycle of *Ixodes* ticks into pertinent animal hosts offers one possible explanation. In the central and eastern state, the white-footed mouse acts as the main animal reservoir in which the spirochetes readily grow and are transmitted to hungry ticks. In contrast, ticks in the Pacific states feed on lizards, in which the

borreliae multiply poorly, limiting the intensity of infection in the tick populations.[52] Lizards also produce an unidentified borreliacidal chemical that may limit growth and transmission from this spirochete reservoir. A similar situation exists in the southeastern states where *I. scapularis* ticks also feed preferentially on lizards, rather than mice, which may also contribute to the infrequency of classical Lyme disease in this region.



■ **FIGURE 20-13** Ixodid tick stages (used with permission from www.permatreat.com).

In Europe as well, the presence of particular rodents within a geographic area increases the transmission of Lyme neuroborreliosis. The presence of edible dormice (*Glis glis*) has been shown to amplify the transmission of spirochetes in central Europe.[284]Black-striped mice also appear to be an important rodent reservoir in central Europe, and account for an abundance of spirochete-infected *I. ricinus* ticks, while lizards are not infected.[286] Nymphal *Ixodes* ticks may also feed on rats in urban areas, so that the presence of infected rats may increase the risk of Lyme disease for city dwellers and visitors alike.[285] The intensity of transmission of spirochetes at particular central European sites appears to correlate directly with the presence of rodent populations and inversely with that of lizards.

Lyme disease is the most commonly reported vector-borne infection in the United States (Fig. 20-13). In endemic areas, the probability of Lyme disease after a tick bite ranges from about 0.012 to 0.05.[266] The frequency of tick infection in some areas of the United States is as high as 75%,[177] and the density of spirochetes in adult ticks varies from several hundred to thousands in published field studies.[26,27,80,99] Careful epidemiologic study of several endemic areas has documented the magnitude of the problem. On Fire Island, New York, symptomatic disease developed in 0.7% to 1.2% of summer residents.[178] Antibodies developed in 4 (3.1%) of 129 persons studied

serologically at the beginning and end of the summer, but only 2 of the persons were symptomatic. In Great Island, Massachusetts, Lyme disease developed in approximately 3% of the population each year, and the disease developed in 16% of the population over the 4-year period of study.[457] In retrospect, the earliest case occurred in 1962. The clinical to subclinical ratio was estimated to be 1:1.

As in syphilis, *B. burgdorferi* may be transmitted from mother to infant,[74,415,416,501] but the full effects of congenital infection are not yet known. Although no cases of Lyme disease have been linked to blood transfusion[501], *B. burdorferi* causes spirochetemia[167,490], and organisms survive for long periods of time in stored red blood cells. Patients being treated for Lyme disease should therefore not donate blood. Specific eligibility criteria for blood donation for patients who have completed a course of antibiotic treatment for Lyme disease or another serious infection are provided at www.redcrossblood.org/donating-blood/eligibility-requirements.

Surveillance case definitions in the United States include both clinical and laboratory criteria for reporting Lyme disease.[20] A case of Lyme disease is defined by having the following clinical criteria: (1) physician-diagnosed EM of ≥5 cm in diameter, or (2) at least one objective late manifestation (i.e., musculoskeletal, cardiovascular, or neurologic) with laboratory confirmation of infection with *B. burdorferi*.[20] Laboratory confirmation requires the following: (1) isolation of *B. burdorferi* from a clinical specimen, or (2) demonstration of diagnostic levels of IgM or IgG antibodies to *B. burdorferi* in serum or CSF.[20]

A total of 248,074 cases of Lyme disease were reported to the CDC as part of the National Notifiable Disease Surveillance System between 1992 and 2006.[20] During this 15-year period, the annual number of cases more than doubled from 9,908 in 1992 to a total of 19,931 cases in 2006 (Fig. 20-14). Although cases have been reported in almost every state, the geographic distribution of cases is highly concentrated (93%) in the Northeast and the North Central regions, while a much smaller number of cases occur on the West Coast (Fig. 20-15). Incidence was highest among children aged 5 to 14 years, and 53% of all Lyme disease cases occurred among males. Most patient presenting with EM had illness onset in June and July, compared with only 37%of patients with arthritis.

Lyme disease is also the most commonly reported vector-borne disease in Europe.[440] Recent estimates show that LB shows a gradient of increasing incidence from west to east with the highest incidences in central Europe (e.g., Slovenia, 155/100,000) and the lowest in the United Kingdom (0.7/100,000) and Ireland (0.6/100,000). A gradient of decreasing incidence also is found from south to north in Scandinavia and north to south in Italy, Spain, and Greece.[253] LB has also been reported around the entire northern hemisphere, including the former Soviet

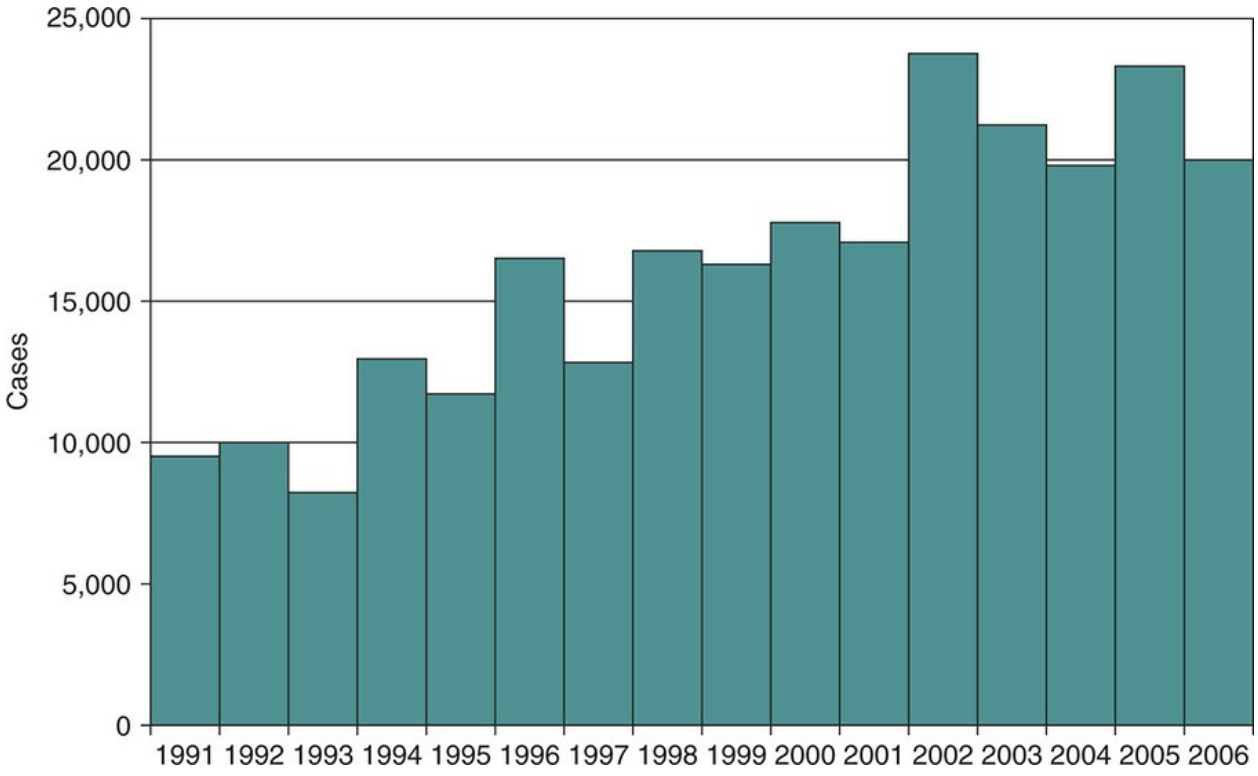
republics.[109]

Based on experimental data, *Ixodes* ticks must remain attached for at least 24 hours to transmit the spirochetes effectively.[356] During the first 12 hours after attachment the body of the tick remains flat, but after feeding for 24 hours the posterior body of the nymph begins to extend, and approximately 5% of infected ticks transmit spirochetes at this time. After 48 hours of feeding, the posterior body is fully distended and appears opalescent; approximately 50% of infected ticks transmit spirochetes at this time. After 4 days of feeding, almost all infected ticks will transmit spirochetes, at which point the ticks are opaque and so bloated that the body is as thick as it is wide.[288] Attempts to culture spirochetes from skin immediately after removal of an infected tick in a hyperendemic area were successful in only 2 of 48 patients, on both of whom the tick had been attached for approximately 24 hours.[33]

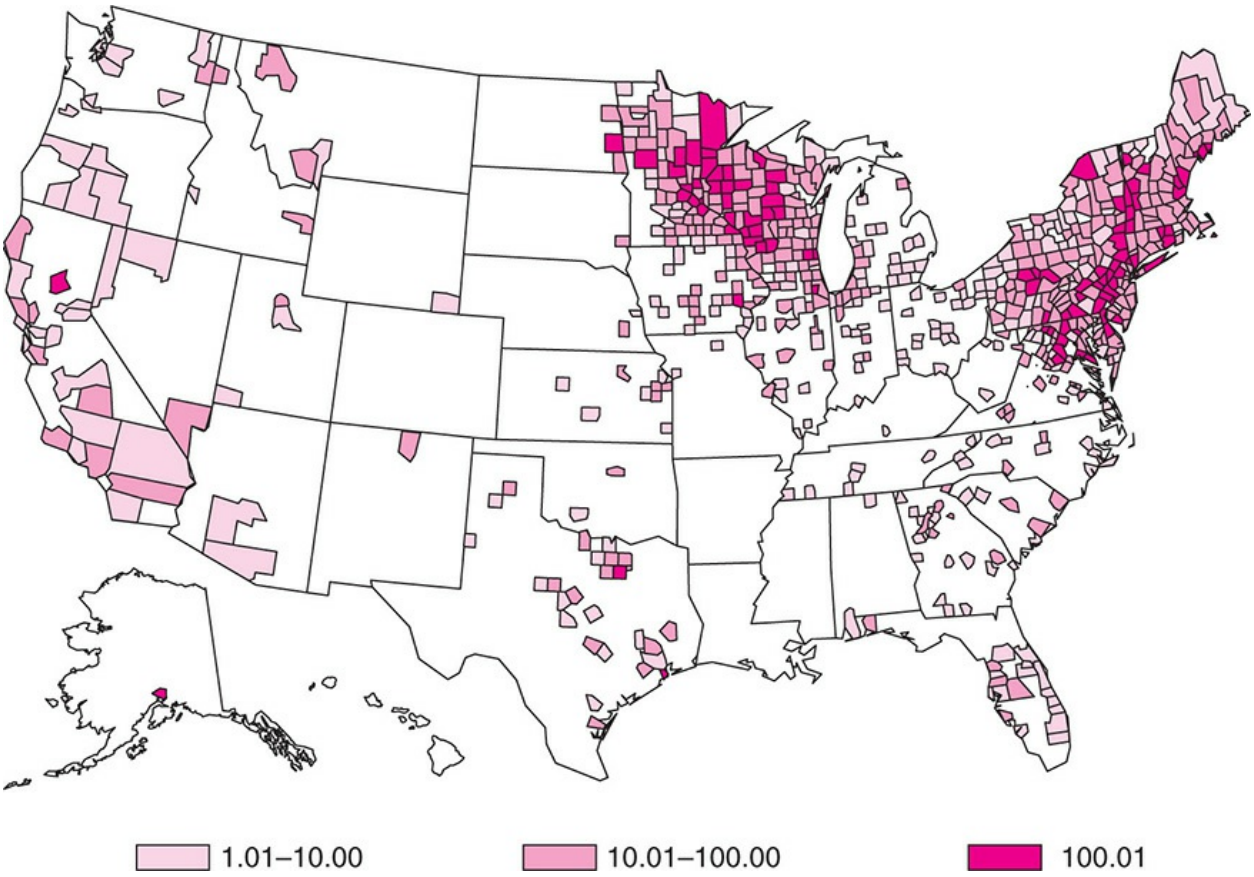
Visualization of the degree of tick engorgement is a subjective assessment. A more objective measurement of tick

1295

engorgement has been proposed as the "scutal index."[137,356] This index is based on the fact that the body of a nymph or adult female will swell as the blood meal is taken, but the rigid scutum will remain unchanged. The ratio of the scutum to the body is therefore a rough indication of the degree of engorgement. The requirement for prolonged feeding before transmission comes from several factors: the spirochetes must pass from the midgut into the hemocele and thence into the salivary glands, and the spirochetes must downregulate the production of *OspA* and upregulate the production of *OspC*.[337,339]



■ **FIGURE 20-14** Number of reported Lyme disease cases, United States (1991–2006). (Adapted from references 80 and 457.)



■ **FIGURE 20-15** Distribution of Lyme disease, United States (2006). (Adapted from references 80 and 457.)

The incubation period from inoculation via a tick bite to the onset of clinical symptoms is usually 1 to 2 weeks but has a wide variability, and may be much shorter (days) or much longer up to months or years. Unless patients present with early localized infection and a classic skin lesion, Lyme disease may be difficult to clinically diagnose because many of the latter symptoms are nonspecific and can occur with other diseases.

Prevention. Avoidance of exposure to the arthropod vectors is the best available method to prevent a tick-borne infection.[501] However, tick exposure is unavoidable in endemic Lyme areas because most people contract the infection in the wooded yards of their homes. Other recommended measures to reduce the risk of infection include wearing long-sleeved shirts and long pants and using insect repellents but these have not been documented

1296

to be effective in controlled studies. Routine checking of the entire body surface after being outside and prompt removal of embedded ticks is also recommended. Ticks should be immediately removed intact if possible using fine-tipped tweezers firmly grasping the tick as close to the skin as possible and then carefully pulling upwards. Failure to remove the mouthparts of the tick is not disastrous because the spirochetes are in its salivary glands. Use of a hot match, nail polish, petroleum jelly or other instruments of torture is not recommended. After removal of the tick, clean the area with an antiseptic (http://www.cdc.gov/ncidod/dvbid/lyme/prevent.htm).

Routine use of antibiotic prophylaxis to prevent Lyme disease after a recognized tick bite is not recommended.[501] Des Vignes and colleagues[111] investigated the transmission of *B. burgdorferi* from infected ticks removed from patients in an endemic area. The removed ticks were fed on mice that were evaluated subsequently for infection. It was estimated that the overall transmission rate was 4.6% from these infected ticks. Magid and colleagues[266] performed a decision-analysis to evaluate the outcomes, costs, and cost-effectiveness of three alternative strategies to treat Lyme disease in patients bitten by Ixodes ticks in endemic areas. Empiric treatment of patients was not found to be warranted when the risk of developing Lyme disease was less than 0.01.[266] Prolonged attachment of a feeding tick in an endemic region increases the likelihood of transmission, and empiric treatment is indicated when the probability of *B. burgdorferi* infection is 0.036 or higher.[266] Although retrieval of the tick may allow for examination and confirmation as *Ixodes*, the detection of *B. burgdorferi* by culture or molecular methods does not necessarily correlate with the development of Lyme disease. Although the duration of tick attachment and degree of engorgement as measured by the scutal index were shown to be predictors of *B. burgdorferi* transmission,[137,356] PCR evaluation of the tick did not predict transmission.

A single dose of doxycycline given within 72 hours of the bite of *I. scapularis* is as effective as longer courses of antibiotics in preventing the subsequent development of Lyme disease.[307] The efficacy of treatment compared to placebo was 87%. A single dose of doxycycline may be offered to adults (200 mg) and children >8 years of age (4 mg/kg up to 200 mg) if the following criteria are met: (1) the tick can be reliably identified as an adult or nymphal *I. scapularis* tick that is estimated to have been attached for ≥36 hours based on the degree of engorgement of the tick with blood or of certainty about the time of exposure to the tick, (2) prophylaxis can be started within 72 hours of the time that the tick was removed, (3) ecologic information indicates that the local rate of infection of these ticks with *B. burgdorferi* is ≥20% (i.e., parts of New England, parts of the mid-Atlantic States, and in part of Minnesota and Wisconsin), and (4) doxycycline treatment is not contraindicated.[501] The choice to prescribe prophylaxis should not be empirically based because drug side effects,

however mild, were more common in patients who received a single dose of doxycycline than in those who were given placebo.

A recombinant vaccine against Lyme disease, based on the outer surface protein A (OspA) of *B. burgdorferi* called LYMErix was developed by GlaxoSmithKline and approved for use by the US FDA in 1998. Two controlled trials using LYMErix vaccine involving more than 100,000 people, showed that the vaccine conferred immunity to *Borrelia* in 49% to 68% of the patients in the first year after two doses of the vaccine, and increased to 76% to 92% effectiveness after a third dose was given in the second year.[419,455] A regular booster injection would be required to maintain efficacy. OspA was chosen as the immunizing antigen, because the borreliacidal antibodies that would be elicited could kill the spirochetes in the salivary gland of the tick and/or at the bite site before disseminated infection had occurred. A national review panel recommended that vaccine use be limited to individuals between the ages of 15 and 70 years who were exposed to areas of high or moderate risk for considerable period of times. Although side effects of the vaccine appeared minimal in the original reports, reports of autoimmune side effects in vaccine recipients surfaced that prompted an investigation by the FDA and the US CDC. No connection was found between the vaccine and these health problems. The commercial viability of LYMErix was negated after the publicized fears of vaccine side effects, and vaccine manufacture was discontinued in February 2002. Currently, the only available Lyme vaccine is for dogs (Novibac Lyme, Intervet/Schering-Plough Animal Health), and is based on both OspA and OspC antigens. New human vaccines are also being research using outer surface protein C (OspC) and glycolipoprotein as immunizing agents.[395]

Clinical Disease. Infection with *B. burgdorferi* sensu stricto, *B. afzelii,* or *B. garinii* produces a multisystem disease with a wide range of specific and nonspecific symptoms. Although the general progression of disease is similar and can be divided into three clinical stages in North America and Europe, the clinical manifestations of each stage may be altered according to the geographic location of the patient and the type of *Borrelia* spp. (Table 20-10). The first two disease stages occur within weeks or months after *Borrelia* infection, while the third or late stage occurs several months or years later. Some degree of overlap may also occur between these stages of Lyme disease. The clinical manifestations of Lyme disease in European patients have distinctive features not experienced as frequently or not at all compared with those in the United States,[335,442] particularly with respect to the development of CNS disease and chronic skin manifestations. This is attributed to infection in Europe primarily with *B. garinii*, which is highly neurotropic. Conversely, widespread disseminated infection appears to be more common in the United States than in Europe. As discussed above, clinical differences have been noted between patients infected in New York by *B. burgdorferi* sensu stricto and Slovenian patients infected by *B. afzelii*. Several detailed

reviews of the clinical manifestations of LB have been previously published.[306,415,416,446,447,501]

As outlined below, the clinical diagnosis of Lyme disease in the absence of pathognomonic skin lesions may be difficult due to the vague nature of many patients' complaints, particularly during later stages of the illness or in the post-Lyme disease phase (musculoskeletal pains, malaise, headache, fatigue, nonspecific neurologic symptoms including sleep disturbances). At one university Lyme disease clinic, 38% of children were found to be overdiagnosed and 8% were underdiagnosed.[141] One-fourth of the patients who had been diagnosed correctly were subsequently treated incorrectly. In a study of diagnostic tests at a prepaid healthcare

plan in California, only 19% of laboratory tests were ordered because the physician suspected Lyme disease.[250] Fully 60%of the tests were ordered as part of a battery of tests for patients with vague complaints. In an area where Lyme disease is uncommon, such indiscriminate test ordering only compounds the inherent limitations of diagnostic LB tests outlined in the next section, and contributes to the problem of false-positive diagnoses.

TABLE 20-10 Differences Between European and American Lyme Neuroborreliosis (LNB)

Clinical Feature	American LNB	European LNB
Causative *Borrelia* subspecies	*B. burgdorferi* sensu stricto	Mostly *B. garinii*, occasionally *B. afzelii*
LNB as a percentage of all Lyme cases	<10%	>35%
Multiple erythema migrans lesions	Common	Uncommon
Painful radiculitis	Rare (<10%)	Common (>50%)
"Aseptic" meningitis presentation	Majority	Minority
Cranial nerve involvement	VII, very rarely others	Usually VII, but can include others
Associated chronic skin manifestation	Never	Not rare

(lymphocytoma or ACA)	Never	Not rare
Associated with Lyme arthritis	Common	Almost never
Chronic encephalomyeloradiculitis	Very rare (<0.1% of LNB)	More frequent, but unusual (<3% of LNB)
Intrathecal antibody production	Minority of cases	Common (>50%)

ACA, acrodermatitis chronic atrophicans.
Adapted from reference 442.

■ **FIGURE 20-16** Erythema migrans (EM)—Lyme disease. (Courtesy of www.microbewiki.kenyon.edu/Borrelia.)

Early Disease (Stage I). The classical clinical sign of early localized infection with *B. burgdorferi* is a circular, outwardly spreading rash called erythema chronicum migrans (i.e., EM).[105,416,454] This classical lesion develops at the site of the tick bite so that EM may be found in multiple anatomic locations and to varying extents. EM is estimated to occur in most infected patients. Flu-like symptoms such as headache,

muscle soreness, fever, and malaise may also be present.[140,416] In New Jersey, EM developed in 93% of the patients and approximately half had systemic symptoms, including regional lymphadenopathy.[45] Similarly, 90% of infected children in Connecticut displayed the skin rash.[160]

The rash is typically red, and may be warm, but is usually painless. Classically, EM is described as a "bull's-eye" rash because the innermost portion is dark red and indurated, the outermost portion is red, but the portion in the middle clears (Fig. 20-16). Peripheral edema with central clearing of the lesion has been emphasized, but homogeneous or central redness was more characteristic in a large series of microbiologically confirmed cases.[425] Central clearing was more common in Slovenian patients infected with *B. afzelii* than in New Yorkers infected with *B. burgdorferi* sensu stricto.[460] The spirochete is most easily cultivated from EM during early infection, or it may be visualized in as many as 40% of biopsy specimens by silver impregnation staining.

Early Disseminated Infection (Stage II). The second stage of Lyme disease results from dissemination of the spirochete throughout the body.[447] EM may develop at body sites other than the original tick-bite site. European patients may also present with lymphocytoma cutis, a discrete purplish lump that usually develops on the face, ear lobe, nipple, or scrotum.[440] Severe acute asymmetric, oligoarticular joint inflammation[453] and neuroborreliosis manifestations are common symptoms of early disseminated infection in untreated patients.[334] Bowen and colleagues[44] documented arthritis in 26% of their patients, meningitis in 10%, and cranial nerve palsies in 8%. The meningitis may appear purulent. Patients with neuroborreliosis may also have symptoms of meningoradiculoneuritis (Bannwarth's syndrome) and mild encephalitis, although altered mental status is the only symptom reported in some cases of early CNS infection.[332,334] In addition, disseminated *Borrelia* infection may also cause an acute

hepatitis, an acute myocarditis with associated atrioventricular block and infection of the eye.

Late Persistent Infection (Stage III). The chronic phase of Lyme disease is characterized in North America primarily by chronic arthritis and less commonly persistent nervous system symptoms.[442] In contrast, European patients infected with *B. afzelli* or *B. garinii* have chronic skin lesions (ACA associated with *B. afzelli* infection), chronic neurologic symptoms, and chronic arthritis (Table 20-11).[440,442] The recurrent episodes of arthritis diminish in frequency and severity each year, but

chronic synovitis and permanent disability develop in some patients.

TABLE 20-11 Clinical Manifestations and Recommended Diagnostic Approach for the Diagnosis of Lyme Borreliosis in Routine Clinical Practice

	Primary Diagnostic Testing	Supporting Diagnostic Testing	Supporting Clinical Findings
Erythema migrans			
Diagnosis on the basis of history and visual inspection of the skin lesion[a]	Laboratory testing not needed or recommended if the lesion is typical. Acute- and convalescent-phase serologic testing[b] is recommended for patients with atypical lesions.[c]	Culture or PCR of a skin biopsy specimen	Tick bite at site; regional lymphadenopathy in North American patients
Lymphocytoma (a rare manifestation)			
Painless bluish-red nodule or plaque, more frequent in children (especially on ear) than in adults	Serologic testing[b] usually positive at time of presentation; if negative, test convalescent-phase sera (2–6 weeks later)	Culture or PCR of a skin biopsy specimen	Tick bite at site; recent or concomitant erythema migrans
Lyme neuroborreliosis			
Adults: meningoradiculitis, meningitis, and peripheral facial palsy; rarely encephalitis, myelitis, very rarely cerebral vasculitis Children: meningitis and peripheral facial palsy	CSF pleocytosis and synthesis of intrathecal antibodies to *Borrelia burgdorferi* sensu lato[d] Serologic testing[b] usually positive at time of presentation; if negative, rest convalescent-phase sera (2–6 weeks later)	Detection of Lyme *Borrelia* by culture or PCR of cerebrospinal fluid Intrathecal synthesis of total IgM, IgG, IgA	Recent or concomitant erythema migrans
Cardiac Lyme borreliosis (a rare manifestation)			
Acute onset of atrioventricular conduction disturbances, rhythm disturbances, and sometimes myocarditis or pericarditis. Other diagnoses should be excluded	Serologic testing[b] usually positive at time of presentation; if negative, rest convalescent-phase sera (2–6 weeks later)	None recommended	Recent or concomitant erythema migrans, neurologic disorders, or both
Ocular manifestations (rare)			
Conjunctivitis, uveitis, papillitis, episcleritis, keratitis	Serologic testing[b]	Detection of *B. burgdorferi* sensu lato by culture or PCR from ocular fluid	Concomitant or previous other well-defined Lyme borreliosis manifestations
Lyme arthritis			
Recurrent episodes or persistent joint swelling in one or more large joints. Other diagnoses should be excluded	Serologic testing[b] As a rule, high concentrations of specific serum IgG antibodies present	Synovial fluid analysis Detection of *B. burgdorferi* sensu lato by PCR of synovial fluid or tissue	Previous other well-defined Lyme borreliosis manifestations
Acrodermatitis chronic atrophicans			
Long-standing red or bluish-red lesions, usually on the exterior surfaces of extremities; initial doughy swelling; lesions eventually become atrophic	Serologic testing[b] As a rule, high concentrations of specific serum IgG antibodies present	Histology Culture of PCR of a skin biopsy specimen	Previous other well-defined Lyme borreliosis manifestations

[a]If less than 5 cm in diameter, a history of tick bite, a delay in appearance after the tick bite of at least 2 days, and an expanding rash at the site of the tick bite are needed.
[b]Two-tier serologic testing is recommended, but newer first tier and immunoblot assays are increasingly incorporating the same peptides or recombinant immunodominant antigens of *Borrelia burgdorferi* sensu lato—whether doing the second tier immunoblot still increases overall specificity of serologic testing is less clear.
[c]As a rule, initial and follow-up samples have to be tested in parallel to avoid misinterpreting changes caused by inter-assay variation.
[d]In early cases, intrathecally produced specific antibodies might still be absent.
Adapted from reference 442.

Treatment. Prompt antimicrobial therapy in the initial stages of Lyme disease is usually effective in controlling symptoms and preventing progression of disease. Practice guidelines have been provided by the Infectious Diseases Society of America.[250] In the later stages of illness, it is less clear that antimicrobial therapy is of use.[222,501]

Antibody Response, Serologic Profile, and Immunity. *B. burgdorferi* sensu lato expresses various surface proteins in response to its environment.[200] Recent microarray gene expression profiling studies show that the organism differentially expresses various genes only within the mammalian host, and that different antigens are expressed at different LB disease stages.[200,327] In addition, antigenic composition is also different between different *B. burgdorferi* sensu lato species.[7] The complex antigenic composition of the organisms, therefore, makes the selection of particular antigens for human LB diagnostic serologic assays challenging, and the choice of antigen effects the performance of LB serology tests in patients presenting at different stages of the infection.[7,499] Strong IgM and IgG responses are developed within a few days after infection to the flagellar protein flagellin (41-kDa), or FlaB, and the flagellar outer sheath protein FlaA, as some of the immunodominant antigens in early LB.[4,5] However, these antigens are highly cross-reactive with other bacterial antigens and epitopes in mammalian tissue[261] so that tests utilizing these proteins lack specificity. Another immunodominant antigen found in early infection is the plasmid-encoded OspC protein (21- to 25-kDa). This antigen is heterogenous among *B. burgdorferi* sensu lato species,[5,495] but conserved epitope regions within this protein have allowed development of a synthetic peptide that contains the conserved C-terminal 10 amino acid Osp C (pepC10).[282,336] BmpA protein is also immunogenic (39-kDa), and encoded by a gene located within the *bmp* cluster (BmpA to -D genes).[55] Due to the heterogeneity of the BmpA protein sequences of different *B. burgdorferi* sensu lato species, this antigen has limited diagnostic utility.[55] A surface-exposed lipoprotein encoded by the linear plasmid lp-28-1 of *B. burgdorferi* B31 designated as Vmp-like sequence expressed protein (VlsE) (34- to 35-kDa) is conserved among *B. burgdorferi* sensu lato species and is highly immunogenic, which has made it viable as a broadly reactive immunodominant antigen for diagnosis of LB.[237,251] Finally, there are several other antigens that are expressed in the mammalian host that are being used diagnostically, including P35/BBK32 (47-kDa), P37, and P66 antigens.[147,270] These antigens are present in the ticks during a blood meal,[147] and are also present during the early stages of human infection as well as highly specific immunodominant antigens.[270]

Detection of IgM versus IgG antibodies to one or more *B. burgdorferi* sensu lato

antigens depends on the duration of infection, the manifestations of LB, and the type and source of antigen used. Using Western IgM immunoblots, the number of antigens detected and the strength of the immune response according to band intensity are the most robust in specimens from symptomatic patients with EM, those with multiple EMs, or those with EM for more than 2 weeks.[7] Patients with early Lyme neuroborreliosis also have an expanded and enhanced immunologic response.[5] In contrast, asymptomatic patients with a solitary EM that has been present for less than 2 weeks have a weak and less expanded immunologic response. Antibodies may be absent early, but are usually present after several weeks.

A response to OspA tends to occur late, but may be detected in low titer or complexed to spirochetes early in the course of infection if special techniques are used.[397] A response to the OspC protein or the less specific flagellin antigen occurs more commonly in early sera.[269] For maximum sensitivity in early Lyme disease, the use of an IgM assay has been recommended, either by immunofluorescence[297] or immunoblot[4] techniques. Specific IgM titers may remain elevated throughout the course of illness and even years after treatment, so the presence of IgM cannot be used to establish acute infection.[194] Collection of a second specimen 8 to 14 days after the baseline sample has been recommended for documentation of seroconversion in early Lyme disease. If IgM alone is detected a month or more after infection, the IgM result is probably a false-positive.

Most patients with *B. burgdorferi* infection have an effective immune response that is protective to reinfection with a similar strain. Although apparently rare, there have been well-documented examples of reinfection with a new strain of *B. burgdorferi* (as determined by molecular analysis of sequential isolates) in patients who have been treated early for EM.[326] It is not clear whether reinfections occur after untreated natural disease.

Symptomatic infection appears not to occur in wildlife, but disease may develop in domestic animals.[148,267] Kornblatt and colleagues[228] have described Lyme arthritis in dogs. Duray has described the histopathology of Lyme disease.[122]

Laboratory Diagnosis. Several excellent detailed reviews have been published on the laboratory diagnosis of Lyme disease.[7,372,494] Serologic tests that document the presence of specific antibodies that are directed toward one or more *Borrelia* antigens continue to be the primary method used for LB diagnosis, although it may also be diagnosed by culture of the spirochete, and by demonstration of the spirochetes in tissue using immunologic or molecular techniques. The comparative overall efficacy of various laboratory techniques in the diagnosis of Lyme diseases in 47 patients with EM is summarized in Box 20-2.

BOX 20-2

Laboratory Investigation of 47 Adult Patients With Erythema Migrans

Laboratory Procedure	Diagnostic Yield (%)
Quantitative PCR of skin biopsy	80.9
Two-stage serologic testing of convalescent specimens	66.0
Conventional nested PCR	63.8
Skin culture	51.1
Blood culture	44.7
Serologic testing of acute specimens	40.4

Adapted from reference 325.

1300

Recommendations for diagnostic methods that were provided by a consensus group in 1997[478] were recently updated,[501,233] but have not changed appreciably. Patient should only be tested for Lyme diseases where the pretest probability based on their exposure history and clinical symptoms ranges between 0.2 and 0.8.[478] It may be difficult, however, to determine the pretest probability in an individual patient because of the nonspecific nature of their symptoms (i.e., fatigue, arthralgias, headache). The indiscriminate use of LB diagnostic tests in unselected patients with a low pretest probability will yield more false-positive results than true cases.[7] LB testing of patients presenting with classical EM is not required since empiric treatment alone has been shown to be more cost-effective due to the low sensitivity of LB antibody assays at this early stage of infection.[316] Even after more than three decades of experience, inappropriate ordering of LB diagnostic tests and inaccurate test results resulting in inappropriate antimicrobial therapy remains a problem.[3,7,150,305,347,364]

Direct Detection. This section refers to a variety of laboratory tests that detect and identify the spirochete, *B. burgdorferi* sensu lato, in biologic specimens such as the tick vectors, host reservoirs, animals that have been experimentally inoculated, and tissues and body fluid samples from patients with LB. Currently, there are four different approaches that have been used for direct detection of *B. burgdorferi* infection, including microscopic examination, detection of specific antigens, in vitro cultivation of the organism, and molecular analysis for *B. burgdorferi*-specific nucleic

acids. Of these, both direct microscopic detection and antigen-capture tests have limited clinical utility in the clinical laboratory, so only a brief description is provided.

Morphologic Detection. Rare numbers of spirochetes are unevenly distributed in clinical samples making the microscopic visualization of *B. burgdorferi* in tissues too insensitive for most stages of the disease.[7,106,123] Spirochete morphology is also variable and may be difficult to distinguish from host tissues in histologic sections.[123] Although silver impregnation methods (Warthin–Starry, Steiner, Dieterle)[106] stain *B. burgdorferi*, and are used to detect the organism in tissue, this staining method is highly nonspecific and may detect any type of bacterium. Specific antisera must, therefore, be used to confirm the spirochete identification in clinical samples. Microscopic examination is mainly used for detection of *B. burgdorferi* in tick vectors during field surveys or surveillance studies.

Antigen Detection Assays. Two types of antigen detection assays are commercially available including the antigen-capture enzyme-linked immunosorbent assay (ELISA), and the reverse Western blot. Although these assays are easily performed in the clinical laboratory, they should not be used for the laboratory diagnosis of active or suspected LB owing to their poor performance and reproducibility.[7,97,223] Klempner and colleagues[223] performed Lyme urine antigen testing on 10 healthy controls and found discrepant test results on aliquots of the same specimen in eight and consistently false-positive results in the other two. Similar problems have been encountered using an antigen-capture assay to detect *B. burdorferi* antigens in CSF samples from patients with suspected LB.[96]

BOX 20-3

Barbour–Stoenner–Kelly Medium for Culture of *Borrelia burgdorferi* (BSK II Medium)

1. Clean all glassware with detergents, rinse thoroughly in glass-distilled water, and autoclave.
2. To 900 mL of glass-distilled water add 100 mL of 10× concentrate of CMRL 1066 medium without glutamine.
3. Add to the 10× CMRL 1066 in the following order:
   5 g neopeptone (Difco Laboratories, Detroit, MI)
   60 g bovine serum albumin, fraction V (Miles Laboratories, Elkhart, IN; No. 81-003)
   2 g yeastolate (Difco)
   6 g *N*-2-hydroxyethylpiperazine-*N*-2-ethanesulfonic acid (HEPES; Sigma Chemical Co., St. Louis, MO)

5 g glucose
0.7 g sodium citrate
0.8 g sodium pyruvate
0.4 g *N*-acetylglucosamine (Sigma)
2.2 g sodium bicarbonate

4. Adjust pH of medium at 20°C–25°C to 7.6 with 1 N NaOH.
5. Add 200 mL of 7% gelatin (Difco) that has been dissolved in boiling water.
6. Sterilize by filtration with air pressure (0.2 fm nitrocellulose, Millipore Corp., Bedford, MA). Store the medium at 4°C.
7. Before use, add unheated rabbit serum ("trace hemolyzed," Pel-Freez Biologicals, Inc., Rogers, AR) to a final concentration of 6%.
8. Dispense to glass or polystyrene tubes or bottles. Fill containers to 50%–90% capacity and cap tightly.

From reference 26.

Culture. Cultivation of *B. burdorferi* was the first detection method used, and it remains the gold standard for laboratory diagnosis of LB. *B. burgdorferi* has been isolated in a cell-free modification of Kelly's medium for spirochetes that was developed by Barbour[26] (Table 20-11 and Box 20-3),

although various modifications to that medium have been made over time.[357] Current media preparations such as Barbour–Stoenner–Kelly II (BSK II) (Box 20-3) demonstrate better growth and recovery of the spirochete at lower inocula in a shorter time. The process is relatively easy when infected ticks are triturated and cultured (see Image Plate 20-1E). Subculture from broth to agar results in the formation of spirochetal colonies with varying morphology.

Culture is most effective in early Lyme disease and is rarely positive in later stages. *B. burgdorferi* sensu lato can be cultured from body fluids (i.e., CSF, blood, synovial fluid) and tissue biopsies (i.e., skin lesions, including EM, ACA, and borrelial lymphocytoma, and rarely cardiac tissue) of patients with LB.[7] Even at the primary stage, however, spirochetes were isolated from skin lesions only in 51% and from blood in 45% of 47 adult patients with a clinical diagnosis of Lyme disease.[325] *B. burgdorferi* sensu stricto cannot usually be recovered from skin cultures of EM lesions in patients receiving antibiotic therapy. The yield appears to be higher when the lesions are large and multiple, as in the secondary disseminated phase of the disease.[298]Citrated blood should be cultured, and tubes are incubated at 34°C to 37°C

in the dark. After incubation for 2 to 3 weeks, cultures are examined by darkfield microscopy or by fluorescence microscopy using either the fluorochrome dye acridine orange or a specific fluorescence-labeled antibody.[372] The identity of any spiral organisms detected must be confirmed as *B. burgdorferi* sensu lato by demonstration of reactivity with specific monoclonal reagents or by detection of specific DNA sequences using PCR.

Molecular Detection. An extensive review of molecular amplification methods in the diagnosis of Lyme disease was provided by Schmidt,[392] Dumler,[119] and more recently by Aguero–Rosenfeld.[3,7] PCR-based methods have mainly been used for the diagnosis of LB, either conventional PCR, nested PCR, quantitative PCR, competitive PCR, or increasingly real-time PCR. The most commonly used targets in PCR are *B. burgdorferi* chromosome genes such as *rrs*, *fla* B, *rec* A, and *p66*, and plasmid-derived *osp* A.[3,392] The performance of *B. burgdorferi* sensu lato PCR-based assays is reliant on the selection of the gene target and primer set for amplification. Molecular detection assays for Lyme disease have not been widely implemented by clinical laboratories due to their variable performance for different clinical specimens, their diminished reliability because of potential sample contamination, their lower sensitivity after administration of antibiotic therapy, and the difficulties with clinical interpretation of a positive result. Because the number of spirochetes in infected tissues or body fluids of patients is low, collection and transport and prompt preparation of DNA from clinical samples are critical for providing consistent and reliable PCR results. *B. burdorferi* amplification tests are also susceptible to false-positive results from cross-contamination or from nucleic acid sequences shared with other organisms.[300,392] Thoroughly validated amplification tests for *B. burgdorferi* are only available through referral of specific clinical specimens (i.e., blood and CSF) to a reference laboratory.

Amplification techniques have demonstrated greater sensitivity than culture or morphologic detection in the skin of EM lesions,[375] in peripheral blood, and in joint fluid.[333] The detection of *B. burgdorferi* DNA by PCR in EM lesions ranges from 36% to 88%.[7] Skin biopsies taken from EM patients during a phase III vaccine trial in the United States were positive in 64% of the patients.[455] In Europe, *B. burgdorferi* DNA was detected in 54% to 100% of skin biopsy samples from patients with ACA depending on the target sequences used for detection.[7] In general, the sensitivity of PCR for detection of *B. burgdorferi* sensu lato DNA in blood, plasma, or serum samples from patients with EM and early disseminated disease is low, and negligible in patients with post-Lyme disease syndromes. Borrelial DNA was documented prospectively in the serum of 14 of 76 patients (18.4%) with EM,[167] and the number of clinical symptoms was the strongest independent predictor of spirochetemia. It appears that the spirochetemia in patients with acute Lyme disease is both low level

and intermittent.[490] However, none of 78 patients with post-Lyme disease syndromes, even in the 39 patients with a positive IgG Western immunoblot, had spirochete DNA detected in blood specimens by PCR.[222] Detection of *B. burgdorferi* DNA by PCR in synovial fluid has a good sensitivity for diagnosis of Lyme arthritis.[7,318,362] A total of 75 (85%) of patients with Lyme arthritis had a positive synovial fluid *B. burgdorferi* PCR in one US study, and of the 73 patients who were untreated or incompletely treated with antibiotics 95% had a positive PCR.[318] This study also demonstrated wide variability in the sensitivity of the PCR test depending on the primer set used.

Patients with a wide range of neurologic symptoms in the United States and Europe have had their CSF specimens tested using *B. burgdorferi*-specific PCR.[119,238,317,318,331] Despite documentation that spirochetal DNA can be found in the CSF of some patients with neurologic symptoms,[262] the interpretation of a positive CSF PCR result can, however, be difficult because of the lack of a standardized definition to support the clinical diagnosis of Lyme neuroborreliosis. Examination of CSF fluid of patients with EM documented borrelial DNA in 8 of 12 patients, 4 of whom had no neurologic abnormalities or symptoms. The sensitivity of PCR in CSF in patients with symptomatic neurologic disease has also been low.[238] The sensitivity of PCR in CSF was 38%in early and 25% in late neuroborreliosis, respectively, in one study in the United States, and PCR results were affected by the administration of prior antibiotic therapy.[317] Similar studies in Europe have shown that the CSF PCR was positive only in LB patients with pleocytosis in the CSF.[331] Results of molecular detection in urine have also been disappointing.[119] Recommendations for increasing the yield of PCR testing in urine have been developed by Bergmann and colleagues.[34]

Real-time PCR assays have been validated with a variety of clinical specimens.[17,259,398] The major advantage of real-time PCR assays is the ability to quantify the number of spirochetes in clinical specimens. A real-time assay was used to detect *rec*A DNA in 80% of 50 patients with EM in the United States, and the number of spirochetes ranged from 10 to 11,000 (mean = 2,462) in a 2-mm skin biopsy sample.[259] Real-time PCR has also been used to quantify the number of spirochetes in synovial fluid and synovial membrane biopsies in patients with Lyme arthropathy.[398]

Although PCR is highly sensitive for detection of *B. burgdorferi* DNA in skin biopsy samples from patients with EM, amplification tests do not add significant value to the early diagnosis of Lyme disease because testing is rarely necessary as

the skin lesion is pathognomonic. Diagnosis of disseminated LB may be aided by PCR

analysis of synovial fluid or tissue in patients with Lyme arthritis, and less commonly by CSF PCR in patients suspected of having neuroborreliosis. Detection of borrelial DNA in CSF despite a low sensitivity may be helpful because of the difficulty in interpretation of antibodies in the central nervous system. The specificity of a molecular test, however, can be increased by an initial evaluation of the patient for the presence of borrelial specific antibodies, which should be uniformly present in serum in the later stages of disease; such screening would raise the pretest probability of specimens tested and the performance of the assay.

Serology. Because methods for the direct detection of *B. burgdorferi* sensu lato in clinical specimens lacks sensitivity and are not feasible for clinical laboratory use, antibody detection methods remain the primary test method to confirm a clinical diagnosis of LB. Development of accurate and reliable serologic assays for diagnosis of LB has been difficult due to the number of antigens that are differentially expressed in the tick and the mammalian host (see Antibody Response, Serologic Profile, and Immunity section). Antigenic differences among the *B. burgdorferi* sensu lato species also mean that test kits also have to be modified depending on the geographic location where the infection is acquired (i.e., the United States or Europe).[7] Finally, serologic tests have had limited validation in patients where a clinical diagnosis of LB has been confirmed by culture as the 'gold standard' method, so that serology also has several diagnostic limitations that will be outlined.

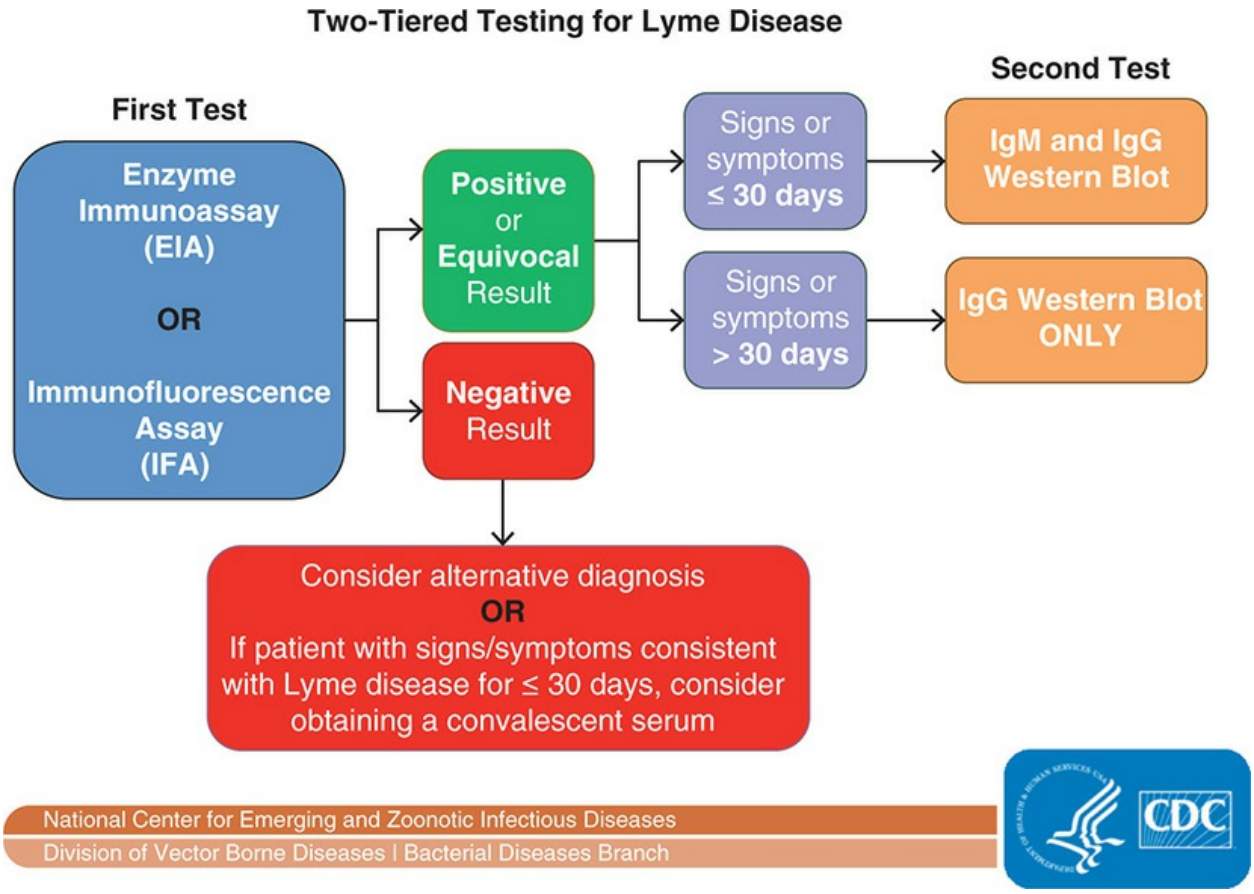
Immunofluorescent-antibody assays. Early serologic assays included direct immunofluorescent-antibody assays (IFAs), which used cultured spirochetes fixed onto glass slides, followed by dilution of a patient's serum, absorption of nonspecific antibodies, the addition of fluorescein isothiocyanate-labeled antibodies, and finally, the detection of the presence of antibodies by fluorescence microscopy.[272] Positive titers of 1:256 or 1:128 for IgG and IgM, respectively, are considered indicative of LB. Because of the subjectivity of interpretation of fluorescence microscopy, this assay was modified to use antigens attached to a membrane (FIAX) with the degree of fluorescence detected by an automated system. Although IFA,[272] quantitative fluorescence immunoassay,[350] and a fluoroimmunoassay[184] have been used, they were replaced by EIAs owing to the improved performance and efficiency due to automation of the latter.

Enzyme immunoassays. Serologic testing of peripheral blood should be done on all patients meeting the criteria for suspected LB. The CDC recommends a two-tiered testing approach to diagnose active disease and previous infections as outlined in Figure 20-17.[78] A highly sensitive EIA or less commonly an IFA should be used as the initial test followed by a Western immunoblot. Negative sera need not be studied further but convalescent sera (drawn 4 weeks after the first) should be collected if clinically indicated. If a patient with suspected early LB has a negative serology, serology should be repeated by testing of paired acute- and convalescent-phase serum samples. All

specimens positive or equivocal according to the initial EIA or IFA test should be confirmed with a standardized Western immunoblot. For patients presenting in the early phase of illness (i.e., first 4 weeks of disease onset), both IgM and IgG Western immunoblots should be done. A positive IgM test result by itself should not be used in determining active disease in persons with more long-standing illness due to the high likelihood of a false-positive result in such patients.[78] A strong IgG Western immunoblot reaction to specific *B. burgdorferi* antigens should be found in serum samples from patients with disseminated or late-stage Lyme disease (see Immunoblots section).[78] Examination of cerebrospinal spinal fluid for intrathecally produced antibodies should also be performed for the diagnosis of Lyme neuroborreliosis although patients in Europe have higher positivity rates than those in the United States. This discrepancy may be due to the difference in *B. burgdorferi* sensu lato species causing LB on these continents. Positive

1303

intrathecal CSF antibody production is measured by the CSF/serum index of *B. burgdorferi* sensu lato antibodies, and the presence of higher titers of antibody in CSF relative to peripheral blood (i.e., antibody index = CSF/serum optical density ratios of >1.3) along with CSF pleocytosis, documents infection of the nervous system.[440,496,501,512] However, given the many difficulties encountered with serologic analysis of peripheral blood, these approaches should be reserved for experienced reference laboratories that have documented the accuracy of their tests.[73]



■ **FIGURE 20-17** Diagnostic testing algorithm for Lyme disease.

In the United States, there are more than 70 serologic assays that have FDA approval for diagnosis of Lyme disease, but few if any of these tests have not been standardized against a panel of well-characterized sera. A similar situation exists in Europe where immunoassays have been modified to better detect *B. burgdorferi* sensu stricto, *B. afazelii,* and *B. garinii*. Overall detection rates for serum antibodies using these assays are not optimal for early disease (i.e., 20% to 50% of cases detected) and the early dissemination stages of the disease (i.e., 70% to 90% of cases detected). However, by late-stage disease, nearly all patients with Lyme disease will test positive.[7,494] Considerable variability has been demonstrated between assays due to their different antigenic composition and in particular, in the reliable detection of IgM antibodies.[5] Most of the earlier commercially available LB EIA assays use antigen mixtures comprised of whole-cell sonicates of *B. burgdorferi* sensu lato for the detection most frequently of IgG and IgM antibodies. Due to the lack of antigen standardization, there have been serious problems with reproducibility and with accuracy of EIA assays, compounding the difficulties of clinical diagnosis. In a proficiency testing program, as many as 21% of participants failed to recognize the

presence of antibody at a titer of 512 or higher.[24] With lower concentrations of antibody, as many as 55% of participants failed to recognize the serum as positive. Conversely, the false-positive rate was up to 7% with a polyvalent conjugate and as high as 27% with an IgG conjugate. Reproducibility of results when the same serum was submitted as a challenge at different times was also suboptimal. These proficiency testing problems are further emphasized by the report from a Lyme disease referral center, where 45% of patients who had been referred with an incorrect diagnosis of Lyme disease had had positive serologic tests for *B. burgdorferi* that could not be confirmed in the reference laboratory.[456] Furthermore, in a single laboratory only 16.3% of positive results using an EIA could be confirmed with an immunoblot.[101]

Specificity of *B. burgdorferi* EIA assays may also be suboptimal, particularly in patients with other infections, exposures to infectious disease agents, or underlying inflammatory or immunologic diseases. Cross-reactions with a variety of infectious agents have been found in sera from patients in whom Lyme disease is suspected. Sera of patients with other borrelial infections, treponemal infections, HIV, Epstein–Barr virus, and rickettsial infections may react in assays for *B. burgdorferi*.[268,308,366]Reports on cross-reaction with *Leptospira* antisera are conflicting. Although cross-reactions develop with specific treponemal antigens, the VDRL test is not positive in patients with Lyme disease. The nonspecific reactions have been reported to be concentrated in the IgG2 class of antibodies in several instances.[414] Kaell and colleagues[212] have also demonstrated increased antibodies to *B. burgdorferi* in 13 of 30 patients (43%) with nonspirochetal endocarditis most likely due to cross-reactivity. The specificity of Lyme serology in this population was only 60%. When immunoblots were performed, only one patient had a pattern of reactivity that suggested prior exposure to the spirochete. Lyme serology may also be false-positive in patients with other multisystem immunologic diseases such as systemic lupus erythematosis.[491]

Lyme disease serologic results must therefore by interpreted in the context of the history of tick exposure risk and the initial and evolving constellation of clinical symptoms and manifestations. Positive EIA serology results are most often straightforward when the patient presents with pathognomonic skin lesions, but may be misleading when the clinical presentation is atypical or the symptoms of the patient are vague. Steere[445] has demonstrated situations wherein there was serologic evidence of exposure of *B. burgdorferi*, but the LB was no longer active and the patient's symptoms were due to another cause. Prior vaccination with the Lyme disease OspA outer surface protein vaccine may also give a positive result using an EIA assay that detects this antigen, but the Western blot will not have a sufficient number of bands to confirm acute infection (see Immunoblots section).[6]

In order to increase the sensitivity for early disease (stages I and II) and the general

specificity of serologic assays, more recently developed serologic assays for Lyme disease have used either a purified, recombinant, or synthetic peptide antigen for detection of IgM, IgG, or polyvalent antibodies to *B. burgdorferi*. However, as reviewed in detail by Aguero-Rosenfeld,[3,7] a single antigen has not demonstrated sufficient performance to enable replacement of the two-tiered testing algorithm. Several immunoassays using recombinant and peptide antigens have been evaluated, but few studies have yet been done comparing these newer EIA tests to the two-tiered testing algorithm.[46,47] Table 20-12 provides a summary of the performance of selected recombinant and peptide antigens evaluated for detection of a serologic response to *B. burgdorferi* during the various LB disease stages both in the United States and Europe. Recombinant antigens used so far have included the outer surface proteins, particularly OspC,[270,282,336,342] the internal portion of flagellin (P41) as well as FlaA,[213,270,343] BBK32,[186] DbpA,[187] and VlsE.[18,271,360] Recombinant OspC assays have improved performance in diagnosing patients with early LB in the United States when testing IgM antibodies,[336] but this has not been the case for European patients.[342] Recombinant VlsE assays also have a comparable sensitivity to the OspC recombinant antigen assays during early disease, but have improved sensitivity for diagnosing neuroborreliosis or late-stage disease.[18,271] Evaluation of recombinant DbpA and BBK32 antigens in Europe shows a high sensitivity for detection of IgG antibodies in patients with neuroborreliosis or late stages disease, and although the BBK32 antigen also showed a high sensitivity (74% to 100%) for detecting antibody at any disease stage including EM, this epitope detects IgM antibody.[186,187]

Peptide-based immunoassays have included two peptides pepC10 (OspC region) and C6 (VlsE invariable region or IR6) that are highly conserved among different *B. burgdorferi* sensu lato species that have been shown to be immunodominant protein antigens.[18,47,360,452] A major advantage of using these well studied peptides is that they are

less cross-reactive than the full-length antigens. The pepC10 peptide preferentially binds IgM antibodies and although the sensitivity in patients with EM or early neuroborreliosis is similar to its parent antigen OspC, the reported specificities are much higher for the peptide assay.[18] A major limitation of pep10 peptide is that it does not detect antibodies in patients with late LB.[282] C6 peptide assays have high sensitivity in all stages of LB, and a much higher sensitivity has been found than recombinant VlsE assays in patients with EM.[271] Bacon and colleagues,[18] however, have demonstrated that the recombinant VlsE assay was better than either a C6

peptide or two-tiered testing approach for detecting IgG antibodies in patients with acute neuroborreliosis. All of the patients were diagnosed using the VlsE assay compared to only 9/15 (69%) for IgG antibodies to C6 and 13/15(87%) using two-tier testing. Burbelo and colleagues have also recently compared the performance of a C6-peptide immunoassay to the use of a synthetic protein, designated VOVO, consisting of a repeated antigenic peptide sequence, VlsE-OspC-VlsE-OspC for diagnosing Lyme disease. Analysis of an independent set of serum samples (n = 139) showed that the VOVO luciferase immunoprecipitation system test had similar performance to the C6 peptide assay.[59] Peptides from another surface protein BBK07 have recently been developed and used to evaluate the reactivity of sera from both humans and dogs with Lyme disease.[94] Although EIA studies of the surface protein BBK07 peptides have an overall lower sensitivity than either the pepC10 or C6 peptides for the detection of early Lyme disease in humans, a subset of serum samples were reactive to BBK07 peptides even though they failed to react with VlsE or OspC peptides. BBK07 may be an additional serodiagnostic marker that could be used as a supplemental test for Lyme disease.

TABLE 20-12 Selected Recombinant and Peptide Antigens Used for Detection of IgM, IgG, or Polyvalent Antibodies to *B. burgdorferi*

Recombinant Antigen of Peptide	Location	Range % Positive in the Indicated LB Disease Stage									References
		EM			*Neurologic*			*Late*

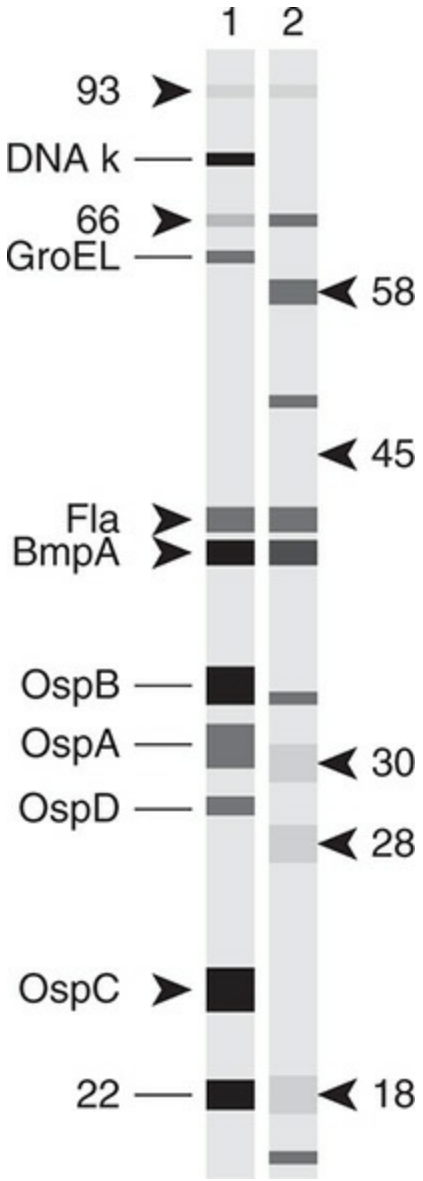
Increasingly, the use of a combination of recombinant or peptide antigens in serologic immunoassays is being evaluated in the hopes of improving the detection of Lyme disease in the earlier stages. Bacon and colleagues compared the use of recombinant VlsE for detection of both IgG and IgM antibodies, the pepC10 peptide for detection of IgM antibodies, and the C6 peptide for detection of IgG antibodies compared to the two-tier approach. The best performance was found using the C6 IgG and pepC10 IgM assays in testing 280 sera from patients with LB (78% were detected vs. 68% using a two-tier approach), particularly in patients with EM (63% were detected compared to only 38% using a two-tier approach). Porwancher and colleagues[360] recently studied the use of a multiplex microsphere immunoassay for simultaneously measuring recombinant VslE-IgG and pepC10-IgM antibodies and compared its performance with Western immunoblotting in the same sample from 82 patients with early disease, 47 with stage I or II disease, 34 patients following antibiotic treatment, and a large number of negative controls.

1305

Compared with Western blotting, the multiplex assay was equally specific but much more sensitive as a diagnostic test for Lyme disease.[360] More combination studies need to be done using standardized serum panels and larger numbers of patients to determine the optimal serologic approach to diagnosing Lyme disease.



■ **FIGURE 20-18** Lyme disease confirmatory immunoblot. Positive Western Blot. Strip (1) outlines the borrelial antigens that antibodies are developed against in Lyme disease patients. Strip (2) highlights the borrelial antigens that a patient with Lyme disease is reactive against, providing confirmation of this diagnosis according to the CDC immunoblot interpretive criteria. (Courtesy of the Centers for Disease Control and Prevention, USA.)

Immunoblots. In order to improve the specificity of LB serology similar in approach to that used for HIV serologic diagnosis, it is recommended that all positive ELISA assays be confirmed by a Western immunoblot (Fig. 20-18). Dressler and colleagues[118] developed the criteria for positive immunoblots in a retrospective study. The best discrimination was obtained if detection of 2 of the 8 most common IgM

bands (18, 21, 28, 37, 41, 45, 58, and 93 kDa) was required for positivity in early disease and detection of at least 5 of the 10 most common IgG bands (18, 21, 28, 30, 39, 41, 45, 58, 66, and 93 kDa) was required for diagnosis after the first weeks of infection. Application of these criteria to more than 300 patients in a prospective study yielded a sensitivity of 32% and a specificity of 100% for the IgM test. The sensitivity and specificity of the IgG test were 83% and 95%, respectively. Slightly different criteria have been suggested by Engstrom and colleagues.[135] Their criteria for positivity of IgM immunoblots include recognition of at least two of the following proteins: 24-(OspC), 39-, and 41- (flagellin) kDa. The sensitivities of the IgG and IgM immunoblots in 55 patients with documented EM were 58.5% and 54.6%, respectively, at the time of diagnosis and 100% after an additional 8 to 12 days. Ma and associates[265] have emphasized the importance of antibody to the 39-kDa antigen for specific diagnosis.

The CDC and Association of State and Territorial Public Health Laboratory Directors currently recommend the IgM criteria of Engstrom and the IgG criteria of Dressler. By using these criteria, Aguero-Rosenfeld and associates[6] observed positive IgM immunoblots at the time of initial study in 43% of a group of 46 patients with culture-positive EM and in 84% of the patients 8 to 14 days later. Although antibodies to *B. burgdorferi* developed in 89% of patients, IgG immunoblots were positive by the recommended criteria in only 22% of convalescent sera. After 1 year, 38% of the IgM immunoblots were still positive. IgM antibodies reactive with 39-, 58-, 60-, 66-, and 93-kDa antigens were most often seen in the first month after diagnosis, and these investigators suggest that the presence of these bands may be helpful in suggesting recent infection in patients from endemic areas.

Hilton and colleagues[192] suggest that two additional antigens be added to the criteria for IgG positivity: 31-kDa (OspA) and 34-kDa (OspB) antigens. Of 136 patients evaluated for Lyme disease, 4 (8%) would have been considered positive only if these two antigens were included in the criteria. These 4 patients had EM or arthritis and lived in endemic zones. It is obvious that the criteria for interpretation of immunoblots are still evolving.

Fine-tuning of the criteria for positive serologic tests will undoubtedly continue, but confirmation of an indeterminate or questionable result with an enzyme immunoassay should be sought by performing an immunoblot in an experienced laboratory. Wormser and colleagues[500] have noted, however, that the confirmatory aspects of the immunoblots are reduced because the two assays are not completely independent.

Relapsing Fever

Relapsing fever is a distinctive clinical disease that was probably recognized by Herodotus in ancient Greece. There are two forms: (1) epidemic LBRF and (2) endemic TBRF. *Borrelia* that cause relapsing fever vary their outer surface antigens, resulting in repeated exposure of the host immune system to a new spirochetemia, which causes fever in the host.[436] The epidemiologic, ecologic, and clinical characteristics are compared and contrasted in Table 20-13. Several pertinent reviews are available,[125,54,145,168]and in several parts of the world, TBRF is emerging as an important vector-borne disease.[374,400,401]

Epidemiology

LBRF is caused by infection with *Borrelia recurrentis*. The spirochetes are transmitted to humans by contact with the hemolymph of an infected human body louse (*Pediculus humanus*).[54] The louse is crushed by scratching which releases the insect's hemolymph and inoculates the host's skin or mucous membranes. The human body louse inhabits humans only, and *B. recurrentis* is not transmitted vertically to succeeding generations of lice. The organism must be maintained by passage from louse to a human host and then back to another louse. The louse remains infected for its entire life. LBRF is a disease fostered by poverty, crowding, and poor sanitation, as is louse-borne typhus. Epidemic disease thus

occurs only under conditions of extreme deprivation, and outbreaks have been reported in Africa, the Middle East, and Asia, but not recently in the New World. For the first half of the last century, epidemics occurred approximately every 20 years. In recent times, Ethiopia has been the only major geographic locus of infection.[464] Travelers to the developing world occasionally import LBRF into the United States.

TABLE 20-13 Characteristics of Relapsing Fever

Characteristics	Louse-Borne	Tick-Borne
Epidemiology	Epidemic	Usually endemic
Etiologic agent	*B. recurrentis*	Various; *B. hermsii*, *B. turicatae*, *B. parkeri* in USA
Vector	*Pediculus humanus* spp.	Various; *Ornithodoros hermsii*, *O. turicatae*, *O.*

		parkeri in USA
Mean duration of primary attack	5.5 days	3.1 days
Mean duration (range) of asymptomatic interval	9.25 days (3–27)	6.8 days (1–63)
Mean number (range) of relapses	3 (0–13)	1 (0–3+)
Mean duration of relapse	1.9 days	2.5 days

Adapted from 54, 125, 145, 168.

TBRF is distributed worldwide. In North America, it is endemic in the western United States, southern British Columbia, and the plateau regions of Mexico.[124,125,126] Many soft-bodied ticks of the family *Argasidae* (*Ornithodoros* species) carry distinctive borreliae. Although most cases of TBRF occur after tick bites, borreliae have also been transmitted by intravenous drug use, blood transfusion, and laboratory worker accidents, including the bite from an infected monkey.[125] In the United States, taxonomists have attempted to use the same name for a tick and its associated spirochete. Thus, *O. hermsii* is the vector for *B. hermsii, O. turicata* is the vector of *B. turicatae, and O. parkeri* is the vector of *B. parkeri*.[145] *O. turicata* is much larger than *O. hermsi*, and has conspicuous conical mammillae and dorsal projections on the distal segment of the front legs. *Ornithodorsos* ticks have a similar life cycle but inhabit different ecologic niches and hosts. Their life cycle includes egg, single larva, and several successive nymphs before becoming adults. All stages are obligate feeders may transmit spirochetes when they quickly obtain a blood meal within 15 to 90 minutes of attachment. Ticks feed at night when their natural or incidental hosts are sleeping. Female soft-ticks lay clutches of eggs after each blood meal which dramatically prolongs their longevity compared to hard-ticks.

The epidemiologic characteristics of TBRF depend on the habits of the local vector. *O. hermsii* is the most common vector and *B. hermsii* the most common *Borrelia* in California, the Pacific Northwest, and Canada.[125,126] *O. hermsii* lives in the remains of dead trees and parasitizes ground squirrels, tree squirrels, and chipmunks living near freshwater lakes, which often carry rustic tourist cabins. *O. parkeri* inhabits caves and burrows of ground squirrels and prairie dogs in the western United States. *B. parkeri* is a relatively infrequent pathogen of humans because of the inaccessibility of its vector. *O. turicata* inhabits caves and animal burrows in the western United States, Mexico, and South America, but it has also been found in closer association with

humans under the foundations of houses in Texas. *O. parkeri* is found in burrows, rodent nests, and caves in arid regions and grasslands throughout much of the western United States. So far, transmission of relapsing fever after the bite of *O. parkeri* has been rare.[125] The tick-borne borreliae have a solid ecologic niche with virtually no possibility of eradication. The spirochete can be passed from generation to generation of ticks without intervention of a vertebrate host. *O. turicata* has been reported to survive in a starving state for 5 years, and survival of borreliae in ticks without loss of infectivity has been reported for up to 12 years.[126]

Most TBRF is endemic, afflicting the unfortunate person who inhabits or visits an endemic area where *Ornithodoros* ticks reside, and becomes an incidental host. Under the right conditions, however, epidemic disease can occur. In 1968, there was an outbreak of TBRF among 42 boy scouts and scoutmasters who were camping near Spokane, Washington.[469] Clinical disease developed in 1 of the 42 persons at risk. In 9 patients an exact incubation period could be calculated because they were only at risk for one night (mean, 6.9 days; range, 3 to 9). The attack rate was higher in those who slept in abandoned cabins than in those who slept in tents, a trend that was also noted by Horton and Blaser in Colorado.[199] The authors noted poetic justice in the concentration of disease among scoutmasters and older scouts, who appropriated the cabins for themselves, leaving the younger scouts to "rough it."

In areas that have no indigenous relapsing fever spirochetes, importation of disease from endemic regions provides a diagnostic challenge.[93] Tick-borne infection is a more likely infection than louse-borne infection for tourists visiting Africa. Parasitologists should keep this diagnostic possibility in mind when examining smears collected for the detection of malaria parasites.

Clinical Disease

The clinical presentation of the two types of relapsing fever is similar. The mean incubation period of TBRF is 7 days (range, 4 to >18 days).[125] Differences in frequency and timing

of relapses are noted in Table 20-13. *Ornithodoros* ticks feed on humans very inconspicuously and for short periods. Most patients, therefore, do not remember a tick bite. The clinical manifestations of TBRF were well described by Dworkin and colleagues[124] in a relatively large number of cases acquired in the northwestern US and southwestern Canada. The onset of disease is typically abrupt, with a high fever, usually near 40°C (104°F), shaking chills, delirium, severe muscle aches, and pains in bones and joints. Hepatosplenomegaly and tenderness may be present, and the patient

may be jaundiced. Neurologic complications, including lymphocytic meningitis and facial palsy, resemble those of *B. burgdorferi* infection.[65] Unusual manifestations of the infection include iritis, uveitis, iridocyclitis, cranial nerve palsy and other focal neurologic deficits, rupture of the spleen, myocarditis, and acute respiratory distress syndrome (ARDS).[124,125] However, ARDS has been more commonly described in more recently reported cases of TBRF.[72] The initial episode of TBRF lasts 3 days (range, 12 hours to 17 days), and typically it terminates with a crisis.[168] In general, LBRF last longer on average 5.5 days (range, 4 to 10 days). Fatalities are very uncommon in TBRF although untreated LBRF has a higher mortality (5%).[168] An outbreak of louse-borne relapsing fever in Ethiopian troops after the cessation of civil war provided an opportunity to review the clinical features.[43] The case fatality rate was 3.6%, and 1.8% for patients who had recrudescent disease. The average time between the initial episode and the first relapse is 7 days for TBRF and 9 days for LBRF.[168] When relapses occur, each cycle tends to be less severe than the preceding one but the patient usually has malaise and feels unwell despite the absence of fever in between episodes. A rash may develop during the initial attack, but it does not usually appear in relapses. Although penicillin is effective against borreliae, tetracycline or erythromycin are more effective at eliminating the spirochetes. Jarisch–Herxheimer (JH) reactions may occur during treatment; in an Ethiopian epidemic of LBRF, 43% of patients experienced this complication. Use of low-dose penicillin leads to more frequent relapses but fewer JH reactions than with tetracycline or larger doses of penicillin.[405] Administration of acetaminophen and hydrocortisone modified the changes in vital signs during the JH reaction, but did not prevent the dramatic rigor that occurs.[62] Transient increases in tumor necrosis factor and interleukin-6 and -8 correlate temporally with the reaction,[314] although not all investigators have been able to detect elevations of these cytokines. Control of the vector is also essential for the control of epidemic louse-borne infection.[464]

Laboratory Diagnosis

Detection and Isolation. Laboratory confirmation of relapsing fever is made by the detection or isolation of spirochetes in the blood of the patient during the febrile illness (Image Plate 20-1C). The diagnosis is often made in the hematology laboratory, because the clinical presentation can be enigmatic for physicians unaccustomed to the disease. Horton and Blaser[199] report a case in which the spirochetes were missed by an automated differential scanner, but were noted by an astute technologist who reviewed the smear. In contrast to other spirochetes the relapsing fever borreliae are well stained by acid aniline dyes, such as Wright's or Giemsa's stains. The borrelial spirochetes are thin, undulant, or overtly spiral organisms that are most visible when

they are located between red blood cells (Image Plate 20-1C).[40] Felsenfeld[145] advocates staining with Wright's stain followed by application of a 1% solution of crystal violet for 10 to 30 seconds.

The sensitivity of detecting borreliae by staining peripheral smears during a febrile episode is estimated at 70%. However, it is unlikely that spirochetes will be detected when the patient is in remission during the afebrile intervals between attacks, although borreliae are still present in the body. Thick and thin films should be made as for malaria, because in some cases spirochetes will be detected only by examination of the thick film.[40] A monoclonal antibody for the identification of *B. hermsii* in peripheral blood smears is available but not widely used.[399]

Alternatively, quantitative buffy coat analysis may be used, and is much more sensitive (100×) than thick smear examination. Goldschmid and Mahomed[165] used a microhematocrit centrifugation technique to concentrate the borreliae in and above the buffy coat. Although the buffy coat procedure has not been widely used, its utility has been confirmed in a study from West Africa that included isolation of *B. crocidurae.*[481] Sciotto and colleagues[403] used the fluorescent acridine orange technique to demonstrate borreliae in peripheral smears (Image Plate 20-1D). The fluorescence procedure greatly enhances the visibility of the spirochetes.

Relapsing fever borreliae can also be cultured from the blood of an infected patient in a modification[26] of Kelly's medium for borreliae,[219] but isolation is not a practical diagnostic test in most clinical laboratories because cultures need to be examined for spirochetes using darkfield microscopy for 2 to 6 weeks after inoculation.

Serology. Confirmation of TBRF using serology is demonstrated with a fourfold rise in antibody titer between an acute and convalescent serum samples or with a single convalescent serum sample that is reactive. However, only a few reference laboratories perform serology for relapsing fever diagnosis because the borreliae need to be cultivated for use in an indirect IFA, and to produce large amounts of whole-cell lysate for use in the ELISA assays. An IFA titer of 1:128 to 1:256 or higher is considered positive. Results of ELISA tests are often reported as an absorbance value (i.e., 0.85) after testing at one dilution. Samples that screen positive by either the IFA or ELISA assays should be confirmed with immunoblot to determine the pattern of reactivity to other antigens specific for relapsing fever borreliae. Because of cross-reactivity with the flagellin protein, patients may have false-positive serology tests for relapsing fever, if they also have reactive tests for other species of spirochetes. Approximately 5% of patients will have a positive VDRL test. Patients with relapsing fever may also have reactive Lyme disease serology.[124]

In order to improve sensitivity and specificity of serology tests, an immunoreactive protein, glycerophosphoryl diester phosphodiesterase (GlpQ), has been identified in

borreliae causing relapsing fever, but not those that cause Lyme disease or syphilis.[359,402] Although the GlpQ recombinant protein is not widely available, it has recently been used in an immunoblot to confirm TBRF due to *B. hermsii* infection in a patient exposed in the mountains near Los Angeles County, California, USA.[401]

1308

Molecular Methods. Tick analysis has been performed using amplification techniques for borrelial nucleic acid and subsequent nucleic acid sequence analysis for identification and characterization. Molecular methods were used to identify and characterize *B. hermsii* found in six ticks in Los Angeles County subsequent to the confirmation of human infection in the above exposed patient.[401] Previously described methods for PCR and DNA sequence analysis were used to characterize several genes including 16S rRNA, flagellar B protein (*fla*B), gyrase B (*gyr*B), *glp*Q, and variable tick protein (*vtp*). Similar techniques have, however, not been widely used to diagnose human disease.

Leptospira

Taxonomy *Leptospira*, together with the genera *Leptonema* and *Turneria*, is a member of the family *Leptospiraceae*. *Leptospira* are motile, obligately aerobic helical rods with characteristic hooked ends that measure 0.1 mm in diameter and 6 to 12 mm in length. They are gram-negative and are only faintly stained by aniline dyes. Darkfield microscopy must be used to visualize unstained *Leptospira* (Fig. 20-18). Originally there were only two recognized species of *Leptospira* that could be separated on the basis of biochemical tests: *L. interrogans* sensu lato which contained all of the human pathogenic species, and *L. biflexa* sensu lato which contained all of the saprophytic environmental species. Leptospires were then further divided into serovars using agglutination after cross-absorption with homologous antisera directed at the surface-exposed epitopes of LPS antigens.[113] *L. biflexa* sensu lato contains more than 60 different serovars, while *L. interrogans* sensu lato contains more than 260 different serovars. A single serovar might be found in several species. For epidemiologic classification purposes, antigenically related *Leptospira* serovars and species are also collected into serogroups. The pathogenic type strain is *L. interrogans* sv. Icterohaemorrhagiae,[209] and the clinical disease is leptospirosis. Several reviews, some from the older literature, reflect the state of knowledge in many areas.[1,131,143,182,183,225,243,290]

Studies of the DNA relatedness among serovars of *Leptospira*[505] have identified

genomospecies, and the number worldwide will continue to expand as unique species are discovered.[1,243,244] The currently recognized genomospecies and the corresponding serogroups of *Leptospira* are detailed in Table 20-14. Recently, the taxonomy of *Leptospira* was changed when it was decided to give the status of species to previously described genomospecies 1, 3, 4, and 5. Thirteen pathogenic species of *Leptospira* are now recognized, including *L. interrogans*, *L. alexanderi*, *L. alstonii* (genomospecies 1), *L. borgpetersenii*, *L. inadai*, *L. fainei*, *L. kirchneri*, *L. licerasiae*, *L. noguchi*, *L. santarosai*, *L. terpstrae* (genomospecies 3), *L. weilii*, and *L. wolffii*, which contain more than 260 serovars. Saprophytic species of *Leptospira* include *L. biflexa*, *L. meyeri*, *L. yanagawae* (genomospecies 5), *L. kmetyi*, *L. vantheilii* (genomospecies 4), and *L. wolbachii*, which contain more than 60 serovars.

Whole-genome sequences have now been published for at least six leptospiral strains including two serovars (Lai and Copenhagen) of *L. interrogans*, two strains of *L. borgpetersenii* serovar Hardjo, and two strains of *L. biflexa* serovar Patoc.[57,309,353,373]These analyses reveal some unique feature of *Leptospira* genetics, and are allowing different virulence genes to be identified in pathogenic compared to saprophytic strains. The genome is comprised of two circular chromosomes, and there is a high degree of homology between pathogenic serovars despite differences in host specificity.[309]

1309

Comparison of the two pathogenic and one saprophytic species has identified 2,052 genes which make up the core leptospiral genome, suggesting a common origin for all pathogenic and saprophytic *Leptospira*.[1] Comparison of the *L. interrogans* and *L. borgpetersenii* genomes also show a high degree of plasticity and large-scale genome rearrangement with a much higher number of pseudogenes, insertion sequences, and genetic remnants than in the saprophytic strain.[57] *L. interrogans* also has a much higher number of genes (~500) that encode proteins of unknown function, which supports the notion that *Leptospira* have unique virulence factors that have not been identified in other spirochetes or bacteria. *Leptospira* have more than 70 genes with a putative regulatory role which is much higher than that found in other spirochetes, some that allow the organism to survive for extended periods in the host and external environment.[309] In particular, three toxin–antitoxin systems may control gene regulation during times of nutritional stress.[515] The loss of gene function in *L. borgpetersenii* may have occurred because the saprophytic *Leptospira* serovars do not survive in the environment and have a stricter host-to-host transmission cycle.[57]

TABLE 20-14 Genomospecies and Serogroups of *Leptospira*

Genomospecies	Serogroup
L. interrogans	Icterohaemorrhagiae, Canicola, Pomona, Australis, Autumnalis, Pyrogenes, Grippotyphosa, Djasiman, Hebdomadis, Sejroe, Bataviae, Ranarum, Louisiana, Mini, Sarmin
L. noguchii	Panama, Autumnalis, Pyrogenes, Louisiana, Bataviae, Tarassovi, Australis, Shermani, Djasiman, Pomona
L. santarosai	Shermani, Hebdomadis, Tarassovi, Pyrogenes, Autumnalis, Bataviae, Mini, Grippotyphosa, Sejroe, Pomona, Javanica, Sarmin, Cynopteri
L. meyeri	Ranarum, Semaranga, Sejroe, Mini, Javanica
L. wolbachii[a]	Codice
L. biflexa[a]	Semaranga, Andamana
L. fainei	Hurstbridge
L. borgpetersenii	Javanica, Ballum, Hebdomadis, Sejroe, Tarassovi, Mini, Celledoni, Pyrogenes, Bataviae, Australis, Autumnalis
L. kirschneri	Grippotyphosa, Autumnalis, Cynopteri, Hebdomadis, Australis, Pomona, Djasiman, Canicola, Icterohaemorrhagiae, Bataviae
L. weilii	Celledoni, Icterohaemorrhagiae, Sarmin, Javanica, Mini, Tarassovi, Hebdomadis, Pyrogenes, Manhao, Sejroe
L. inadia	Lyme, Shermani, Icterohaemorrhagiae, Tarassovi, Manhao, Canicola, Panama, Javanica
L. parva[a]	Turneria
L. alexanderi	Manhao, Hebdomadis, Javanica, Mini

[a] No pathogenic serogroups associated with this species to date.
Adapted from reference 113.

Transmission of *Leptospira* to humans occurs through direct or indirect contact with the urine of an infected animal, or with contaminated water or soil. Leptospires usually enter the body through small cuts of abrasion, or by contact with mucous membranes such as the conjunctiva or through wet skin. During the initial bacteremic phase of the illness, spirochetes circulate in the bloodstream for up to 7 days. Once the host generates an antibody response, the organisms are cleared from the bloodstream. However, in severe cases, *Leptospira* may rapidly penetrate and disseminate in the body, establishing persistent colonization in the renal tubules. The pathogenic mechanisms that cause leptospiral host disease and host tissue damage have not been elucidated, although leptospires likely migrate through intercellular junctions. Leptospiral toxin(s) or toxic cellular components are likely involved in the development of symptoms. Damage to the endothelium of small blood vessels leads to localized organ ischemia, which causes renal tubular necrosis, pulmonary damage, hepatocellular damage, and inflammation of the meninges, myocardium, muscles, and placenta.[103,104,169,406,511]

Leptospirosis

Leptospirosis is a systemic disease of humans and animals. Although commonly designated as Weil's syndrome in the older literature, many other names have also been attached to the illness (i.e., canicola fever, nanukayami fever, 7-day fever, Rat Catcher's Yellows, Fort Bragg fever, black jaundice, and pretibial fever).[243] Adolf Weil first reported a case of "icterohemorrhagic fever" in 1886 where the patient had acute infection with splenomegaly, jaundice, and nephritis.[131] *Leptospira* spirochetes were initially observed from postmortem renal tissue sections in 1907. Leptospirosis as a cause of febrile illness has been misdiagnosed worldwide, but global attention has recently established that this zoonosis is a neglected problem that has a major health impact in resource-limited countries in tropical areas.

Epidemiology. Leptospirosis is a spirochetal zoonosis that is globally reemerging due to urban epidemics in poor communities of industrialized and resource-limited nations. *Leptospira* are distributed worldwide and infect many types of domestic and wild animals. Humans become incidental, "dead-end" hosts because transmission from humans to animals or to other humans does not occur. Most human cases occur in tropical countries because the spirochetes are better able to survive in warm, humid conditions. Leptospirosis is, therefore, a seasonal disease in temperate climates, with cases occurring in the summer or fall.

Domestic rats infected with pathogenic strains of *Leptospira* have been classically associated with this disease, but domestic animals, mainly dogs, cattle, and pigs, may be infected like humans as incidental hosts. Foxes, raccoons, skunks, shrews, and hedgehogs are among the many types of wild animals worldwide that may also carry

the leptospires. Animal hosts are usually not symptomatic and antibody does not develop in them, despite overwhelming infection. Several different serovars of *Leptospira* may be carried by a single animal genus, however, and a single serovar may be associated with more than one animal host. Dairy cattle may become infected with serovars Pomona and Hardjo, pigs with Bratislava, Tarassovi, or Pomona, and dogs with Canicola.[243]

A key factor to the persistence and epidemiology of leptospirosis is the renal carrier state of diseased animals. Leptospires have a propensity to colonize the surface of renal proximal tubular epithelial cells. Spirochetes are excreted into the urine of the host in high concentration, either continuously or intermittently, surviving best in alkaline urine.

Leptospirosis has divergent epidemiologic patterns for the poor in rural and urban areas in resource-limited countries, compared to the more affluent people in these same countries. Leptospirosis worldwide is acquired through environmental exposure with contaminated water or soil, either due to occupation, day-to-day activities, or recreation. Leptospirosis due to occupational disease has been concentrated among workers in sewers, abattoirs, and agriculture, particularly subsistence farmers in rice and sugarcane fields in resource-limited countries.[243] Epidemiologic factors that were associated with leptospirosis in Hawaii included catchment of rainwater for household use, contact with cattle and cattle urine, or handling of animal tissues.[216] Since the 1970s, only a small number of cases have occurred in the United States because of occupational contact.

More recently, leptospirosis has increasingly been recognized as an urban problem worldwide. The dramatic migration of poor rural people to urban slum communities and the increased number of urban homeless people create ecologic conditions for rodent-borne transmission. Urban leptospirosis was initially recognized in US inner-city homeless populations. Annual outbreaks of leptospirosis are also reported in poor urban communities in Brazil, India, and others parts of the world during the same seasonal monsoon period of heavy rainfall.

Leptospirosis is also a risk for affluent people who pursue recreational activities in endemic areas, particularly those who participate in backcountry and extreme sports. Imported disease must therefore be considered in travelers presenting with a febrile illness.[479] Leptospirosis has been reported in association with kayaking.[418] Epidemic disease occurred during a triathlon in Illinois, where it was associated with brief exposure to the water in a pond,[205] and among

1310

white water rafters in Costa Rica.[76]Participants in an Eco-Challenge race in Borneo

also contracted acute leptospirosis during the race due to contact with the Segama River during kayaking, spelunking, and swimming.[82]

Epidemic disease may also occur from flooding or another common waterborne source. A large outbreak of 'hemorrhagic fever' followed flooding in rural Nicaragua in 1995 when 2,259 residents developed a febrile illness and 15 died of severe pulmonary hemorrhage.[474] In Brazil, more than 10,000 cases of severe leptospirosis are annually reported due to rainfall-associated urban epidemics in poor urban slums.[380] Several large outbreaks have also occurred in India after monsoons or cyclones.[407,408] In Italy, an outbreak occurred due to a leptospire-infected hedgehog being trapped in a water reservoir.[64] Several waterborne outbreaks have also occurred in the United States.[507] A waterborne outbreak of leptospirosis also occurred in Illinois that was traced to a contaminated pond; a drought was hypothesized to have increased the risk of exposure to infected animal excreta.[205]

A small outbreak due to exposure to contaminated soil also occurred in a suburb of St. Louis, Missouri.[144] *Leptospira interrogans* sv. icterohaemorrhagiae was isolated from rats and house pets and from soil in the yards of homes. Some of the dogs from whom they isolated leptospires had been immunized with commercially available anti-*Leptospira* vaccines.

Clinical Disease. Leptospirosis in humans varies in severity based on a number of host factors and the infecting *Leptospira* serovar. Classical leptospirosis is a biphasic disease, which consists of an initial bacteremic phase that lasts for a week, and a secondary immune phase characterized by antibody production, dissemination of spirochetes to tissues, particularly the renal tubules, and excretion of leptospires in the urine. After an asymptomatic interval of 1 to 3 days, the immune phase of the infection develops. Leptospires are rapidly cleared from the blood and CSF, and an inflammatory process develops. A CSF pleocytosis will develop in 90% of patients during the second week of illness, but only half of these patients have symptoms of aseptic meningitis.

Leptospirosis starts abruptly with fever, headache, myalgia, malaise, conjunctival suffusion, and occasionally a transient rash. Patients may present with skin rashes that are macular, maculopapular, urticarial, or hemorrhagic. A distinctive pretibial rash accompanied an epidemic of *L. interrogans* sv. Autumnalis infection and was named Fort Bragg fever. This pretibial rash has accompanied infections with other serovars. Although the symptoms are incapacitating in the initial stage, most patients recover without developing the complications that are seen in the more severe forms of the disease. Severe disease manifestations may occur with infections due to any of the pathogenic serovars, but milder disease is usually caused by Hardjo and others.[1] Despite recovery from the disease symptoms, patients may remain weak, fatigued,

and depressed for weeks to months after the initial illness.

Infection with serovars icterohaemorrhagiae, Copenhageni, Lai, and others are usually associated with severe disease.[1] Although most patients with leptospirosis are asymptomatic or develop mild disease, there is a major burden of illness worldwide due to the severe disease forms, Weil's disease (jaundice, acute renal failure, and hemorrhage) and severe pulmonary hemorrhage syndrome (SPHS). Patients with SPHS have a high mortality rate (>50%), while over 10% of patients with Weil's disease also die. Older adults (>30 to 40 years of age) are more likely to die.[103,104] Several studies have also demonstrated that acute renal failure, respiratory failure, hypotension, arrhythmias, and altered mental status are independent prognostic markers for mortality.[121]

Leptospirosis initially causes a unique nonoliguric hypokalemic form of acute renal insufficiency that if diagnosed early can be treated with volume repletion and potassium replacement.[406] SPHS due to leptospirosis infection usually manifests as ARDS, pulmonary infiltrates, and hemoptysis that may not be evident until intubation.[169] The leptospiral burden in the lungs of patients with SPHS is extremely high even though few spirochetes have been observed at autopsy, suggesting that this is an immune-mediated condition.

Pregnant patients with leptospirosis, whether they have mild or severe forms of the disease, are at risk for intrauterine infection and fetal death. Congenital transmission of leptospirosis from mother to infant has not been reported.

Patients with severe leptospirosis often require intensive care including ventilator support and dialysis to survive. Because the Jarisch–Herxheimer reaction has been reported after treatment, caution should be used in prescribing antibiotics to patients with self-limited mild disease.[133] The rationale for treating patients with severe disease with antibiotics has, however, been reviewed.[488] Clinical trials in Thailand have also demonstrated equivalent efficacy of treatment with ceftriaxone, cefotaxime, and doxycycline compared with penicillin therapy.[466]

Humoral immunity to leptospirosis mediated by specific antibody production occurs in both humans and animals. LPS is the major antigen recognized by convalescent sera, and immunity is restricted following naturally occurring infection to serovars with antigenically related LPS.[2] Recent studies have also shown that mice require intact TLR2 and TLR4 activation pathways to control a lethal infection.[88]

Laboratory Diagnosis. Diagnosis of leptospirosis must be confirmed by the laboratory because of the wide range of clinical manifestations of this disease. Although culture allows a definitive diagnosis, it is rarely performed because it is slow and not widely available. Leptospirosis may also be demonstrated by detection of the organisms in specimens, or by the detection of antigens or nucleic acid, but serology

remains the main diagnostic method. Monoclonal antibodies have been used to detect leptospiral antigen in urine in specimens from Thailand, but there are no commercial antigen tests so this will not be discussed further.[387]

Direct Detection. *Leptospira* may be detected by microscopic examination of blood, CSF, or urine, but spirochetes in blood can only be detected during the early bacteremic phase of the illness. Centrifugation of specimens at low speed of oxalated or heparinized blood to remove cellular elements and then at high speed to concentrate *Leptospira* has been recommended. Darkfield microscopy examination may be attempted but a high leptospire concentration (10^4/mL) must be present for spirochetes to be visualized.[486] Nonspecificity is also a problem using darkfield examination because fibrils or extrusions from red blood cells are misinterpreted

as spirochetes. Although examination of CSF and urine are somewhat less likely to contain artifacts that may produce a false-positive result, similar caveats apply.[426] Silver staining using the Warthin–Starry stain has been widely used for histologic examination of tissues. Immunohistochemical staining can also be performed at a reference laboratory (i.e., CDC).[511]

Culture. *Leptospira* can be isolated from blood, peritoneal dialysate, and CSF during the first week of illness. During the immune stage, the organisms disappear from the blood and CSF, but *Leptospira* are excreted in the urine for up to 1 month (Image Plate 20-1G). The most commonly used commercial culture media are Fletcher's semisolid medium (Difco, BD Diagnostic Systems, sparks, MD) or semisolid bovine serum albumin–Tween 80 (oleic acid) medium (Ellinghausen–McCullough–Johnson–Harris [EMJH, Difco]) that contains 200 µg of 5-fluorouracil. The media may be stored at room temperature for long periods. It is recommended that at least four 10-mL tubes of culture media from two different lots be inoculated with the clinical specimen. For recovery of fastidious serotypes, 0.4% to 1.0% sterile rabbit serum may also be added to the bovine serum albumin–Tween 80 medium. Only very small blood or urine volumes (50 µL) should be inoculated, because larger volumes will introduce interfering substances. Media should be inoculated with one to two drops of specimen per tube. If the procedure cannot be done at the bedside, oxalated or heparinized blood may be sent to the laboratory. A triturated clot may also be inoculated, but citrated blood may be inhibitory. When urine is tested, the pH should be immediately neutralized by sodium bicarbonate, and an undiluted specimen and a 10-fold dilution should be inoculated. When CSF is used, 0.5 to 5.0 mL should be inoculated.

The cultures are incubated in the dark at 28°C to 30°C for 6 to 12 weeks and examined weekly by darkfield microscopy for the presence of spirochetes (Fig. 20-

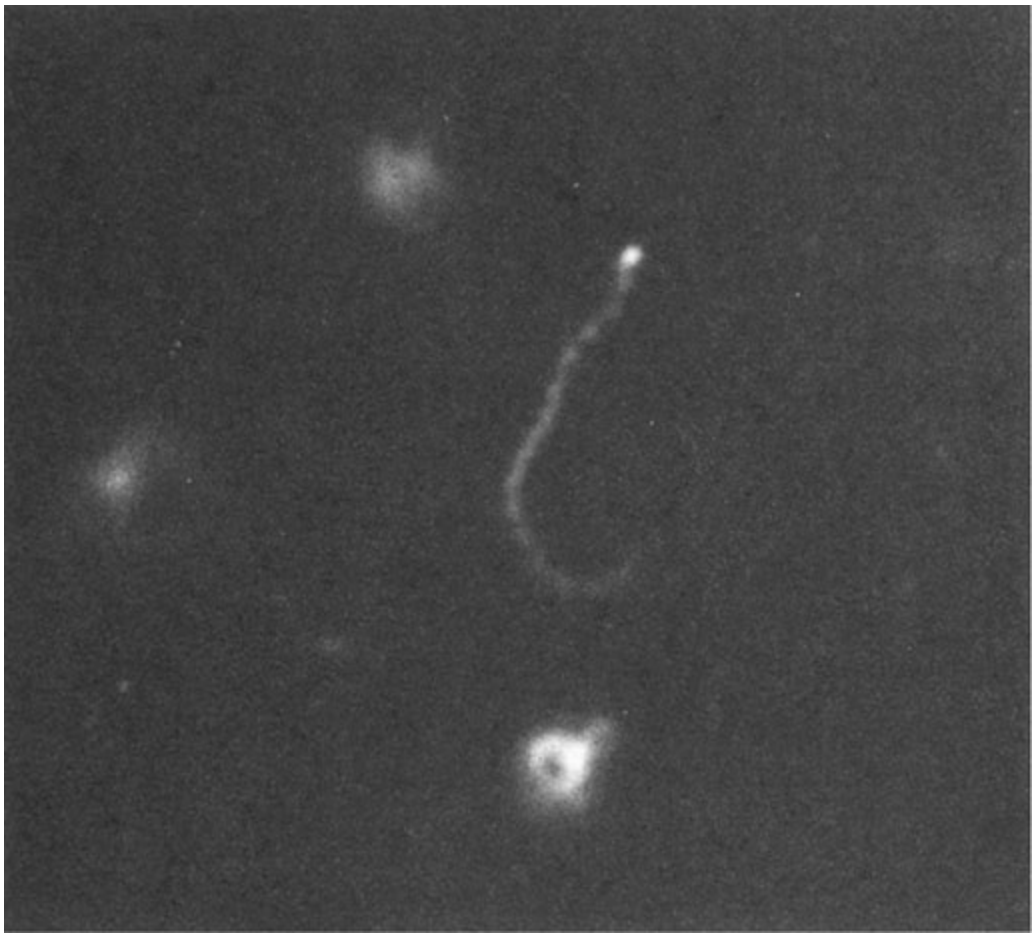
19). Growth is often delayed for several weeks but occurs considerably earlier in EMJH media. *Leptospira* typically grow as a band 0.5 to 1.0 cm below the surface of semisolid media, known as Dinger's ring (Image Plate 20-1H)

Palmer and colleagues[341] demonstrated that commercial blood culture systems had variable ability to maintain viability of leptospires. In general, the combination of an aerobic blood culture and an incubation temperature of 30°C enhanced the viability of leptospires for up to a week in some systems. However, a positive signal from an automated blood culture system is not likely to occur in a patient's sample since the organisms do not grow in conventional media.

Identification of Leptospira recovered in culture must be done using serologic cross-agglutination absorption methods in order to establish a serovar.[113] Isolates should be referred to a reference laboratory that maintains an extensive antisera bank for this purpose. Genomospecies identification must also be done using sequence analysis of 16S rRNA or other genes.[301]

Serology. Leptospirosis is mainly diagnosed by detection of antibody using serologic tests. Patients begin to produce antibody toward the end of the initial 7-day illness.

Microagglutination test. The gold standard serologic test continues to be the microagglutination test (MAT) whereby leptospiral antigen suspensions are reacted with the sera.[473] MAT is performed by mixing diluted patient sera with leptospiral cultures in a 1:1 ratio, incubating the mixture for 2 to 4 hours at 30°C or room temperature, and then using darkfield microscopy to examine them for agglutination. The reaction is positive when the proportion of free leptospires is less than 50% compared to the control suspension. The highest dilution of serum that shows 50% agglutination compared to the control mixture determines the end-point titer. The MAT test, often considered serovar-specific, is, in fact, serogroup-specific. Only certain reference laboratories perform MAT testing because it is a complex test to perform and interpret. Furthermore, the sensitivity of MAT in the acute phase is low, and paired sera must be collected to confirm leptospiral infection. The difficulty of maintaining large numbers of cultures of *Leptospira* is obvious. Formalin-killed leptospira are used as a practical compromise, but they result in somewhat lower sensitivity. A large number of antigens must be tested against the sera; WHO has recommended 19 serovars or 16 serogroups. The serovar that demonstrates the highest titer in MAT is considered to be the infecting serovar (serogroup), but the test has been shown to be an inaccurate predictor in this regard.[245,430] Sera may be screened using commercially available serogroup-specific leptospiral antigens in a macroscopic agglutination test, but positive reactions should be confirmed by the MAT in a reference laboratory.



■ **FIGURE 20-19** Darkfield examination of *Leptospira interrogans* culture. The spiral coils, which are not clearly demonstrated, appear as alternating bright and dark areas. The very bright upper end of the organism may represent the hooked end that many leptospira possess. It is easy for inexperienced observers to confuse cell debris and artifacts with leptospira in clinical specimens. ×1000. (Photomicrograph courtesy of David Miller, DVM, MS.)

A titer of ≥1:100 in the MAT test is usually considered evidence of past infection. The CDC has suggested a titer of >1:200 in a single serum specimen by the MAT test as presumptive evidence of leptospirosis in a patient with a compatible clinical illness, but in endemic areas other experts have suggested a titer of 1:800 or 1:1600 as better cutoffs. Titers may reach extremely high levels and take months or years to decrease, so the height of the titer cannot be used for determination of recent infection.[380,381]

1312

Other serology tests. Other antibody detection tests have been developed that

enable rapid screening but similar to MAT they have suboptimal sensitivity during the early stages of infection, and some of these assays may also have poor accuracy in areas with endemic leptospirosis.[21,127,243,246,247,428,429,489] A comprehensive discussion of other serologic test evaluations has been published.[243,473] Techniques such as latex agglutination,[413,428] dipstick,[174,409,427,506] enzyme immunoassays,[21,127,246] indirect hemagglutination (IHA),[243,247] and lateral flow assays[413,429] have been reported, but some of these tests have not been extensively evaluated. These assays contain lipopolysaccharide (LPS) antigens from nonpathogenic *Leptospira biflexa* serovar Patoc,[283] and detect IgM and/or IgG antibodies against LPS from all pathogenic serovars due to the cross-reactivity with Patoc LPS. An IHA developed by the CDC is approved by the US FDA. This IHA uses sensitized red blood cells to detect both IgM and IgG antibodies, and initially was shown to have a sensitivity of 92% and a specificity of 95% compared to the MAT.[463] In more recent studies, however, the IHA was positive in only 44% of acute-phase sera taken approximately 5 days after symptom onset.[249]Hull-Jackson and colleagues[201] more recently evaluated a commercial latex agglutination test using a well-characterized sera bank that included 40 patients with leptospirosis, as well as doing a prospective study of consecutive patients admitted to hospital with an acute febrile illness. Although the sensitivity of the latex agglutination test was similar in the two groups of patients, the specificity was considerably less using the well-characterized sera bank (81%) versus during the prospective study (98%). This study demonstrates that newer tests for leptospirosis need to be evaluated and validated in different populations before being implemented for routine use.

Patients with leptospirosis also produce antibodies to several other protein antigens, some of which are present during the acute disease phase.[116,173] Identification of one or more antigens has led to the development of recombinant protein-based diagnostic assays for leptospirosis, but the performance of rLipL41- and rOmoL1-based EIA assays has shown variable sensitivity.[115,151,310] *Leptospira*-immunoglobulin-like (Lig) proteins (i.e., outer membrane proteins) have been shown to be better at diagnosing early disease using an immunoblot assay than either whole *Leptospira*-based assays or recombinant assays.[98] Other antigens that have recently been used in recombinant-based diagnostic assays include Lp29, MPL17, MPL21, and LipL21 in EIAs,[315,329] LipL32 in a dipstick assay,[42] and Lip41 in both a latex agglutination and flow-through immunoassay.[413] Improved, rapid diagnostic tests for leptospirosis are needed in endemic areas that are able to detect acute-phase disease. Identification and use of other immunogenic protein antigens that are conserved among pathogenic leptospires will enable the development and testing of an expanding number of rapid tests for this purpose.

Molecular Detection. Various genes have been the target of leptospiral DNA amplification by PCR, particularly for the diagnosis of acute-phase disease. Although PCR has been used for research, few methods were evaluated for diagnostic use.[50,51,170,292]Merien and colleagues[292] amplified a 331-bp fragment of the *rrs* (16S rRNA) gene of both pathogenic and nonpathogenic leptospires. Two primer sets, G1/G2 for the *sec*Y gene and B64I/64II for the flagellin gene are included in the WHO manual.[498] The G1/G2 primers do not amplify all pathogenic serovars necessitating use of a multiplex assay.[170] These two primer sets have been used clinically to detect leptospiral DNA in the serum, urine, aqueous humor, CSF, and tissues at autopsy of patients with leptospirosis.[243,473] More recently, several targets (i.e., *rrs*, *lig*A and B, *lip*32, *sec*Y, and genomic locus LA0322 in serovar Lai) have been used to develop real-time PCR assay using both hydrolysis (i.e., TaqMan) probes and SYBR green fluorescence.[248,422,458,473]

Rat-Bite Fever (Sodoku)

RBF is a bacterial zoonosis that occurs after being bitten by a rat and inoculated with one of two organisms in the animal's oral flora. This term is used to describe two distinct diseases with different microbial etiologies. Cases in North America are caused by *Streptobacillus moniliformis*, a highly pleomorphic, filamentous, gram-negative, nonmotile, and non–acid-fast rod, while most cases in Asia are caused by *Spirillum minus*, an oral spirochete. This section describes RBF due to the latter, or sodoku the name used for this disease in Asia.

Spirillum minus

S. minus is a gram-negative spirochete that is spiral-shaped and measures 0.2 to 0.5 mm wide and 1.7 to 5 mm long. The bacterium is actively motile by bipolar bundles of flagella and the six spirals that give the organism its coiled appearance. *S. minus* was first described as the cause of RBF in 1916, 30 years after spiral bacteria called "*Spirillum minor*" were found in wet mounts of wild rat blood.[157] Several other names were also given to this organism in the older literature prior to it being named *S. minus* in 1924.[157]

RBF due to *S. minus* is an infection that more commonly occurs in Asia, but rarely occurs in the United States. The frequency of infection relates to the amount of contact between rats, other rodents, and humans. Although overall a rare infection, RBF is still a threat when there is rodent exposure. A few cases have also occurred in children and adolescents in contact with wild field mice, or in people who have gerbils

as pets.[157] Rats are also being kept as pets such that pet shop employees and rodent owners may also be at risk for acquiring RBF.[328] Human-to-human transmission has not been documented. One to four weeks after the bite a systemic illness occurs, characterized by chills, headache, vomiting, and fever. The site of the bite, which had healed, ulcerates to form a chancre-like lesion, and is accompanied by regional lymphadenitis and a blotchy maculopapular rash that may affect the palms and soles. In contrast to the streptobacillary form of RBF, polyarthritis rarely occurs with sodoku. Relapsing fever with a periodicity of every 2 to 3 days may occur for weeks, months, or years in untreated patients. Complications include endocarditis, myocarditis, meningitis, nephritis, hepatitis, and splenomegaly.[157]

Spirillum minus cannot be cultured on artificial media; so little is known about the phenotypic or genotypic characteristics of this organism. Animal inoculation remains the only way to recover the organism, and no specific serologic tests

1313

are available. False-positive serologic tests for syphilis occur in 50% of patients with RBF. The spirochetes may be visualized in blood, exudates, or tissue using Giemsa's or Wright's stain or darkfield microscopy.

CHAPTER 21

Mycology

thePoint For additional ancillary materials related to this chapter, please visit the point.

Introduction

Patients at Risk for Fungal Infections

General Signs and Symptoms Suggesting Fungal Infection

Clinical Categorization of Fungal Infections

Common Mycologic Terms

Laboratory Approach to the Diagnosis of Fungal Infections

Specimen Collection and Transport

Specimen Processing

Direct Examination

Preparation of Mounts From Cultured Isolates

Selection and Inoculation of Culture Media

Incubation of Fungal Cultures

Laboratory Approach to the Presumptive Identification of Fungal Isolates

Extent of Laboratory Genus/Species Identification
Genus and Species Identification of the Major Groups of Fungi

***Zygomycetes* (Glomeromycetes) and Zygomycosis**

Major Genera of Zygomycetes
Histopathology of Infections Caused by the *Zygomycetes*

Hyaline Molds and Hyalohyphomycosis

Aspergillus Species and Aspergillosis
Laboratory Presentation
Colony Morphology
Microscopic Features
Histopathology
Diagnosis Using Nonculture Techniques

Other Hyaline Septate Molds
Colony Characteristics

Genera of Hyaline Filamentous Molds Producing Conidia in Chains
Penicillium Species
Paecilomyces and *Purpureocillium* Species
Scopulariopsis Species

Identification of Hyaline Molds Producing Conidia in Clusters
Acremonium Species
Fusarium Species
Gliocladium Species
Trichoderma Species

Identification of the Genera of Hyalohyphomycetes Producing Conidia Singly
Pseudallesceria boydii complex
Chrysosporium Species
Sepedonium Species
Beauveria Species

Identification of the Dermatophytes

Identification of *Microsporum* Species
Microsporum canis
Microsporum gypseum
Microsporum nanum

Identification of *Trichophyton* Species
Trichophyton mentagrophytes
Trichophyton rubrum
Trichophyton tonsurans

Trichophyton verrucosum
Epidermophyton floccosum
Diagnosis Using Nonculture Techniques

The Dimorphic Fungi

Blastomyces dermatitidis and Blastomycosis
Laboratory Presentation
Diagnosis Using Nonculture Techniques
Coccidioides immitis, Coccidioides posadasii, and Coccidioidomycosis
Laboratory Presentation
Histoplasma capsulatum and Histoplasmosis
Laboratory Presentation
Diagnosis Using Nonculture Techniques
Sporothrix schenckii Complex and Sporotrichosis
Laboratory Presentation
Diagnosis Using Nonculture Techniques
Paracoccidioides brasiliensis and Paracoccidioidomycosis
Laboratory Presentation
Diagnosis Using Nonculture Techniques

Dematiaceous Fungi

Agents of Phaeohyphomycosis

Serologic Diagnosis of Fungal Diseases

Introduction

The diagnosis of a fungal infection requires the cooperative efforts of the clinician, the anatomic pathologist, and the microbiologist. The clinical team is responsible for recognizing the signs and symptoms of fungal infections and for the appropriate collection and transport of specimens to the laboratory. It is important for the clinicians to communicate their clinical considerations to the microbiologist, when certain types of fungal infection are suspected for which special procedures may be needed. For example, when zygomycosis is suspected, then more delicate specimen processing techniques will be used. The surgical pathologist and cytopathologist must be alert to the tissue reactions that suggest a fungal infection and must be able to recognize fungal elements in stained tissue sections. The mycologist is responsible for implementing the laboratory techniques for optimal detection and recovery of fungi in culture; for making an accurate identification; and, if necessary, for performing antifungal susceptibility testing.

Patients at Risk for Fungal Infections

Following are the individuals who are immunosuppressed:

- Patients with advanced HIV infection.
- Organ transplant recipients, particularly during the posttransplantation period of immunosuppression.[201]
- Patients with malignant neoplasms, particularly those with leukemia and lymphoma, or during periods of chemotherapy.
- Patients with a variety of debilitating immunologic and metabolic disorders, including systemic lupus erythematosus (SLE), and other collagen vascular diseases, diabetes mellitus, dysgammaglobulinemia, and alcohol or IV drug abuse.
- Recipients of corticosteroids, cytotoxic agents, prolonged antibiotic therapy, and newer modulators of the immune system (e.g., tumor necrosis—α inhibitors).

Travelers to or inhabitants of regions of the world known to be endemic for fungal infections are also at risk. Participants in activities or occupations that bring them in direct contact with infected animals, humans, and/or contaminated materials are at risk for fungal infections.

General Signs and Symptoms Suggesting Fungal Infection

The early presenting symptoms leading to the suspicion of a fungal infection commonly are atypical, vague, and nonspecific, reducing the chance for making the correct clinical diagnosis. Low-grade fever, night sweats, weight loss, lassitude, easy fatigability, cough, and chest pain are common presenting symptoms. Deep-seated or disseminated fungal diseases may mimic other infections, such as tuberculosis, brucellosis, syphilis, sarcoidosis, and metastatic cancer. Careful examination of the skin and mucous membranes should always be performed, as systemic fungal infections often present with mucocutaneous lesions.

- Ulcerating lesions in the intestine, larynx, pharynx, genitals, and tongue may complicate disseminated histoplasmosis in up to 50% of patients.
- Patients with blastomycosis may initially present with verrucous or pustular lesions of the skin or ulcerating granulomas of mucous membranes, including the larynx,[72] the esophagus, and the oral cavity, including the tongue.[210]
- Coccidioidomycosis in patients with profound immunosuppression may present as papular or macular skin lesions, or as eosinophilic, basilar meningitis.[227]

1324

The signs, symptoms, and probable agents of pulmonary mycoses are listed in Table 21-1. The signs, symptoms, and probable agents of extrapulmonary mycoses are summarized in Table 21-2.

Nonspecific laboratory findings such as accelerated erythrocyte sedimentation rate, increase in C-reactive protein, elevations in gamma globulin, or low-grade and persistent elevations in the peripheral blood neutrophils and/or monocytes may provide initial clues to the presence of a fungal infection.

Clinical Categorization of Fungal Infections

Fungal infections are often characterized by the location of the infection. These may be referred to as superficial, subcutaneous, or systemic, which is also referred to as deep-seated. Although these broad categorizations remain useful, it is important to recognize that in the context of profound immunosuppression, fungi that are commonly superficial may cause subcutaneous infection and those that are subcutaneous may disseminate. In addition, fungi that are uncommon pathogens or even usual contaminants may cause disease in the absence of an immune response. The following terms allow for better communication between clinicians and mycologists.

The terms *deep-seated* and *systemic* classically refer to a group of fungal infections caused by agents that inherently can be highly virulent, that can invade deeply into tissues and organs, and that have the capability of spreading widely throughout the body. Classically, these terms are often used to refer to infections caused by the dimorphic fungi. These are fungi that exist in the form of mold in the environment (i.e., at room temperature incubation) and exist as yeasts or a yeast-like fungus when in the body. All of the dimorphic fungi, except *Coccidioides,* are thermally dimorphic, which means the yeast or yeast-like form can be demonstrated by incubating the cultured fungus at 35°C to 37°C (i.e., body temperature). Currently, because of the increase in the number of individuals who are immunosuppressed, many fungi, which were formerly considered only as "saprobes" or "contaminants," are now agents of systemic disease. One prime example is the hyaline mold *Penicillium marneffei*, which causes a disseminated reticuloendothelial infection in patients with AIDS in Southeast Asia that resembles histoplasmosis clinically and pathologically.

The term *opportunistic* is now used to describe fungi that may be present in the environment or as part of our commensal microbiota that do not normally cause infection, but are able to infect when conditions change (i.e., the opportunity arises). These are fungi, usually of inherently low or limited virulence. Conditions that favor opportunistic infection include changes in the mucosal microbiota (e.g., antibiotics suppress bacteria and promote candidiasis); immunologic suppression (e.g., invasive zygomycosis in patients with poorly controlled diabetes mellitus); foreign material (e.g., *Candida* infections of indwelling intravascular catheters); and physical (e.g., sporotrichosis following inoculation trauma).

TABLE 21-1 Signs and Symptoms of Pulmonary Mycoses

Type of Infection	Signs and Symptoms
General	A transient influenza-like syndrome or pneumonia that localizes in one lobe or spreads to other lobes. Cough, minimal sputum production, dyspnea, tachypnea, hemoptysis. Chest pain, frequently pleuritic in nature. Rales or rhonchi and a pleural friction rub may be detected on auscultation. Roentgenography of the chest may reveal small pulmonary infiltrates and hilar adenopathy or more diffuse and confluent opacities.
Allergic bronchopulmonary	Symptoms characteristic of asthma: nonproductive cough, wheezing, and tightness in the chest. Episodic bronchospasm. Segmental atelectasis caused by plugging of bronchioles by mucus. Charcot-Leyden crystals and eosinophils in sputum; peripheral blood

	eosinophilia. Cutaneous hypersensitivity reaction to antigens of *Aspergillus* spp. Elevated serum IgE concentration and IgG anti- *Aspergillus* antibodies.
Fungus ball	Growth of fungus colony within a preexisting cavity. Hemoptysis, despite little or no invasion of cavity wall. Dissemination is rare, even in patients receiving corticosteroids.
Invasive	Symptoms of acute pneumonia. Low-grade, undulant fever. Cough may be productive or nonproductive; chest pain usually present. Progressive dyspnea and shortness of breath. Hemoptysis may indicate infarction and parenchymal necrosis. Chest radiography may reveal a diffuse infiltrate emanating from the hilum, finely nodular fibrosis, multifocal abscesses, or cavitation, depending on the fungus species. Clues to specific agents: "Millet seed" fibrosis: histoplasmosis Peripheral coin lesion: coccidioidomycosis Cavitary lesions: histoplasmosis, aspergillosis and other causes of hyalohyphomycosis, or coccidioidomycosis

1325

TABLE 21-2 Signs, Symptoms, and Probable Agents of Extrapulmonary Mycoses

Type of Infection	Signs and Symptoms
Cutaneous	Superficial scaling lesions—varying in size, shape, and color—of the thorax or back: tinea versicolor secondary to *Malassezia furfur* infection.
	Itching, scaling lesions known as tinea or ringworm: dermatophytosis
	Thickened, crusting, hyperkeratotic, exophytic fungoid affliction known as favus: *Trichophyton tonsurans, T. violaceum,* and *T. schoenleinii*
	Scaling or crusting lesions confined to the moist intertriginous areas of skin suggest yeast infections: *Candida albicans*.
	Primary subcutaneous pustular infection at the site of inoculation, with

	proximal spread and evolution of secondary skin ulcers along the course of the lymphatics: *Sporothrix schenckii* complex
	Nonhealing pustules, ulcers, or draining sinuses: disseminated dimorphic fungal diseases and mycetomas secondary to a variety of fungal agents.
	Purpuric lesions and subcutaneous cysts: phaeohyphomycosis.
	Fungating, discolored, hemorrhagic lesions: chromoblastomycosis.
CNS	Insidious onset of headaches that increase in frequency and severity, accompanied by nausea, irritability, and clumsiness; cryptococcosis. Meningitis and meningoencephalitis: zygomycosis, particularly in diabetics. Brain abscesses: *Cladophialophora bantiana*, other dematiaceous fungi; *Aspergillus* species.
Urinary tract	Pyelitis and pyelonephritis associated with long-term administration of antibiotics, corticosteroids, immunosuppressants, antineoplastic drugs, and prolonged insertion of indwelling catheters for urinary drainage, particularly in elderly women: candidiasis.
	Limited pyuria, lower abdominal pain, frequency of urination: nonbacterial cystitis in middle-aged women: *Candida glabrata*.
Ocular infections	Conjunctivitis, corneal infections, and keratoconjunctivitis: *Fusarium* spp., *Aspergillus* spp., *Cladosporium/Cladophialophora* spp., *Acremonium* spp., *Bipolaris* and others. Intraocular infections, usually following trauma or eye surgery: *Candida albicans*, *Aspergillus* spp., or *Zygomycetes* spp.
Endocarditis	Low-grade fever, cardiac murmurs, positive echocardiogram: *Candida* spp., *Aspergillus* spp., *Paecilomyces* spp. and others.
Sinusitis	Facial pain and cutaneous hyperemia, headache, low-grade fever, radiographic evidence of the filling of a sinus or air-fluid levels: *Aspergillus fumigatus*, *Alternaria* spp., *Pseudallescheria boydii* complex, and others.

Aspergillus species, *Candida* species, and members of the Zygomyces (i.e., agents of mucormycosis) are the three groups of fungi that cause the majority of opportunistic infections. However, as noted earlier, any fungus is a potential pathogen

in the profoundly immunocompromised host. This includes various genera of less commonly encountered hyaline and darkly pigmented (i.e., dematiaceous) molds that formerly were considered to be contaminants.

The general term for invasive infections caused by hyaline molds, which is usually used prior to the identification of the etiologic agent, is *hyalohyphomycosis*, whereas the general term for invasive infections caused by dematiaceous fungi is *phaeohyphomycosis*.[5,6] When the specific etiologic agent is known, then specific terminology of infection may be employed, such as aspergillosis or fusariosis. One could also state that the disease in a particular patient was a hyalohyphomycosis caused by *Pseudallescheria,* for example. The most important point to all this terminology is one of communication. This is because if the type of etiologic agent is not known, then more broad-spectrum antifungal agents will be used, whereas if the specific etiologic agent is known, then the possibility to tailor therapy may exist.

Common Mycologic Terms

A few additional terms warrant definition. The term *mycology* itself is derived from the Greek word *mykes*, a direct counterpart of the Latin word *fungus*, which is in turn thought to be a modification of the Greek word *sponges*, from which our word "sponge" is derived. There remains controversy around members of what has been traditionally referred to as *Zygomycetes*. Taxonomically, these are being

reassigned from the phylum *Zygomycota* to the phylum *Glomeromycota*, which is problematic, since the terms *zygomycosis* and *mucormycosis* are so ingrained in medical practices and in the medical literature for disease caused by these fungi. Clinicians would not know what glomeromycosis would represent if this term was universally used tomorrow. Many have continued to use zygomycosis, until the newer terminology becomes more well recognized. This is acceptable, since the reporting objective of the medical mycologist is to communicate to the physician the cause of disease so that appropriate therapy may be given. Finally, with respect to the *Zygomycetes*, the term *aseptate hyphae* has also become quite ingrained in medical practice and literature, although this is not technically correct, since rare septations may occur. Therefore, the term pauciseptate (i.e., few septations) or mucoraceous hyphae is preferred. This is important, since the failure to recognize zygomycete hyphae, because of the presence of rare septations, could lead to an inappropriate therapeutic decision, since *Zygomycetes* are innately resistant to voriconazole. Formerly, it was common to refer the fungus that demonstrated only asexual reproductive structures by the **anamorph** name, whereas if sexual reproductive structures were present, then the **teleomorph** nomenclature may be used. This, too,

was terribly confusing to our clinical colleagues and could contribute to errors in medicine. Fortunately, with the widespread genomic analysis of most of these organisms, it is now best practice to refer to the fungus by a single name. This was a true contribution of molecular methods to medical mycology. The continued application of molecular techniques should better define the true taxonomic position of fungi of medical importance, and hopefully will not be associated with too much reclassification, which often causes confusion.

Fungi are contained within their own kingdom, fungi, because of the characteristics unique to this group, as well as the lacking of characteristics present in other organisms. Fungi are **eukaryotic** (i.e., they possess a membrane-bound nucleus, as well as organelles, such as endoplasmic reticulum, Golgi apparatus, and mitochondria). They also possess a rigid cell wall composed of chitin (*N*-acetyl-D-glucosamine linked by β1-4 glycoside bonds) and mannans (polymers of glucose in α or β glycoside bonds). These cell wall constituents adsorb several dyes, which provide for the application of special stains by which they can be identified in laboratory mounts and tissue sections.

Fungi that exist predominantly as single cells, especially when in a liquid environment, and reproduce by budding are known as **yeasts**. Those with multiple cells forming a filamentous mycelium, which are more adapted to growing on or into a solid substrate, are known as **molds**. Fungi reproduce through the production of **spores**, which may be either sexually or asexually derived. The spores most commonly encountered in the laboratory are asexually derived and are referred to as **conidia**. There are a variety of different types of spores or conidia. These may be derived directly from the vegetative mycelium, such as **arthrospores, chlamydospores,** and **blastospores**, or special fruiting bodies (**conidiophores**). The morphology, arrangement, and mode of derivation of spores serve as important criteria by which genus and species identifications can sometimes be made. Additional terms used in the laboratory workup of fungi are presented in Box 21-1.

BOX 21-1

Terms Useful in the Examination of Fungi

The fundamental microscopic unit of a mold is the threadlike structure called a *hyphum.* Several hyphae combine to form the matt of growth known as the *mycelium.* Hyphae that are subdivided into individual cells by relatively abundant transverse walls or septae are called *septate;* those with very rare septations (i.e., the *Zygomycetes*) are *pauciseptate.* Sometimes in an individual preparation no septations are seen, and so the hyphae have been described as *aseptate,* when in fact they are *pauciseptate.* Pseudohyphae form from elongation of budding yeast cells (i.e., *blastoconidia*), and

show sausage-like constrictions between segments (Fig. 21-1).

The portion of the mycelium that extends into the substratum of the culture medium, and is responsible for absorbing water and nutrients, is the *vegetative mycelium*; the portion that projects above the substrate is the *aerial mycelium,* also called the *reproductive mycelium,* since special spore or conidia-bearing fruiting bodies (i.e., *conidiophores*) derive from this portion of the mycelium.

The traditional identification and classification of fungi are based primarily on the morphologic differences in reproductive structures and the manner in which spores or conidia are formed from specialized cells called *conidiogenous cells.*

Three general types of reproduction are commonly observed in the fungal species of medical importance, *vegetative* sporulation, *aerial* sporulation, and *sexual* sporulation.

Vegetative Reproduction

Three types of spores or conidia may form directly from the vegetative mycelium: *blastoconidia, chlamydoconidia*, and *arthroconidia*. The term *spore* should technically be reserved for reproductive elements that arise from meiosis (i.e., sexual reproduction), such as ascospores, oospores, or zygospores, whereas those that are derived from mitosis (i.e., asexual reproduction) are termed *conidia.* The term *endospore* is also used for asexually derived structures produced within the spherule of a *Coccidioides* species.

Blastoconidia are the familiar budding forms characteristically produced by yeasts. A bud scar (dysjunctor) often remains at the point at which the conidium becomes detached.

Chlamydoconidia (chlamydospores) are formed from preexistent cells in the hyphae, which become thickened and often enlarged. Although *chlamydoconidia* is the correct terminology, the term *chlamydospores* is also commonly used. Chlamydospores may be found within (*intercalary*), along the side (*sessile*), or at the tip (*terminal*) of the hyphae. This type of conidiation is characteristic of *C. albicans*.

Arthroconidia also are formed from preexisting cells in the hyphae, which become enlarged and thickened. This type of conidiation is characteristic of the mold form of *Coccidioides immitis* and *Geotrichum* species, among others.

Aerial Reproduction

Emanating from the hyphae and extending from the mycelial surface are specialized fruiting bodies that give rise to a variety of conidia. Fruiting bodies may form closed sacs called *sporangia,* within which spores called *sporangiospores* are produced (Note: these are termed sporangio *spores* even though they are asexually derived, which is a deviation from the rule described above). The specialized hyphal segment that supports the sporangium is called the *sporangiophore* (the suffix "phore" [Greek

phoros] means "bearing") (Fig. 21-2). This type of sporulation is characteristic of the *Zygomycetes*. Many other fungi produce elaborate fruiting bodies that give rise to conidia, which is derived from a word meaning dust. The specialized hyphal segment that supports a conidia-bearing fruiting head is called a *conidiophore* (Fig. 21-2).

The conidiophore may produce cells called *metulae,* which in turn produce conidia-producing segments, called *phialides.* This property of branching into metulae and phialides is characteristic of the fingerlike fruiting body of *Penicillium* species. Phialides by definition are conidiogenous cells that produce conidia from a locus inside its apex, which does not increase in width or length during conidiogenesis. This is in contrast to *annellide* formation, in which the tip of the conidiogenous cell cyclically extends and retracts when conidia are formed, leaving a succession of scars or rings. The conidia of *Scopulariopsis* spp. and *Exophiala* spp., for example, are *annelloconidia;* that is, form in basipetal sequence in which the conidiogenous part of each conidium elongates at the time a new conidium is formed, and then contracts to form a *ringlike scar, annulus,* or *collarette* at the truncated base. Conidia may be borne singly, in long chains (*catenulate*), or in tightly bound clusters. *Acropetal* is a term used to describe the process of chain formation in which each new conidium is derived in sequence from the previous one, so that the youngest cell is at the tip (e.g., *Penicillium* spp.). In contrast, *basipetal sporulation,* in which each new conidium forms at the base of the chain, pushing all other conidia in the chain ahead, so that the oldest cell is at the tip (e.g., *Paecilomyces* species).

Tiny one-celled conidia, usually borne either directly from the sides of the hyphae or supported by a hairlike conidiophore, are called *microconidia,* in contrast to the much larger, multicelled *macroconidia,* which assume a variety of sizes and shapes. A multicelled macroconidia that is divided by both transverse and longitudinal septations, giving a mosaic appearance, is a *dictyospore,* more commonly referred to as *muriform* (resembling a stone wall). The term *aleuriospore* refers to a conidium, usually a macroconidium that is attached to the hyphae by a supporting cell that fractures when the conidium is released (e.g., *Microsporum canis*). The detection of single-celled aleurospore produced by the submerged vegetative hyphae is important for the identification of *Aspergillus terreus.*

Sexual Sporulation

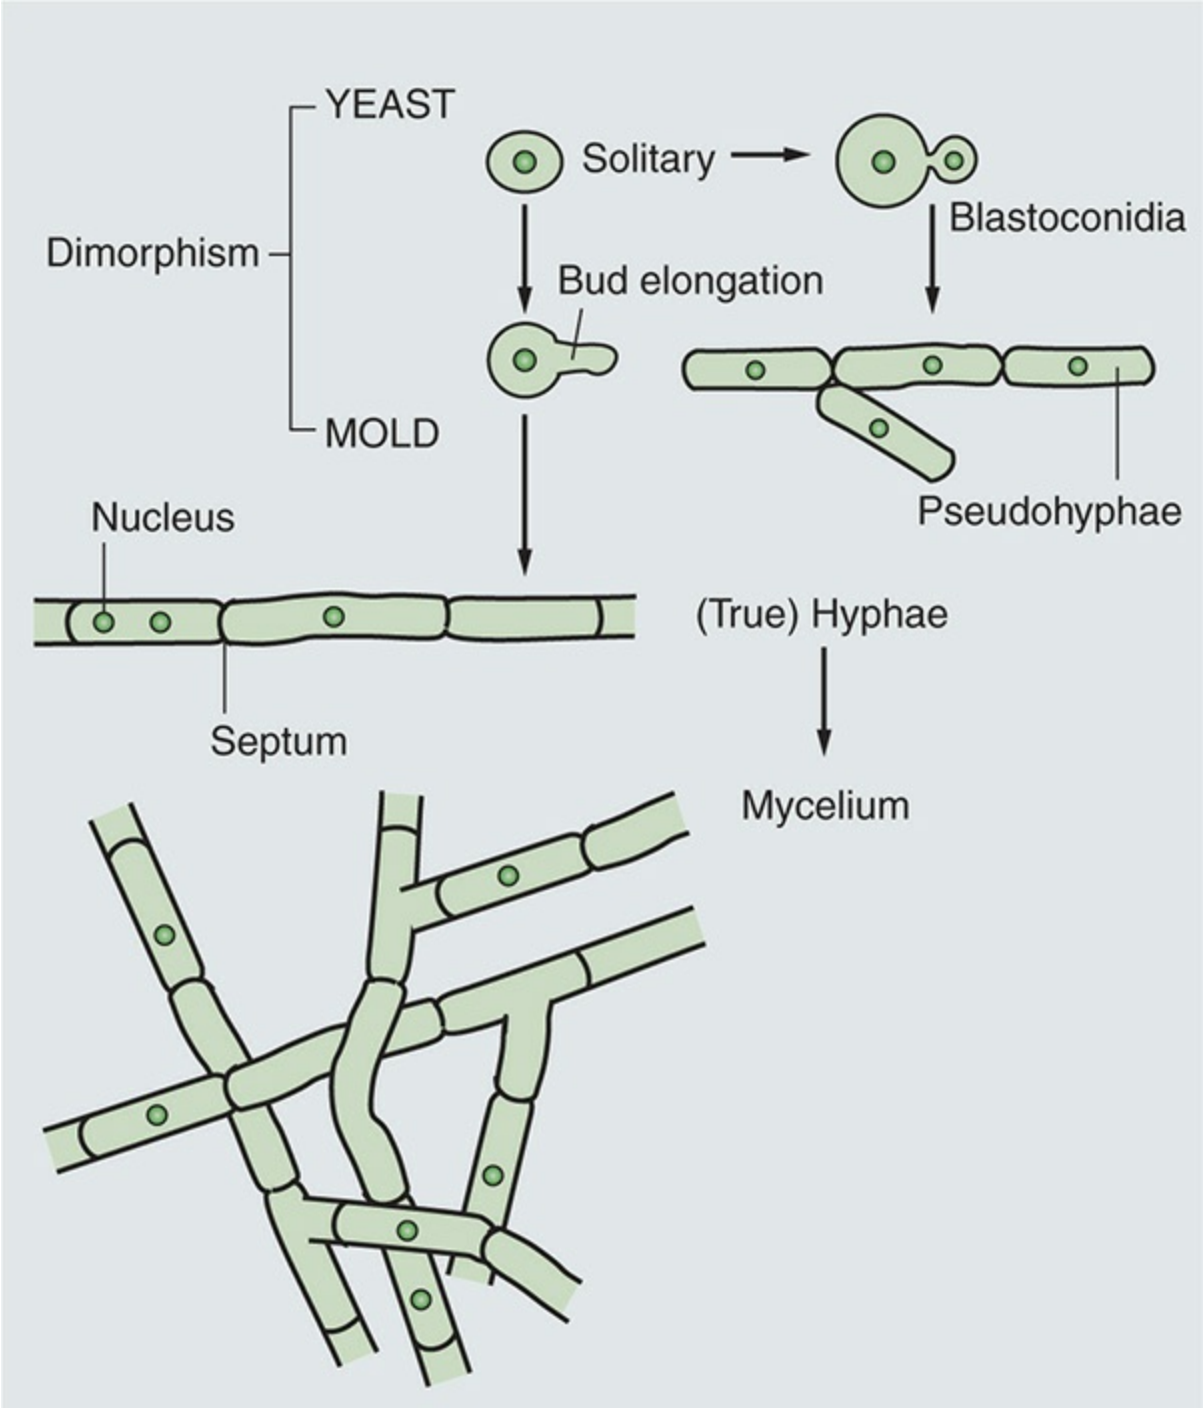
Sexual sporulation requires the merging and nuclear recombination of two specialized haploid, fertile cells (i.e., sex cells derived from meiosis). If the reproductive cells formed by fusion of morphologically identical cells, often from the same hyphae (homothallic), the spore is called a *zygospore,* characteristic of the *Zygomycetes*. If the fusing reproductive cells are derived from two different cells, often derived from separate hyphal segments, the resulting spore is called an *oospore* (Fig. 21-3).

The sexual spores of several members of the class *Ascomycetes,* previously mentioned, which are of medical importance, are called *ascospores.* For example, certain strains of *Aspergillus* species, notably of the *A. nidulans* and *A. glaucus* groups, produce large closed, baglike structures called *cleistothecia*, which in turn

contain smaller baglike structures called *asci* (Fig. 21-3). Within each ascus are four ascospores, the product of meiotic division. Medically important fungi, other than *Aspergillus* species, in which sexual sporulation may be observed include *Saccharomyces* spp. and members of the *Pseudallescheria boydii* complex (Fig. 21-3).

The sexual form of a fungus is known as a *teleomorph,* in contrast to the term *anamorph,* which refers to the various asexual reproductive forms or structures produced by an imperfect fungus (such as phialides, annellides, branching chains, etc.). The traditional approach of assigning different anamorphic and teleomorphic names, when both the asexual and sexual states are known is being changed, since it is now possible to definitively assign a fungus a genus and species based on genetic analysis. Therefore, the nomenclature in mycology will, hopefully, be less confusing in the future.

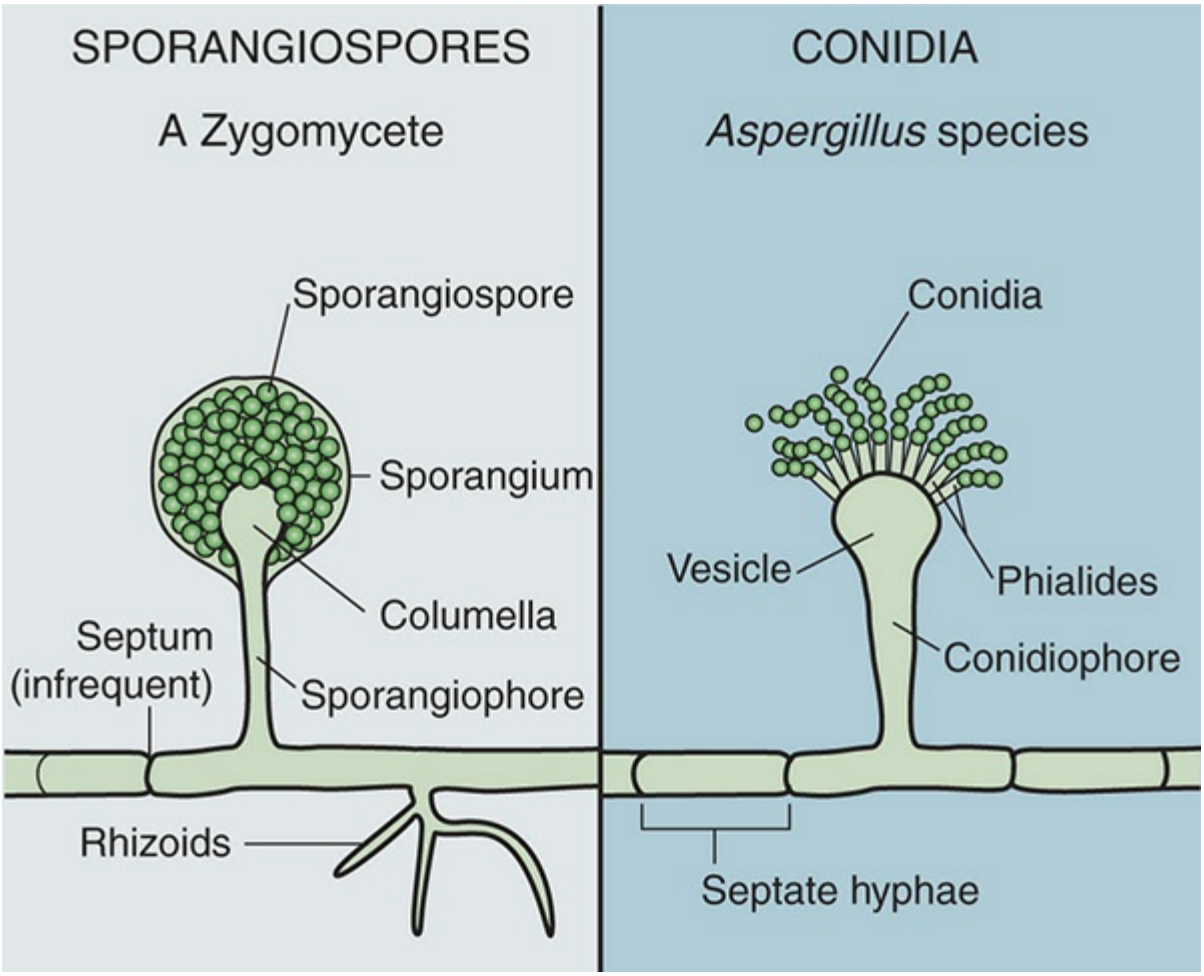
1328



■ **FIGURE 21-1** Sketches illustrating basic fungal structures.

Laboratory Approach to the Diagnosis of Fungal Infections

Once a fungus is recognized in culture, a presumptive-to-definitive identification is made based on a visual examination of the colony morphology, in conjunction with microscopic observations of a direct mount preparation. If only a presumptive identification is possible, consultation with the primary physician may be warranted to determine whether full genus or species identification is needed.



■ **FIGURE 21-2** Sketches illustrating complex asexual reproductive structures of a zygomycete and *Aspergillus*.

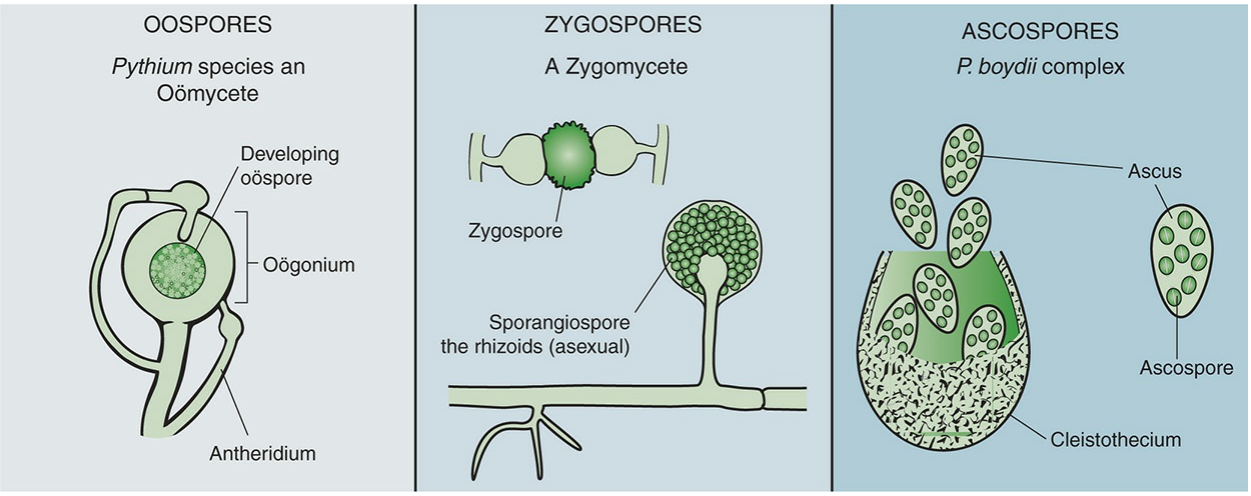
Although most fungal identifications are based primarily on the assessment of colony morphology and microscopic features, key biochemical tests may be required to differentiate closely related genera or species. Nucleic acid probe assays are available for the definitive identification of the dimorphic pathogenic fungi that are commonly encountered in North America. Serologic studies and antigen-detection tests are available for some fungi; these are used in some instances to aid in the diagnosis, assess the status of a previously diagnosed mycosis, or determine the efficacy of

therapy. Guidelines, therefore, will be set forth in this chapter to assist the mycologist in performing these various tasks, expanding from the laboratory observations to include assessments of the clinical parameters and the histopathologic criteria that must be interwoven to make a definitive diagnosis. Additionally, there is CLSI guidance on this topic: *Principles and Procedures for Detection of Fungi in Clinical Specimens—Direct Examination and Culture; Approved Guideline (M54-A).*[49]

The final laboratory identification of a fungal isolate, based on colonial and microscopic features, will be covered later in this chapter. The analytic phase begins with the performance of the direct examination, which may provide the first definitive evidence of a fungal infection. After this, the culture is reviewed for growth. Procedures must also be in place to provide guidelines for the workup of an unknown isolate, which should include the appropriate selection of differential tests, when needed, to make a genus/species identification. The paragraphs that follow detail these steps.

When appropriate, sections will also be included to briefly describe nonculture methods for establishing the identity of a given fungal species, using antibody, antigen, and molecular techniques. Nucleic acid sequencing is an option for difficult-to-identify fungi, particularly those that fail to sporulate. Prior to sending these for sequence-based identification, it is prudent to assure that they are actually thought to be responsible for the disease state of the patient. They are most commonly offered in academic settings and reference laboratories.[116] At this juncture, because of the technical expertise requirements and the cost of instrumentation and supplies, this technology will not be implemented in smaller laboratories, in which only basic practices are performed. However, more recently introduced mass spectrometry–based identification is becoming routine for the cost-effective identification in many laboratories. These methods have been demonstrated to perform well in the identification of yeasts, and protocols for the filamentous fungi are being worked out.

Likely, the most widely used, commercially available system for sequence-based identification of fungi has been the Applied Biosystems (Foster City, CA) MicroSeq D2 large-subunit rDNA fungal sequencing kit. A study of the use of nucleic acid sequencing for the identification of yeasts showed that 98% of 19 different species of *Candida* species seen in the clinical laboratory were correctly identified compared with identification by phenotypic methods.[115] DNA sequencing identified 32 isolates of yeasts belonging to nine genera, including *Trichosporon*, *Cryptococcus,* and others. Approximately 81% were correctly identified, and the primary reason for most incorrect identifications resulted from



■ **FIGURE 21-3** Sketches illustrating the structures of sexual reproduction.

a lack of data entries in the library containing sequences for many yeasts. Many of these issues have been addressed since these early studies. It is important to recognize that the quality of the identification is largely dependent on the quality of the sequence database, since the generation of high-quality DNA sequence is usually no longer a technical challenge. Other options include the use of public databases; although informative, these are not adequately curated, and so individuals who take this approach should review the quality of the sequence, the credentials of the laboratory that submitted the sequence, and use this information in conjunction with phenotypic features, whenever possible. SmartGene (www.smartgene.com) provides fee-for-service access to their curated database, which represents another option.

The identification of filamentous fungi has proven more challenging than the identification of yeasts. In another study performed at the Mayo Clinic to determine the usefulness of sequencing in identifying molds, nucleic acid sequencing identified 234 isolates (67.5%) to the correct genus or species level.[116] Incorrect identifications were primarily due to an incomplete list of sequences in the database. Each laboratory can construct a custom database of sequences or purchase access to curated databases, greatly enhancing the accuracy of performance. This technology offers great promise of simplifying the identification of yeasts and molds recovered from clinical specimens as well as those important to industry and agriculture. The Clinical Laboratory Standards Institute (CLSI) has published *Interpretive Criteria for Identification of Bacteria and Fungi by DNA Target Sequencing; Approved Guideline (MM18-A),* which is a must for the benchtop of those working in this area. How much DNA sequence–based identification will be used in the routine laboratory remains to be seen, but it will likely remain the means by which fungi are definitively characterized.

MALDI-TOF is a method of mass spectrometry, which has been introduced into

many laboratories in the form of one of two FDA-approved instruments. These both have FDA-approved libraries for the identification of yeasts, but no libraries are yet approved for filamentous fungi. As with bacteria, this approach, for the most part, is fast, accurate, and inexpensive. The traditional approach to yeast identification (i.e., biochemicals, assimilations, and cornmeal agar morphology) is already changing in laboratories that have validated and implemented this technology. Westblade et al. evaluated a collection of 852 medically important yeasts by MALDI-TOF mass spectrometry and reported that 96.6% were identified to the genus level and 96.1% were identified to the species level. DNA sequencing of the D2 region was used as the comparative gold standard.[287] Others have reported similar findings, which demonstrate the usefulness of this technology. Applications for the filamentous fungi are being developed.

Specimen Collection and Transport

There are many preanalytic parameters that are important for the optimal recovery of fungi from clinical specimens. A lapse in any of these may result in a failure or delay of recovery of the pathogenic agent, which, in turn, could result in untoward clinical consequences. Preanalytic parameters of importance begin with only culturing those patients in whom mycoses are suspected. Once this is determined, proper collection of the specimen is paramount. The use of swabs is inappropriate for the detection of infections caused by filamentous fungi due to inadequate sampling and an inability to disassociate the hyphal elements from the human tissues in which they are invading. Next to be considered is suboptimal specimen transport and/or processing, which may result in a loss of viability. Specimens should be delivered to the laboratory promptly. Specimens that are not processed immediately should be held at room temperature. *Cryptococcus neoformans*, *Histoplasma capsulatum,* and *Blastomyces dermatitidis* do not survive well in frozen or iced specimens. Several fungal species, including the above-named species, and *Aspergillus* spp. can be recovered from samples that have been in transit for as long as 16 days if not allowed to dry out; therefore, an attempt should always be made to recover fungi even if processing is delayed.[244]

1330

Sealed, sterile transport containers should be used for all liquid or moist specimens. Skin scrapings, nail fragments, and hairs can be transported dry in an envelope, Petri dish, or other convenient conveyance. To curtail the growth of commensal bacteria possibly present in nonsterile specimens that may be delayed in processing or mailed to a reference laboratory, penicillin (20 U/mL), streptomycin (100,000 mg/mL), or chloramphenicol (0.2 mg/mL) can be added to the specimen. Directions for the proper packaging and labeling of specimens for shipping and mailing are discussed in Chapter

2.

Physicians, nurses, ward personnel, and laboratory technologists must work together in developing protocols that ensure the proper collection and prompt transport of specimens submitted for fungus culture. The selection of appropriate collection devices and transport containers, affixing labels that include pertinent patient information, and establishing a means of communication for special requests are possibly the most important considerations in ensuring the accurate diagnosis of fungal infections.

General guidelines for the collection and transport of specimens for culture are given in Chapter 2. Guidelines for the collection of various types of specimens are presented in Table 21-3. The criteria by which a specimen is judged unacceptable for culture and rejected should be written in the laboratory procedure manual. This information should also be noted in the test directory for the laboratory and communicated to clinicians. In Box 21-2, select rejection criteria and the actions to be taken for handling unacceptable specimens are presented. These criteria must also be understood by physicians, nurses, and other personnel who are assigned to collect the specimen, as not only will time and money be saved in the mycology laboratory, but an unacceptable delay in establishing the diagnosis can be avoided. Individual criteria must be established within each practice setting to accommodate practice in the local setting. With experience, the individual collecting the specimen can make a preliminary assessment of the material obtained and immediately collect a second specimen, if necessary.

Specimen Processing

Then, following the prompt transport of the specimen and receipt in the laboratory, it is important that specimens are inoculated onto the appropriate primary fungal culture media. Once received in the laboratory, a specimen should be examined as soon as possible. As mentioned, swab specimens are inadequate for the recovery of molds. These, however, are acceptable for the recovery of yeasts from patients with mucosal candidiasis (e.g., thrush or vulvovaginal candidiasis). Whenever possible, aspirated material or tissue biopsies should be submitted, as these are the optimal specimens. Direct wet mounts or smears should be prepared (see below), if appropriate, and a portion of the specimen transferred to appropriate fungal culture media. It is critical that when tissue specimens are submitted that portions of tissue are placed onto and pushed into the agar media to enhance recovery. The appropriate processing of specimens is critical in the ultimate recovery of fungi and should not be neglected or delegated to marginally trained personnel. Further guidelines for the processing and direct examination of clinical specimens are presented in Table 21-4.

TABLE 21-3 Recommendations for Specimen Collection for Fungus Culture

Specimen	Recommended Procedure
Sputum	The first early-morning sample should be collected after rising, but before breakfast. Patients are instructed to vigorously rinse their mouths with water immediately before coughing 1/2–1 oz of sputum into a sterile, screw-capped container. Sputum induction with a heated aerosol saline suspension may be required if an adequate specimen cannot be obtained.
Bronchoscopy	Bronchial brushings, biopsy, or bronchoalveolar lavage fluid should be transported promptly to the laboratory in sterile, sealed containers. Middlebrook 7H11 broth is used in some laboratories as a transport medium because mycobacteria will also be preserved.
Cerebrospinal fluid	As much CSF as possible should be used for the culture of fungi. If processing is to be delayed, samples should be left at room temperature because CSF is an adequate fluid culture medium in which fungal elements can survive until subcultured.
Urine	The first early-morning urine sample is preferred; random samples are acceptable. Specimens should be collected aseptically in sterile, screw-cap containers and sent immediately for processing. If a delay in processing beyond 2 hours is anticipated, the urine sample should be refrigerated at 4°C to inhibit overgrowth by rapidly growing bacteria.
Prostatic secretions	Some deep-seated mycoses, notably blastomycosis and, less commonly, histoplasmosis or coccidioidomycosis, may infect the prostate. The bladder is first emptied, followed by prostatic massage. Secretions should be inoculated directly into appropriate fungal culture media; also, 5–10 mL of urine should be collected in a separate container.
Exudates	The skin over pustular lesions should be disinfected and exudates aspirated using a sterile needle and syringe. The aspirated material should be discharged into a sterile specimen transport container, and the needle-bearing syringe discharged in an appropriate biohazard (i.e., “sharps”) container. The needle-bearing syringe should not be sent to the laboratory, as this represents an occupational hazard. Biopsy of the lesion may be necessary if the aspirate fails to yield fungi.
	First, swab the area of skin to be sampled with 70% alcohol to remove surface bacterial contaminants. Sample the peripheral,

Skin, nails, hair	erythematous, growing margin of typical "ringworm" lesions, scraping with the side of a glass microscope slide or the edge of a scalpel blade. Infected nails should be sampled from beneath the nail plate to obtain softened material from the nail bed. If this is not possible, scrape away the surface of the nail before collecting shavings from the deeper portions. Hairs should be collected from areas of scaling or alopecia, or those that fluoresce when viewed under a Wood's (long-wavelength) ultraviolet lamp.
Tissue biopsies	Tissue biopsies of suspected sites of infection should be transported in a sterile gauze moistened with physiologic, nonbacteriostatic, sterile saline solution in a screw-cap container. The specimen should not be frozen or allowed to dehydrate prior to culture. If the tissue biopsy is not bisected with half sent for histopathologic review, then a second biopsy, adjacent to the first, should be submitted for this purpose.
Blood	Standard blood cultures are sufficient for the recovery of most yeasts. However, a fungal blood culture that utilizes a lysis-centrifugation systems, such as the Isolator (Wampole Laboratories, Cranbury, NJ), is highly recommended, particularly for the recovery of *H. capsulatum*.

1331

BOX 21-2

Criteria for Specimen Rejection

Situation: Absence of patient identification on the container, or a discrepancy between the information on the request form and the container label.
Action: Return to sender for resolution.

Situation: Sputum specimen with >25 squamous epithelial cells per low-power field (i.e., criteria for rejection of respiratory samples submitted for bacterial culture).
Action: The criteria for rejection of specimens submitted for bacterial culture do not pertain to fungal specimens. Pathogenic fungi may be recovered from such specimens in the presence of oral contamination, if an antibiotic-containing selective culture medium is used, which is recommended.

Situation: A dried-out swab is received or the material collected is insufficient in

volume.
Action: Inform the person submitting the specimen to send a second sample, if possible. As a general criterion, swab specimens are not suitable for the recovery of fungi, with the exception of yeasts from a mucosal surface (e.g., vagina) and should be rejected, except in unusual circumstances. Rather, deep aspiration or biopsy of the affected site may be necessary, depending on the clinical presentation.

Situation: The sample is submitted in an improper container or in an unsuitable condition (evidence of drying, leakage, or lack of sterility).
Action: Notify the individual submitting the specimen that the chance for obtaining relevant results is compromised. If a second specimen cannot be conveniently obtained, process the specimen, but indicate on the final report that the quality of the specimen was compromised and that the result can be interpreted only in light of the clinical presentation.

Situation: A 24-hour sputum or urine specimen for fungal culture is received.
Action: It should be understood in the rejection protocol that 24-hour sputum and urine samples are suboptimal for the recovery and identification of fungi. Chances for contamination with bacteria and environmental molds are high, confusing any results that may follow. Establish in the protocol that first early-morning samples should be obtained on three successive days. As is the case with the culture recovery of mycobacteria, fungi also tend to be shed at intermittent intervals, thus making the chance of recovery much higher if successive samples over 3 days are collected.

Direct Examination

It is highly recommended that a direct microscopic examination be made on most specimens submitted for fungal culture. This may provide the first definitive evidence of a fungal infection for the physician. It may also aid in the selection of appropriate culture media, but in practicality, the inoculation of media is usually performed simultaneously with the preparation of the slides for the direct examination. KOH/calcofluor mounts are likely the most commonly used direct examination preparations, although laboratories without fluorescence microscopy capabilities may perform KOH preparations and traditional microscopy. The advantage of the former is the ease of detection of fungal elements, which fluoresce brightly when stained with calcofluor white. In either preparation, the KOH serves to dissolve human cells, which lack a cell wall.

In settings wherein there is a high prevalence of HIV, the India ink stain remains useful. Although this method of direct examination is not as sensitive as the cryptococcal antigen test, it is rapid, inexpensive, and may be highly specific when

used by an experienced microscopist. The frozen section evaluation of tissues removed during surgeries is also a form of direct examination. All these methods afford the opportunity to provide rapid results to the clinician, which may translate into the more rapid administration of antifungal therapy and better outcomes for the patient.

When fungal elements are recognized in a direct examination, there should be an attempt to further characterize the structures present. Reporting of the fungal elements as "fungal elements" is only marginally useful to the clinician. This should only be reported in instances wherein it is not possible to further characterize the structures present. If one is in this situation, a consultation with a more experienced microscopist should be considered. The microscopist performing the direct examination should try to characterize the fungal elements as budding yeasts, yeasts with pseudohyphae and/or true hyphae, hyaline septate hyphae, dematiaceous hyphae or mucoraceous hyphae (i.e., broad, pauciseptate hyphae). If specialized fungal forms are seen, such as the spherule of *Coccidioides* or the broad-based bud and double-contoured cell walls of *Blastomyces dermatitidis*, then these should be reported, as they provide a definitive diagnosis from the direct specimen.

1332

TABLE 21-4 Guidelines for Direct Examination and Processing of Specimens Submitted for Fungal Cultures

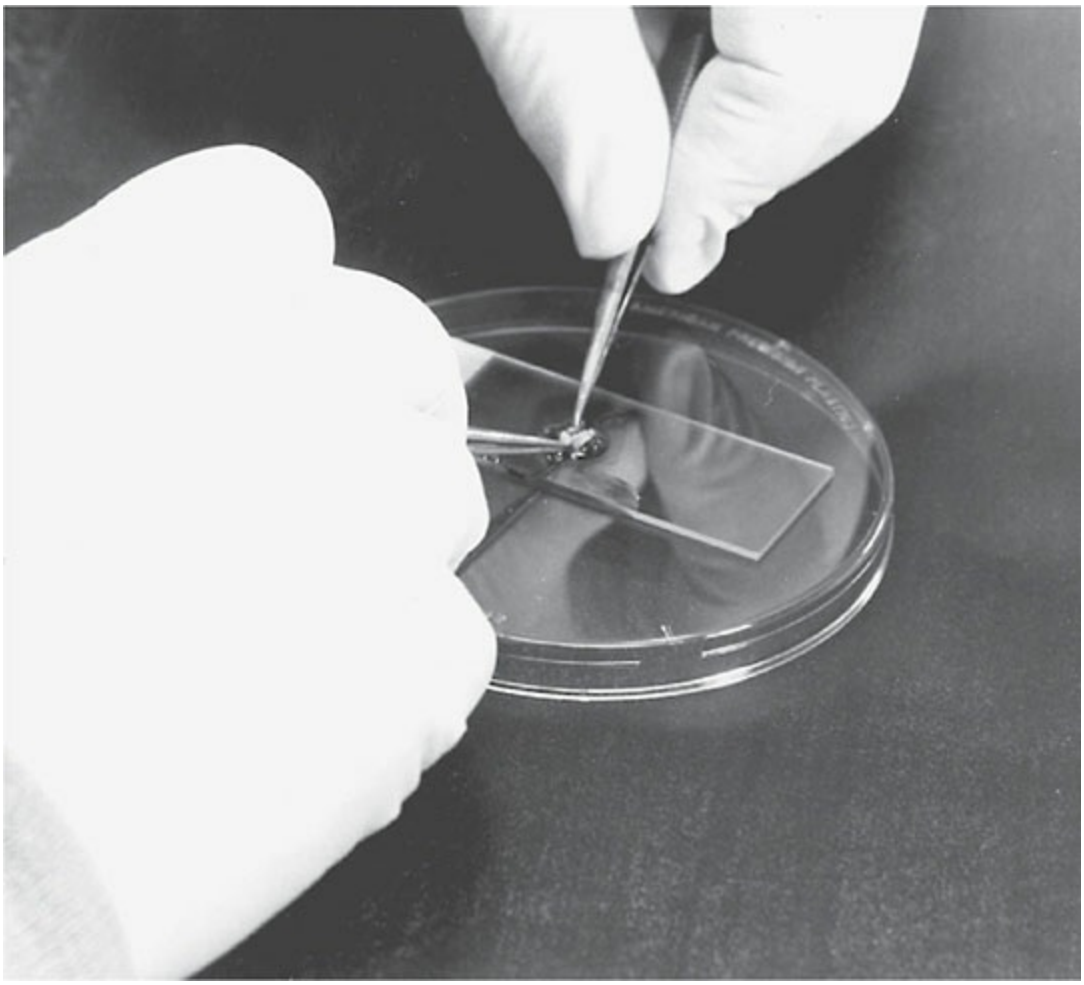
Respiratory	The sputum quality-grading system described in Chapter 2 is not applicable to specimens submitted for fungal cultures. Select the most purulent or blood-flecked parts of the sample. If the sample is highly viscid, it should be homogenized by adding a small amount of crystalline *N*-acetyl-L-cystine to the specimen. NaOH or other digesting agents, used for the processing of specimens for the recovery of mycobacteria, should not be used prior to fungal culture. Prepare a mount of the homogenized sample for direct microscopic examination and inoculate about 0.5 mL to each of the culture media to be used. Because respiratory secretions are often contaminated with bacteria, media containing antibiotics should be used. A combination of a nonselective agar, such as potato flake agar, and an inhibitory agar such as brain-heart infusion with chloramphenicol and cycloheximide are recommended.
	CSF samples may be centrifuged at 1,500–2,000 *g* for 20 minutes and the sediment inoculated onto the surface of noninhibitory culture media, such as potato flake agar. Preferably, if more than 2 mL of fluid is available,

Cerebrospinal fluid	pass fluid through a 0.45-µm membrane filter. Place the filtrate side of the filter paper face down on the surface of appropriate culture medium. The paper should be repositioned to other sites on the medium using sterile forceps on an every-other-day schedule. If only a scant amount of fluid is provided, spot-inoculate the surface of the agar medium directly in three- or four-drop aliquots. The India ink (nigrosin is an acceptable substitute) mounts may be prepared when *Cryptococcus neoformans* is suspected, but performing cryptococcal antigen testing is preferred as a more sensitive alternative. To prepare the mount, either a drop of the centrifuged sediment or a small amount of material from the surface of the membrane is mixed with a drop of India ink on a microscope slide. A coverslip is applied and the mount microscopically examined for the presence of encapsulated, budding yeast forms.
Urine	Centrifuge about 10 mL of urine sample, then inoculate 0.5 mL of sediment to both a noninhibitory agar, such as potato flake agar, and to an inhibitory medium, such as brain-heart infusion agar, containing chloramphenicol and cycloheximide. Direct mounts can be prepared and examined microscopically for yeast or hyphal forms, but this is rarely done in practice.
Skin, nails, hair	Skin scales, nail scrapings, and hairs should be examined after KOH treatment. The KOH preparation is made by emulsifying the specimen in a drop of 10% KOH on a microscope slide. The purpose of the KOH is to clear out any background scales or cell membranes that may be confused with hyphal elements. Clearing can be accelerated by gently heating the mixture over the flame of a Bunsen burner or more commonly on a slide warmer. A coverslip is applied, and the specimen is examined for the presence of narrow, regular hyphae that characteristically break up into arthroconidia. The visualization of hyphae is improved by adding calcofluor white to the potassium hydroxide reagent and examining with a fluorescence microscope fitted with filters of appropriate wavelengths. With hairs, mosaic arrangement of spores may be seen on the surface of the shaft (ectothrix infection) or hyphal fragments and arthroconidia may be seen internally (endothrix infection). Skin scales, nail scrapings, or hairs should be placed directly on the surface of the culture medium, such as brain-heart infusion agar with chloramphenicol and cycloheximide (commercially available as Mycosel or Mycobiotic agars). With a straight inoculating wire, submerge a few of the fragments beneath the agar surface. Examine in the areas of inoculation at frequent intervals for the appearance of surface colonies. Hold cultures for a minimum of 30 days before discarding as negative.

Tissue	When processing tissues for the recovery of fungi, the use of a mortar and pestle or a tissue grinder should be avoided. The hyphal forms can easily be destroyed by grinding, making it difficult to recover viable organisms in culture, particularly if the pauciseptate hyphae of one of the *Zygomycetes* are present. Rather, mince the tissue into 1-mm cubes with sterile scissors or a sharp scalpel blade and place the tiny fragments directly onto the agar, submerging them slightly beneath the surface with an inoculating needle. A 5–10 mL sample of tissue homogenate, bone marrow, or fluid specimen sediment should be placed onto the surface of appropriate culture media. Nonselective culture media, without antibiotics, such as potato flake agar, is adequate, as these specimens are usually sterile and antibiotic inhibition is not necessary.
Blood	Commercial blood culture bottles, designed for the recovery of bacteria from blood are adequate for the recovery of yeasts associated with bloodstream infections (e.g., *Candida* species). The Wampole Isolator Blood Culture System (Alere) is recommended for the detection of *H. capsulatum*. The filamentous fungi rarely grow in blood cultures, with the exception being *Fusarium* species.

Preparation of Mounts From Cultured Isolates

The tease mount, the dig mount, the cellophane tape preparation and the microslide technique are four commonly used methods for the microscopic examination of filamentous fungi (i.e., molds).[153] The tease mount (Figure 21-4) is accomplished by obtaining surface or aerial hyphae and conidiophores with a loop or hook. The dig mount is rarely used, but as the name implies, the loop or hook is used to dig out mycelium that is submerged, so as to demonstrate structures produced in this area, such as aleuroconidia. The cellophane tape preparation (Figure 21-5) uses this type of tape to touch the aerial hyphae and conidiophores, which become adherent to the tape for subsequent microscopic evaluation. Finally, the microslide culture technique (Figure 21-6) is usually reserved for those instances wherein a mold cannot be identified using the former methods, but is considered clinically important. This method involves the cultivation of the mold directly onto glass slides, which affords the assessment



■ **FIGURE 21-4** Tease mount preparation, illustrating dissection of the colony fragment with needles in a drop of lactophenol aniline blue prior to placement of the coverslip. These preparations should be performed in a biological safety cabinet.

of their microscopic morphology with minimal mechanical disruption.

In each instance, a portion of the mold colony is mounted in a drop of lactophenol aniline (cotton) blue stain on a glass slide and examined microscopically. The techniques for performing the tease mount (Box 21-3), the cellophane tape preparation (Box 21-4), and for the microslide culture (Box 21-5) are presented. Additional terms used in the laboratory workup of fungi are presented in Box 21-1.

Selection and Inoculation of Culture Media

The battery of culture media for the recovery of fungi from clinical specimens need not be elaborate. Although the recovery rate may be somewhat enhanced by using a variety of isolation media, considerations of cost, storage, and incubator space and demands on technologist time generally dictate a more conservative approach in most

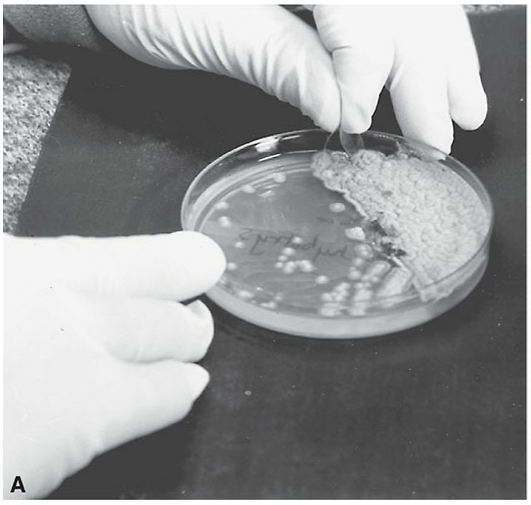
laboratories.

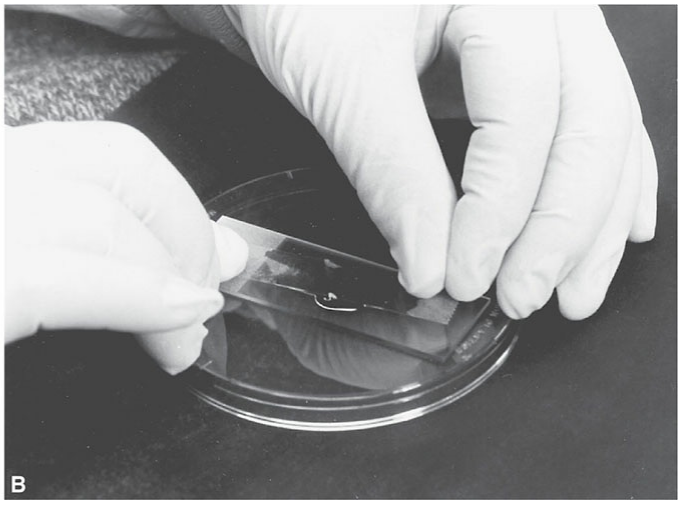
Three general types of culture media are essential to ensure the primary recovery of all clinically significant fungi from clinical specimens. One medium should be nonselective, such as potato dextrose, potato flake or brain-heart infusion agar. This type of media not only will permit the growth of virtually all clinically relevant fungal species, but also will support the growth of some bacteria. The use of Sabouraud's dextrose agar (SDA) as a primary recovery medium is discouraged because it is insufficiently rich to recover certain fastidious pathogenic species, particularly most of the dimorphic fungi. Rather, the use of potato flake agar (PFA), potato dextrose agar (PDA), inhibitory mold agar (IMA), or combination of Sabouraud's dextrose agar with heart infusion (SABHI) agar is recommended.[153] SDA is sufficient for the recovery of dermatophytes from cutaneous samples or yeasts from mucosal cultures. The use of either Mycosel or Mycobiotic agar, which essentially is SDA with cycloheximide and chloramphenicol added, may be considered for the recovery of dermatophytes.

V8 agar or carnation leaf agar are glucose-poor media that are useful for the subculture of fungi recovered on enriched medium to enhance typical sporulation. Czepak's agar has classically been used for the subculture of *Aspergillus* species, if the colony morphology is not typical and deemed important for the identification of an unknown isolate.

For the recovery of the more fastidious dimorphic fungi, such as *Blastomyces dermatitidis* and *H. capsulatum*, an enriched agar base such as IMA, SABHI, or brain–heart infusion (with cycloheximide and chloramphenicol) should be considered. Table 21-5 lists the more commonly used fungal isolation media, the key ingredients in each formula, and the specific applications for which each is designed.

The use of a secondary media that contains antibacterial antibiotics should be used for the culture of fungi from





■ **FIGURE 21-5** **A.** Transparency tape preparation: the sticky side of tape being pressed to the surface of the fungus colony. **B.** Transparency tape preparation: stretching the inoculated tape over a drop of lactophenol aniline blue on the surface of a microscope slide. These preparations should be performed in a biological safety cabinet.

■ **FIGURE 21-6** Series of photographs outlining the preparation of a microculture. See Box 21-5 for details. These preparations should be performed in a biological safety cabinet.

BOX 21-3

Procedure: The Tease Mount

- With a pair of dissecting needles or pointed applicator sticks, dig out a small

portion of the colony to be examined, including portions of the subsurface agar.
- Place the colony fragment on a microscope slide in a drop of lactophenol aniline blue, tease the colony apart with the dissecting needles (Fig. 21-4), and overlay with a coverslip.
- Gentle pressure on the surface of the coverslip with the eraser end of a pencil may help to disperse the mount, particularly if small pieces of agar are present.
- Examine the preparation microscopically, first under the low-power (10×) objective and then under high-power (40×) objective or under oil immersion (100×), if necessary. Oil immersion microscopy is usually not necessary, but is helpful in visualizing annellides.
- Teasing the colony often disrupts the delicate fruiting structures of the filamentous molds, making it difficult in some instances to observe the characteristic spore arrangements or hyphal attachments necessary for a definitive identification. In such cases, a transparency tape mount or microslide culture may be required.

clinical specimens that are from anatomic sites that normally contain bacterial microbiota. The addition of one or more antibiotics, including penicillin (20 U/mL), streptomycin (40 U/mL), gentamicin (5 mg/mL), or chloramphenicol (16 mg/mL) may be used to inhibit the growth of bacteria. IMA is perhaps a poorly named media that actually contains antibacterial antibiotics that inhibit bacterial growth (i.e., it does not inhibit the growth of molds).

Just as bacterial overgrowth may interfere with the recovery of a slowly growing fungal pathogen, so, too, may rapidly growing fungal contaminants overgrow a culture plate and interfere or inhibit the recovery of the more slowly growing fungal pathogen. This third type of media contains cycloheximide (Acti-Dione) in a concentration of 0.5 mg/mL which is added to prevent the overgrowth of certain rapidly growing environmental molds. If a medium that incorporates

BOX 21-4

Procedure: Cellophane Tape Preparation

- The cellophane or transparency tape method of preparing cultures for microscopic examination is often helpful because the conidial arrangements of the more delicate filamentous molds are better preserved.
- Press the sticky side of unfrosted, clear cellophane tape gently but firmly to the surface of the colony, picking up a portion of the aerial mycelium (Fig. 21-5A).

This operation should always be performed under a biologic safety hood. Gloves should always be worn, but still take care not to touch the surface of the colonies and contaminate the gloves.

- The preparation is made by placing a drop of lactophenol aniline blue stain on a microscope slide.
- Stick one end of the tape to the surface of the slide adjacent to the drop of stain.
- Stretch the tape over the stain, gently lowering it so that the mycelium becomes permeated with stain (Fig. 21-5B).
- Pull the tape taught and stick the opposite end to the glass, avoiding as much as possible the trapping of air bubbles.
- Some practice may be needed in removing the sticky surface of the tape since gloves are worn.
- The preparation can now be examined microscopically in the same manner as described above for the tease mount preparation, with the exception that the use of oil immersion is generally less than satisfactory because of interference from the substance of the tape.
- The transparency tape method is inexpensive, rapid, simple to perform, and, with few exceptions, allows one to make an accurate identification.

BOX 21-5

Procedure: The Microslide Culture Technique

The microslide culture technique is recommended in instances wherein neither the tease mount nor the transparency tape preparation establishes an accurate identification, or when permanent slide mounts are desired for further study or for study use by students. Although somewhat tedious to perform, high-quality preparations in which the spore structures and arrangements are beautifully preserved can be made. The technique is as follows:

1. Place a round piece of filter paper or gauze flat on the bottom of a sterile Petri dish. Place a pair of thin glass rods or applicator sticks cut to length to fit on top of the filter paper to serve as supports for a 3-in.× 1-in. glass microscope slide (Fig. 21-6A).
2. Place a block or plug of cornmeal agar or PDA (Fig. 21-6B) on the surface of the microscope slide (Fig. 21-6C). Two blocks, separated by about 1 in., can be placed on the same microscope slide if more than one mount is desired.
3. Inoculate the margins of the agar plug in three or four places with a small portion of the colony to be studied, using a straight inoculating wire or the tip of a dissecting needle (Fig. 21-6D and E).
4. Gently heat a coverslip by passing it quickly through the flame of a Bunsen burner

and immediately place it directly on the surface of the inoculated agar block. Heating the coverslip produces a tight seal between the bottom of the coverslip and the surface of the agar, which is briefly melted by the warm glass.

5. Pipette a small amount of water into the bottom of the Petri dish to saturate the filter paper or the gauze. Place the lid on the Petri dish and incubate the assembly at room temperature (or 30°C) for 3 to 5 days.
6. When growth visually appears to be mature (Fig. 21-6F), the coverslip can be gently lifted from the surface of the agar with a pair of forceps, taking care not to disrupt the mycelium adhering to the bottom of the coverslip (Fig. 21-6G).
7. Place the coverslip on a small drop of lactophenol aniline blue applied to the surface of a second 3-in.× 1-in. glass slide (Fig. 21-6H). The mount can be preserved for future study by rimming the outside margins of the coverslip with mounting fluid or clear fingernail polish. This activity should be performed under a biologic safety hood.
8. After the coverslip has been removed from the agar block (or blocks), the agar block itself can be removed by prying it away from the glass slide with an applicator stick. This operation is performed over a beaker or pan containing 5% phenol decontamination fluid, into which the agar blocks are placed. The mycelium adhering to the surface of the original glass slide after the block is removed can also be stained with lactophenol aniline blue and a coverslip overlaid, serving as a second stained mount. Again, the mount can be preserved for future study by rimming the coverslip with mounting fluid or fingernail polish, as previously described.

1336

TABLE 21-5 Common Fungal Culture Media and Indications for Use

Culture Media	Essential Ingredients	Indications for Use
Brain-heart infusion agar	Calf brain and beef-heart infusions; proteose peptone, NaCl, disodium phosphate, and agar. (Cycloheximide and chloramphenicol may be added for selective recovery of dermatophytes and dimorphic molds.)	Primary recovery of saprophytic and dimorphic fungi
Inhibitory Mold Agar (IMA)	Tryptone, beef extract, yeast extract, dextrose, starch, dextrin, chloramphenicol, gentamicin, and	Primary for the recovery of fungi from specimens that contain bacterial

	saline buffers	microbiota
Mycosel/Mycobiotic agars	Phytone peptone, dextrose, agar, cycloheximide, chloramphenicol	Primary recovery of dermatophytes and dimorphic fungi
Sabouraud's heart infusion agar (SABHI)	Potato flakes, dextrose, agar	Primary recovery of saprophytic and dimorphic fungi, particularly fastidious strains
Sabouraud's dextrose agar	Dextrose, neopeptone, agar	Although this is a traditionally used medium, it is not optimal. Fungi grow well on the medium, but do not sporulate well due to the high glucose content
Potato flake agar	Potato flakes, dextrose, agar	Primary recovery of saprophytic and dimorphic fungi, particularly fastidious and slow-growing strains

cycloheximide is used in the battery of fungal media, then it is imperative that a nonselective medium must always be used in parallel. Opportunistic pathogenic fungi, such as *Cryptococcus neoformans* and *Aspergillus fumigatus,* are partially or totally inhibited by cycloheximide, and could be missed, if only a cycloheximide-containing medium was used for fungal culture. Cycloheximide-containing media are particularly useful for fungal cultures for dermatophytes and dimorphic fungi. It is particularly useful for dermatophyte cultures, since some specimens, like nails, may contain transient fungal microbiota that would overgrow and obscure the presence of the dermatophyte. Similarly, some of the dimorphic pathogens, like *H. capsulatum*, are slow-growing and could potentially be overgrown by a stray spore of a contaminating species (e.g., *Aspergillus niger*). The presence of cycloheximide would inhibit the growth of the contaminating fungus and allow the pathogen to grow.

Again, whenever cycloheximide is used, it is critical to include a similar medium without cycloheximide in parallel. This is because the disease of the patient may actually be caused by a fungal species that is susceptible to cycloheximide, and if a cycloheximide-containing medium alone were used, then a false-negative culture result

would be given.

Incubation of Fungal Cultures

It is currently recommended that all fungal cultures be incubated at a controlled 30°C. A former practice of incubating a second set of plates at 35°C for the recovery of the yeast forms of dimorphic fungi is not cost-effective nor needed given the molecular methods currently available to confirm dimorphic fungal pathogens. Similarly, the previous practice of attempting to convert fungal isolates suspected of being dimorphic molds to their yeast form has largely been replaced by nucleic acid probe assays or other molecular methods. The probe assay can be performed as soon as colonies are visualized on the primary recovery media, prior to the observation of diagnostic sporulation, in instances wherein disease secondary to these fungi is suspected.

All fungal cultures should be incubated for a minimum of 30 days before discarding as negative, even if plates appear contaminated with bacteria or other fungi. Colonies of *H. capsulatum*, for example, may be observed growing on the surface of colonies of *Candida albicans* or on the top of contaminating molds.

The choice between the use of culture tubes or plates is optional. Some low-volume laboratories, staffed with personnel who may not be as familiar with the handling of fungi, or where incubator and storage space may be at a premium, have opted for the use of tubes. Large culture tubes (150 × 25 mm) with screw-cap lids are recommended. The media should be poured in thick slants to prevent dehydration during the prolonged incubation period. After the medium is inoculated, the cap should not be tightened too much, because the anaerobic environment that will soon result will inhibit fungal growth. The cap should be tightened enough so that it will not fall off, but not so much that it is completely tightened (i.e., it should "jiggle" when lightly shaken). The ease of transport of cultures recovered in tubes is an added advantage. The chief disadvantage is the difficulty in preparing stained mounts for microscopic examination. The use of tubes has significantly declined in recent years, likely because of this latter disadvantage.

Petri dishes, in contrast to tubes, have the advantage of providing a larger surface for growth, resulting in better colony separation and making the cultures easier to examine and subculture. Fungal colonies in mixed culture are easier to separate and work with as individual colonies. Tease mounts or transparency tape preparations are more effectively made from plate cultures, potentially leading to an improved chance for making a more rapid identification. Because plate cultures may become dehydrated during the prolonged incubation period, they may be placed into a sealed, moisturized polyester bag, or the edge of the Petri dish may be sealed with

oxygen-permeable tape. If an incubator is used only for fungal cultures, placing a flat, open pan of water on the bottom shelf serves to provide the humidity needed for optimal recovery. Routine cleaning of the water basin is necessary, however, to control the growth of environmental mold in the water.

Laboratory Approach to the Presumptive Identification of Fungal Isolates

Once the observation of a culture plate reveals the growth of a probable fungus, several characteristics of the colony may be assessed to determine within which major group of fungi the isolate may belong. A guide to the genus and species identification of medically important fungi based on the colony morphology and microscopic features of clinical isolates is presented in Table 21-6, which is based on the observation of primary fungal isolates incubated at 30°C. If the fungal isolate presents a distinct wooly or cottony aerial mycelium, one of several species of molds must be considered. If the mold is rapidly growing, does not display an outer border, and fills the Petri dish within 48 to 72 hours, then one of the *Zygomycetes* must be considered (Display 21-1 at the end of this chapter).

Molds that grow within 3 to 5 days, have a distinct border, and are white or pastel on the surface, often with a white apron of new growth at the periphery, most likely belong to the hyaline, septate group of molds. Keys to the identification of the hyaline septate molds are presented in Display 21-2, and for the identification of molds recovered from skin scrapings, nail shavings, or hairs, are potentially dermatophytes which are discussed further in Display 21-3.

One of the dimorphic species should be considered for molds that are generally slower-growing (7 to 14 days), have a delicate or cobweb aerial mycelium, and are usually white to gray. The dimorphic molds are in the filamentous form when incubated at ambient temperature (25°C to 30°C), and in the yeast form when incubated at body temperature (35°C to 37°C). Upon initial isolation, the colonies of certain dimorphic molds may appear focally yeast-like when incubated at 30°C; these will become more fully filamentous with time, but this feature is important to recognize to avoid misidentifications. Dimorphic molds can be converted, sometimes with difficulty, from the mold to the yeast form by incubating a subculture on enriched agar at 35°C to 37°C, but as mentioned above this is rarely performed given the availability of molecular methods. The approach to the species identification of the dimorphic molds is presented in Display 21-4.

One of the dematiaceous molds should be considered when colonies that develop a dark gray to black mycelium, which is best determined by observing a brown or black reverse of the colony. The genus and species separation of the more rapidly growing

saprophytic species of this group is shown in Display 21-5. The keys to the identification of the slower-growing, pathogenic dematiaceous species, associated with chromoblastomycosis and mycetoma, are shown in Display 21-6.

If the colony has a smooth, creamy, viscous, or pasty appearance, a yeast must be considered. For the genus and species identification of common and less commonly encountered yeasts, including the yeast-like, arthroconidia-producing species that may produce a low aerial mycelium and the "black yeasts," see Display 21-7.

Once the initial observations outlined in Table 21-6 are made, and a fungal isolate has been placed within one of the groups outlined therein, further studies will be required to make a final genus/species identification, using the following microscopic criteria:

- If hyphae are observed, determine the structure of the hyphae. Are they
  - septate or coenocytic (i.e., pauciseptate/aseptate)?
  - branching (if so, at what angles), or not branching?
  - pigmented or not pigmented?
  - even or uneven in width?
  - composed of arthroconidia or pseudohyphae?
- Determine the structure and derivation of fruiting bodies.
  - Visualize the type of conidiation
  - The size, shape, and arrangement of the conidia
- Look for the presence of special diagnostic structures: pycnidia, cleistothecia, Hülle cells.
- If only yeast cells are observed:
  - Note their size, shape, and arrangement.
  - Look for the presence or absence of a capsule.
  - Determine the type of blastoconidiation—are daughter cells single or multiple?
- Further guidelines for the presumptive identification of fungi based on direct microscopic examination of clinical specimens are presented in Table 21-7.

Extent of Laboratory Genus/Species Identification

Table 21-6 can also be used as a guide for the extent to which genera and species identifications are required in most clinical situations. As virtually any filamentous mold recovered in pure culture from normally sterile body sites may represent an opportunistic pathogen, clinical correlations are recommended before the isolate is discarded as insignificant. Species identifications need not go beyond those listed in the algorithm; other isolates not specifically identified should be reported with the appropriate genus name and, if typically performed, species (e.g., *Aspergillus fumigatus* and *Fusarium* species).

Because yeasts are commonly recovered as commensals from skin and respiratory

specimens, the definitive workup should be limited and performed only when clinically indicated. Clinically significant yeast isolates recovered from tissues (particularly if fungal elements are observed in stained tissue sections), normally sterile body fluids and aspirates should be identified to both the genus and species level. This is readily accomplished by commercially available methods. The identification of certain species, *Candida krusei* for example, predicts resistance to select antifungal agents, such as the imidazoles. Isolates recovered from swabs or superficial wounds must be evaluated as to their clinical significance. The criteria by which the fungi included in Table 21-6 can

TABLE 21-7 Presumptive Identification of Fungi Based on Direct Microscopic Examination of Material from Clinical Specimens

Presumptive Direct Microscopic Observations	Identification
Hyphae relatively small (3–6 μm) and regular in size, dichotomously branching at 45-degree angles with distinct cross-septa	*Aspergillus* spp. or other hyaline molds (e.g., *Fusarium* or *Pseudallescheria*)

Hyphae irregular in size (6–50 μm), ribbonlike, and pauciseptate	*Zygomycetes: Rhizopus, Mucor, Lichtheimia*
Hyphae small (2–3 μm) and regular, some branching, with rectangular arthrospores sometimes seen; found only in skin, nail scrapings, and hair	Dermatophyte group *Microsporum* spp. *Trichophyton* spp. *Epidermophyton* spp.
Hyphae regular in diameter (3–6 μm), parallel walls, irregular branching, septate, dark golden-brown	Dematiaceous fungi
Hyphae, distinct points of constriction simulating link sausages (pseudohyphae), with budding yeast forms (blastospores) often seen	*Candida* spp.
Yeast cells spherical and irregular in size (5–20 μm), classically with a thick polysaccharide capsule (not all cells appear encapsulated), with one or more buds attached by a narrow constriction	*Cryptococcus neoformans* *Cryptococcus* spp.
Small budding yeast, relatively uniform in size (3–5 μm), with a single bud attached by a narrow base, extracellular or within macrophages	*Histoplasma capsulatum, Candida glabrata,* and other small yeasts
Yeast forms, large (8–20 μm), with cells appearing to have a thick, double-contoured wall, with a single bud attached by a broad base	*Blastomyces dermatitidis*
Large, irregularly sized (10–50 μm), thick-walled spherules, many of which contain small (2–4 μm), round endospores	*Coccidioides* spp.

be identified follow. The presentation of more detailed identification criteria for several groups of fungi will follow the order in the columns of Table 21-6, with linkages to Displays 21-1 through 21-7, located at the end of this chapter.

Zygomycetes (Glomeromycetes) and Zygomycosis

Major Genera of Zygomycetes

The fungi belonging to the Phylum Zygomycota have undergone taxonomic reclassification and are now known as Glomerulomycota. Traditionally terminology is retained here, because this is commonly used in medical practice. The fungi in this group are widely distributed environmental inhabitants of soil, dung, and vegetative matter. They are most commonly encountered as bread molds. Humans usually

become infected through the inhalation of airborne spores, although ingestion of contaminated foodstuffs may result in primary gastrointestinal disease. Direct inoculation and contamination of wounds may lead to primary cutaneous infection. Most members of the *Zygomycetes* have a proclivity for hyphal invasion of the walls of blood vessels (i.e., angioinvasion) once a primary infection is established, often resulting in the dissemination of mycotic thrombi and the development of metastatic foci in many organs. Additionally, these fungi may tract along the loose connective tissue surrounding nerves (i.e., the perineurium) as a means of local spread of infection.

The medically important *Zygomycetes* are separated into two orders, *Mucorales* and *Entomophthorales*.[159] It is the fungi in the former category that are most commonly encountered in clinical medicine. The six members of the *Mucorales* that are presented here, as outlined in Display 21-1, are *Rhizopus* spp., *Mucor* spp., *Lichtheimia* (formerly *Absidia*) spp., *Syncephalastrum* spp., *Circinella* spp., and *Cunninghamella* spp. These may be identified by the criteria outlined. *Rhizomucor pusillus, Saksenaea vasiformis, Apophysomyces elegans*, and the entomophthoromycotic agents, *Conidiobolomyces coronatus* and *Basidiobolobus* spp., are rarely encountered in clinical laboratories and will not be presented here.

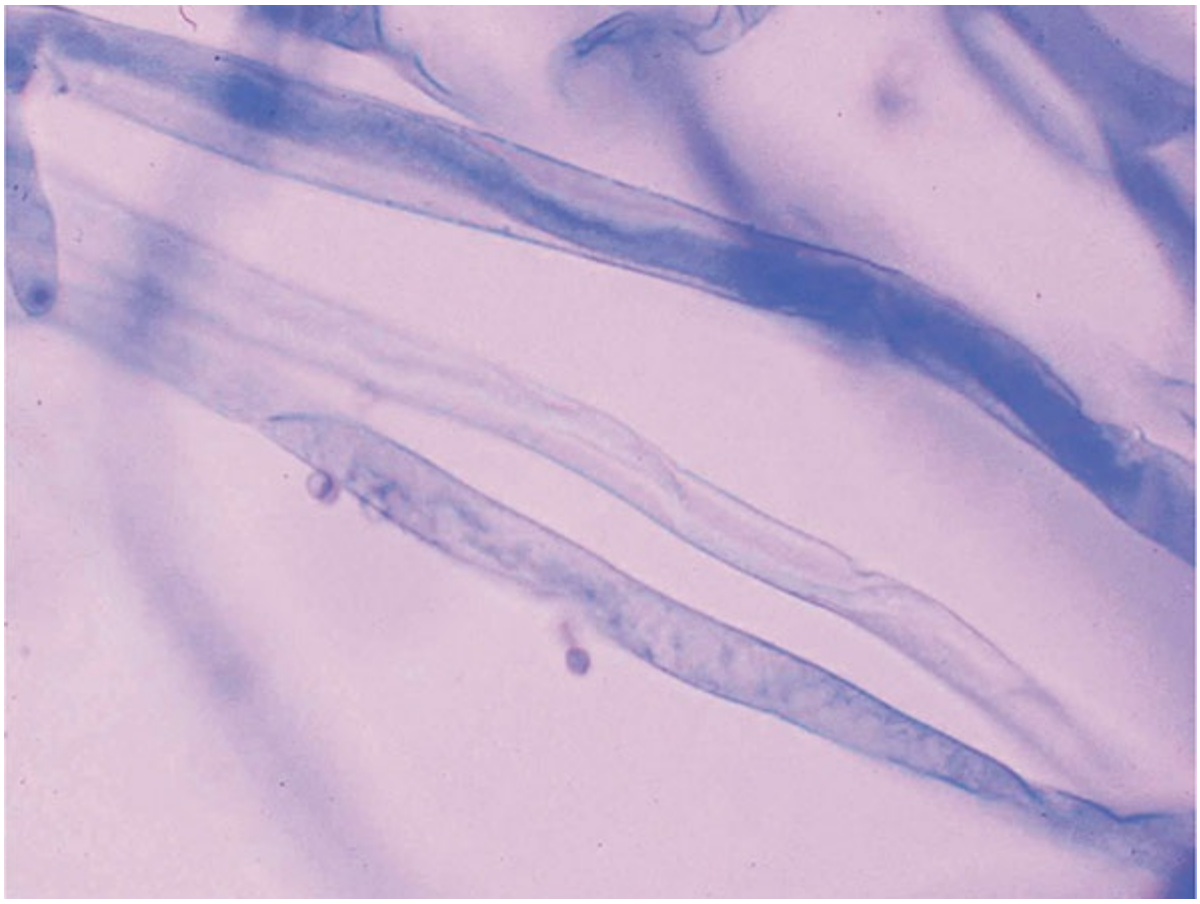
As outlined in Display 21-1, the initial clue to the diagnosis of zygomycosis is the recovery of a rapidly growing colony on primary fungal recovery culture medium, usually within 48 to 72 hours, with the surface of the agar covered with a wooly mycelium that extends from border to border in the Petri dish; these have been referred to as "lid-lifters" because of their rapid growth (Image Plate 21-1A and B). Microscopic examination of a mount made from the colony reveals broad hyphae with irregular width that appears ribbonlike. The hyphae is pauciseptate (i.e., septations are rare) and may be aseptate hyphae in any particular microscopic field (Fig. 21-7). The spores, termed sporangiospores, are produced in saclike structures called sporangia (Fig. 21-8) in the most commonly encounter species (e.g., *Rhizopus* and *Mucor*). Following detection and characterization of the sporangia, the microscopist should search for the presence or absence of

The genus-level identifications, which is all that is medically necessary, can then be made following the criteria outlined in Display 21-1; the descriptions and figure cross-references are presented below.

***Rhizopus* Species.** The key to the identification of *Rhizopus* species is the production of and location of distinct

rootlike structures called **rhizoids.** Rhizoids that are characteristically derived from the hyphae immediately at the base of the sporangiophores are called "**nodal**" (Fig. 21-

10). The sporangiophores of *Rhizopus* species may measure up to 1,000 µm terminate in a concave columella that extends into the saclike sporangium. The umbrella-like collapse of the post-mature sporangium is better illustrated in the close-up view in Figure 21-11. This collapse, which is often observed as a secondary feature in older cultures, is particularly helpful in making a preliminary identification when rhizoids are poorly developed.

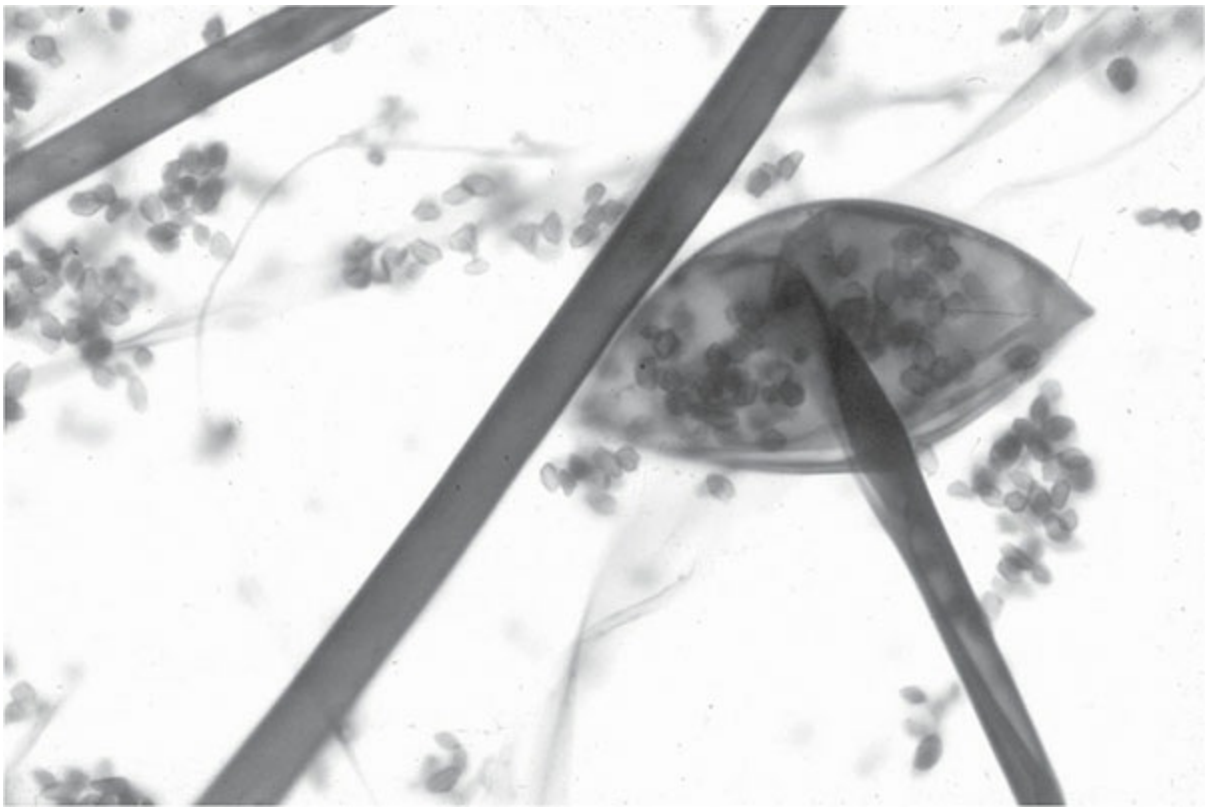


■ **FIGURE 21-7** Photomicrograph of the broad, ribbonlike hyphae of *Zygomycetes* species. Note the clear cytoplasm and the absence of transverse septations in this field.

■ **FIGURE 21-8** Photomicrograph of a sporangium of *Mucor* species, the asexual reproductive structure produced by many of the *Zygomycetes*.

■ **FIGURE 21-9** Photomicrograph of the rootlike rhizoids of *Rhizopus* species, an important differentiating feature within the *Zygomycetes*.

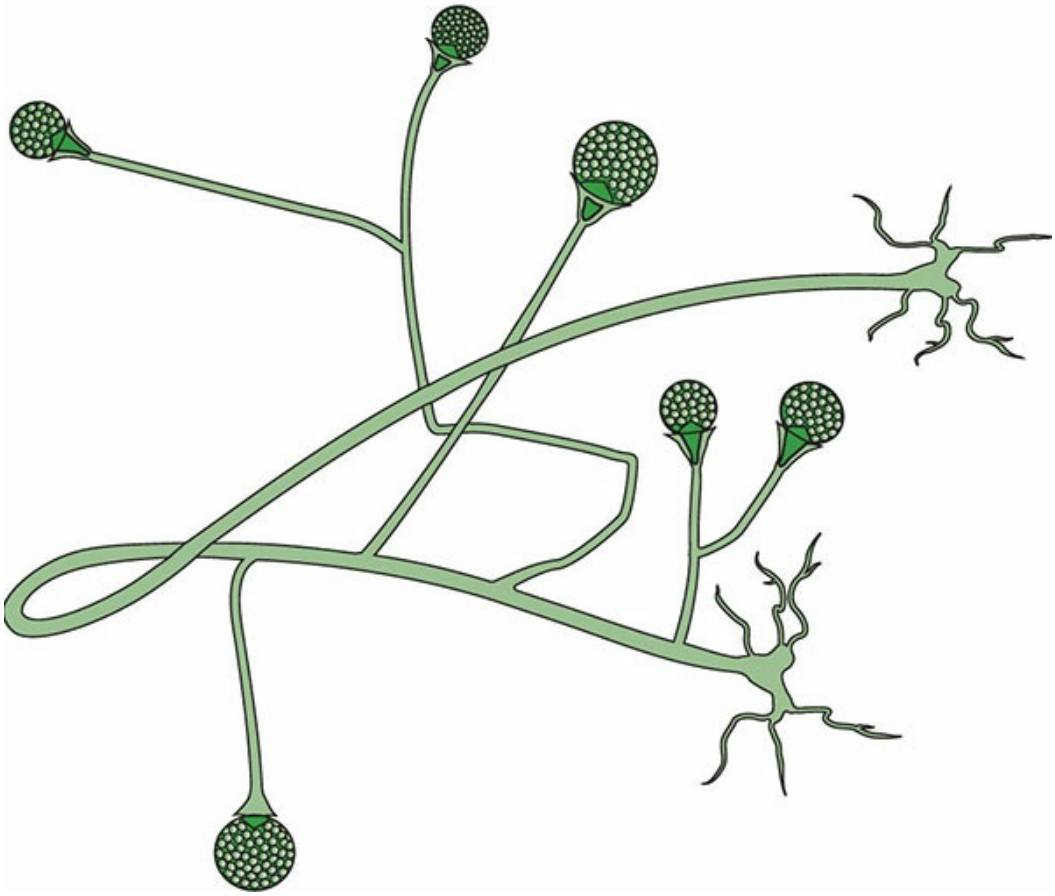
■ **FIGURE 21-10** Photomicrograph of the fruiting structure of *Rhizopus* species. The rhizoids (*arrow*) in *Rhizopus* occur at the base of the sporangiophore in what is termed a "nodal" location. In this preparation, the sporangiophores have burst releasing the sporangiospores.



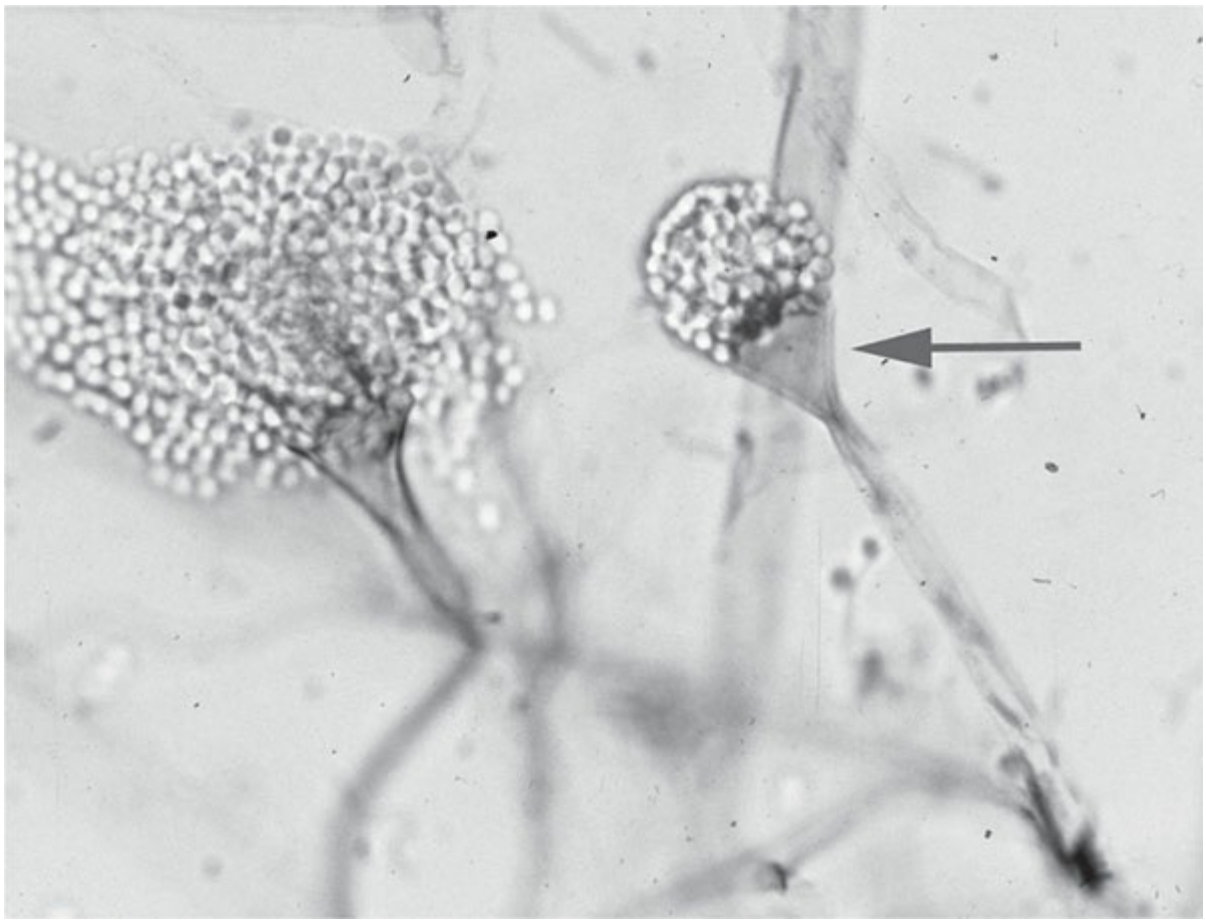
■ **FIGURE 21-11** Close-up view of a post-mature sporangium of *Rhizopus* species illustrating the characteristic umbrella-like collapse.

rootlike structures called rhizoids (Fig. 21-9).

***Lichtheimia* (Formerly) Species.** *Lichtheimia* spp. share with *Rhizopus* spp. the production of rhizoids. The rhizoids of *Lichtheimia* spp., however, differ from those of *Rhizopus* in that they are generally more delicate and have an origin from the hyphae between the conidiophores, a derivation known as "**internodal**" (Fig. 21-12). The sporangiophores may branch. A secondary feature of importance, particularly



■ **FIGURE 21-12** Photomicrograph and sketch of the fruiting structure of *Lichtheimia* species, illustrating the characteristic internodal derivation of the conidiophores. Note the intranodal location of the rhizoids (i.e., not at the base of the sporangiophore).



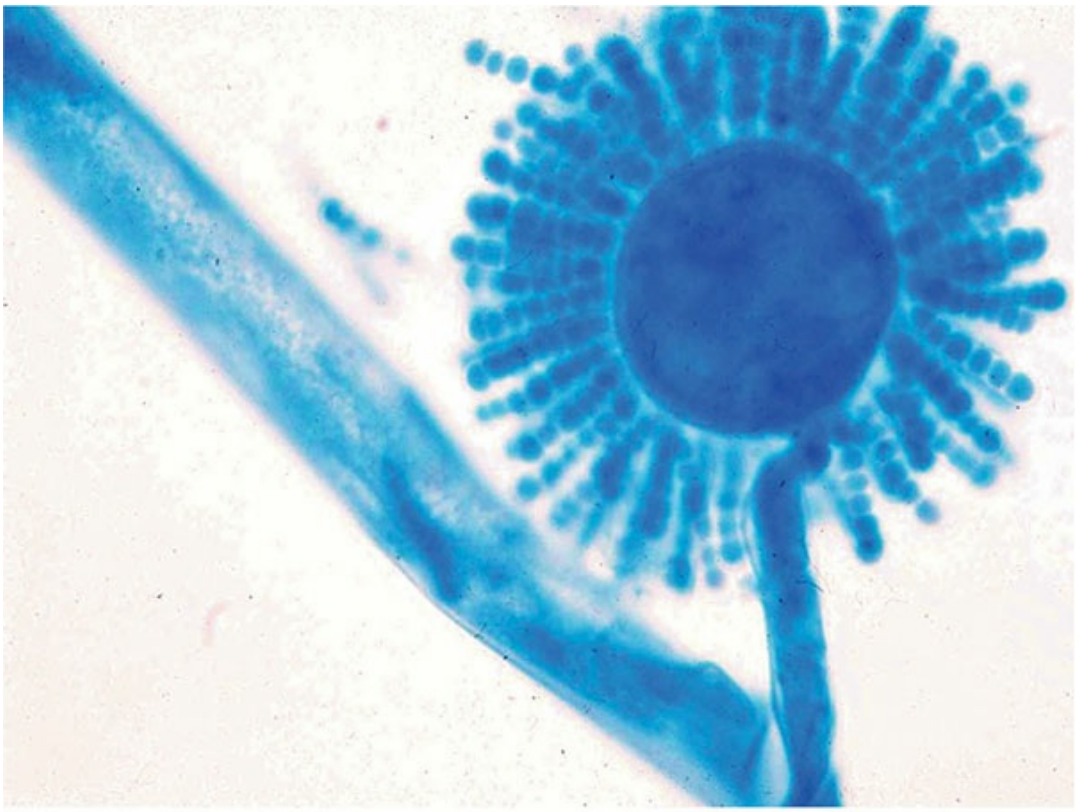
■ **FIGURE 21-13** Higher magnification of the apophysis (*arrow*) of *Lichtheimia* species, the funnel-like expansion of the terminal end of a sporangiophore.

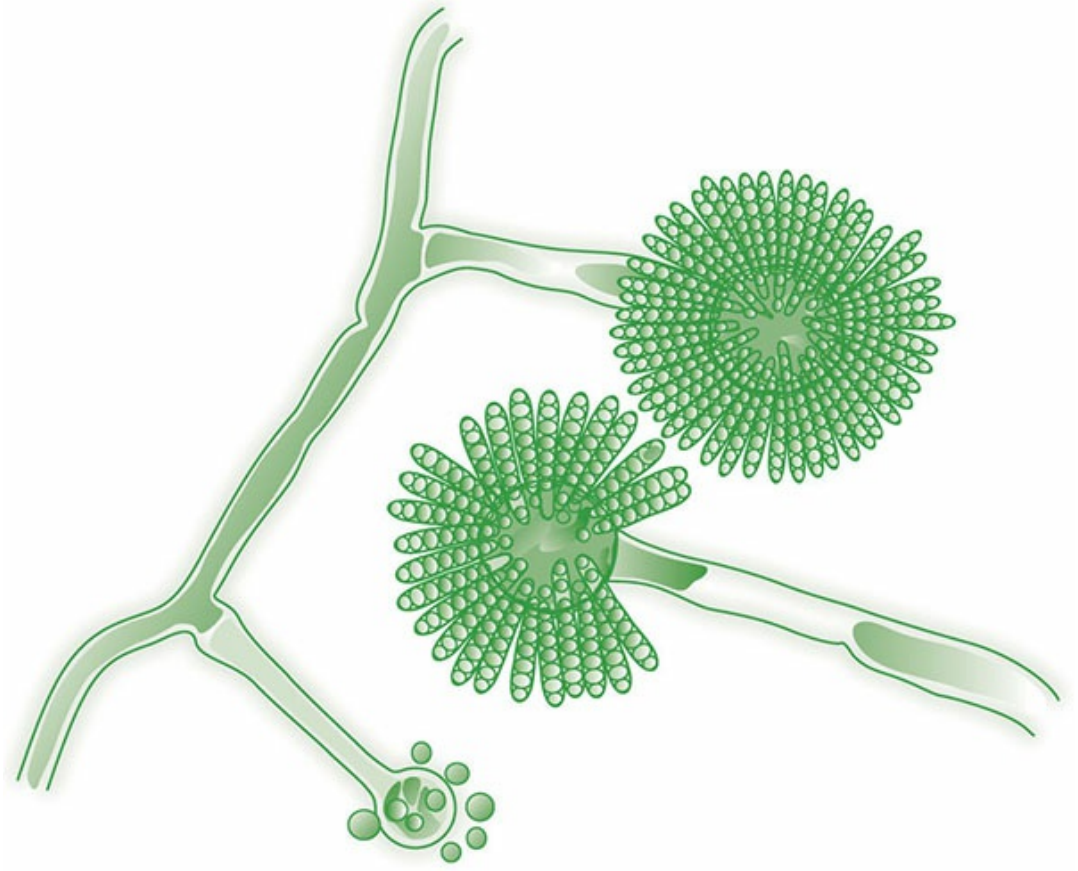
in strains in which the rhizoids are poorly developed, is the funnel-like expansion of the terminal conidiophore into a structure known as the **apophysis** (Fig. 21-13).

***Syncephalastrum* Species.** *Syncephalastrum* spp. differ from the other *Zygomycetes* in the shape and arrangement of the sporangia. Rather than being in the shape of a spherical sporangium, *Syncephalastrum* produces **merosporangia**, which are cylindrical and arranged as "daisy petals" around a relatively small (10 to 50 µm), spherical columella (Fig. 21-14). The sporangiospores are aligned one after another in tandem within each merosporangium. At low magnification, this appearance is reminiscent of *Aspergillus flavus;* however, when the colony morphology, structure of the hyphae and details of the fruiting body are scrutinized, the differentiation is readily

made. Rudimentary rhizoids are occasionally seen with this fungus.

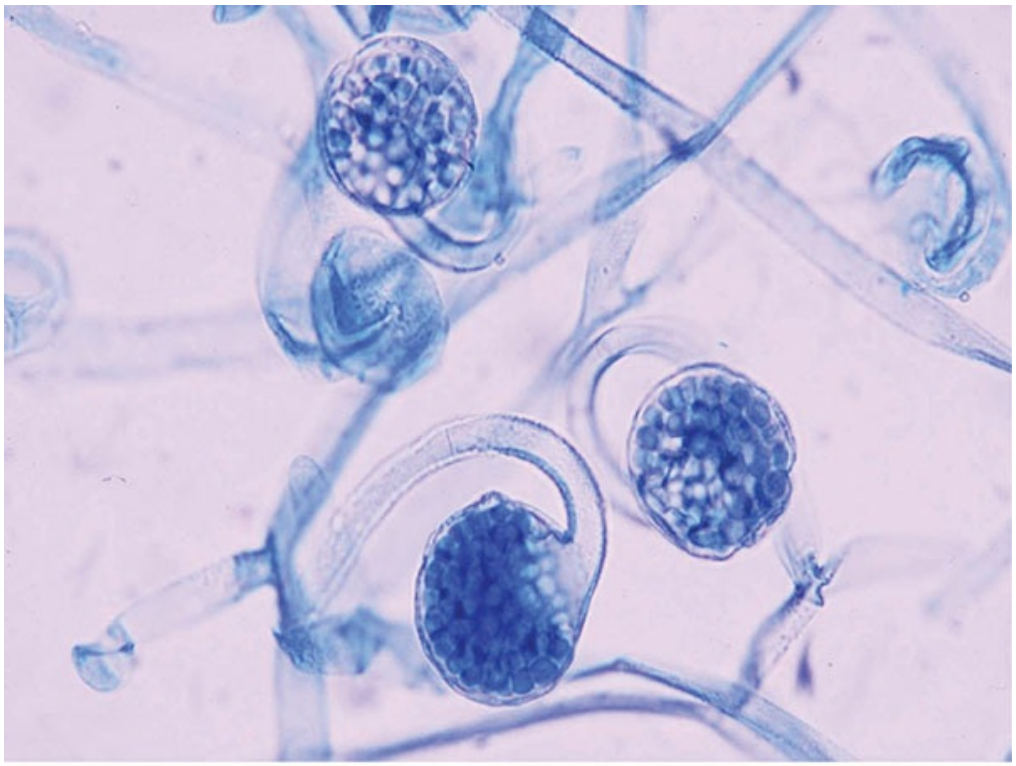
***Circinella* Species.** The key identifying feature of *Circinella* spp. is the distinctive backward curve of the sporangiophores. The sporangiophores are borne laterally from the hyphae, curve directly in reverse and terminate in a globose sporangium that usually is filled with brown-staining

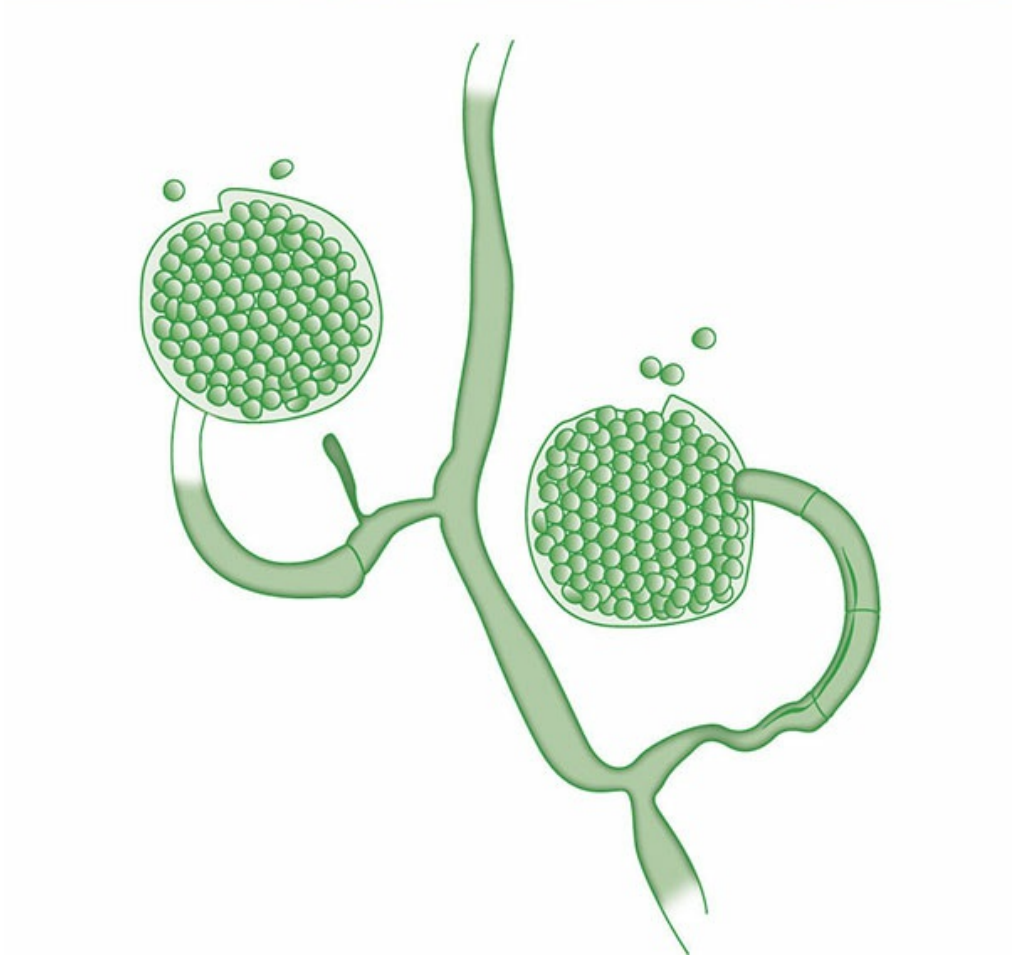




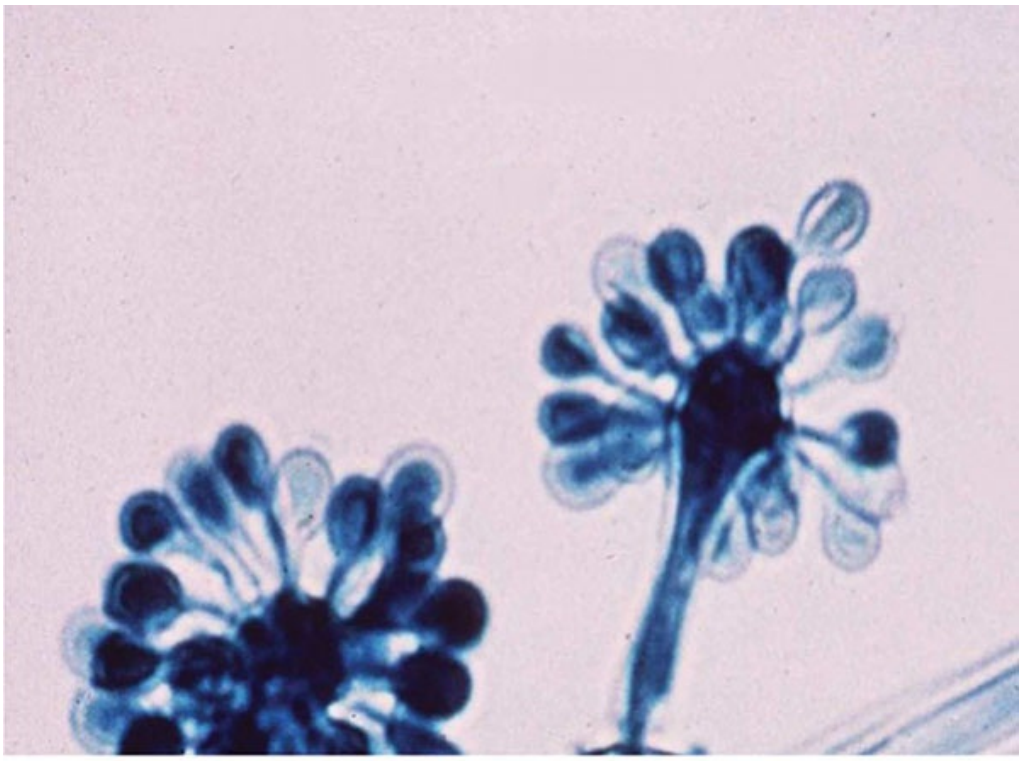
■ **FIGURE 21-14** Photomicrograph and sketch of the fruiting structure of *Syncephalastrum* species, illustrating the radiating sporangia around a spherical columella. At low magnification, these can be mistaken for an *Aspergillus* species by the novice mycologist.

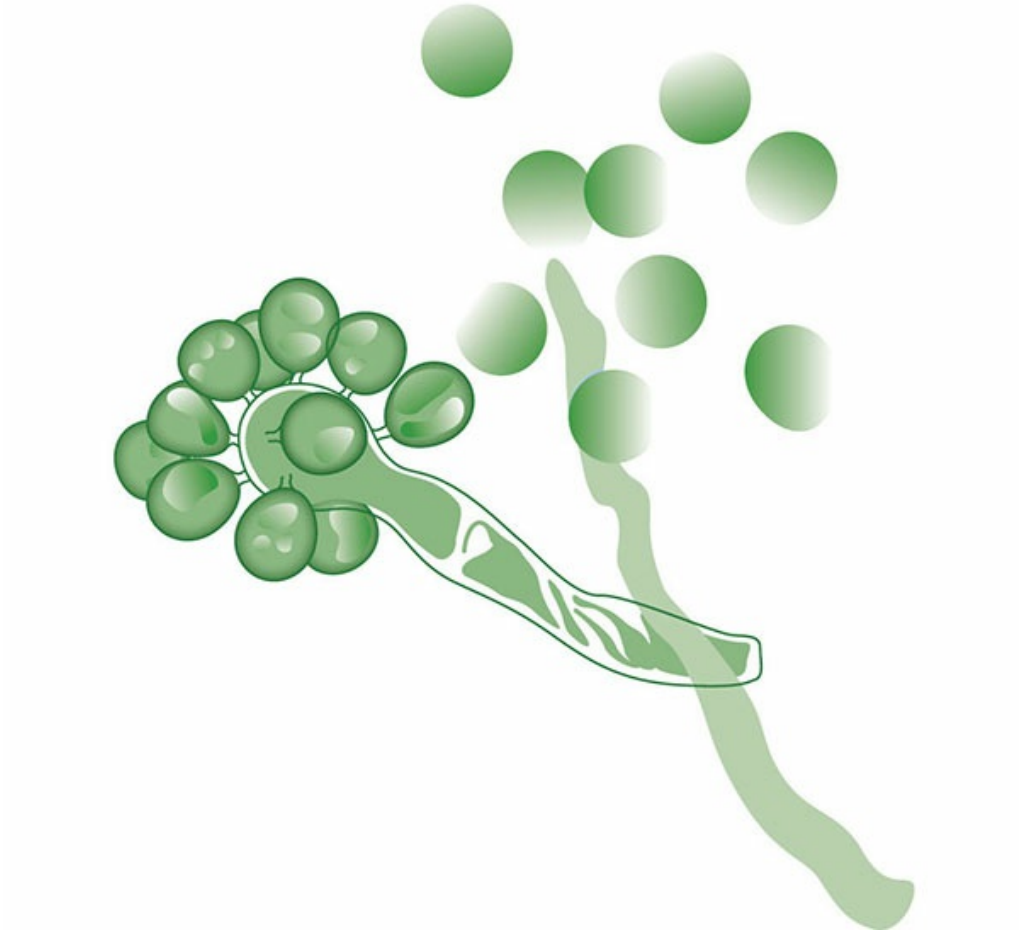
1342





■ **FIGURE 21-15** Photomicrograph and sketch of the fruiting structure of *Circinella* species, illustrating the characteristic backward curve of the sporangiophores.



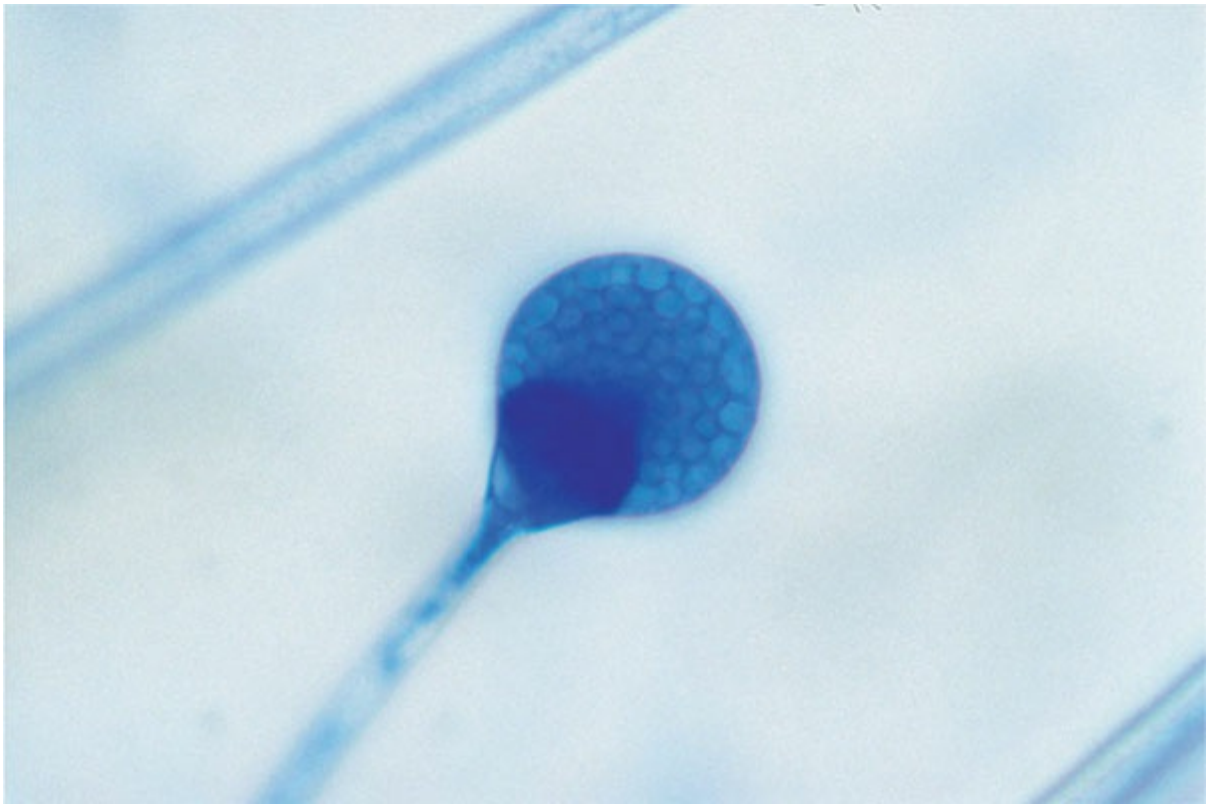


■ **FIGURE 21-16** Photomicrograph and sketch of the fruiting structure of *Cunninghamella* species, illustrating spherical sporangiola arising from the surface of a globe-like columella.

sporangiospores (Fig. 21-15). *Circinella* spp. do not produce rhizoids.

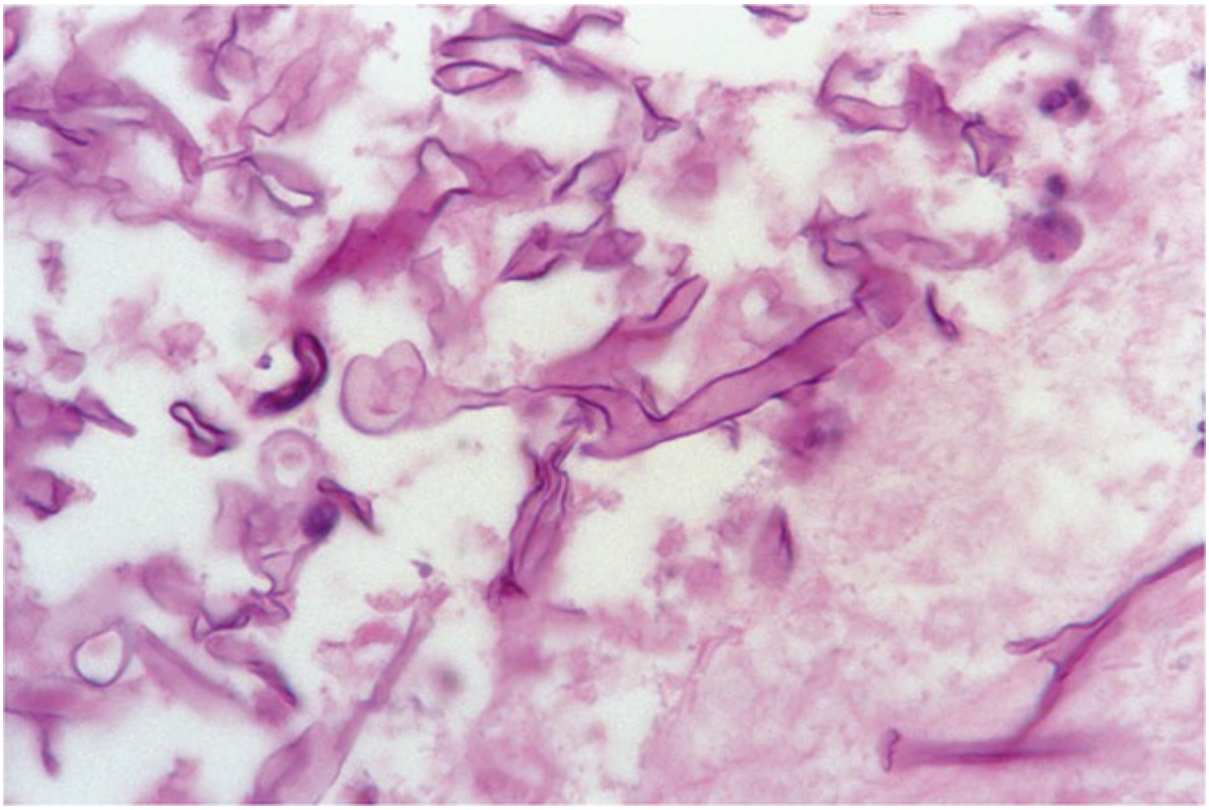
***Cunninghamella* Species.** The sporulation of *Cunninghamella* spp. differs from that of the other *Zygomycetes* by producing specialized spherical spores, called **sporangiola,** from the surface of a large, globose columella; unlike the other *Zygomycetes* described, these are not encased within a sporangium (Fig. 21-16). A tiny hairlike **denticle** may be observed at higher magnification which connects each sporangiole with a spot on the columella.

***Mucor* Species.** The identification of *Mucor* spp. is often made after each of the other *Zygomycetes* described has been excluded. *Mucor* spp. do not produce rhizoids. Sporangiophores are derived singly from the mycelium and may be either branched or not branched. Each sporangiophore ends in a slightly bulbous columella, which extends within a spherical smooth-walled sporangium (Fig. 21-17). The sporangiospores are spherical or ellipsoid and may be hyaline or pigmented yellow-brown.



■ **FIGURE 21-17** Photomicrograph of the fruiting structure of a *Mucor* species. Note the lack of rhizoids. The sporangiophores terminate in a globe-like columella within the sporangia that contains sporangiospores.

1343



■ **FIGURE 21-18** Photomicrograph of a tissue section illustrating irregular-sized, broad, fragmented aseptate-to-pauciseptate hyphae characteristic of one of the *Zygomycetes* species (H&E, 400×)

Histopathology of Infections Caused by the Zygomycetes.

The ribbonlike, broad, pauciseptate-to-aseptate hyphae of the *Zygomycetes* are generally distinct from the hyphae of other filamentous fungi in tissue sections. The hyphae range from 3 to 25 μm in width, have non-parallel walls, and often tend to break up into small fragments (Fig. 21-18). The hyphae often do not stain well with periodic acid–Schiff (PAS) or Gomori methenamine silver (GMS) fungal stain. The background tissue reaction is typically purulent, and both intact and fragmented hyphae are usually seen amid neutrophils and neutrophilic debria. Occasional septa

may be observed, which is why the designation of pauciseptate is preferred to aseptate. A newer term **mucoraceous hyphae** has been suggested to describe the hyphae from these fungi. The *Zygomycetes* also have a predilection for invading blood vessels, causing hemorrhagic infarction, which is one reason that the infected tissue often appears charred. These fungi often track along the perineurium, as a mechanism of local invasion. In addition to invasive zygomycosis, these fungi can also present as a fungus ball in body cavities; in such locations, the typical fruiting heads complete with sporangia and sporangiospores may occasionally be observed.

The clinical syndromes produced by the *Zygomycetes* are presented in Clinical Correlation Box 21-1.

Hyaline Molds and Hyalohyphomycosis

Ajello[6] originally coined the term "Hyalohyphomycosis" to represent a group of opportunistic fungal infections caused by

CLINICAL CORRELATION BOX 21-1 Zygomycosis

The fungi belonging to the *Zygomycetes* are widely distributed environmental inhabitants of soil, dung, and vegetative matter. Humans usually become infected in the upper respiratory tract through the inhalation of airborne spores, although ingestion of contaminated foodstuffs may result in primary gastrointestinal disease, or direct inoculation of traumatic breaks in the skin and mucous membranes may lead to primary mucocutaneous infection. A proclivity for the hyphae to invade the walls of blood vessels once a primary infection is established results in the dissemination of mycotic thrombi and the formation of metastatic foci in many organs.

Zygomycosis most commonly occurs as opportunistic infections in immunocompromised hosts. Host risk factors include diabetes mellitus, particularly during periods of acidosis, neutropenia, sustained immunosuppressive therapy (as may occur following bone marrow transplantation),[60] the prolonged use of antibiotics, and a breakdown in the integrity of the cutaneous barrier secondary to trauma, surgical wounds, needle sticks, or burns.[233] These authors also indicate that angioinvasive disease is a common complication, resulting in vascular thrombosis, infarction of the involved tissue, and tissue destruction from the action of proteases, lipases, and mycotoxins. Release of mycotic thrombi from the primary sites may lead to disseminated disease. Rhinocerebral, pulmonary, cutaneous, and disseminated forms of disease are most commonly encountered.

A review by Prabhu and Patel[226] reiterates most of the background risk factors

already mentioned. In particular, hematologic malignancy, bone marrow or peripheral blood stem cell transplantation, neutropenia, solid organ transplantation, diabetes mellitus with or without ketoacidosis, overuse of corticosteroids, and deferoxamine therapy for iron overload are cited as causing patients to be predisposed to infection. Emphasis is placed on reducing the high mortality rates, reaching as high as 100%, depending on underlying diseases. Successful outcomes depend on early diagnosis, treatment of the underlying medical condition, surgery when indicated, and amphotericin B therapy. High-dose lipid formulations of amphotericin B and the use of hyperbaric oxygen are the particular strategies that have shown potential value in the treatment of zygomycosis, as outlined by Gonzalez, Rinaldi, and Sugar.[103] Of critical importance is the fact that these fungi are innately resistant to voriconazole. *Rhizopus* is the genus of *Zygomycetes* recovered most frequently in culture from human infections, followed in incidence by *Mucor* species. Other *Zygomycetes* are less frequently encountered. *Cunninghamella* species are infrequently encountered in clinical laboratories. Nevertheless, several case reports indicate that this organism has been recovered as the causative agent of each of the more common forms of zygomycosis—rhinocerebral, pulmonary, cutaneous, and disseminated disease. Kontoyianis et al.[155] describe the common

clinical predispositions of *Cunninghamella bertholetiae* infections; namely, previous corticosteroid therapy, prolonged severe granulocytopenia, and diabetes mellitus. Fever and pneumonia were the most common clinical presentations in this series of patients, usually an indication of disseminated disease. *Cunninghamella* infections are usually rapidly progressive, and the outcome in most cases reported in the literature has been almost uniformly fatal. Aggressive treatment with amphotericin B, resection of infected tissues, and control of the underlying disease may reverse this trend.

Rhinocerebral Disease

This form of infection often begins as sinusitis, progressing to local invasive disease, with edema of the eyelids, proptosis, malar anesthesia, and internal and external ophthalmoplegia. In many instances, infection is rapidly progressive, although slowly progressive, chronic forms have also been reported.[121] A thick, dark, blood-tinged nasal discharge may be observed; material debrided from the sinus may appear blackened and hemorrhagic because of vascular invasion and infarction. Meningitis and cerebritis may develop by direct extension, and are usually fatal. Localized cerebral disease is uncommon, occurring most frequently among IV drug users.[187] Nenoff et al.[197] report an ascending cerebral infection in a patient after transplantation, in whom bilateral total amaurosis (blindness) developed. Cerebral disease has also been reported in patients with AIDS, presumably related to drug

injection. Confusion and mood disturbances are more common presenting signs of cerebral involvement. Space-occupying lesions and brain abscesses are seen in drug addicts. Once cerebral symptoms set in, the process is often rapidly fatal. Noninvasive fungus ball infections of the nasal sinuses may also be seen.

Pulmonary Disease

Ill-defined, finely nodular or diffuse infiltrates may be seen radiologically.[193] **Fungus ball involvement** in preexisting natural or postinfection cavitary lesions may also be seen. Chest pain, hemoptysis, and cough productive of purulent or blood-tinged sputum are common clinical presentations. Subacute pulmonary disease is usually intrabronchial, with the formation of mucin plugs. The pleura may occasionally be involved. Pulmonary infections occur in immunocompromised hosts, including lung transplant recipients.

Cutaneous Disease

Cutaneous disease usually occurs secondary to trauma and soil contamination,[277] in patients with burns,[56] and episodically, from direct implantation with Elastoplast bandages.[214] Occasionally, subcutaneous involvement via hematogenous spread may complicate disseminated disease. Lesions ranging from small violaceous plaques to cellulitis, ulceration, and gangrene may be seen. *Zygomycetes* belonging to the order *Entomophthorales* have recently been cited in cases of subcutaneous disease, particularly in children and young adults in tropical or subtropical locales. Gugnani[105] has reviewed infections caused by *Basidiobolus ranarum*, presenting as fluctuant granulomatous lesions primarily of the legs and trunk, secondary to skin trauma and/or bites of insects. Potassium iodide, amphotericin B, and azole drugs have been successfully used in treatment of these cases.

Disseminated Disease

Virtually any organ may be involved, spreading from primary infections in the lung, sinuses, and gastrointestinal tract.[235] Most commonly affected are individuals who are immunosuppressed because of their age (the very young and the very old), drug therapy, or underlying diseases such as hematologic malignancies (particularly during periods of profound leukopenia), diabetes mellitus, and lupus erythematosus.[133] Although not an AIDS-defining illness, disseminated disease is more likely to occur in HIV-positive patients, as reviewed by Van den Saffele and Boelaert.[280] Metastatic spread occurs from the propensity of hyphae to invade the vasculature, resulting in thrombosis and the release of mycotic emboli into the circulation. Zygomycosis has also been reported in cases of iron overload, specifically in patients undergoing hemodialysis who are receiving deferoxamine therapy.[26] The growth of many microorganisms, including members of the *Zygomycetes*, is enhanced by an increased concentration of iron. The relationship between zygomycosis and deferoxamine therapy hinges on the primary chelating action of the drug, resulting in an increased

local iron concentration that stimulates proliferation of the fungus.

a variety of rapidly growing, saprophytic molds. He thought this designation would be less confusing to physicians than using individual names, such as penicilliosis, paecilomycosis, fusariosis, and the like. Since that time, however, laboratory personnel have become more proficient in making genus identifications of the various fungi included in this group, and physicians have had additional experience in the clinical applications of laboratory reports that list the genus or species names of the more commonly recovered hyaline molds. Culture identification of the causative agent of hyalohyphomycosis should be made. It is important to distinguish these fungi, given more options than ever for systemic antifungal drugs and that some of these fungi are resistant to amphotericin B. Culture-based identification is particularly important, since *Aspergillus* spp. and other hyaline molds that may appear similar in histologic sections. Each mycologist must determine the extent to which genus/species identifications are reported to best suit the needs of the physicians being served.

1345

Aspergillus *Species and Aspergillosis*

Aspergillus species are commonly discussed as a separate subset of the hyaline molds, given their ubiquity in nature and the frequency with which they are recovered in clinical laboratories as agents of mycotic diseases. *Aspergillus* spp. are widely distributed in nature; they are found in soil, on decaying vegetation, and on a wide variety of organic matter. The inhalation of spore-contaminated dust is the most common mode of infection in humans, resulting in sinusitis or bronchopulmonary disease. Schubert[249] describes three invasive (acute necrotizing, chronic invasive, and granulomatous invasive) and two noninvasive (fungal ball and allergic fungal) forms of fungal rhinosinusitis.

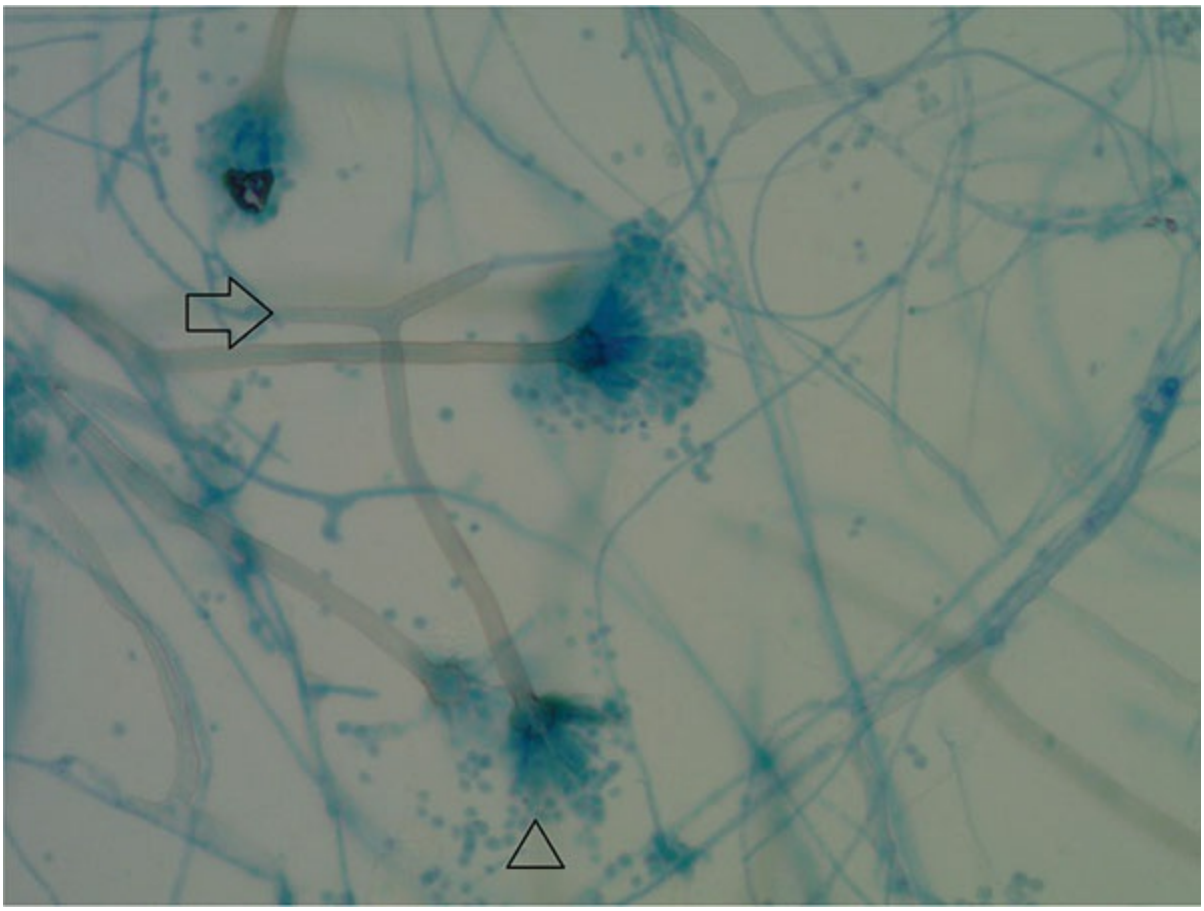
There may be an increase in the rate of infection during periods of building construction, particularly in zones surrounding hospitals, so controlling dust leakage from areas of construction into patient care areas is important. The report many years ago of an outbreak of aspergillosis among cancer patients, related to the fire-proofing operation in the resident hospital is apropos.[4] Surveillance studies should always include sampling of hospital air filters, which commonly reveal high fungal spore counts.[258]Ventilation ducts in particular may become contaminated with dirt and fragments of vegetative matter that become airborne from the disruption of the soil and vegetative undergrowth.[208] The incidence of nosocomial aspergillosis is in direct proportion to the mean ambient airborne spore count, which is highest when mini-

bursts of spores are released into the air via the shaking out of contaminated clothing or from disruption of accumulated contaminated dust on floors or other surfaces during cleanup operations.[232] Patients who are immunocompromised or who are receiving immunosuppressive drugs, notably bone marrow and organ transplant recipients, and those with hematologic malignancies, are particularly susceptible to infection. Therefore, some institutions have opted to hepafilter the air that will enter to rooms of highly immunocompromised patients.

Laboratory Presentation. The *Aspergillus* species most commonly encountered in clinical laboratories include *Aspergillus fumigatus, A. flavus, A. niger,* and *A. terreus.* The majority of serious infections are caused by *A. fumigatus*.[161] *A. nidulans* is also mentioned in this section because most strains readily produce the sexual or telomorphic forms in culture. These forms, termed cleistothecia, enclose meiotically-derived, lemon-shaped ascospores.

Colony Morphology. Colonies of *Aspergillus* spp. can be suspected in culture if an isolate grows within 3 to 5 days and has a distinct outer margin (i.e., a white apron at the advancing area of growth). The appearance as described below may vary depending on the culture medium being used. Early colonies may have a cottony consistency; however, with maturity, the surface becomes more granular as conidia are produced. Descriptions of the colonies when grown on SDA and characteristic of each of the species mentioned above follow.

Microscopic Features. Microscopically, *Aspergillus* species are characterized by the production of uniform, 4 to 6 μm in diameter, **hyaline, septate hyphae** with parallel walls. The **45-degree angle dichotomous branching** so characteristic of the invasive mycelium seen in tissue sections is less commonly seen in microscopic mounts made from culture plates. A specialized hyphal segment, known as a **foot cell,** serves as the base of origin of the **conidiophore** (Fig. 21-19). Conidiophores terminate in a swollen **vesicle,** from the surface of which are borne one (**uniseriate**) or two (**biseriate**) rows of cells. **Phialides** arise directly from the vesicle in a uniseriate conidiophore, whereas with the biseriate conidiophore, there is an inner row of cells are called **metulae** that arise from the vesicle which in turn give rise to the phialides. The phialides are the **conidiogenous cells** that give rise to chains of pigmented conidia (Fig. 21-20). The length, width, and texture (i.e., rough vs. smooth) of the conidiophores; the size and contour of the vesicle; the presence/absence of metulae (i.e., uniseriate vs. biseriate); the arrangement of the phialides; and the color and size of the conidia are features used in making species identifications. The presence of additional "special structures" that may be produced by some species of *Aspergillus,* if present, is useful for the identification of these species. These include the cleistothecia (Fig 21-21) mentioned above, as well as Hülle cells and aleuroconidia.



■ **FIGURE 21-19** Photomicrograph of an aspergillum *(arrowhead)*, the fruiting body of *Aspergillus* species, from *A. nidulans*. The conidiophore (i.e. the aspergillum in this instance) is derived from a foot cell *(arrow)*.

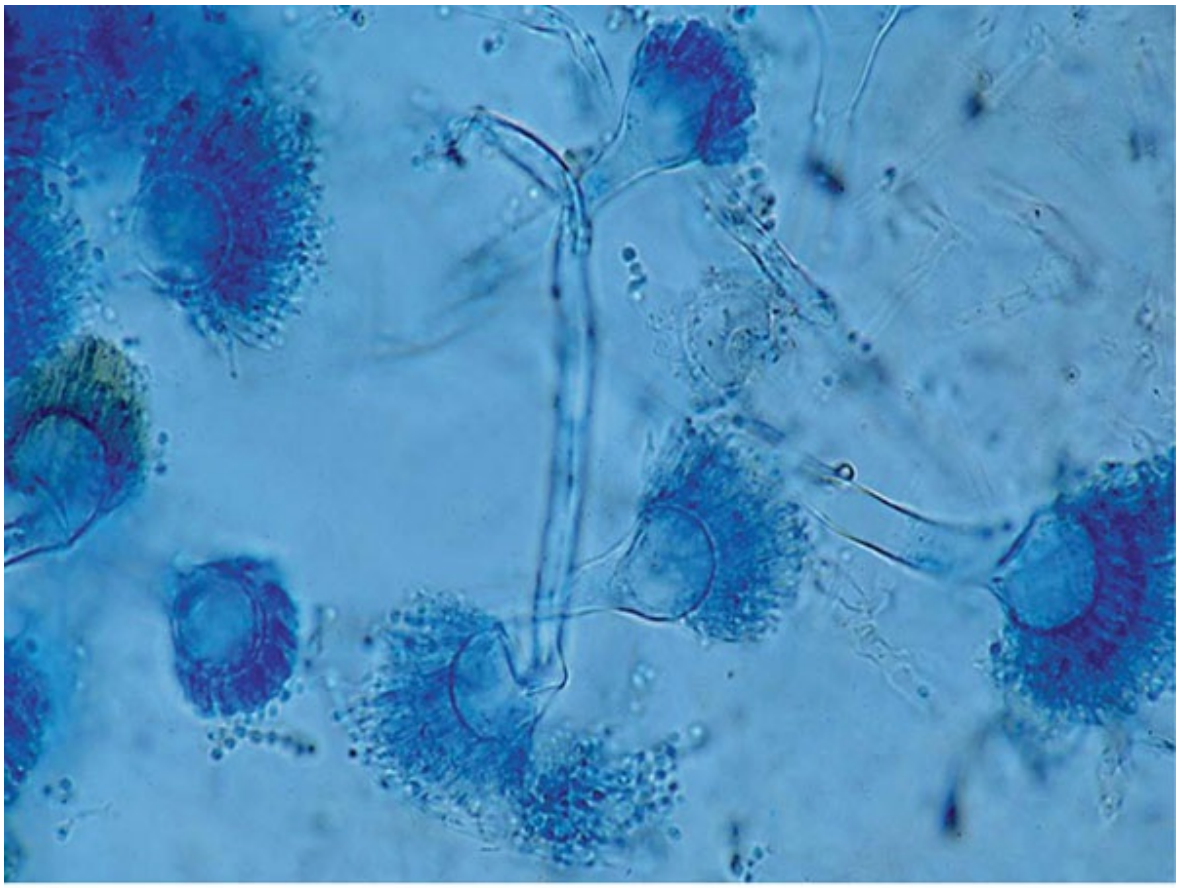
Aspergillus fumigatus. Colonies of *A. fumigatus* are granular to cottony and usually have some shade of blue to blue-green pigmentation (Image Plate 21-1C).

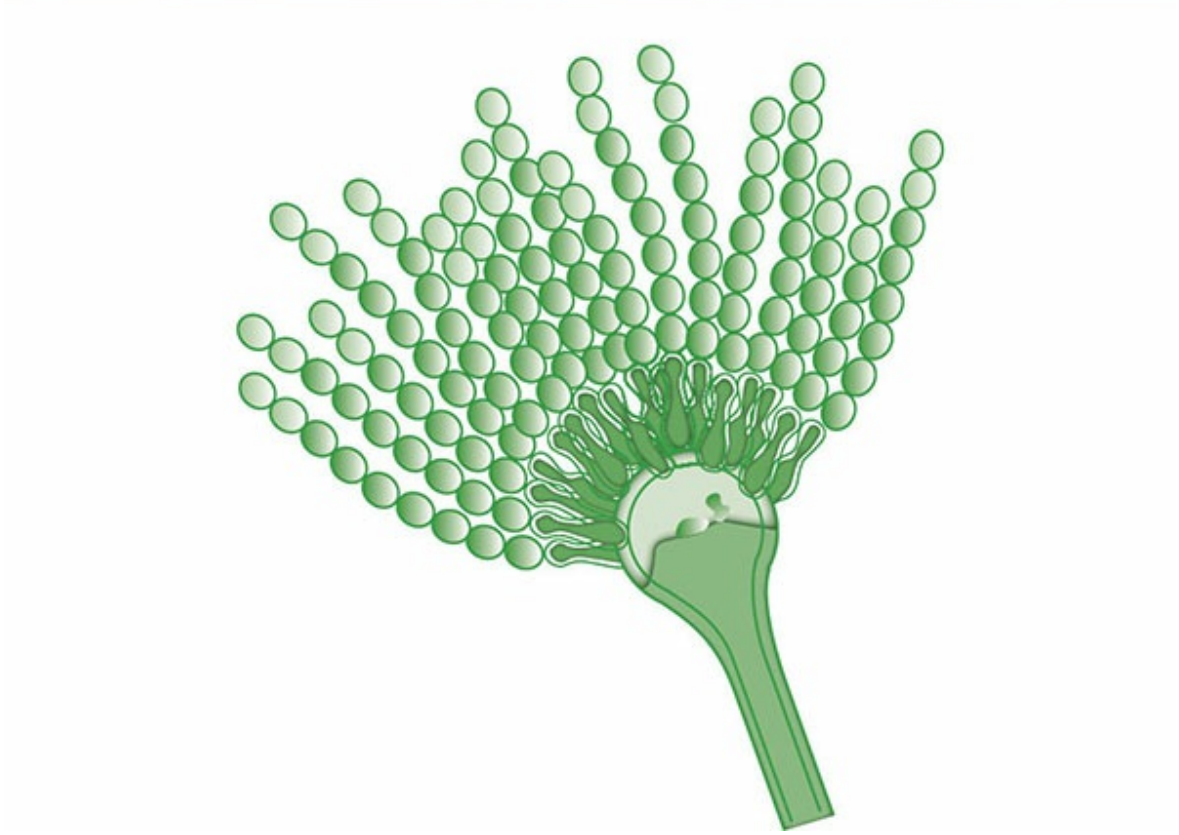
Microscopically, there is a single row of phialides that covers the upper two-third of a club-shaped vesicle (Fig. 21-22). The conidia are spherical, usually smooth, and arranged in a columnar fashion. The conidiophores are relatively long (300 to 500 µm), and, as denoted above, each is derived from a special segment of a septate hypha known as a foot cell (Fig. 21-19).

Aspergillus flavus. Colonies of *A. flavus* are granular to wooly and present with some shade of yellow, yellow-green, or yellow-brown (Image Plate 21-1D).

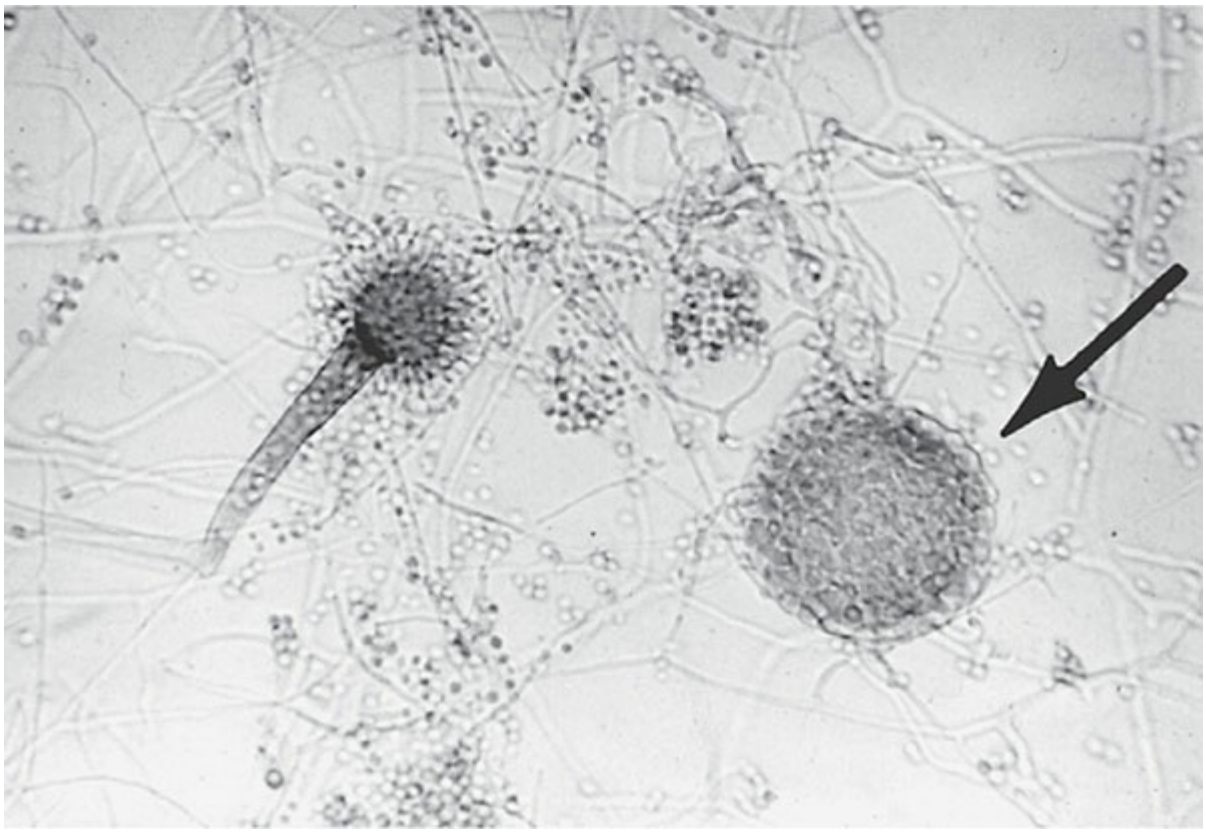
On microscopic examination, the phialides cover the entire vesicle and the conidia are arranged in what appears to some to resemble a daisy-petal-like arrangement. The conidiophores may be either uniseriate or biseriate (Fig. 21-23). The conidiophores are relatively long (500 to 800 µm). The length of the conidiophores proximal to the vesicle is distinctly roughened, which is a key feature used for the

1346

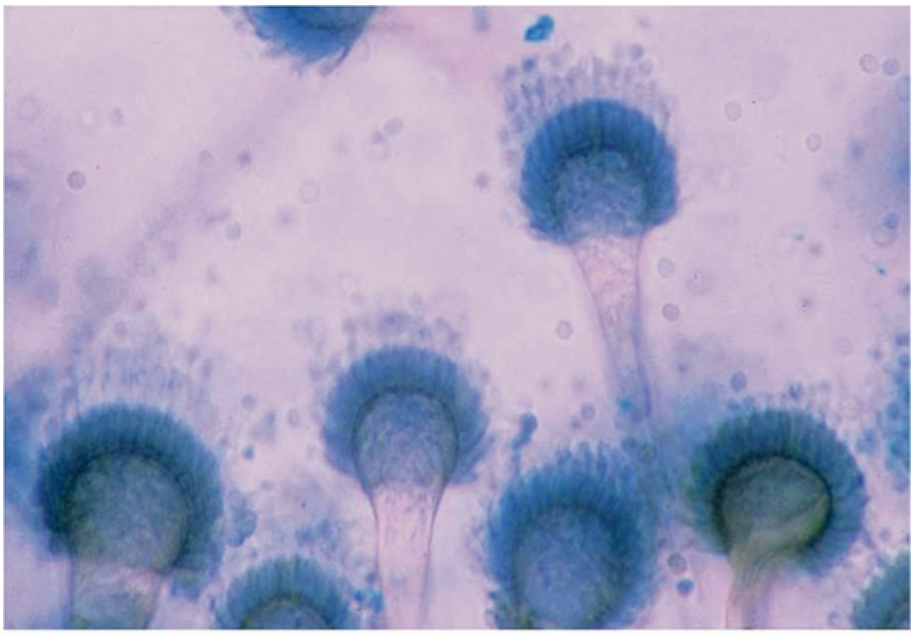




■ **FIGURE 21-20** Photomicrograph and sketch of a generic fruiting head of an *Aspergillus* species, illustrating the swollen vesicle giving rise to phialides from which chains of conidia are produced.



■ **FIGURE 21-21** Photomicrograph of a cleistothecium (*arrow*) of *Aspergillus glaucus,* illustrating the sexual or telomorphic form of reproduction. A typical anamorphic fruiting head (i.e., aspergillum) is seen to the left.



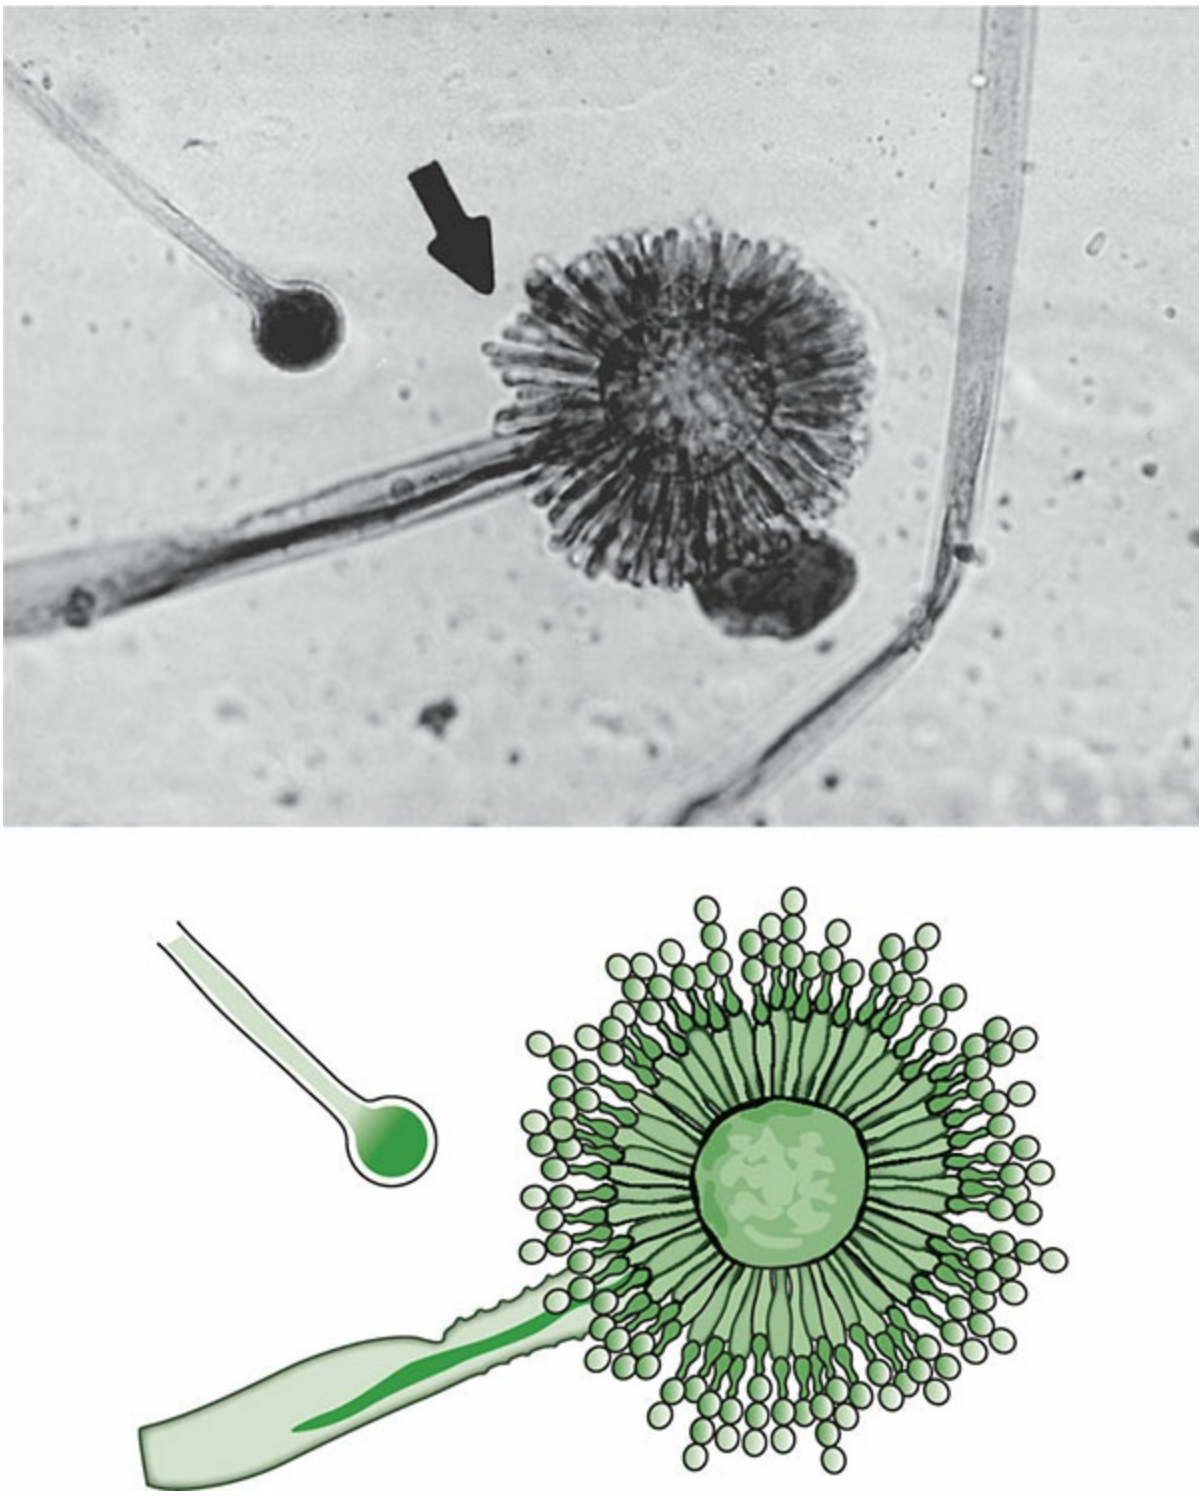
■ **FIGURE 21-22** Photomicrograph and sketch of the fruiting structure of *Aspergillus fumigatus,* illustrating a single row of phialides derived from the top half of a vesicle from which chains of conidia are produced.

identification of this species. The conidia are spherical, smooth, or slightly roughened with maturity, and have a yellow-brown pigmentation.

Aspergillus niger. The surface of a mature colony of *A. niger* is covered by a dense aggregate of jet-black conidia, giving a characteristic peppered effect (Image Plate 21-1E). The reverse of the colony is buff or yellow-gray, in contrast to the deeper brown-black pigmentation of the dematiaceous fungi to be described below.

Microscopically, there is usually profuse conidiation, with dense aggregates of single and short chains of jet-black, rough (echinulate) conidia. The entire surface of the vesicle is covered (Fig. 21-24, A). The conidiophores of *A. niger* are biseriate and the vesicle is globose (Fig. 21-24, B and C).

1347



■ **FIGURE 21-23** Photomicrograph and sketch of the fruiting structure of *Aspergillus flavus,* illustrating a central spherical vesicle supporting a double row of phialides derived from the entire surface.

Aspergillus terreus. Colonies of *A. terreus* are granular, radially rugose, and cinnamon buff, brown, or orange-brown (Image Plate 21-1F). This color is not commonly encountered, so when seen it should raise the possibility of *A. terreus*, which is important not to misidentify for therapeutic reasons.

The fruiting bodies (i.e., conidiophores) of *A. terreus* are similar to those of *A. fumigatus* in that phialides cover the upper two-third of the vesicle. Closer examination, however, reveals that the vesicles of *A. terreus* are smaller, the phialides are much longer, and the conidiophore is biseriate; however, the phialides and metulate are somewhat interdigitated, which obscures the line of division between the two cells (Fig. 21-25). The definitive identification of *A. terreus* can be achieved by demonstrating spherical aleuroconidia that arise directly from subsurface hyphae; a dig mount is used to demonstrate these structures (Fig. 21-26).

Aspergillus nidulans. *Aspergillus nidulans* is rarely encountered in clinical laboratories, but a brief discussion is included here because this species commonly produces sexual reproductive structures (cleistothecia and ascospores) in culture, which are discussed below. The colonies are generally white or gray-white, cottony to granular in consistency, and may have radial rugae (Image Plate 21-2G). A dark stippled effect may be noted with mature colonies as cleistothecia are produced. ***Aspergillus glaucus*** is another *Aspergillus* species that should be considered if cleistothecia and ascospores are seen. The colony generally is cottony to

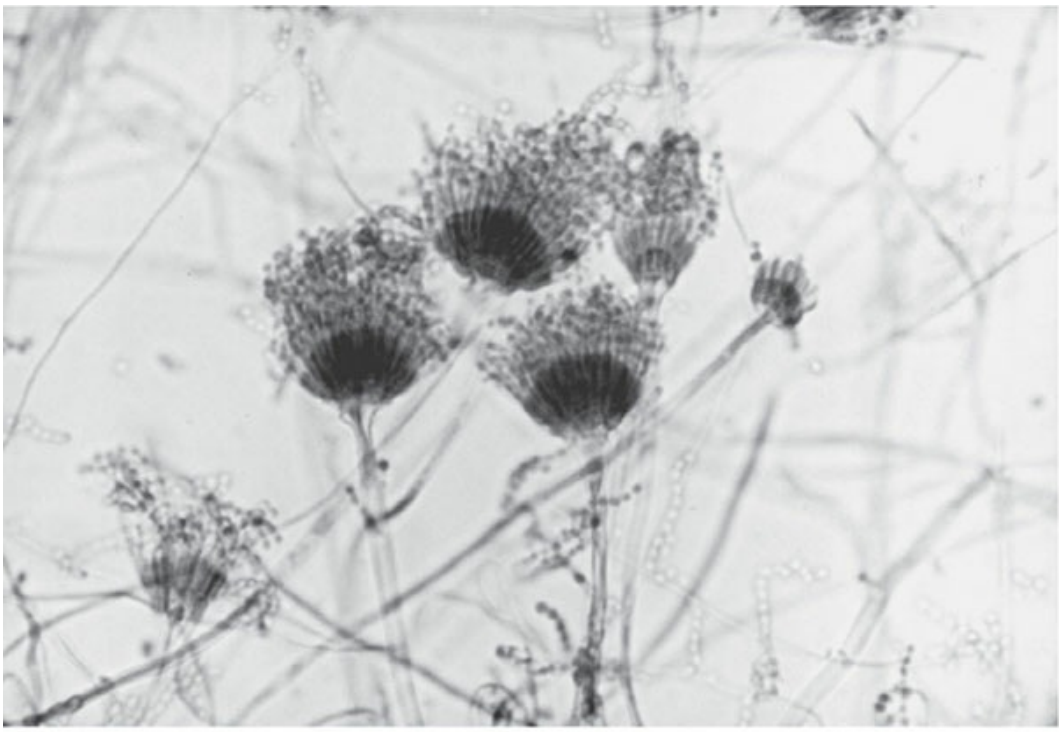
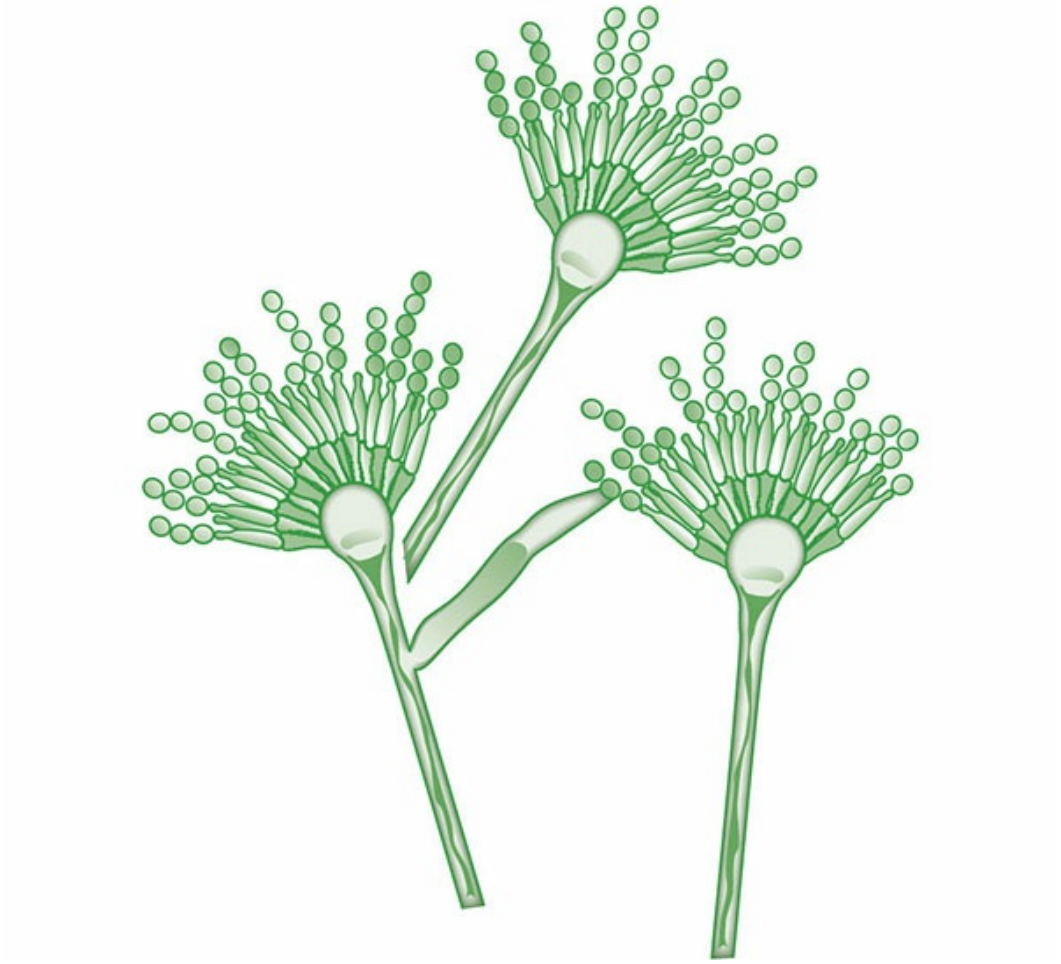
C

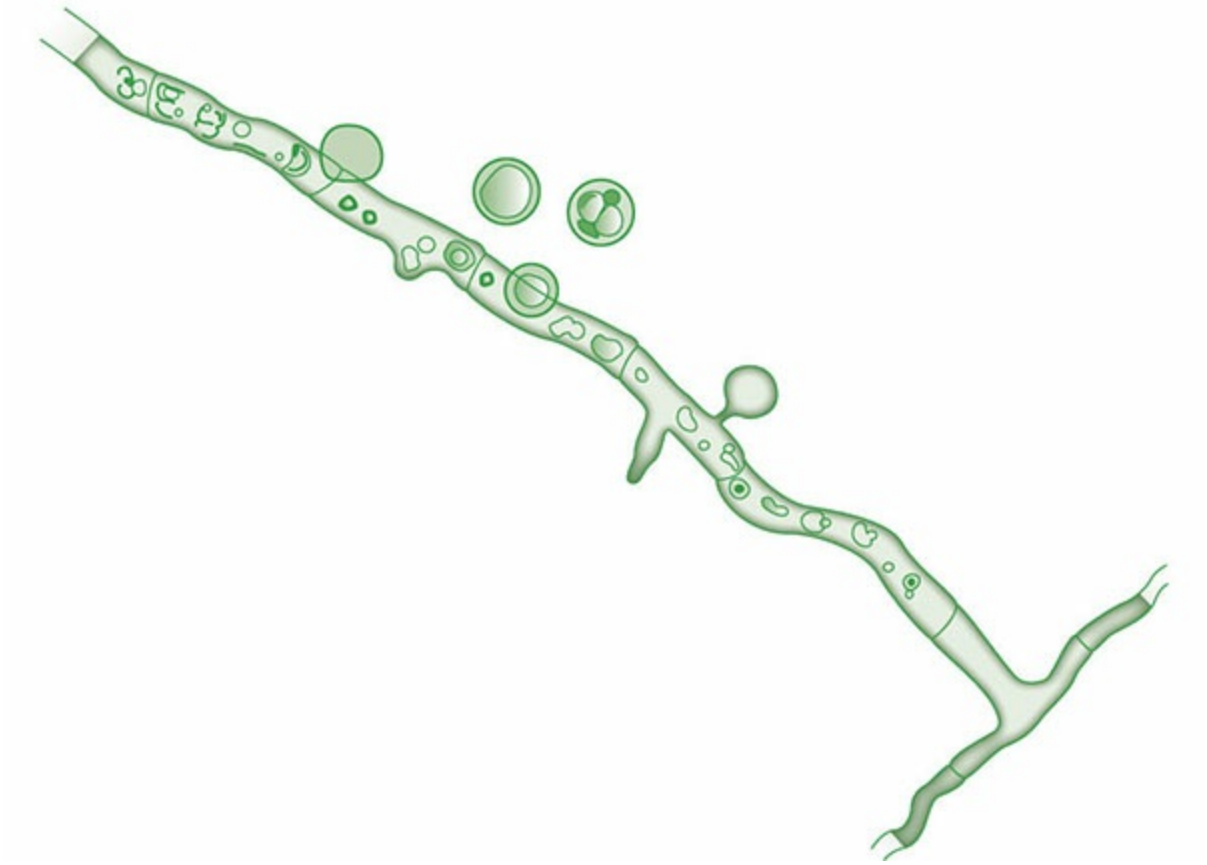
■ **FIGURE 21-24** These photomicrographs (**A, B**) and sketch (**C**) of *A. niger* demonstrate the long conidiophores characteristic of this species (**A**). The conidiation is often dense and arises around the entire vesicle (**B**). The biseriate nature of the the conidiophores is more clearly seen in the drawing (**C**) than in the photomicrographs.

1348

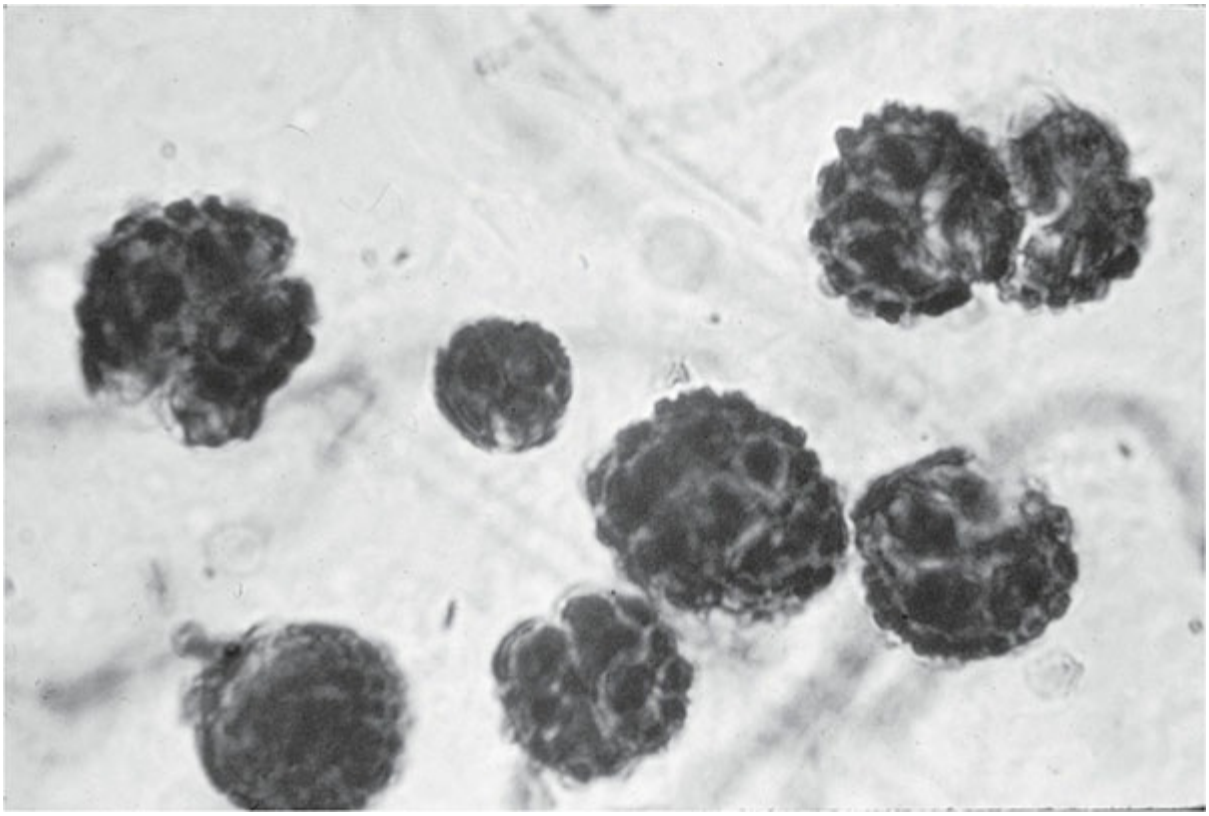




■ **FIGURE 21-25** Photomicrograph and sketch of the fruiting structure of *Aspergillus terreus* revealing conidiophores terminating in a swollen vesicle from the top half of which are derived a double row of sterigmata giving rise to chains of conidia.



■ **FIGURE 21-26** Photomicrograph and sketch of subsurface vegetative mycelia of *Aspergillus terreus,* illustrating spherical aleuroconidia characteristic of the species.



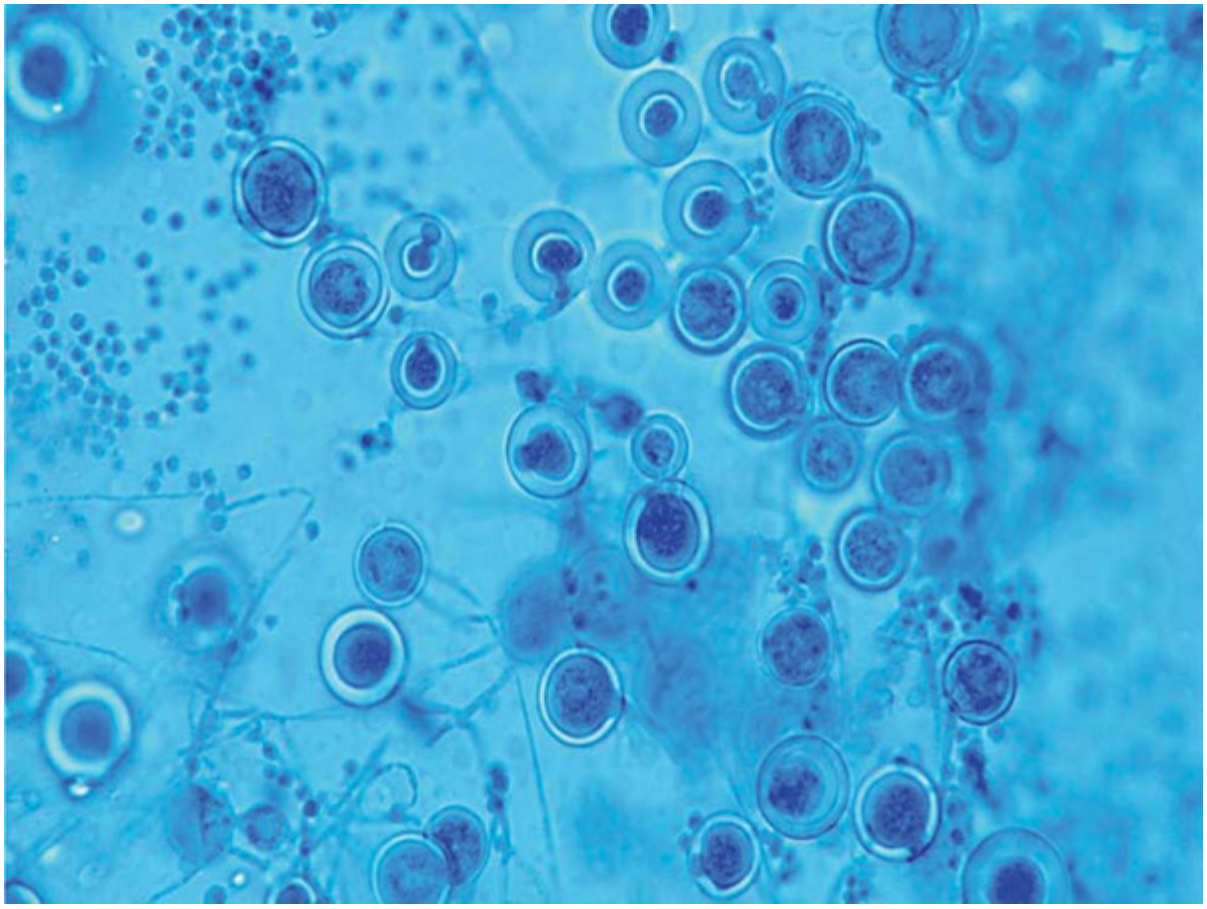
■ **FIGURE 21-27** Photomicrograph of several cleistothecia of *Aspergillus nidulans*; these saclike structures contain ascospores.

granular, and has a variegated green and yellow pigmentation (Image Plate 21-1H).

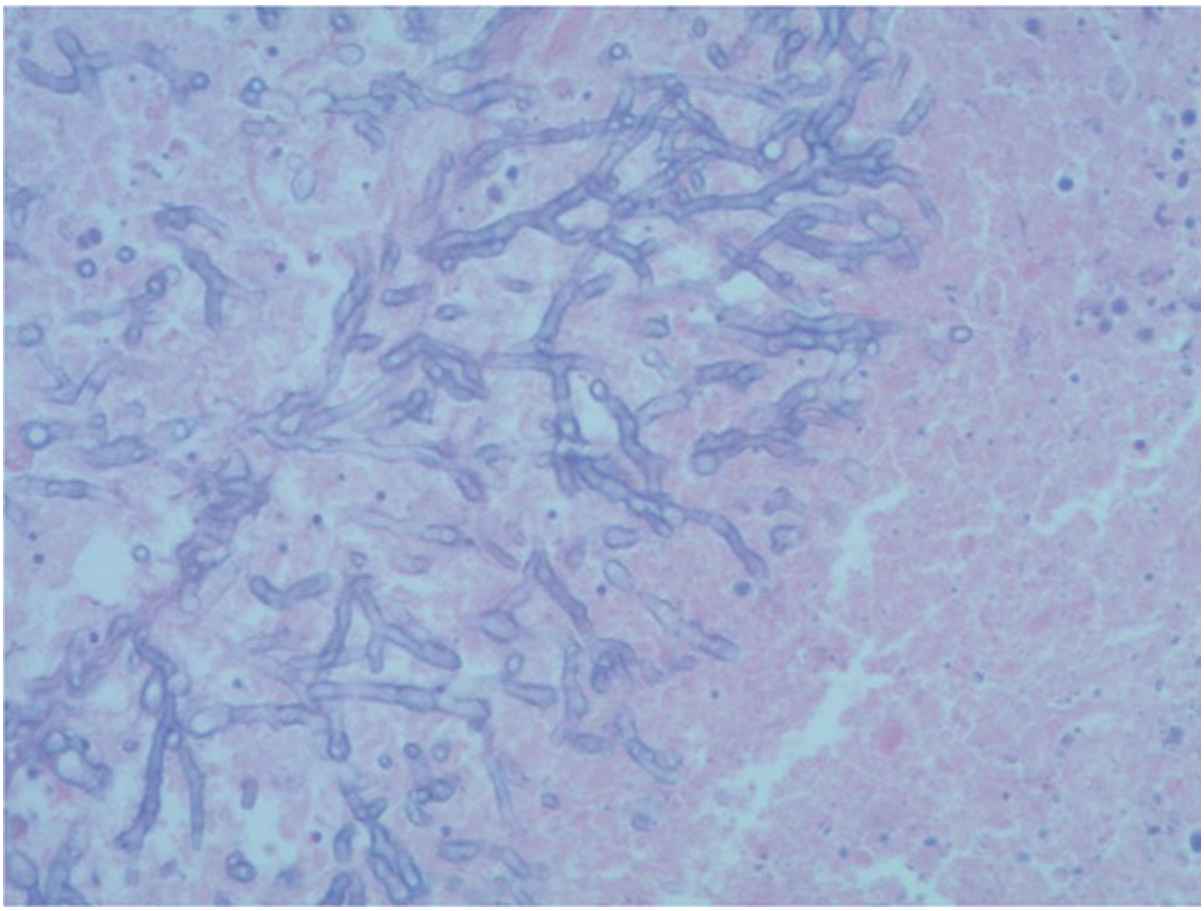
The aspergilli, belonging to the class *Ascomycetes,* are capable of sexual recombination through the union of two meiotically-derived (i.e., haploid) cells. The sexually reproductive structure that occurs in these and some other medically important fungi are spherical structures without a pore or opening; these are termed **cleistothecia** (Fig. 21-27). Within each cleistothecium are myriad asci, each containing four or eight **ascospores**. In addition to cleistothecia, some strains also produce spherical, hyaline bodies known as Hülle cells; these are the large spherical bodies in Figure 21-28. The precise function of Hülle cells is unknown. However, detection of the presence of Hülle cells is similar to the detection of cleistothecia in that their presence limits the identification of possible *Aspergillus* species to those able to produce these structures. Neither cleistothecia nor Hülle cells are commonly seen in clinical specimens.

Histopathology. The hyphae of *Aspergillus* spp., as observed in stained histologic sections or cytologic preparations, are characteristically hyaline, septate, and regular in outline and have parallel walls. They average from 3 to 6 µm in diameter and are divided by transverse septa (Fig. 21-29). The regular dichotomous branching is at approximately 45-degree angles. Although these features are helpful in differentiating these hyphae from those of *Zygomycetes*, they are not helpful in differentiating *Aspergillus* species from other causes

1349



■ **FIGURE 21-28** Photomicrograph of clusters of thin-walled, spherical, hyaline Hülle cells produced by *Aspergillus nidulans*.



■ **FIGURE 21-29** The dichotomously branching hyphae of *Aspergillus fumigatus* are illustrated in the necrotic tissues of this patient with invasive aspergillosis.

of invasive hyalohyphomycosis, such as *Fusarium* spp. or members of the *Pseudallescheria boydii* complex. The hyphae of *Aspergillus* species are usually visible in hematoxylin and eosin (H&E) sections, but are better highlighted using the PAS and GMS stains. The tissue reaction in immunocompetent hosts infected with these fungi may first be purulent, but in some disease states may become granulomatous. In severely immunocompromised hosts, in which infections are most likely to occur, hyphal invasion of the tissues is accompanied by a minimal-to-no cellular response, depending on the degree of neutropenia. In such instances, tissue necrosis may be the only response to injury. *Aspergillus* species, like the *Zygomycetes* and some other fungi, have a particular predilection to invade blood vessels, causing thrombosis and hemorrhagic infarction.

When a fungus colony grows, usually in a noninvasive manner, within a preexisting cavity, such as in a nasal sinus, bronchiectatic airway or within a congenital or inflammatory lung cyst, the lesion is known as a "fungus ball." The hyphae often appear amorphous and stain poorly. Fruiting heads with well-formed vesicles and

chains of conidia may be seen within cavities that are connected to open bronchi and exposed to air (Fig. 21-30). The lining of the cavity is often intact, with no evidence of extension into the surrounding tissue. Although any filamentous fungus can cause a fungus ball, *Aspergillus niger* is recognized as a common cause of fungus ball formation. The presence of black, rough (echinulate) conidia is a clue to the presence of this mold, if sporulation occurs. In addition, this fungus produces oxalic acid as a metabolic by-product and birefringent oxalate crystals, which have a "sheaf of wheat" appearance, may be seen. It is important that the exact crystal morphology is seen, since other types of crystals may be produced by other fungi.

■ **FIGURE 21-30** This photomicrograph from an *Aspergillus* fungus ball illustrates a typical aspergillum with the conidiophore terminating in a club-shaped vesicle upon which the phialides arise. (H&E stain, 400×)

Bronchopulmonary aspergillosis is a disease that is really misnamed, since fungi other than *Aspergillus*, as well as aerobic actinomycetes, cause the disease. This is caused by the inhalation of large quantities of these organisms. The aerosolization of hyphae fragments and filamentous bacteria when the material (e.g., harvested corn or grain) on which these organisms are growing is disturbed. The bronchi and bronchioles of the patient often are dilated and filled with viscid, mucinous material in which are

trapped cellular debris, many eosinophils, scattered neutrophils, lymphocytes, plasma cells, Charcot-Leyden crystals and hyphal or bacterial fragments. Invasion into tissue is not seen.

Diagnosis Using Nonculture Techniques. The galactomannan assay is a sandwich enzyme-linked immunosorbent assay (ELISA) kit that is currently available in many reference laboratories. This assay provides a means for the detection and monitoring of circulating galactomannan.[185] Although variation in sensitivity and specificity of this procedure has been found in different clinical trials and research studies, if used appropriately, this assay represents a major advance in the early detection of invasive aspergillosis in patients at risk for disseminated disease. Under study are the possible factors that affect the release of the *Aspergillus* antigen, the nature of the epitope that reacts with the monoclonal antibody used in the ELISA, its diffusion from the site of infection, and the manner in which it binds to substances present in the blood. This assay is best used to *monitor* the galactomannan

1350

levels in the blood of a patient at risk, rather than attempts to use it as a single, diagnostic test. Monitoring levels allows the clinician to follow trends and diminishes the chance of acting on a single spuriously high false-positive reaction.

Musher et al.[195] evaluated the performance of the galactomannan assay (GM EIA, Bio-Rad, Benicia, CA) in the detection of *Aspergillus* antigen or DNA in bronchoalveolar lavage fluid obtained from patients with invasive pulmonary aspergillosis (IPA). In the study of 47 patients with IPA and 46 control patients, the GM EIA assay performed with a sensitivity of 76% and a specificity of 94%. These authors cite the relatively low cost, ease of processing, and rapid results yielded by this assay using bronchoscopy as a viable alternative to an invasive biopsy to establish a diagnosis of invasive aspergillosis, particularly in high-risk patients. Similarly, Hayden et al.[122] found that galactomannan antigenemia preceded clinical, microbiologic, and radiologic evidence of invasive aspergillosis in pediatric oncology patients.

The several clinical presentations of aspergillosis are presented in Clinical Correlation Box 21-2.

CLINICAL CORRELATION BOX 21-2 Aspergillosis

Aspergillosis may present as well-defined clinical syndromes involving a variety of sites and organ systems: pulmonary, disseminated, central nervous system, cutaneous,

endocardial, and naso-orbital. Pulmonary aspergillosis is the most common, since the infective conidia usually gain access to the body through inhalation. Three broad categories that have been used to describe the involvement of the lungs by *Aspergillus* species are (1) the fungus ball, (2) allergic bronchopulmonary aspergillosis, and (3) invasive aspergillosis, which may be further subcategorized.[254]

These clinical forms of pulmonary disease are distinct entities, but invasive aspergillosis could develop from either of the former, depending largely on the immunologic status of the patient. Disseminated aspergillosis, which most commonly occurs in severely immunosuppressed patients, often begins as IPA. Dissemination may involve any organ in the body, including the brain with the formation of a fungal brain abscess.

Fungus Ball

A fungus ball is a mass of hyphae (i.e., a mycelium) from one or more molds that are growing in a saprophytic nature in a preexisting cavity. Old cavitary lung lesions caused by tuberculosis are a favored site of growth, in areas with a high prevalence of tuberculosis. The sinus cavities, pathologically dilated airways (i.e., bronchiectatic) and the external auditory canal are also sites wherein fungus balls may occur. A wide variety of fungi may be the cause of a fungus ball, but *Aspergillus* species, particularly *A. niger*, are well-recognized causes. A fungus ball that is caused by an *Aspergillus* species may be termed an aspergilloma. Interestingly, in many instances the fungus may outgrow its saprophytic food supply and die; thus, the fungus ball identified by the surgical pathologist or seen in the direct examination may not grow in culture. When the fungus is present in a cavity that connects with the air supply, then conidiation may occur; therefore, an aspergilloma may be definitively identified on a morphologic basis, if an aspergillum fruiting head is detected.

In most instances, the fungus ball remains confined to the cavity without invasion of the surrounding parenchyma. Regardless, the histopathologist should examine all associated tissue to assure the absence of invasion. Importantly, Nolan et al.[200]warn that aspergillomas should not be considered an indolent condition, as instances of intermittent or exsanguinating hemoptysis have been reported; in addition, erosion into adjacent structures may result in morbidity or death.

Allergic Bronchopulmonary Aspergillosis

Allergic bronchopulmonary aspergillosis is somewhat of a misnomer in that it is a usually caused by the inhalation of a variety of aerobic actinomycetes and fungi, which may or may not include *Aspergillus* species. Hallmarks of disease include peribronchiolar inflammation, infiltrating eosinophils, and Charcot-Leyden crystals trapped within mucin plugs expectorated in sputum specimens. Lee et al.[162] suggest that the following criteria pertain to make a diagnosis of allergic

bronchopulmonary aspergillosis: episodic bronchial obstruction, peripheral blood eosinophilia, cutaneous reactivity to *A. fumigatus* antigen, precipitating serum antibodies to *A. fumigatus*, elevated total serum IgE, history of pulmonary infiltrates, elevated serum IgE and serum IgG to *A. fumigatus*, and proximal bronchiectasis.

In cases of bronchopulmonary aspergillosis, serum IgE and IgG against *Aspergillus* fumigatus may be elevated in both serum and bronchoalveolar lavage specimens. The most common *Aspergillus* species causing allergic bronchopulmonary disease are *A. flavus* and *A. fumigatus*.

Invasive Pulmonary Aspergillosis

This form occurs almost exclusively in patients who are immunosuppressed or have neutropenia, particularly in those with leukemias and lymphomas.[283] The disease often presents as pneumonia (cough, fever, signs of respiratory distress). Pleural invasion may result in chest pain and a pleural friction rub. Because of the propensity for advancing hyphae to invade blood vessels, disseminated disease with metastatic spread to the central nervous system and other organs is possible.

1351

Although *Aspergillus* fumigatus and less commonly *Aspergillus* flavus are the two species most commonly involved,[161] *Aspergillus terreus* has also recently been incriminated. Woods and Goldsmith[303] reported four cases of disseminated disease caused by *A. terreus*, and reviewed five additional cases reported in the medical literature. In a more recent review of invasive *A. terreus* infections, Iwen et al.[134] culled 13 patients from the literature, 10 of whom died following distant dissemination of the disease. Most of the involved strains were resistant to amphotericin B.

Disseminated Aspergillosis

Because *Aspergillus* species has a propensity to invade into blood vessels, widespread dissemination into virtually any tissue or organ remains a threat in any cases of localized disease. Denning and Stephens,[67] in a review of over 2,000 cases of aspergillosis culled from the literature, found that aspergillosis in bone marrow transplant recipients is particularly devastating, with a mortality rate of 94% in reported cases, despite therapy. The overall rate of response to amphotericin B therapy of all cases reviewed in this series was 55%.

Ho and Yuen[127] postulate that the high mortality rate caused by invasive aspergillosis among bone marrow transplant recipients is the delay in diagnosis because an inflammatory response is blunted by immunosuppression.

Although AIDS per se is not considered a risk factor for IPA, the underlying risk factors, including leukopenia, use of corticosteroids, and IV drug abuse, put these patients at particular risk. In a series of patients with AIDS with aspergillosis reviewed by Singh et al.,[259] 79% were found to have one or more of these known predisposing risk factors. Invasive aspergillosis most commonly occurs in the later stages of AIDS, when the $CD4^+$ count is low, and when diagnosed it has a dismal prognosis. Only early diagnosis can improve the prognosis.[144]

Miscellaneous conditions associated with *Aspergillus* infections include otitis externa ("swimmer's ear," a chronic local inflammation of the auditory canal characterized by itching, pain, and scaling), which is most commonly caused by *A. niger*. Most cases can be cured by topical antifungal therapy and avoiding water exposure. *Aspergillus* sinusitis, often indistinguishable clinically from viral, bacterial, or allergic sinusitis and occurring in immunocompetent hosts, has occurred in at least 29 reported cases since 1987.[47] Several isolated cases of aspergillosis involving virtually every organ system have been reported, with predisposing conditions in these studies most commonly related to prolonged neutropenia, hematologic malignancies, spinal trauma or surgery, and prolonged used of corticosteroids.

Other Hyaline Septate Molds

Colony Characteristics. Display 21-2 outlines some of the other important hyaline septate molds or members of the hyalohyphomycetes. These can be suspected if rapidly growing, cottony, wooly, or granular colonies are recovered in culture within 3 to 5 days, usually presenting with a variety of surface colors, often of the pastel variety. The colonies are typically entire and have an outer margin, with the exception of *Gliocladium* spp. and *Trichoderma* spp., the colonies of which grow border to border over the surface, forming a green or yellow "lawn." Colonies appear more or less granular on the surface, depending on the degree of sporulation. The reverse of hyaline molds is light gray or buff in color.

Although in the past many of these were considered to be nonharmful saprophytes, several of the hyaline molds have emerged during the past two decades as agents of opportunistic fungal infections with significant morbidity and mortality. The patients at risk for infections by these fungi are the same as those at risk for invasive aspergillosis, namely those with severe underlying illnesses and compromised host defenses. These emerging infections are directly related to the success of medical community in controlling or curing certain diseases, but with therapeutics that produce either a transient or permanent immunosuppression. Examples include chemotherapeutics producing bone marrow suppression, immunosuppressive regimens used to control rejection in patients who have undergone transplantation, and new immunomodulating

drugs, like tumor necrosis factor-α inhibitors used to control or suppress inflammation in diseases such as rheumatoid arthritis, among others. The opportunistic fungi that cause disease in this setting include *Fusarium* species, *Acremonium* species, *Paecilomyces* species, *Pseudallescheria boydii* complex, and *Scedosporium prolificans*, among others.

The individual hyaline molds of medical significance, and most commonly recovered in clinical laboratories, are divided into three subgroups, depending on whether the conidia are: (1) produced in chains from phialides, (2) produced in clusters from conidiophores, or (3) borne singly and directly from the hyphae (Display 21-2). Each of these subgroups is presented in the following paragraphs.

Genera of Hyaline Filamentous Molds Producing Conidia in Chains

The hyaline molds featured here are characterized by the production of conidia in chains (Display 21-2).

***Penicillium* Species.** The colonies of *Penicillium* spp. are granular and entire, and generally those most commonly encounter produce surface colors in various shades of green, although yellow and yellow-brown variants are sometimes encountered (Image Plate 21-2A). Color is an important feature for the differentiation of these organisms from *Paecilomyces* species, which may produce a superficially similar conidiophore; *Paecilomyces* are not green. The vast majority of *Penicillium* species that are encountered are contaminants. It is important to accurately identify these both to finalize the culture and to differentiate these fungi

from *Paecilomyces,* which may be a pathogen. One species of *Penicillium*, *Penicillium marneffei*, has been shown to be a pathogen in patients with AIDS. This species is a dimorphic pathogen, producing a yeast-like form in the human body, and an infection similar to that of disseminated histoplasmosis in this population. This species, which is geographically limited to Southeast Asia, produces a wine-red pigment that diffuses into the agar (Image Plate 21-2B). The identity of isolates suspected to possibly represent *P. marneffei* can be confirmed by demonstrating thermal dimorphism or through molecular methods.

Microscopically, all *Penicillium* species produce **"penicillus"** (brush) structures. These are a conidiophore with the terminal production of primary metulae and secondary phialides, the latter of which produces chains of conidia (Fig. 21-31). It is important to observe that the tips of the phialides are blunt, in contrast to the long and tapered phialides produced by *Paecilomyces* and *Purpureocillium*. The conidia are spherical, regular in size, and evenly staining, representing an **acropetal** type of

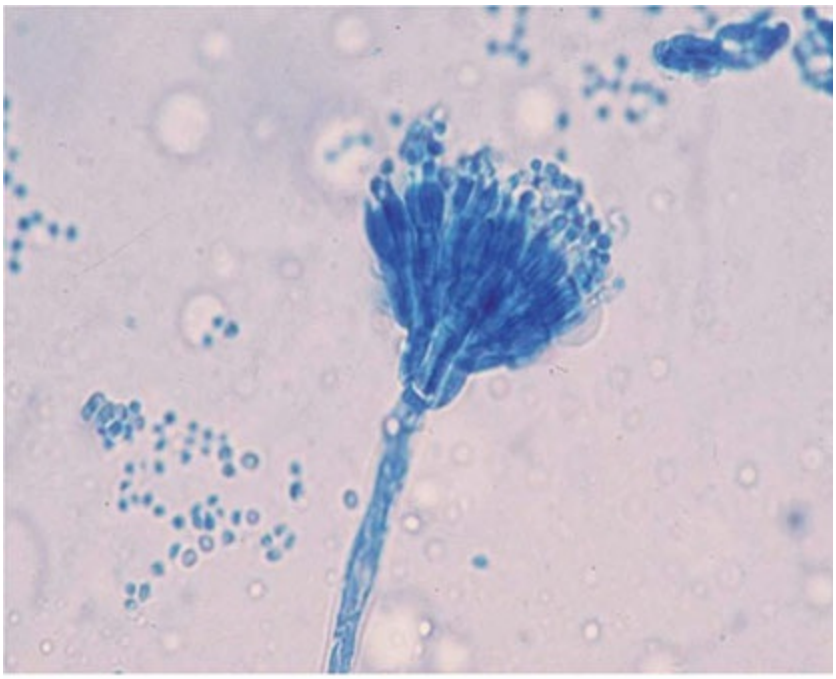
conidiation in which identical conidia are produced in sequence from the tips of the conidia previously formed (Box 21-1).

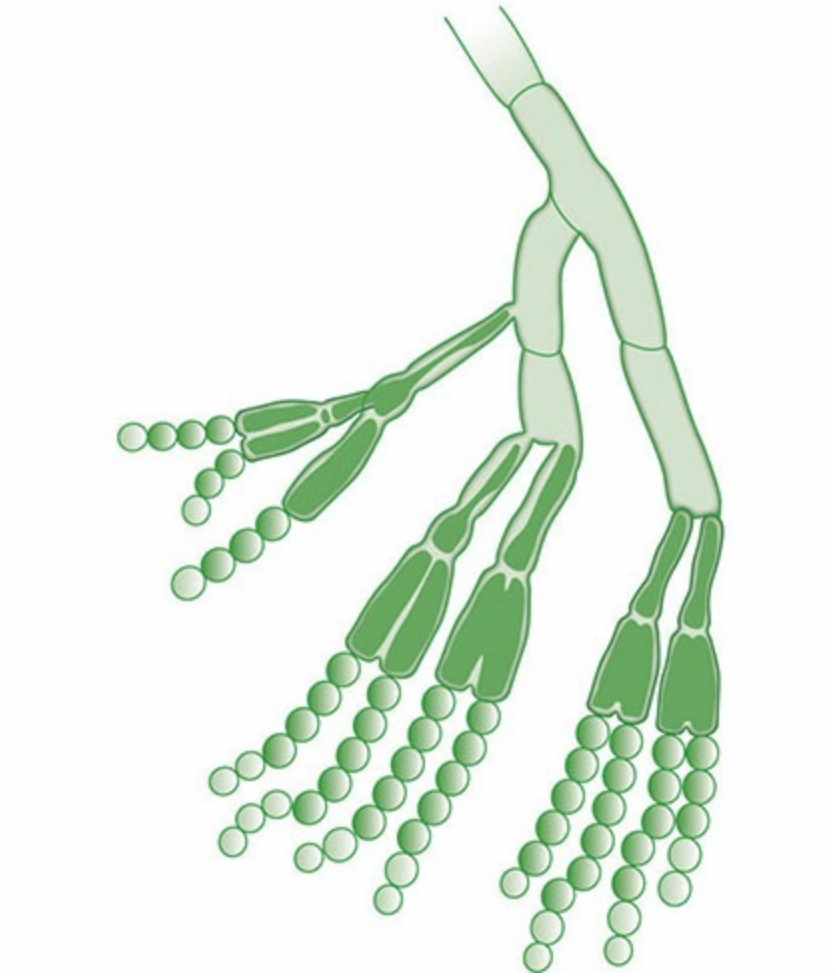
***Paecilomyces* and *Purpureocillium* Species.** In the past, both these fungi were included in the genus *Paecilomyces*, but subsequently the species *lilacinus* has been reassigned to the newly formed genus *Purpureocillium.* The colonies of *Paecilomyces variotii* are usually buff, tan or light brown, whereas those of *Purpureocillium lilacinus*, not surprisingly, are light purple. The surface of the colonies of these fungi tends to be quite granular because of the production of myriad conidia (Image Plate 21-2C).

Two important microscopic observations are useful for the identification of *Paecilomyces* or *Purpureocillium* spp. The tips of the phialides of these organisms are **long and tapered**, terminating in a point, in contrast to the blunt ends of phialides seen with *Penicillium* spp. (Fig. 21-32). Secondly, the conidia are oval to elliptical, irregular in size, and uneven in staining, representing **basipedal** conidiation in which each new conidium is formed directly from the tip of the phialide, pushing the previous conidium ahead of it. Therefore, the "older" conidia at the tips are larger and more deeply staining than those produced previously.

***Scopulariopsis* Species.** There are two *Scopulariopsis* species of medical importance, a dematiaceous species, *S. brumptii,* and the hyaline species, *S. brevicaulis* covered here. The colonies are characteristically yellow-brown to buff and granular and develop radial rugae emanating from the center to the periphery (Image Plate 21-2D).

The identification of *Scopulariopsis* spp. can be made microscopically from observation of the size and morphology of the conidia. The conidia are two to three times larger than those of *Penicillium* spp. and *Paecilomyces* spp., are entirely spherical, except for the presence of a distinct flat or truncated base. They are arranged in chains, with the truncated base of each successive conidium attached to the round terminus of the previous conidium (Fig. 21-33). Initially, the conidia are smooth; however, as the colony matures, the outer wall becomes distinctly roughened (**echinulate**). Sharp focus of the microscope objective may reveal a short, rodlike connection between adjacent conidia. The production of conidia for *Scopulariopsis* spp. is **annellogenic;** that is, when each new conidium is produced there remains behind a portion of the thickened truncated base or scar known as an **annellide**. When a new conidium is formed, it pushes the previous conidium forward and the chain of conidia is formed.



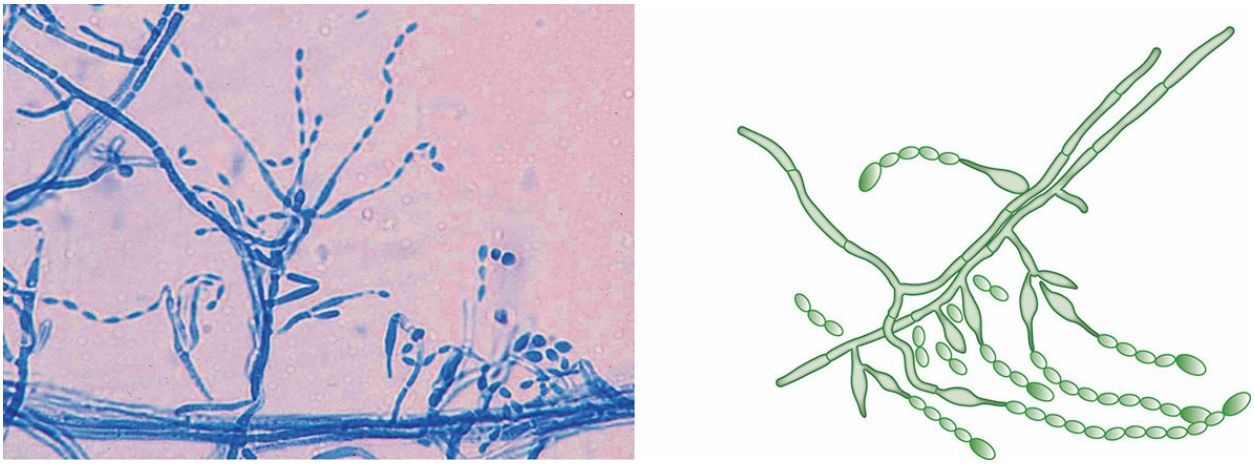


■ **FIGURE 21-31** Photomicrograph and sketch of the fruiting structure of *Penicillium* species, illustrating the branching phialides from which are produced chains of spherical conidia.

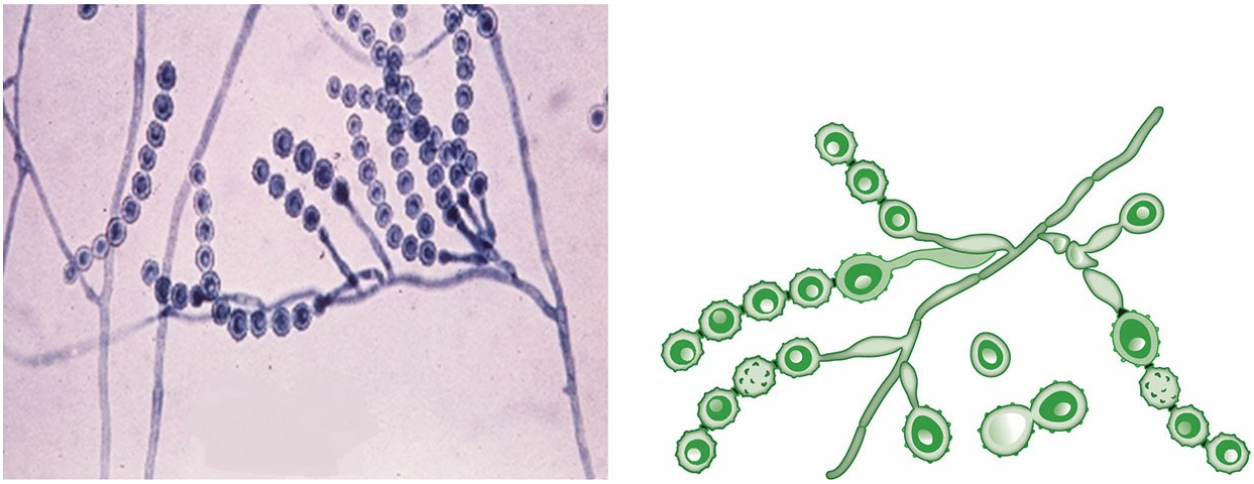
Identification of Hyaline Molds Producing Conidia in Clusters

This group of hyaline fungi is characterized by the formation of conidia in clusters. The conidia may be elongated or

1353



■ **FIGURE 21-32** Photomicrograph and sketch of the fruiting structure of *Paecilomyces* species, illustrating the long tapered phialides from the tips of which are produced chains of elliptical conidia. Note: the terminal conidium is often slightly larger than the rest.



■ **FIGURE 21-33** Photomicrograph and sketch of the fruiting structure of

Scopulariopsis species, illustrating the chains of characteristic large, circular annelloconidia.

elliptical, as with *Acremonium* and *Fusarium* spp., or spherical, as with *Gliocladium* and *Trichoderma* spp. Among these four, *Fusarium* spp. are unique in that they produce both microconidia and macroconidia. Guidelines for the separation of these three species are outlined in Display 21-2.

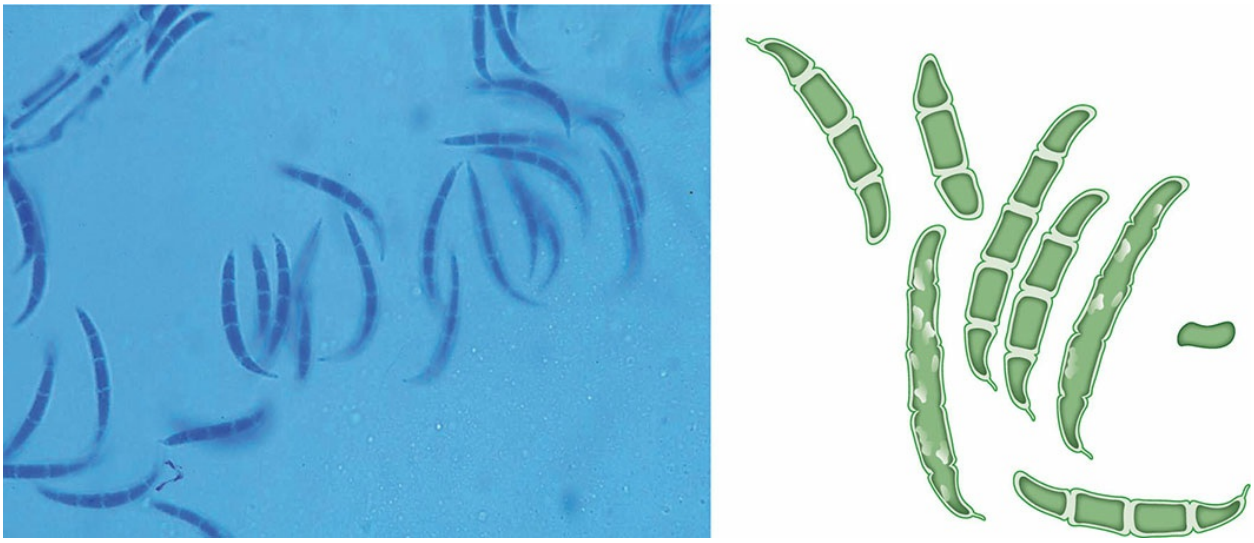
***Acremonium* Species.** The colonies of *Acremonium* spp. generally appear less wooly or granular than other hyaline molds, but rather are smooth, glabrous, or cottony in appearance because of the production of a very delicate mycelium. Colonies may be white or various shades of light pastel green or yellow (Image Plate 21-2E).

As observed microscopically, the conidia of *Acremonium* spp. are elongated to spherical, and arranged in loose clusters (Fig. 21-34). Each cluster is borne at the tip of a long, slender, delicate conidiophore that ends in a blunt tip. Important for the identification of *Acremonium* is the presence of a septum at the base of the tapered conidiophore (i.e., a basal septum). Macroconidia are not observed.

***Fusarium* Species.** There are a wide variety of *Fusarium* species, many of which are plant pathogens. In most instances, attempts are not made at species-level identification. These are important to promptly identify, as they are an important cause of hyalohyphomycosis (i.e., fusariosis) in immunocompromised patients. The colonies are generally cottony or wooly, and have distinctive pastel coloration; the surface of these may be lavender, pink, deeper red, or magenta. The reverse side also typically displays some pigmentation (Image Plate 21-2F).

Of the hyaline filamentous molds reviewed here, *Fusarium* spp. are unique in that they produce both **microconidia** and **macroconidia.** The microconidia are similar to those produced by *Acremonium* spp. The key feature used for the identification of *Fusarium* spp. is the observation of long, sickle-shaped, multicelled macroconidia; transverse septa separate the cells from one another within the macroconidia (Fig. 21-35). Exact focusing on the hilar cell reveals a hairlike extension, which designates this as the **"foot cell."** The

■ **FIGURE 21-34** Photomicrograph and sketch of the fruiting structure of *Acremonium* species, illustrating the delicate conidiophore supporting a loose cluster of elliptical conidia arranged in a "diphtheroidal" pattern.



■ **FIGURE 21-35** Photomicrograph and sketch of the long, multicelled, canoe-shaped macroconidia characteristic of *Fusarium* species.

presence of a foot cell is helpful in separating *Fusarium* spp. (foot cell present) from *Cylindrocarpon* spp. (foot cell absent), the latter being a soil organism rarely encountered in clinical laboratories.

***Gliocladium* Species.** The colonies of *Gliocladium* spp. are green or green-yellow and extend from edge to edge of the agar plate as a "lawn" of growth, without a margin. The surface is generally powderlike (Image Plate 21-2H).

The regular-sized, spherical conidia of *Gliocladium* spp. as observed

microscopically are also tightly clustered, and appear similar to those produced by *Trichoderma* spp. (below). However, in contrast to *Trichoderma* spp., in which each conidium is derived at the tip of a single conidiophore, the cluster of conidia produced by *Gliocladium* spp. is supported at the tips of three or four tapered conidia on what appears to be a rudimentary penicillus structure (Fig. 21-36).

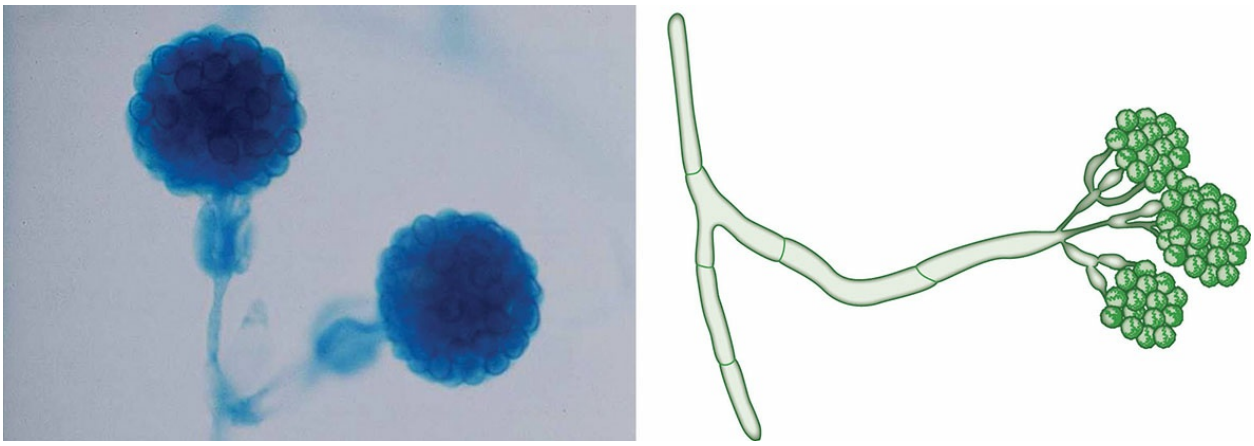
***Trichoderma* Species.** The colonies are similar to those of *Gliocladium* spp., also producing a granular "lawn" of growth that extends from one edge of the agar plate to the other. Colors tend to be yellow and green.

The conidia of *Trichoderma* spp. as observed microscopically are regular in size, spherical, and tightly clustered (Fig. 21-37). The conidia form adherent to one another at the tip of the conidiophore. Although a similar spore mass is produced by *Gliocladium* spp., those produced by *Trichoderma* spp. are located at the tips of individual tapered phialides. Although usually smaller to some these appear similar to those of *Paecilomyces* spp. in that the conidiophore is derived laterally from the hyphae.

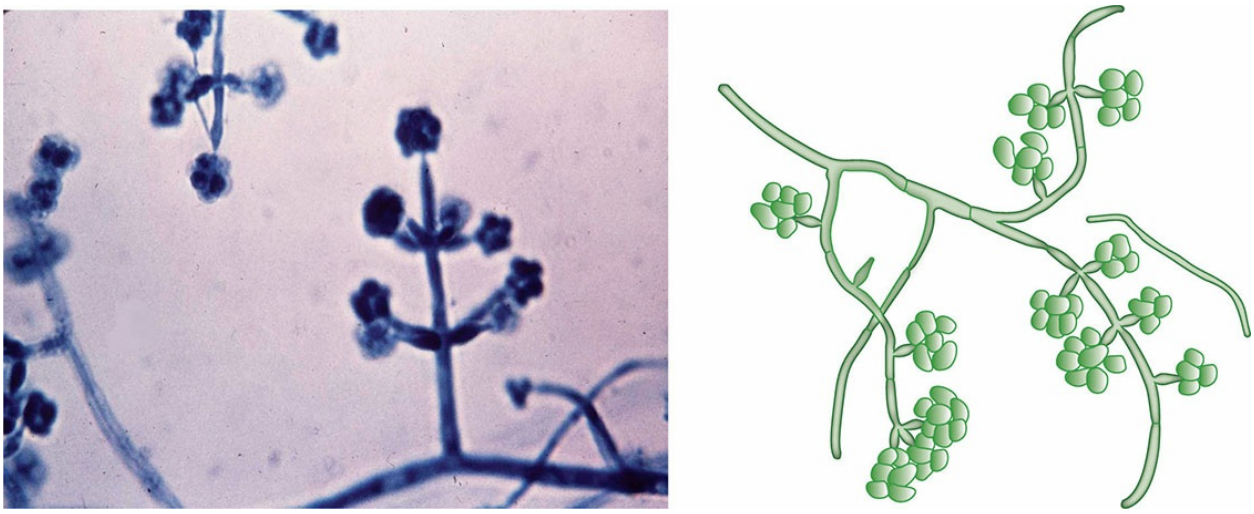
Identification of the Genera of Hyalohyphomycetes Producing Conidia Singly

For many years, *Pseudallescheria boydii* was thought to be the teleomorphic or sexual form of *Scedosporium apiospermum*. However, as with several other groups of fungi, DNA sequence analysis of taxonomically-important genes

1355



■ **FIGURE 21-36** Photomicrograph and sketch of the fruiting structure of *Gliocladium* species, illustrating the fingerlike phialides supporting compact clusters of spherical conidia.



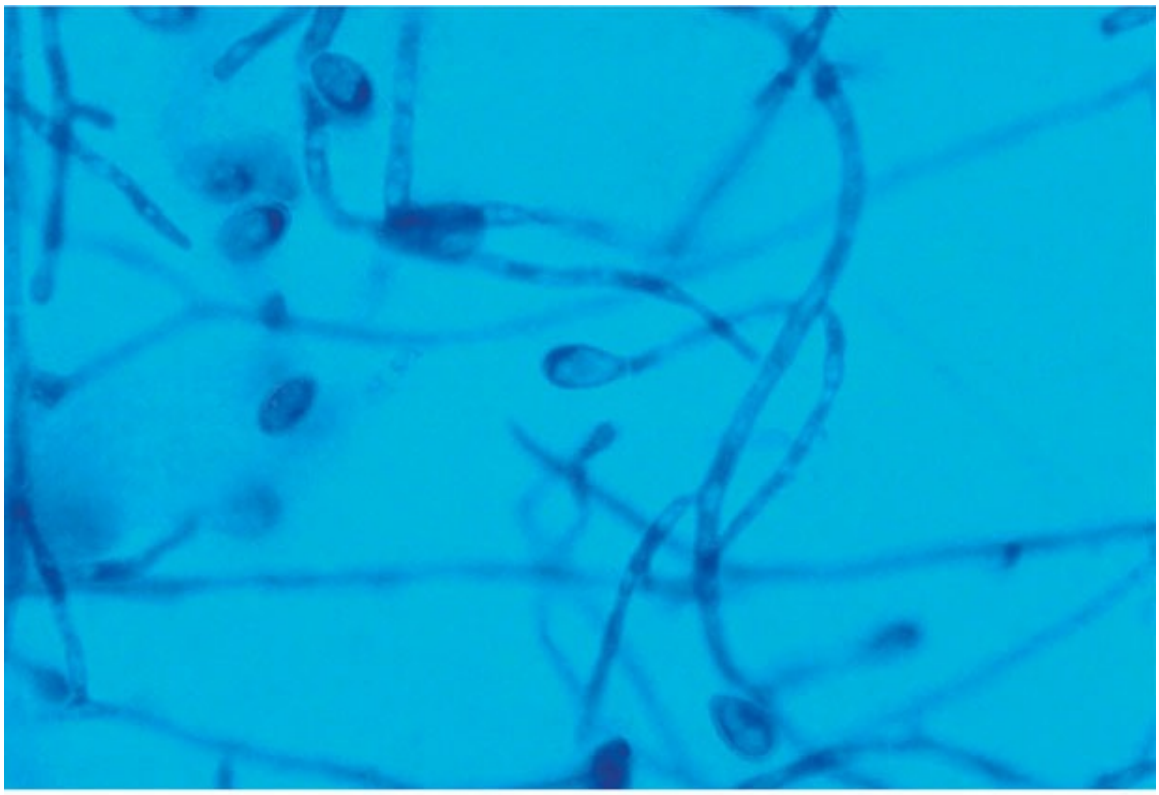
■ **FIGURE 21-37** Photomicrograph and sketch of the fruiting structure of *Trichoderma* species, illustrating the laterally placed tapered phialides supporting compact clusters of spherical conidia.

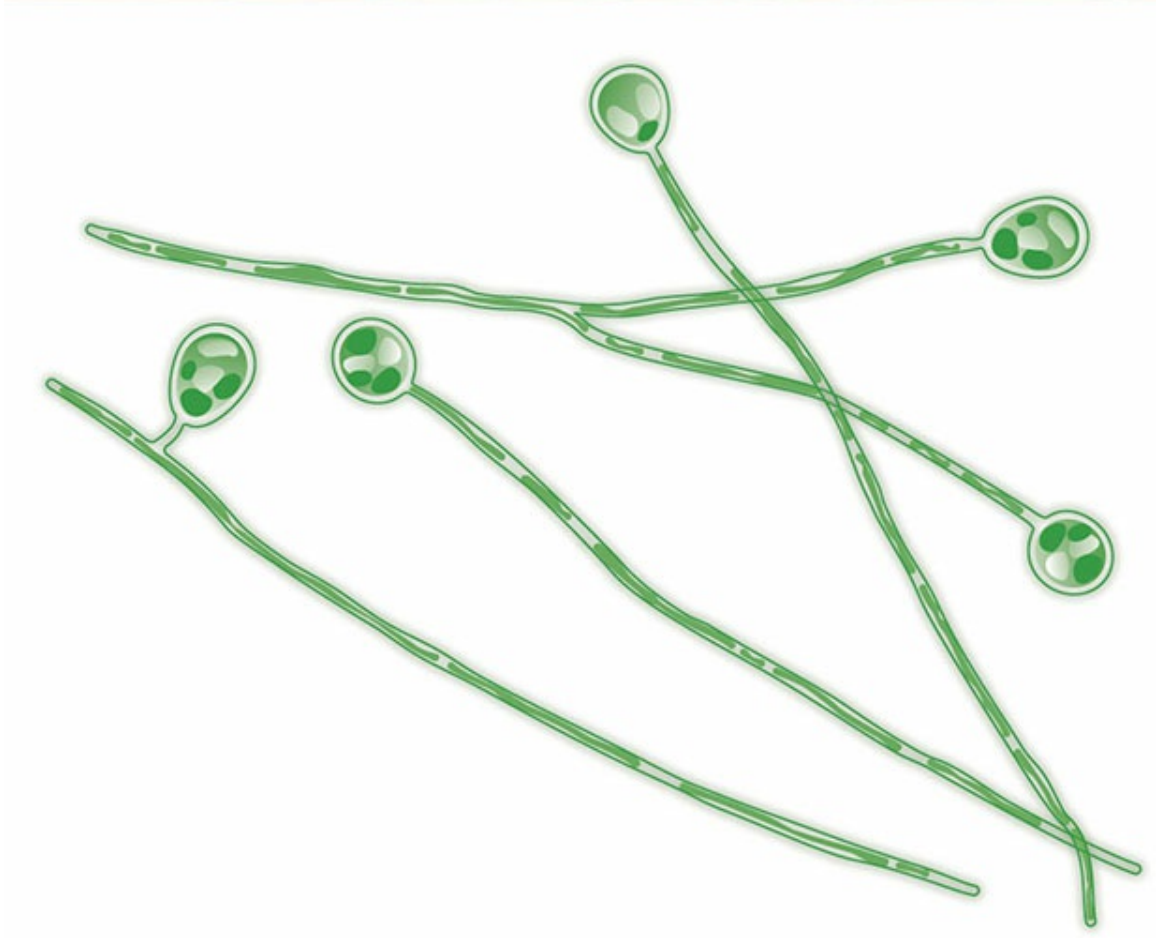
has disclosed the short comings of purely morphologically-based taxonomy. It is now known that there are several different organisms within the group we will refer to as the *Pseudallesheria boydii* complex. This group produces colonies with the so-called "house-mouse gray" coloration. The reverse may be buff to light brown and darkens with time. The colony morphology of the other fungi covered here (i.e., *Chyrsosporium* etc.) is not distinctive. These colonies are usually entire, white to gray, smooth to slightly granular, and often rugose. Microscopic examination is required to make a genus separation, as discussed below. This group of hyaline fungi is characterized by the formation of conidia singly from the tips of individual, straight, or branched conidiophores. The unique microscopic features of each of these species are described below, as outlined in Display 21-2.

***Pseudallescheria boydii* Complex.** The members of the *Pseudallescheria boydii* complex are an important cause of infection in immunocompromised patients. Interestingly, there is also an association with near-drowning events. Microscopically, the hyaline septate hyphae are present from which arise non-descript, straight conidiophores. Members of the *P. boydii* complex produce characteristic thin, smooth-walled, pyriform-to-ovoid, conidia 3 to 5 μm in diameter from the tips of unbranched conidiophores (Fig. 21-38). It is important to note that the conidiophores are not swollen at the base or "inflated," which is the characteristic of a dematiaceous *Scedosporium* variant, *S. prolificans* (Fig. 21-39). Mature conidia take on a dark pigmentation with age, thus resulting in the house-mouse gray colony previously described. The tips of the conidiophores actually extend when a spore is produced, with the formation of annellides, which are difficult to see with light microscopy, but

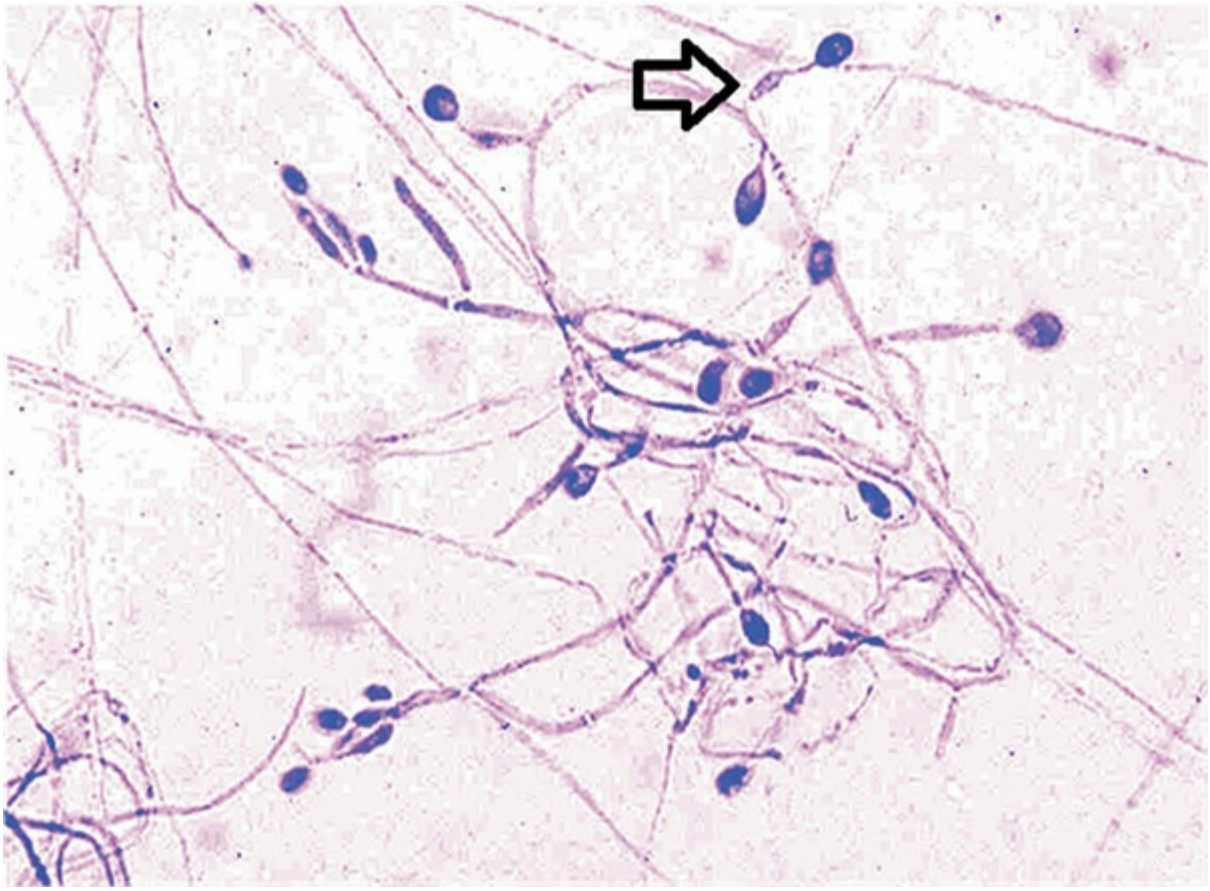
are readily evident in scanning photomicrographs. The annelloconidiation also imparts a flattened end at the smaller end of the pyriform conidia. In some strains, there may be the parallel bundling of conidiophores to form the graphium anamorph (Fig. 21-40). Detached conidia may occur singly or may aggregate in loose clusters.

1356

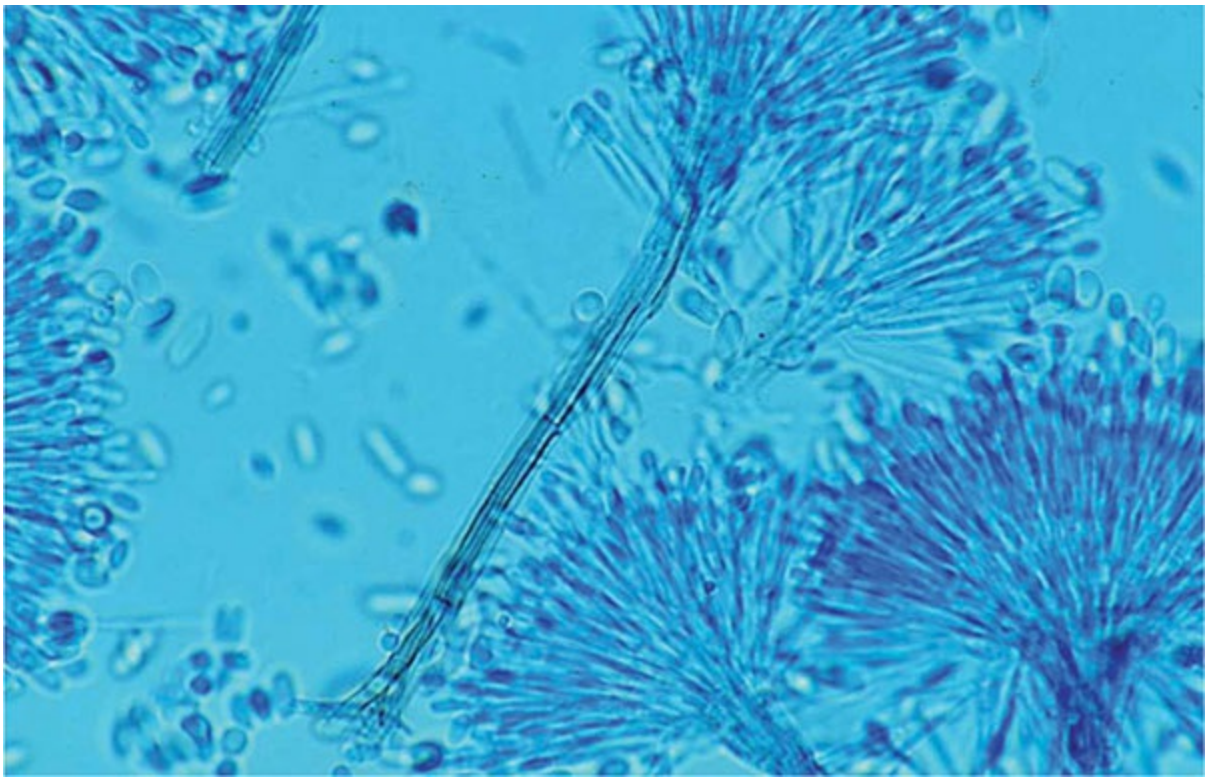




■ **FIGURE 21-38** Photomicrograph and sketch of the long, straight, delicate conidiophores, each supporting a single oval, dark-staining conidium characteristic of a member of the *P. boydii* complex.



■ **FIGURE 21-39** Photomicrograph of the conidia of *Scedosporium prolificans,* illustrating the characteristic urn-shaped swelling of the base of the conidiophore (*arrow*).

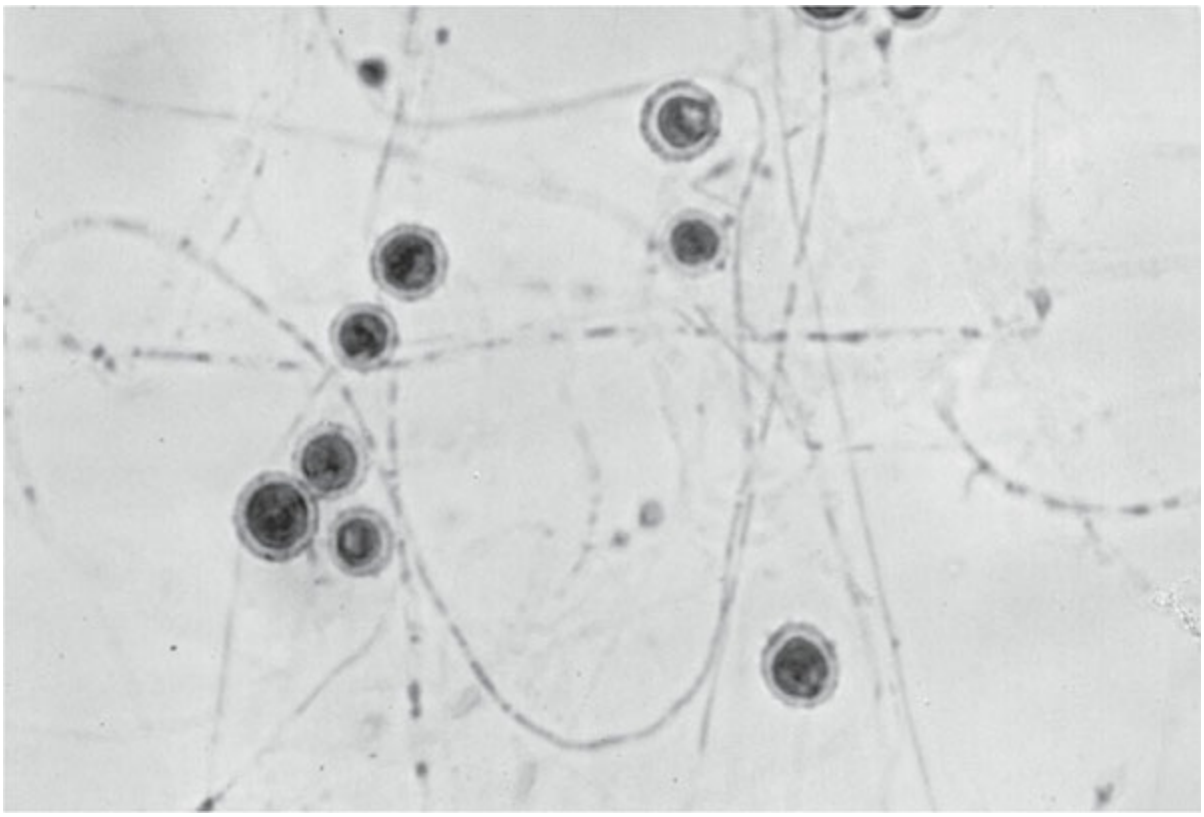


■ **FIGURE 21-40** Photomicrograph of the graphium anamorph of a member of the *P. boydii* complex, which is arranged in fan-like bundles simulating sheaves of wheat. (Compliments of Dr. Glenn Roberts, PhD.)

***Chrysosporium* Species.** The colonies of *Chrysosporium* spp. are not distinctive. These are white to gray, cottony, or wooly, and develop after 2 to 4 days of incubation. Microscopically spherical, subglobose to pyriform conidia are borne singly at the tips of long lateral conidiophores; these closely resembling the conidia of *Blastomyces dermatitidis* (Fig. 21-41). The bases of the conidia may appear flattened and scarred from annelloconidiation. The colonies of *Chrysosporium* spp. generally grow more rapidly than those of *B. dermatitidis*; in contrast to *B. dermatitidis* do not grow on cycloheximide-containing selective culture media; and, unlike *B. dermatitidis*, cannot be converted to a yeast form upon incubation at 35°C to 37°C. In practice, nucleic acid probe or other molecular studies (e.g., DNA sequencing) may be performed on colony extracts to exclude the possibility of *B. dermatitidis* and support the identification of *Chrysosporium*.

■ **FIGURE 21-41** Photomicrograph of *Chrysosporium* spp., illustrating spherical to oval-shaped conidia each supported by a short, straight conidiophore ("lollipops"). This organism is a morphologic mimic for members of the *P. boydii* complex and *Blastomyces dermatitidis*.

1357

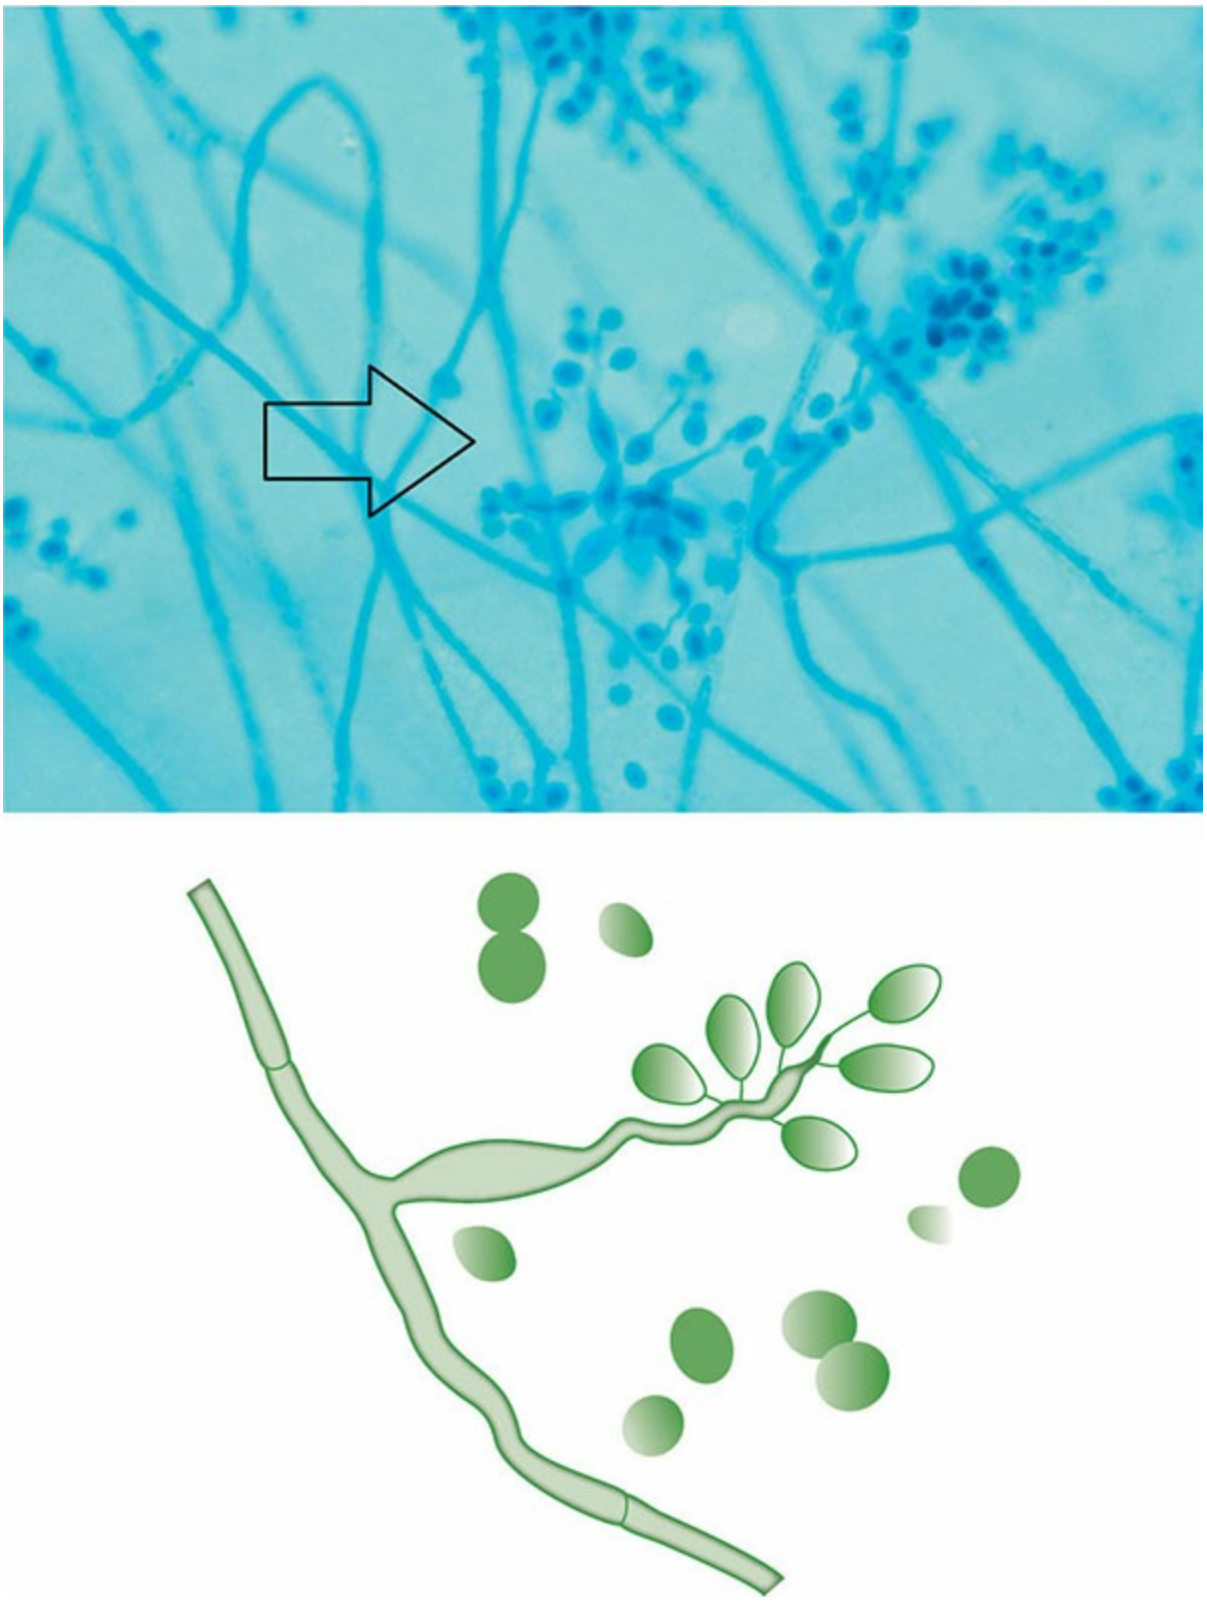


■ **FIGURE 21-42** Photomicrograph illustrating large, spherical, finely echinulate conidia characteristic of *Sepedonium* species.

***Sepedonium* Species.** The colonies of *Sepedonium* spp. are similar to those of *Chrysosporium* spp. described above, and cannot be distinguished visually. Microscopically, the observation of large, spherical, bluntly spiked macroconidia, simulating those of *H. capsulatum,* is characteristic (Fig. 21-42). The colonies of *Sepedonium* species grow more rapidly than those of *H. capsulatum*; unlike *H. capsulatum*, this fungus is inhibited on selective media containing cycloheximide; and, *Sepedonium* species cannot be converted to a yeast form on incubation at 35°C to 37°C. Smaller, ovate conidia, borne singly from short conidiophores, may also be observed in some strains, but are not common. These elongated microconidia are useful in differentiating *Sepedonium* species from *H. capsulatum*, which produce spherical microconidia. In practice, a DNA probe or other molecular technology (e.g., DNA sequencing) is used to exclude the possibility of *H. capsulatum* and support the identification of the fungus as *Sepedonium.*

***Beauveria* Species.** *Beauveria* is a very uncommon human pathogen. This is, however, an important insect pathogen and was responsible for the death of countless silkworms and the decline of the silkworm industry that Louis Pasteur was called on to investigate. The colonies have a white, cottony surface. The reverse of the colony is a

light buff. Microscopically, tiny, globose microconidia are densely aggregated around delicate, short, swollen conidiophore that near the terminus bends in a zigzag manner. This "bent knee" configuration is termed **geniculate** (Fig. 21-43). Each conidium is borne in one plane, after which the conidiophore turns before bearing another conidium in another plane, and so forth. Therefore, the type of conidiation produces conidia from all sides of the conidiophore, a configuration that is termed **sympodial.**



■ **FIGURE 21-43** Photomicrograph and sketch illustrating the delicate, zigzag conidiophores of *Beauveria* spp., with denticles each supporting a single, oval-shaped

conidium.

The various clinical manifestations of opportunistic infections with hyaline molds are presented in Clinical Correlation Box 21-3.

CLINICAL CORRELATION BOX 21-3 Hyalohyphomycosis

Mycetoma, onychomycosis,[106] and mycotic keratitis[160] are the infections most commonly caused by this group of filamentous molds. Reports of other infections, including sinusitis with or without fungus ball formation, meningitis, osteomyelitis, endocarditis, and otomycosis may also be caused by hyaline septate molds. Many of the earlier reports have been summarized by Rippon.[235]

Aspergillus species are the most common cause of hyalohyphomycosis and have been presented in Clinical Correlation Box 21-2. *Fusarium* species and members of the *P. boydii* complex are the next most frequent causes of invasive disease in the immunocompromised host, but it should be remembered that any fungus may cause disease in the profoundly immunosuppressed patient.

Vajpayee et al.[278] found *Fusarium* species to be the most common cause of mycotic keratitis among 156 patients with mycotic corneal ulcer disease, most commonly complicating allergic conjunctivitis and a combination

of antibiotic and corticosterone therapy. A comprehensive review of the taxonomy, mycology, laboratory features, and clinical syndromes related to *Fusarium* species has been published by Nielsen et al.[198] These authors also cite *Fusarium* species as the most common cause of mycotic keratitis in the United States, usually following corneal trauma from ocular implantation of vegetable fragments or soil matter during outdoor activities. Fungal keratitis has been reported in 4% to 27% of contact lens wearers, with *Fusarium* species being recovered most frequently.[296] Low et al.[173] report a case of *Beauveria*-related keratitis that was cured with deep dissection. Predisposing conditions include improper contact lens care, the presence of an underlying corneal infection such as herpes simplex infection, and the prolonged use of local corticosteroid and antibiotic medication.

In a 10-year (1986–1995) retrospective study of patients with hematologic malignancy, Boutati and Anaissie[29] found cases of disseminated *Fusarium* species infection in 43 patients, 40 with disseminated disease and 3 with invasive pulmonary infection. Although drug therapy was efficacious in 13 of these patients, in the main, recovery from the infection occurred only on reversal of myelosuppression and

neutropenia. The recovery of *Fusarium* species from the bloodstream in patients with a variety of malignancies has been reported by Krcmery et al.[157]

Cutaneous infections may occur from direct penetration of the skin by contaminated vegetative material. The author served as a consultant in an unreported case of posttraumatic *Fusarium* mycetoma in a 35-year-old woman. Initially, a species of *Alternaria* species, susceptible to amphotericin B by in vitro studies, was recovered from a superficial biopsy of the lesion. When the patient did not improve on amphotericin B therapy, a deeper biopsy was performed, from which an amphotericin B-resistant strain of *Fusarium* species was recovered. The condition regressed when itraconazole was administered.

Members of the *Pseudallescheria boydii* complex, which includes *Scedosporium apiospermum,* are one of the more common causes of subcutaneous mycetomas in the United States. The presence of soft-to-firm, white-to-yellow, spherical grains points to this organism, but this finding is not specific. Pulmonary infections with the *P. boydii* complex often resemble infections with *Aspergillus* spp., and the hyphae have a similar appearance in stained tissue sections. In addition to causing disease in the immunocompromised, *P. boydii* infections are also associated with episodes of near-drowning. Sinusitis, including fungus ball formation, meningitis, osteomyelitis, endocarditis, mycotic keratitis, endophthalmitis, and otomycosis are other *P. boydii* infections extensively reviewed by Rippon.[235] Perez et al.[217] report a patient with a brain abscess caused by *Pseudallescheria boydii* in association with an infected central venous catheter. Tamm et al.[271] report infections with *P. boydii* in seven lung transplant recipients in whom pulmonary infection developed. This organism was documented in BAL specimens of all seven patients and all showed airway problems, including early ischemic airway stenosis in one and bronchiolitis obliterans syndrome in the other six. Combined treatment with itraconazole and fluconazole was not able to eradicate the infection. Four of the seven patients died with advanced bronchiolitis obliterans 3–35 months after the diagnosis.

Scedosporium prolificans (formerly *S. inflatum*) is a dematiaceous fungus, but covered here as it is morphologically similar to *P. boydii* and other members of this complex. Salkin et al.,[241] who reported 15 human infections. Wilson et al.[300] added another 11 cases of *Scedosporium prolificans* infection to the literature, almost always in patients who had penetrating trauma or surgery. *Scedosporium* species, in particular *S. prolificans* have been found to be resistant to amphotericin B, miconazole, and ketoconazole and other antimycotic agents, one important reason for differentiating these from *Aspergillus* species. Pickles et al.,[225] however, report success in effecting cures through the use of fluconazole, and new triazoles are even more promising.

Alvarez et al.[10] report on a nosocomial outbreak of four fatal infections with *Scedosporium prolificans* in patients with severe neutropenia resulting from leukemia chemotherapy. The infections occurred sequentially within a 1-month period in two rooms during a phase of hospital reconstruction when the patients were
