TABLE 39-1 illustrates the main types of epithelial tissue, indicates their locations in the body, and describes their functions (pages 824–825). We can distinguish three types of epithelial cells based on their shape. *Squamous* epithelial cells are thin, flat cells shaped like flagstones. *Simple squamous epithelium* lines the blood vessels and the air sacs in the lungs. *Cuboidal* epithelial cells are short cylinders. When you look at them from the side, they appear cube-shaped, like dice. Actually, each cuboidal cell is typically hexagonal in cross section, making it an eight-sided polyhedron. *Simple cuboidal epithelium* lines the kidney tubules.

When viewed from the side, *columnar* epithelial cells look like columns or cylinders. The nucleus is usually located near the base of the cell. Viewed from above or in cross section, these cells often appear hexagonal. On its free surface, a columnar epithelial cell may have cilia that beat in a coordinated way, moving materials over the tissue surface. Most of the upper respiratory tract is lined with ciliated *columnar epithelium* that moves particles of dust and other foreign material away from the lungs.

Epithelial tissue is also classified by number of layers. *Simple epithelium* is composed of one layer of cells. It is usually located where substances are secreted, excreted, or absorbed, or where materials diffuse between compartments. For example, simple squamous epithelium lines the air sacs in the lungs. The structure of this thin tissue allows diffusion of gases in and out of air sacs.

Stratified epithelium, which has two or more layers, protects underlying tissues. For example, stratified squamous epithelium, which makes up the outer layer of your skin, is continuously sloughed off during normal wear and tear. It must also continuously regenerate. The cells of *pseudostratified epithelium* appear layered, but they are not. Although all its cells rest on a basement membrane, not every cell extends to the exposed surface of the tissue. This arrangement gives the

impression of two or more cell layers. Some of the respiratory passageways are lined with pseudostratified epithelium equipped with cilia.

The lining of blood and lymph vessels is called endothelium. Endothelial cells have a different embryonic origin from "true" epithelium. However, these cells are structurally similar to squamous epithelial cells and can be included in that category.

Glands are made of epithelial cells

A **gland** consists of one or more epithelial cells specialized to produce and secrete a product such as sweat, milk, mucus, wax, saliva, hormones, or enzymes (FIG. 39-1). Epithelial tissue lining the cavities and passageways of the body typically has some specialized mucus-secreting cells called **goblet cells**. The mucus lubricates these surfaces, offers protection, and facilitates the movement of materials.

Glands are classified as exocrine or endocrine. **Exocrine glands**, like goblet cells and sweat glands, secrete their products onto a free epithelial surface, typically through a duct (tube). **Endocrine glands** lack ducts. These glands release their products, called **hormones**, into the **interstitial fluid** (tissue fluid) or blood. Hormones are typically transported by the cardiovascular system. (Endocrine glands are discussed in Chapter 49.)

Epithelial cells form membranes

An *epithelial membrane* consists of a sheet of epithelial tissue and a layer of underlying connective tissue. Types of epithelial membranes include mucous membranes and serous membranes. A **mucous membrane**, or *mucosa*, lines a body cavity that opens to the outside of the body, such as the digestive tract or respiratory tract. Goblet cells in the epithelial layer secrete mucus that lubricates the tissue and protects it from drying.

A **serous membrane** lines a body cavity that does not open to the outside of the body. It consists of simple squamous epithelium over a thin layer of loose connective tissue. This type of membrane secretes fluid into the cavity it lines. Examples of serous membranes are the pleural membranes lining the pleural cavities around the lungs and the pericardial membranes lining the pericardial cavity around the heart.

Connective tissues support other body structures

Almost every organ in the body has a framework of **connective tissue** that supports and cushions it. Compared with epithelial tissues, connective tissues contain relatively few cells. Connective tissue cells are embedded in an extensive **intercellular substance** consisting of threadlike, microscopic **fibers** scattered throughout a **matrix**, a thin gel of polysaccharides that the cells secrete. The structure and properties of the intercellular substance help determine the nature and function of each kind of connective tissue.

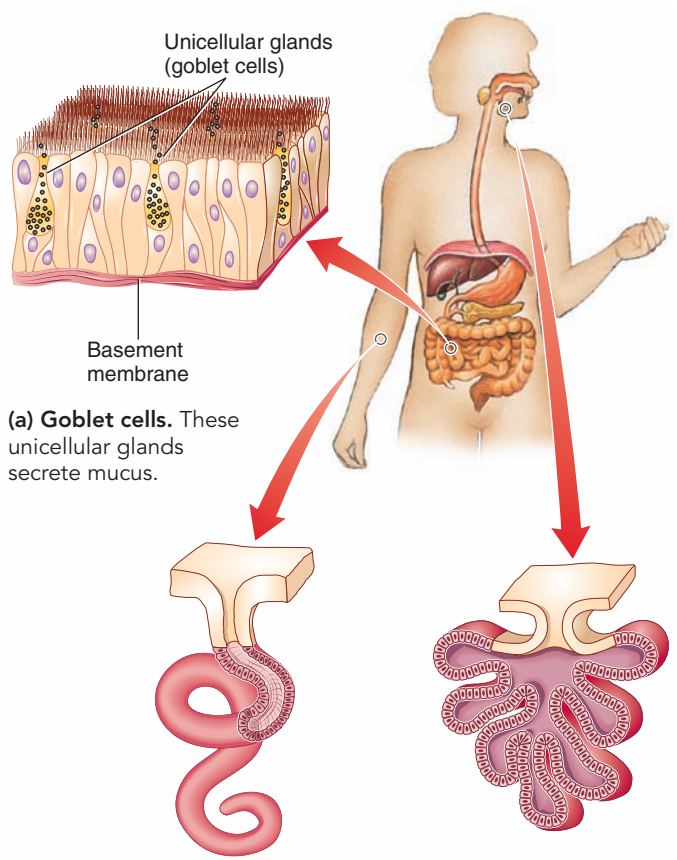

Figure 39-1 Glands
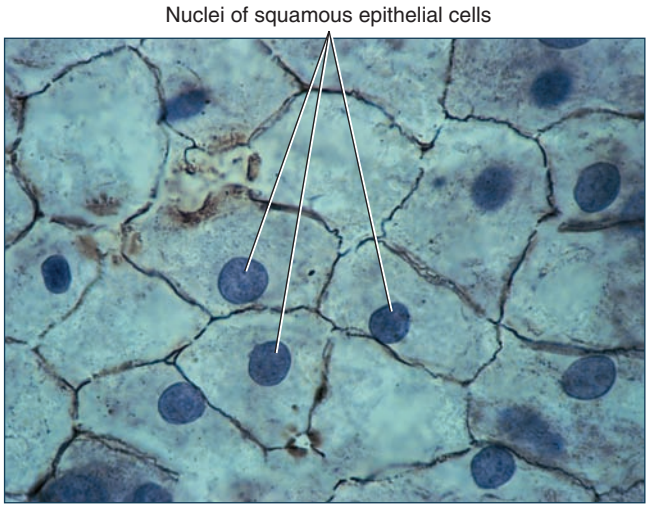
A gland consists of one or more epithelial cells.

Connective tissue typically contains three types of fibers: collagen, elastic, and reticular. *Collagen fibers*, the most numerous type, are made of **collagens**, a group of fibrous proteins found in all animals (see Fig. 3-23b). Collagens are the most abundant proteins in mammals, accounting for about 25% of their total protein mass. Collagen is very tough (meat is tough because of its collagen content). The tensile strength (ability to stretch without tearing) of collagen fibers is comparable to that of steel. Collagen fibers are wavy and flexible, allowing them to remain intact when tissue is stretched.

Elastic fibers branch and fuse to form networks. They can be stretched by a force and then (like a stretched rubber band) return to their original size and shape when the force is removed. Elastic fibers, composed of the protein elastin, are an important component of structures that must stretch.



Reticular fibers are very thin, branched fibers that form delicate networks joining connective tissues to neighboring tissues. Reticular fibers consist of collagen and some glycoprotein.

The cells of various kinds of connective tissues differ in their shapes and structures and in the kinds of fibers and

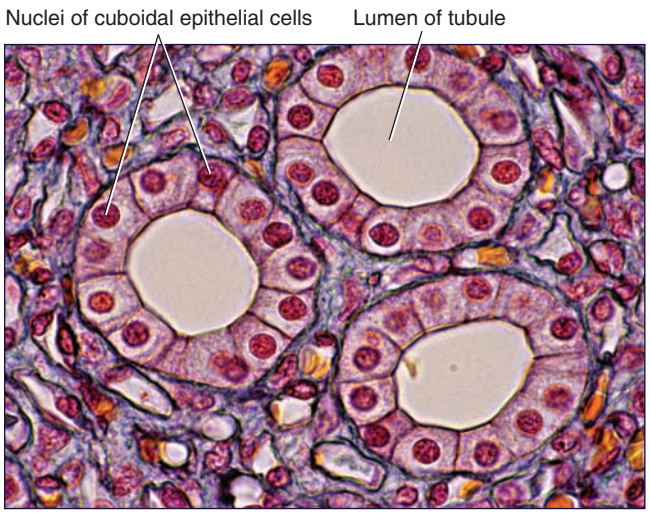
Table 39-1 Epithelial Tissues

Ed Reschke/Getty Images

LM of simple squamous epithelium.

Simple Squamous Epithelium

Main Locations



Air sacs of lungs; lining of blood vessels

Functions

Passage of materials where little or no protection is needed and where diffusion is major form of transport

Description and Comments

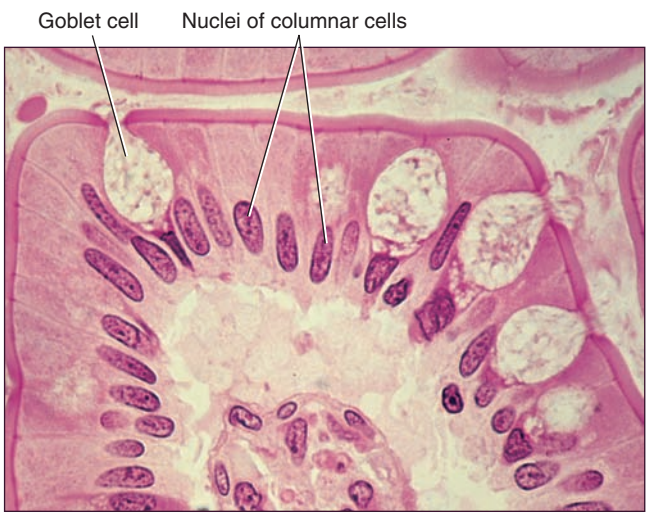
Cells are flat and arranged as single layer

Ed Reschke/Peter Arnold/Getty Images

LM of simple cuboidal epithelium.

Simple Cuboidal Epithelium

Main Locations



Linings of kidney tubules; gland ducts

Functions

Secretion and absorption

Description and Comments

Single layer of cells; LM shows cross section through tubules; from the side each cell looks like a short cylinder; some have microvilli for absorption

Ed Reschke/Getty Images

LM of simple columnar epithelium.

Simple Columnar Epithelium

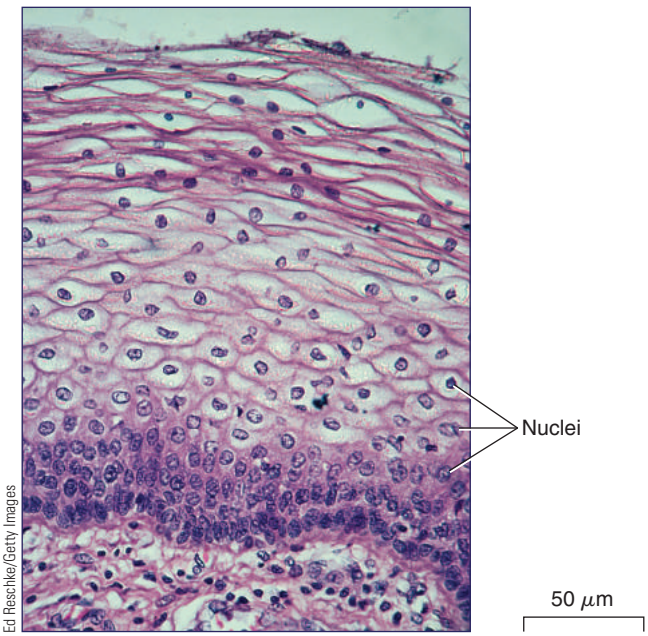
Main Locations

Linings of much of digestive tract and upper part of respiratory tract

Functions

Secretion, especially of mucus; absorption; protection; moves layer of mucus

Description and Comments



Single layer of columnar cells; highly developed Golgi complex; often ciliated; goblet cells secrete mucus

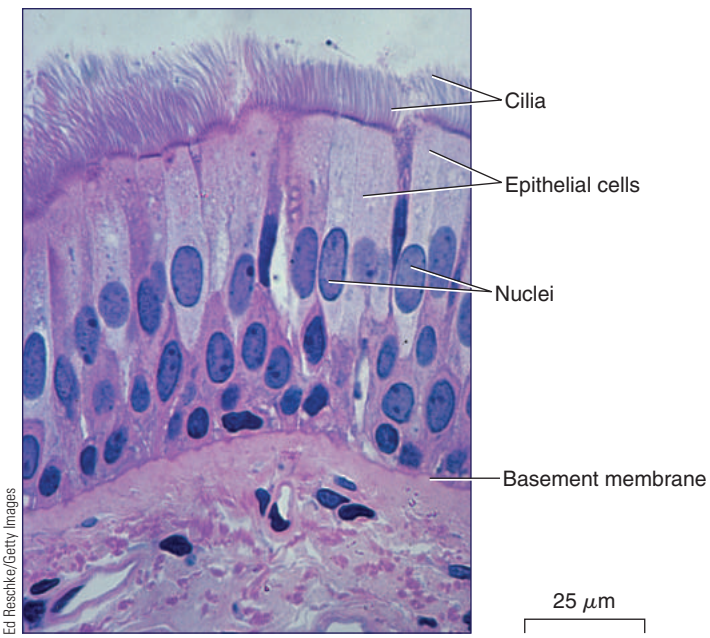
Table 39-1 Epithelial Tissues (*continued*)

Ed Reschke/Getty Images

LM of stratified squamous epithelium.

Stratified Squamous Epithelium

Main Locations



Skin; mouth lining; vaginal lining

Functions

Protection only; little or no absorption or transit of materials; outer layer continuously sloughed off and replaced from below

Description and Comments

Several layers of cells, with only the lower ones columnar and metabolically active; division of lower cells causes older ones to be pushed upward toward surface, becoming flatter as they move

Ed Reschke/Getty Images

LM of pseudostratified columnar epithelium, ciliated.

Pseudostratified Epithelium

Main Locations

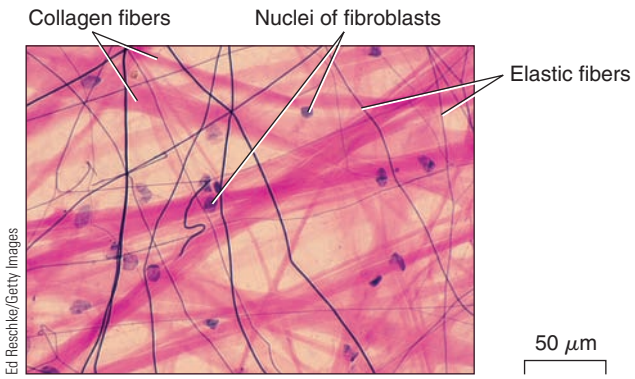
Some respiratory passages; ducts of many glands

Functions

Secretion; protection; moves layer of mucus

Description and Comments

Ciliated, mucus-secreting, or with microvilli; comparable in many ways to columnar epithelium except that not all cells are the same height; so, although all cells contact the same basement membrane, the tissue appears stratified



matrices they secrete. **Fibroblasts** are connective tissue cells that produce the fibers, as well as the protein and carbohydrate complexes, of the matrix. Fibroblasts release protein components that become arranged to form the characteristic fibers. These cells are especially active in developing tissues and are important in healing wounds. As tissues mature, the number of fibroblasts decreases, and they become less active. **Macrophages**, the body's scavenger cells, commonly wander through connective tissues, cleaning up cell debris and phagocytosing foreign matter, including bacteria.

Some of the main types of connective tissue are (1) loose and dense connective tissues; (2) elastic connective tissue; (3) reticular connective tissue; (4) adipose tissue; (5) cartilage; (6) bone; and (7) blood, lymph, and tissues that produce blood cells. These tissues vary widely in their structural details and in the functions they perform (TABLE 39-2).

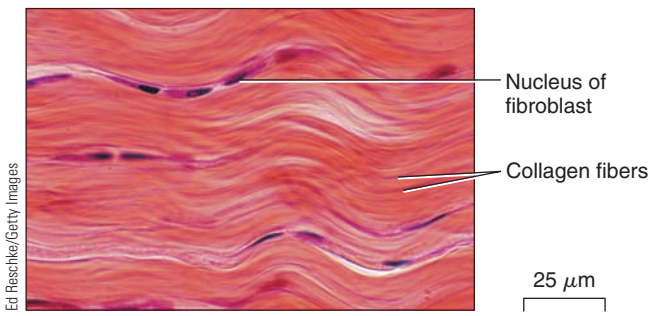
Table 39-2 Connective Tissues

LM of loose connective tissue.

Loose Connective Tissue

Main Locations



Everywhere that support must be combined with elasticity, such as subcutaneous tissue (the layer of tissue beneath the dermis of the skin)

Functions

Support; reservoir for fluid and salts

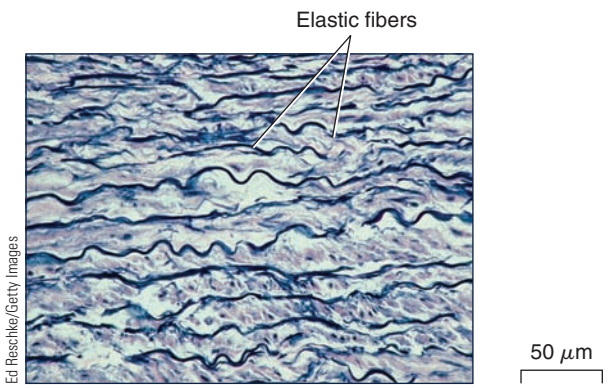
Description and Comments

Fibers produced by fibroblast cells embedded in semifluid matrix; other types of cells, e.g., macrophages, present

LM of dense connective tissue.

Dense Connective Tissue

Main Locations



Tendons; many ligaments; dermis of skin

Functions

Support; transmits mechanical forces

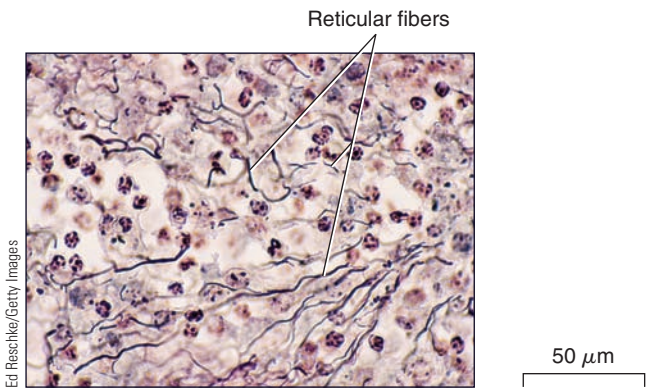
Description and Comments

Collagen fibers may be regularly or irregularly arranged

LM of elastic connective tissue.

Elastic Connective Tissue

Main Locations



Structures that must both expand and return to their original size, such as lung tissue and large arteries

Function

Confers elasticity

Description and Comments

Branching elastic fibers interspersed with fibroblasts

LM of reticular connective tissue.

Reticular Connective Tissue

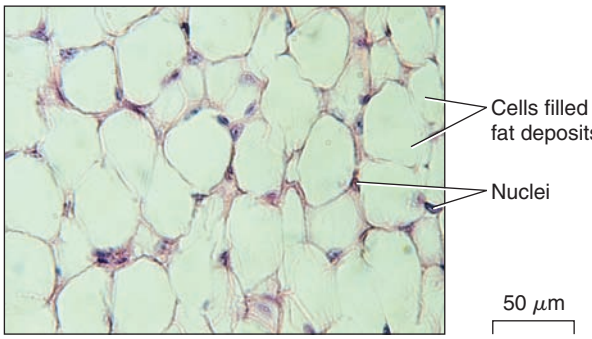
Main Locations

Framework of liver; lymph nodes; spleen

Function

Support

Description and Comments



Consists of interlacing reticular fibers

Continued

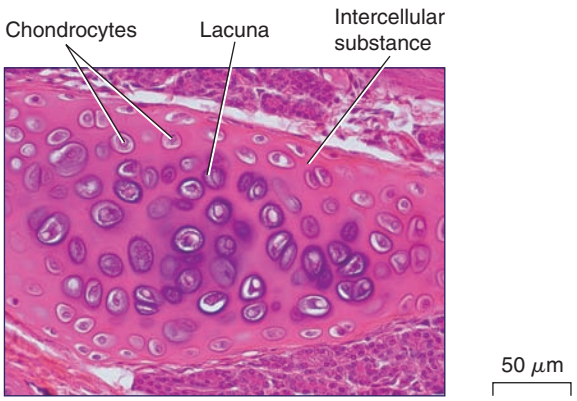
Table 39-2 Connective Tissues (*continued*)

LM of adipose tissue.

Adipose Tissue

Main Locations



Subcutaneous layer; forms protective pads around certain internal organs

Functions

Stores fat; insulation; supports organs such as mammary glands, kidneys

Description and Comments

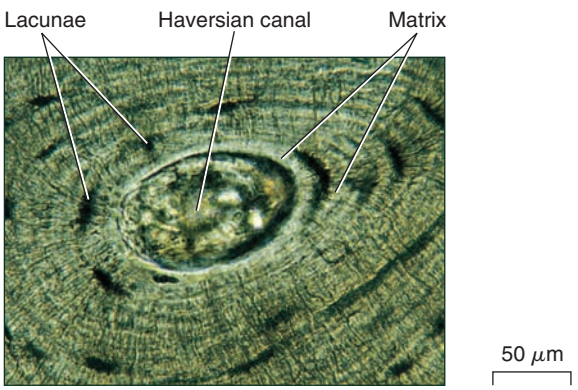
Fat cells are star shaped at first; fat droplets accumulate until typical ring-shaped cells are produced

Ed Reschke/Getty Images

LM of cartilage.

Cartilage

Main Locations



Supporting skeletons in sharks and rays; ends of bones in mammals and some other vertebrates; supporting rings in wall of trachea; tip of nose; external ear

Function

Flexible support

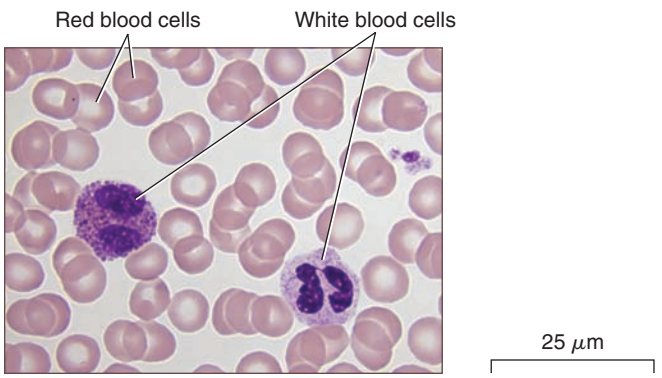
Description and Comments

Cells (chondrocytes) separated from one another by intercellular substance; cells occupy lacunae

LM of bone.

Bone

Main Locations



Forms skeletal structure in most vertebrates

Functions

Supports and protects internal organs; calcium reservoir; skeletal muscles attach to bones

Description and Comments

Cells (osteocytes) in lacunae; in compact bone lacunae embedded in lamellae, concentric circles of matrix surrounding Haversian canals

Ed Reschke/Getty Images

LM of blood.

Blood

Main Locations

Within heart and blood vessels of circulatory system

Functions

Transports oxygen, nutrients, wastes, and other materials; white blood cells defend against disease organisms

Description and Comments

Consists of red blood cells, white blood cells, and platelets dispersed in fluid matrix (plasma)

Loose connective tissue is the most widely distributed connective tissue in the vertebrate body. Together with adipose tissue, loose connective tissue forms the subcutaneous (below the skin) layer that attaches skin to the muscles and other structures beneath. Nerves, blood vessels, and muscles are wrapped in loose connective tissue. This tissue also forms a thin filling between body parts and serves as a reservoir for fluid and salts. Loose connective tissue consists of fibers running in all directions through a semifluid matrix. Its flexibility permits the parts it connects to move.

Dense connective tissue, found in the dermis (lower layer) of the skin, is very strong, but is somewhat less flexible than loose connective tissue. Collagen fibers predominate. **Tendons**, the cords that connect muscles to bones, and **ligaments**, the cables that connect bones to one another, consist of dense connective tissue in which collagen bundles are arranged in a definite pattern.

Elastic connective tissue consists mainly of bundles of parallel elastic fibers. This tissue is found in structures that must expand and then return to their original size, such as lung tissue and the walls of large arteries.

Reticular connective tissue is composed mainly of interlacing reticular fibers. It forms a supporting internal framework in many organs, including the liver, spleen, and lymph nodes.

The cells of **adipose tissue** store fat and release it when fuel is needed for cellular respiration. Adipose tissue is found in the subcutaneous layer and in tissue that cushions internal organs.

The supporting skeleton of a vertebrate is made of cartilage or of both cartilage and bone. **Cartilage** is the supporting skeleton in the embryonic stages of all vertebrates. In most vertebrates bone replaces cartilage during development. However, cartilage remains in some supporting structures. In humans, for example, cartilage is found in the external ear, the supporting rings in the walls of the respiratory passageways, the tip of the nose, the ends of some bones, and the discs that serve as cushions between the vertebrae.

Cartilage is firm yet elastic. Its cells, called **chondrocytes**, secrete a hard, rubbery matrix that surrounds them. They also secrete collagen fibers, which become embedded in the matrix and strengthen it. Chondrocytes eventually come to lie, singly or in groups of two or four, in small cavities in the matrix called *lacunae*. These cells remain alive and are nourished by nutrients and oxygen that diffuse through the matrix. Cartilage tissue lacks nerves, lymph vessels, and blood vessels.

Bone, the main vertebrate skeletal tissue, is like cartilage in that it consists mostly of matrix material. The bone cells, called **osteocytes**, are contained within lacunae. Osteocytes secrete and maintain the matrix (FIG. 39-2). Unlike cartilage, however, bone is a highly vascular tissue, with a substantial blood supply. Osteocytes communicate with one another by means of their long cytoplasmic extensions.

A typical bone has an outer layer of **compact bone** surrounding a filling of *spongy bone*. Compact bone consists of spindle-shaped units called **osteons**. Within each osteon, osteocytes are arranged in concentric layers of matrix called *lamellae*. In turn, the lamellae surround central microscopic channels known as **Haversian canals**, through which capillaries and nerves pass.

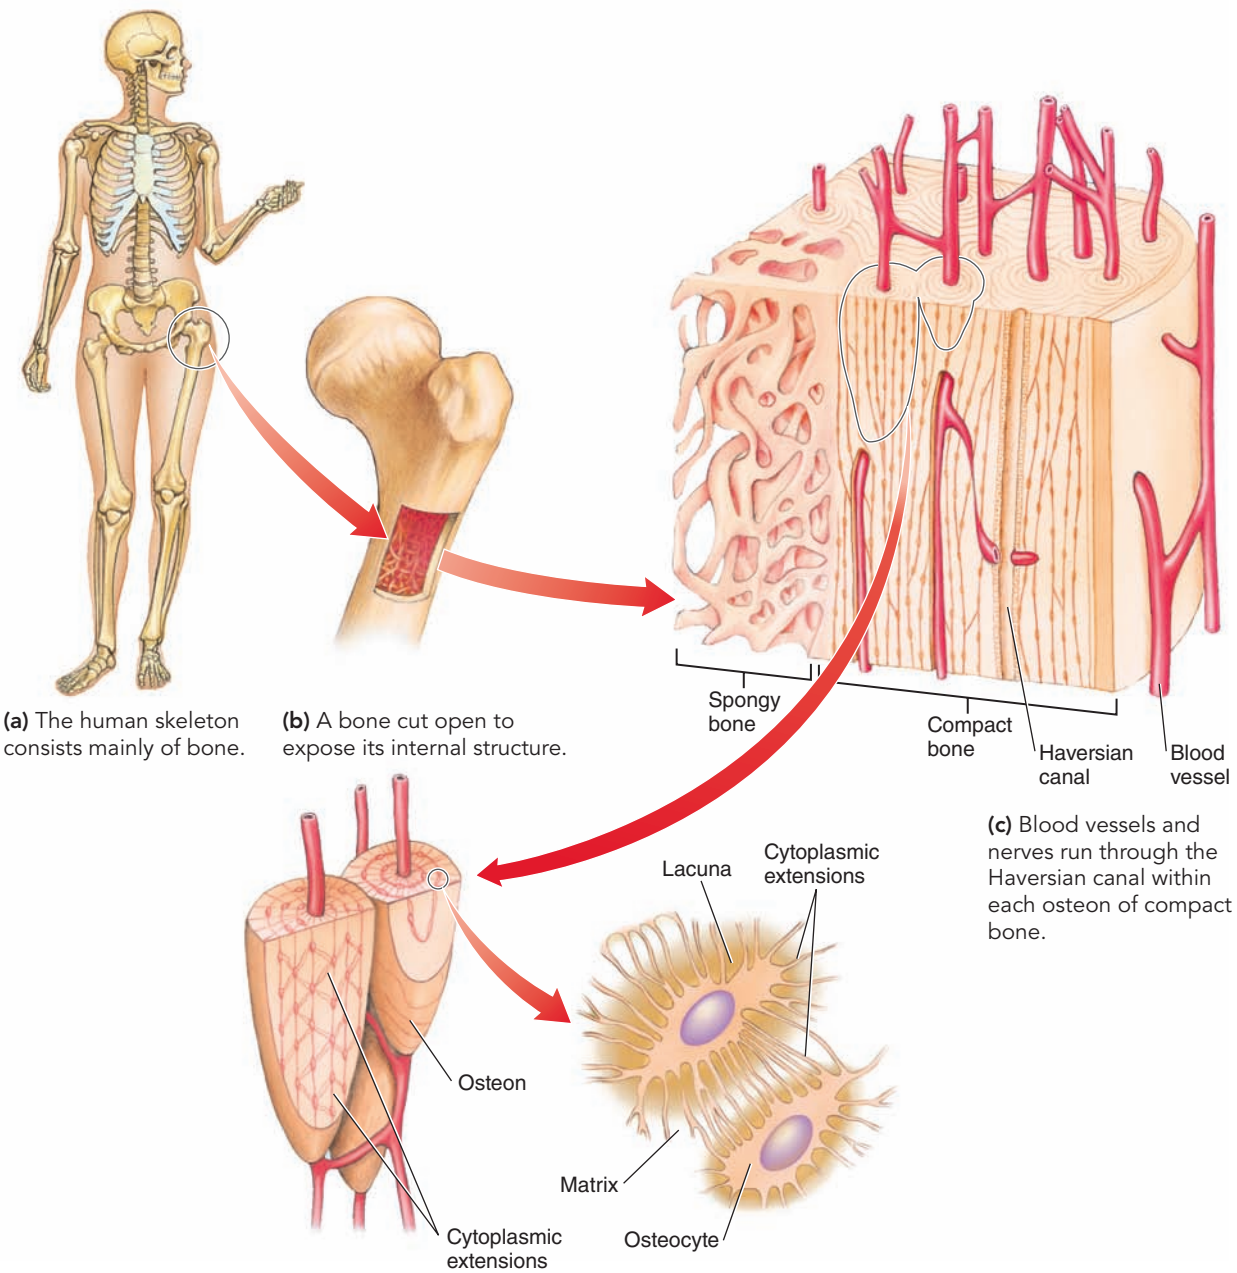
Bones are amazingly light and strong. Calcium salts of bone render the matrix very hard, and collagen prevents the bony matrix from being overly brittle. Most bones have a large, central *marrow cavity* that contains a spongy tissue called *marrow*. Yellow marrow consists mainly of fat. Red marrow is the connective tissue in which blood cells are produced. We discuss bone in more detail in Chapter 40.

Blood is a circulating tissue that helps other parts of the body communicate and interact. Like other connective tissues, blood consists of specialized cells dispersed in an intercellular substance. In mammals blood consists of **red blood cells**, **white blood cells**, and **platelets**, all suspended within **plasma**, the liquid, noncellular part of the blood. In humans and other vertebrates, red blood cells contain the respiratory pigment that transports oxygen. White blood cells defend the body against disease-causing microorganisms (discussed in Chapter 45). Platelets, small fragments broken off from large cells in the bone marrow, play a key role in blood clotting. Plasma consists of water, proteins, salts, and a variety of soluble chemical messengers such as hormones that it transports from one part of the body to another. We discuss blood in Chapter 44.

Lymph tissue, which is important in immune functions, is a type of connective tissue with large numbers of lymphocytes, a type of white blood cell. Lymph tissue organizes to form small masses of tissue called lymph nodes and larger organs, including the tonsils and spleen. We discuss lymph tissue further in Chapters 44 and 45.

Muscle tissue is specialized to contract

Most animals move by contracting the long, cylindrical or spindle-shaped cells of **muscle** tissue. Muscle cells are called muscle fibers because of their length. Each **muscle fiber** contains many thin, longitudinal, parallel contractile units called **myofibrils**. Two proteins, **myosin** and **actin**, are the chief components of myofibrils. Myosin and actin play a key role in contraction of muscle fibers.



Many invertebrates have skeletal and smooth muscle. Vertebrates have three types of muscle tissue: skeletal, cardiac, and smooth (TABLE 39-3 on page 830). **Skeletal muscle** makes up the large muscle masses attached to the bones of the body. Skeletal muscle fibers are very long, and each fiber has many nuclei. The nuclei of skeletal muscle fibers lie just under the plasma membrane, which frees the entire central part of the skeletal muscle fiber for the myofibrils. This adaptation appears to increase the efficiency of contraction. When skeletal muscles contract, they move parts of the body. Skeletal muscle fibers are generally under voluntary control. In contrast, you do not normally contract your cardiac and smooth muscle fibers at will.

Light microscopy shows that both skeletal and cardiac fibers have alternating light and dark transverse stripes, or *striations*, that change their relative sizes during contraction. Striated muscle fibers contract rapidly but cannot remain contracted for a long period. They must relax and rest momentarily before contracting again. (Muscle contraction is discussed in Chapter 40.)

Cardiac muscle is the main tissue of the heart. When cardiac muscle contracts, the heart pumps the blood. The fibers of cardiac muscle join end to end, and they branch and rejoin to form complex networks. One or two nuclei lie within each fiber. A characteristic feature of cardiac muscle tissue is the presence of *intercalated discs*, specialized junctions where the fibers join.

(a) The human skeleton consists mainly of bone.

(b) A bone cut open to expose its internal structure.

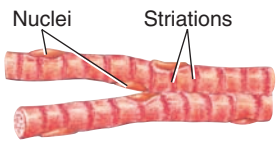
(c) Blood vessels and nerves run through the Haversian canal within each osteon of compact bone.

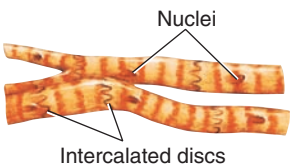
(d) The bone matrix is rigid and hard. Osteocytes become trapped within lacunae but communicate with one another by way of cytoplasmic extensions that extend through tiny canals.

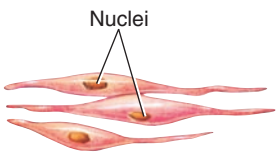
Figure 39-2 Bone

Smooth muscle occurs in the walls of the digestive tract, uterus, blood vessels, and many other internal organs. Contraction of smooth muscle is necessary for these organs to perform certain functions. For example, smooth muscle contraction in the wall of the stomach and intestine moves food through the digestive tract. When smooth muscle in the walls of arterioles (small arteries) contracts, these blood vessels constrict, raising blood pressure. Each spindle-shaped smooth muscle fiber contains a single, central nucleus.

Nervous tissue controls muscles and glands







Nervous tissue consists of neurons and glial cells. **Neurons** are specialized for receiving and transmitting signals. **Glial cells** support and nourish the neurons, destroy pathogens, and modulate transmission of impulses (FIG. 39-3).

A typical neuron has a **cell body** containing the nucleus as well as two types of cytoplasmic extensions (discussed in Chapter 41). **Dendrites** are cytoplasmic extensions specialized

Table 39-3 Muscle Tissues

	Skeletal	Cardiac	Smooth
Location	Attached to skeleton	Walls of heart	Walls of stomach, intestines, blood vessels, uterus
Type of control	Voluntary	Involuntary	Involuntary
Shape of fibers	Elongated, cylindrical, blunt ends	Elongated, cylindrical, fibers that branch and fuse	Elongated, spindle shaped, pointed ends
Striations	Present	Present	Absent
Number of nuclei per fiber	Many	One or two	One
Position of nuclei	Peripheral	Central	Central
Speed of contraction	Most rapid	Intermediate (varies)	Slowest
Resistance to fatigue (with repetitive contraction)	Least	Intermediate	Greatest
	 Skeletal muscle fibers	 Cardiac muscle fibers	 Smooth muscle fibers

for receiving signals and transmitting them to the cell body. The single **axon** transmits signals, called *nerve impulses*, away from the cell body. Axons range in length from 1 or 2 mm to more than a meter. Those extending from the spinal cord down the arm or leg in a human, for example, may be a meter or more in length.

Certain neurons receive signals from the external or internal environment and transmit them to the spinal cord and brain. Other neurons relay, process, or store information.

Ed Reschke/Getty Images

Figure 39-3 LM of nervous tissue
Neurons transmit information in the form of electrical and chemical signals. Glial cells support, protect, and nourish neurons. They also communicate and help regulate neural function.

Still others transmit signals from the brain and spinal cord to the muscles and glands. Neurons communicate at junctions called **synapses**. A **nerve** consists of a great many neurons bound together by connective tissue.

In this chapter we have focused on normal tissues. For a discussion of some abnormal tissues, see *Inquiring About: Unwelcome Tissues: Cancers*.

Tissues and organs make up the organ systems of the body

Tissues associate to form **organs**. Although an animal organ may be composed mainly of one type of tissue, other types are needed to support, protect, provide a blood supply, and transmit information. For example, the heart is mainly cardiac muscle tissue, but its chambers are lined with endothelium, and its walls contain blood vessels made of endothelium, smooth muscle, and connective tissue. The heart also has nerves that transmit information and help regulate the rate and strength of its contractions.

An organized group of tissues and organs that together perform a specialized set of functions make up an **organ system**. Working together in a very coordinated way, organ systems perform the functions required by the **organism**. We can identify 11 major organ systems that work together to carry out the physiological processes of a mammal: **integumentary system**, **skeletal system**, **muscular system**, **nervous system**, **endocrine system**, **cardiovascular system**, **lymphatic system** (which functions as the **immune system**), **respiratory system**, **digestive system**, **urinary system**, and **reproductive system**. FIGURE 39-4 summarizes the principal organs and functions of each organ system.

Inquiring About

Unwelcome Tissues: Cancers

A **neoplasm** ("new growth"), or **tumor**, is an abnormal growth of cells. A neoplasm may be benign ("kind") or malignant (cancerous). A benign neoplasm tends to grow slowly, and its cells stay together. Because benign tumors form masses with distinct borders, they can typically be removed surgically. A **malignant** ("wicked") **neoplasm**, or **cancer**, typically grows much more rapidly and invasively than a benign tumor.

In Chapter 17 you learned that cancer results from abnormal expression of specific genes critical for cell division (see Fig. 17-20). Most cancer cells divide rapidly and in an uncontrolled way. Unlike normal cells, which respect one another's boundaries and form tissues in an orderly, organized manner, cancer cells multiply chaotically and infiltrate normal tissues. They no longer receive or respond appropriately to signals from surrounding cells; communication is lacking (see figure).

Moredun Animal Health Ltd/Science Source

50 μm

When cancer cells multiply, they invade normal tissues and interfere with their functions. This SEM shows a mass of malignant cells (*pink*) in a pulmonary air sac (*center*). Cancer cells that have separated from the main tumor can be seen in other air sacs. Microvilli on the surface of the cancer cells give them a fuzzy appearance.

Unlike the cells of benign neoplasms, cancer cells do not retain normal structural features. When a cancer cell multiplies, all the cells derived from it are also abnormal. Most human cancers originate in epithelial tissue and are called *carcinomas*. This group includes breast, prostate, colon, lung cancer, and most ovarian cancers. Cancers that develop from connective tissues or muscle are referred to *as sarcomas*.

Death from cancer typically results from **metastasis**, migration of cancer cells through blood or lymph channels to other parts of the body. Once there, cancer cells multiply, forming new malignant neoplasms that interfere with the normal functions of the tissues being invaded. Cancer often spreads so rapidly and extensively that surgeons cannot locate or remove all the malignant masses.

Solid tumors, which account for more than 85% of cancer deaths, require blood vessels to ensure delivery of nourishment and oxygen. Some tumors grow to several millimeters in diameter and then enter a dormant stage, which may last for months or even years. Eventually, cancer cells release a chemical substance that stimulates nearby blood vessels to develop new capillaries. These blood vessels grow into the abnormal mass of cells. Nourished by its new blood supply, the neoplasm may grow rapidly. Newly formed blood vessels have leaky walls that provide a route for metastasis. Malignant cells enter the blood through these walls and are transported to new sites.

Worldwide, cancer causes more than seven million deaths each year. In the United States, cancer is the second leading cause of death. One in three people in the United States develops cancer at some time in his or her life. More than 1.7 million new cancer cases are diagnosed each year. Currently, the key to survival is early diagnosis and treatment with some combination of surgery, hormonal treatment, radiation therapy, chemotherapy, inhibitors that suppress development of new blood vessels, immunotherapy, and targeted therapies. Many treatments are under investigation, including new agents that inhibit the development of new blood vessels. Immunotherapy for cancer will be discussed in Chapter 45. Cancer is a large family of closely related diseases (there are hundreds of distinct varieties), and treatment must be tailored to the particular type of cancer.

Most cancers are thought to be triggered by **carcinogens**, cancer-producing agents, in the environment, and by diet and lifestyle, for example cigarette smoking. Alleles of some genes appear to affect an individual's level of tolerance to carcinogens. You can decrease your risk of developing cancer by following these recommendations:

1. Do not smoke or use tobacco. Smoking is responsible for more than 80% of lung cancer cases, and it increases the risk for many other cancers.
2. Avoid prolonged exposure to the sun. When in the sun, use sunscreen or sunblock. Exposure to the sun is responsible for almost all of the more than two million cases of skin cancer reported each year in the United States alone.
3. Eat a healthy diet, including fresh, unprocessed fruits, vegetables, and grains. Limit intake of red meat. Avoid smoked, salt-cured, and nitrite-cured foods. Limit intake of alcoholic beverages. Reduce intake of foods and drinks that contribute to weight gain. Obesity increases the risk of cancer.
4. Exercise. Physical inactivity has been linked with increased risk of colon, breast, and other cancers.
5. Avoid unnecessary exposure to X-rays.
6. Self-examination and screening can lead to early diagnosis. Beginning at age 50, both men and women should be screened for colorectal cancer. Detection and removal of polyps (benign growths that can become malignant) can prevent cancer.
7. Self-examination and screening for women includes examining their breasts each month and having regular mammograms after age 40. Cervical cancer can be prevented with regular screening tests, such as the Papanicolaou (Pap) and human papilloma virus (HPV) tests. Certain HPV strains cause cervical cancer; vaccines are available.
8. Men over age 55 should discuss with their doctor the benefits of screening for prostate cancer with the prostate-specific antigen (PSA) blood test.
9. Consider genetic testing. If you have a family history of certain cancers, you may be at higher risk genetically for cancer. Genetic tests are now available to determine if you have mutations in the *BRCA1* or *BRCA2* genes, which increase risk for breast, ovarian, and pancreatic cancers. Mutations in several other genes indicate increased risk for colon, uterine, stomach, and urinary tract cancer. If you are at increased risk for cancer, a genetic counselor can advise you of measures you can take to reduce that risk.

CHECKPOINT 39.1

- **CONNECT** What are the main differences in structure and function between epithelial tissue and connective tissue?
- What type of tissue lines the air sacs of the lungs? How is its structure adapted to its function?
- What are some differences between the three types of muscle tissue? How is the structure of each type adapted for its function?
- What are the main functions of each of the following organ systems: (1) respiratory, (2) urinary, and (3) endocrine? (Consult Figure 39-4 for help.)

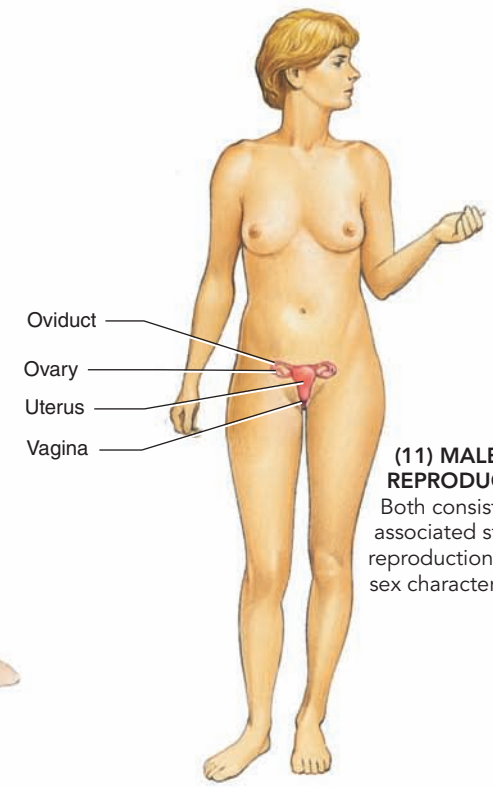
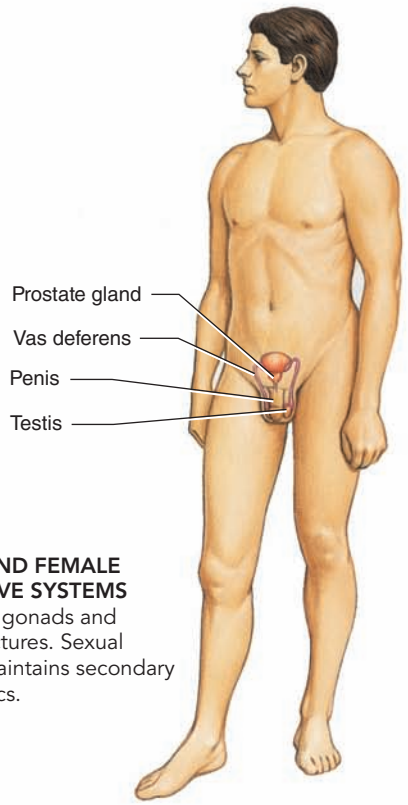
(7) IMMUNE/LYMPHATIC SYSTEM
Lymphatic vessels, lymph, lymph nodes, spleen, thymus, tonsils. Returns excess tissue fluid to blood, absorbs lipids, defends against disease.



(8) RESPIRATORY SYSTEM
Lungs, air passageways. Supplies oxygen to blood, excretes carbon dioxide.



(9) DIGESTIVE SYSTEM
Digestive tract and glands that secrete digestive juices. Processes food, eliminates wastes.

(10) URINARY SYSTEM
Kidneys, urinary bladder, associated ducts. Kidneys remove metabolic wastes and excess materials from blood, produce urine. Helps regulate blood chemistry.

(11) MALE AND FEMALE REPRODUCTIVE SYSTEMS
Both consist of gonads and associated structures. Sexual reproduction; maintains secondary sex characteristics.

Key Point

In a negative feedback system, the response of the integrator is opposite to the input of the sensor. For example, when the glucose concentration in the blood is too low, alpha cells in the pancreas secrete a hormone that increases glucose concentration.

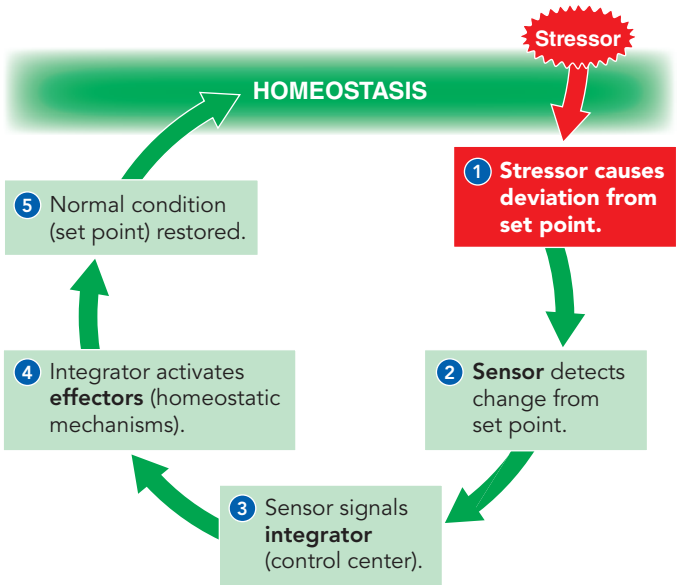

Figure 39-5 Negative feedback

PREDICT If you drank a soda (high in carbohydrates), what would happen to the glucose concentration in your blood? How do you think your body would respond?

39.2 Regulating the Internal Environment

LEARNING OBJECTIVE

7 Define *homeostasis* and contrast negative and positive feedback systems.

To survive and function, animals must regulate the composition of the fluids that bathe their cells. They must maintain pH and internal temperature within relatively narrow limits. The body must also maintain the appropriate concentration of nutrients, oxygen, and other gases, ions, and compounds needed for metabolism at all times.

Cells, tissues, organs, and organ systems work together to maintain appropriate conditions in the body. The balanced internal environment is referred to as **homeostasis**. Homeostasis is a basic concept in physiology. First coined by U.S. physiologist Walter Cannon, the word *homeostasis* is derived from the Greek *homoios*, meaning "same," and *stasis*, "standing." Although the internal environment never really stays the same, it is a dynamic equilibrium in which conditions are maintained within narrow limits. We call this a **steady state**. The control processes that maintain these conditions are **homeostatic mechanisms**.

Stressors, changes in the internal or external environment that affect normal conditions within the body, continuously challenge homeostasis. An internal condition that moves out of its homeostatic range (either too high or too low) causes **stress**. An organism functions effectively because homeostatic mechanisms continuously operate to manage stress.

Many animals are **conformers** for certain environmental conditions. Some of their internal states vary with changes in their surroundings. For example, most marine invertebrates conform to the salinity of the surrounding sea water. Mammals are superb **regulators**. They have complex homeostatic mechanisms that maintain relatively constant internal conditions despite changes in the outside environment. How do homeostatic mechanisms work? Many are **feedback systems**, sometimes called "biofeedback systems."

Negative feedback systems restore homeostasis

In a **negative feedback system**, a change in some steady state (e.g., normal body temperature) triggers a response that counteracts, or reverses, the change. A **sensor** detects a change, a deviation from the normal condition or **set point**. The sensor signals an **integrator**, or control center. Based on the input of the sensor, the integrator activates homeostatic mechanisms that restore the steady state (FIG. 39-5). The response counteracts the inappropriate change, thereby restoring the steady state.

Note that in a negative feedback system, the response of the integrator is *opposite* (negative) to the output of the

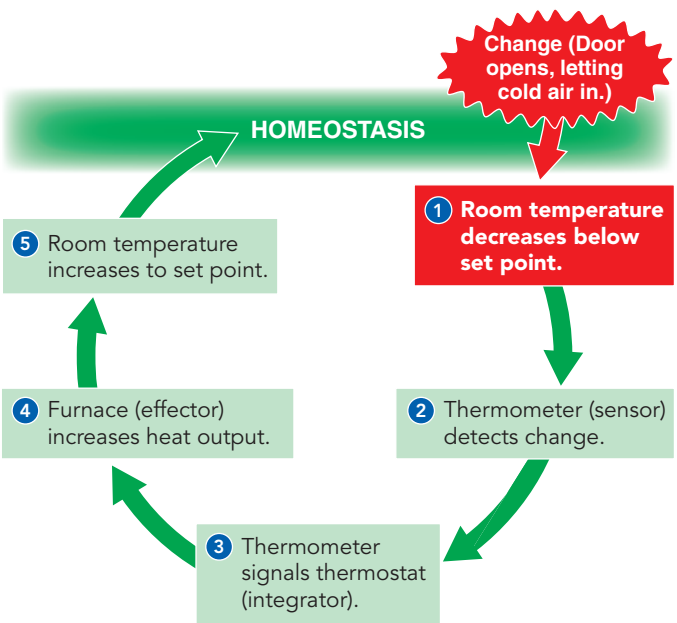
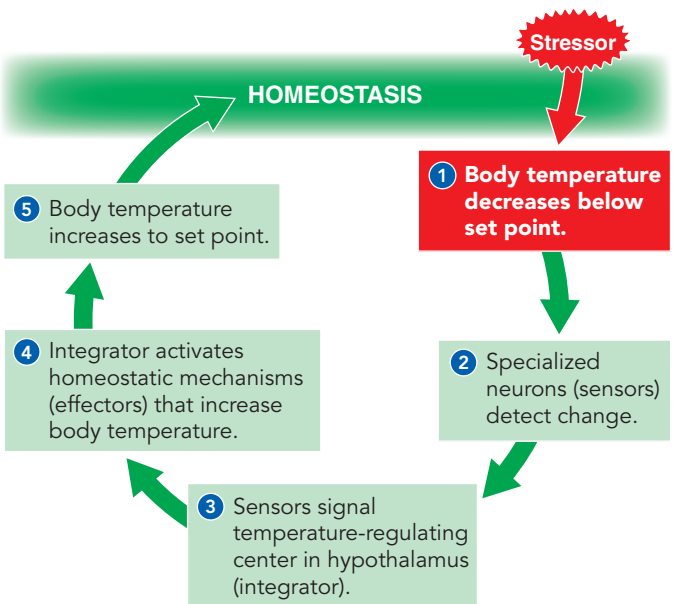
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

sensor. When some condition varies too far from the steady state (either too high or too low), a control system using negative feedback brings the condition back to the steady state. For example, when the glucose concentration in the blood *decreases* below its homeostatic level, negative feedback systems *increase* its concentration. Most homeostatic mechanisms in the body are negative feedback systems.



Let us discuss heat regulation, a common example of a negative feedback system. The temperature-regulating system in the human body is somewhat similar to how you regulate temperature in your home. You might set a particular room temperature on your thermostat. If the temperature in the room falls, the thermometer in the thermostat acts as a sensor that detects a change, or deviation, from the set point (FIG. 39-6a). The thermometer sends a signal to the thermostat, which then acts as an integrator, or control center. The thermostat compares the sensor's input with the set point. The thermostat then signals the furnace, which is the **effector** in this system. An effector is the device, organ, or process that helps restore the steady state. The furnace increases its heat output, a corrective response that brings the room temperature back to the set point. When the thermometer no longer detects a change from the set point, the thermostat and furnace are switched off.

As shown in FIGURE 39-6b, the negative feedback system that regulates body temperature works like a home thermostat. When body temperature decreases below normal limits, specialized nerve cells (sensors) signal the temperature-regulating center in the hypothalamus of the brain (the integrator). The integrator activates effectors that bring the temperature back to the set point. The return to normal temperature signals the sensors, and the temperature-regulating center switches off the effectors.



A few positive feedback systems operate in the body

In a **positive feedback system**, a change in some steady state sets off a response that intensifies (rather than reverses) the changing condition. Although some positive feedback mechanisms are beneficial, they do not maintain homeostasis. For example, a positive feedback cycle operates during the birth of a baby. As the baby's head pushes against the cervix (lower part of uterus), a reflex action causes the uterus to contract. The contraction forces the head against the cervix again, stimulating another contraction, and the positive feedback cycle repeats again and again until the baby is born. Some positive feedback sequences, such as those that deepen circulatory shock following severe hemorrhage, can disrupt steady states and lead to death. A simplified example is shown in FIGURE 39-7.

Homeostatic mechanisms maintain the internal environment within the physiological limits that support life. As you continue your study of animal processes, you will learn many ways in which organ systems interact to maintain the steady state of the organism. In the next section, we discuss some specific homeostatic mechanisms that help regulate body temperature.

(a) Regulation of room temperature.

(b) Regulation of body temperature.

Figure 39-6 Negative feedback in temperature regulation
Note that the diagram in **(b)** is highly simplified. Figure 39-9 shows greater detail.

Key Point

Positive feedback intensifies the change taking place, moving conditions farther away from homeostasis; in some situations such as hemorrhage, the results can be fatal.

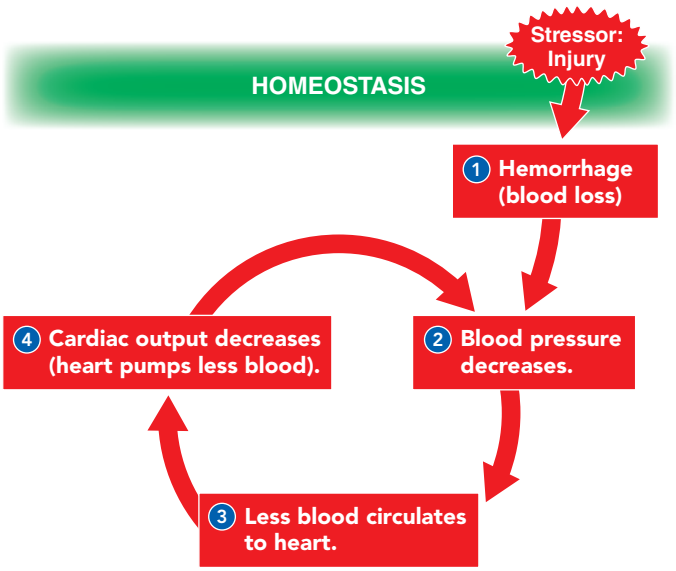

Figure 39-7 Positive feedback

In positive feedback, the changes that occur increase the deviation from the set point. Conditions move away from the normal range. Loss of blood decreases blood pressure. Less blood reaches the heart, so heart function decreases. The resulting decrease in cardiac output (the volume of blood pumped by the left ventricle of the heart into the aorta in 1 minute) further decreases blood pressure. Conditions move farther from homeostasis.

PREDICT What might happen if you could convert this positive feedback system to a negative feedback system?

CHECKPOINT 39.2

- Contrast negative and positive feedback systems.

39.3 Regulating Body Temperature

LEARNING OBJECTIVES

8 Compare the costs and benefits of being an ectotherm, and describe strategies ectotherms use to adjust their body temperature.

9 Compare the costs and benefits of being an endotherm, and describe strategies endotherms use to adjust their body temperature.

10 Describe strategies animals use to adjust to challenging temperature changes.

Many animals have elaborate homeostatic mechanisms for regulating body temperature. Some are physiological, and others are structural or behavioral. **Thermoregulation** is the process of maintaining body temperature within certain limits despite changes in the surrounding temperature. Animals produce heat as a byproduct of metabolic activities. Body temperature is determined by the rate at which heat is produced and the rate at which heat is lost to, or gained from, the outside environment.

An animal's structural, physiological, and behavioral strategies for maintaining body temperature may restrict the type of environment it can inhabit. Each species has an optimal environmental temperature range and is adapted to a specific environment. Some animals, such as snowshoe hares, snowy owls, and weasels, can survive in cold arctic regions. Others, such as the Cape ground squirrel, which inhabits South Africa, are adapted to hot tropical climates. Although some animals can survive at temperature extremes, most survive only within moderate temperature ranges.

Ectotherms absorb heat from their surroundings

Ectotherms are animals that depend on the environment for their body heat. Their body temperature is determined mainly by the changing temperature of their surroundings. Most of the heat for their thermoregulation comes from the sun. In contrast, **endotherms** have homeostatic mechanisms that maintain body temperature despite changes in the external temperature. You may be surprised to learn that most animals are ectotherms.

An ectotherm's metabolic rate tends to change with the weather. These animals have a far lower daily energy expenditure than endotherms because they do not maintain a high metabolic rate. They therefore survive on less food and convert more of the energy in their food to growth and reproduction than do endotherms. Ectothermy also has costs. One disadvantage is that daily and seasonal temperature conditions may limit their activity.

Many ectotherms use behavioral strategies to adjust body temperature. For example, lizards may keep warm by burrowing in the soil at night. During the day, lizards take in heat by basking in the sun, orienting their bodies to expose the maximum surface area to the sun's rays (FIG. 39-8a). Many animals migrate to warmer climates during the winter. Another behavioral strategy for regulating temperature is *hibernation*.

Some insects use a combination of structural, behavioral, and physiological mechanisms to regulate body temperature. The "furry" body of the moth helps conserve body heat. When a moth prepares for flight, it contracts its flight muscles with little movement of its wings. The metabolic heat generated enables the moth to sustain the intense metabolic activity needed for flight.

Endotherms derive heat from metabolic processes

Birds and mammals, as well as some species of fish (e.g., tuna and certain sharks) and some insects, are endotherms. The

Charles Martin

(a) Ectotherm. The iguana increases its body temperature by sunning itself. Photographed in Florida, where this green iguana (*Iguana iguana*) is an invasive, exotic species.

Charles Martin

(b) Endotherm. Great blue heron (*Ardea herodias*) spreads its wings, exposing more of its body to the sun's warmth. Birds regulate their temperature physiologically. However, as illustrated here, they also have behavioral adaptations that help maintain body temperature.

Figure 39-8 Behavioral adaptations for thermoregulation

most important benefit of endothermy is the high metabolic rate, which can be as much as six times higher than that of ectotherms. The constant body temperature of endotherms allows a higher rate of enzyme activity than is possible for ectotherms living in the same habitat. Endotherms also can respond more rapidly to internal and external stimuli than ectotherms. Although they can be active even in low winter temperatures, these animals must pay the high energy cost of thermoregulation even during times when they are inactive. You must maintain your body temperature even when you are asleep!

Endotherms have structural adaptations for maintaining body temperature. For example, the insulating feathers of birds, hair of mammals, and insulating layers of fat in birds and mammals reduce heat loss from the body. Birds and mammals also have behavioral adaptations for maintaining body temperature. The Cape ground squirrel positions its tail to shade its body from the direct rays of the sun. Elephants spray themselves with cool water.

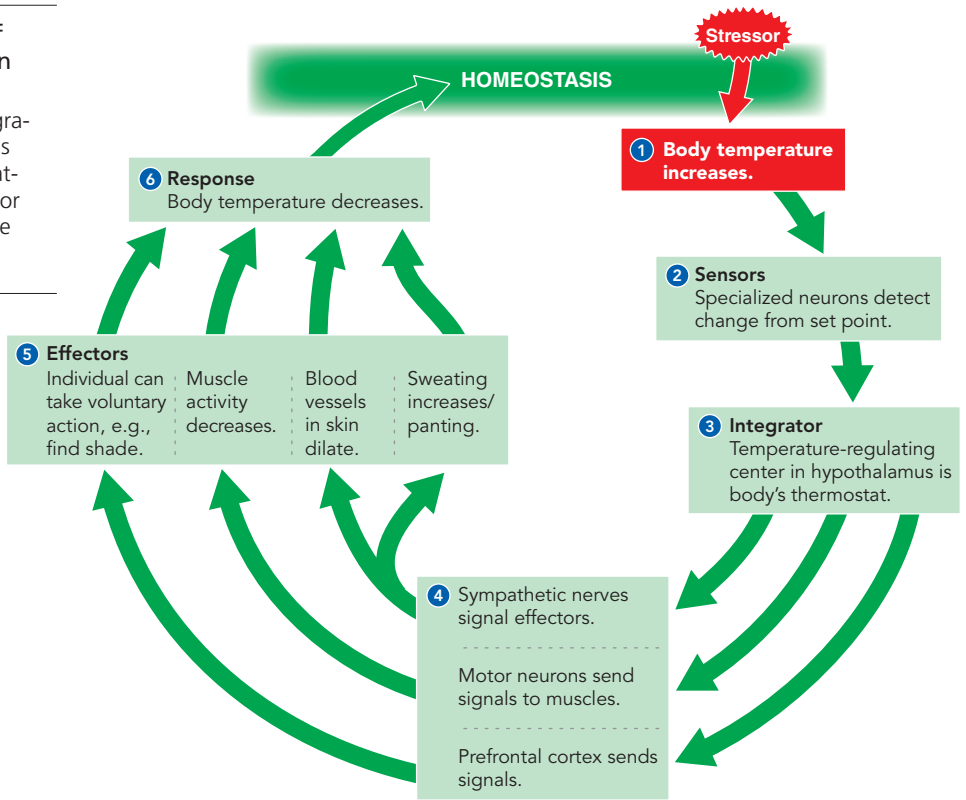
Endotherms have a variety of physiological mechanisms for maintaining temperature homeostasis. They regulate heat production and regulate heat exchange with the environment. Most of their body heat comes from their own metabolic processes (see *Inquiring About: Electron Transport and Heat* in Chapter 8).

In mammals, receptors located in the hypothalamus of the brain and in the spinal cord regulate temperature. Heat from metabolic activities can be increased directly or can be increased indirectly by the action of hormones (such as thyroid hormones) that increase metabolic rate. In cold weather, many animals shiver, which contracts muscles, producing heat.

When body temperature rises, birds and many mammals pant, and some mammals sweat. These processes provide fluid for evaporation: the conversion of a liquid, such as sweat, to water vapor. (Recall from Chapter 2 that when molecules enter the vapor phase, they take their heat energy with them.) Heat transfers from the body to the surroundings, resulting in evaporative cooling.

In the human body, about 2.5 million sweat glands secrete sweat. As sweat evaporates from the skin surface, body temperature decreases. Constriction and dilation of capillaries in the skin are also homeostatic mechanisms for regulating body temperature.

In humans, when body temperature increases above normal, specialized nerve cells signal the temperature-regulating center in the hypothalamus (FIG. 39-9). This center sends messages by way of nerves to the sweat glands, which increase sweat secretion. At the same time, the hypothalamus sends messages to smooth muscle in the walls of blood vessels in the skin that cause them to dilate. More blood circulates through the skin, bringing heat to the body surface. The skin acts as a heat radiator that allows heat to radiate from the body surface into the environment. These homeostatic mechanisms help return body temperature to normal.



When body temperature decreases below normal, the hypothalamus signals the anterior pituitary gland to release a hormone that signals the thyroid gland. Secretion of thyroid

hormones increases, which raises metabolic rate. Body tissues increase heat production. The hypothalamus also sends neural signals that cause blood vessels in the skin to constrict. As a result, less heat is brought to the body surface. In addition, nerves signal muscles to shiver, which increases body temperature. Endotherms also use behavioral strategies to regulate body temperature. For example, birds spread their wings, increasing the body surface exposed to the sun (FIG. 39-8b), and you can warm up by voluntarily moving your muscles.

Many animals adjust to challenging temperature changes

Animals adjust to seasonal changes, a process called **acclimatization**. A familiar example is the thickening of a dog's coat in the winter. As water temperature decreases during fall and winter, a trout's enzyme systems decrease their level of activity, allowing the trout to remain active at the lowest metabolic cost.

When stressed by cold, many small endotherms sink into **torpor**, a short-term state in which metabolic rate decreases, sometimes dramatically. Torpor saves the energy that the animal would use to maintain a high body temperature. Instead, body temperature decreases below normal levels. The decrease in body temperature is brought about by a decrease in the temperature set point in the hypothalamus. Heart and respiratory rates decrease, and animals are less responsive to external stimulation. Daily torpor occurs in some small endotherms, such as hummingbirds and shrews. We can think of torpor as an adaptive hypothermia that helps animals survive during times of cold temperatures.

Hibernation is long-term torpor in response to winter cold and scarcity of food. Animals that hibernate store unsaturated fats to use as energy sources. **Estivation** is a state of torpor caused by lack of food or water during periods of high temperature. During estivation, some mammals retreat to their burrows. The cactus mouse enters a state of hibernation during the winter in response to cold and scarcity of food. In the summer, it estivates in response to lack of either food or water.

CHECKPOINT 39.3

- What are some costs and benefits of ectothermy? How do ectotherms adjust body temperature?
- What are some costs and benefits of endothermy?

Summary: Focus on Learning Objectives

39.1 Tissues, Organs, and Organ Systems *(page 822)*

1 Compare the structure and function of the four main kinds of animal tissues: epithelial, connective, muscle, and nervous tissues.

- A **tissue** consists of a group of similarly specialized cells that associate to perform specific functions. **Epithelial tissue** (*epithelium*) forms a continuous layer, or sheet, of cells covering a body surface or lining a body cavity. Epithelial tissue functions in protection, absorption, secretion, and sensation.
- **Connective tissue** consists of relatively few cells separated by an **intercellular substance**, composed of **fibers** scattered throughout a **matrix**. The intercellular substance contains three types of fibers: collagen, elastic, and reticular.
- Connective tissue contains specialized cells such as **fibroblasts** and **macrophages**. Connective tissue joins other tissues of the body, supports the body and its organs, and protects underlying organs.
- **Muscle** tissue consists of cells specialized to contract. Each cell is an elongated muscle fiber containing many contractile units called **myofibrils**. **Nervous tissue** consists of elongated cells called neurons, specialized for transmitting impulses, and **glial cells**, which support and nourish the neurons.

2 Compare the main types of epithelial tissue and describe their functions.

- Epithelial cells may be *squamous*, *cuboidal*, or *columnar* in shape. Epithelial tissue may be *simple*, *stratified*, or *pseudostratified* (summarized in Table 39-1).
- *Simple squamous epithelium* lines blood vessels and the air sacs in the lungs; it permits exchange of materials by diffusion. *Simple cuboidal epithelium* and *columnar epithelium* line passageways and are specialized for secretion and absorption. *Stratified squamous epithelium* forms the outer layer of the skin and lines passageways into the body; it provides protection. *Pseudostratified epithelium* also lines passageways and protects underlying tissues.
- Some epithelial tissue is specialized to form **glands**. **Goblet cells** are unicellular glands that secrete mucus. Goblet cells are **exocrine glands** that secrete their product through a duct onto an exposed epithelial surface. In contrast, **endocrine glands** release hormones into the **interstitial fluid** or blood.
- An *epithelial membrane* consists of a sheet of epithelial tissue and a layer of underlying connective tissue. **A mucous membrane** lines a cavity that opens to the outside of the body. A **serous membrane** lines a body cavity that does not open to the outside.

3 Compare the main types of connective tissue and describe their functions.

- The cells of connective tissue are embedded in an intercellular substance that consists of microscopic *collagen fibers*, *elastic fibers*, and *reticular fibers* (thin branched fibers) scattered through a **matrix**, a thin gel of polysaccharides. **Loose connective tissue** consists of fibers running in various directions through a semifluid matrix; it forms a covering for nerves, blood vessels, and muscles.
- **Dense connective tissue** is strong but less flexible than loose connective tissue. It forms **tendons**, cords that connect muscles to bones, and **ligaments**, cables that connect bones to one another.
- Elastic connective tissue consists of bundles of parallel elastic fibers; it is found in lung tissue and in walls of large arteries. *Reticular connective tissue*, which consists of interlacing reticular fibers, forms a supporting framework for many organs.
- **Adipose tissue** is made up of fat cells; it is found along with loose connective tissue in subcutaneous tissue.
- **Cartilage** consists of **chondrocytes** that lie in lacunae, small cavities in a hard matrix. **Osteocytes** secrete and maintain the matrix of **bone**. Unlike cartilage, bone is quite vascular. Cartilage and bone form the skeleton of vertebrates.
- **Blood** and lymph are circulating tissues that help various parts of an animal communicate with one another. The intercellular substances of blood and lymph are more fluid than those of other tissues.

4 Contrast the three types of muscle tissue and describe their functions.

- **Skeletal muscle** is striated and under voluntary control. Each elongated, cylindrical **muscle fiber** has several nuclei. When skeletal muscles contract, they move parts of the body.
- **Cardiac muscle** is also striated, but its contractions are involuntary. Its elongated, cylindrical fibers branch and fuse; each fiber has one or two central nuclei. When this muscle contracts, the heart pumps the blood.
- **Smooth muscle** contracts involuntarily; its elongated, spindle-shaped fibers lack striations. Each fiber has a single central nucleus. Smooth muscle is responsible for movement of body organs; for example, it pushes food through the digestive tract.

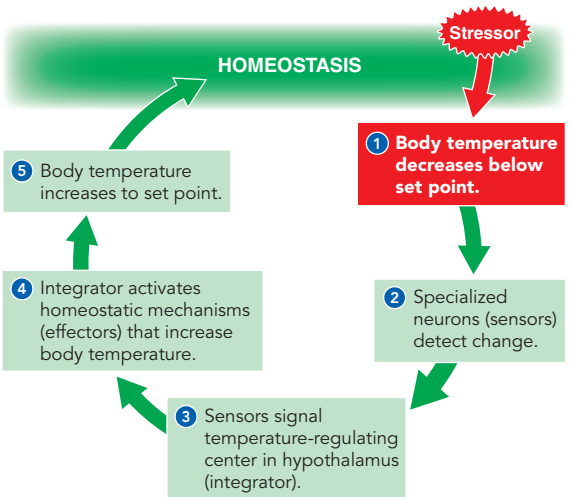
5 Relate the structure of the neuron to its function.

- The elongated **neuron** is adapted for receiving and transmitting information. **Dendrites** receive signals and transmit them to the **cell body**. The **axon** transmits signals away from the cell body to other neurons or to a muscle or gland. A **synapse** is a junction between neurons.

6 Briefly describe the organ systems of a mammal and summarize the functions of each organ system.

- Tissues and **organs** work together, forming **organ systems**. In mammals 11 organ systems work together to carry out the functions required by the **organism**: the **integumentary**, **skeletal**, **muscular**, **nervous**, **endocrine**, **cardiovascular**, **lymphatic** (which functions as part of the **immune system**), **respiratory**, **digestive**, **urinary**, and **reproductive systems** (summarized in Figure 39-4). Each organ system functions to maintain homeostasis.

39.2 Regulating the Internal Environment *(page 834)*



7 Define homeostasis and contrast negative and positive feedback systems.

- **Homeostasis** is the balanced internal environment, or steady state. The control processes that maintain these conditions are **homeostatic mechanisms**, mainly **negative feedback systems**. When a stressor causes a change in some steady state, a response is triggered that counteracts

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

the change. A **sensor** detects the change, a deviation from the normal condition or **set point**. The sensor signals an **integrator**, or control center. Based on the output of the sensor, the integrator activates one or more **effectors**, organs or processes that restore the steady state.

- In a **positive feedback system**, a deviation from the steady state sets off a series of changes that intensifies (rather than reverses) the changes.

39.3 Regulating Body Temperature *(page 836)*

8 Compare the costs and benefits of being an ectotherm, and describe strategies ectotherms use to adjust their body temperature.

- Animals have structural, behavioral, and physiological strategies for **thermoregulation**, the process of maintaining body temperature within certain limits despite changes in the surrounding temperature.
- In **ectotherms** body temperature depends to a large extent on the temperature of the environment. A benefit of ectothermy is that very little energy is used to maintain metabolic rate. A disadvantage is that activity may be limited by daily and seasonal temperature conditions. Many ectotherms use behavioral strategies to adjust body temperatures.

9 Compare the costs and benefits of being an endotherm, and describe strategies endotherms use to adjust their body temperature.

- **Endotherms** have homeostatic mechanisms for regulating body temperature within a narrow range. The most important benefit of endothermy is a high metabolic rate. Another advantage is that constant body temperature allows a higher rate of enzyme activity. Many endotherms are active even in low winter temperatures. A disadvantage of endothermy is its high energy cost.

10 Describe strategies animals use to adjust to challenging temperature changes.

- **Acclimatization** is the process of adjustment to seasonal changes.
- When challenged by a drop in surrounding temperature, many small endotherms enter a state of torpor. **Torpor** is an adaptive hypothermia; body temperature is maintained below normal levels. **Hibernation** is long-term torpor in response to winter cold. **Estivation** is torpor caused by lack of food or water during summer heat.

Test Your Understanding

Know and Comprehend

1. Tissue that contains fibroblasts and a great deal of intercellular substance is (a) connective tissue (b) muscle tissue (c) nervous tissue (d) pseudostratified epithelium (e) simple squamous epithelium
2. Tissue that contracts and is striated and involuntary would most likely be found in (a) the leg (b) the wall of the stomach (c) the exocrine glands (d) body structures requiring very rapid contraction (e) the heart
3. Which organ system has the homeostatic function of helping regulate volume and composition of blood and body fluids? (a) integumentary (b) muscular (c) reproductive (d) urinary (e) exocrine
4. Most homeostatic functions in the body are maintained by (a) exocrine glands (b) negative feedback systems (c) set points (d) stressors (e) positive feedback systems
5. Which of the following is *not* true of torpor? (a) it is an adaptive state of low body temperature (b) the temperature set point in the hypothalamus decreases (c) metabolic rate increases (d) it is a strategy used by some endotherms (e) respiratory rate decreases
6. An ectotherm (a) has a higher rate of enzyme activity than a typical endotherm (b) has a variety of homeostatic mechanisms for regulating body temperature (c) depends on sensors in the hypothalamus to regulate temperature (d) may use behavioral strategies to help adjust body temperature (e) must expend more energy on thermoregulation than an endotherm

Apply and Analyze

7. **VISUALIZE** Draw (a) simple cuboidal epithelium lining a kidney tubule and (b) loose connective tissue.
8. **VISUALIZE** Draw a flowchart showing the relationship among organ systems, tissues, cells, and organs.
9. **PREDICT** Jim has lost a great deal of epithelium due to a chemical burn. What effects might this change have on his body and its ability to function?
10. **PREDICT** The intercellular substance of the connective tissue in a dog's skin is decreasing due to a rare disease. What effect might this change have on the dog's body?
11. **PREDICT** A high concentration of carbon dioxide in the blood and interstitial fluid results in more rapid breathing. What effect would rapid breathing have on homeostasis?

Evaluate and Synthesize

12. **EVOLUTION LINK** From an evolutionary perspective, why do you think most animals are ectotherms? (*Hint*: What are some benefits of ectothermy?)
13. **SCIENCE, TECHNOLOGY, AND SOCIETY** Imagine that you are a health care professional. If a patient told you that she had a family history of breast cancer, would you advise her to be genetically tested? Why or why not? What if you had a family history of cancer? Would you want to be tested?

40 Protection, Support, and Movement

KEY CONCEPTS

40.1 Many structures and processes have evolved in animals for protection, support, and movement. Epithelial coverings are adapted for protecting underlying tissues and may be specialized for gas exchange, sensory reception, secretion, or other functions.

40.2 Skeletal systems, whether they are hydrostatic skeletons, exoskeletons, or endoskeletons, are adapted for supporting and protecting the body and for transmitting mechanical forces important in movement.

40.3 Muscles are adapted for contracting; during contraction, energy from ATP is used to move muscle filaments so that the muscle shortens. Body parts move when muscles pull on them.

PHOTO: Grasshopper in midjump. This two-striped grasshopper (*Melanoplus bivittatus*) uses powerful muscles in its hind legs to catapult itself into the air. Insect muscles attach to the exoskeleton.
Michael Durham/Minden Pictures/Getty Images

In Chapter 39 we described animal tissues, organs, and organ systems, laying the foundation for the more detailed discussions in this and later chapters. Here we focus on epithelial coverings, skeletons, and muscles, structures that work together to protect, support, and move the body and its parts. In our survey of the animal kingdom (Chapters 30–32), we described many adaptations involving these structures. For example, we discussed how the arthropod *exoskeleton* contributes to the great biological success of insects. In this chapter we compare these systems in several animal groups and then focus on their structure and function in mammals.

The *epithelial coverings* of animals protect underlying tissues and have several other functions as well. One of the most interesting is secretion of peptides and other substances that kill harmful bacteria and certain other pathogens. Frogs and toads, in particular, secrete a variety of potent peptides that protect them against harmful bacteria, fungi, and protozoa. Secretions of the frog *Rana ridibanda* have been shown to kill "superbugs," such as MRSA (methicillin-resistant *Staphylococcus aureus*; see Chapter 25). The skin of amphibians is a promising potential source of new antibiotics and other drugs.

Most animals are also protected by a *skeletal system*. Whether it is a fluid-filled compartment, a shell, or a system of bones, the skeletal system protects internal organs and provides support for the body. The skeletal system and *muscular system* work together to produce movement. Muscle tissue is specialized to contract. Although a few animals remain rooted to one spot, sweeping their surroundings with tentacles, most animals move from place to place in the environment (locomotion). Muscles responsible for locomotion anchor to the skeleton, which gives them something firm on which to act. In most

vertebrates, bones serve as levers that transmit the force necessary to move various parts of the body.

During the course of evolution, most animals have developed adaptations for dependable, rapid, and responsive movement. Animals creep, walk, run, jump, swim, or fly (see photograph). These adaptations enable them to find food and escape from predators. In complex animals, effective movement depends on the cooperation and interactions of several body systems, including the muscular, skeletal, nervous, circulatory, respiratory, and endocrine systems. The precisely regulated interactions among tissues, organs, and organ systems make complex function and maintenance of homeostasis possible. These interactions are a dynamic example of systems biology in action.

40.1 Epithelial Coverings

LEARNING OBJECTIVES

1. Compare the functions of the epithelial coverings of invertebrates and vertebrates.
2. Relate the structure of vertebrate skin to its functions.

Epithelial tissue covers all external and internal surfaces of the animal body. The structure and functions of the external epithelial covering are adapted to the animal's environment and lifestyle. However, in both invertebrates and vertebrates, epithelial coverings protect the body. Epithelial coverings may also be specialized for secretion, gas exchange, or temperature regulation and typically contain receptors that receive sensory signals from the environment.

Invertebrate epithelium may secrete a cuticle

In many invertebrates the outer epithelium is specialized to secrete protective or supportive layers of nonliving material. In insects and many other animals, the secreted material forms an outer covering called a **cuticle**. Some animals, including corals and mollusks, secrete a shell made mainly of calcium carbonate.

In many species the epithelium contains cells that secrete lubricants or adhesives. Such cells may release odorous secretions used for communication or for marking trails. In other species secretory cells produce toxins used for offense or defense. The earthworm epithelium secretes lubricating mucus that promotes efficient diffusion of gases across the body wall and reduces friction during movement through the soil. Epithelial cells may be modified as sensory cells that are selectively sensitive to light, chemical stimuli, or mechanical stimuli, such as contact with an object, or pressure.

Vertebrate skin functions in protection and temperature regulation

The **integumentary system** of vertebrates includes the skin and structures that develop from it. In many fishes, in some reptiles, and in the ant-eating pangolin (a mammal; see Fig. 18-15c), skin has developed into a set of scales formidable enough to be considered armor. Even human skin has considerable strength. The thin, moist skin of many amphibians is adapted for gas exchange as well as for defense.

Derivatives of skin differ considerably among vertebrates. Fishes have bony or toothlike scales. Amphibians have naked skin covered with mucus, and some species are equipped with poison glands. Reptiles have epidermal scales, mammals have hair, and birds have feathers that provide even more effective insulation than fur. The feathers of birds and the fur of mammals are insulating structures that help maintain body temperature by trapping heat in the body. Skin and its derivatives are often brilliantly colored, which helps in communication, for example, in courtship rituals and in territorial displays.

In mammals, structures derived from skin include claws (modified as fingernails and toenails in primates), hair, sweat glands, oil (sebaceous) glands, and several types of sensory receptors that give mammals the ability to feel touch, pressure, temperature, and pain. The skin of mammals also contains mammary glands, specialized in females for secretion of milk.

In humans and other mammals, oil glands empty via short ducts into hair follicles. A *hair follicle* is the part of a hair below the skin surface, together with the surrounding epithelial tissue. Oil glands secrete *sebum*, a mixture of fats and waxes that inhibits the growth of harmful bacteria.

Although the skin of fishes, frogs, snakes, pelicans, and elephants appears very different, the basic structure of skin is the same in all vertebrates. The outer layer of skin, the **epidermis**, is a waterproof protective barrier. The epidermis consists of several strata, or sublayers. The deepest is **stratum basale**, and the most superficial is **stratum corneum** (FIG. 40-1). Pigment cells in stratum basale and in the dermis below produce **melanin**, a pigment that contributes to the color of the skin. In stratum basale, epithelial cells continuously divide and are pushed outward as other cells are produced below them. Epidermal cells mature as they move toward the skin surface.

As they move toward the body surface, epidermal cells manufacture **keratin**, an elaborately coiled protein that gives the skin considerable mechanical strength and flexibility. Keratin is insoluble and serves as a diffusion barrier for the body surface. As epidermal cells move through stratum corneum, they die. When they reach the outer surface of the skin, they wear off and must be continuously replaced.

Beneath the epidermis lies the **dermis**, a dense, fibrous connective tissue made up mainly of collagen fibers (see Fig. 40-1). Collagen imparts strength and flexibility to the skin. The dermis also contains blood vessels that nourish the skin and sensory receptors for touch, pain, and temperature. Hair follicles and, in most mammals, sweat glands are embedded in the dermis. In birds and mammals, the dermis rests on a layer of *subcutaneous tissue*. This tissue consists mainly of adipose tissue that insulates the body from outside temperature extremes.

In humans exposure to ultraviolet (UV) radiation—the short, invisible rays from the sun—causes the epidermis to thicken and stimulates pigment cells in the skin to produce melanin at an increased rate. Melanin is an important

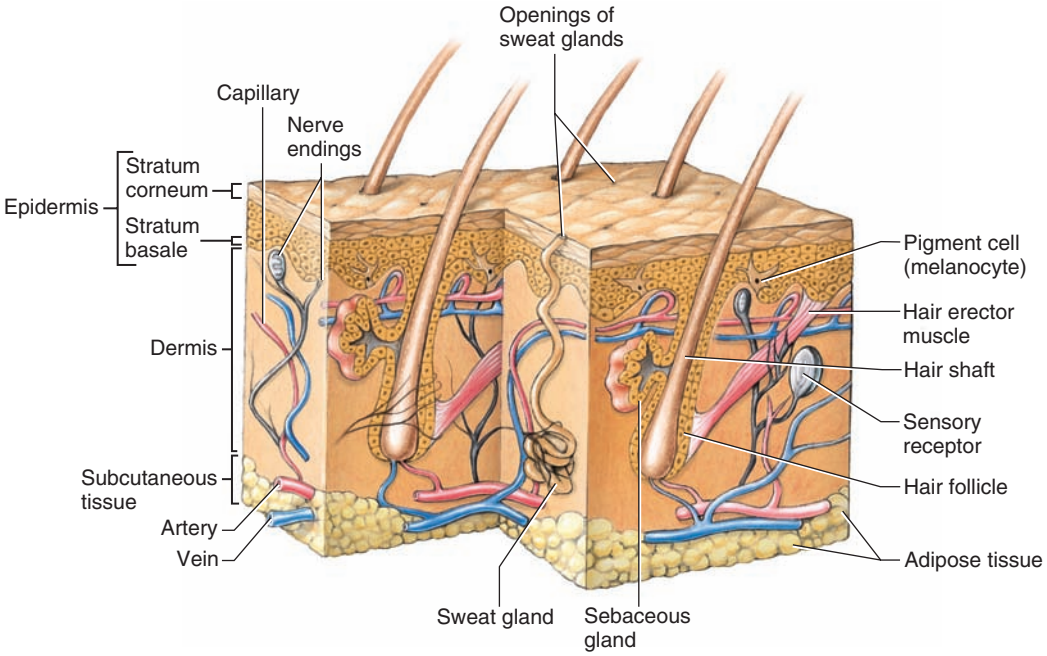

Figure 40-1 Human integumentary system

The integumentary system of humans and other mammals is a complex organ system consisting of skin and structures, such as hair and nails, that develop from it. The outer layer of the skin, the epidermis, consists of several sublayers, or strata.

protective screen against the sun because it absorbs some of the harmful UV rays. An increase in melanin causes the skin to darken. The suntan so prized by sun worshippers is actually a sign that the skin has been exposed to too much UV radiation. When the melanin cannot absorb all the UV rays, the skin becomes inflamed, or sunburned. Dark-skinned people have more melanin, so they suffer less sunburn, wrinkling, and skin cancer than lighter-skinned people. However, they still require protection from UV rays.

UV radiation damages DNA, causing mutations that lead to malignant transformation of cells (see Chapter 17). Skin cancer is the most common type of cancer in humans, and most cases of skin cancer are caused by excessive, chronic exposure to UV radiation. The incidence of *malignant melanoma*, the most lethal type of skin cancer, is increasing faster than any other type of cancer. Greater understanding of the Ras/ERK cell signaling pathway has led to research aimed at developing targeted drugs for treating melanoma. (Recall from Chapter 6 that this pathway is the main signaling cascade for cell division and differentiation. Also see Figure 17-20 in Chapter 17.)

CHECKPOINT 40.1

40.2 Skeletal Systems

LEARNING OBJECTIVES

3 Compare the structure and functions of different types of skeletal systems, including the hydrostatic skeleton, exoskeleton, and endoskeleton.

4 Describe the main divisions of the vertebrate skeleton and identify the bones that make up each division.

5 Describe (or draw and label) the structure of a typical long bone and contrast the roles of osteoblasts and osteoclasts in bone remodeling.

6 Compare the main types of vertebrate joints.

In addition to having an epithelial covering, many animals are protected by a **skeletal system** that forms the framework of the body. The skeleton also functions in locomotion. Muscles typically act on hard structures such as chitin or bone. These skeletal structures *transmit* mechanical forces generated by muscle contraction and *transform* them into the variety of motions that animals make. Most invertebrates have *hydrostatic skeletons* or *exoskeletons*. (You may recall from Chapter 32 that echinoderms are an exception. These invertebrates have an endoskeleton consisting of calcium carbonate plates and spines.) Vertebrates have *endoskeletons* of cartilage or bone.

In hydrostatic skeletons body fluids transmit force

Many soft-bodied invertebrates have **hydrostatic skeletons** made of fluid-filled body compartments. Imagine an elongated balloon full of water. If you pull on the balloon, it lengthens and becomes thinner. It does the same if you squeeze it. Conversely, if you push the ends toward the center, the balloon shortens and thickens.

Many invertebrates, including most cnidarians, flatworms, annelids, and roundworms, have hydrostatic skeletons that work something like a balloon filled with water. Fluid in a closed compartment of the body is held under pressure. When muscles in the compartment wall contract, they push against the tube of fluid. Because fluids cannot be compressed, the force is transmitted through the fluid, changing the shape and movement of the body.

In *Hydra* and other cnidarians, cells of the two body layers can contract. The contractile cells in the outer epidermal layer lie longitudinally, whereas the contractile cells of the inner layer (the gastrodermis) are arranged circularly around the central body axis. The two groups of cells work in *antagonistic* fashion: what one can do, the other can undo. When the inner (circular) layer contracts, the hydra thins, and its fluid contents force it to lengthen (FIG. 40-2a). In contrast, when the epidermal (longitudinal) layer contracts, the hydra shortens. Due to the fluid in the gastrovascular cavity, force is transmitted so that the hydra thickens as well (FIG. 40-2b).

Mechanically, the hydra is a bag of fluid that acts as a hydrostatic skeleton. It transmits force when the contractile cells contract against it. Although technically not a closed compartment, the gastrovascular cavity functions as a hydrostatic skeleton because its opening is small. Hydrostatic skeletons permit only crude mass movements of the body or its appendages. Delicate movements are difficult because force tends to be transmitted equally in all directions throughout the entire fluid-filled body of the animal. For example, it is not easy for the hydra to thicken one part of its body while thinning another.

(a) Contraction of circular contractile fibers (*red*) elongates the body.

(b) Contraction of longitudinal fibers (*red*) shortens the body.

Figure 40-2 Hydrostatic skeleton

In *Hydra*, fluid in the gastrovascular cavity transmits force when contractile cells in the body wall contract against it. The longitudinally arranged contractile cells of *Hydra* are antagonistic to the cells arranged circularly around the body axis.

The more complex hydrostatic skeleton of the annelid worm lets it move with increased flexibility. An earthworm's body consists of a series of segments divided by transverse partitions, or septa (see Fig. 31-19). The septa isolate portions of the body cavity and the coelomic fluid they contain. This arrangement allows the hydrostatic skeleton of each segment to be largely independent. As a result, contraction of the circular muscle in the elongating anterior end does not interfere with the action of the longitudinal muscle in the segments at the posterior end.

You can find some examples of hydrostatic skeletons in invertebrates equipped with shells or endoskeletons and even in vertebrates with endoskeletons of cartilage or bone. For example, sea stars and sea urchins have an endoskeleton, but they move their tube feet by an ingenious adaptation of a hydrostatic skeleton (see Chapter 32). And the human penis becomes erect and stiff because of the turgidity of pressurized blood in its internal spaces.

Mollusks and arthropods have nonliving exoskeletons

In most animals the skeleton is a lifeless shell, or **exoskeleton**, deposited atop the outer epithelial covering. In mollusks the exoskeleton is a calcium carbonate shell secreted by the mantle, a thin sheet of epithelial tissue that extends from the body wall. The exoskeleton provides protection, a retreat used in emergencies. The bulk of the tasty, naked body is exposed at other times.

Exoskeletons of arthropods serve not only to protect but also to transmit forces. In this respect they are comparable to the skeletons of vertebrates. The arthropod exoskeleton is a nonliving *cuticle* that contains the polysaccharide **chitin**. This exoskeleton consists of large, thick, inflexible plates that completely cover the body. These plates are separated from one another by thin, flexible joints arranged segmentally. Enough joints are present to make the arthropod's body as flexible as those of many vertebrates. The arthropod exoskeleton is adapted to a vast variety of lifestyles, and parts of it are modified to function as specialized tools or weapons.

A disadvantage of the rigid arthropod exoskeleton is that to accommodate growth an arthropod must shed its exoskeleton and replace it with a new, larger one (FIG. 40-3). Recall from Chapter 31 that this process, called **molting**, or **ecdysis**, is characteristic of the **Ecdysozoa**, a major branch of invertebrates. During ecdysis, the animal is weak and vulnerable to predators.

Internal skeletons are capable of growth

Echinoderms and chordates have internal skeletons, or **endoskeletons**. Composed of living tissue, the endoskeleton grows along with the animal as a whole. This skeleton consists of plates or shafts of calcium-impregnated tissue (such as cartilage or bone). The echinoderm endoskeleton consists of spines and plates of calcium salts embedded in the body wall, beneath an epidermis that covers the body. This endoskeleton forms what amounts to an internal shell that provides support and protection (FIG. 40-4). Many echinoderm endoskeletons bear spines that project to the outer surface.

Judy Davidson/SPL/Science Source

Figure 40-3 Ecdysis

A greengrocer cicada (*Magicicada*) requires 13 years to mature. It then emerges from the soil, climbs a tree, and sheds its exoskeleton prior to reproducing.

You are probably most familiar with the endoskeleton of vertebrates. This endoskeleton provides support and protection and transmits muscle forces. Members of class Chondrichthyes (sharks and rays) have skeletons of cartilage, but in most vertebrates the skeleton consists mainly of bone. Many bones form systems of levers that transmit muscle forces. Bones store calcium and are important in maintaining homeostatic levels of calcium in the blood.

The vertebrate skeleton has two main divisions

The two main divisions of the vertebrate skeleton are the axial and appendicular skeletons (FIG. 40-5). The *axial skeleton*, located along the central axis of the body, consists of the skull, vertebral column, ribs, and sternum (breastbone). The *appendicular skeleton* consists of the bones of the limbs (arms and legs) plus the bones making up the girdles that connect the limbs to the axial skeleton, the pectoral (shoulder) girdle, and most of the pelvic (hip) girdle.

The *skull*, the bony framework of the head, consists of the cranial and facial bones. In the human skull, 8 cranial bones enclose the brain, and 14 bones make up the facial portion of the skull. Several cranial bones that are single in the adult human result from the fusion of 2 or more bones that are separate in the fetus or newborn.

George Cathcart/Getty Images

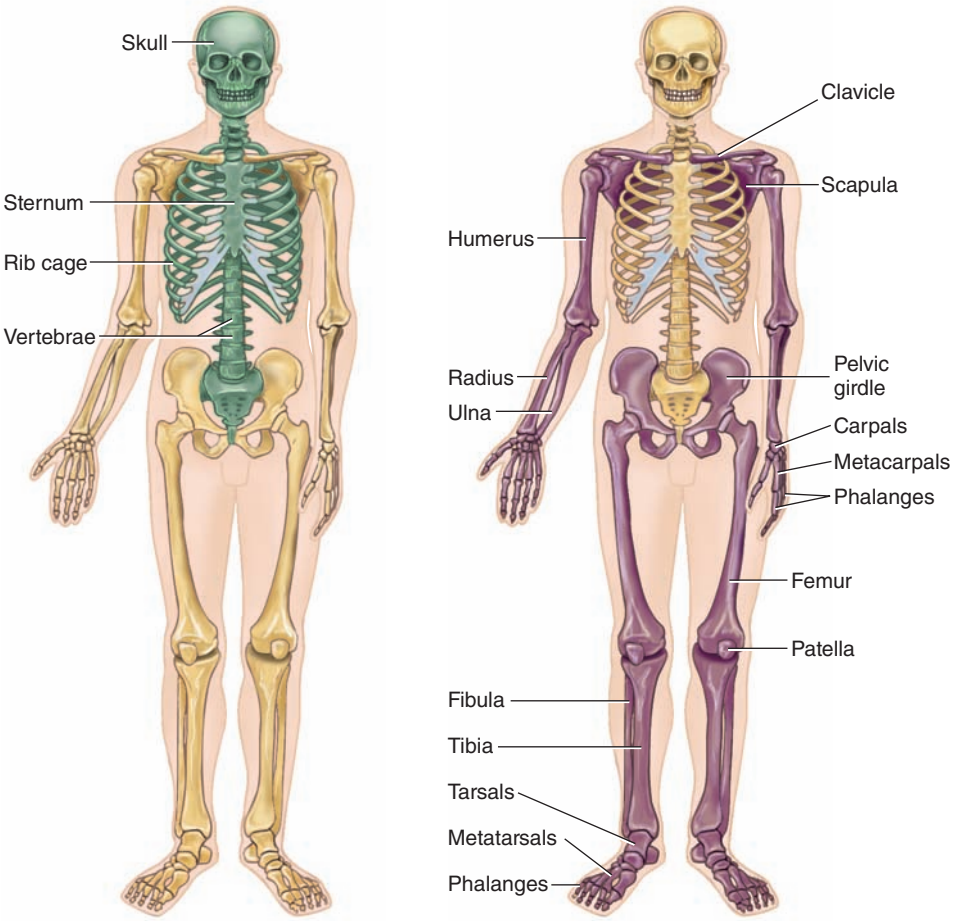
Figure 40-4 The echinoderm endoskeleton

Like other echinoderms, this sunflower sea star (*Pycnopodia* sp.) has a spiny surface. Its endoskeleton is composed of spines and plates of nonliving calcium salts embedded in the body wall. The endoskeleton provides support and protection.

The vertebrate spine, or **vertebral column**, supports the body and bears its weight. In humans it consists of 24 **vertebrae** and 2 bones composed of fused vertebrae: the *sacrum* and *coccyx*. The vertebral column consists of the *cervical* (neck) region, with 7 vertebrae; the *thoracic* (chest) region, with 12 vertebrae; the *lumbar* (back) region, with 5 vertebrae; the *sacral* (pelvic) region, with 5 fused vertebrae; and the *coccygeal* region, also composed of fused vertebrae.

The *rib cage* is a bony "basket" formed by the *sternum* (breastbone), thoracic vertebrae, and, in mammals, 12 pairs of ribs. The rib cage protects the internal organs of the chest, including the heart and lungs. It also supports the chest wall, preventing it from collapsing as the diaphragm contracts with each breath. Each pair of ribs is attached dorsally to a separate vertebra. Of your 12 pairs of ribs, the first 7 are attached ventrally to the sternum; the next 3 are attached indirectly by cartilage; and the bottom 2, the "floating ribs," have no attachments to the sternum.

The *pectoral girdle* consists of 2 collarbones, or *clavicles*, and 2 shoulder blades, or *scapulas*. The *pelvic girdle* consists of a pair of large bones, each composed of 3 fused hip bones. Whereas the pelvic girdle is securely fused to the vertebral column, the pectoral girdle is loosely and flexibly attached to it by muscles.



Each human limb consists of 30 bones and terminates in five *digits*, the fingers and toes. The more specialized appendages of other tetrapods may be characterized by four digits (as in the pig), three (the rhinoceros), two (the camel), or one (the horse).

A typical long bone amplifies the motion generated by muscles

The radius, one of the two bones of the forearm, is a typical long bone (FIG. 40-6). Its numerous muscle attachments are arranged in such a way that the bone rotates about its long axis and operates

(a) Axial skeleton (*green*). (b) Appendicular skeleton (*purple*).

Figure 40-5 The human skeletal system
Only a few of the 206 named bones are labeled here.

as a lever, amplifying the motion generated by the muscles. By themselves, muscles cannot shorten enough to produce large movements of the body parts to which they are attached.

Like other bones, the radius is covered by a connective tissue membrane, the *periosteum*, to which muscle tendons and ligaments attach. The periosteum can produce new layers of bone, thus increasing the bone's diameter. The main shaft of a long bone is its *diaphysis*, and each expanded end is an *epiphysis*. In children a disc of cartilage, the *metaphysis*, lies between the epiphyses and the diaphysis. Metaphyses are growth centers that disappear at maturity, becoming vague *epiphyseal lines*. Long bones have a central cavity that contains **bone marrow**. Yellow marrow consists mainly of a fatty connective tissue; the red marrow in certain bones produces blood cells.

The radius has a thin outer shell of **compact bone**, which is very dense and hard. Compact bone lies primarily near the surfaces of a bone, where it provides great strength. Recall from Chapter 39 that compact bone consists of interlocking spindle-shaped units called **osteons** (see Fig. 39-2). Within an osteon, **osteocytes** (bone cells) lie in small cavities called *lacunae* (sing., *lacuna*). The lacunae are arranged in concentric circles around central **Haversian canals**. Blood vessels that nourish the bone tissue pass through the Haversian canals. Osteocytes are connected by threadlike extensions of their cytoplasm that extend through narrow channels (called *canaliculi*).

Interior to the thin shell of compact bone is a filling of **spongy bone** that provides mechanical strength. Spongy bone consists of a network of thin strands of bone. Its spaces are filled with bone marrow.

Bones are remodeled throughout life

Bones are modeled during growth and remodeled continuously throughout life in response to physical stress and other changing demands. As muscles develop in response to physical activity, the bones to which they are attached thicken and become stronger. **Osteoblasts** are bone-building cells. They secrete the protein collagen, which forms the strong fibers of bone. The compound hydroxyapatite, composed mainly of calcium phosphate, is present in the interstitial fluid (tissue fluid). It automatically crystallizes around the collagen fibers to form the hard matrix of bone. As the matrix forms around the osteoblasts, they become isolated within the lacunae. The trapped osteoblasts are then called **osteocytes**.

Osteoclasts are large, multinucleated cells that resorb (break down) bone. The osteoclasts move about, secreting hydrogen ions that dissolve the crystals and enzymes that digest the collagen. Osteoclasts and osteoblasts are synergistic; together they shape bones. The remodeling process is an extensive process of breaking down and rebuilding bone. The adult human skeleton is completely replaced every 10 years!

In *osteoporosis*, the most common progressive and degenerative bone disease, bone is broken down more rapidly than it is rebuilt. In women, the decrease in estrogen after menopause accelerates bone resorption. Osteoporosis patients lose so much bone mass that their bones become fragile and fracture easily.

Joints are junctions between bones

Joints, or articulations, are junctions between two or more bones. Joints facilitate flexibility and movement. At the joint, the outer surface of each bone consists of *articular cartilage*.

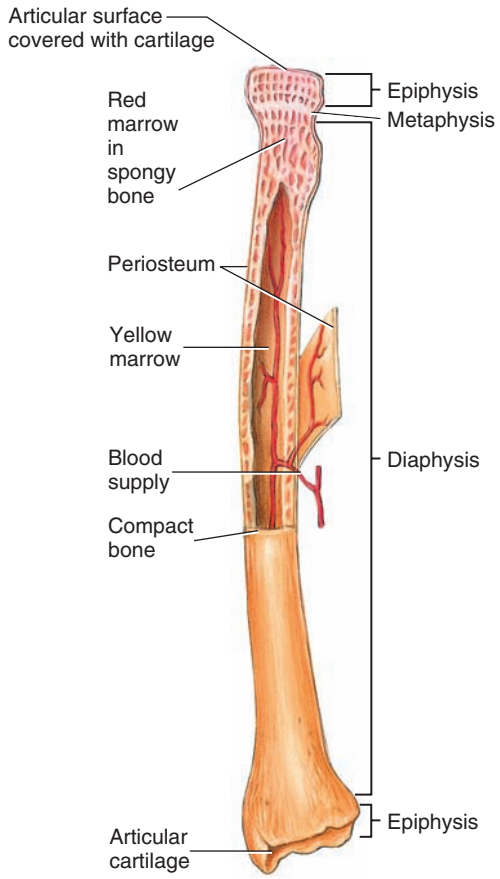

Figure 40-6 A typical long bone
A long bone has a thin shell of compact bone and a filling of spongy bone that contains marrow.

One way to classify joints is according to the degree of movement they allow. The *sutures* between bones of the human skull are *immovable joints*. In a suture, bones are held together by a thin layer of dense fibrous connective tissue, which may be replaced by bone in the adult. *Slightly movable joints*, found between vertebrae, are made of cartilage. These joints help absorb shock.

Most joints are *freely movable joints*. Each is enclosed by a joint capsule of connective tissue and lined with a membrane that secretes a lubricant called *synovial fluid*. This viscous fluid reduces friction during movement and absorbs shock. The joint capsule is typically reinforced by **ligaments**, bands of fibrous connective tissue that connect bones and limit movement at the joint.

With time and use, joints wear down. In *osteoarthritis*, a group of common joint disorders, cartilage repair does not keep up with degeneration, and the articular cartilage wears out. Inflammation of the joint capsule may occur, and bone outgrowths, or spurs, may develop. In *rheumatoid arthritis*, an autoimmune disease, the synovial membrane thickens and becomes inflamed. Synovial fluid accumulates, causing pressure, pain, stiffness, and progressive deformity, leading to loss of function.

CHECKPOINT 40.2

- **CONNECT** How do the septa in the annelid worm contribute to the effectiveness of its hydrostatic skeleton?
- What are some advantages of an exoskeleton? some disadvantages?
- What are the main bones in each division of the human skeleton?
- How do osteoblasts and osteoclasts remodel bone?

40.3 Muscle Contraction

LEARNING OBJECTIVES

7 Relate the structure of insect flight muscles to their function.
8 Describe the structure of skeletal muscles and their antagonistic actions.
9 List, in sequence, the events that take place during muscle contraction.
10 Compare the roles of glycogen, creatine phosphate, and ATP in providing energy for muscle contraction.
11 Compare the structures and functions of the three types of skeletal muscle fibers.
12 Describe factors that influence muscle contraction.

Most animals have the ability to move from place to place. Throughout most of the animal kingdom, a *muscular system* generates the mechanical forces and motion necessary for locomotion and for manipulation of objects. Muscle also powers many physiological actions necessary to maintain homeostasis. Many animals have digestive systems that push food along with peristaltic contractions and hearts that pump internal circulating fluids. Some animals also have blood vessels that maintain their pressure with gentle squeezing.

Animals with very simple body plans do not have muscle tissue, but all eukaryotic cells do contain the contractile protein **actin**. The major component of microfilaments (see Fig. 4-27), actin is important in many cell processes, including amoeboid movement and attachment of cells to surfaces. In most cells actin is functionally associated with the contractile protein **myosin**. Actin and myosin are most highly organized in muscle fibers.

Invertebrate muscle varies among groups

Earlier in this chapter, we discussed the contractile cells of the hydrostatic skeleton of *Hydra* and other cnidarians. In most other animal groups, muscle is a specialized tissue organized into definite layers, or straplike bands. Some invertebrate phyla have skeletal and smooth muscle. Bivalve mollusks, such as clams, have two sets of muscles for opening and closing the shell. Their specialized smooth muscle, which is capable of slow, sustained contraction at low energy cost, keeps the two shells tightly closed for long periods, even weeks at a time.

Striated muscle, which contracts rapidly, is used to swim and to shut the shell quickly when the mollusk is threatened. Arthropod muscles are striated, even in the walls of the digestive tract.

Insects were the first animals in which flight evolved, an adaptation that has contributed to their impressive biological success (see Chapter 31). Just how insects fly has been an aerodynamic mystery, and scientists are working to understand their remarkable ability to maneuver. Insect flight muscles contract more rapidly than any other known muscle, up to 1000 contractions per second! Not surprisingly, insect flight muscles in action have the highest known metabolic rate of any muscle tissue.

As you might imagine, insect flight muscles are structurally well adapted to their function. They contain more mitochondria than any other known variety of muscle. Their mitochondria have more cristae (folds of their inner membranes) and can consume oxygen twice as fast as mammalian mitochondria. Insect muscles are also elaborately infiltrated with *tracheae*, tiny air-filled tubes that carry oxygen directly to each muscle fiber.

Many insects must warm up before they fly because an increase in body temperature increases the rate of ATP synthesis. Butterflies and some other insects bask in the sun before they fly. Honeybees "shiver" their muscles to increase body temperature.

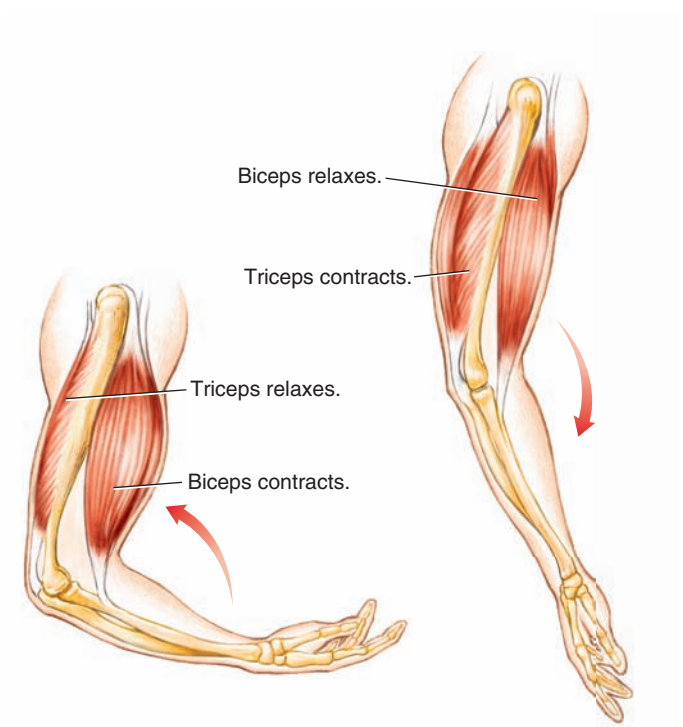
Vertebrate skeletal muscles act antagonistically to one another

Skeletal muscles produce movements by pulling on **tendons**, tough cords of connective tissue that anchor muscles to bone. Tendons then pull on bones. Skeletal muscles, or their tendons, pass across a joint and are attached to the bones on each side of the joint. When the muscle contracts, it pulls one bone toward or away from the bone with which it articulates.

Because muscles can only contract, they can only pull; they cannot push. Muscles act **antagonistically** to one another, which means that the movement produced by one can be reversed by another. For example, contraction of the biceps muscle flexes (bends) your arm, whereas contraction of the triceps muscle extends it (FIG. 40-7).

The muscle that contracts to produce a particular action is known as the *agonist*. The muscle that produces the opposite movement is the *antagonist*. When the agonist is contracting, the antagonist is relaxed. Generally, movements are accomplished by groups of muscles working together, so several agonists and several antagonists may take part in any action. Note that muscles that are agonists in one movement may serve as antagonists in another. Some of the superficial skeletal muscles of the human body are shown in FIGURE 40-8.

A vertebrate muscle may consist of thousands of muscle fibers



Skeletal muscle is the most abundant tissue in the vertebrate body. Its elongated cells, called **muscle fibers**, are organized in bundles wrapped by connective tissue. The biceps in your arm, for example, consists of thousands of individual muscle fibers and their connective tissue coverings.

Each striated muscle fiber is a long, cylindrical cell with many nuclei (FIG. 40-9). The plasma membrane, known as the **sarcolemma** in a muscle fiber, has multiple inward extensions that form a set of **T tubules** (transverse tubules). The cytoplasm of a muscle fiber is called *sarcoplasm*, and the endoplasmic reticulum is called the **sarcoplasmic reticulum**.

Myofibrils are threadlike structures that run lengthwise through the muscle fiber. They consist of even smaller structures called **filaments**. There are two types of filaments: myosin and actin filaments. **Myosin filaments** are thick, consisting mainly of the protein myosin. The thin **actin filaments** consist mostly of the protein actin; they also contain the proteins **tropomyosin** and **troponin**, which regulate the actin filament's interaction with myosin filaments.

Myosin and actin filaments are organized into repeating units called **sarcomeres**, the basic units of muscle contraction. Hundreds of sarcomeres connected end to end make up a myofibril. Sarcomeres are joined at their ends by a thin band of interweaving filaments called the *Z line*. Each sarcomere consists of overlapping myosin and actin filaments. The filaments overlap lengthwise in the muscle fibers, producing the pattern of transverse bands or striations characteristic of striated muscle (FIG. 40-10 on page 852; also see Fig. 40-9).

The bands in striated muscle are designated by the letters *A*, *H*, and *I*. The *I band* consists of parts of actin filaments of two

(a) Flexion. When the biceps muscle contracts, the arm flexes (bends).

(b) Extension. When the triceps muscle contracts, the arm extends.

adjacent sarcomeres. The *A band* is the wide, dark region that includes overlapping myosin and actin filaments. Within the A band is a narrow, light area, the *H zone*, made up exclusively of myosin filaments; the actin filaments do not extend into this region. A system of proteins holds each stack of myosin filaments together. These proteins are visible as a thin line, the *M line*, that extends down the center of the H zone within the A band.

Contraction occurs when actin and myosin filaments move past one another

Muscle contraction occurs when the muscle fibers, and thus the sarcomeres, shorten. This explanation of muscle contraction, known as the **sliding filament model**, was developed in the 1950s by two British biologists, Hugh Huxley and Andrew Huxley. (The Huxleys were not related. They worked separately, and they independently came to the same general conclusions at about the same time.) Thanks to the Huxleys, we now understand that the muscle shortens as the actin and myosin filaments use a ratcheting mechanism to move past one another, increasing their overlap. You might think of an extension ladder. The overall ladder length changes as the ends get closer or farther apart, but the length of each ladder section stays the same. The I band and H zone decrease in length, but neither the actin nor myosin filaments themselves shorten.

Motor neurons transmit messages from the brain or spinal cord to muscle fibers. When a motor neuron transmits a

Key Point

A muscle contracts when actin and myosin filaments move past one another. The length of each filament remains the same.

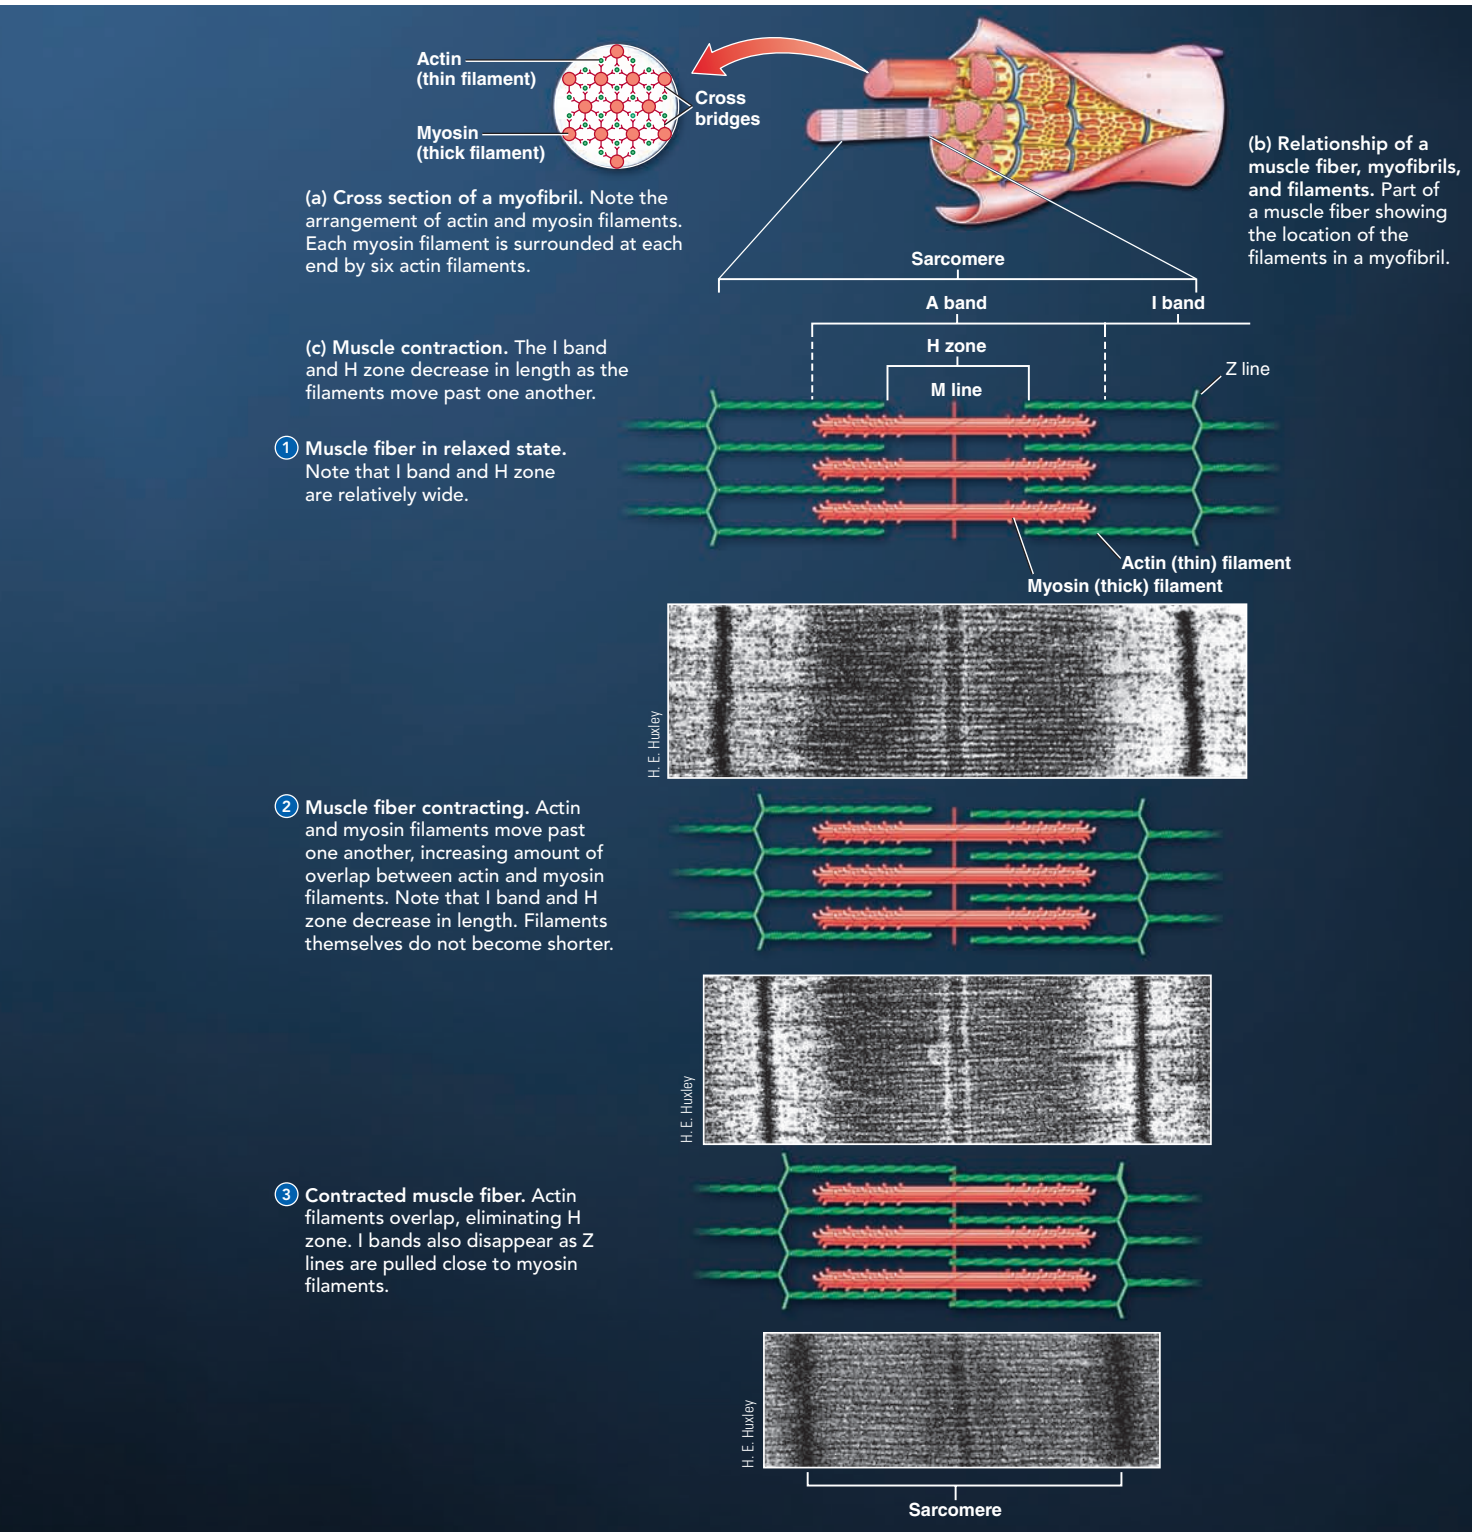

Figure 40-10 The sliding filament model of muscle contraction

Myosin and actin filaments are organized into repeating units called sarcomeres. As the sarcomeres become shorter, the muscle fiber shortens, but the size of the filaments does not change. (The I band consists of actin filaments of two adjacent sarcomeres.)

PREDICT How would the volume of myofibrils in a muscle fiber affect the force that the muscle can generate?

message, it releases the neurotransmitter **acetylcholine** into the **synaptic cleft**, a small space between the motor neuron and each muscle fiber. Acetylcholine binds with receptors on each muscle fiber, causing **depolarization**, a change in the distribution of electric charge across its sarcolemma. Depolarization can generate an **action potential**, an electrical signal that travels along the membrane of the muscle fiber (or neuron).

In a muscle fiber, an action potential is a wave of depolarization that travels along the sarcolemma and into the system of T-tubule membranes. Depolarization of the T tubules opens calcium channels in the sarcoplasmic reticulum, and stored calcium ions are released into the myofibrils. Calcium ions bind to the protein troponin on the actin filaments, which changes the shape of the troponin. This change results in the troponin pushing tropomyosin away from the *active sites* on the actin filament (FIG. 40-11). These active sites, also called *myosin-binding sites*, are now exposed.

One end of each myosin molecule is folded into two globular structures called *heads*. The rounded heads of the myosin molecules extend away from the body of the myosin filament. Each myosin molecule also has a long tail that joins other myosin tails to form the body of the thick filament. ATP is bound to the myosin when the muscle fiber is at rest (not contracting). Myosin is an adenosine triphosphatase (ATPase), an enzyme that splits ATP to form ADP and inorganic phosphate (P_i). Myosin converts the chemical energy of ATP into the mechanical energy of sliding filaments.

According to the current model of muscle contraction, when ATP is split, the ADP and P_i initially remain attached to the myosin head. The myosin head (with ADP and P_i still bound to it) is in an energized state; it is "cocked." The myosin head binds to an exposed active site on the actin filament, forming a **cross bridge** linking the myosin and actin filaments. The inorganic phosphate is then released, which triggers a conformational change in the myosin head. The myosin head bends about 45 degrees, in a flexing motion. This movement, the *power stroke*, pulls the actin filament closer to the center of the sarcomere. During the power stroke, the ADP is released.

A new ATP must bind to the myosin head before the myosin can detach from the actin. If sufficient calcium ions are present, the cycle begins anew. Energized once again, myosin heads contact a second set of active sites on the actin filament. This next set is farther down the filament, closer to the end of the sarcomere. The process repeats with a third set of active sites, and so on. This series of stepping motions pulls the actin filaments toward the center of the sarcomere.

Each time the myosin heads attach, move 45 degrees, detach, and then re-attach farther along the actin filament, the muscle shortens. One way to visualize this process is to imagine the myosin heads engaging "hand over hand" with the actin filaments. When many sarcomeres contract simultaneously, they contract the muscle as a whole. The sequence of events in muscle contraction can be summarized as follows:

1. A motor neuron releases acetylcholine, which binds with receptors on the muscle fiber; binding causes depolarization and generation of an action potential.
2. The action potential spreads through T tubules, triggering Ca^{2+} release from the sarcoplasmic reticulum.
3. Ca^{2+} bind to troponin, causing troponin to change shape, which exposes the active sites on the actin filaments.
4. ATP (attached to myosin) is split, and the energized myosin head is cocked; it binds to the active site on the actin filament, forming a cross bridge.
5. The release of P_i from the myosin head triggers the power stroke.
6. During the power stroke, the myosin head pulls the actin filament toward the center of the sarcomere, shortening the muscle; ADP is released.
7. The myosin head binds a new ATP and detaches from actin. If the concentration of Ca^{2+} is high enough, the cycle repeats from step 3.

ATP powers contraction through repeated cycles of cross bridge formation followed by myosin heads pulling actin filaments toward the center of the sarcomere.

When impulses from the motor neuron cease, the enzyme acetylcholinesterase in the synaptic cleft inactivates acetylcholine. Muscle fibers return to their resting state. Calcium ions are pumped back into the sarcoplasmic reticulum by active transport, a process that requires ATP. Calcium removal is the key step in muscle relaxation. Without Ca^{2+}, tropomyosin once again covers active sites on the actin filaments. The actin filaments move back to their original position, and the muscle relaxes. This entire series of events happens in milliseconds.

ATP powers muscle contraction

Muscle cells often perform strenuously and need large amounts of energy. As noted, the immediate source of energy for muscle contraction is ATP. Energy stored in ATP molecules powers attachment of the myosin heads to the actin filaments, bending of the cross bridges, and release of the myosin heads. Note that energy is needed not only for the pull exerted by the cross bridges, but also for their release from each active site.

Rigor mortis, the temporary but very marked muscle stiffening that occurs after death, results from ATP depletion. When death occurs, cellular respiration ceases, and ATP is used up. However, at the time of death, many muscle fibers are in the process of contraction, and cross bridges have formed. Because ATP is essential for release of the myosin heads, cross bridges remain intact. Rigor mortis does not persist indefinitely because the entire contractile apparatus of the muscles eventually decomposes, restoring pliability. The phenomenon is temperature dependent, so given the prevailing temperature, a medical examiner can estimate the time of death of a cadaver from its degree of rigor mortis.

ATP molecules can provide energy for only a few seconds of strenuous activity. Muscle fibers have a backup energy storage compound, **creatine phosphate**, that can be stockpiled. The energy stored in creatine phosphate is transferred to ATP as needed, but during vigorous exercise the supply of creatine

Key Point

The energy of ATP powers muscle contraction. During the power stroke, myosin heads move actin filaments toward the center of the sarcomere, which shortens the muscle.

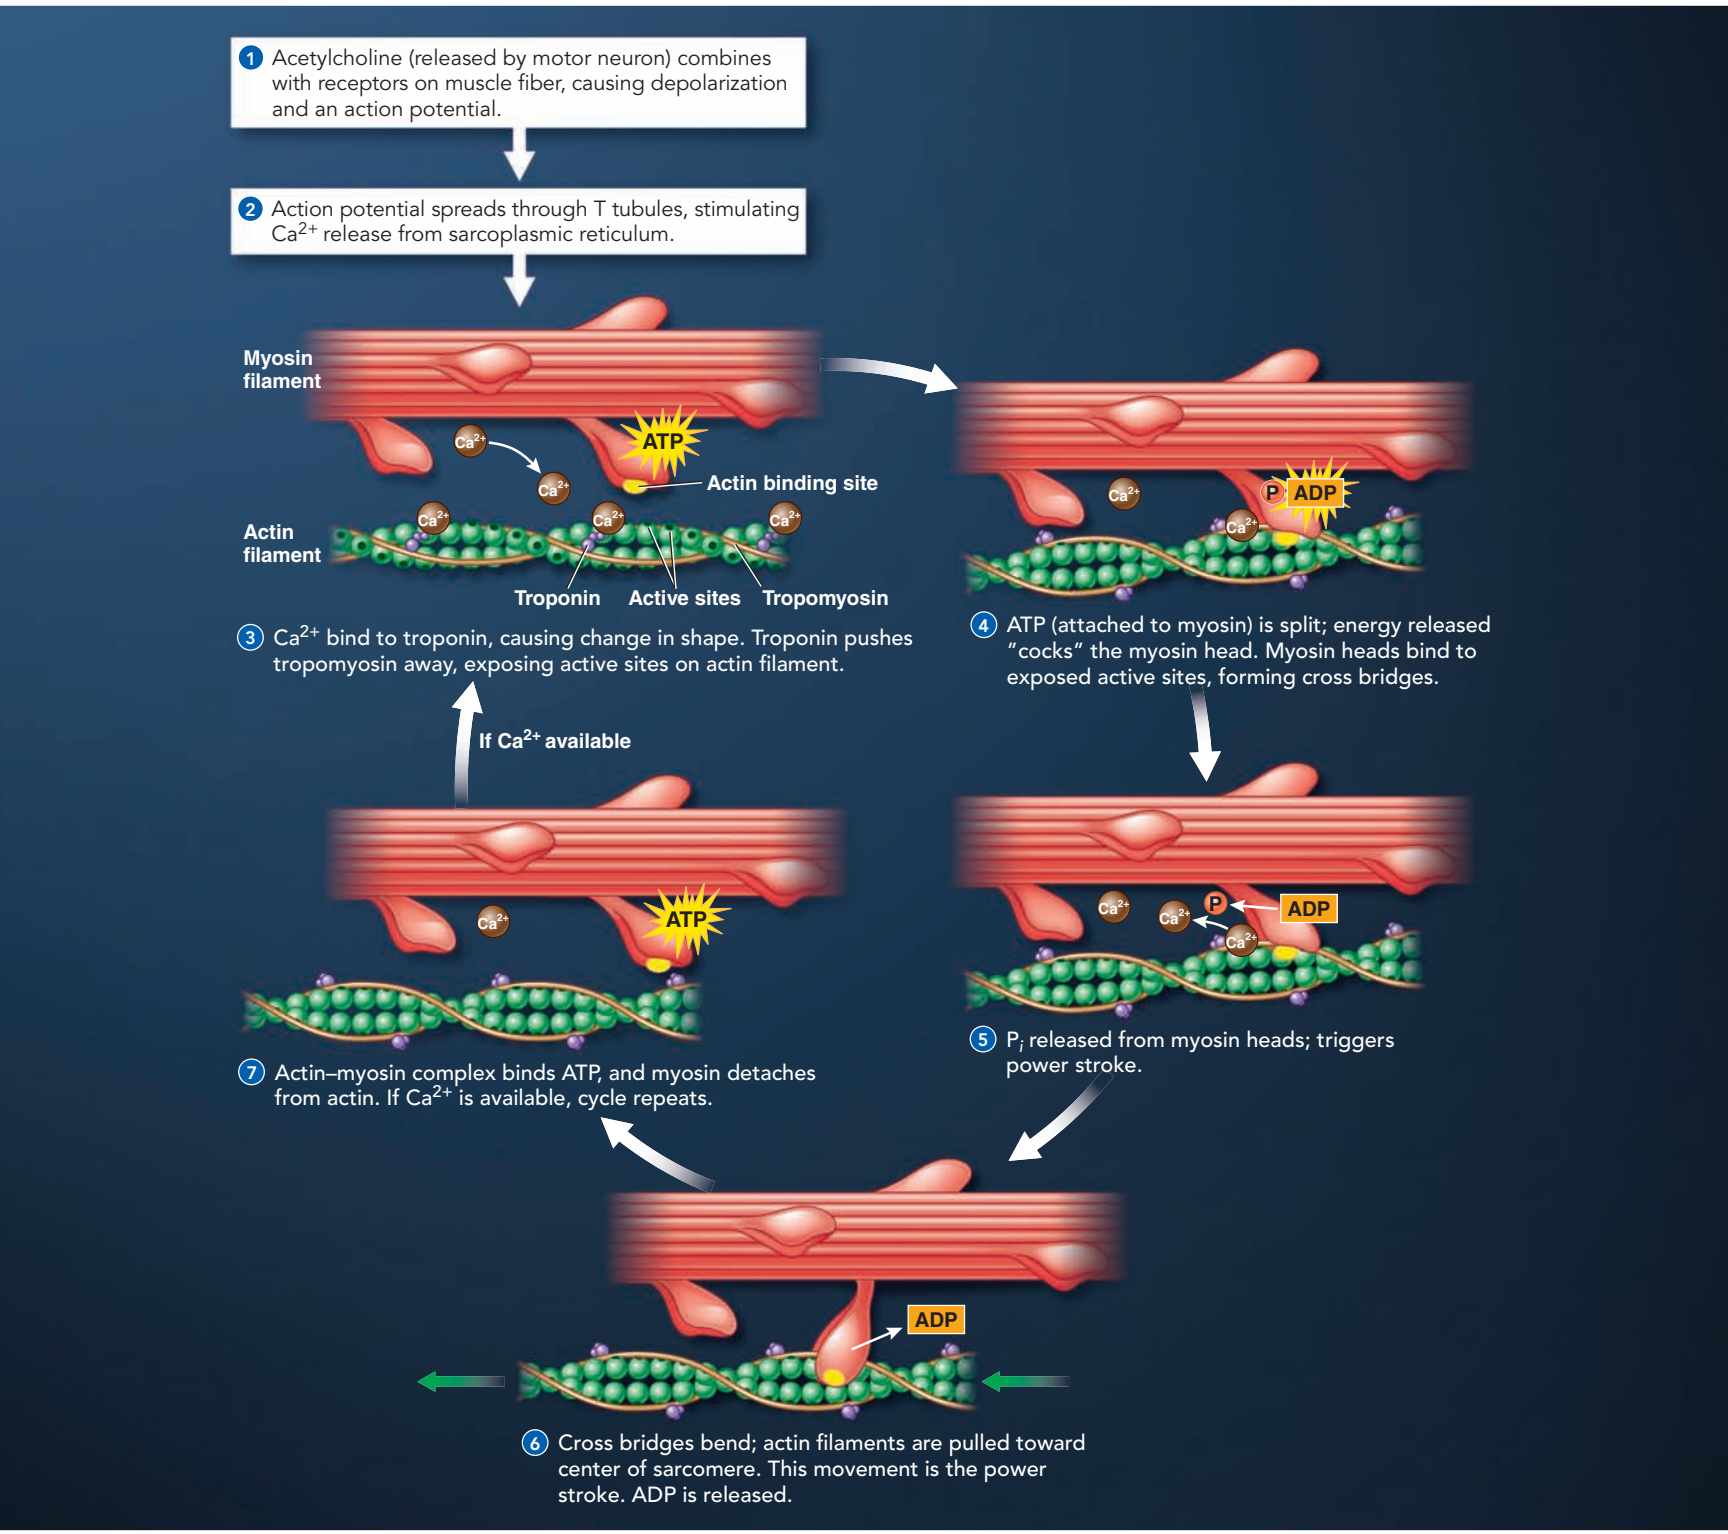

Figure 40-11 Muscle contraction: model of actin and myosin interactions
Contraction results when actin filaments move toward the center of individual sarcomeres of a myofibril. After step 7, the cycle repeats from step 3 if calcium ions are available. In the absence of calcium ions, the muscle relaxes.

PREDICT How would muscle contraction be affected if the body stopped producing acetylcholine?

phosphate is quickly depleted. Muscle cells must replenish their supplies of these energy-rich compounds.

Fortunately, there is yet another backup energy storage compound. Muscle fibers store chemical energy in **glycogen**, a large polysaccharide formed from hundreds of glucose molecules. Glycogen can be degraded, yielding glucose, which is then degraded in cellular respiration (see Chapters 3 and 8). When sufficient oxygen is available, enough energy is captured from glucose to produce needed quantities of ATP and creatine phosphate.

During a burst of strenuous exercise, the circulatory system cannot deliver enough oxygen to keep up with the demand of the rapidly metabolizing muscle fibers. The result is an **oxygen debt**. Under these conditions, muscle fibers break down fuel molecules anaerobically (without oxygen) for short periods. Lactic acid fermentation is a method of generating ATP anaerobically, but not in great quantity (see Fig. 8-14c). ATP depletion results in weaker contractions and muscle fatigue. Accumulation of the waste product **lactic acid** also contributes to muscle fatigue. Well-conditioned athletes develop the ability to tolerate the high levels of lactic acid generated during high-performance activity. The period of rapid breathing that generally follows strenuous exercise pays back the oxygen debt by consuming lactic acid.

The type of muscle fibers determines strength and endurance

Three major types of skeletal muscle fibers have been identified in vertebrates: slow-oxidative, fast-oxidative, and fast-glycolytic fibers (TABLE 40-1). **Slow-oxidative fibers** are well adapted for endurance activities such as swimming and running long distances. These fibers also help maintain posture. They contract slowly and fatigue slowly. Slow-oxidative fibers require a steady supply of oxygen. They derive most of their energy from aerobic respiration and are rich in mitochondria and capillaries. Slow-oxidative fibers are rich in **myoglobin**, a red pigment similar to hemoglobin, which stores oxygen in red blood cells. Myoglobin enhances rapid diffusion of oxygen from blood into muscles during strenuous muscle exertion. Because of their myoglobin, slow-oxidative fibers are red and are sometimes called red fibers.

Fast-oxidative fibers contract rapidly and have an *intermediate* rate of fatigue. Like slow-oxidative fibers, they are rich in mitochondria and obtain most of their ATP from aerobic respiration. They also have a high myoglobin content and a red color.

Fast-glycolytic fibers generate a great deal of power and carry out rapid movements but can sustain that activity for only a short time. They are important in activities such as sprinting and weight lifting. Fast-glycolytic fibers contract rapidly, have few mitochondria, and obtain most of their energy from glycolysis. When their glycogen supply is depleted, they fatigue rapidly. These fibers have a low myoglobin content and are white. (They are sometimes referred to as white fibers.) People who are sedentary have more fast-glycolytic fibers than do physically fit individuals. With physical training, these fibers change to fast-oxidative fibers.

Entire muscles may be specialized for quick or slow responses. In chickens, for instance, the white breast muscles are efficient for quick responses, perhaps because a short flight is an escape mechanism for chickens. However, they walk about on the ground all day; the dark (red) meat of the leg and thigh is muscle specialized for more sustained activity. Birds that fly have red breast muscles specialized to support sustained activity.

In humans most muscles have a mixture of different types of fibers. The proportions of the types of fibers vary among individuals and from muscle to muscle in the same person. Aerobic exercise, such as jogging or bicycling, increases endurance. *Aerobic training* increases capillary density, the number of mitochondria, and the myoglobin content of muscle fibers. In *strength training*—for example, weight lifting—specific muscles are repeatedly contracted under heavy loads. This action increases the number of filaments in the muscle fibers, which increases the size of the muscle.

Several factors influence the strength of muscle contraction

In addition to the types of muscle fibers making up the muscle, contraction of a whole muscle depends on the number of muscle fibers contracting, the tension developed by each fiber, frequency of stimulation, condition of the muscle (e.g., whether or not it is fatigued), and the load on the muscle. As more muscle fibers contract, the tension in the muscle increases.

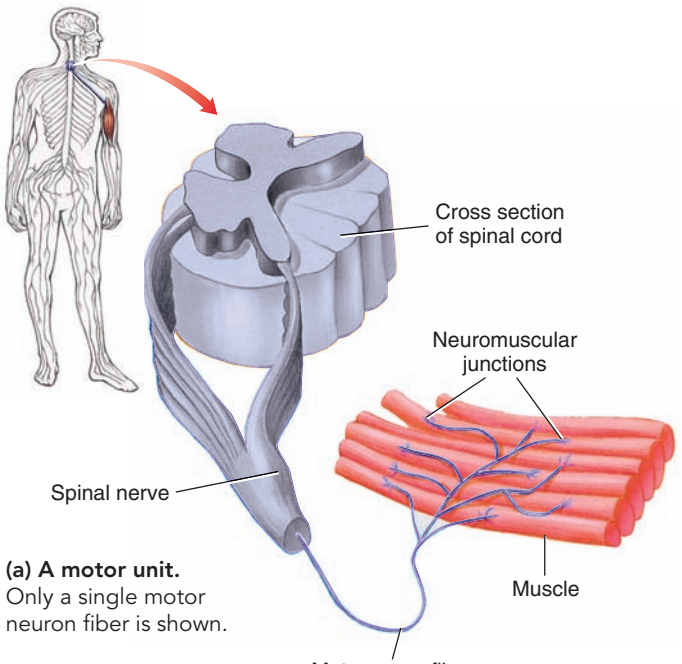

Table 40-1 Characteristics of Skeletal Muscle Fibers

Characteristics	Slow-Oxidative Fibers	Fast-Oxidative Fibers	Fast-Glycolytic Fibers
Contraction speed	Slow	Fast	Fast
Rate of fatigue	Slow	Intermediate	Fast
Major pathway for ATP synthesis	Aerobic respiration	Aerobic respiration	Glycolysis
Mitochondria	Many	Many	Few
Intensity of contraction	Low	Intermediate	High
Myoglobin content	High	High	Low
Color of fiber	Red	Red	White

In a **motor unit**, a motor neuron is functionally connected with an average of about 150 muscle fibers (FIG. 40-12). However, some motor units have fewer than a dozen motor neurons, and others have several hundred. Each junction of a motor neuron with a muscle fiber is called a *neuromuscular junction*. Messages from the brain or spinal cord activate motor units. The more motor units *recruited*, the stronger the contractions.

(a) A motor unit. Only a single motor neuron fiber is shown.

(b) SEM of some of the motor neuron fibers in a motor unit. Note how neurons branch to innervate all muscle fibers in the motor unit.

Figure 40-12 A motor unit
A motor unit consists of a motor neuron and the muscle fibers that it innervates.

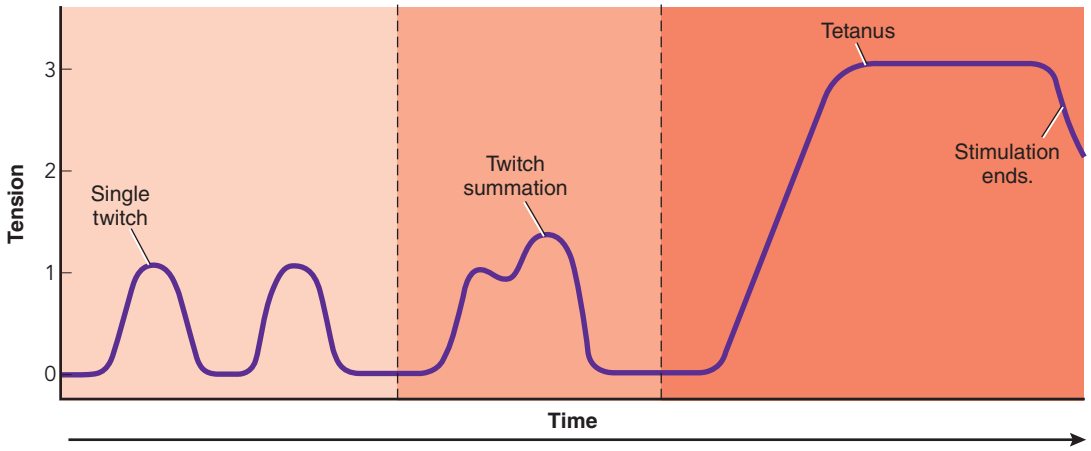
An important factor affecting the tension of contracting muscle fibers is the frequency of stimulation. In response to a single, brief electrical stimulus, skeletal muscle contracts with a single, quick contraction called a *simple twitch*. When a second stimulus is received before the first contraction is complete, the two twitches may add together, a process called **summation** (FIG. 40-13). Typically, skeletal muscle receives a series of separate stimuli timed very closely together. Summation results in a smooth, sustained contraction called *tetanus*. The identity and number of our muscle fibers that are tetanically contracting help determine whether we can play the piano, draw a picture, rock a baby, drive a car, or run a mile.

When you lift a heavy object, you place a load on the muscles affected. As the weight of the load increases, the muscles contract more strongly (within limits).

Even when you are not moving, your muscles are in a state of partial contraction known as **muscle tone**. At any given moment, some muscle fibers are contracted, stimulated by messages from motor neurons. Muscle tone is an unconscious process that keeps muscles prepared for action. When the motor nerve to a muscle is cut, the muscle becomes limp (completely relaxed, or flaccid) and eventually atrophies (decreases in size).

Smooth muscle and cardiac muscle are involuntary

The three types of vertebrate muscle—skeletal, smooth, and cardiac—are compared in Table 39-3. All three types of muscle have thin actin filaments that move along thick myosin filaments in response to an increase in calcium ion concentration. All three muscle types use ATP to power contraction. However, each type of muscle is specialized for particular types of responses. Neither smooth muscle nor cardiac muscle is under voluntary control.



Smooth muscle is not attached to bones but instead forms tubes that squeeze like the muscle tissue in the body wall of the earthworm. Smooth muscle contracts in response to simple stretching, and its contraction tends to be sustained. It is well adapted to performing such tasks as regulating blood pressure by sustained contraction of the walls of the arterioles. Although smooth muscle contracts slowly, it shortens much more than striated muscle does; it squeezes impressively.

Smooth muscle is not striated because its actin and myosin filaments are not organized into myofibrils or into sarcomeres. The fibers of smooth muscle tissue function as a unit because they are connected by *gap junctions* (see Fig. 5-23c). Gap junctions permit electrical signals to pass rapidly from fiber to fiber. Although smooth muscle contraction is similar to skeletal muscle contraction (occurring by a sliding filament mechanism), the cross bridges in smooth muscle remain in the attached state longer. For this reason, less ATP is required to maintain a high level of force in smooth muscle than in skeletal muscle.

Cardiac muscle contracts and relaxes in alternating rhythm, propelling blood with each contraction. Sustained contraction of cardiac muscle would be disastrous! Cardiac

(a) When a muscle fiber is allowed to completely relax and is then stimulated a second time, the second twitch is the same magnitude as the first twitch.

(b) When a muscle fiber is stimulated a second time before it has completely relaxed, the second twitch is added on to the first twitch. The result is summation.

(c) A volley of rapid stimuli does not allow the muscle fiber to relax between stimuli. The result is a sustained contraction called tetanus.

Figure 40-13 Summation and tetanus

muscle fibers are electrically coupled by junctions called **intercalated discs**. Gap junctions within the intercalated discs allow action potentials to spread rapidly from one cardiac fiber to another.

Each heartbeat is initiated by a *pacemaker*, a mass of specialized cardiac muscle. A conduction system transmits the signal throughout the cardiac muscle. The cardiac fibers within the atria contract as a functional unit, and the cardiac fibers within the ventricles also function as a functional unit. The heart beats in a regular rhythm independent of a nerve supply. However, the heart rate is regulated, according to the needs of the body, by neurons in the cardiac centers in the medulla of the brain (discussed in Chapter 44).

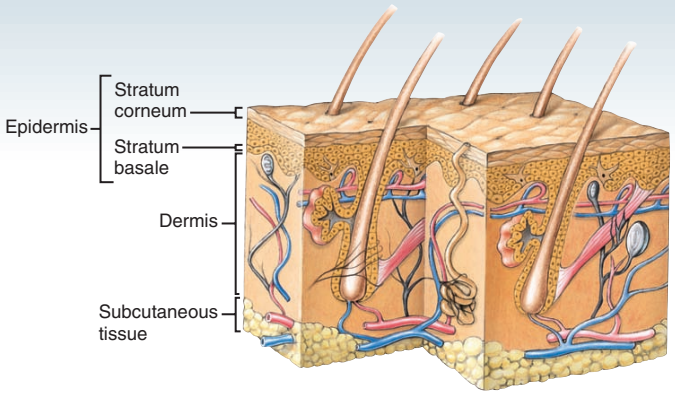
CHECKPOINT 40.3

- **VISUALIZE** Sketch a longitudinal section of a sarcomere in a relaxed state. Label the Z lines, thin filaments, and thick filaments. Which filaments are actin? myosin?
- What is the sequence of events that occur when a muscle fiber contracts (begin with release of acetylcholine and include cross-bridge action)?
- Compare and contrast the functions of ATP, creatine phosphate, and glycogen in muscle contraction.
- Compare skeletal, smooth, and cardiac muscle.

Summary: Focus on Learning Objectives

40.1 Epithelial Coverings *(page 843)*

1 Compare the functions of the epithelial coverings of invertebrates and vertebrates.



- **Epithelial tissue** protects underlying tissues and may be specialized for sensory or respiratory functions. The outer epithelium may be specialized to secrete antibacterial or poisonous substances.
- In many invertebrates, the outer epithelium is specialized to secrete a protective **cuticle**, or a shell.
- The **integumentary system** of vertebrates includes the skin and structures that develop from it. Mammalian skin includes hair, claws or nails, sweat glands, oil glands, and sensory receptors.

2 Relate the structure of vertebrate skin to its functions.

- The feathers of birds and the hair of mammals form an insulating layer that helps maintain a constant body temperature. Mammalian skin protects the body from the wear and tear that occurs as it interacts with the outer environment. **Stratum corneum**, the most superficial layer of the **epidermis**, consists of dead cells filled with **keratin**, a protein that gives mechanical strength to the skin and reduces water loss. Cells in **stratum basale**, the deepest layer of the epidermis, divide and are pushed upward toward the skin surface. These cells mature, produce keratin, and eventually die and slough off.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

- The **dermis** consists of dense, fibrous connective tissue. In birds and mammals, the dermis rests on a layer of *subcutaneous tissue* composed largely of insulating fat.

40.2 Skeletal Systems *(page 844)*

3 Compare the structure and functions of different types of skeletal systems, including the hydrostatic skeleton, exoskeleton, and endoskeleton.

- The **skeletal system** supports and protects the body and transmits mechanical forces generated by muscles. Many soft-bodied invertebrates have a **hydrostatic skeleton**; fluid in a closed body compartment is used to transmit forces generated by contractile cells or muscle.
- **Exoskeletons** are characteristic of mollusks and arthropods. The arthropod skeleton, composed partly of **chitin**, is jointed for flexibility and adapted for many lifestyles. This nonliving skeleton does not grow, making it necessary for arthropods to undergo **ecdysis** (**molting**) periodically.
- The **endoskeletons** of echinoderms and chordates consist of living tissue and therefore can grow.

4 Describe the main divisions of the vertebrate skeleton and identify the bones that make up each division.

- The vertebrate skeleton consists of an *axial skeleton* and an *appendicular skeleton*. The axial skeleton consists of the *skull*, the **vertebral column**, the *rib cage*, and the *sternum*. The appendicular skeleton consists of the bones of the limbs, the *pectoral girdle*, and the *pelvic girdle*.

5 Describe (or draw and label) the structure of a typical long bone and contrast the roles of osteoblasts and osteoclasts in bone remodeling.

- A typical long bone consists of a thin outer shell of **compact bone** surrounding the inner **spongy bone** and a central cavity that contains **bone marrow**.
- **Osteoblasts**, cells that produce bone, and **osteoclasts**, cells that break down bone, work together to shape and remodel bone.

6 Compare the main types of vertebrate joints.

- **Joints** are junctions of two or more bones. **Ligaments** are connective tissue bands that connect bones and limit movement at the joint.
- The sutures of the skull are *immovable joints*. Joints between vertebrae are *slightly movable joints*. A *freely movable joint* is enclosed by a joint capsule lined with a membrane that secretes *synovial fluid*.

40.3 Muscle Contraction *(page 848)*

7 Relate the structure of insect flight muscles to their function.

- Large numbers of mitochondria and tracheae (air tubes) present in insect flight muscles support the high metabolic rate required for flight.

8 Describe the structure of skeletal muscles and their antagonistic actions.

- Vertebrates, as well as most invertebrates, have a *muscular system*. As muscle tissue contracts (shortens), it moves body parts by pulling on them.
- Vertebrate skeletal muscles pull on **tendons**, connective tissue cords that attach muscles to bones. When a muscle contracts, it pulls a bone toward or away from the bone with which it articulates.
- Skeletal muscles act *antagonistically* to one another. The muscle that produces a particular action is the *agonist*; the *antagonist* produces the opposite movement.
- A skeletal muscle such as the biceps is an organ made up of hundreds of **muscle fibers**. Each fiber consists of threadlike **myofibrils** composed of smaller **filaments**. The striations of skeletal muscle fibers reflect the overlapping of their **actin filaments** and **myosin filaments**. A **sarcomere** is a contractile unit of actin (thin) and myosin (thick) filaments.

9 List, in sequence, the events that take place during muscle contraction.

- **Acetylcholine** released by a motor neuron binds with receptors on the surface of a muscle fiber. This may cause **depolarization** of the sarcolemma and transmission of an **action potential**. The action potential spreads through the **T tubules**, releasing calcium ions from the **sarcoplasmic reticulum**.
- Calcium ions bind to **troponin** in the actin filaments, causing the troponin to change shape. Troponin pushes **tropomyosin** away from the binding sites on the actin filaments.
- ATP binds to myosin; ATP is split, putting the myosin head in a high-energy state (it is "cocked"). Energized myosin heads attach to the exposed binding sites on the actin filaments, forming **cross bridges** that link the myosin and actin filaments.
- After myosin attaches to the actin filament, the cross bridge flexes as phosphate is released. This power stroke pulls the actin filament toward the center of the sarcomere. ADP is released during the power stroke.
- The myosin head binds a new ATP, which lets the myosin head detach from the actin. As long as the calcium ion concentration remains elevated, the new ATP is split, and the sequence repeats. The myosin re-attaches to new active sites so that the filaments are pulled past one another, and the muscle continues to shorten.

10 Compare the roles of glycogen, creatine phosphate, and ATP in providing energy for muscle contraction.

- ATP is the immediate source of energy for muscle contraction. ATP hydrolysis provides the energy to "cock" the myosin. Muscle tissue has an intermediate energy storage compound, **creatine phosphate**. **Glycogen** is the fuel stored in muscle fibers.

11 Compare the structures and functions of the three types of skeletal muscle fibers.

- **Slow-oxidative fibers** are specialized for endurance activities. They contract slowly, fatigue slowly, are rich in mitochondria, and obtain most of their ATP from aerobic respiration.

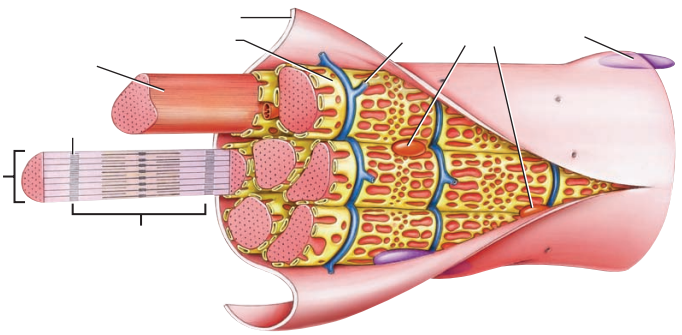
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

These fibers have a red color because they have a high content of **myoglobin**, a red pigment that stores oxygen.

- **Fast-oxidative fibers** are specialized for rapid response. They contract quickly and have an intermediate rate of fatigue. Like slow-oxidative fibers, they are rich in mitochondria, obtain most of their ATP from aerobic respiration, have a high myoglobin content, and have a red color.
- **Fast-glycolytic fibers** generate a great deal of power for a brief period. These white fibers contract rapidly, fatigue quickly, have few mitochondria, and use glycolysis as a major pathway for ATP synthesis.

12 Describe factors that influence muscle contraction.

- Contraction of a whole muscle depends on several factors, including the number of muscle fibers contracting, tension developed by each fiber, frequency of stimulation, condition of the muscle, and load on the muscle.
- A **motor unit** consists of all the skeletal muscle fibers stimulated by a single motor neuron. Messages from the brain or spinal cord activate motor units. The more motor units *recruited*, the stronger the contractions.
- When activated by a brief electrical stimulus, skeletal muscle responds with a *simple twitch*. When a second stimulus is received before the first contraction is complete, the two twitches can add together, a process called **summation**. Typically, skeletal muscle is stimulated by a series of separate stimuli timed close together and responds with a smooth, sustained contraction called *tetanus*.
- **Muscle tone** is the state of partial contraction characteristic of muscles.
- In contrast to skeletal muscle, **smooth muscle** and **cardiac muscle** are not under voluntary control. The sustained contractions of smooth muscle are adapted for tasks such as regulating blood pressure by contraction of arteriole walls. Cardiac muscle contracts and relaxes in an alternating rhythm, pumping blood with each contraction. **Intercalated discs** are junctions that electrically couple cardiac muscle fibers. These discs allow action potentials to spread rapidly from one cardiac muscle fiber to another.



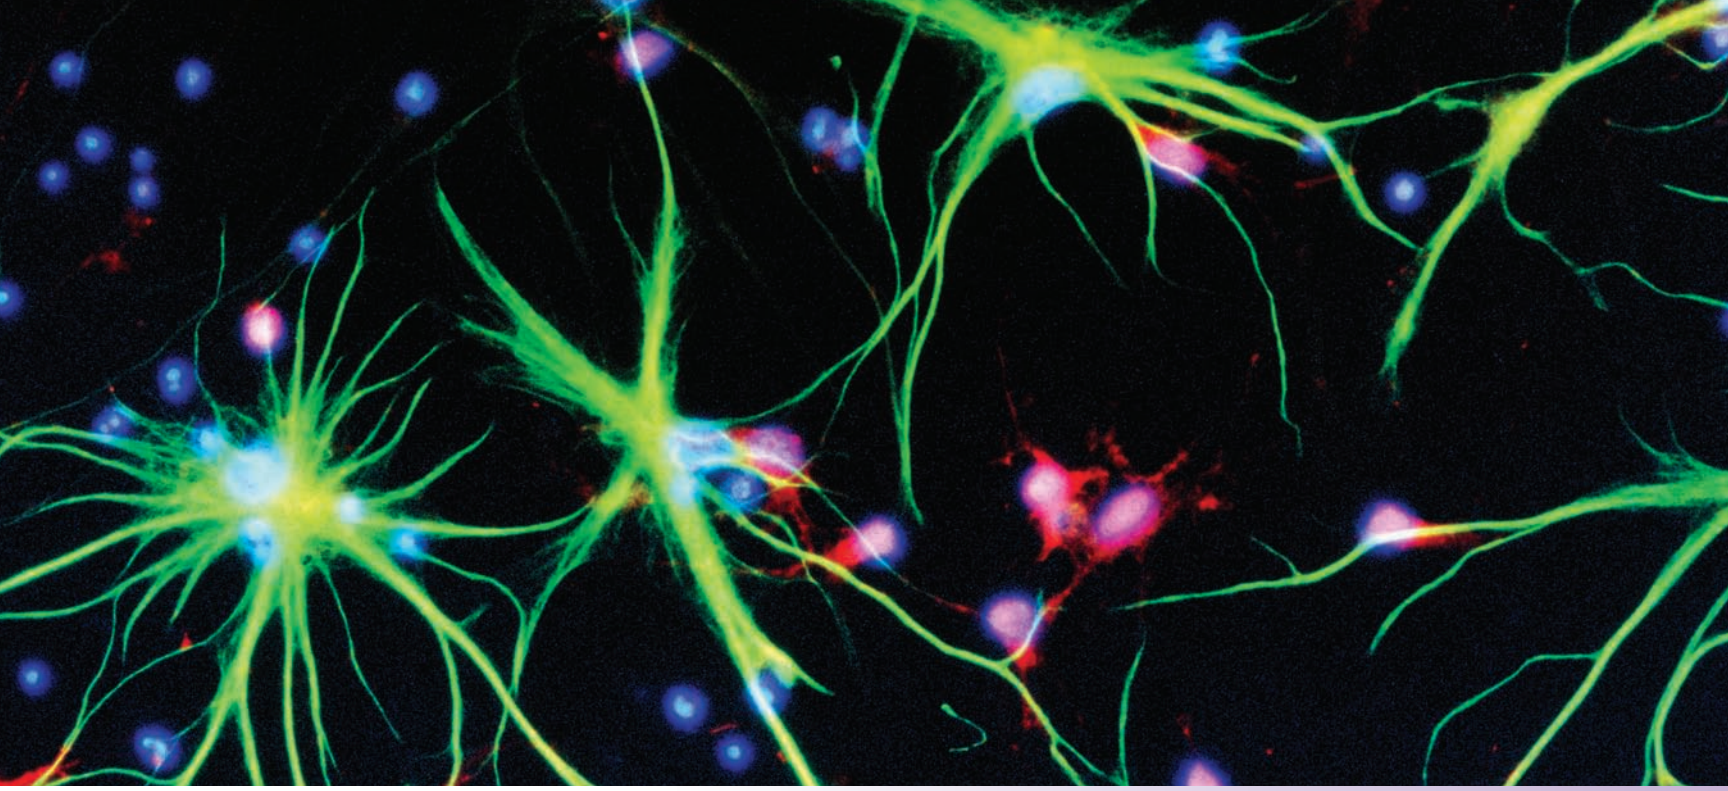
Test Your Understanding

Know and Comprehend

1. An endoskeleton (a) is typically composed of dead tissue (b) is characterized by fluid in a closed compartment (c) is found mainly in echinoderms and vertebrates (d) is typical of echinoderms and arthropods (e) requires the animal to molt
2. Which of the following is part of the vertebrate appendicular skeleton? (a) skull (b) vertebral column (c) pelvic girdle (d) rib cage (e) sternum
3. An energy storage compound that can be stockpiled in muscle cells for short-term use is (a) myoglobin (b) ADP (c) troponin (d) myosin (e) creatine phosphate
4. Calcium ions are released from the sarcoplasmic reticulum. What happens next? (a) acetylcholine is released (b) active sites on the actin filaments are exposed (c) filaments move past one another, and the muscle fiber shortens (d) myosin is activated (e) P_i is released, and the cross bridge flexes
5. Myosin binds to actin, forming a cross bridge. What happens next? (a) acetylcholine is released (b) calcium ions stimulate exposure of active sites (c) myosin filaments move past one another, and the muscle fiber shortens (d) myosin is activated (e) P_i is released, and the cross bridge flexes
6. When skeletal muscle is stimulated by a series of closely timed separate stimuli, (a) white fibers respond (b) a simple twitch occurs (c) the muscle responds with a smooth, sustained contraction called tetanus (d) red fibers respond (e) summation is inhibited

Apply and Analyze

7. Insect flight muscles have a very high metabolic rate. In what way is this characteristic adaptive?
8. **VISUALIZE** Label the diagram.



Evaluate and Synthesize

9. **INTERPRET DATA** Examine Figure 40-13. Based on the summation of two stimuli shown in that graph, draw a curve showing summation when the muscle fiber is stimulated three times.
10. Skeletal muscles are able to shift functions, sometimes acting as an agonist and other times acting as an antagonist. How is this ability to shift functions advantageous?
11. **CONNECT** What is the functional relationship between skeletal and muscle tissues? How can muscle damage affect skeletal tissue?
12. **EVOLUTION LINK** Very different skeletal systems have evolved in arthropods and vertebrates. What are some benefits and some disadvantages of each type of skeleton? In what way is the insect skeleton an adaptation to the insect lifestyle?
13. **EVOLUTION LINK** What does human muscle contraction have in common with cellular movement in single-cell organisms?
14. **SCIENCE, TECHNOLOGY, AND SOCIETY** Explore the relationships between society's need for joint replacements and the interconnections of science and technology with this need.

41 Neural Signaling

KEY CONCEPTS

41.1 Neural signaling involves reception, transmission, integration, and action by effectors.

41.2 Neurons are specialized to receive stimuli and transmit signals; glial cells support, protect, and nourish neurons, and they can modify neural signals.

41.3 The resting potential of a neuron is maintained by ion channels and ion pumps. Depolarization of the neuron plasma membrane to threshold level generates action potentials, the electrical signals transmitted by axons.

41.4 Most neurons signal other cells by releasing neurotransmitters at chemical synapses.

41.5 During integration, incoming neural signals are summed; temporal and spatial summation can bring a neuron to threshold level.

41.6 Neurons are organized in specific pathways called neural circuits, which, in turn, are organized to form neural networks.

PHOTO: Some specialized cells in the central nervous system. This immunofluorescent light micrograph of mammalian spinal cord tissue shows astrocytes (*green*) and neurons (the smaller cells stained *pink*). Astrocytes are glial cells, regulatory cells thought to be important in learning and memory. The smaller *blue* dots are the nuclei of other types of glial cells. Nancy Kedersha/UCLA/Getty Images

An animal's ability to survive and to maintain homeostasis depends largely on how effectively it detects and responds to *stimuli*, the changes that take place in its environment. Most animals have a *nervous system* that takes in information, transmits it to the spinal cord and brain where it is integrated, and then responds. The nervous system is composed mainly of two specialized types of cells: *neurons* and *glial cells* (see photograph). Just how animals respond to stimuli depends on how their neurons are organized and connected to one another. A single neuron in the vertebrate brain may be functionally connected to thousands of other neurons.

The nervous system is the principal regulatory system in animals. Regulation requires communication, and the nervous system transmits information to and from all parts of the body. Neurobiology is one of the most exciting areas of biological research. Active areas of research include *neurotransmitters*, the chemical messengers used by neurons to signal other neurons, and the *receptors* that bind with the neurotransmitters.

Neurogenesis, the production of new neurons, has been a very interesting focus of research. One of the most time-honored views about the nervous system was that the brain of mammals could not generate new neurons after birth. Nobel laureate Santiago Ramon y Cajal promoted this concept at the beginning of the 20th century, and the idea that we are born with all the brain cells we will ever have was widely held for almost a century. Another enduring idea was that glial cells, the most common cells in the brain, simply provide support services for neurons. As we discuss in this chapter, researchers have demonstrated that both of these hypotheses are false.

In this chapter we focus on how information is communicated by neurons and glial cells. In Chapter 42 we discuss nervous systems, and in Chapter 43 we explore sensory reception.

41.1 Neural Signaling: An Overview

LEARNING OBJECTIVE

1 Describe the processes involved in neural signaling: reception, transmission, integration, and action by effectors that brings about the actual response.

Thousands of stimuli constantly bombard an animal. Survival depends on identifying and evaluating these stimuli, and then responding effectively. Information about each stimulus must be transmitted *to* the nervous system, and then information *from* the nervous system must be transmitted to muscles and glands. Animals respond to changes in temperature, sound, light, odors, and movement that may indicate the presence of a predator or of prey. Internal signals, such as hunger, pain, fluctuations in blood pressure, or changes in blood glucose concentration, also demand responses. In most animals responses to stimuli depend on **neural signaling**, the transmission of information by **neurons**, conducting cells of the nervous system. Neural signaling typically involves four processes: reception, transmission, integration, and the action by effectors (muscles or glands) that brings about the actual response.

Reception, the process of detecting a stimulus, is the job of neurons and of specialized *sensory receptors* such as those in the skin, eyes, and ears (FIG. 41-1). **Neural transmission** is the process of sending messages along a neuron, from one neuron to another, or from a neuron to a muscle or gland. In vertebrates a neural message is transmitted from a receptor to the **central nervous system (CNS)**, which consists of the brain and spinal cord. Neurons that transmit information to the CNS are called **afferent neurons** (meaning "to carry toward"); they are also called **sensory neurons**.

Afferent neurons generally transmit information to **interneurons**, also known as association neurons, in the CNS. Most neurons, perhaps 99% of them, are interneurons. Their function is to *integrate* input and output. **Integration** involves sorting and interpreting incoming sensory information and determining the appropriate response.

Efferent neurons (meaning "to carry away") transmit neural messages from the CNS to **effectors** (muscles and glands). Efferent neurons that signal skeletal muscle are called **motor neurons**. The *action by effectors* brings about the actual **response** to the stimulus. Sensory receptors and afferent and efferent neurons are part of the **peripheral nervous system (PNS)**. In summary, information flows through the nervous system in the following sequence:

reception by sensory receptor → transmission by afferent neuron → integration by interneurons in CNS → transmission by efferent neuron → action by effectors → actual response

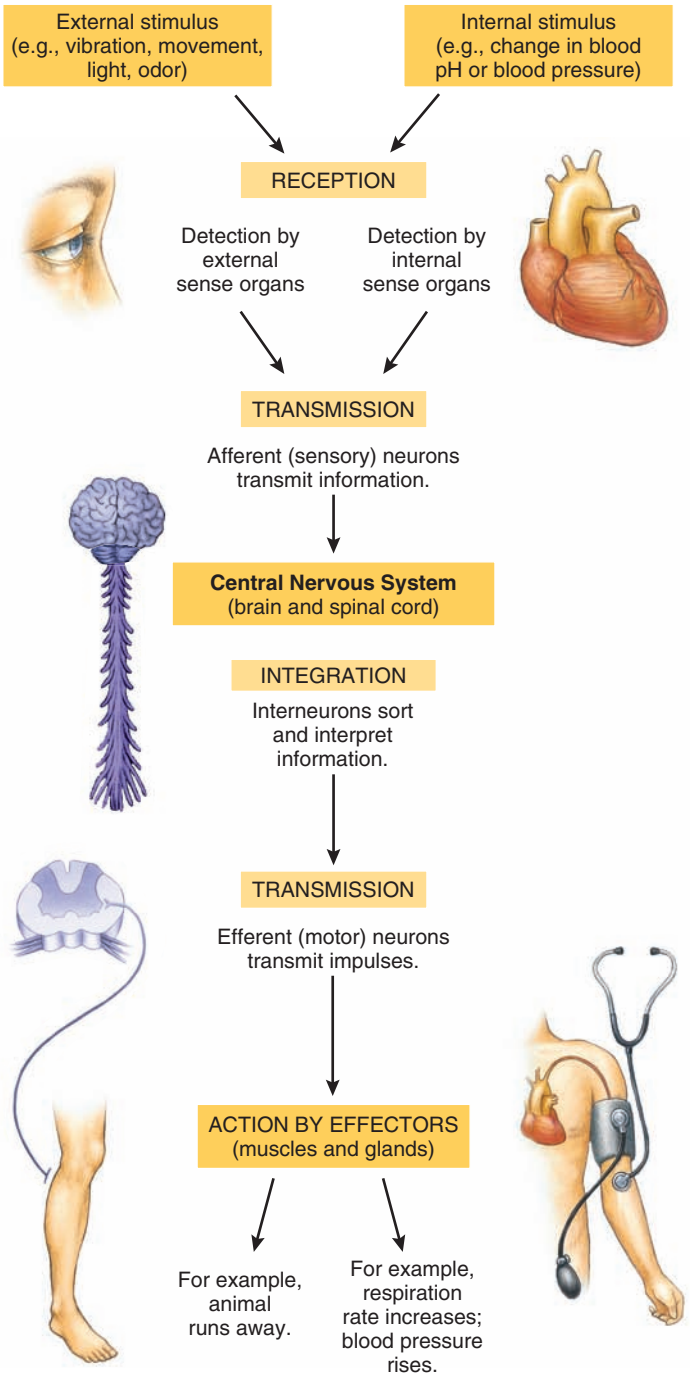

Figure 41-1 Response to a stimulus

Whether a stimulus originates in the outside world or inside the body, information must be received, transmitted to the central nervous system, integrated, and then transmitted to effectors (muscles and glands) that carry out some action, the actual response.

CHECKPOINT 41.1

- **CONNECT** Imagine that you are swimming and suddenly spot a shark fin moving in your direction. What sequence of processes must take place within your nervous system before you can make your escape?
- What happens after neural signals are integrated in the CNS?

41.2 Neurons and Glial Cells

LEARNING OBJECTIVES

2 Draw and label a typical neuron and give the function of each of its parts.

3 Identify the main types of glial cells and describe the functions of each.

Neurons and glial cells are unique to the nervous system. Neurons are specialized to receive and send information. Glial cells support and protect neurons and carry out many regulatory functions.

Neurons receive stimuli and transmit neural signals

The neuron is highly specialized to receive and transmit information. Neurons produce and transmit electrical signals called *nerve impulses*, or *action potentials*. The neuron is distinguished from other cells by its long *processes* (cytoplasmic extensions). Examine the structure of a common type of neuron, the multipolar neuron shown in FIGURE 41-2.

The largest portion of the neuron, the **cell body**, contains the bulk of the cytoplasm, the nucleus, and most of the other organelles. Typically, two types of processes project from the cell body of a multipolar neuron. Numerous *dendrites* extend from one end, and a long, single *axon* projects from the opposite end. **Dendrites** are typically short, highly branched processes specialized to receive stimuli and send signals to the cell body. The cell body integrates incoming signals.

Although microscopic in diameter, an **axon** may be 1 m (more than 1 yd) or more in length and may divide, forming branches called *axon collaterals*. The axon conducts nerve impulses away from the cell body to another neuron or to a muscle or gland. At its end the axon divides, forming many *terminal branches* that end in *synaptic terminals*, also called *axon terminals*. The synaptic terminals release **neurotransmitters**, chemicals that transmit signals from one neuron to another or from a neuron to an effector. The junction between a synaptic terminal and another neuron (or effector) is called a **synapse**. Typically, a small space exists between these two neurons. Neurons communicate with one another at synapses.

In vertebrates the axons of many neurons outside the CNS are surrounded by a series of **Schwann cells**. The plasma membranes of these glial cells contain *myelin*, a white, fatty material. Schwann cells wrap their plasma membranes around the axon, forming an insulating covering called the **myelin sheath**. Gaps in the myelin sheath, called **nodes of Ranvier**, occur between successive Schwann cells. At these points the axon is not insulated with myelin. Axons more than 2 μm in diameter have myelin sheaths and are described as *myelinated*. Those of smaller diameter are generally *unmyelinated*. (The discussion in this chapter refers to both types of neurons unless otherwise stated.)

Certain regions of the CNS produce new neurons

At the beginning of this chapter, we described Cajal's idea that **neurogenesis**, the production of new neurons, does not occur in the CNS after birth. Cajal's idea was widely accepted for many years. However, in science prevailing hypotheses are continuously challenged by new findings. Researchers investigating seemingly unrelated problems made observations that shed new light on the neurogenesis issue.

Since the 1970s Fernando Nottebohm at Rockefeller University has studied birdsong, including its neural basis. Nottebohm found that birds produce new neurons daily in the brain center that regulates their songs. His work was at first dismissed as a phenomenon peculiar to birds and not relevant to mammals.

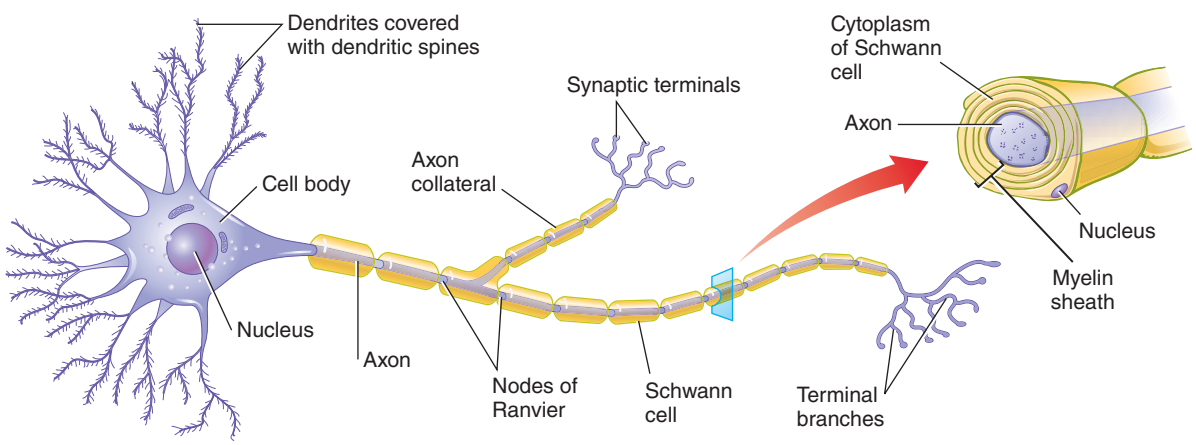

Figure 41-2 Structure of a multipolar neuron

The cell body contains most of the organelles. Many dendrites and a single axon extend from the cell body. Schwann cells form a myelin sheath around the axon by wrapping their own plasma membranes around the neuron in jelly-roll fashion.

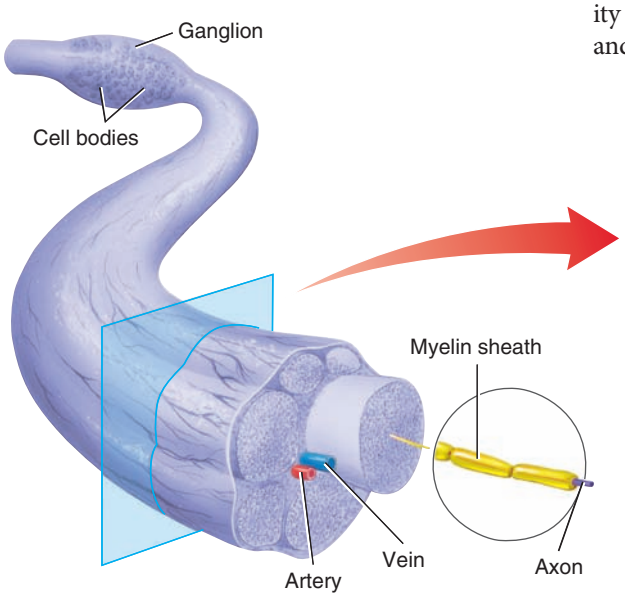
However, other investigators, notably psychologist Elizabeth Gould at Princeton University, have provided additional data that together have falsified Cajal's hypothesis. Gould demonstrated neuron proliferation in primates. She and her research team also discovered that stress damages the brain and inhibits mitosis in neurons. They stressed newborn rats by separating them from their mothers for up to 3 hours a day. The stressed rats did not learn how to cope with stress, and as adults they had fewer new neurons in certain areas of their brains than control rats. Neurobiologists now agree that neurogenesis does occur regularly in the adult mammalian brain, at least in certain areas of the hippocampus and in the lining of the lateral ventricles. The paradigm shift away from Cajal's long accepted hypothesis demonstrates the power and importance of the process of science.

Axons aggregate to form nerves and tracts

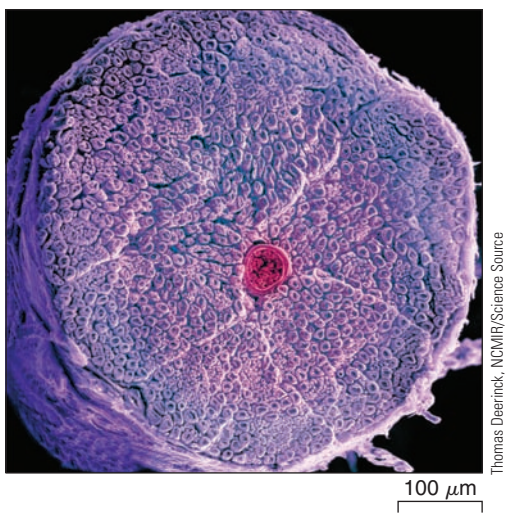
A **nerve** consists of hundreds or even thousands of axons wrapped together in connective tissue (FIG. 41-3). We can compare a nerve to a telephone cable. The individual axons correspond to the wires that run through the cable, and the sheaths and connective tissue coverings correspond to the insulation. Within the CNS, bundles of axons are called **tracts** or *pathways* rather than nerves.

Outside the CNS, a mass of neuron cell bodies is called a **ganglion** (plural, *ganglia*). Inside the CNS, a collection of cell bodies is called a **nucleus**, rather than a ganglion.

Glial cells play critical roles in neural function



Glial cells collectively make up the *neuroglia* (literally, "nerve glue"). Glial cells were once thought to be passive cells that simply support and protect the neurons. Armed with more sophisticated technology, neurobiologists are discovering that glial cells communicate and carry out major regulatory functions.



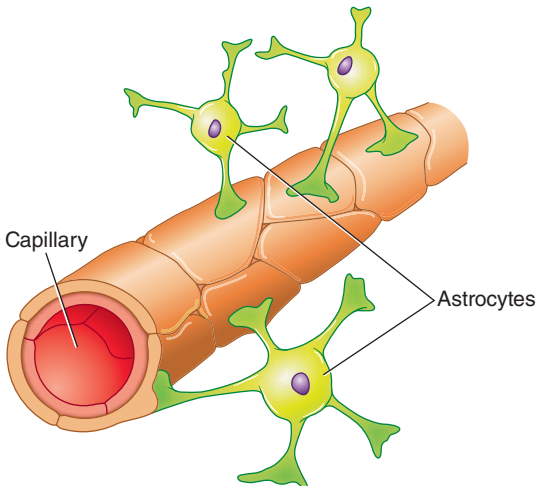
More than 75% of the cells in the human CNS are glial cells. They account for only about 50% of the brain volume because they do not branch as extensively as neurons. Four types of glial cells are found in the vertebrate CNS: astrocytes, oligodendrocytes, ependymal cells, and microglia (TABLE 41-1).

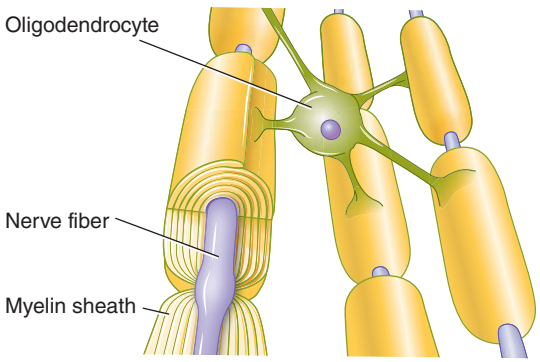
Astrocytes, the most numerous glial cells, are star-shaped. These cells provide both physical support and nutrients for neurons. They help regulate the composition of the extracellular fluid in the CNS by removing excess potassium ions. This action helps maintain normal neuron excitability.

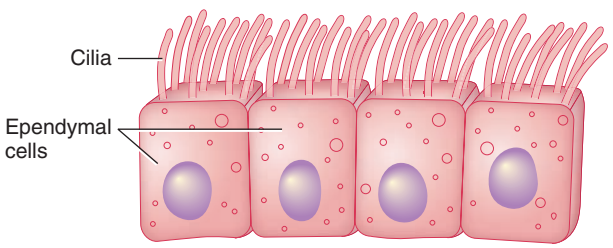
Some astrocytes position the ends of their long processes on blood vessels in the brain. In response, endothelial cells lining the blood vessels form *tight junctions* (see Fig. 5-23a) that prevent many potentially harmful substances in the blood from entering the brain tissue. This protective wall is the *blood–brain barrier*. Astrocytes also help regulate self-cleaning mechanisms in the brain that involve flushing out wastes with cerebrospinal fluid.

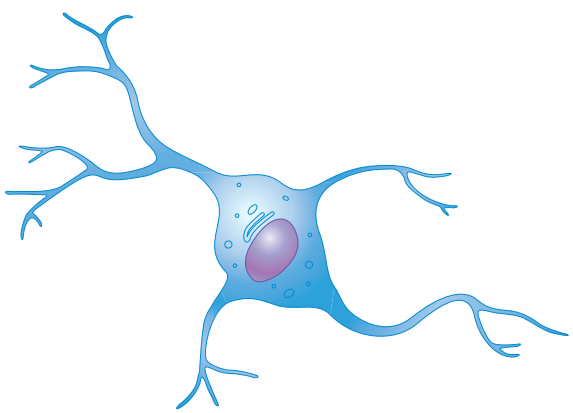
Neurobiologists have shown that astrocytes are functionally connected throughout the brain. These interesting glial cells participate in information signaling by coordinating activity among neurons. They communicate through *gap junctions* and with signaling molecules. Although astrocytes can generate

(a) A nerve consists of bundles of axons held together by connective tissue. The cell bodies belonging to the axons of a nerve are grouped in a ganglion.









(b) SEM (false colored) of a cross section through a spinal nerve. The tissue was freeze-fractured to show the bundle of myelinated axons (*purple*) that make up the nerve. The blood vessel (*red*) in the center of the nerve contains red blood cells. A covering of connective tissue (epineurium) surrounds the nerve.

only weak electrical signals, they communicate with one another and with neurons by means of chemical signals. Astrocytes appear to respond to neurotransmitters released by neurons. They also help regulate the reuptake of excess neurotransmitters from synapses. Astrocytes induce synapse formation and can strengthen activity of synapses in the brain. Their actions appear to be important in learning and memory.

Astrocytes play a role in development by guiding neurons to appropriate locations in the body. Certain astrocytes function as stem cells in the brain and spinal cord. These cells can give rise to new neurons, additional astrocytes, and certain other glial cells. Taken out of their normal environment in the adult mouse brain, astrocytes can give rise to cells of all germ layers (the embryonic tissue layers: ectoderm, mesoderm, and endoderm). Human astrocytes may someday be used to produce specific types of cells needed for treating various medical conditions.

Oligodendrocytes are glial cells that envelop neurons in the CNS, forming insulating myelin sheaths around them. Because myelin is an excellent electrical insulator, its presence speeds transmission of neural impulses. In the neurological disease **multiple sclerosis**, patches of myelin deteriorate at irregular intervals along axons in the CNS and are replaced by scar tissue. This damage interferes with conduction of neural impulses, and the victim suffers loss of coordination, tremor, and partial or complete paralysis of parts of the body. Multiple sclerosis affects more than 2 million people worldwide.

Do not confuse oligodendrocytes with Schwann cells. Although sometimes considered glial cells, Schwann cells are located outside the CNS. (Recall that Schwann cells form myelin sheaths around axons of many neurons that are part of the PNS.)

Ependymal cells are ciliated glial cells that line the internal cavities of the CNS. Ependymal cells help produce and circulate the *cerebrospinal fluid* that bathes the brain and spinal cord of vertebrates (discussed in Chapter 42). There is some evidence that ependymal cells function as neural stem cells, and that they have the potential to give rise to new neurons, as well as to glial cells.

Microglia are actually specialized macrophages (phagocytic cells that ingest and digest cell debris and bacteria). Microglia respond to signals from neurons and are important in mediating responses to injury or disease. These cells are found near blood vessels. When the brain is injured or infected, microglia multiply and move to the affected area. There they remove bacteria and cell debris by phagocytosis. In addition, they release signaling molecules (also produced by macrophages and certain other cells in the immune system) that mediate inflammation. Microglia appear to help regulate the number of neurons in the developing brain by destroying neurons that are not needed.

CHECKPOINT 41.2

- **VISUALIZE** Sketch a multipolar neuron and label the cell body, dendrites, axon, and synaptic terminals. Give the function of each structure.
- How is a neuron different from a nerve?
- What are the functions of astrocytes? of microglia?

41.3 Transmitting Information along the Neuron

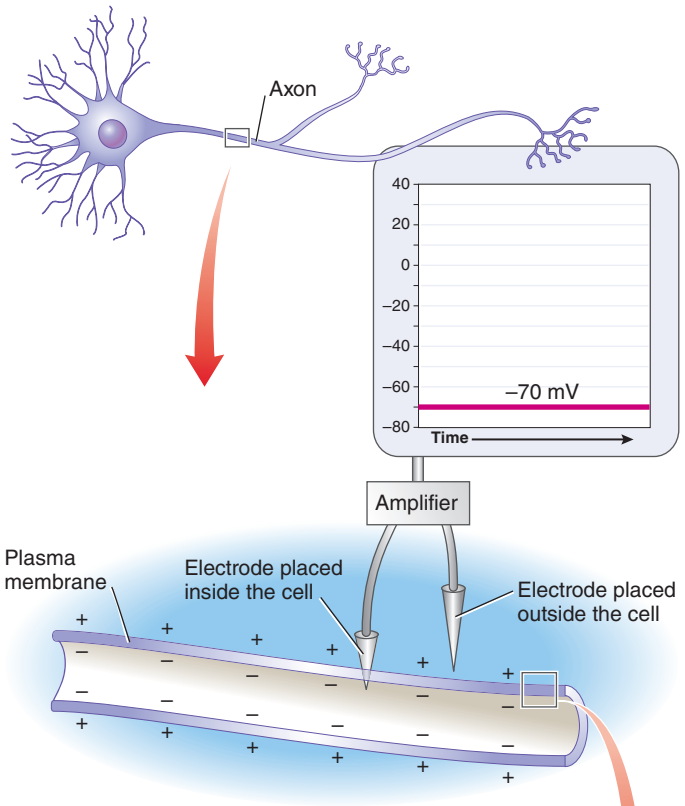
LEARNING OBJECTIVES

4 Explain how the neuron develops and maintains a resting potential.
5 Compare a graded potential with an action potential, describing the production and transmission of each.
6 Contrast continuous conduction with saltatory conduction.

Most animal cells have a difference in electric charge across the plasma membrane: the electric charge inside the cell is more negative than the electric charge of the extracellular fluid. The plasma membrane is said to be electrically *polarized*, meaning that one side, or pole, has a different charge than the other side. When electric charges are separated in this way, a potential energy difference exists across the membrane.

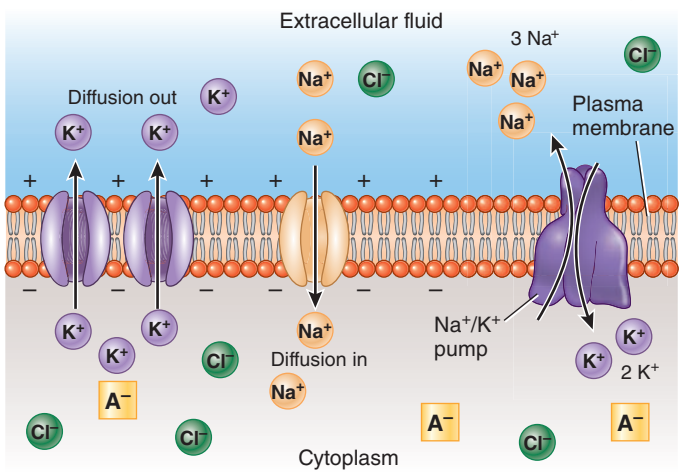
The difference in electric charge across the plasma membrane gives rise to an *electrical gradient*. Voltage is the force that causes charged particles to flow between two points. The voltage measured across the plasma membrane is a form of potential energy called the **membrane potential**. If the charges are permitted to come together, they have the ability to do work. Thus, the cell can be thought of as a biological battery. In excitable cells, such as neurons and muscle cells, the membrane potential can change rapidly. Such changes can transmit signals to other cells.

Ion channels and pumps maintain the resting potential of the neuron



The membrane potential in a resting (not excited) neuron or muscle cell is its **resting potential**. The resting potential is generally expressed in units called *millivolts* (mV). (A millivolt equals one thousandth of a volt.) Like other cells that can produce electrical signals, the neuron has a resting potential of about 70 mV. By convention, this value is expressed as −70 mV because the cytosol close to the plasma membrane is negatively charged relative to the extracellular fluid (FIG. 41-4a).

Biologists can measure the potential across the membrane by placing one electrode inside the cell and a second electrode outside the cell and connecting them through a very sensitive voltmeter or oscilloscope. If you place both electrodes on the outside surface of the neuron, no potential difference between them is registered. (All points on the same side of the membrane have the same charge.) However, once one of the electrodes penetrates the cell, the voltage changes from zero to approximately −70 mV.



Two main factors determine the magnitude of the membrane potential: (1) differences in the concentrations between specific ions inside the cell and those in the extracellular fluid and (2) selective permeability of the plasma membrane to these ions. The distribution of ions inside neurons and in the extracellular fluid surrounding them is like that of most other cells in the body. The potassium ion (K^+) concentration is about 10 times greater inside the cell than outside the cell. In contrast, the sodium ion (Na^+) concentration is about 10 times greater

(a) Measuring the resting potential of a neuron. The axon is negatively charged compared with the surrounding extracellular fluid. The difference in electric charge across the plasma membrane is measured by placing an electrode just inside the neuron and a second electrode in the extracellular fluid just outside the plasma membrane.

(b) Permeability of the neuron membrane. The membrane is less permeable to Na^+ than to K^+. Passive ion channels allow K^+ to diffuse out along their concentration gradient. Potassium ions are mainly responsible for the voltage across the membrane. Sodium–potassium pumps in the plasma membrane actively pump Na^+ out of the cell and pump K^+ in. The plasma membrane is permeable to negatively charged Cl^-, and they contribute slightly to the negative charge. Large anions (A^-) such as proteins also contribute to the negative charge.

Figure 41-4 Resting potential

outside than inside. This asymmetric distribution of ions across the plasma membrane at rest is brought about by the action of selective ion channels and ion pumps. In vertebrate neurons (and skeletal muscle fibers), the resting membrane potential depends mainly on the diffusion of ions down their *concentration gradients* (see discussion of diffusion in Chapter 5).

Ions cross the plasma membrane by diffusion through ion channels

Recall that net movement of ions occurs from an area of higher concentration of that type of ion to one of lower concentration. Membrane proteins form ion channels that typically allow only specific types of ions to pass. Neurons have three types of ion channels: *passive ion channels, voltage-activated channels,* and *chemically activated ion channels*. **Passive ion channels** permit the passage of specific ions such as Na^+, K^+, Cl^-, and Ca^{2+} (FIG. 41-4b). Unlike voltage-activated and chemically activated ion channels, passive ion channels are not controlled by gates.

Potassium channels are the most common type of passive ion channel in the plasma membrane, and cells are more permeable to potassium than to other ions. In fact, in the resting neuron, the plasma membrane is up to 100 times more permeable to K^+ than to Na^+. When pumped out of the neuron, Na^+ cannot easily pass back into the cell. However, K^+ pumped into the neuron easily diffuses out.

Potassium ions leak out through passive ion channels following their concentration gradient. As K^+ diffuse out of the neuron, they increase the positive charge in the extracellular fluid relative to the charge inside the cell. The resulting change in the electrical gradient across the membrane influences the flow of ions. This electrical gradient forces some of the positively charged potassium ions back into the cell.

The membrane potential at which the flow of K^+ inward (due to the electrical gradient) equals the flow of K^+ outward (because of the concentration gradient) is the **equilibrium potential** for K^+. The equilibrium potential for any particular ion is a steady state in which opposing chemical and electrical flows are equal and there is no net movement of the ion. The equilibrium potential for K^+ in the typical neuron is -90 mV. The equilibrium potential for Na^+ is $+60$ mV; it differs from the equilibrium potential of K^+ because of the difference in concentration of Na^+ across the membrane (concentration is high outside and low inside the cell). Because the membrane is much more permeable to K^+ than to Na^+, the resting potential of the neuron is closer to the potassium equilibrium potential than to the sodium equilibrium potential. (Remember that the resting potential of the neuron is about -70 mV.)

The resting potential is primarily established by the net flow of K^+ into the neuron. However, the net flow of Na^+ outward contributes to the resting potential. Because the plasma membrane is permeable to negatively charged chloride ions, Cl^- also contribute slightly. These ions accumulate in the cytosol close to the plasma membrane. Negative charges on large molecules such as proteins add to the negative charge in the cytosol. These large anions cannot cross the plasma membrane.

Ion pumping maintains the gradients that determine the resting potential

The neuron plasma membrane has very efficient **sodium–potassium pumps** that actively transport Na^+ out of the cell and K^+ into the cell (see Fig. 41-4b; also see Fig. 5-16). These pumps require ATP to pump Na^+ and K^+ against their concentration and electrical gradients. For every three Na^+ pumped out of the cell, two K^+ are pumped in. Thus, more positive ions are pumped out than in. The sodium–potassium pumps maintain a higher concentration of K^+ inside the cell than outside and a higher concentration of Na^+ outside than inside.

In summary, the development of the resting potential depends mainly on the diffusion of K^+ out of the cell. However, once the neuron reaches a steady state, net Na^+ diffusion into the cell is greater than net K^+ diffusion out of the cell. This situation is offset by the sodium–potassium pumps that pump three Na^+ out of the cell for every two K^+ pumped in.

Graded local signals vary in magnitude

Neurons are excitable cells. They respond to stimuli and can convert stimuli into nerve impulses. An electrical, chemical, or mechanical stimulus may alter the resting potential by increasing the membrane's permeability to sodium ions.

When a stimulus causes the membrane potential to become less negative (closer to zero) than the resting potential, that region of the membrane is **depolarized**. Because depolarization brings a neuron closer to transmitting a neural impulse, it is described as *excitatory*. In contrast, when the membrane potential becomes more negative than the resting potential, the membrane is **hyperpolarized**. Hyperpolarization is *inhibitory*; it decreases the neuron's ability to generate a neural impulse.

A stimulus may change the potential in a relatively small region of the plasma membrane. Such a **graded potential** is a local response. It functions as a signal only over a very short distance because it fades out within a few millimeters of its point of origin. A graded potential varies in magnitude; that is, the potential charge varies depending on the strength of the stimulus applied. A larger stimulus causes a larger change in permeability and a greater change in membrane potential.

Axons transmit signals called action potentials

When a stimulus is strong enough, a rapid, large change in membrane potential occurs, depolarizing the membrane to a critical point known as the **threshold level**. At that point, the neuron fires a *nerve impulse*, or **action potential**, an electrical signal that travels rapidly down the axon into the synaptic terminals. All cells can generate graded potentials, but only neurons, muscle cells, and a few cells of the endocrine and immune systems can generate action potentials.

In a series of experiments in the 1940s, pioneering English researchers Alan Hodgkin and Andrew Huxley inserted electrodes into large axons found in squids. By measuring voltage changes as they varied ion concentrations, these investigators showed that passage of Na^+ ions *into* the neuron and K^+ ions *out* of the neuron resulted in an action potential. The process of Na^+ rushing into the cell may be thought of as fueling the action, whereas the process of K^+ leaving the cell brakes the action potential. In 1963, Hodgkin and Huxley received the Nobel Prize in Physiology or Medicine for this research.

We now know that changes in voltage regulate specific **voltage-activated ion channels** (also called *voltage-gated ion channels*) in the plasma membrane of the axon and cell body. Biologists can study these channels by using the **patch clamp technique** to measure currents across a very small segment of the plasma membrane rather than across the entire membrane (FIG. 41-5). The patch of membrane measured is so small that it may contain a single channel.

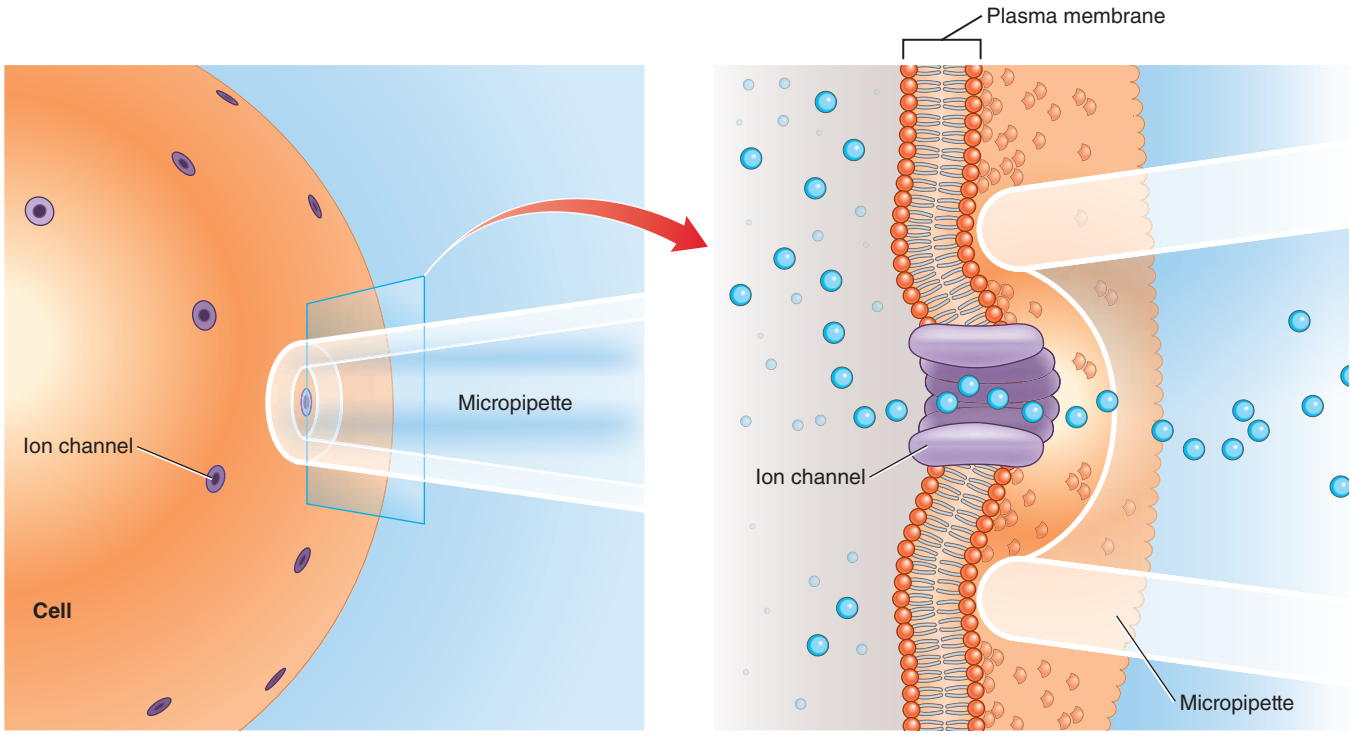
Biologists have used certain toxins that affect the nervous system to investigate how membrane channels function. For example, the poison tetrodotoxin (TTX) binds to voltage-activated Na^+ channels, blocking the passage of Na^+. Using TTX and other toxins, researchers were able to identify the channel protein. TTX was first isolated from the Japanese puffer fish, which is eaten as a delicacy (FIG. 41-6). In tiny amounts TTX tingles the taste buds, but a slightly larger amount can prevent breathing. (The Japanese government operates a certification program that teaches puffer fish chefs to carefully remove the organs containing the toxin.)

Investigators have established that voltage-activated ion channels have charged regions that act as gates. Voltage-activated Na^+ channels have two gates: an *activation gate* and an *inactivation gate* (FIG. 41-7a). Voltage-activated K^+ channels have a single gate (FIG. 41-7b).

Local anesthetics, such as procaine (novocaine) and lidocaine (Xylocaine) as well as cocaine, bind to voltage-activated Na^+ channels and block them. These blocked channels cannot open in response to depolarization, and the neuron cannot transmit an impulse through the anesthetized region. Signals do not reach the brain, so pain is not experienced.

An action potential is generated when the voltage reaches threshold level

The membrane of most neurons can depolarize by about 15 mV—that is, to a potential of about −55 mV—without initiating an action potential. However, when depolarization is greater than −55 mV, the threshold level is reached, and an action potential is generated. The neuron membrane quickly reaches zero potential and even *overshoots* to +35 mV or more as a momentary reversal in polarity takes place. The sharp rise and fall of the action potential is called a *spike*. FIGURE 41-8a on page 870 illustrates an action potential recorded by placing one electrode inside an axon and one just outside.



At resting potentials, activation gates of the voltage-activated Na^+ channels are closed, and Na^+ cannot pass into the neuron (FIG. 41-8b on page 870). Follow the steps illustrated in Figure 41-8b as you read about transmission of action potentials, repolarization, and return to the resting state. When the voltage reaches threshold level, the channel proteins change shape, opening the activation gates. Sodium ions can then flow through the voltage-activated Na^+ channels. As a

Research Method

WHY IS IT USED? The patch clamp technique allows researchers to study the action of a single ion channel over time, even in very small cells. This research method was developed in the mid-1970s by Erwin Neher and Bert Sakmann, both of the Max Planck Institute in Germany. They were awarded a Nobel Prize in Physiology or Medicine in 1991 for this work.

HOW IS IT DONE? The tip of a micropipette is tightly sealed to a patch of membrane so small that it generally contains only a single ion channel. The flow of ions through the channel can be measured using an extremely sensitive recording device. Cell biologists have found that the current flow is intermittent and corresponds to the opening and closing of the ion channel. The permeability of the channel affects the magnitude of the current.

Figure 41-5 The patch clamp technique

The patch clamp technique has been modified in many ways and has been applied to studies in both plants and animals of the roles of ion channels in a wide range of cellular processes. For example, neuroscientists once thought that transmitting action potentials was a very inefficient process. They thought that there was a high degree of overlap between the time that Na^+ rush into the cell and K^+ move out of the cell. This process would be a waste of energy because it would be like stepping on the gas and brake pedals at the same time. Henrik Alle, a neuroscientist at the Max Planck Institute for Brain Research in Frankfurt, Germany, and his colleagues used the patch clamp technique to record currents in neurons of the learning and memory areas of rat brains. They found that the flows of Na^+ and K^+ were almost completely separated in time. Na^+ have almost finished entering the neuron before K^+ ions begin to exit. In contrast to earlier estimates of 30% efficiency for transmission of signals, neurons may transmit action potentials with more than 70% efficiency.

result, the inside of the neuron becomes positively charged relative to the fluid outside the plasma membrane, generating an action potential. Inactivation gates that are open in the resting neuron close slowly in response to depolarization. Sodium ions can pass through the channel only during the brief period when both activation and inactivation gates are open.

The generation of an action potential depends on a **positive feedback system**. (Recall from Chapter 39 that in a positive feedback system, a change in some condition triggers a response that *intensifies* the change.) As just discussed, when a neuron becomes depolarized, voltage-activated Na^+ channels open, increasing the membrane permeability to Na^+. Sodium ions diffuse into the cell, moving from an area of higher concentration to an area of lower concentration. As Na^+ flow into the cell, the cytosol becomes positively charged relative to the extracellular fluid. The positive charge further depolarizes the neuron so that more voltage-activated Na^+ channels open, which increases membrane permeability to Na^+.

The neuron repolarizes and returns to a resting state

After a certain period, inactivation gates close in the Na^+ channels, and the membrane again becomes impermeable to

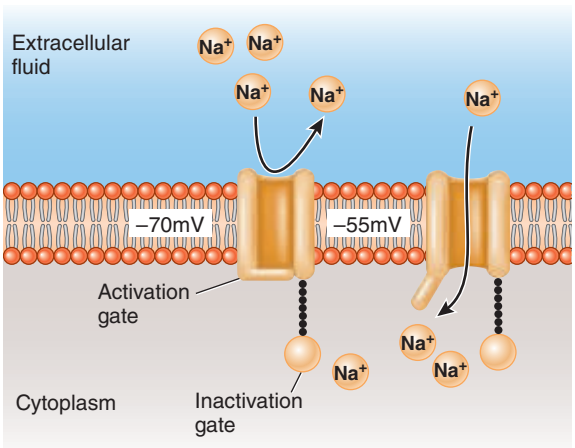
Figure 41-6 Fish with tetrodotoxin

Like the Japanese puffer fish (*Fuju rubripes*), this closely related porcupine fish has tetrodotoxin in its internal organs. This fish can inflate its body by swallowing air or water. When it is larger and rounder, it is safer from many predators.

Na^+. This inactivation begins the process of **repolarization**, during which the membrane potential returns to its resting level. Voltage-activated K^+ channels slowly open in response to depolarization. When Na^+ have almost stopped rushing into the neuron, K^+ channels open, and K^+ leak out of the neuron. This decrease in intracellular K^+ returns the interior of the membrane to its relatively negative state, repolarizing the membrane. Voltage-activated K^+ channels remain open until the resting potential has been restored.

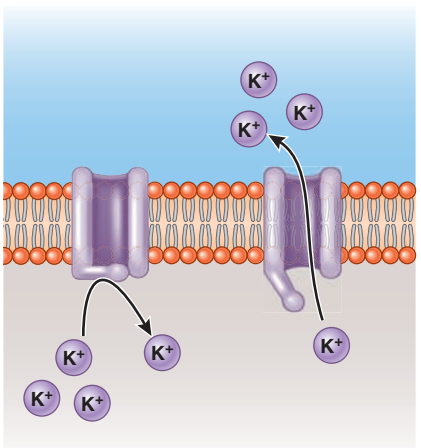
As a *wave of depolarization* moves down the membrane of the neuron, the normal polarized state is quickly re-established behind it. The entire process—depolarization and then repolarization—can take place in less than 1 millisecond.

During the millisecond or so in which it is depolarized, the axon membrane is in an *absolute* **refractory period**: it cannot transmit another action potential no matter how great a stimulus is applied because the voltage-activated Na^+ channels are inactivated. Until their gates are reset, they cannot open again. When enough Na^+ channel gates have been reset, the neuron enters a *relative* refractory period that lasts for a few more milliseconds. During this period, the axon can transmit impulses, but the threshold is higher (less negative). Even with the limits imposed by their refractory periods, most neurons can transmit several hundred impulses per second.



In summary, neural action proceeds as follows:

> neuron in resting state → stimulus causes depolarization → threshold reached → action potential transmits signal → repolarization and return to resting state



The action potential is an all-or-none response

Any stimulus too weak to depolarize the plasma membrane to threshold level cannot fire the neuron. It merely sets up a local signal that fades and dies within a few millimeters from the point of stimulus. Only a stimulus strong enough to depolarize the membrane to its critical threshold level results in transmission of an impulse along the axon. An action potential is an **all-or-none response** because either it occurs or it does not. No variation exists in the strength of a single impulse.

If the all-or-none law is valid, how can we explain differences in the levels of intensity of sensations? After all, we have no difficulty distinguishing between the pain of a severe toothache and that of a minor cut on the arm. We can explain this apparent inconsistency by understanding that the intensity of sensation depends on several factors, including the *number of neurons stimulated* and their *frequency of discharge*. For example, suppose that you burn

(a) Sodium channels. In the resting state, voltage-activated Na^+ channels are closed (*left*). When the voltage reaches threshold level, activation gates open quickly, allowing Na^+ to pass into the cell (*right*). After a certain time, inactivation gates close, blocking the channels (*not shown*). Inactivation gates are open when a neuron is in the resting state; they close slowly in response to depolarization. The ion channel is open only during the brief period when both activation and inactivation gates are open.

(b) Potassium channels. Voltage-activated K^+ channels have activation gates that open slowly in response to depolarization. The activation gates close after the resting potential has been restored. Potassium channels have no inactivation gates.

Key Point

When the neuron plasma membrane is depolarized to threshold level, voltage-activated Na^+ channels open and Na^+ rush into the neuron, causing greater depolarization; an action potential is generated.

(a) Action potential. When the axon depolarizes to about −55 mV, an action potential is generated. (The numerical values vary for different nerve cells.)

1 Resting state. Voltage-activated Na^+ and K^+ channels are closed.

2 Depolarization. At threshold, voltage-activated Na^+ channels open. Na^+ rush into the neuron, causing further depolarization. Action potential is generated.

3 Repolarization. Voltage-activated Na^+ channels become inactivated. Voltage-activated K^+ channels are open; K^+ diffuse out of cell, restoring negative charge to inside of cell.

4 Return to resting state. Voltage-activated Na^+ and K^+ channels close. Na^+/K^+ pumps (*not shown*) move Na^+ out of the cell and K^+ into the cell, restoring the original ion distribution.

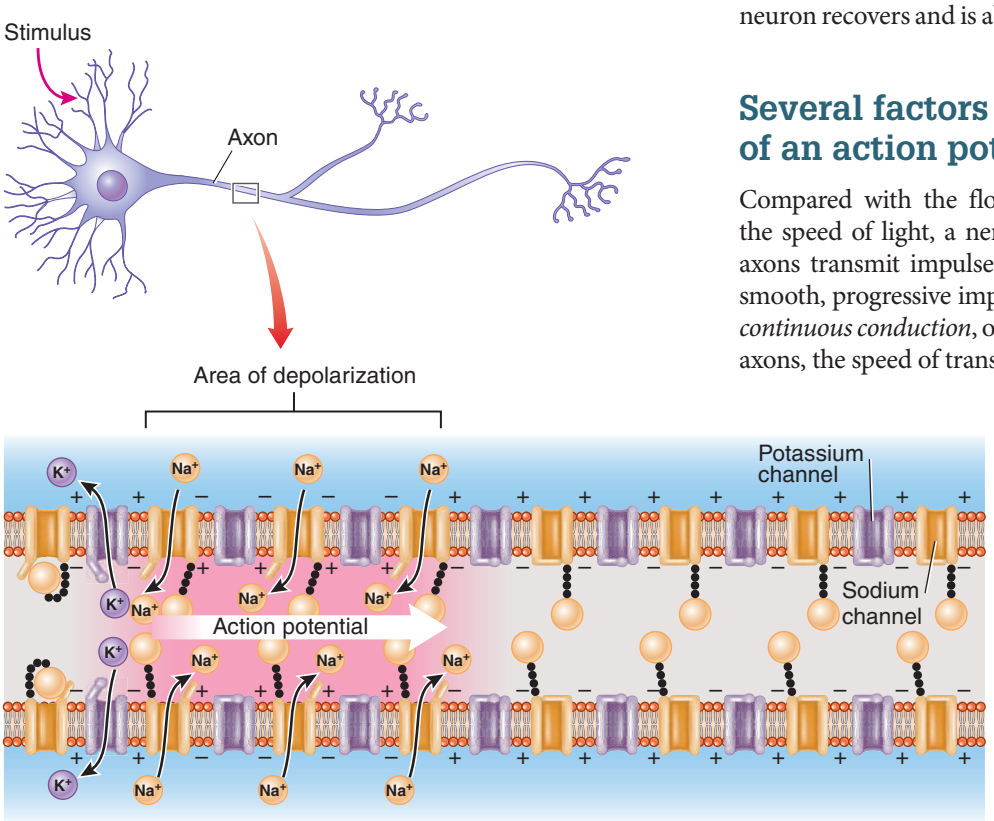
(b) The action of ion channels in the plasma membrane determines the state of the neuron.

Figure 41-8 Action potentials depend on voltage-gated ion channels
Generation of an action potential depends on the action of voltage-gated sodium and potassium ion channels in the plasma membrane.

PREDICT One of the toxins (charybdotoxin) produced by scorpions blocks K^+ channels. What effect would this toxin have on the action of a neuron?

your hand. If a large area is burned, more pain receptors are stimulated and more neurons become depolarized. Also, each neuron transmits more action potentials per unit of time.

An action potential is self-propagating



Once initiated, an action potential continues along the neuron. During depolarization, the affected area of the membrane

is more positive relative to adjacent regions where the membrane is still at resting potential. The difference in potentials between active and resting membrane regions causes ions to flow between them (an electric current). The flow of Na^+ into the adjacent region induces the opening of voltage-activated Na^+ channels in that area of the membrane (FIG. 41-9). The process is repeated like a chain reaction until the end of the axon is reached. Thus, an action potential is a **wave of depolarization** that travels down the length of the axon.

Transmission of an action potential is sometimes compared with a flame moving along a trail of gunpowder. Once the gunpowder is ignited at one end of the trail, the flame moves steadily to the other end by igniting the powder particles ahead of it. An amazing difference is that after a brief refractory period, the neuron recovers and is able to transmit another action potential.

1 An action potential is transmitted as a wave of depolarization that travels down the axon. At the region of depolarization, Na^+ diffuse into the cell.

2 As an action potential progresses along the axon, repolarization occurs quickly behind it.

Figure 41-9 Transmission of an action potential along the axon

When the dendrites (or cell body) of a neuron are stimulated sufficiently to depolarize the membrane to its threshold level, a strong pulse of voltage change travels down the axon. This pulse is the action potential.

Several factors determine the velocity of an action potential

Compared with the flow of electrons in electrical wiring or the speed of light, a nerve impulse travels rather slowly. Most axons transmit impulses at about 1 to 10 m per second. The smooth, progressive impulse transmission just described, called *continuous conduction*, occurs in unmyelinated neurons. In these axons, the speed of transmission is proportional to the diameter of the axon. Axons with larger diameters transmit faster than those with smaller diameters because an axon with a large diameter presents less internal resistance to the ions flowing along its length. Squids and certain other invertebrates have giant axons, up to 1 mm in diameter, which allow them to respond rapidly when escaping from predators.

In vertebrates, another strategy that speeds transmission has evolved—myelinated neurons. Myelin acts as an effective electrical insulator around the axon. However, the axon is not myelinated at the nodes of Ranvier. At these nodes, the plasma membrane of the axon makes direct contact with the surrounding extracellular fluid. Voltage-activated Na^+ and K^+ channels are concentrated at the nodes. In fact, in myelinated neurons, ion movement across the membrane occurs only at the nodes.

The ion activity at an active node results in diffusion of ions along the axon that depolarize the next node. The action potential appears to jump from one node of Ranvier to the next (FIG. 41-10). This type of impulse transmission is known as **saltatory conduction** (from the Latin word *saltus*, meaning "to leap").

In myelinated neurons, the distance between successive nodes of Ranvier affects speed of transmission. When nodes are farther apart, less of the axon must depolarize,

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

and the axon conducts the impulse faster. Using saltatory conduction, a myelinated axon can conduct an impulse up to 50 times faster than the fastest unmyelinated axon.

Saltatory conduction has another advantage over continuous conduction: it requires less energy. Ions move across the plasma membrane only at the nodes, so fewer Na^+ and K^+ are displaced. As a result, the sodium–potassium pumps do not expend as much ATP to re-establish resting conditions each time an impulse is conducted.

CHECKPOINT 41.3

- How do ion channels and sodium–potassium pumps contribute to the resting potential?
- Describe the sequence of events that occurs when threshold level is reached in a neuron.
- Contrast an action potential with a graded potential.
- What are the benefits of saltatory conduction compared with continuous conduction?

41.4 Transmitting Information across Synapses

LEARNING OBJECTIVES

7 Describe the actions of the neurotransmitters identified in this chapter.
8 List the sequence of events that take place in synaptic transmission and draw diagrams to support your description.
9 Compare excitatory and inhibitory signals and their effects.

A **synapse** is a junction between two neurons or between a neuron and an effector (a muscle or gland cell). A neuron that *terminates* at a specific synapse is called a **presynaptic neuron**, whereas a neuron that *begins* at that synapse is a **postsynaptic neuron**. Note that these terms are relative to a specific synapse. A neuron that is postsynaptic with respect to one synapse may be presynaptic to the next synapse in the sequence.

Signals across synapses can be electrical or chemical

Based on how presynaptic and postsynaptic neurons communicate, two types of synapses have been identified: electrical synapses and chemical synapses. In an **electrical synapse**, the presynaptic and postsynaptic neurons occur very close together (within 2 nm of one another) and form *gap junctions* (see Fig. 5-23c). The interiors of the two neurons are physically connected by a protein channel. Electrical synapses let ions pass from one cell to another, permitting an impulse to be directly and rapidly transmitted from a presynaptic to a postsynaptic neuron. The escape responses of many animals involve electrical synapses. For example, the "tail-flick" escape response of the crayfish involves giant neurons in the nerve cord that form electrical synapses with large motor neurons. The motor neurons signal muscles in the abdomen to contract. Electrical synapses are important in the mammalian nervous system as well. For example, many interneurons communicate by way of electrical synapses. They are also found in cardiac muscle and in the retina.

Key Point

In saltatory conduction, Na^+ rapidly diffuse from one node of Ranvier to the next. Action potentials appear to leap from node to node.

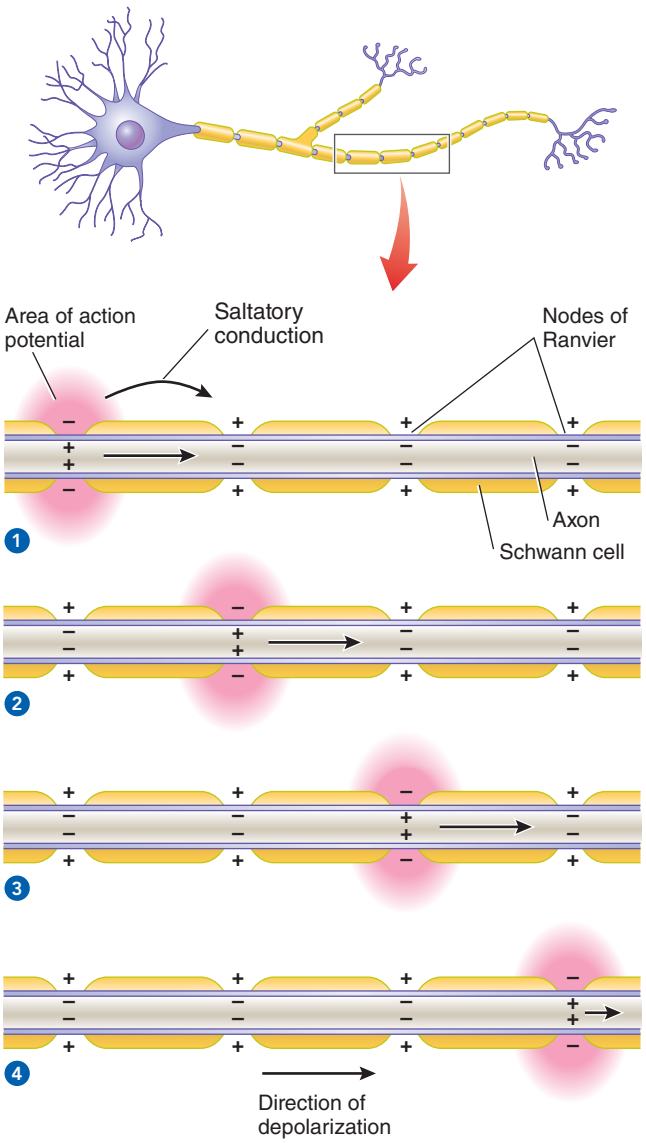

Figure 41-10 Saltatory conduction
This sequence of diagrams (steps 1 through 4) illustrates transmission of an action potential in a myelinated neuron. The *arrows* in the axons indicate diffusion of Na^+.

PREDICT How might the disease multiple sclerosis affect transmission of action potentials along a myelinated neuron?

The majority of synapses are **chemical synapses**. Presynaptic and postsynaptic neurons are separated by a space, the **synaptic cleft**, which is about 20 nm wide (less than one-millionth of an inch). Depolarization is a property of the plasma membrane, so when an action potential reaches the end of the axon, it cannot jump the gap. The electrical signal must be converted into a chemical one.

When an action potential reaches a synaptic terminal, it triggers the release of a *neurotransmitter*, a chemical messenger that conducts the neural signal across the synapse. Neurotransmitter molecules then bind to receptors that are chemically activated ion channels in the membrane of the postsynaptic neuron. This binding triggers specific gated ion channels to open (or close), resulting in changes in permeability of the postsynaptic membrane. When a postsynaptic neuron reaches its threshold level of depolarization, it transmits an action potential.

Neurons use neurotransmitters to signal other cells

Neurotransmitters signal other neurons, muscle fibers, or gland cells. About 100 different neurotransmitters are known or suspected. We can categorize them in several chemical groups, including acetylcholine, biogenic amines, amino acids, neuropeptides, and gaseous neurotransmitters (TABLE 41-2).

Acetylcholine is a low-molecular-weight neurotransmitter that is released from motor neurons and triggers muscle contraction. Acetylcholine is also released by some neurons in the brain and in the autonomic nervous system (see *Inquiring About: Alzheimer's Disease*; also see Chapter 42). Cells that release acetylcholine are called **cholinergic neurons**.

Neurons that release norepinephrine are called **adrenergic neurons**. **Norepinephrine**, **epinephrine**, and the neurotransmitter **dopamine** are **catecholamines**. The catecholamines and the neurotransmitters **serotonin** and **histamine** belong to a class of compounds called **biogenic amines**. Biogenic amines affect mood, and their imbalance has been linked to several disorders, including major depression, anxiety disorders, attention deficit hyperactivity disorder (ADHD), and schizophrenia.

Several amino acids function as neurotransmitters. **Glutamate** is the major excitatory neurotransmitter in the brain. One type of glutamate receptor is the target of several mind-altering drugs, including phencyclidine (known as PCP or "angel dust").

The amino acid **glycine** and a modified amino acid, **gamma-aminobutyric acid (GABA)**, are neurotransmitters that inhibit neurons in the spinal cord and brain. Glycine is the main inhibitory neurotransmitter in the spinal cord. GABA is the neurotransmitter used at most rapid inhibitory synapses throughout the brain. Many drugs that reduce anxiety enhance the actions of GABA by permitting lower concentrations of GABA to open Cl^- channels. These drugs include benzodiazepines, such as diazepam (Valium) and alprazolam (Xanax), and barbiturates, such as phenobarbital.

Neuropeptides, such as endorphins and enkephalins, appear to function mainly as *neuromodulators*, messenger molecules that stimulate long-term changes that enhance or inhibit synaptic function. Some neurobiologists consider them a group of neurotransmitters, but others classify them as a separate group. **Endorphins**, such as *beta-endorphin*, and **enkephalins** are the body's own endogenous opioids. Opiate drugs—for example, morphine and codeine—are powerful analgesics, drugs that relieve pain without causing loss of consciousness. Endorphins and enkephalins bind to opioid receptors (the same receptors to which opiate drugs bind) and block pain signals. Opioids modulate the effect of other neurotransmitters, including **substance P**, which activates pathways that transmit pain signals from certain sensory neurons to the CNS. (We discuss pain perception in Chapter 43.)

The signaling molecule **nitric oxide (NO)** is a gas that diffuses across cell membranes. It can transmit information from the postsynaptic neuron to the presynaptic neuron, the opposite direction of transmission from other neurotransmitters. Thus, it acts as a *retrograde messenger* at some synapses.

Neurotransmitters bind with receptors on postsynaptic cells

Neurotransmitters are stored in synaptic terminals within hundreds of small membrane-enclosed sacs called *synaptic vesicles* (FIG. 41-11a on page 876). Each time an action potential reaches a synaptic terminal, voltage-gated Ca^{2+} channels open. Calcium ions from the extracellular fluid then flow into the synaptic terminal. The Ca^{2+} induce synaptic vesicles to fuse with the presynaptic membrane and release neurotransmitter molecules into the synaptic cleft by exocytosis (FIG. 41-11b on page 876; also see Chapter 5).

Neurotransmitter molecules diffuse across the synaptic cleft and bind with specific receptors on the dendrites or cell bodies of postsynaptic neurons (or on the plasma membranes of effector cells). Many neurotransmitter receptors are chemically activated ion channels known as **ligand-gated channels** (see Chapter 6). When the neurotransmitter, the *ligand*, binds with the receptor, the ion channel opens (FIG. 41-11c on page 876). (Recall that a ligand is a molecule that binds to a specific site in a receptor.) The acetylcholine receptor, for example, is a ligand-gated ion channel that permits the passage of Na^+ and K^+.

Some neurotransmitters, such as serotonin, operate by a different mechanism. They work indirectly through a **second messenger**. Binding of the neurotransmitter with a receptor activates a **G protein**. The G protein then activates an enzyme, such as adenylyl cyclase, in the postsynaptic membrane. Adenylyl cyclase converts ATP to **cyclic AMP (cAMP)**, which acts as a second messenger (see Chapters 6 and 49). Cyclic AMP activates a kinase that phosphorylates a protein, which then closes K^+ channels.

For a postsynaptic neuron to repolarize quickly, any excess neurotransmitter in the synaptic cleft must be removed. Some neurotransmitters are inactivated by enzymes. For example, the enzyme acetylcholinesterase degrades excess acetylcholine into its chemical components, choline and acetate. Other neurotransmitters, such as the biogenic amines, are actively transported back into the synaptic terminals, a process known as *reuptake*. These neurotransmitters are repackaged in vesicles and recycled.

Many drugs inhibit the reuptake of neurotransmitters. For example, some antidepressant medications are selective serotonin reuptake inhibitors (SSRIs). SSRIs such as fluoxetine

Table 41-2 Selected Neurotransmitters

Neurotransmiter	Site of Action	Action	Comments
ACETYLCHOLINE	CNS, neuromuscular junctions	Excitatory effect on skeletal muscle; inhibitory effect on cardiac muscle; excitatory or inhibitory at other sites	Important role in learning and memory; concentration decreases in the brain during the progression of Alzheimer's disease; helps regulate both neural and immune system function
BIOGENIC AMINES			
Norepinephrine	CNS, PNS	Excitatory or inhibitory; concentration in brain affects mood, sleep, wakefulness, attention; mainly inactivated by reuptake into axon terminal	Amphetamines stimulate release and block their reuptake; certain antidepressants also block reuptake; Ritalin (methylphenidate) stimulates release
Dopamine	CNS	Helps maintain balance between excitation and inhibition of neurons; important in motor function; concentration in brain affects mood involved in motivation and reward	Abnormal amounts in attention-deficit disorder and schizophrenia; amount reduced in Parkinson's disease; amphetamines and cocaine stimulate release and cocaine also inhibits reuptake
Serotonin (5-hydroxytryptamine, 5-HT)	CNS	Excitatory effect on pathways that control muscle action; inhibitory effect on sensory pathways; helps regulate food intake, sleep, and wakefulness; affects mood	Concentration highest during alert states; concentration lowest during sleep; many antidepressants, for example, Prozac (fluoxetine) and Zoloft (paroxetine), block serotonin reuptake
AMINO ACIDS			
Glutamate	CNS, invertebrate neuromuscular junctions	Principal excitatory neurotransmitter in vertebrate brain; functions in learning and memory; excitatory effect at invertebrate neuromuscular junctions	THC, the main psychoactive ingredient of cannabis, decreases glutamate release
Gamma-aminobutyric acid (GABA)	CNS, invertebrate neuromuscular junctions	Major inhibitory neurotransmitter in mammalian CNS	Barbiturates and benzodiazepines increase effect of GABA
NEUROPEPTIDES			
Endorphins and enkephalins (opioids)	CNS, PNS	Endogenous opiates; bind with opiate receptors; inhibit release of substance P—this action inhibits pain	Morphine-like
Substance P	CNS, PNS	Activates pathways that transmit pain signals	
GASEOUS NEUROTRANSMITTERS			
Nitric oxide, carbon monoxide, hydrogen sulfide	Most neurons?	Diffuse across cell membranes; retrograde messengers; transmit signals from postsynaptic to presynaptic neurons	

(Prozac) and escitalopram (Lexapro) selectively inhibit the reuptake of serotonin in the brain. This action concentrates serotonin in the synaptic cleft, elevating mood. A few antidepressants inhibit the reuptake of both serotonin and norepinephrine or serotonin and dopamine.

Activated receptors can send excitatory or inhibitory signals

A postsynaptic neuron may have receptors for several types of neurotransmitters. Some of its receptors may be excitatory, and others may be inhibitory. As a result, the same neurotransmitter can have different effects depending on the type of postsynaptic receptor with which it combines. For example, acetylcholine has an excitatory effect on skeletal muscle and an inhibitory effect on cardiac muscle.

When neurotransmitter molecules bind to receptors, the activated receptor can directly or indirectly open or close ion channels; this action changes the permeability of the postsynaptic membrane to certain ions. The resulting redistribution of ions changes the electrical potential of the membrane, and the membrane may depolarize. For example, when neurotransmitter molecules combine with receptors that open Na^+ channels, the resulting influx of Na^+ partially depolarizes the membrane. If sufficiently intense, a local depolarization can set off an action potential.

A change in membrane potential that brings the neuron closer to firing is called an **excitatory postsynaptic potential (EPSP)**. Imagine that sufficient sodium ions enter to change the membrane potential from −70 to −60 mV. The membrane would be only −5 mV away from threshold. Under such conditions, an additional relatively weak stimulus, causing a small influx of Na^+, can cause the neuron to fire. *Note that unlike action potentials, postsynaptic potentials are graded responses.*

Some neurotransmitter–receptor combinations hyperpolarize the postsynaptic membrane, causing the membrane potential to become more negative. Because such an action takes the neuron farther away from the firing level, a potential change in

Inquiring About

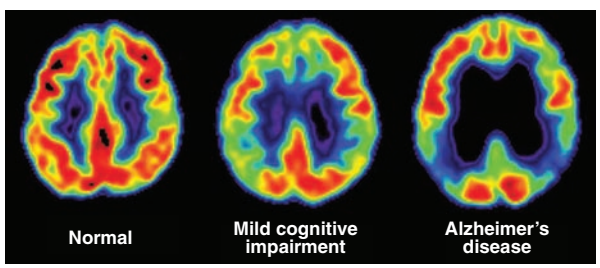
Alzheimer's Disease

What is Alzheimer's disease, and what causes it? **Alzheimer's disease (AD)** is a progressive, degenerative brain disorder in which neural signaling is disrupted and neurons become damaged and die prematurely. Alzheimer's disease is the leading cause of senile dementia, the loss of memory, judgment, and ability to reason that is sometimes associated with aging. The first symptom of AD is mild cognitive impairment, typically a problem with short-term memory. As the disease progresses, the ability to read, write, and think logically becomes compromised, and long-term memory is affected. Eventually, the AD patient loses the ability to carry on routine daily activities, such as dressing, bathing, and eating, and may no longer recognize family members and close friends. Patients typically die within 10 to 12 years of diagnosis.

Worldwide, more than 35 million people are affected by AD, and more than 5 million people in the United States suffer from this disease. One in eight older individuals in the United States has AD, and this disease is the sixth leading cause of death. According to the national Alzheimer's Association (alz.org), AD is the only one of the top 10 causes of death in the United States that cannot be prevented or cured (or even slowed).

Only 4% of those with AD are under age 65. These early-onset cases are caused by mutations in one of three genes. There is some evidence that you can reduce your risk for AD by engaging in regular physical exercise, pursuing higher education, and working in a profession that is cognitively challenging, staying cognitively active, and interacting socially with other people.

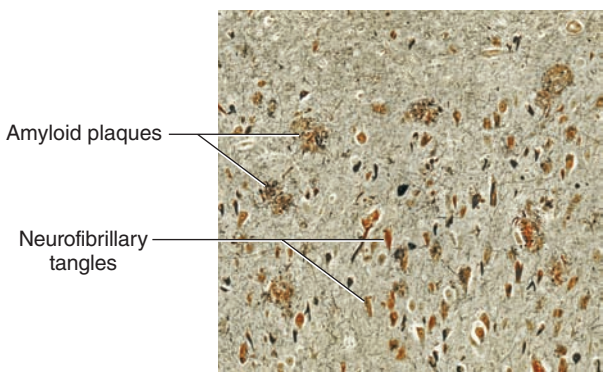
AD typically develops over several decades. One startling study demonstrated that a person's writing early in life can predict the disease. Young adults whose writings had a lower density of ideas were more likely to develop the disease than those whose density of ideas was higher. Early changes in the brain can now be detected by positron emission tomography scans, magnetic resonance imaging, and spinal taps years before AD symptoms are apparent (see Figure 1).



In AD, neurons are damaged in the cerebral cortex and hippocampus, areas of the brain important in thinking and remembering. Neurons that secrete the neurotransmitter acetylcholine are especially affected. Three abnormalities that develop in brain tissue as humans age are especially characteristic of AD: amyloid plaques, neurofibrillary tangles, and death of neurons. Understanding the biochemistry and genetic basis of both plaques and tangles may provide clues to the causes and cures of AD.

Amyloid plaques were first identified in autopsied brains in 1906 by Alois Alzheimer, a German physician. These plaques are extracellular deposits of a peptide called amyloid-beta (amyloid-β) that are surrounded by degenerating dendrites and axons. Researchers found that amyloid-β is cut from a precursor protein called β-APP, a large protein in neuron plasma membranes. Normal amyloid-β molecules have 40 amino acids. However, about 10% of the peptides produced have two additional amino acids. This longer peptide appears to form the plaques. Neurons near these plaques appear swollen and misshapen. Microglia are typically present, suggesting an attempt to remove the damaged cells or the plaques themselves. The microglia cause inflammation and release toxic compounds that damage nearby neurons. The abnormal peptide appears to disrupt calcium regulation, which destroys neurons in the brain. There is also evidence that amyloid-β damages mitochondrial enzymes, releasing harmful free radicals.

Amyloid-β and its toxic effects may lead to formation of **neurofibrillary tangles**. These tangles, which form in the neuron cytoplasm, are another piece of the AD puzzle. The cytoskeletal protein known as *tau* normally associates with the protein tubulin, which forms microtubules. According to one hypothesis, amyloid-β interferes with the way the tau protein binds to microtubules, resulting in abnormal microtubules that cannot effectively transport materials through axons. Abnormal tau proteins accumulate in the cytoplasm, forming fibrous deposits that make up the neurofibrillary tangles (see Figure 2). These tangles interfere with neural signaling. Researchers have suggested that tau proteins, like prions, can become misfolded. These misfolded proteins can then cause other tau proteins to misfold. (See the discussion of prions in Chapter 24.)



AD is currently treated with two types of drugs. The first type—for example, Aricept and Exelon—inhibits the enzyme acetylcholinesterase. This action slows the breakdown of acetylcholine, a neurotransmitter that plays a role in memory and thought. The second type of drug, memantine (Namenda), affects glutamate, a neurotransmitter important in learning and memory. Namenda-type drugs slow cognitive decline. However, these drugs do not prevent the eventual damage that occurs in the brain.

Several new drugs are being developed. For example, a vaccine (AADvac1) in clinical trials stimulates the immune system to attack an abnormal tau protein, which may slow or stop the disease process.

Susan M. Landau, Cindee Madison, and William Jagust

Figure 1 These fluorodeoxyglucose (FDG)-PET scans measure glucose metabolism. FDG-PET scanning is one of the major methods used by the Alzheimer's Disease Neuroimaging Initiative (ADNI) to track progression of Alzheimer's disease. *Orange* and *yellow* colors indicate metabolic activity. Note reduced metabolic activity in the PET scan image of the brain of a patient with Alzheimer's disease.

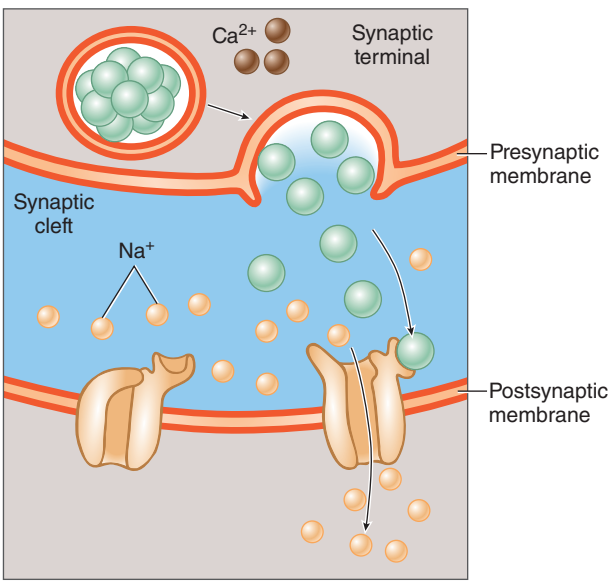
Key Point

At most synapses the action potential cannot jump across the synaptic cleft between the two neurons. This problem is solved by chemical signaling across synapses.



(a) The TEM shows synaptic terminals filled with synaptic vesicles.

(b) How a neural impulse is transmitted across a synapse.

1. Action potential reaches synaptic terminals at the end of a presynaptic neuron.
2. Calcium channels open in membrane, letting Ca^{2+} from the extracellular fluid enter the synaptic terminal.
3. Ca^{2+} cause synaptic vesicles to fuse with the plasma membrane and release neurotransmitter into the synaptic cleft.
4. Neurotransmitter binds with receptors on the membrane of postsynaptic neuron.
5. In response, specific ion channels open or close, resulting in either depolarization or hyperpolarization. When depolarization reaches threshold level, an action potential is generated in a postsynaptic neuron.

(c) Neurotransmitter binds with receptor. Ligand-gated channel opens, resulting in depolarization.

Figure 41-11 Neural signaling across a synapse

this direction is called an **inhibitory postsynaptic potential (IPSP)**. For example, if the membrane potential changes from −70 to −80 mV, the membrane is farther away from threshold, and a stronger stimulus is required to fire the neuron.

Like an EPSP, an IPSP can be produced in several ways. Two types of GABA receptors are known to produce IPSPs. When GABA binds to a $GABA_B$ receptor, K^+ channels open. As K^+ diffuse out, the neuron becomes more negative, hyperpolarizing the membrane. Activated $GABA_A$ receptors produce IPSPs by opening Cl^- channels. In this case, the influx of negative ions hyperpolarizes the membrane. Although the mechanisms are different, the inhibiting effect of GABA is the same in both cases.

In summary, neural signaling across synapses involves the following sequence of events:

action potential reaches synaptic terminal → calcium ions enter synaptic terminal → synaptic vesicles release neurotransmitter into the synaptic cleft → neurotransmitter diffuses across synaptic cleft → neurotransmitter binds with receptors in membrane of postsynaptic neuron → ion channels open or close, resulting in depolarization or hyperpolarization of postsynaptic membrane

- **VISUALIZE** Sketch the sequence of events that takes place at a chemical synapse.
- How are EPSPs produced? IPSPs?

41.5 Neural Integration

LEARNING OBJECTIVE

10 Define *neural integration* and describe how a postsynaptic neuron sums incoming stimuli and "decides" whether to fire.

Each neuron may synapse with hundreds of other neurons. Indeed, thousands of synaptic terminals of presynaptic neurons may cover as much as 40% of a postsynaptic neuron's dendritic surface and cell body. It is the job of the dendrites and the cell body of every neuron to integrate the messages that continually bombard them.

Neural **integration** is the process of summing, or integrating, incoming signals. EPSPs and IPSPs are produced continually in postsynaptic neurons, and IPSPs cancel the effects of some EPSPs. It is important to remember that each EPSP and IPSP is not an all-or-none response. Rather, each is a graded response that does *not* travel like an action potential but may be added to or subtracted from other EPSPs and IPSPs.

As the membrane of the postsynaptic neuron continuously updates its molecular tabulations, the neuron may be inhibited or brought to threshold level. This mechanism integrates hundreds of signals (EPSPs and IPSPs) before an action potential is actually transmitted along the axon of a postsynaptic neuron. Local responses permit the neuron and the entire nervous system a far greater range of response than would be possible if every EPSP generated an action potential.

Postsynaptic potentials are summed over time and space

Each EPSP or IPSP is a graded potential that varies in magnitude depending on the strength of the stimulus applied. One EPSP is usually too weak to trigger an action potential by itself. Its effect is below threshold level. However, even though subthreshold EPSPs do not produce an action potential, they do affect the membrane potential. EPSPs can be added together in a process called **summation** (FIG. 41-12).

Temporal summation occurs when a presynaptic neuron fires multiple times in rapid succession, resulting in repeated stimulation of a postsynaptic neuron. New EPSPs develop before previous EPSPs have decayed. The summation of several EPSPs may bring the neuron to the critical firing level.

Spatial summation can also bring the postsynaptic neuron to threshold level. **Spatial summation** is the summing of several postsynaptic potentials resulting when closely spaced presynaptic neurons release neurotransmitter simultaneously. The postsynaptic neuron may be stimulated at multiple regions at the same time.

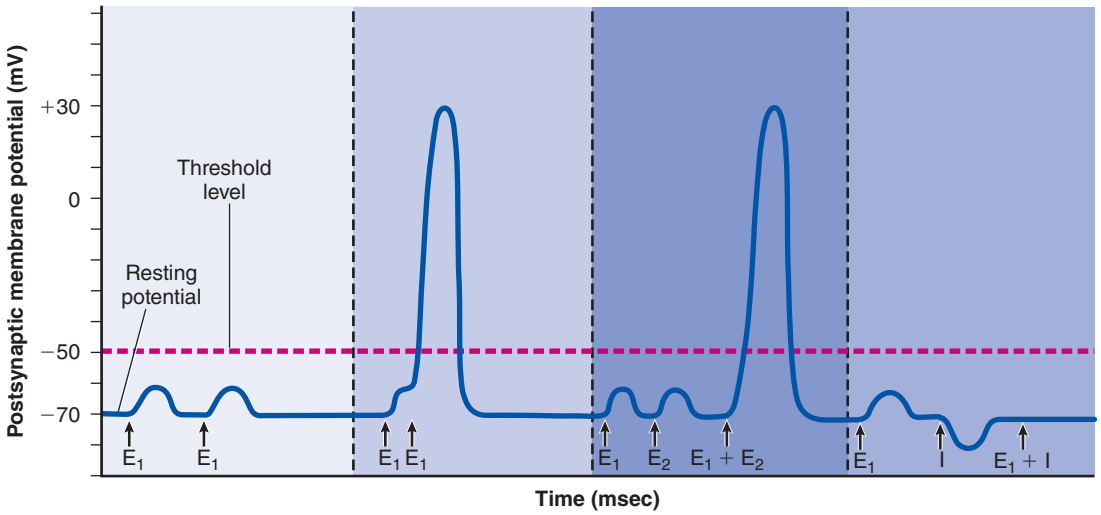
Neurons sum IPSPs as well as EPSPs. As IPSPs occur, they move the membrane potential farther away from threshold.

Where does neural integration take place?

On a molecular level, every neuron tabulates the thousands of bits of information that continuously bombard it. In vertebrates more than 90% of the neurons in the body are located in the CNS, so most neural integration takes place there, within the brain and spinal cord. These neurons are responsible for making most of the "decisions." The brain and spinal cord are examined in some detail in the next chapter.

CHECKPOINT 41.5

- What is neural integration?
- How do temporal and spatial summation differ?
- Where does most neural integration take place in vertebrates?



41.6 Neural Circuits: Complex Information Signaling

LEARNING OBJECTIVE

11 Distinguish between convergence and divergence, and explain why each is important to the functioning of neural circuits.

(a) Subthreshold (no summation). Each stimulus is at a subthreshold level, so no action potential is generated.

(b) Temporal summation. The second EPSP occurs before the first dies off, so the two EPSPs are summed. An action potential is generated.

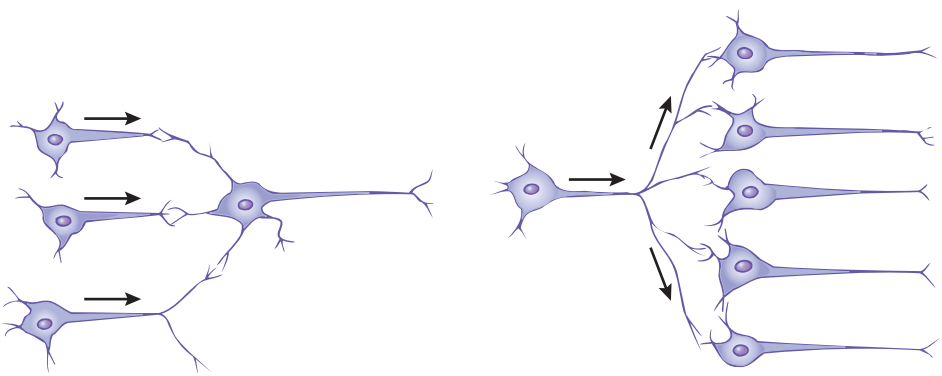
(c) Spatial summation. EPSPs generated by input from two different presynaptic neurons are summed.

(d) Spatial summation of EPSPs and IPSPs. EPSPs and IPSPs are also summed and can cancel each other out.

Figure 41-12 Neural integration

E_1 and E_2 are excitatory stimuli. I represents an inhibitory stimulus.

The CNS contains millions of neurons, but it is not just a tangled mass of nerve cells. Its neurons are functionally arranged in specific pathways, or **neural circuits**. A neural circuit typically consists of one or more afferent neurons, one or more interneurons, and one or more efferent neurons.



Neural circuits are organized into *neural networks*. Although each network has some specific characteristics, the neural circuits in all the networks share many organizational features. For example, convergence and divergence are characteristic of them all.

In **convergence** of neural input, a single neuron receives converging signals (inputs) from two or more presynaptic neurons (FIG. 41-13a). An interneuron in the spinal cord, for instance, may receive converging information from sensory neurons entering the spinal cord, from neurons bringing information from various parts of the brain, and from neurons coming from different levels of the spinal cord. Information from all these sources must be integrated before an action potential is transmitted and an appropriate motor neuron is stimulated.

In **divergence** of neural input, a single presynaptic neuron makes connections with many postsynaptic neurons (FIG. 41-13b). Each presynaptic neuron may branch and synapse with thousands of different postsynaptic neurons. For example, a single neuron transmitting an impulse from the motor area of the brain may make connections with hundreds of interneurons in the spinal cord, and each of them may diverge, in turn, so that hundreds of muscle fibers are stimulated.

CHECKPOINT 41.6

- **VISUALIZE** Draw simple sketches that contrast convergence of neural input with divergence of neural input.

(a) Convergence of neural input. Several presynaptic neurons synapse with one postsynaptic neuron.

(b) Divergence of neural output. A single presynaptic neuron synapses with many postsynaptic neurons.

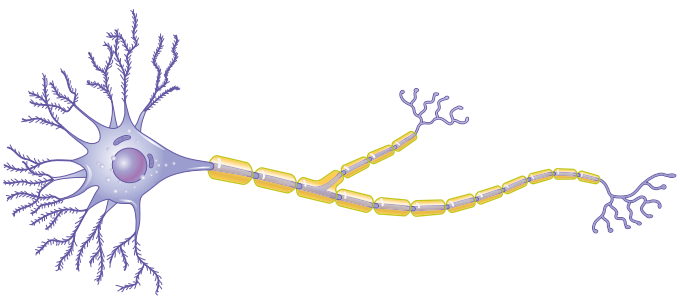
Summary: Focus on Learning Objectives

41.1 Neural Signaling: An Overview *(page 861)*



1 Describe the processes involved in neural signaling: reception, transmission, integration, and action by effectors that brings about the actual response.

- Neural signaling involves (1) **reception** of information by a sensory receptor; (2) **neural transmission** by an **afferent neuron** to the **central nervous system (CNS)**, which consists of the brain and spinal cord; (3) **integration** by **interneurons** in the central nervous system; (4) transmission by an **efferent neuron** to other neurons or to an effector; and (5) action by **effectors**, the muscles and glands that bring about the actual **response** to the stimulus. Sensory receptors and neurons outside the CNS make up the **peripheral nervous system (PNS)**.

41.2 Neurons and Glial Cells *(page 862)*

2 Draw and label a typical neuron and give the function of each of its parts.

- **Neurons** are specialized to receive stimuli and transmit electrical and chemical signals. In a typical neuron, a **cell body** contains the nucleus and most of the organelles. Many branched **dendrites** extend from the cell body; they are specialized to receive stimuli and send signals to the cell body.
- The single long **axon** extends from the cell body and forms branches called *axon collaterals*. The axon transmits signals into its *terminal branches*, which end in synaptic terminals.
- Many axons are surrounded by an insulating **myelin sheath**. In the PNS the myelin sheath is formed by **Schwann cells**. **Nodes of Ranvier** are gaps in the sheath between successive Schwann cells.
- A **nerve** consists of several hundred axons wrapped in connective tissue; a **ganglion** is a mass of neuron cell bodies in the PNS.

3 Identify the main types of glial cells and describe the functions of each.

- **Glial cells** support and nourish neurons and are important in neural communication. **Astrocytes** are glial cells that physically support neurons. They help regulate the composition of the extracellular fluid in the CNS by taking up excess potassium ions. Astrocytes communicate with one another and with neurons; they also induce and stabilize synapses.
- **Oligodendrocytes** are glial cells that form myelin sheaths around axons in the CNS. **Ependymal cells** line cavities in the CNS and help produce and circulate cerebrospinal fluid. **Microglia** are phagocytic cells.

41.3 Transmitting Information along the Neuron *(page 865)*

4 Explain how the neuron develops and maintains a resting potential.

- Neurons use electrical signals to transmit information along axons. The plasma membrane of a resting neuron, one that is not transmitting an impulse, is *polarized*. The inner surface of the plasma membrane is negatively charged relative to the extracellular fluid just outside the membrane. The voltage measured across the plasma membrane is the **membrane potential**.
- The **resting potential** is the potential difference of about −70 mV that exists across the membrane. The magnitude of the resting potential is determined by (1) differences in concentrations of specific ions (mainly Na^+ and K^+) inside the cell relative to the extracellular fluid and (2) selective permeability of the plasma membrane to these ions.
- Ions pass through specific **passive ion channels**. K^+ leak out more readily than Na^+ can leak in. The resting potential is mainly due to the net flow of K^+ out of the neuron. Cl^- and large anions inside the neuron contribute negative charges.
- The opposing Na^+ and K^+ gradients are maintained by ATP-requiring **sodium–potassium pumps** that continuously transport three Na^+ out of the neuron for every two K^+ transported in.

5 Compare a graded potential with an action potential, describing the production and transmission of each.

- If a stimulus causes the membrane potential to become less negative, the membrane becomes **depolarized**. If the membrane potential becomes more negative than the resting potential, the membrane is **hyperpolarized**.
- A **graded potential** is a local response that varies in magnitude depending on the strength of the applied stimulus. A graded potential fades out within a few millimeters of its point of origin.
- If voltage across the membrane decreases to a critical **threshold level**, **voltage-activated ion channels** open, allowing Na^+ to flow into the neuron, and an **action potential** is generated. The action potential is a *wave of depolarization* that moves down the axon.
- As the action potential moves down the axon, **repolarization** occurs behind it. During depolarization, the axon enters an *absolute* **refractory period**, a time when it cannot transmit another action potential. When enough gates controlling Na^+ channels have been reset, the neuron enters a *relative* refractory period, a time when the threshold to fire the neuron is higher.

Copyright 2019 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

- The action potential is an **all-or-none response**; no variation exists in the strength of a single impulse. Either the membrane potential exceeds threshold level, leading to transmission of an action potential, or it does not. Once begun, an action potential is self-propagating.

6 Contrast continuous conduction with saltatory conduction.

- *Continuous conduction*, which involves the entire axon plasma membrane, takes place in unmyelinated neurons.
- **Saltatory conduction**, which is more rapid and requires less energy than continuous conduction, takes place in myelinated neurons. Depolarization appears to leap along the axon from one node of Ranvier to the next.

41.4 Transmitting Information across Synapses *(page 872)*

7 Describe the actions of the neurotransmitters identified in this chapter.

- The junction between two neurons or between a neuron and effector is a **synapse**. Most synapses are chemical. In synaptic transmission a **presynaptic neuron** releases a neurotransmitter, a chemical messenger, from its *synaptic vesicles*.
- **Acetylcholine** is a neurotransmitter that triggers contraction of skeletal muscle.
- The **biogenic amines**, which include **norepinephrine**, **serotonin**, and **dopamine**, have multiple functions. They play important roles in regulating mood. Dopamine is also important in motor function.
- Several amino acids function as neurotransmitters, including **glutamate**, the main excitatory neurotransmitter in the brain, and **GABA**, a widespread inhibitory neurotransmitter.
- The neuropeptides, which are opioids, include the **endorphins** (e.g., *beta-endorphin*) and the **enkephalins**.
- **Nitric oxide (NO)**, a gaseous neurotransmitter, transmits signals from postsynaptic neurons to presynaptic neurons, the opposite direction from other neurotransmitters.

8 List the sequence of events that take place in synaptic transmission and draw diagrams to support your description.

- Calcium ions induce synaptic vesicles to fuse with the presynaptic membrane and release neurotransmitter into the **synaptic cleft**. The neurotransmitter diffuses across the synaptic cleft and combines with specific receptors on a postsynaptic neuron (see Fig. 41-11b).
- Many neurotransmitter receptors are proteins that form **ligand-gated channels**. Others activate a G protein and work through a **second messenger** such as **cAMP**.

9 Compare excitatory and inhibitory signals and their effects.

- Binding of a neurotransmitter to a receptor can cause either an **excitatory postsynaptic potential (EPSP)** or an **inhibitory postsynaptic potential (IPSP)**, depending on the type of receptor. EPSPs bring the neuron closer to firing. IPSPs move the neuron farther away from its firing level.

41.5 Neural Integration *(page 877)*

10 Define *neural integration* and describe how a postsynaptic neuron sums incoming stimuli and "decides" whether to fire.

- Neural **integration** is the process of summing, or integrating, incoming signals.
- Each EPSP or IPSP is a graded potential that varies in magnitude depending on the strength of the stimulus applied. **Summation** is the process of adding and subtracting incoming signals. By summation of several EPSPs, the neuron may be brought to the critical firing level.
- **Temporal summation** occurs when repeated stimuli cause new EPSPs to develop before previous EPSPs have decayed. **Spatial summation** occurs when several closely spaced synaptic terminals release neurotransmitter simultaneously, stimulating the postsynaptic neuron at several different places.

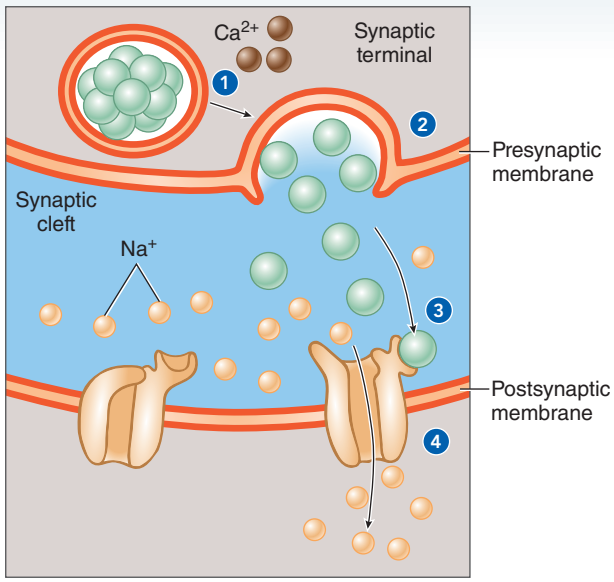
41.6 Neural Circuits: Complex Information Signaling *(page 877)*

11 Distinguish between convergence and divergence, and explain why each is important to the functioning of neural circuits.

- Complex **neural circuits** are possible because of associations such as convergence and divergence. In **convergence** a single neuron is affected by signals from two or more presynaptic neurons. Convergence allows the CNS to integrate incoming information from various sources. In **divergence** a single presynaptic neuron stimulates many postsynaptic neurons, allowing widespread effect.

Test Your Understanding

Know and Comprehend



1. Summing incoming neural signals is part of (a) reception (b) transmission (c) integration (d) action by effectors (e) afferent neuron transmission
2. The myelin sheath is produced around axons in the PNS by (a) ganglia (b) neuron cell bodies (c) dendrites (d) Schwann cells (e) oligodendrocytes
3. Which of the following occurs first when voltage reaches the threshold level in a neuron plasma membrane? (a) voltage-activated Na^+ channels open (b) K^+ channels open (c) the membrane hyperpolarizes (d) neurotransmitter is released (e) K^+ channels close
4. Saltatory conduction (a) requires more energy than continuous conduction (b) occurs in unmyelinated neurons (c) occurs when the action potential jumps from one node of Ranvier to the next (d) slows transmission of an impulse (e) depends on the action of GABA
5. Receptors for serotonin and many other neurotransmitters (a) are voltage-activated ion channels (b) permit influx of chloride ions, leading to depolarization (c) inhibit EPSPs (d) are ligand-gated channels (e) are passive ion channels
6. A presynaptic neuron in the cerebrum transmits information to hundreds of other neurons. This process is an example of (a) convergence (b) divergence (c) temporal summation (d) spatial summation (e) a graded potential

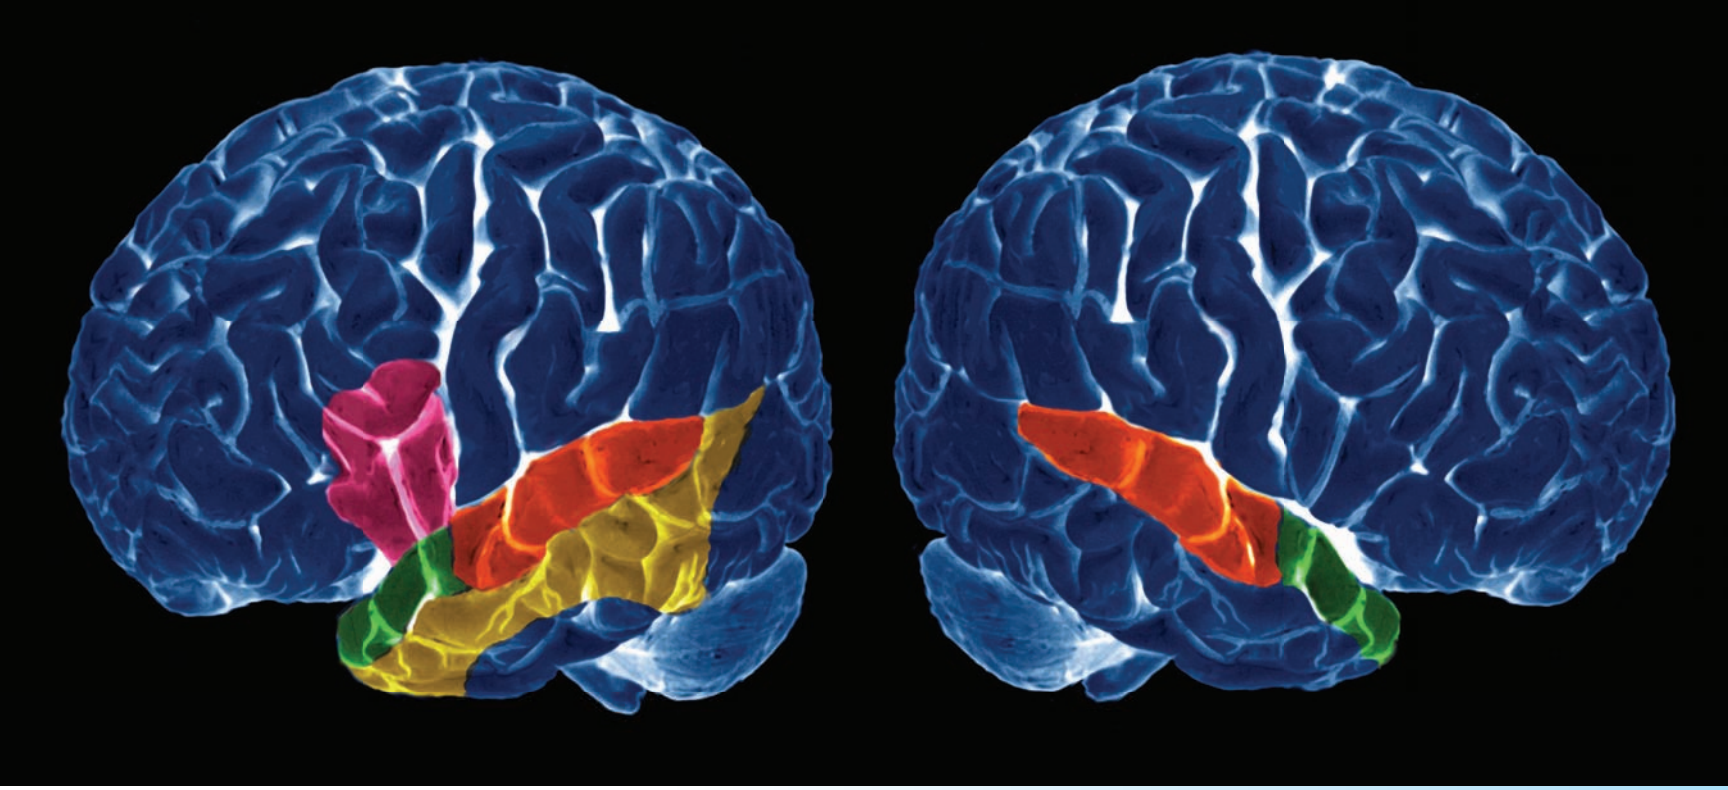
Apply and Analyze

7. **VISUALIZE** Describe the action taking place at each of the numbered steps in the figure.

8. **VISUALIZE** Using the diagram in question 7, add several red spheres in the synaptic cleft to represent molecules of an antidepressant medication. Illustrate a potential mechanism of action for the antidepressant molecules. (Extend the diagram if you like.)

9. **INTERPRET DATA** State whether each of the following would result in an EPSP or IPSP (explain your answer). (a) Na^+ enter postsynaptic neuron (b) K^+ diffuse out of postsynaptic neuron (c) Cl^- enter postsynaptic neuron.



Evaluate and Synthesize

10. Develop a hypothesis to explain why acetylcholine has an excitatory effect on skeletal muscle but an inhibitory effect on cardiac muscle.
11. **SCIENCE, TECHNOLOGY, AND SOCIETY** A test for risk of Alzheimer's disease is available. Based on gene markers that can be identified in a saliva sample, a healthy person can learn his or her approximate risk for AD. How might this information be useful to people? Would you be concerned about the psychological consequences of a person knowing that he or she has a high risk of AD? Would you want to know?
12. **SCIENCE, TECHNOLOGY, AND SOCIETY** Investigators have genetically engineered cells to produce acetylcholine, dopamine, GABA, and other neurotransmitters. In what ways might these cells be useful in neurobiological research? How might they be useful in clinical medicine?
13. **EVOLUTION LINK** From the perspective of adaptation, hypothesize the advantages of neural circuits characterized by a great deal of convergence and divergence.

42 Neural Regulation

KEY CONCEPTS

42.1 The trend in the evolution of invertebrate nervous systems is toward greater complexity, with increased number and concentration of neurons and greater specialization of function.

42.2 The vertebrate nervous system consists of a central nervous system (CNS), which includes the brain and spinal cord, and a peripheral nervous system (PNS), which includes sensory receptors and nerves.

42.3 During the evolution of the vertebrate brain, the cerebrum and cerebellum have become larger and more complex.

42.4 The CNS receives sensory information from both the internal and external environments, integrates it, and determines appropriate responses. The association areas of the brain are responsible for learning, memory, language, thought, and judgment.

42.5 The PNS has two divisions. The somatic division transmits information between the external environment and the CNS. The autonomic division transmits information between the internal environment and the CNS.

42.6 Many prescribed and illicit drugs affect mood by affecting neurotransmitter concentrations in the brain.

A frog flicks out its tongue with lightning speed to capture a fly, a rabbit escapes from a predator, and you learn biology, perhaps not that quickly. In a complex nervous system, millions of neurons work together to transmit information from the external environment to the central nervous system (CNS). After the information is integrated, neural signals are transmitted to the effectors that can produce effective responses.

The nervous system also regulates heart rate, breathing, and hundreds of other internal activities. Nerves must transmit information from all the organs in the body to the CNS. Then, other nerves transmit back the information that will allow organs to make the adjustments necessary to maintain homeostasis. Researchers have focused extensively on just how neurons interact. However, we are only beginning to understand the mechanisms that propel the many vital functions of the nervous system.

Neurobiologists use a variety of methods to study the mechanisms of neural function. For example, improved imaging methods, including positron emission tomography (PET) and functional magnetic resonance imaging (fMRI), have provided investigators with a window through which to observe brain activity (see photograph).

PHOTO: Brain activation during hearing. Colored positron emission tomography (PET) scan data, showing brain activity (colored) from hearing a known language. The PET data has been laid over three-dimensional magnetic resonance imaging (MRI) scans of profiles of the left (in the brain shown on the *left*) and right (in the brain on the *right*) brain hemispheres. The front of the brain (frontal lobe) is positioned at the far left and right. The *red* and *green* areas visible in the temporal lobe of the brain are auditory areas. The *yellow* area (in the left temporal lobe) recognizes known words. The *pink* area (in the left frontal lobe) is Broca's area, which controls the ability to speak. Zephyr/Science Source

These methods permit investigators to study the responses of neural networks in the brain while an individual is performing a task, such as hearing. When performing a task, neurons in the area of the brain involved become active and consume more oxygen. The flow of oxygen-rich blood increases to that area. PET and fMRI detect changes that take place in response to a very brief stimulus.

In this chapter we compare several types of nervous systems. We then examine the structure and function of the vertebrate nervous system, with emphasis on the function of the human brain. We explore some of the frontiers of neurobiology, such as mechanisms involved in information processing and drug addiction.

42.1 Invertebrate Nervous Systems: Trends in Evolution

LEARNING OBJECTIVES

1. Contrast nerve nets and radial nervous systems with bilateral nervous systems.
2. Identify trends in the evolution of invertebrate nervous systems.

An animal's lifestyle is closely related to the organization and complexity of its nervous system. *Hydra* and other cnidarians have a **nerve net** consisting of interconnected neurons with no central control organ. Sensory cells are located in the epidermis, and the cnidarian can respond to stimuli from any direction (see Chapter 31). When a neuron is stimulated, electrical signals are sent from neuron to neuron in all directions (FIG. 42-1). Responses may involve large parts of the body.

An advantage of the nerve net is that the cnidarian responds effectively to predator or prey approaching from any direction. *Hydra* responds by discharging nematocysts (stinging structures) and coordinating the movements of its tentacles to capture food. Some cnidarians have two or more nerve nets. In some jellyfish a slow-transmission nerve net coordinates movement of the tentacles, and a second nerve net, which is faster, coordinates swimming.

The *radial nervous system* of the sea star and other echinoderms is a modified nerve net. This system shows some degree of selective organization of neurons into more than a diffuse network. It consists of a nerve ring around the mouth, from which a large radial nerve extends into each arm. Branches of these nerves, which form a network somewhat similar to the nerve net of *Hydra*, coordinate the animal's movement.

Bilaterally symmetrical animals have a *bilateral nervous system*. In planarian flatworms the head region contains concentrations of nerve cells called *cerebral ganglia* (FIG. 42-2). These ganglia serve as a primitive brain and have some control over the rest of the nervous system. Typically, two solid, ventral, longitudinal *nerve cords* extend from the ganglia to the posterior end of the body. A **nerve cord** is a bundle of nerves that extends from a central ganglion (or brain) and gives rise to smaller nerves. In planaria, transverse nerves connect the two nerve cords and connect the brain with the eyespots. This arrangement is called a "ladder-type" nervous system.

Annelids and arthropods typically have a solid ventral nerve cord (FIG. 42-3). The cell bodies of many of the neurons are massed into **ganglia**. Afferent and efferent neurons lie in lateral nerves that link the ganglia with muscles and other body structures. If an earthworm's brain is removed, the animal can move almost as well as before. However, when it bumps into an obstacle, it persists in a futile effort to move forward rather than turn aside. To respond adaptively to environmental change, the earthworm needs its brain.

The cerebral ganglia of some arthropods differ from those of annelids in that they have specific functional regions. These areas are specialized for integrating information transmitted to the ganglia from sense organs.

Mollusks with inactive lifestyles have relatively simple nervous systems with little cephalization and very simple sense organs. Typically, there are two nerve cords; one extends down each side of the body. Several pairs of ganglia are located along the cords.

The cephalopod mollusks (squids and octopods) have complex nervous systems that include well-developed sense organs. The cephalopod nervous system is adapted to the active, predatory lifestyle of these animals. Neurons

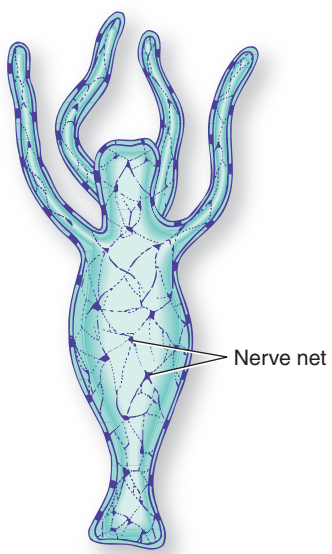

Figure 42-1 *Hydra*'s nerve net
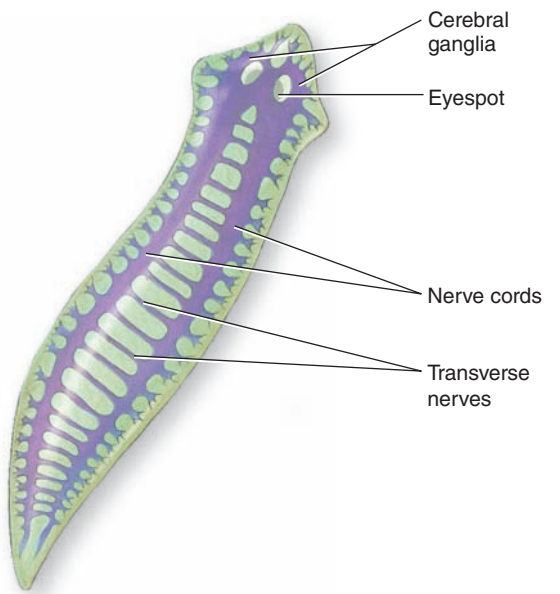
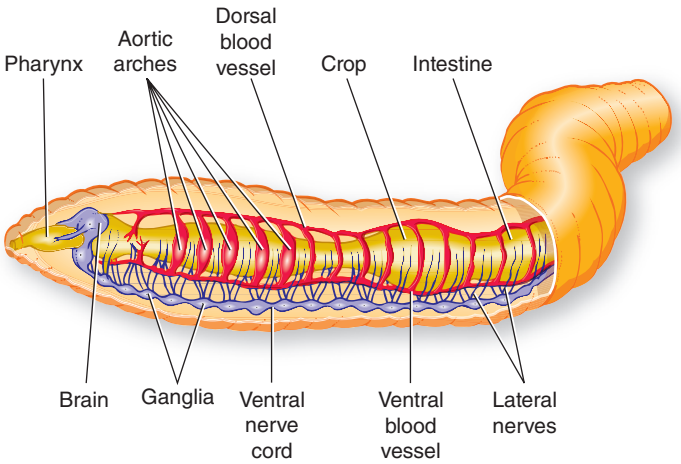
Hydra and other cnidarians have a network of neurons with no central control organ.





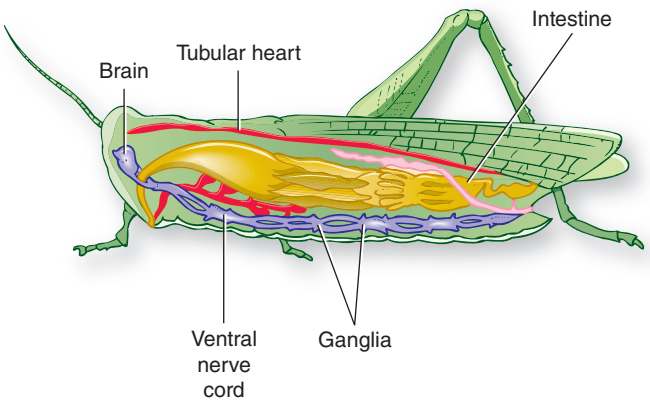


Figure 42-2 Ladder-type nervous system of flatworms
Cerebral ganglia in the head region serve as a simple brain. The longitudinal nerve cords are connected by transverse nerves.

(a) Earthworm nervous system. Annelids have a dorsal anterior brain and one or more ventral nerve cords. Cell bodies of the neurons are located in ganglia that are connected by the ventral nerve cord.

(b) Insect nervous system. The arthropod brain is continuous with the ventral nerve cord. The brain is more specialized than in annelids.

Figure 42-3 The annelid and arthropod nervous systems

concentrated in ganglia are massed in a ring surrounding the esophagus; they make up a brain that contains about 168 million nerve cells. Like the vertebrate brain, the cephalopod brain has lobes and intricate folds, and particular areas are specialized as centers for specific functions. The octopus is capable of considerable learning and can be taught difficult tasks. In fact, cephalopods are considered the most intelligent invertebrates.

We can identify the following trends in the evolution of nervous systems:

1. *Increased number of nerve cells.*
2. *Concentration of nerve cells.* The nerve cells form masses of tissue that become *ganglia* (concentrations of nerve cell bodies) and *brain*, and they form thick cords of tissue that become *nerve cords* and *nerves*.
3. *Specialization of function.* For example, transmission of nerve impulses in one direction requires both **afferent nerves**, which conduct impulses toward a central nervous system (CNS), and **efferent nerves**, which transmit impulses away from the CNS to the **effectors** (muscles and glands). Certain parts of the CNS become specialized to perform specific functions, and distinct structural and functional regions can be identified.
4. *Increased number of interneurons and more complex synaptic contacts.* These contacts permit greater integration of incoming messages, provide a greater range of responses, and allow more precise responses.
5. **Cephalization**, *or formation of a head.* A bilaterally symmetrical animal generally moves in a forward direction. Concentration of sense organs at the front end of the body lets the animal detect an enemy quickly enough to escape or to see, hear, or smell food in time to capture it. Response can be rapid if short pathways link sense organs to decision-making nerve cells nearby. Therefore, nerve cells are typically concentrated in the head region and organized to form ganglia or a **brain**.

CHECKPOINT 42.1

- Contrast the nervous system of the insect with that of the flatworm.
- What are some trends in the evolution of nervous systems?
- What are some advantages of cephalization?

42.2 Overview of the Vertebrate Nervous System

LEARNING OBJECTIVE

3 Describe the two main divisions of the vertebrate nervous system and summarize their functions.

An animal's range of possible responses depends in large part on how many neurons it has and how they are organized in the nervous system. Some invertebrate nervous systems have only a few hundred neurons. As animal groups evolved, nervous systems became increasingly complex. A common roundworm has 302 neurons. Elephant, whale, and human brains have billions. How neurons are organized is critical in determining learning ability and flexibility of behavior.

The vertebrate nervous system has two main divisions: the **central nervous system (CNS)** and the **peripheral nervous system (PNS)** (FIG. 42-4). The CNS consists of a highly developed brain that is continuous with the dorsal, tubular nerve cord, or **spinal cord**. Serving as central control, these organs integrate incoming information and determine appropriate responses.

The PNS is made up of the sensory receptors (e.g., tactile, auditory, and visual receptors) and the nerves, which are the communication lines. Various parts of the body are linked to the CNS by cranial nerves and by spinal nerves. Afferent (sensory) neurons in these nerves continuously inform the CNS of changing conditions. Then efferent neurons transmit the "decisions" of the CNS to appropriate muscles and glands, which make the adjustments needed to maintain homeostasis.

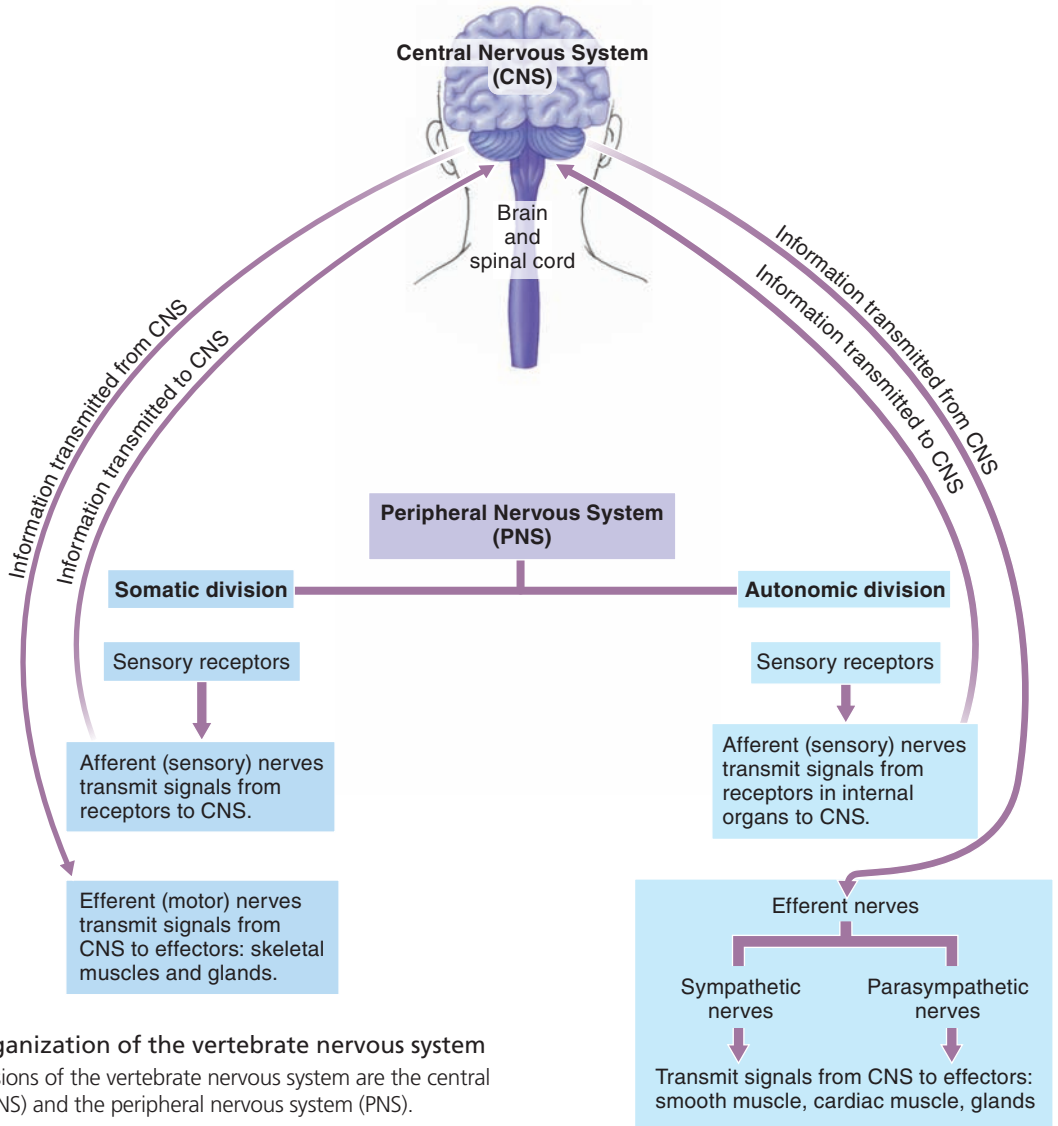

Figure 42-4 Organization of the vertebrate nervous system
The two main divisions of the vertebrate nervous system are the central nervous system (CNS) and the peripheral nervous system (PNS).

For convenience, the PNS is subdivided into *somatic* and *autonomic divisions*. Most of the receptors and nerves concerned with changes in the external environment are somatic. Those that regulate the internal environment are autonomic. Both divisions have afferent nerves, which transmit messages from sensory receptors to the CNS, and efferent nerves, which transmit information back from the CNS to the structures that respond. The autonomic division has two kinds of efferent pathways: sympathetic and parasympathetic nerves (discussed later in the chapter).

CHECKPOINT 42.2

- **VISUALIZE** Draw a diagram showing the main components of the CNS and the main components of the PNS.
- Describe the functions of each component of the CNS and PNS.

42.3 Evolution of the Vertebrate Brain

LEARNING OBJECTIVE

4 Trace the development of the principal vertebrate brain regions from the hindbrain, midbrain, and forebrain, and compare the brains of fishes, amphibians, reptiles, birds, and mammals.

All vertebrates, from fishes to mammals, have the same basic brain structure; different parts of the brain are specialized in the various vertebrate classes. The evolutionary trend is toward increasing complexity, especially of the cerebrum and cerebellum.

In the early vertebrate embryo, the brain and spinal cord differentiate from a single tube of tissue, the **neural tube**. Anteriorly, the tube expands and develops into the brain. Posteriorly, the tube becomes the spinal cord. Brain and spinal

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

cord remain continuous, and their cavities communicate. As the brain begins to differentiate, three bulges become visible: the hindbrain, midbrain, and forebrain (FIG. 42-5).

The hindbrain develops into the medulla, pons, and cerebellum

As indicated in TABLE 42-1, the **hindbrain** subdivides to form the *metencephalon*, which gives rise to the **cerebellum** and **pons**, and the *myelencephalon*, which gives rise to the **medulla**. The medulla, pons, and midbrain make up the **brain stem**, the elongated portion of the brain that looks like a stalk holding up the cerebrum.

The medulla, the most posterior part of the brain, is continuous with the spinal cord. Its cavity, the *fourth ventricle*, is continuous with the central canal of the spinal cord and with a channel that runs through the midbrain. The fourth **ventricle** is one of four interconnected chambers in the brain through which cerebrospinal fluid flows. The walls of the medulla are thick and made up largely of *nerve tracts* (bundles of axons) that connect the spinal cord with various parts of the brain. The medulla contains centers that regulate life-sustaining functions such as respiration, heartbeat, and blood pressure. Other reflex centers in the medulla regulate activities such as swallowing, coughing, and vomiting.

The cerebellum is responsible for muscle tone, posture, and equilibrium. It also refines and coordinates muscle activity. In humans the cerebellum provides input to motor areas in the cerebral cortex, and in this way it helps plan and initiate voluntary activity. Certain regions of the cerebellum store implicit memories (unconscious memories for perceptual and motor skills, such as swimming and skating).

The size and shape of the cerebellum vary among the vertebrate classes (FIG. 42-6). Development of the cerebellum is roughly correlated with the extent and complexity of muscular activity, reflecting the principle that the relative size of a brain part correlates with its importance to the behavior of the species. The cerebellum is not well developed in jawless fishes, amphibians, and non-avian reptiles. In jawed fishes, birds, and mammals, the cerebellum is large and well developed.

Injury or removal of the cerebellum results in impaired muscle coordination. A bird without a cerebellum cannot fly, and its wings thrash about jerkily. When the human cerebellum is injured by a blow or by disease, muscular movements are uncoordinated. Any activity requiring delicate coordination, such as typing a text on your cell phone, becomes very difficult if not impossible.

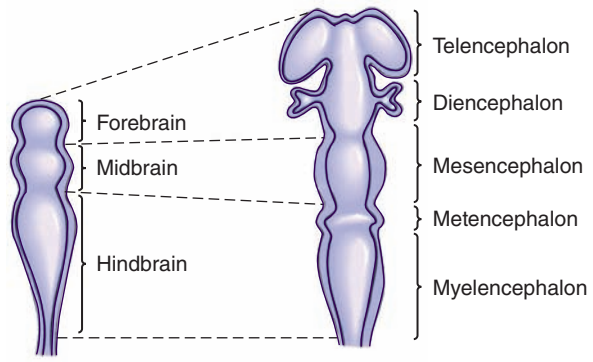

Figure 42-5 Early development of the vertebrate nervous system

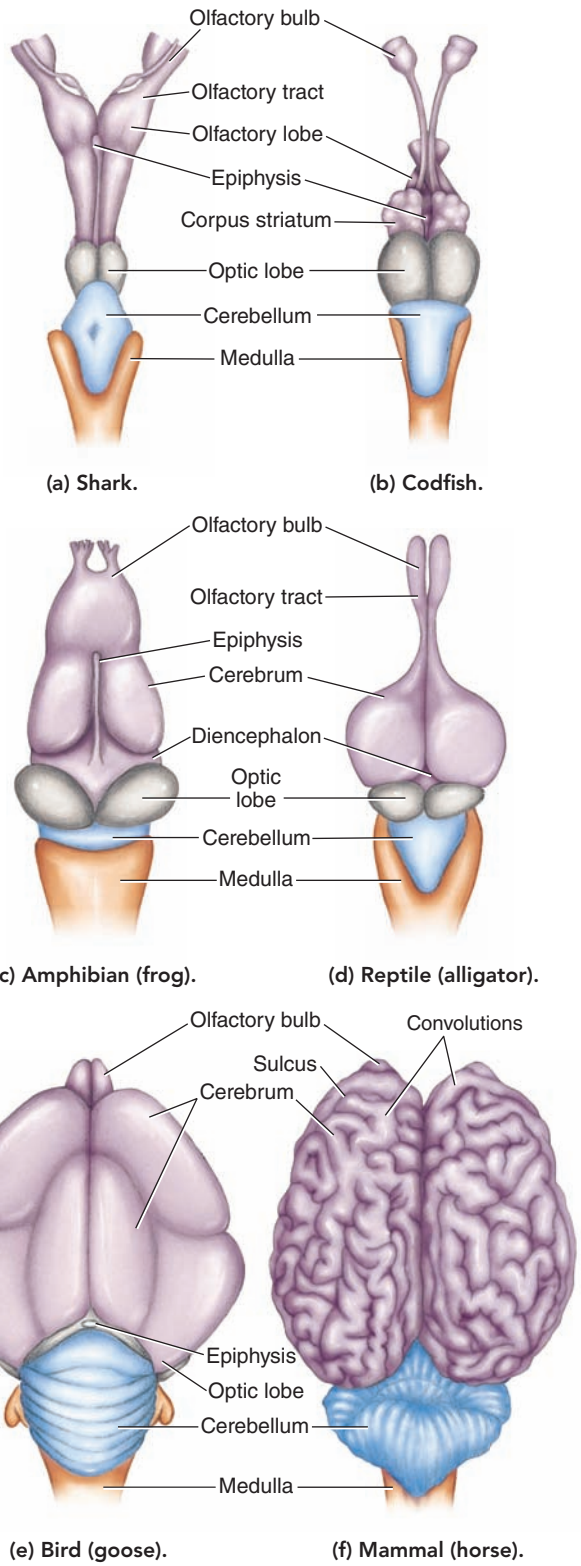
Early in the development of the vertebrate embryo, the anterior end of the neural tube differentiates into the hindbrain, midbrain, and forebrain. These primary divisions subdivide and eventually give rise to specific structures of the adult brain.

In mammals the pons contains a thick bundle of fibers that transmits information between the two sides of the cerebellum. The pons also serves as a bridge that connects the medulla and cerebellum with other regions of the brain. The pons contains centers that help regulate respiration and nuclei that relay impulses from the cerebrum to the cerebellum. Recall from Chapter 41 that a **nucleus** is a group of cell bodies within the CNS.

The midbrain is prominent in fishes and amphibians

In fishes and amphibians, the **midbrain**, or *mesencephalon*, is the most prominent part of the brain and serves as the main association area. It receives incoming sensory information, integrates it, and sends decisions to appropriate motor nerves. The dorsal portion of the midbrain is differentiated to some extent. For example, the optic lobes are specialized for visual interpretations.

Table 42-1 Differentiation of CNS Structures



Early Embryonic Divisions	Subdivisions	Derivatives in Adult	Cavity
BRAIN			
Forebrain	Telencephalon	Cerebrum	Lateral ventricles (first and second ventricles)
	Diencephalon	Thalamus, hypothalamus, epiphysis (pineal body)	Third ventricle
Midbrain	Mesencephalon	Optic lobes in fish and amphibians; superior and inferior colliculi in mammals	Cerebral aqueduct
Hindbrain	Metencephalon	Cerebellum, pons	
	Myelencephalon	Medulla	Fourth ventricle
SPINAL CORD		Spinal cord	Central canal

Key Point

Although different parts of the brain are specialized in various vertebrate groups, there is an evolutionary trend toward larger size and greater complexity of the cerebrum and cerebellum.

In reptiles (including birds) and mammals, many functions of the optic lobes are assumed by the cerebrum, which develops from the forebrain. In mammals the midbrain consists of the *superior colliculi*, centers for visual reflexes such as pupil constriction, and the *inferior colliculi*, centers for certain auditory reflexes. The inferior colliculi are major integration centers for incoming auditory information. The mammalian midbrain also contains a center (the *red nucleus*) that helps maintain muscle tone and posture.

The forebrain gives rise to the thalamus, hypothalamus, and cerebrum

The **forebrain** subdivides to form the *telencephalon* and *diencephalon*. The *diencephalon* gives rise to the thalamus and hypothalamus.

In all vertebrate classes, the **thalamus** is a relay center for motor and sensory messages. In mammals all sensory messages except those from the olfactory receptors are delivered to the thalamus, where they are integrated before they are relayed to the sensory areas of the cerebrum.

The **hypothalamus**, which lies below the thalamus, forms the floor of the third ventricle. The hypothalamus is a major coordinating center for regulating autonomic and somatic responses. It integrates incoming information and provides input to centers in the medulla and spinal cord that regulate activities such as heart rate, respiration, and digestive system function. In birds and mammals, the hypothalamus controls body temperature. It also contains olfactory centers, regulates appetite and water balance, and is important in emotional and sexual responses. As we discuss in Chapter 49, the hypothalamus links the nervous and endocrine systems and produces certain hormones.

The *telencephalon* gives rise to the **cerebrum**. The *lateral ventricles* (also called the first and second ventricles) lie within the cerebrum. Each lateral ventricle connects with the third ventricle (within the diencephalon) by way of a channel. In most vertebrate groups, the telencephalon also gives rise to the **olfactory bulbs**. These structures are important in the chemical sense of smell, which is the dominant sense in most aquatic and terrestrial vertebrates. In fact, much of brain development in vertebrates appears to focus on integrating olfactory information.

Figure 42-6 Evolution of the vertebrate brain

Comparison of the brains of members of six vertebrate groups reveals basic similarities and evolutionary trends. (Brains are not drawn to scale.) Note that different parts of the brain are specialized in the various groups. The large olfactory lobes in the shark brain **(a)** are essential to this predator's highly developed sense of smell. **(b–f)** During the course of evolution, the cerebrum and cerebellum have become larger and more complex. In mammals **(f)**, the cerebrum is the most prominent part of the brain; the cerebral cortex, the thin outer layer of the cerebrum, is highly convoluted (folded), which greatly increases its surface area. The diencephalon and part of the brain stem are covered by the large cerebrum.

PREDICT Imagine that humans continue to thrive during the next several thousand years. Predict evolutionary changes that might occur in the human brain.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

In fishes and amphibians, a large part of the cerebrum is devoted to this function. In birds, centers in the cerebrum control eating, flying, singing, and other action patterns.

In most vertebrates the cerebrum is divided into right and left *cerebral hemispheres*. Most of the cerebrum is made of **white matter**, which consists mainly of myelinated axons that connect various parts of the brain. In mammals and in the majority of reptiles, the **cerebral cortex** makes up the outer portion of the cerebrum. The cerebral cortex is composed of **gray matter**, which consists of cell bodies, dendrites, and unmyelinated axons.

Certain reptiles and all mammals have a type of cerebral cortex called the *neocortex*. Most of the neocortex consists of *association areas*, regions that link sensory and motor functions and that are responsible for higher functions, such as learning and reasoning. The neocortex is very extensive in mammals, making up the bulk of the cerebrum. In humans most of the cerebral cortex is neocortex that consists of six distinct cell layers. Part of the limbic system (discussed later in this chapter) has only three layers. This region is referred to as the *paleocortex* (ancient cortex).

In mammals the cerebrum is the most prominent part of the brain. During embryonic development, it expands and grows backward, covering many other brain structures. The surface area of the human cerebral cortex is greatly expanded by numerous folds called **convolutions**. The furrows between them are called **sulci** (sing., *sulcus*) if shallow and **fissures** if deep. In mammals the cerebrum is responsible for numerous functions performed by other parts of the brain in other vertebrates. In addition, the mammalian cerebrum has highly developed association functions.

CHECKPOINT 42.3

- What structures are derived from the vertebrate embryonic forebrain? the hindbrain? What are the functions of these structures?
- Compare the brain of a mammal with the brain of an amphibian.

42.4 The Human Central Nervous System

LEARNING OBJECTIVES

5 Describe the structure and functions of the human spinal cord.
6 Describe the structure and functions of the human cerebrum.
7 Summarize the sleep–wake cycle and contrast rapid eye movement (REM) sleep with non-REM sleep.
8 Describe the actions of the limbic system; include the role of the amygdala in emotional expression and in response to danger.
9 Summarize how the brain processes information; include a description of synaptic plasticity and the neurobiological changes that take place during learning.

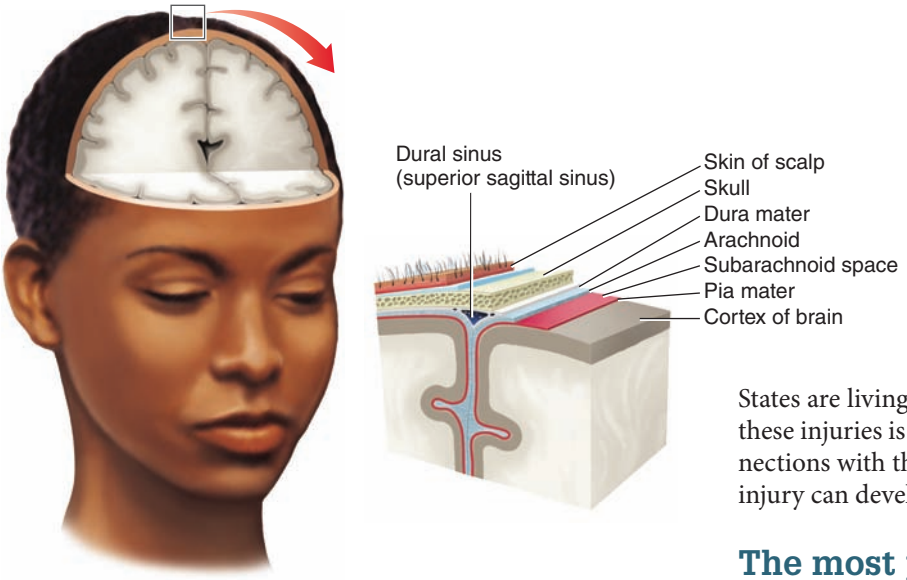
The soft, fragile human brain consists of billions of neurons that are connected by trillions of synapses. This 3-pound mass of tissue perceives and processes information and determines effective responses more capably and efficiently than the most sophisticated computer.

The brain and spinal cord are well protected. Encased within bone, they are covered by three layers of connective tissue, collectively called the **meninges**. The three meningeal layers are the tough, outer **dura mater**; the middle **arachnoid**; and the thin, vascular **pia mater**, which adheres closely to the tissue of the brain and spinal cord (FIG. 42-7). *Meningitis* is a disease in which these coverings become infected and inflamed.

The space between the arachnoid and the pia mater is the subarachnoid space, which contains **cerebrospinal fluid (CSF)**. This shock-absorbing fluid cushions the brain and spinal cord against mechanical injury. It also serves as a medium for exchange of nutrients and waste products between the blood and brain. CSF is produced by special networks of capillaries, collectively called the *choroid plexus*, which extend from the pia mater into the ventricles. After circulating through the ventricles, CSF passes into the subarachnoid space. It is then reabsorbed into large blood sinuses within the dura mater.

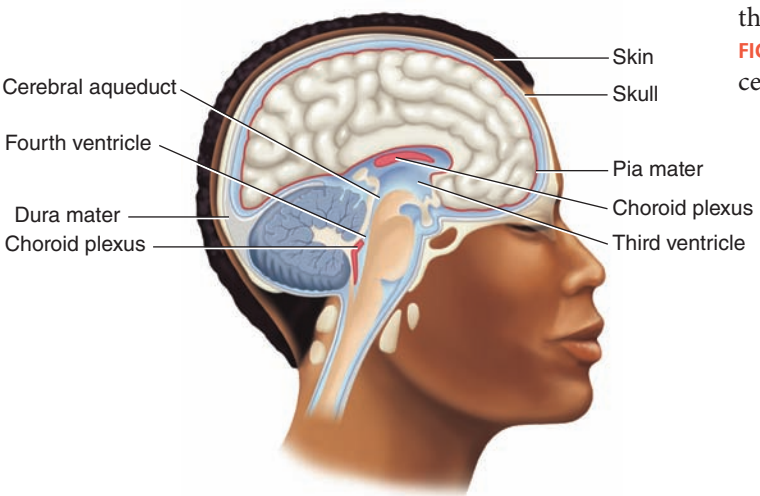
The spinal cord transmits impulses to and from the brain

The tubular **spinal cord** extends from the base of the brain to the level of the second lumbar vertebra. A cross-section view through the spinal cord reveals a small *central canal* surrounded by an area of gray matter shaped a bit like the letter H (FIG. 42-8). The gray matter consists of large masses of cell bodies, dendrites, unmyelinated axons, and glial cells.



The white matter, found outside the gray matter, consists of myelinated axons arranged in bundles called *tracts* or *pathways*. *Ascending tracts* conduct impulses up the cord to the brain. For example, the spinothalamic tracts in the anterior and lateral columns of the white matter conduct pain and temperature information from sensory neurons in the skin. The pyramidal tracts are *descending tracts* that convey impulses from the cerebrum to motor nerves at various levels in the cord. We describe the spinal nerves later in this chapter.

In addition to transmitting impulses to and from the brain, the spinal cord controls many reflex activities. A **reflex action** is a relatively simple, involuntary motor response to a stimulus. Although most reflex actions are more complex, let us consider a *withdrawal reflex*, in which a neural circuit consisting of three types of neurons carries out a response to a stimulus (FIG. 42-9). Suppose that your hand accidentally touches a flame. Almost instantly, and even before you become consciously aware of what has happened, you jerk your hand away.



The instant your skin contacts the flame, a sensory neuron transmits a message from pain receptors in the skin to the spinal cord. Within the spinal cord, a sensory neuron transmits the signal to an interneuron. The interneuron integrates the information and signals an appropriate efferent (motor) neuron, which conducts the information to groups of muscles. The muscles respond by contracting, jerking the hand away from the flame.

(a) Frontal section through the superior part of the brain. Note the dural sinus, a blood sinus, between two layers of the dura mater. Blood leaving the brain flows into such sinuses and then circulates to the large jugular veins in the neck.

(b) Sagittal section through the brain. The CSF, which cushions the brain and spinal cord, is produced by the choroid plexi in the walls of the ventricles. This fluid circulates through the ventricles and subarachnoid space. It is continuously produced and then reabsorbed into the blood of the dural sinuses.

Figure 42-7 Protection of the brain and spinal cord
The CNS is well protected by the skull and meninges and by cerebrospinal fluid (CSF).

Actually, many neurons in sensory, association, and motor nerves participate in such a reflex action. Generally, we are not even consciously aware that all these responding muscles exist. In summary, signals are transmitted through a withdrawal reflex in the following sequence:

reception by sensory receptor in skin → sensory neuron transmits signal to CNS → interneuron in CNS integrates information → efferent (motor) neuron transmits signal to muscle → muscle contracts

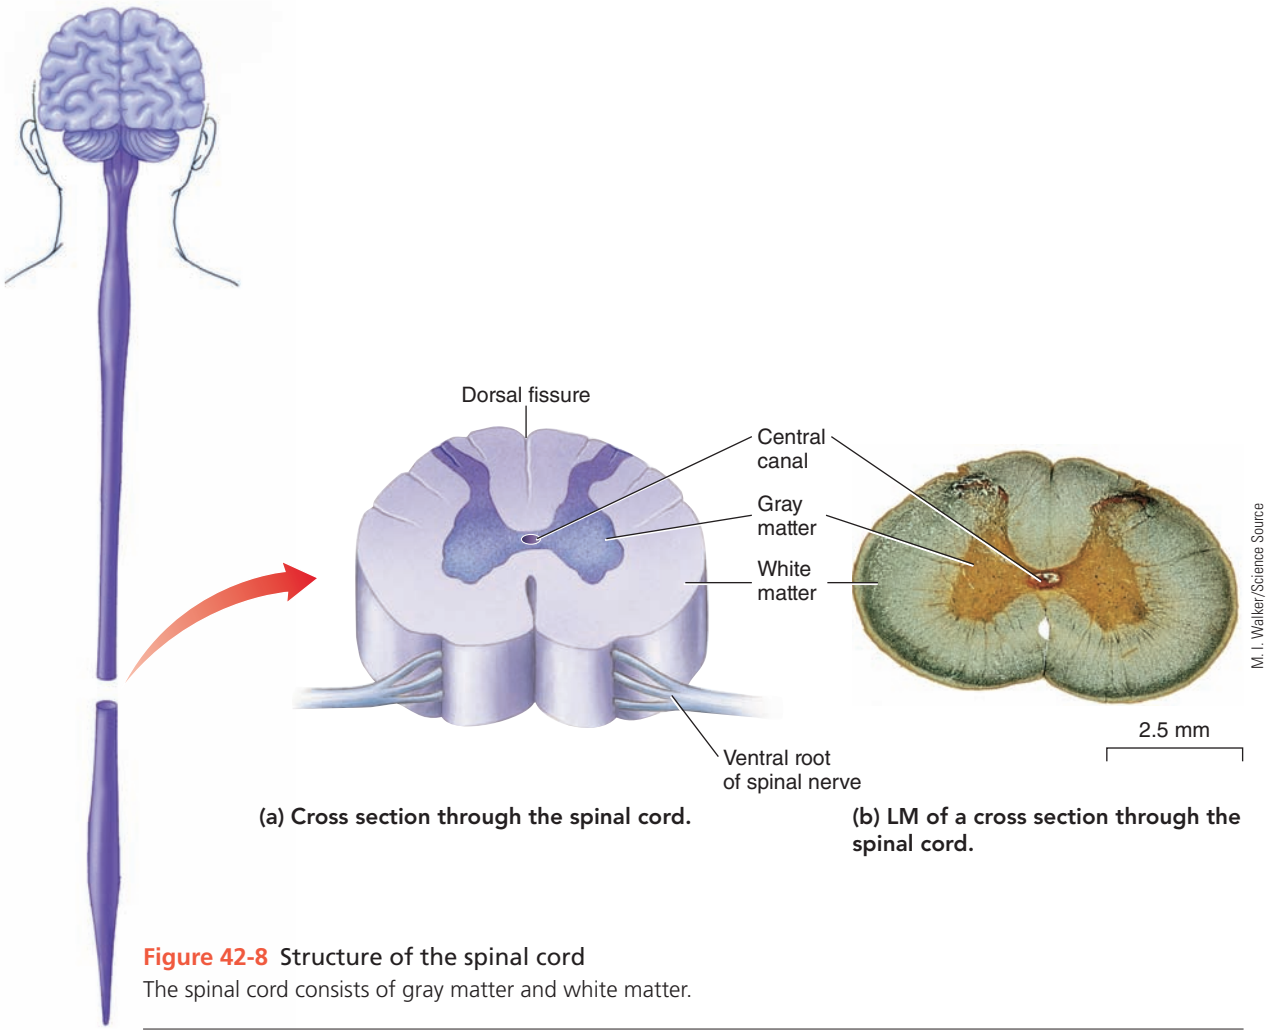
At the same time that the reflex pathway is activated, a message is sent up the spinal cord to the conscious areas of the brain. As you pull your hand away from the flame, you become aware of what has happened and feel the pain. This awareness, however, is not part of the reflex response.

The spinal cord has some plasticity and is capable of training. For example, sensory feedback from exercise increases the strength of neural connections in the spinal cord. Approximately 300,000 people in the United States are living with spinal cord injury.[1] The leading cause of these injuries is motor vehicle crashes. When descending connections with the brain are intact, some victims of spinal cord injury can develop at least some limited ability to walk again.

The most prominent part of the human brain is the cerebrum

The structure and functions of the main parts of the human brain are summarized in TABLE 42-2, and major regions of the brain are illustrated in FIGURE 42-10 on page 892 and FIGURE 42-11 on page 893. As in other mammals, the human cerebral cortex consists of right and left *cerebral hemispheres*.

Specific areas of the cerebrum are specialized for performing specific functions The cerebral cortex is functionally divided into three areas: (1) *sensory areas* receive incoming signals from the sense organs; (2) *motor areas* control voluntary movement; and (3) **association areas** link the sensory and motor areas and are responsible for thought, learning, language, memory, judgment, decision making, and personality. You can see positron-emission tomography (PET) scans showing some functional areas of the cerebrum in FIGURE 42-12 on page 894.



Investigators have mapped the cerebral cortex, locating the areas responsible for different functions. The **occipital lobes** contain the visual centers. Stimulation of these areas, even by a blow on the back of the head, causes the sensation of light; their removal causes blindness. The centers for hearing are located in the **temporal lobes** of the brain above the ear; stimulation by a blow causes a sensation of noise. Removal of both auditory areas causes deafness. Removal of one does not cause deafness in one ear; instead, it produces a decrease in the auditory acuity of both ears. Association areas in the temporal lobes help us identify incoming sound stimuli.

A groove called the *central sulcus* crosses the top of each hemisphere from medial to lateral edge. This groove partially

Table 42-2 The Human Brain

Structure	Description	Function
BRAIN STEM		
Medulla	Continuous with spinal cord; primarily made up of nerves passing from spinal cord to rest of brain	Contains vital centers (clusters of neuron cell bodies) that control heartbeat, respiration, and blood pressure; contains centers that control swallowing, coughing, and vomiting
Pons	Forms bulge on anterior surface of brain stem	Connects various parts of brain with one another; contains respiratory and sleep centers
Midbrain	Just above pons	Center for visual and auditory reflexes (e.g., pupil reflex, blinking, and adjusting ear to volume of sound)
THALAMUS	At top of brain stem	Main sensory relay center for conducting information between spinal cord and cerebrum; neurons in thalamus sort and interpret all incoming sensory information (except olfaction) before relaying messages to appropriate neurons in cerebrum
HYPOTHALAMUS	Just below thalamus; pituitary gland is connected to hypothalamus by stalk of neural tissue	Contains centers for control of body temperature, appetite, and fat metabolism; regulates pituitary gland; important in emotional and sexual responses, and in sleep–wake cycle
CEREBELLUM	Second-largest division of brain	Muscle coordination and refinement of movements; muscle tone, posture, and equilibrium; helps plan and initiate voluntary activity; stores implicit memories
CEREBRUM	Largest, most prominent part of human brain; longitudinal fissure divides cerebrum into right and left hemispheres, each divided into frontal, parietal, temporal, and occipital lobes	Center of intellect, memory, judgment, consciousness, and language; also controls sensation and motor functions
Cerebral cortex (outer gray matter)	Arranged into convolutions (folds) that increase surface area; functionally, cerebral cortex is divided into:	
	1. Motor areas	1. Control movement of voluntary muscles
	2. Sensory areas	2. Receive incoming information from eyes, ears, touch receptors, and other sensory receptors
	3. Association areas	3. Centers for intellect, memory, language, and emotion; interpret incoming sensory information
White matter	Consists of myelinated axons of neurons that connect various regions of brain; axons are arranged in bundles (tracts)	Connects the following: 1. Neurons within same hemisphere 2. Right and left hemispheres 3. Cerebrum with other parts of brain and spinal cord

separates the **frontal lobes** from the **parietal lobes**. The frontal lobes have important motor and association areas. The **prefrontal cortex** is an association area in each frontal lobe that is crucial in evaluating information, making decisions, planning, organizing responses, and interpreting incoming sensory information. The *motor areas* in the frontal lobes control the skeletal muscles. The *somatosensory area* in the anterior region of the parietal lobes receives information regarding touch, pressure, heat, cold, and pain from sense organs in the skin. This region also receives information regarding position of the body. Association areas in the parietal lobes are important in helping us pay attention to such incoming information.

The size of the motor area in the brain for any given part of the body is proportional to the complexity of movement involved, not to the amount of muscle. Predictably, areas that control the hands and face are relatively large (FIG. 42-13 on page 895). A similar relationship exists between the sensory area and the sensitivity of the region of the skin from which it receives impulses. These relationships are visually represented as the sensory homunculus ("little person") and the motor homunculus in Figure 42-13.

Neural fibers in the brain cross so that one side of the brain controls the opposite side of the body. Also, as can be seen in Figure 42-13b, the uppermost part of the cortex controls the lower limbs of the body.

When all the areas of known function are plotted, they cover almost all the rat's cortex, a large part of the dog's, a moderate amount of the monkey's, and only a small part of the total surface of the human cortex. The remaining cortical areas are association areas. Somehow the association regions integrate the diverse impulses reaching the brain so that an appropriate response is made. When disease or accident destroys the functioning of one or more association areas, the ability to recognize certain kinds of symbols may be lost. For example, the names of objects may be forgotten, although their functions are remembered and understood.

The two cerebral hemispheres are specialized for certain functions. As will be discussed later in this chapter, the left hemisphere is specialized for language functions. This part of the

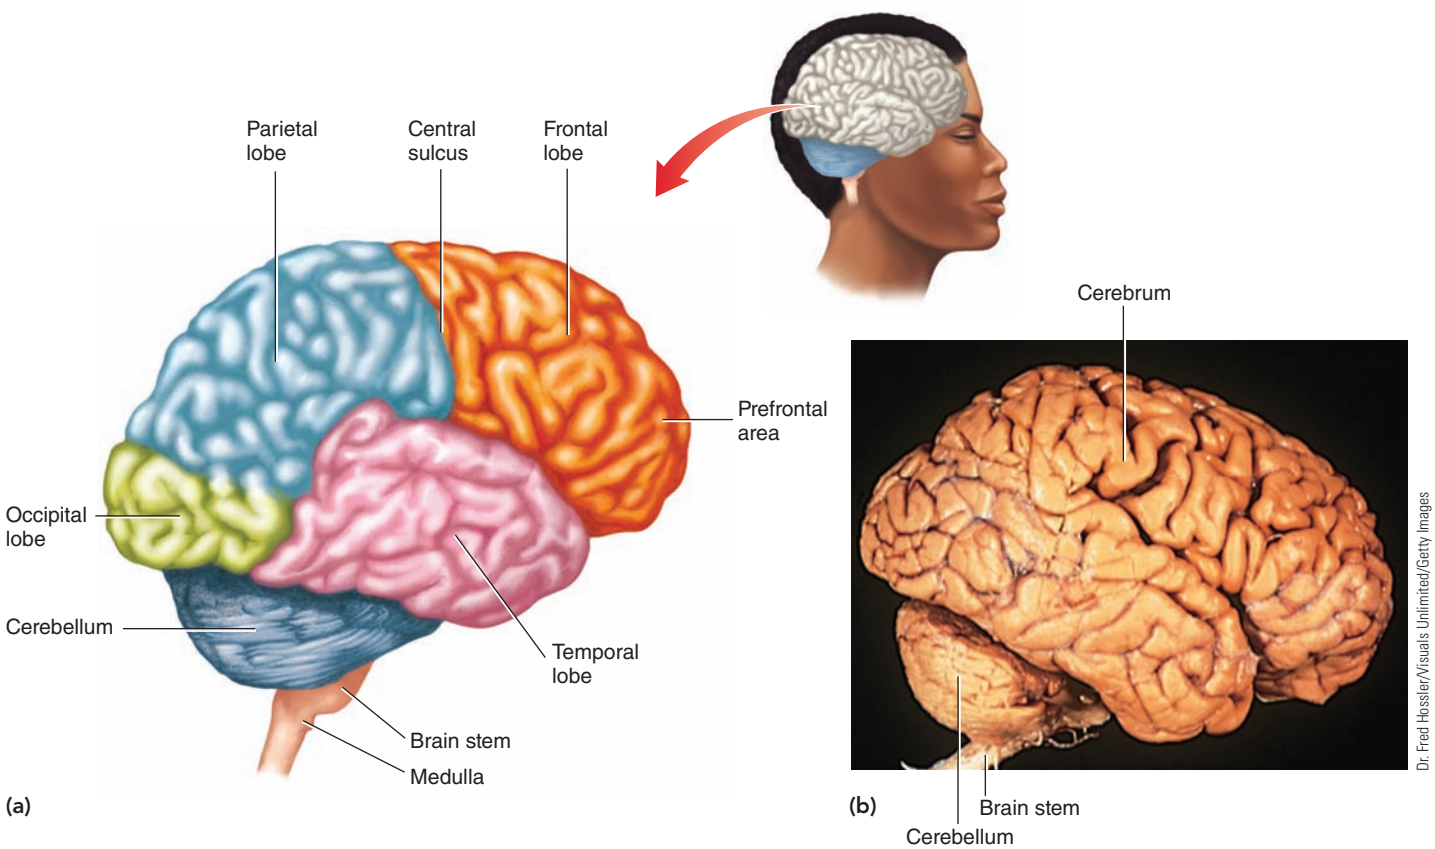

Figure 42-10 The human brain

Human brain, lateral view. Each cerebral hemisphere is divided into four major lobes. The diencephalon and part of the brain stem are covered by the cerebrum. Compare the diagram **(a)** with the photograph of a human brain **(b)**.

brain is also specialized for logical decision making and retrieval of facts. The right hemisphere is specialized for emotional processing and for visual–spatial tasks such as recognizing faces.

Axons in the white matter of the cerebrum connect parts of the brain

The white matter of the cerebrum lies beneath the cerebral cortex. Nerve fibers of the white matter connect the cortical areas with one another and with other parts of the nervous system (see Table 42-2). A large band of white matter, the **corpus callosum**, connects the right and left hemispheres (see Fig. 42-11).

Deep within the white matter of the cerebrum lie the *basal ganglia*, paired groups of nuclei (gray matter). These nuclei play an important role in coordinating movement. The basal ganglia send signals to and receive signals from the *substantia nigra* in the midbrain. Neurons from the substantia nigra that project (extend) to the basal ganglia produce **dopamine**, a neurotransmitter that helps balance inhibition and excitation of neurons involved in motor function. (See the discussion of neurotransmitters in Chapter 41.) Other neurons from the substantia nigra signal nuclei in the thalamus, which in turn relay information to the motor cortex. Neurons from the substantia nigra that signal the thalamus release the neurotransmitter **gamma-aminobutyric acid (GABA)**. Just how these areas work together to coordinate motor function is not yet fully understood.

Nearly one million people in the United States alone are affected by Parkinson's disease, a progressive neurological disorder that affects movement. In this disease dopamine-producing neurons die over time, decreasing the available dopamine. This decrease causes a progressive decrease in effective neural messages regarding motor responses. The resulting symptoms include tremors in the limbs and face, a slowing of movement, poor muscle coordination, and impaired walking and balance. Several medications, including a dopamine precursor (l-DOPA), are used to treat symptoms of the disorder.

The body follows a circadian rhythm of sleep and wakefulness

Researchers have determined that many animals, including nematodes and fruit flies, sleep. Predators typically sleep for longer periods than animals that are preyed upon. For example, rabbits sleep only for a few minutes at a time. In some birds and aquatic mammals, one cerebral hemisphere sleeps at a time, allowing the animal to remain aware of its environment. Sleeping with one hemisphere permits eared seals and whales to move to the surface to breathe without awakening.

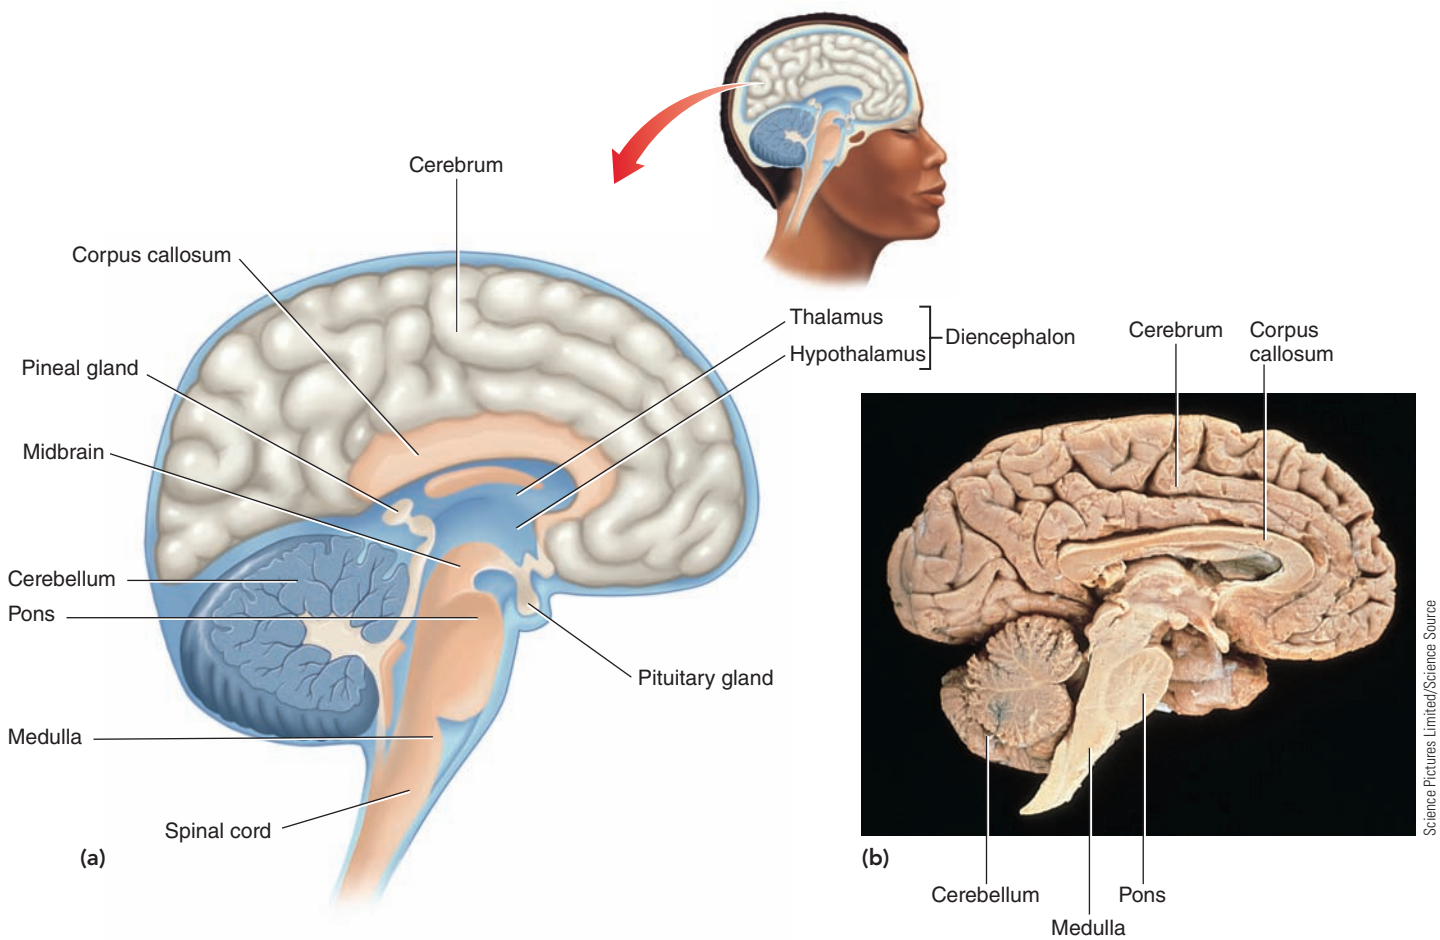

Figure 42-11 Midsagittal section through the human brain

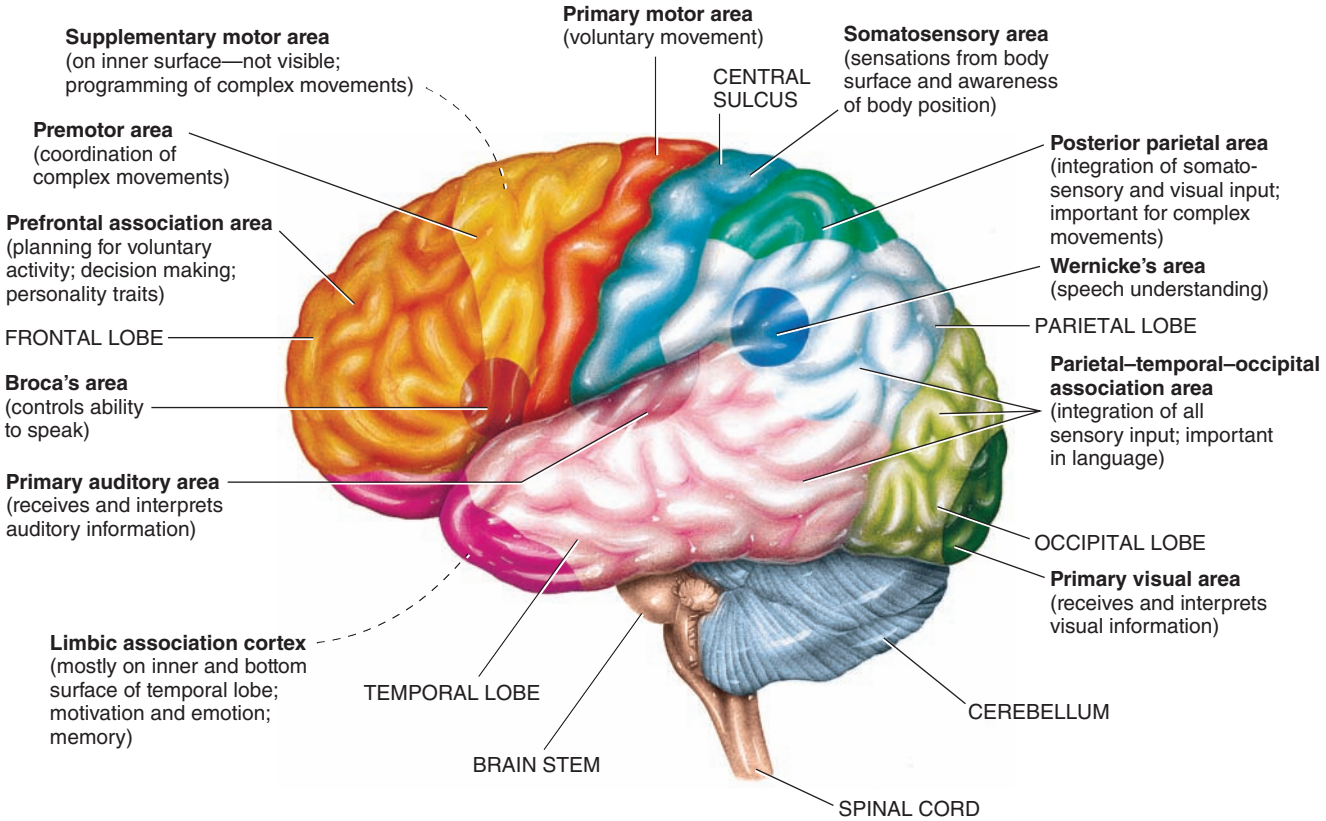
Half of the brain has been cut away, exposing structures normally covered by the cerebrum. Compare the diagram **(a)** with the photograph of a human brain **(b)**.

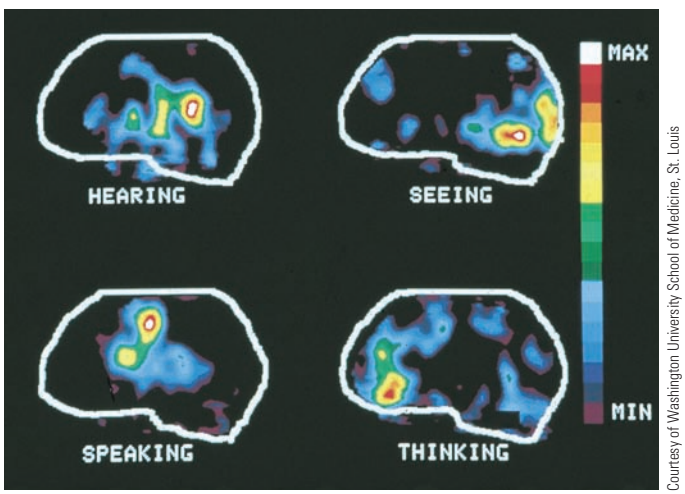
Humans and many other animals follow a 24-hour **circadian** (daily) rhythm of sleeping and then being awake. When we are awake, we are typically aware of the external world and of ourselves, including our thoughts, perceptions, and emotions. In contrast, when we are asleep, the body receives messages from the environment, but we are not aware of them.

The **suprachiasmatic nucleus**, the most important of the body's biological clocks, is located in the hypothalamus. The suprachiasmatic nucleus receives information about the duration of light and dark from the retina of the eye and transmits information to other nuclei and neurons. The suprachiasmatic nucleus signals the **pineal gland** about light and dark. This endocrine gland is located in the midline of the diencephalon.



The pineal gland produces **melatonin**, a hormone that plays a role in regulating the sleep–wake cycle. The pineal gland secretes up to 10 times as much melatonin during darkness as during daylight. *Jet lag*, the state of fatigue and decreased physical and mental performance we experience when we fly to a different time zone, occurs because the body is no longer synchronized with its light–dark cycle. Some individuals take melatonin supplements to promote sleep, but their effectiveness has not been proven.

The hypothalamus, thalamus, and brain stem are all involved in regulating the sleep–wake cycle. Neurons in these regions secrete several neurotransmitters important in regulating sleep, including acetylcholine, norepinephrine, and serotonin. The **reticular activating system (RAS)** is a neural pathway within the brain stem and thalamus. The RAS receives messages from neurons in the spinal cord and from many other parts of the nervous system, and it communicates with the cerebral cortex by complex neural circuits. When certain neurons of the RAS bombard the cerebral cortex with stimuli, an individual feels alert and can focus on specific thoughts. If the RAS is severely damaged, the person may pass into a deep, permanent coma.



After many hours of activity, the sleep–wake cycle may be affected by fatigue of the RAS. Sleep centers are then activated, and their neurons release **serotonin**. During *REM sleep*, a stage of sleep characterized by rapid eye movement, neurons in the RAS stimulate heightened activity in certain regions of the brain. After sufficient rest, the inhibitory neurons of the sleep centers become less excitable, and the excitatory neurons of the RAS become more excitable.

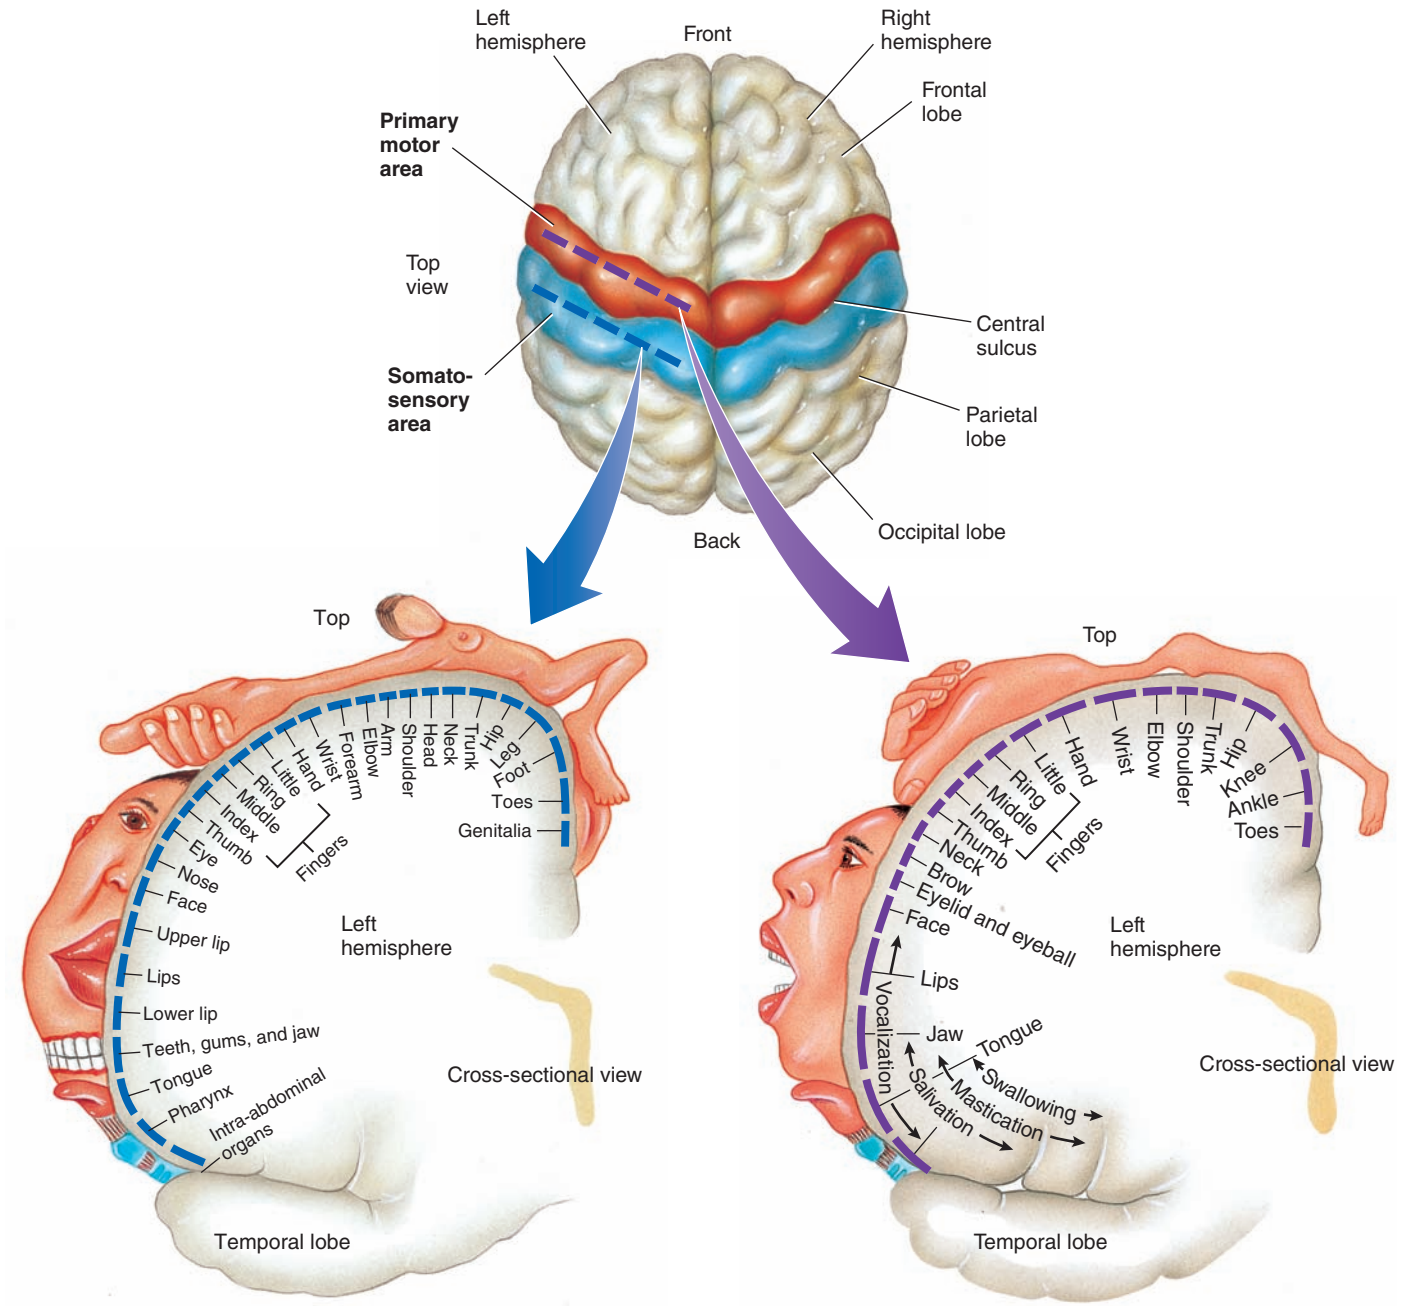
(a) Various areas of the cerebral cortex are responsible for specific types of neural processing. (Lateral view of the brain.)

Courtesy of Washington University School of Medicine, St. Louis

(b) Specific areas of the brain "light up" on positron-emission tomography (PET) scans as an individual performs various tasks. When a specific region of the brain becomes more active, more blood flows to that area. PET scans detect the magnitude of blood flow. Thus, PET scans are pictures of the brain at work, performing specific tasks. The color scale at the right indicates progressively greater activity, from the *purple* color at the bottom to the *white* at the top, which indicates maximum activity.

Figure 42-12 Functional areas of the cerebrum

Specific types of activity are associated with certain brain wave patterns Brain activity can be studied by measuring and recording the electrical potentials, or "brain waves," generated by thousands of active neurons in various parts of the brain. This electrical activity can be recorded by a device known as an *electroencephalograph*. A recording of this electrical activity, called an *electroencephalogram (EEG)*, can be obtained by taping a set of electrodes to standard regions of the scalp and measuring the activity of the cerebral cortex (FIG. 42-14). The EEG shows that the brain is continuously active.



Certain patterns of brain waves are elicited by specific types of activity. For example, when you are resting quietly with eyes closed, your brain emits *alpha rhythm patterns*. In contrast, as you are reading this biology text, your brain is emitting *beta rhythm patterns*, which have a fast-frequency rhythm. Beta rhythm patterns are characteristic of heightened mental activity, such as information processing. During certain stages of sleep, the brain emits slow, high-amplitude *theta waves* and *delta waves*.

Certain brain conditions and diseases change the pattern of brain waves. Individuals with epilepsy, for example, exhibit a recognizable, abnormal wave pattern. The location of a brain tumor or the site of brain damage caused by a blow to the head can sometimes be determined by noting the part of the brain that emits abnormal waves.

Sleep progresses through several stages *Sleep* is an alteration of consciousness during which there is decreased electrical activity in the cerebral cortex and from which a

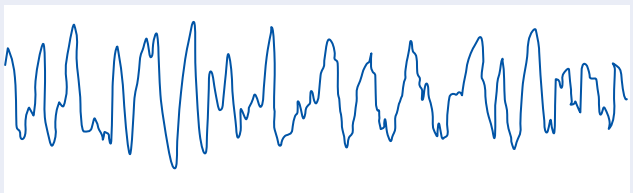
(a) Sensory homunculus. This cross section through the anterior region of the parietal lobe shows the distribution of sensory input to the somatosensory area from various parts of the body. The homunculus is proportioned to reflect the relative amount of cerebral cortex that receives sensory information from each body part.



(b) Motor homunculus. This cross section through the posterior part of the frontal lobe shows which area of the cerebral cortex controls each body part. Note that more of the cerebral cortex is devoted to controlling those body structures capable of skilled, complex movement. The primary motor area is involved in coordinated movement of many muscle groups.

Figure 42-13 Maps of the primary sensory and motor areas

person can be aroused. Based on changes in electrical activity, we can identify four stages of *non-REM* sleep during the first hour of sleep. (Note that *REM* is an acronym for *rapid eye movement*.) The deepest sleep is thought to occur during the fourth stage, when it is difficult to awaken the sleeping person. Slow-frequency, higher-amplitude waves (theta and delta waves) are characteristic of non-REM sleep. This electrical activity is thought to be generated spontaneously by the cerebral cortex when it is not driven by impulses from other parts of the brain. During non-REM sleep, body movement, heart rate, breathing, blood pressure, metabolic rate, and body temperature all decrease.

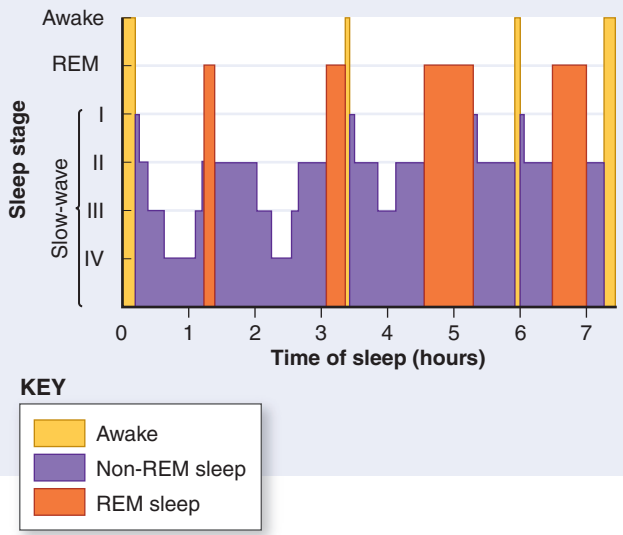
Non-REM sleep, stage IV



REM sleep

Awake, eyes open

(a) EEG recordings show brain wave rhythms during different stages of sleep. During non-REM, stage IV sleep, the brain emits slow-frequency, high-amplitude waves. During REM sleep, the brain emits high-frequency activity similar to that of a person who is awake.

(b) A typical sleep pattern in a young adult.

Figure 42-14 Brain wave activity and cyclical pattern of sleep

Every 90 minutes or so, a sleeping person enters the REM sleep stage for a time. During this stage (about 20% of total sleep time), the eyes move about rapidly beneath the closed but fluttering lids. Brain waves change to a desynchronized pattern. Everyone dreams, especially during REM sleep. PET scans of sleeping subjects indicate that during REM sleep, blood flow in the frontal lobes is reduced. In contrast, blood flow increases in limbic system areas that produce visual scenes and emotion. Body movement, heart rate, breathing, blood pressure, metabolic rate, and body temperature all increase. Increased secretion of the neurotransmitter GABA by certain neurons in the brain and spinal cord inhibits muscle contraction in some large groups of muscles. This action results in a type of temporary paralysis during REM sleep.

Sleep may have several functions Although most animals have a sleep–wake cycle, neurobiologists are not certain why sleep is necessary. One hypothesis holds that sleep allows certain synaptic connections set during the day to reset. Neurons may strengthen their synaptic contacts with certain neurons and weaken their connections with other neurons. In this way, the brain prunes unneeded synaptic contacts. Memories may be consolidated during REM sleep.

Another hypothesis suggests that non-REM sleep may provide time for the brain to restore itself. When a person stays awake for unusually long periods, fatigue and irritability result, and even routine tasks are not performed well. For example, fatigue is a leading cause of automobile accidents. Sleep also provides the body with the opportunity to conserve energy and replace glycogen stores.

The limbic system affects emotional aspects of behavior

The **limbic system**, present in all mammals, influences the emotional aspects of behavior, evaluates rewards, and is important in motivation. The limbic system influences the endocrine system and the autonomic division of the nervous system. It plays a role in sexual behavior, biological rhythms, and autonomic responses. The limbic system includes regions of the cerebrum (parts of the prefrontal cortex, cingulate cortex, temporal lobe, basal ganglia, hippocampus, amygdala, and olfactory bulb), regions of the thalamus, the hypothalamus, several nuclei in the midbrain, and neural pathways that connect these structures (FIG. 42-15).

Emotions are feeling states that we experience both physiologically and cognitively. Humans are born with the capacity to experience and express emotions, including fear, anger, sadness, and happiness. The **amygdala** filters incoming sensory information and interprets it in the context of emotional needs and survival. This part of the limbic system is important in the experience of fear and aggression. When it perceives danger, the amygdala sends information to the hypothalamus and to other parts of the brain. The hypothalamus sends signals to the adrenal glands, which release epinephrine (adrenaline) and norepinephrine (noradrenaline). These fight-or-flight hormones activate the body so that we can respond quickly. A traumatic experience can cause the body to remain hyper-alert (see *Inquiring About: The Neurobiology of Traumatic Experience*).

Structures of the limbic system are essential in an infant's bonding with a consistent, nurturing caregiver during the

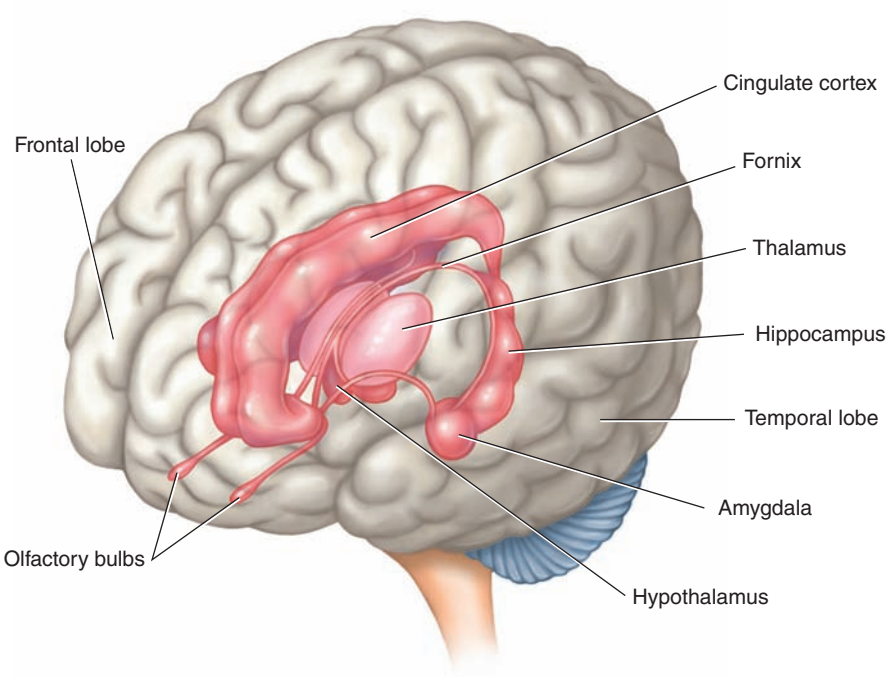

Figure 42-15 The limbic system

The limbic system consists of a ring of forebrain structures that surround the brain stem and are interconnected by complex neural pathways. This system includes the amygdala, hippocampus, parts of the prefrontal cortex, the cingulate cortex, and areas in the thalamus and hypothalamus. The limbic system is important in assessing danger, in emotional expression, sexual behavior, motivation, and learning.

first year of life. The caregiver encourages the baby to express emotions and helps her learn how to regulate them. The quality of early attachment between child and caregiver affects brain development and future behavior. The development of a secure attachment bond between infant and caregiver is the foundation for all future emotional and social connections between the child and other human beings. Attachment also determines how vulnerable (or resilient) the individual will be to traumatic experiences later in life.

Researchers discovered in the 1950s that the limbic system is part of an important motivational system when they implanted electrodes in certain areas of the brains of laboratory animals. They found that a rat quickly learns to press a lever that stimulates *reward centers* in the brain. In fact, the rat will press the lever as many as 5000 times per hour, choosing this self-stimulation over food and water, until it drops from exhaustion.

The brain has reward centers that give us pleasure when we carry out vital activities such as eating, drinking, and sexual activity. These centers are important in experiencing emotion and in motivation. When stimulated, they activate reward circuits that allow us to feel pleasure in response to certain experiences.

The *mesolimbic dopamine pathway*, a major reward circuit, includes two important midbrain areas: the *substantia nigra* and the adjacent *ventral tegmental area*. These areas, which extend into behavioral control centers in the limbic system, contain the largest group of neurons in the brain that release dopamine. Novel stimuli associated with reward or pleasure activate these dopamine neurons. The neurons signal information about surprising events or stimuli that predict rewards. Such signals may motivate us to act when something important is happening. Dopamine pathways are also important in the neurobiology of drug addiction (discussed later in this chapter).

As researchers continue to unravel the mechanisms of dopamine pathways, we may better understand such disorders as attention deficit hyperactivity disorder (ADHD) and schizophrenia, conditions associated with excessive amounts of dopamine and other neurotransmitters in the brain. People with these disorders have difficulty filtering out sensory stimuli. The presence of excess dopamine may drive them to attend to so many sensory stimuli that they have difficulty focusing on the most important stimuli.

Learning and memory involve long-term changes at synapses

Neurobiologists are beginning to understand how the nervous system functions, including how we learn and remember. **Learning** is the process by which we acquire knowledge or skills as a result of experience. For learning to occur, we must be able to remember what we experience. **Memory** is the process of encoding, storing, and retrieving information or learned skills.

To what extent are the brain's functions **hard-wired**, that is, preset? Many areas of the brain once thought to be hard-wired are now known to be flexible and capable of change. Even animals with very simple nervous systems can learn to repeat behaviors associated with reward and to avoid behaviors that cause pain. Such changes in behavior are possible because of **synaptic plasticity**, the ability of synaptic connections to change in response to experience. Such change involves structure and function.

Familiar examples of plasticity in human motor skills include learning to walk, ride a bicycle, or catch a baseball. At first, you were probably clumsy, but with practice your performance became smoother and more precise. For that to happen, changes must occur at synapses in neural circuits. Similarly, the ability to learn languages, solve problems, and perform scientific experiments depends on synaptic plasticity.

What are the mechanisms by which we learn diverse activities, such as skilled movement and the study of biology? Canadian psychologist Donald O. Hebb proposed in 1949 that when two neurons connected by a synapse (i.e., presynaptic and postsynaptic neurons) are active simultaneously, the synapse is strengthened. We can credit Hebb for the axiom "Neurons that fire together, wire together." Hebb's hypotheses have been supported by experimental studies. Experience and practice do affect how neural circuits in our brains organize themselves.

Inquiring About

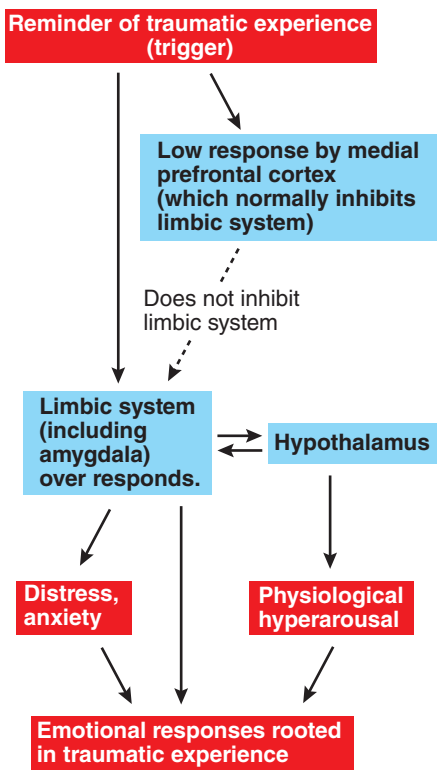
The Neurobiology of Traumatic Experience

Have you ever been involved in a serious automobile accident, or have you been the victim of a violent crime? Are you a combat veteran of Iraq or Afghanistan? Perhaps you are a survivor of a natural disaster, such as a hurricane or earthquake. Or you may have endured childhood neglect or abuse. If you are a survivor of any of these experiences or of some other terrifying event, you may have experienced the *effects* of trauma. A *traumatic experience* is an event that causes intense fear.

Most of us have strategies for effectively processing *moderately* disturbing experiences. For example, if you were involved in a car accident or were one of the millions of people who watched on television as wounded people were carried away from the scene of a mass shooting, you may have been disturbed by the events you experienced or witnessed. You probably processed what you saw and heard by thinking about it and talking to your friends and family about what happened. You may have dreamed about your experience. As the brain actively reviews and sorts out a disturbing experience, we try to make sense of what happened and we process the memory. The emotional intensity decreases, and we store the memory along with other memories of more ordinary past events. The memory of the uncomfortable experience fades in importance and intensity.

Traumatic events are more difficult to process than moderately disturbing events. If you survived an experience in which you thought you were going to die or be seriously hurt or if you witnessed someone else being wounded or killed, your body's response to real or perceived danger may be very intense. Years later, your body may still be secreting abnormally high amounts of stress hormones and you may remain hyper-alert, your body poised to deal with any new threat.

How does the brain respond in a traumatic experience, and how does the experience affect the brain? When danger threatens, the amygdala sends messages to both the hypothalamus (which signals the autonomic division of the nervous system and the endocrine system) and the cerebral cortex (which allows us to be aware of our experience). The amygdala is programmed to remember the smells, sounds, visual aspects, and sensations that are part of the experience. Until the memories of the experience are fully processed, similar smells, sounds, sights, and sensations remind us of the traumatic event and trigger the body to prepare for danger. The traumatized individual typically experiences fear and anxiety.



Because they are so overwhelming, traumatic memories are very difficult to process. They cause us so much discomfort and anxiety that we tend to avoid them rather than intentionally focus on them and sort them out. As a result, traumatic memories stay "stuck" in the limbic system. When triggered, the experience may be replayed with its original emotional intensity (a flashback). Some trauma survivors develop post-traumatic stress disorder (PTSD), a condition in which they experience (1) intrusive thoughts, images, sensory experiences, memories, and dreams; (2) an urge to avoid reminders of the traumatic event; and (3) physiological hyperarousal, a condition in which the body remains on high-alert status, scanning the environment for potential danger.

Several studies have shown an association between prolonged trauma (e.g., severe childhood neglect or abuse) and long-term changes in the brain. These changes include EEG abnormalities; smaller size of certain regions of the brain; compromised right brain development (the right brain is specialized for processing information related to emotion, social interaction, and physiological states); differences in neural circuits connecting cortical and subcortical areas (which can decrease the individual's sense of self and lead to poor connections with other people); abnormal concentrations of certain neurotransmitters, which affect mood and the ability to inhibit inappropriate behavior; inappropriate modulation of the limbic system, in which its responses are exaggerated; and long-term changes in the sympathetic nervous system and endocrine response to stress, including a faster, more intense response to stress.

Neuroimaging studies have demonstrated changes in brain function, including over-response by the amygdala and decreased response by the medial prefrontal cortex (which normally inhibits the amygdala). When the amygdala over responds, the individual experiences anxiety, distress, and physiological hyperarousal. These physiological states can lead to intense emotional responses that are rooted in the traumatic experience.

Broca's area, a region in the posterior part of the left frontal cortex, is also affected by trauma. Broca's area is critically important in generating words and thus in expressing language (see Fig. 42-12). Researchers have shown that when subjects are exposed to accounts of their traumatic experiences, activity in Broca's area decreases. This deactivation appears to be the physiological basis for the difficulty that trauma survivors have describing their experience in words. Trauma survivors have described a state of "speechless terror" that they experience during flashbacks of traumatic experiences. Without words, it is difficult to process and resolve a traumatic experience.

Based on many studies, it is clear that traumatic experiences can cause both structural and functional changes in the brain. The exaggerated responses of the amygdala to harmless stimuli perceived as threatening are disconnected from the influence of the prefrontal cortex that would normally modulate the limbic system. Responses generated by the limbic system are rooted in emotion rather than in rationality and judgment (see figure). PTSD can severely affect and limit one's life. Fortunately, this disorder can be resolved with appropriate treatment.

Some limbic system responses to reminders of traumatic experiences.

Learning involves the storage of information and its retrieval **Implicit memory**, also called *procedural memory*, is unconscious memory for perceptual and motor skills, such as running, playing a guitar, or texting a message. Implicit memory is about "how" to do something and involves repeating the behavior until it becomes routine. **Declarative memory**, also called *explicit memory*, involves factual knowledge of people, places, or objects and requires conscious recall of the information. The **hippocampus**, part of the limbic system, is critical in forming and retrieving declarative memories.

How long do you remember? You are constantly bombarded with thousands of bits of sensory information. At this very moment, your eyes are receiving information about the words on this page, the objects around you, and the intensity of the

light in the room. At the same time, you may be hearing a variety of sounds, such as music, your friends talking in the next room, or the hum of an air conditioner. Your olfactory epithelium may sense cologne or the smell of coffee. Maybe you are eating as you read. Sensory receptors in your hands may be receiving information regarding the weight and position of your book or notebook computer. We may hold such sensory information in *immediate memory* for fractions of a second. Most sensory stimuli are not important to remember any longer and are filtered out.

Short-term memory lasts only for seconds or for a few minutes. Typically, we can hold only about seven chunks of information (e.g., seven words or numbers) at a time in short-term memory. Short-term memory lets us recall information for a few minutes. When we look up a phone number, for example, we usually remember it only long enough to call it. If we need the same number an hour later, most of us have to look it up again.

When we select information for **long-term memory**, we must process it. The brain rehearses the material and *encodes* it. We recognize patterns and meaningfully *associate* the stimuli to past experience or knowledge. We practice recalling the information. The hippocampus temporarily holds new information and may integrate various aspects of an experience, including odors, sounds, and other information. The hippocampus helps place our experiences in categories so that they can be stored along with similar memories. We integrate new information with other knowledge already stored in the brain.

Memory consolidation allows memories to be transferred to the cerebral cortex and *stored* for long periods. Consolidation involves expression of genes and protein synthesis, and it depends on new neural connections at synapses. Time (several minutes, hours, or even longer) is required for the brain to *consolidate* a new memory.

If a person suffers a brain concussion, memory of what happened immediately before the incident may be completely lost. This condition is known as *retrograde amnesia*. When the hippocampus is damaged, long-term memory may not be impaired, and the patient may be able to recall information stored in the past. However, new experiences (and the short-term memories of them) can no longer be converted to long-term memories.

Where are memories stored? When large areas of the mammalian cerebral cortex are destroyed, information is lost somewhat in proportion to the extent of lost tissue. No specific area can be labeled the "memory bank." Rather, memories seem to be stored within many areas of the brain. Visual memories, for example, may be stored in the visual centers of the occipital lobes; similarly, auditory memories may be stored in the temporal lobes. Memories are integrated in many areas of the brain, including association areas of the cerebral cortex, amygdala, hippocampus, thalamus, and hypothalamus. *Wernicke's area* in the temporal lobe has been identified as an important association area for complex thought processes. Neurons within the association areas form interconnected pathways that permit complicated information transfer.

Retrieval of information stored in long-term memory is of considerable interest, especially to students! The challenge is to find information when you need it. When you seem to forget something, the problem may be that you have not searched effectively for the memory. Information retrieval can be improved by careful encoding, such as by forming strong associations between items you want to remember. On the other hand, unimportant, unused memories are typically forgotten over time. Forgetting can be useful when it clears the brain of unnecessary information.

Neurobiological changes occur during learning Short-term memory involves changes in the neurotransmitter receptors of postsynaptic neurons. These changes strengthen synaptic connections. The receptors are linked by second messengers (e.g., cyclic AMP) to ion channels in the plasma membrane.

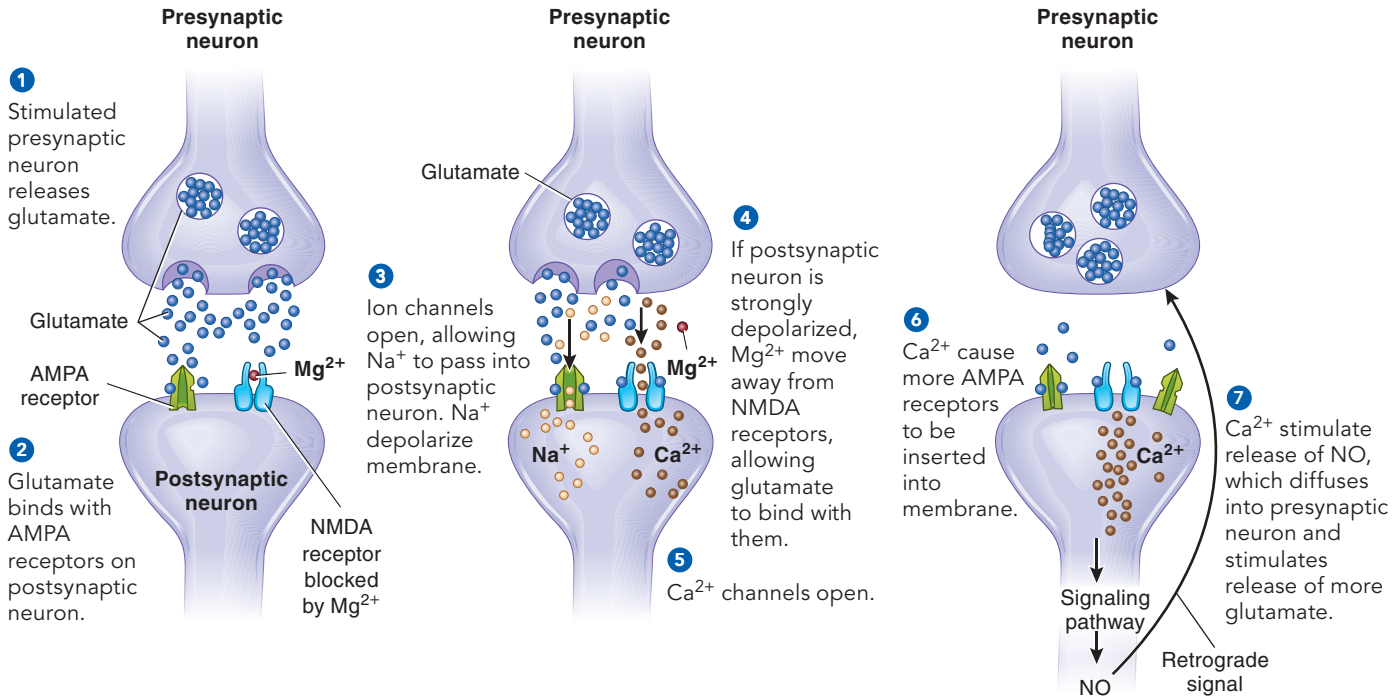
In some types of learning, changes take place in presynaptic terminals or postsynaptic neurons that permanently enhance or inhibit the transmission of impulses. In some cases, specific neurons may become more sensitive than usual to a particular neurotransmitter. Neurons typically transmit action potentials in bursts, and the amount of a neurotransmitter released by each action potential may increase or decrease.

Repeated electrical stimulation of neurons causes a functional change at synapses. When a presynaptic neuron continues to transmit action potentials at a high rate for a minute or longer, there is a long-lasting strengthening of the connection between the presynaptic and postsynaptic neurons. This increased strength of the synaptic connection is known as **long-term potentiation (LTP)**. (*Potentiation* is the process of "strengthening or making more potent.")

In contrast, low-frequency stimulation of neurons results in a long-lasting *decrease* in the strength of their synaptic connections. This decrease is called **long-term depression (LTD)** (not related to the mood disorder). Information storage and forgetting depend on the strengthening and weakening of synaptic connections brought about by LTP and LTD.

Induction of LTP and LTD requires activation of two types of glutamate receptors: *NMDA receptors* and *AMPA receptors*. (Each of these receptors is named for the compound that artificially activates it. NMDA is the acronym for N-methyl-D-aspartate, and AMPA stands for α-amino-3-hydroxyl-5-methyl-4-isoxazole-propionate.) NMDA and AMPA receptors are present on the plasma membranes of postsynaptic neurons. They control the passage of calcium ions into neurons. NMDA receptors respond to the neurotransmitter *glutamate* by opening Ca^{2+} channels. However, when the postsynaptic neuron is at its resting potential, NMDA ion channels are blocked by Mg^{2+}.

A model for the mechanism of LTP is illustrated in FIGURE 42-16. A presynaptic neuron releases glutamate, which binds with AMPA receptors. The postsynaptic neuron becomes depolarized. If depolarization of the postsynaptic neuron is sufficiently strong, Mg^{2+} move away from the NMDA receptors, unblocking them. Glutamate can then bind with these receptors, opening Ca^{2+} channels and letting Ca^{2+} move into the cell. Calcium ions appear to be an important trigger for LTP.



Calcium ions act as second messengers that initiate long-term changes ultimately responsible for LTP. For example, calcium ions activate a Ca^{2+}-dependent second-messenger pathway that results in the insertion of more AMPA receptors in the

Key Point

When glutamate binds to NMDA receptors, Ca^{2+} enter the postsynaptic neuron and activate intracellular signaling systems, leading to changes responsible for LTP.

(a) Activation of AMPA receptors. Glutamate released by a presynaptic neuron binds with AMPA receptors on the postsynaptic neuron. Note that NMDA receptors are blocked by Mg^{2+}.

(b) Activation of NMDA receptors. The combination of strong stimulation and glutamate binding activates NMDA receptors. Calcium channels open, allowing Ca^{2+} to enter the postsynaptic neuron.

(c) Long-term potentiation. Calcium ions activate pathways, leading to changes that are ultimately responsible for LTP.

Figure 42-16 A proposed model for the mechanism of long-term potentiation (LTP)

PREDICT Imagine that Ca^{2+} channels did not open (in step 5). How would this affect synaptic connections and LTP?

postsynaptic membrane. This step is important because additional AMPA receptors increase sensitivity to glutamate. More EPSPs (excitatory postsynaptic potentials) are produced, which strengthens the synapse (i.e., helps maintain the LTP). Recall from Chapter 41 that an EPSP is a change in membrane potential that brings the neuron closer to its threshold level.

Calcium ions also activate a pathway that leads to release of a retrograde signal, a signal that moves backward, from the postsynaptic neuron to the presynaptic neuron. The soluble gas *nitric oxide (NO)* has been identified as the retrograde signal. This signal enhances neurotransmitter release by the presynaptic neuron. Note that this positive feedback loop strengthens the connection between the two neurons.

Long-term memory involves gene expression Gene expression and protein synthesis take place during the process of establishing long-term memory. This process involves slower, but longer-lasting, changes in synaptic connections. Long-term memory depends on activated receptors linked to G proteins (see Chapter 6). Cyclic AMP acts as a second messenger.

A high level of cyclic AMP activates a protein kinase that enters the nucleus, leading to gene activation and protein synthesis. In this process, protein kinase phosphorylates a transcription factor known as *cyclic AMP response element binding protein (CREB)*, which then turns on the transcription process of certain genes. CREB has been shown to be a signaling molecule in the memory pathway in many animals, including fruit flies and mice. The molecules and processes involved in learning and memory have been highly conserved during evolution.

Experience affects development and learning Many studies have demonstrated synaptic plasticity in rats, mice, and other laboratory animals exposed to enriched environments. In contrast with rats housed in standard cages and provided with the basic necessities, those exposed to enriched environments are given toys and other stimulating objects as well as the opportunity to socially interact with other rats. Animals reared in an enriched environment exhibit increased synaptic contacts. They process and remember information more quickly than animals lacking such advantages. Mice exposed to enriched

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

environments develop significantly greater numbers of neurons in the hippocampus and learn mazes faster than control animals.

Early environmental stimulation can also enhance the development of motor areas in the brain. For example, the brains of rats encouraged to exercise become slightly heavier than those of control animals. Characteristic changes occur within the cerebellum, including the development of larger dendrites.

Apparently, during early life certain critical or sensitive periods of nervous system development occur that are influenced by environmental stimuli. For example, when the eyes of young mice first open, neurons in the visual cortex develop large numbers of dendritic spines (structures on which synaptic contact takes place). If the animals are kept in the dark and deprived of visual stimuli, fewer dendritic spines form. If the mice are exposed to light later in life, some new dendritic spines form, but never as many as develop in a mouse reared in a normal environment.

Studies linking the development of the human brain with environmental experience have demonstrated that early stimulation is important for the sensory, motor, intellectual, and social development of children. Such studies argue for the importance of informed parenting as well as for early childhood education programs, such as Head Start. Investigators have also shown that environmental stimulation is needed to maintain the status of the cerebral cortex in later life.

Language involves comprehension and expression

Language is a form of communication in which we use words to symbolize objects and convey ideas. In about 97% of humans, including most individuals who are left-handed, the areas of the brain responsible for language are located in the left hemisphere (see Fig. 42-12). **Wernicke's area**, located in the temporal lobe, is an important center for language comprehension. This area helps us recognize and interpret both spoken and written words. Wernicke's area also helps us formulate the choice and sequence of words and transfers information to **Broca's area**. Located near motor areas in the left frontal lobe, Broca's area controls our ability to speak. This area is also important in language processing and speech comprehension.

CHECKPOINT 42.4

- How is the human CNS protected? What is the function of the cerebrospinal fluid?
- What are two main functions of the vertebrate spinal cord?
- **VISUALIZE** Draw a lateral view of the human brain and label the major structures, including the lobes; write the functions of each lobe.
- **CONNECT** What role does the limbic system play in emotions? in traumatic experience?
- **CONNECT** In what ways does your success on a biology exam depend on synaptic plasticity? (Include the roles of LTP, gene expression, and NMDA receptors in your answer.)

42.5 The Peripheral Nervous System

LEARNING OBJECTIVES

10 Describe the organization of the peripheral nervous system and compare its somatic and autonomic divisions.

11 Contrast the sympathetic and parasympathetic divisions of the autonomic system and give examples of the effects of these systems on specific organs.

The peripheral nervous system consists of the sensory receptors, the nerves that link these receptors with the central nervous system, and the nerves that link the CNS with effectors (muscles and glands). The somatic division of the PNS helps the body respond to changes in the external environment. The nerves and receptors that maintain homeostasis despite internal changes make up the autonomic division.

The somatic division helps the body adjust to the external environment

The **somatic division** of the PNS includes the receptors that react to changes in the external environment, the sensory neurons that inform the CNS of those changes, and the motor neurons that adjust the positions of the skeletal muscles that help maintain the body's posture and balance. In mammals 12 pairs of **cranial nerves** emerge from the brain. They transmit information to the brain from the sensory receptors for smell, sight, hearing, and taste. For example, cranial nerve II, the optic nerve, transmits signals from the retina of the eye to the brain. The cranial nerves transmit information to the brain from general sensory receptors, especially in the head region.

Cranial nerves also transmit orders from the CNS to the voluntary muscles that control movements of the eyes, face, mouth, tongue, pharynx, and larynx. Cranial nerve VII, the facial nerve, transmits signals to the muscles used in facial expression and to the salivary glands.

In humans 31 pairs of **spinal nerves** emerge from the spinal cord. Named for the general region of the vertebral column from which they originate, they include 8 pairs of cervical, 12 pairs of thoracic, 5 pairs of lumbar, 5 pairs of sacral, and 1 pair of coccygeal spinal nerves. The ventral branches of several spinal nerves form tangled networks called *plexi* (sing., *plexus*). Within a plexus, the fibers of a spinal nerve may separate and then regroup with fibers that originated in other spinal nerves. Thus, nerves emerging from a plexus consist of neurons from several different spinal nerves.

The autonomic division regulates the internal environment

The **autonomic division** of the PNS helps maintain homeostasis in the internal environment. For example, it regulates the heart rate and helps maintain a constant body temperature. The autonomic system works automatically and without

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

voluntary input. Its effectors are smooth muscle, cardiac muscle, and glands. Like the somatic system, it is functionally organized into reflex pathways. Receptors within the viscera relay information via afferent nerves to the CNS. The information is integrated at various levels. Then the "decisions" are transmitted along efferent nerves to the appropriate muscles or glands.

Afferent and efferent neurons of the autonomic division lie within cranial and spinal nerves. For example, afferent fibers of cranial nerve X, the *vagus nerve*, transmit signals from many organs of the chest and upper abdomen to the CNS. Its efferent fibers transmit signals from the brain to the heart, stomach, small intestine, and several other organs.

The efferent portion of the autonomic division is subdivided into **sympathetic** and **parasympathetic systems** (TABLE 42-3). Many organs are innervated by both types of nerves. In general, sympathetic and parasympathetic systems have *opposite* effects (FIGS. 42-17 and 42-18). For example, the heart rate is speeded up by messages from sympathetic nerve fibers and slowed by impulses from its parasympathetic nerve fibers. In many cases, sympathetic nerves operate to stimulate organs and to mobilize energy, especially in response to stress, whereas the parasympathetic nerves influence organs to conserve and restore energy, particularly during quiet, calm activities.

Instead of using a single efferent neuron, as in the somatic division, the autonomic division uses a relay of two neurons between the CNS and the effector. The first neuron, called the *preganglionic neuron*, has a cell body and dendrites within the CNS. Its axon, part of a peripheral nerve, ends by synapsing with a *postganglionic neuron*. The dendrites and cell body of the postganglionic neuron are in a ganglion outside the CNS. Its axon terminates near or on the effector.

The sympathetic ganglia are paired, and a chain of them—the *paravertebral sympathetic ganglion chain*—runs on each side of the spinal cord from the neck to the abdomen. Some sympathetic preganglionic neurons do not end in these ganglia but pass on to *collateral ganglia* in the abdomen, close to the aorta and its major branches. Parasympathetic preganglionic neurons synapse with postganglionic neurons in *terminal ganglia* near or within the walls of the organs they innervate.

The sympathetic and parasympathetic systems also differ in the neurotransmitters they release at the synapse with the effector. Both preganglionic and postganglionic parasympathetic neurons secrete acetylcholine. Preganglionic sympathetic neurons also secrete acetylcholine, whereas sympathetic postganglionic neurons release norepinephrine.

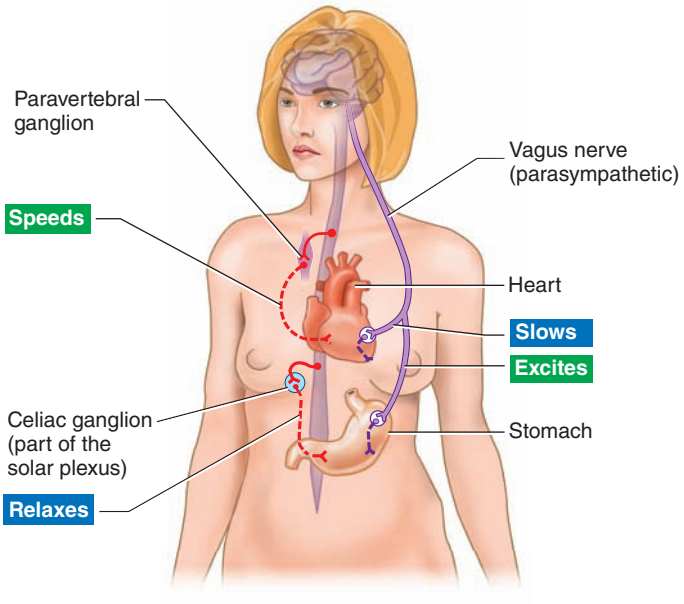

Figure 42-17 Dual innervation of the heart and stomach

Most organs are innervated by both sympathetic and parasympathetic nerves. A sympathetic nerve increases the heart rate, whereas a parasympathetic nerve, the vagus nerve, slows the heartbeat. In contrast, sympathetic nerves slow contractions of the stomach and intestine, whereas the vagus nerve stimulates contractions of these digestive organs. Sympathetic nerves are shown in *red*; postganglionic fibers are shown as *dotted lines*.

The autonomic division got its name from the original idea that it was independent of the CNS, that is, autonomous. Neurobiologists have disproved this concept and shown that the hypothalamus and many other parts of the CNS help regulate the autonomic division. Although the autonomic system usually functions automatically, its activities can be consciously influenced.

Biofeedback provides a person with visual or auditory evidence concerning the status of an autonomic body function. For example, a tone may be sounded when blood pressure reaches a desirable level. Using such techniques, individuals have learned to control autonomic activities such as blood pressure, brain wave pattern, heart rate, and blood glucose level. Even certain abnormal heart rhythms can be consciously modified.

Table 42-3 Comparison of Sympathetic and Parasympathetic Systems

	Sympathetic System	Parasympathetic System
General effect	Prepares body to cope with stressful situations	Restores body to resting state after stressful situation; actively maintains normal body functions
Extent of effect	Widespread throughout body	Localized
Duration of effect	Lasting	Brief
Outflow from CNS	Thoracic and lumbar nerves from spinal cord	Cranial nerves and sacral nerves from spinal cord
Location of ganglia	Chain and collateral ganglia	Terminal ganglia
Neurotransmitters released	Preganglionic: acetylcholine	Preganglionic: acetylcholine
	Postganglionic: norepinephrine (usually)	Postganglionic: acetylcholine

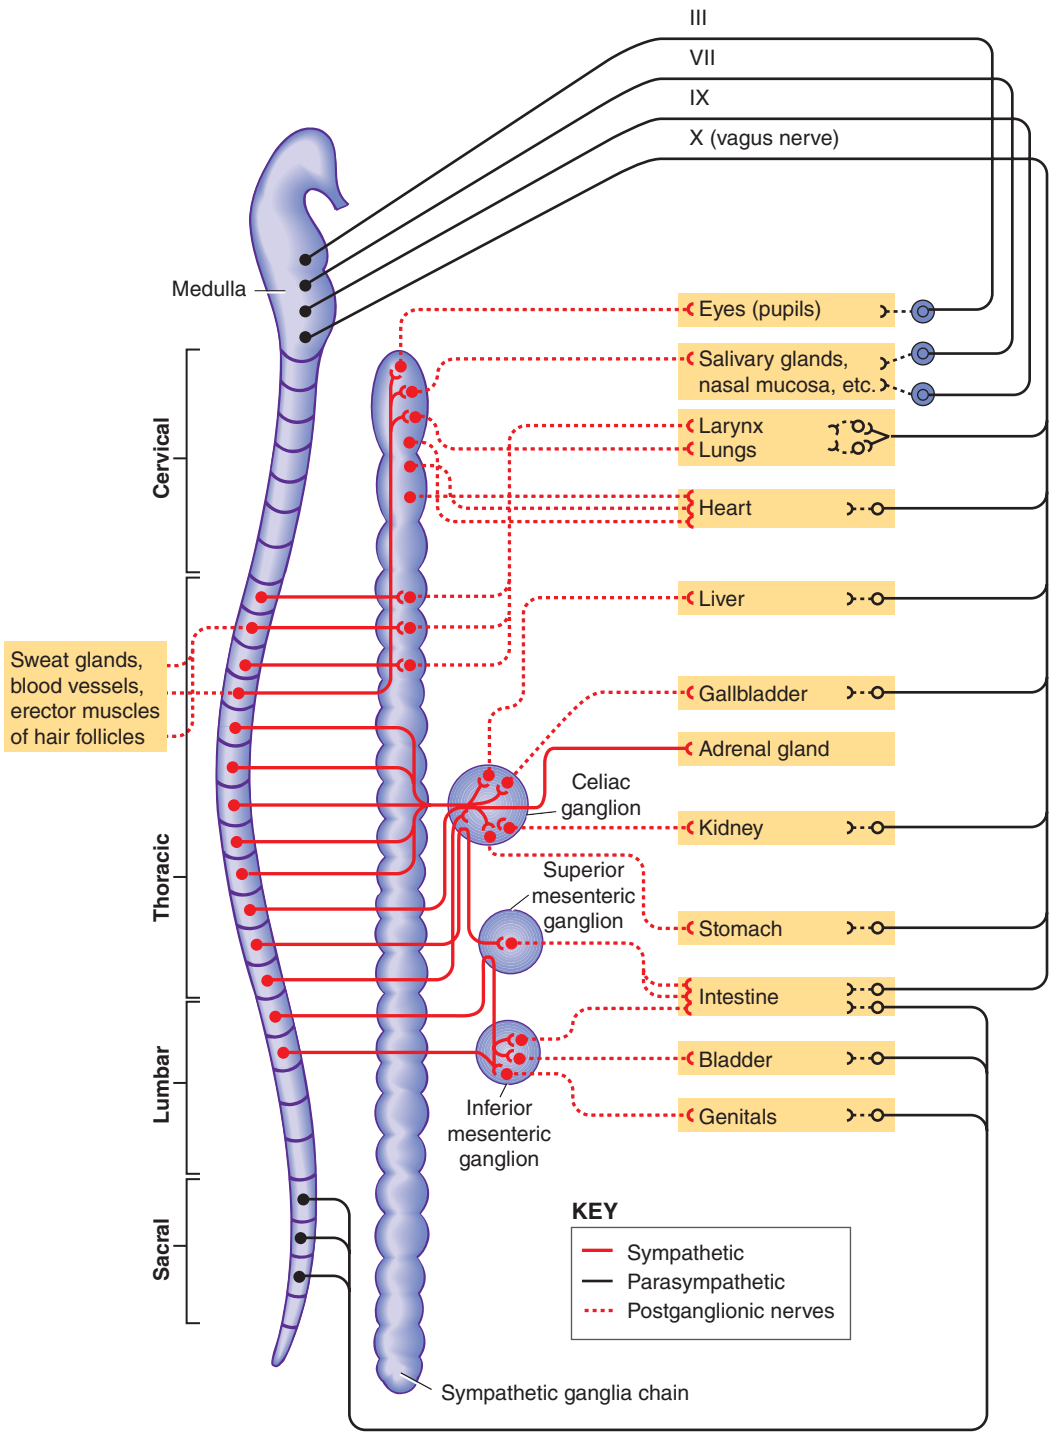

Figure 42-18 The sympathetic and parasympathetic systems

Complex as it appears, this diagram has been greatly simplified. *Red lines* represent sympathetic nerves; *black lines* represent parasympathetic nerves. *Dotted lines* represent postganglionic nerves.

CHECKPOINT 42.5

- Compare the function of the somatic division of the PNS with that of the autonomic division of the PNS.
- Contrast the sympathetic and parasympathetic systems with respect to their general effect and the types of neurotransmitters they release.

42.6 Effects of Drugs on the Nervous System

LEARNING OBJECTIVE

12 Distinguish among psychological dependence, tolerance, and drug addiction, and describe the biological actions and effects on mood of alcohol, antidepressants, barbiturates, anti-anxiety drugs, antipsychotic drugs, opiates, stimulants, hallucinogens, and marijuana.

Copyright 2019 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in

Copyright 2019 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

About 25% of all prescribed drugs are taken to alter psychological conditions, and almost all the commonly abused drugs affect mood. Many act by changing the levels of neurotransmitters within the brain. Changing levels of norepinephrine, serotonin, and dopamine influence mood. Abuse of prescription drugs, particularly painkillers, has become a serious problem, especially among teens and young adults.

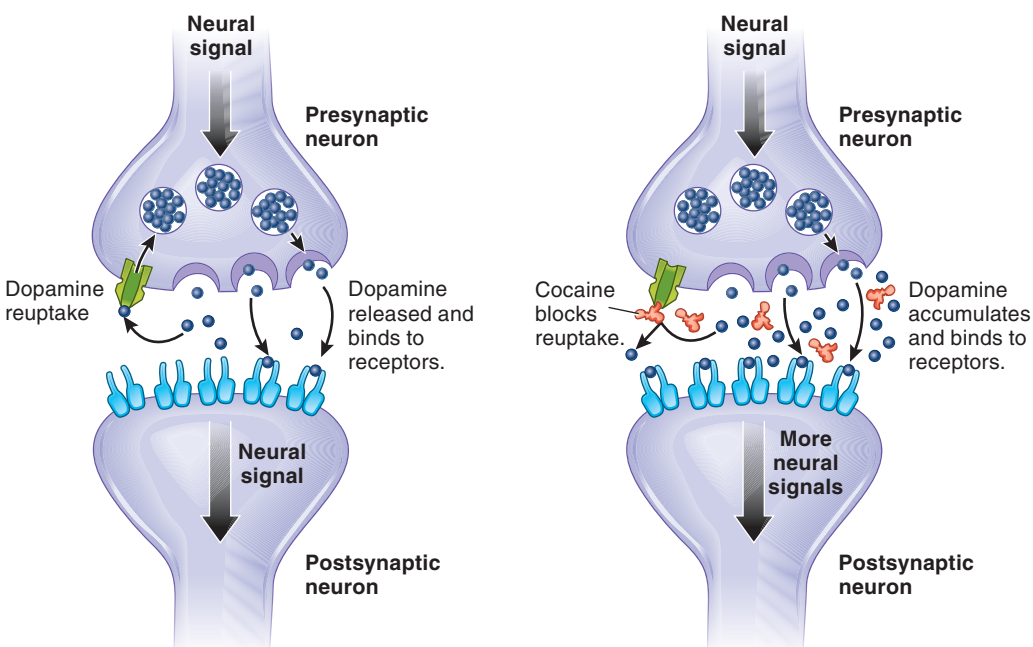
According to a national survey on illicit drug use, in 2015 48.8% of persons 12 years and older have used illicit drugs in their lifetimes. During the past month, 17.8% of individuals ages 12 years and older have used illicit drugs.[2]

Although legal, alcohol is the most commonly used and abused drug. (See *Inquiring About: Alcohol: The Most Abused Drug*.) An estimated 28 million children live with a parent dependent on alcohol and/or illicit drugs.[3]

TABLE 42-4 lists several commonly used and abused drugs and gives their effects.

Drug addiction is a serious issue

Habitual use of almost any mood-altering drug can result in *psychological dependence*, in which the user becomes emotionally dependent on the drug. When deprived of it, the user craves the feeling of euphoria (well-being) the drug induces. Some drugs induce *tolerance* after several days or weeks; response to the drug decreases, and greater amounts are required to obtain the desired effect. Tolerance often occurs because the liver cells are stimulated to produce more of the enzymes that metabolize and inactivate the drug. It can also occur when the number of postsynaptic receptors that bind with the drug decrease (*down-regulation*).



Drug addiction is a serious societal problem that involves compulsive use of a drug despite negative health consequences and negative effects on the ability to function socially, occupationally, and in school. Use of some drugs, such as tobacco, alcohol, barbiturates, and heroin and other opiates (morphine, codeine, and oxycodone), can also result in physical dependence; physiological changes occur that make the user dependent on the drug. For example, when heroin or alcohol is withheld, the addict suffers characteristic withdrawal symptoms. Physical addiction can occur when a drug—for example, morphine—has components similar to substances that body cells normally manufacture on their own. Some highly addictive drugs, such as crack cocaine and methamphetamine, do not cause serious withdrawal symptoms.

The neurobiological mechanisms for drug addiction involve the *mesolimbic dopamine pathway*, a major reward circuit (described earlier in this chapter in connection with the limbic system). Many of the neurons in this pathway project from the *ventral tegmental area* in the midbrain and signal neurons in the limbic system, including the amygdala and an area called the *nucleus accumbens*. Projections of this nucleus are thought to be involved in the reinforcement people experience from taking drugs.

Effects on neurons in the mesolimbic dopamine pathway have been demonstrated in nicotine, heroin, amphetamine, and cocaine addiction. For example, amphetamines stimulate dopamine release. Cocaine blocks the reuptake of dopamine into presynaptic neurons, thus prolonging the stimulation (**FIG. 42-19**). Both amphetamines and cocaine can increase dopamine concentration in the limbic system by up to 1000 times normal amounts! Prolonged drug use alters gene expression and changes neuron structure.

Opioid overdose is an epidemic

More than 50,000 people died in 2016 as a result of drug overdoses, mainly from prescription opioids and heroin. According to the Centers for Disease Control and Prevention (CDC), "the United States is in the midst of an opioid overdose epidemic." Opioids include the illegal drug heroin, synthetic opioids

(a) Reuptake of the neurotransmitter dopamine. Dopamine binds with a transporter (*green*) that shuttles it back into the presynaptic terminal.

(b) Effect of cocaine. Cocaine blocks the reuptake of dopamine by binding competitively with the dopamine reuptake transporter. As a result, more dopamine is available to bind with postsynaptic receptors.

Figure 42-19 Mechanism of cocaine action

Inquiring About

Alcohol: The Most Abused Drug

How does alcohol affect health, families, and society? Alcohol is the fourth leading preventable risk factor for premature death in the United States. In addition, alcohol use is the biggest risk factor for deaths among young people aged 15–29. According to the World Health Organization, alcohol abuse results in 3.3 million deaths worldwide every year.*

Most alcohol-related deaths result from injuries, cancer, liver cirrhosis, and cardiovascular diseases. In addition, alcohol-related violence is a major factor in domestic abuse, road rage, and gang activity.

According to the National Institute of Alcohol Abuse and Alcoholism, "an estimated 679,000 adolescents ages 12–17 had an AUD" (alcohol use disorder) in 2014 (the last year for which statistics are available at the time of this writing). In 2014, approximately 59.8% of college students ages 18–22 years old drank alcohol during the month preceding a survey (compared with 51.5% of others of similar age). Approximately two-thirds of these students also *binge drink*. They acknowledge drinking 5 or more alcoholic beverages at a time. About 12% of college students are *heavy drinkers*. They acknowledge drinking 5 or more alcoholic beverages at least 5 times during the past month. Excessive alcohol intake increases the risk for breast cancer and other cancers, heart disease, sexually transmitted diseases, and unintended pregnancy.†

Almost 3 million students between the ages of 18 and 24 report that they drove a motor vehicle under the influence of alcohol during the past year. According to Mothers against Drunk Driving, teens who drink alcohol kill about 6000 people every year. (The number of deaths is greater than those caused by teen use of all illegal drugs combined.) Every year, about 700,000 college students between the ages of 18 and 24 are assaulted by another student who has been drinking.‡ Almost 2000 college students between the ages of 18 and 24 die each year from alcohol-related nonintentional injuries.

Based on many studies, CDC reports that youth who drink alcohol are likely to experience serious problems, including disruption of normal growth and sexual development; abnormal brain development that may have lifelong effects; memory problems; school, social, and legal problems; and higher risk for suicide, homicide, and death from alcohol poisoning. Adults who first used alcohol when they were 14 years old or younger were more than five times as likely to have a problem with alcohol dependence or abuse than adults who had their first drink at age 21 or older. Alcohol abuse and dependence result in physiological, psychological, and social impairment and have serious negative consequences for family, friends, and society.

Each of the following has been linked to alcohol abuse:

- More than 30% of all traffic fatalities. (Drugs other than alcohol—e.g., marijuana and cocaine—are involved in about 18% of motor vehicle deaths.)
- Almost 50% of violent crime.
- More than 60% of child-abuse and spouse-abuse cases.
- More than 50% of college sexual assaults.
- About 25% of suicides.
- The birth of thousands of babies each year with serious birth defects. (Fetal alcohol spectrum disorders are the leading cause of preventable intellectual disability in the United States.)
- Increased risk of mouth, larynx, and throat cancers. Alcohol is also a risk factor for primary liver cancer, breast cancer, and colon cancer. These cancers have been linked to regular alcohol consumption.

A single drink—that is, 12 oz of beer, 5 oz of wine, or 1.5 oz of 72-proof liquor—results in a blood alcohol concentration of approximately 20 mg/dL (milligrams per deciliter). This level represents about 0.5 oz of pure alcohol in the blood. Alcohol accumulates in the blood because absorption occurs more rapidly than oxidation and excretion. Every cell in the body can take in alcohol from the blood.

At first, the drinker may feel stimulated, but alcohol actually depresses the CNS. As blood alcohol concentration rises, information processing, judgment, memory, sensory perception, and motor coordination all become progressively impaired. Depression and drowsiness generally occur. Contrary to popular belief, alcohol decreases sexual performance. Some individuals become loud, angry, or violent.

A blood alcohol concentration of 80 mg/dL (0.08 gm/100 mL) legally defines driving under the influence, or DUI. A 170-lb man typically reaches this level by drinking four drinks in an hour on an empty stomach. The National Transportation Safety Board has recommended that states lower the legal allowable blood alcohol concentration to 50 mg/dL (0.05 gm/100 mL). Alcohol metabolism occurs at a fixed rate in the liver. About one drink per hour is metabolized. Only time, not coffee or other remedies, decreases the effects of alcohol intake. Because alcohol inhibits water reabsorption in the kidneys, more fluid is excreted as urine than is consumed in the alcohol. The result is dehydration that, together with a low blood sugar level, may cause the stupor produced by excessive drinking.

In chronic drinkers cells of the CNS adapt to the presence of the drug, which causes *tolerance* (more and more alcohol is needed to experience the same effect) and physical dependence. Abrupt withdrawal can result in sleep disturbances, severe anxiety, tremors, seizures, hallucinations, and psychosis.

Evidence suggests that many neurotransmitters are involved in alcohol addiction, including glutamate, serotonin, GABA, and opioid peptides. Treatment for alcohol addiction includes various forms of psychotherapy and use of anticraving drugs (such as naltrexone and acamprosate) and disulfiram, which is an aversion drug. The group support offered by Alcoholics Anonymous (AA) has proved effective for many struggling with alcohol dependence. Participation in AA includes attending frequent meetings, having a sponsor within the program, and working on its 12 steps.

* See www.who.int/mediacentre/factsheets/fs349/en/.

‡ See pubs.niaaa.nih.gov/publications/CollegeFactSheet/CollegeFactSheet.pdf.

(for example, fentanyl), and other prescription drugs used for pain, such as codeine, morphine, oxycodone (OxyContin), and hydrocodone (Vicodin). Prescription opioids account for nearly 50% of all deaths resulting from opioid overdose. Increasingly, deaths from opioids have involved fentanyl, a fast-acting, extremely powerful synthetic opioid. Overdoses can occur within a few minutes.

The drug naloxone blocks the effects of opioids on the CNS. Naloxone can reverse the effects of fentanyl and other opioid overdose. Some communities have made this lifesaving antidote to opioid overdose available in "rescue kits." The kits can be distributed to first responders, primary care physicians, treatment programs, support groups, and even to high-risk individuals. Unfortunately, the drug companies that manufacture naloxone products (for example, nasal spray, auto-injector) have increased their prices by several hundred percent, making them unaffordable to most individuals.

The FDA has approved several drugs to treat the symptoms of opioid withdrawal. Methadone, an opioid sometimes prescribed for pain management, was the first drug used to treat opioid use disorders. Because methadone itself is addictive, newer drugs (for example, naltrexone) are being used.

CHECKPOINT 42.6

- How do the following drugs affect the CNS: alcohol, antipsychotic drugs, antidepressants, amphetamines, opiates such as oxycodone, and MDMA ("Ecstasy")?

Table 42-4 Effects of Some Commonly Abused Drugs

Name of Drug	Effect on Mood	Actions on Body	Side Effects/Dangers Associated with Abuse
ANTIDEPRESSANTS			
Selective serotonin reuptake inhibitors (SSRIs) (e.g., Prozac, Zoloft, Lexapro, Pristiq)	Relieve depression; used to treat obsessive–compulsive behavior	Block serotonin reuptake; some also block norepinephrine reuptake	Sometimes cause nausea, headache, insomnia, anxiety
Tricyclic antidepressants (e.g., Elavil, Anafranil)	Elevate mood; relieve depression; used to treat obsessive–compulsive behavior	Most block reuptake of biogenic amines (especially norepinephrine), increasing their concentration in synapses	Sedation, weight gain, sexual dysfunction
MAO (monoamine oxidase) inhibitors (e.g., Parnate, Nardil)	Relieve depression	Block enzymatic breakdown of biogenic amines, increasing their concentration in synapses	Liver toxicity, excessive CNS stimulation; overdose may affect blood pressure, may cause hallucinations
ANTI-ANXIETY MEDICATIONS			
Benzodiazepines (e.g., Xanax, Ativan, Valium)	Sedation; induce sleep	Depress CNS; bind to GABA receptors on postsynaptic neuron; increase effectiveness of GABA in opening chloride channels, causing hyperpolarization; cause relaxation of skeletal muscles	Drowsiness, confusion; psychological dependence, addiction; effects additive with alcohol
Barbiturates ("downers") (e.g., phenobarbital)	Sedation; induce sleep; used as anesthesia; used to treat epilepsy	Depress CNS; bind to GABA receptors on chloride channels; the channels open so that more chloride ions move in, causing hyperpolarization	Drowsiness, confusion; psychological dependence, tolerance, addiction; severe CNS depression, resulting in coma and death (especially lethal in combination with alcohol)
ANTIPSYCHOTIC MEDICATIONS			
Phenothiazines (e.g., Thorazine, Mellaril, Stelazine)	Relieve symptoms of schizophrenia; reduce impulsive and aggressive behavior	Block dopamine receptors	Tardive dyskinesia, a neurological syndrome characterized by repetitive involuntary movements, muscle spasms, and shuffling gait
Atypical antipsychotic medications (e.g., Abilify, Risperdal)	Similar to phenothiazines, but also increase motivation	Block dopamine and certain other neurotransmitter receptors	Fewer side effects than with the phenothiazines
NARCOTIC ANALGESICS (also called opiates) (commonly abused prescription drugs, as well as certain street drugs)			
Opioids (e.g., fentanyl, morphine, codeine, oxycodone [OxyContin], hydrocodone [Vicodin]; heroin)	Euphoria; sedation; pain relief	Depress CNS; block pain; mimic actions of endorphins; bind to opiate receptors; like cocaine, inhibit reuptake of dopamine; constrict pupils	Tolerance, psychological dependence, addiction; depress respiration; impair coordination; cause brain damage; convulsions, death from overdose
COCAINE			
"Coke," "rock," "snow"	Brief, intense high with euphoria, followed by fatigue and depression; paranoia	Stimulates release and inhibits reuptake of dopamine, leading to CNS stimulation followed by depression; autonomic stimulation; dilation of pupils; local anesthesia	Mental impairment, convulsions, hallucinations, unconsciousness; death from overdose
MARIJUANA (cannabis)			
"Pot," "weed"; most commonly used illicit substance; main psychoactive ingredient is THC; THC-based drugs are used to treat pain, nausea, and other medical conditions	Euphoria	Impairs coordination; impairs depth perception and alters sense of timing; impairs ability to focus and to learn; impairs short-term memory (probably by decreasing acetylcholine levels in the hippocampus); inflames eyes; causes peripheral vasodilation	Psychological dependence; in large doses, sensory distortions, hallucinations, evidence of lowered sperm counts and testosterone levels

Table 42-4 Effects of Some Commonly Abused Drugs (*continued*)

Name of Drug	Effect on Mood	Actions on Body	Side Effects/Dangers Associated with Abuse
AMPHETAMINES			
"Uppers," "pep pills," "crystal meth"; amphetamines (e.g., Dexedrine, levoamphetamine); methamphetamine is a popular club drug	Euphoria, stimulation, hyperactivity	CNS stimulants; stimulate release and block reuptake of dopamine and norepinephrine; enhance flow of impulses in RAS, leading to increased heart rate and blood pressure; pupil dilation	Tolerance, addiction; hallucinations; increased blood pressure; psychotic episodes; death from overdose
Amphetamine-type prescription stimulants commonly used to treat attention deficit hyperactivity disorder (ADHD) (e.g., methylphenidate [Ritalin, Concerta, Adderall])	CNS stimulation, but has calming effect on many children and adults who have ADHD; increases focus	Not addictive at prescribed doses; like cocaine, amphetamines block dopamine transporter, which increases dopamine concentration in synapses	Tolerance and physical addiction occur when abused; when used in higher doses than prescribed, can cause irregular heartbeat and respiration, hallucinations, delusions, convulsions; causes long-term changes in brain function
MDMA (3,4-methylenedioxymethamphetamine); "Ecstasy," "Molly" (a popular club drug)	Stimulation, sense of pleasure, self-confidence, feelings of closeness to others; mild hallucinogenic	CNS stimulant; damages serotonin pathways in rat and monkey brains	Hyperthermia (excessive body heat); overdose causes rapid heartbeat, high blood pressure, panic attacks, seizures; long-term neurological changes; cognitive impairment
ROHYPNOL, KETAMINE, and GHB			
"Date rape" drugs; rohypnol is a benzodiazepine not legally available in the U.S.	Sedation, anxiety reduction	Rohypnol and ketamine depress the CNS	Psychological dependence, addiction; withdrawal may cause seizures; may be lethal when mixed with alcohol and/or other depressants
PCP (phencyclidine)			
A hallucinogen; "angel dust," "ozone"; originally used as general anesthetic for surgery, but discontinued because it caused delirium with psychotic features; now illegal	Feelings of strength, power, invulnerability, and a numbing effect on the mind; chronic use can cause depression	Affects several neurotransmitters; can cause psychotic symptoms; increase in blood pressure and heart rate; shallow respiration; flushing, profuse sweating; numbness of extremities; difficulty coordinating muscles; changes in body awareness, similar to those associated with alcohol intoxication	Psychological dependence, craving; in adolescents interferes with hormones related to growth and development; chronic use causes memory loss, difficulties with speech, thinking, and learning; causes hallucinations, delusions; high doses cause drop in blood pressure and heart rate, seizures, coma, and death
LSD (lysergic acid diethylamide)			
A hallucinogen; "acid" (manufactured from lysergic acid, which is found in ergot, a fungus that grows on rye and other grains)	Effects unpredictable; typically extreme changes in mood; over-excitation	Alters levels of neurotransmitters in brain; potent CNS stimulator; dilates pupils, sometimes unequally; increases heart rate; raises blood pressure	Impaired judgment leading to irrational behavior; sensory distortions, hallucinations, panic attacks; psychosis; flashbacks
METHAQUALONE (e.g., Quaalude, Sopor)			
A synthetic barbiturate-type drug; no longer legally available in U.S.	Sedative–hypnotic; reduces anxiety; causes euphoria	Depresses CNS; depresses certain spinal reflexes	Tolerance, addiction; overdose can lead to seizures, coma, or death
CAFFEINE	Increases mental alertness; decreases fatigue and drowsiness	CNS stimulant; relaxes smooth muscle; stimulates cardiac and skeletal muscle; increases urine volume	Tolerance, psychological dependence, addiction; large amounts cause anxiety, irritability
NICOTINE			
Typically inhaled in tobacco smoke (which contains more than 19 chemical compounds that cause cancer)	Decreases anxiety; increases alertness; may induce a sense of well-being	Stimulates sympathetic nervous system; increases dopamine in mesolimbic pathway	Tolerance, psychological dependence, addiction; withdrawal can cause anxiety, depression, headaches, difficulty concentrating; nicotine stimulates synthesis of lipid in arterial wall, leading to atherosclerosis
ALCOHOL			
(See *Inquiring About: Alcohol: The Most Abused Drug*)	Euphoria, relaxation, release of inhibitions	Depresses CNS by affecting GABA receptors; impairs vision, coordination, judgment; lengthens reaction time	Tolerance, psychological dependence, addiction; damage to pancreas and liver (e.g., cirrhosis); brain damage; increased risk of depression

Summary: Focus on Learning Objectives

42.1 Invertebrate Nervous Systems: Trends in Evolution *(page 883)*

1 Contrast nerve nets and radial nervous systems with bilateral nervous systems.

- **Nerve nets** and *radial nervous systems* are typical of radially symmetrical invertebrates, such as cnidarians. An animal with a radial nervous system can respond effectively to predator or prey approaching from any direction.
- In planarian flatworms the *bilateral nervous system* includes *cerebral ganglia* and, usually, two solid ventral nerve cords connected by transverse nerves. Annelids and arthropods typically have a ventral nerve cord and numerous ganglia. The cerebral ganglia of arthropods have specialized regions. Octopods and other cephalopod mollusks have highly developed nervous systems with neurons concentrated in a central region.
- The bilateral nervous system is adaptive for bilaterally symmetrical animals that typically move in a forward direction. Nerve cells concentrate to form **nerves**, **nerve cords**, **ganglia**, and the **brain**; typically, sense organs are concentrated in the head region.

2 Identify trends in the evolution of invertebrate nervous systems.

- Trends in nervous system evolution include increased number and concentration of nerve cells; specialization of function; increased number of association neurons; more complex synaptic contacts; and **cephalization**, the formation of a head.

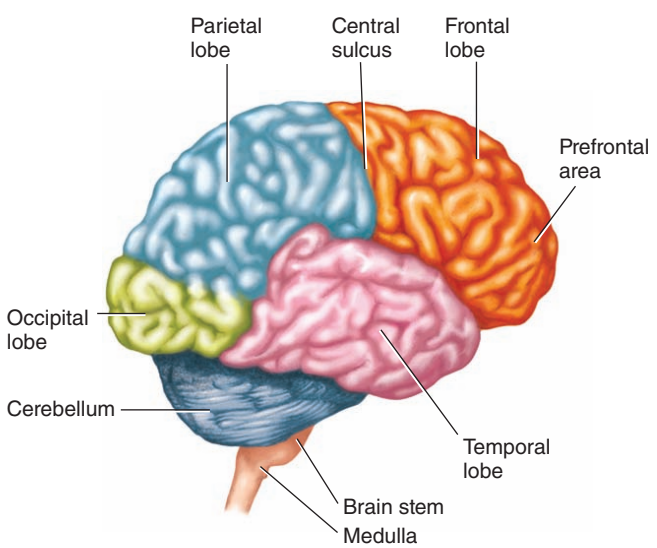
42.2 Overview of the Vertebrate Nervous System *(page 884)*

3 Describe the two main divisions of the vertebrate nervous system and summarize their functions.

- The **central nervous system (CNS)**, which consists of the brain and spinal cord, is specialized to integrate incoming information. The **peripheral nervous system (PNS)**, which consists of sensory receptors and nerves, transmits signals between sensory receptors and the CNS, and between the CNS and effectors.

42.3 Evolution of the Vertebrate Brain *(page 885)*

4 Trace the development of the principal vertebrate brain regions from the hindbrain, midbrain, and forebrain, and compare the brains of fishes, amphibians, reptiles, birds, and mammals.



- In the vertebrate embryo, the brain and spinal cord arise from the **neural tube**. The anterior end of the tube differentiates into the **hindbrain**, **midbrain**, and **forebrain**.
- The hindbrain subdivides into the metencephalon and myelencephalon. The myelencephalon develops into the **medulla**, which contains vital centers and other reflex centers. The fourth ventricle, the cavity of the medulla, communicates with the central canal of the spinal cord. The metencephalon gives rise to the **cerebellum**, which is responsible for muscle tone, posture, and equilibrium, and to the **pons**, which connects various parts of the brain.
- The midbrain is the largest part of the brain in fishes and amphibians. It is their main association area, linking sensory input and motor output. In reptiles, birds, and mammals, the midbrain serves as a center for visual and auditory reflexes. The medulla, pons, and midbrain make up the **brain stem**.
- The forebrain differentiates to form the diencephalon and telencephalon. The diencephalon develops into the thalamus and hypothalamus. The **thalamus** is a relay center for motor and sensory information. The **hypothalamus** controls autonomic functions; links nervous and endocrine systems; controls temperature, appetite, and fluid balance; and is involved in some emotional and sexual responses.
- The telencephalon develops into the cerebrum and **olfactory bulbs**. In most vertebrates the **cerebrum** is divided into right and left cerebral hemispheres. In fishes and amphibians, the cerebrum mainly integrates incoming sensory information. In birds the corpus striatum controls complex behavior patterns, such as flying and singing.
- In mammals the *neocortex* accounts for a large part of the **cerebral cortex**, which consists of **gray matter**. The cerebrum has complex association functions.

42.4 The Human Central Nervous System *(page 888)*

5 Describe the structure and functions of the human spinal cord.

- The human brain and spinal cord are protected by bone and three layers of connective tissue, the **meninges**: the **dura mater**, **arachnoid**, and **pia mater**. The brain and spinal cord are cushioned by **cerebrospinal fluid (CSF)**.
- The **spinal cord** transmits impulses to and from the brain and controls many **reflex actions**. The spinal cord consists of *ascending tracts*, which transmit information to the brain, and *descending tracts*, which transmit information from the brain. Its gray matter contains nuclei that serve as reflex centers.
- A *withdrawal reflex* involves sensory receptors; sensory neurons, interneurons, and motor neurons; and effectors, such as muscles.

6 Describe the structure and functions of the human cerebrum.

Copyright 2019 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in

Copyright 2019 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

- The human cerebral cortex consists of gray matter, which forms folds or **convolutions**. Deep furrows between the folds are called **fissures**.
- The cerebrum is functionally divided into *sensory areas* that receive incoming sensory information; *motor areas* that control voluntary movement; and **association areas** that link sensory and motor areas and are responsible for learning, language, thought, and judgment. The cerebrum consists of lobes, including the **frontal lobes**, **parietal lobes**, **temporal lobes**, and **occipital lobes**.
- The **white matter** of the cerebrum lies beneath the cerebral cortex. The **corpus callosum**, a large band of white matter, connects right and left hemispheres. The *basal ganglia*, a cluster of nuclei within the white matter, are important centers for motor function.

7 Summarize the sleep–wake cycle and contrast rapid eye movement (REM) sleep with non-REM sleep.

- The body's main biological clock—the **suprachiasmatic nucleus**—receives information about light and dark and transmits it to other nuclei that regulate sleep.
- The **reticular activating system (RAS)** is an arousal system; its neurons filter sensory input, selecting which information is transmitted to the cerebrum.
- The hypothalamus, thalamus, and brain stem regulate the sleep–wake cycle. *Sleep* is an alteration of consciousness with decreased electrical activity in the cerebral cortex.
- Electrical activity of the cerebral cortex and metabolic rate slow during *non-REM sleep*; dreaming occurs during *REM sleep*.

8 Describe the actions of the limbic system; include the role of the amygdala in emotional expression and in response to danger.

- The **limbic system** affects the emotional aspects of behavior, motivation, sexual activity, autonomic responses, and biological rhythms. The **amygdala** evaluates incoming information and signals danger; it is important in the experience of fear and aggression.

9 Summarize how the brain processes information; include a description of synaptic plasticity and the neurobiological changes that take place during learning.

- **Synaptic plasticity** is the ability of the nervous system to modify synapses, which allows learning and remembering.
- **Learning** is the process by which we acquire knowledge or skills as a result of experience. **Memory** is the process by which information is encoded, stored, and retrieved.
- *Immediate memory* holds sensory information for fractions of a second. **Short-term memory** holds a small amount of information for a few minutes. Information can be transferred from short-term memory to **long-term memory**. The **hippocampus** is important in categorizing information and consolidating memories.
- Learning and memory involve long-term functional changes at synapses. Known as **long-term potentiation (LTP)**, such changes involve increased sensitivity to an action potential by a postsynaptic neuron. **Long-term depression (LTD)** is a long-lasting decrease in the strength of synaptic connections. Long-term memory storage involves gene expression. The transcription factor *CREB* is an important signaling molecule in the memory pathway.

42.5 The Peripheral Nervous System *(page 901)*

10 Describe the organization of the peripheral nervous system and compare its somatic and autonomic divisions.

- The PNS consists of sensory receptors and nerves, including the **cranial nerves** and **spinal nerves** and their branches. The **somatic division** of the PNS responds to changes in the external environment. The **autonomic division** of the PNS regulates the internal activities of the body.

11 Contrast the sympathetic and parasympathetic divisions of the autonomic system and give examples of the effects of these systems on specific organs.

- The **sympathetic system** permits the body to respond to stressful situations. The **parasympathetic system** influences organs to conserve and restore energy. Many organs are innervated by sympathetic and parasympathetic nerves, which function in opposite ways. For example, the sympathetic system increases heart rate, whereas the parasympathetic system decreases heart rate.

42.6 Effects of Drugs on the Nervous System *(page 903)*

12 Distinguish among psychological dependence, tolerance, and drug addiction, and describe the biological actions and effects on mood of alcohol, antidepressants, barbiturates, anti-anxiety drugs, antipsychotic drugs, opiates, stimulants, hallucinogens, and marijuana.

- Many drugs alter mood by increasing or decreasing the concentrations of specific neurotransmitters within the brain. See Table 42-4 for a summary of these drugs.
- Habitual use of mood-altering drugs can result in *psychological dependence* or *drug addiction*. Many drugs induce *tolerance*, in which the body's response to the drug decreases so that greater amounts are needed to obtain the desired effect.

Test Your Understanding

Know and Comprehend

1. A radially symmetrical animal such as *Hydra* is likely to have (a) a forebrain (b) a nerve net (c) cerebral ganglia (d) a ventral nerve cord (e) cerebral ganglia and a nerve net
2. Which part of the vertebrate brain maintains posture, muscle tone, and equilibrium? (a) cerebrum (b) medulla (c) cerebellum (d) neocortex (e) thalamus
3. The main association area in the amphibian brain is the (a) cerebrum (b) medulla (c) neocortex (d) midbrain (e) arachnoid
4. The suprachiasmatic nucleus (a) secretes melatonin (b) stimulates long-term potentiation (LTP) in the hippocampus (c) filters incoming sensory information and determines whether it is threatening (d) is critical in memory consolidation (e) is important in regulating the sleep–wake cycle

Copyright 2019 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

5. The heart rate is slowed by (a) sympathetic nerves (b) parasympathetic nerves (c) rapid firing in the corpus callosum (d) both sympathetic and parasympathetic nerves (e) the hippocampus working together with sympathetic nerves
6. Amphetamines (a) affect neurons in the mesolimbic dopamine pathway (b) decrease the amount of dopamine secreted (c) affect the CNS in the same way as alcohol (d) are often prescribed to reduce anxiety (e) are CNS depressants

Apply and Analyze

7. Which sequence best describes transmission of information in a withdrawal reflex? 1. afferent neuron transmits signal to CNS 2. muscle contracts 3. reception by sensory neuron 4. interneuron in CNS integrates information 5. efferent neuron transmits signal (a) 3, 1, 4, 5, 2 (b) 2, 1, 4, 5, 3 (c) 3, 5, 1, 4, 2 (d) 3, 1, 5, 4, 2 (e) 5, 3, 1, 4, 2
8. **VISUALIZE** Label the diagram of the human brain.

9. **EVOLUTION LINK** What general trends can you identify in the evolution of the vertebrate brain?

Evaluate and Synthesize

10. **SCIENCE, TECHNOLOGY, AND SOCIETY** Imagine that you have just become a parent. What kinds of things can you do to enhance the development of your child's intellectual abilities?
11. What is the adaptive function of the limbic system when an alligator is chasing you?
12. **EVOLUTION LINK** CREB has been shown to be a signaling molecule in the memory pathway in many animals, including fruit flies and mice. What does that suggest about the evolution of learning and memory?
13. Hypothesize a possible relationship between inheritance and intelligence based on gene activation during information processing.

43 Sensory Systems

Have you heard dolphins make clicking sounds? Humans can hear only a limited number of the wide range of sound frequencies that dolphins emit. Dolphins, bats, and a few other vertebrates detect distant objects by *echolocation*, sometimes called biosonar. Echolocation works something like radar but uses sound rather than radio waves. For example, a bat emits high-pitched sounds that bounce off objects in its path and echo back. By rapidly responding to the echo, the bat skillfully avoids obstacles and captures prey (see photograph). Using echolocation, bats and dolphins determine the size, shape, texture, and density of an object as well as its location.

The ability to detect sounds emitted by some foraging bats has evolved in certain moths and other insect prey. Through the course of evolution, some species of bats have adapted to this ability of their prey and now emit even higher-frequency sounds that their prey cannot detect.

Sensory systems transfer information from the outside world to the animal. They inform the animal about predators, food, water, possible mates, temperature, and other changes in the environment. The kinds of sensory receptors an animal has and the way in which its brain *perceives* incoming sensory information determine what the animal's world is like. We humans live in a world of rich colors, numerous shapes, and varied sounds. But we cannot hear the high-pitched whistles that are audible to dogs and cats or the ultrasonic echoes by which bats navigate. Unlike some migratory animals, we cannot use magnetic fields to navigate. Nor do we ordinarily recognize our friends by their distinctive odors. And although vision is our dominant and most refined sense, we are blind to the ultraviolet (UV) hues that light up the world for insects.

We humans are most familiar with the senses of sight, hearing, smell, taste, and touch, but we have other senses. In fact, touch is a

KEY CONCEPTS

43.1 Sensory processing includes sensory reception, energy transduction, transmission of signals, and interpretation in the central nervous system (CNS).

43.2 Thermoreceptors respond to heat and cold.

43.3 Some predatory species of sharks, rays, and bony fishes have electroreceptors that detect electric fields generated in the water by the activity of other animals.

43.4 Dendrites of certain sensory neurons are nociceptors (pain receptors).

43.5 Mechanoreceptors respond to touch, pressure, gravity, stretch, or movement.

43.6 Most animals have chemoreceptors for taste and smell that detect chemical substances in food, water, and air.

43.7 Almost all animals have photoreceptors that respond to light, and most animals have eyes that form images; the retina of the vertebrate eye contains photoreceptor cells called rods and cones.

compound sense that allows us to detect pressure, pain, and temperature. Some sensory receptors allow us to sense balance, muscle tension, and joint position, providing us with an awareness of our bodies.

In this chapter we first examine how sensory systems function. Next we introduce the major types of sensory receptors. We then discuss several types of sensory systems with emphasis on auditory and visual systems.

43.1 How Sensory Systems Work

LEARNING OBJECTIVES

1. Describe how sensory systems function; include descriptions of sensory receptors, energy transduction, receptor potential, sensory adaptation, and perception.
2. Classify sensory receptors according to the location of the stimuli to which they respond and according to the types of energy they transduce.

A **sensory receptor** detects information about changes in the external or internal environment. Sensory receptors consist of the endings of afferent neurons or cells in close contact with neurons that are specialized to detect specific types of energy in the environment. Along with other types of cells, sensory receptors make up complex **sense organs**, such as the eyes, ears, nose, and taste buds. A human taste bud, for example, consists of taste receptor cells that detect chemicals dissolved in saliva, and epithelial cells that support the receptor cells.

Several steps take place in sensory processing, including sensory reception, energy transduction, transmission of the signal, and interpretation in the brain. With minor variations, all sensory systems operate in this way.

Sensory receptors receive information

Sensory receptors receive stimuli from the external or internal environment. In the process of reception, they absorb a small amount of energy from some stimulus. Each kind of sensory receptor is especially sensitive to one particular form of energy. For example, the photoreceptors of the human eye are stimulated by an extremely faint beam of light; similarly, taste receptors are stimulated by a minute amount of a chemical compound.

Sensory receptors transduce energy

Sensory receptors *transduce*, or convert, the energy of the stimulus into electrical signals, the information currency of the nervous system. This process is known as *energy transduction*. When unstimulated, a sensory receptor maintains a *resting potential*, that is, a difference in charge between the inside and outside of the cell (see Chapter 41). Transduction couples a stimulus with the opening or closing of ion channels in the plasma membranes of sensory receptors. The permeability of the plasma membrane to various ions is altered.

A change in ion distribution causes a change in voltage across the membrane. If the difference in charge increases, the receptor becomes hyperpolarized. If the potential decreases, the receptor becomes depolarized. A change in membrane potential is a **receptor potential**. A receptor potential does not directly trigger an action potential. Like an excitatory postsynaptic potential, or EPSP (see Chapter 41), the receptor potential is a **graded potential** in which the magnitude of change depends on the strength of the stimulus.

If the receptor is a separate cell, receptor potentials stimulate the release of a neurotransmitter, which flows across the synapse and binds to receptors on an *afferent neuron*, or **sensory neuron** (FIG. 43-1). When a sensory neuron becomes sufficiently depolarized to reach its threshold level, an action potential is generated. Thus, receptor potentials can generate action potentials that transmit information to the central nervous system (CNS).

Many receptors are specialized neurons rather than separate cells. In these neurons the specialized region of the plasma membrane that transduces energy does not generate action potentials. Current generated by receptor potentials flows to a region along the axon where an action potential can be generated.

We can summarize the process of sensory reception as follows:

stimulus (such as light energy) → sensory receptor absorbs energy from stimulus → energy transduction of stimulus into electrical energy → receptor potential produced → action potential in sensory neuron → signal transmitted to CNS

Sensory input is integrated at many levels

Sensory integration begins in the receptor itself. For example, receptor potentials produced by various stimuli are integrated by summation (see Chapter 41). However, integration occurs mainly in the spinal cord and at various locations in the brain.

Sensory receptors adapt to stimuli Many sensory receptors do not continue to respond at the initial rate, even if the stimulus continues at the same intensity. This change in response rate, called **sensory adaptation**, occurs for two reasons. First, during a sustained stimulus, the receptor sensitivity decreases and produces a smaller receptor potential (resulting in a lower frequency of action potentials in the sensory neurons). Second, changes take place at synapses in the neural pathway activated by the receptor. For example, the release of neurotransmitter from a presynaptic terminal may decrease in response to a series of action potentials.

Some receptors, such as those for pain or cold, adapt so slowly that they continue to trigger action potentials as long as the stimulus persists. Other receptors adapt rapidly, permitting us to ignore persistent unpleasant or unimportant stimuli. For example, when you first pull on a pair of tight jeans, your pressure receptors let you know that you are being squished, and you may feel uncomfortable. Soon, though, these receptors adapt, and you hardly notice the sensation of the tight fit. In the same way, people quickly adapt to odors

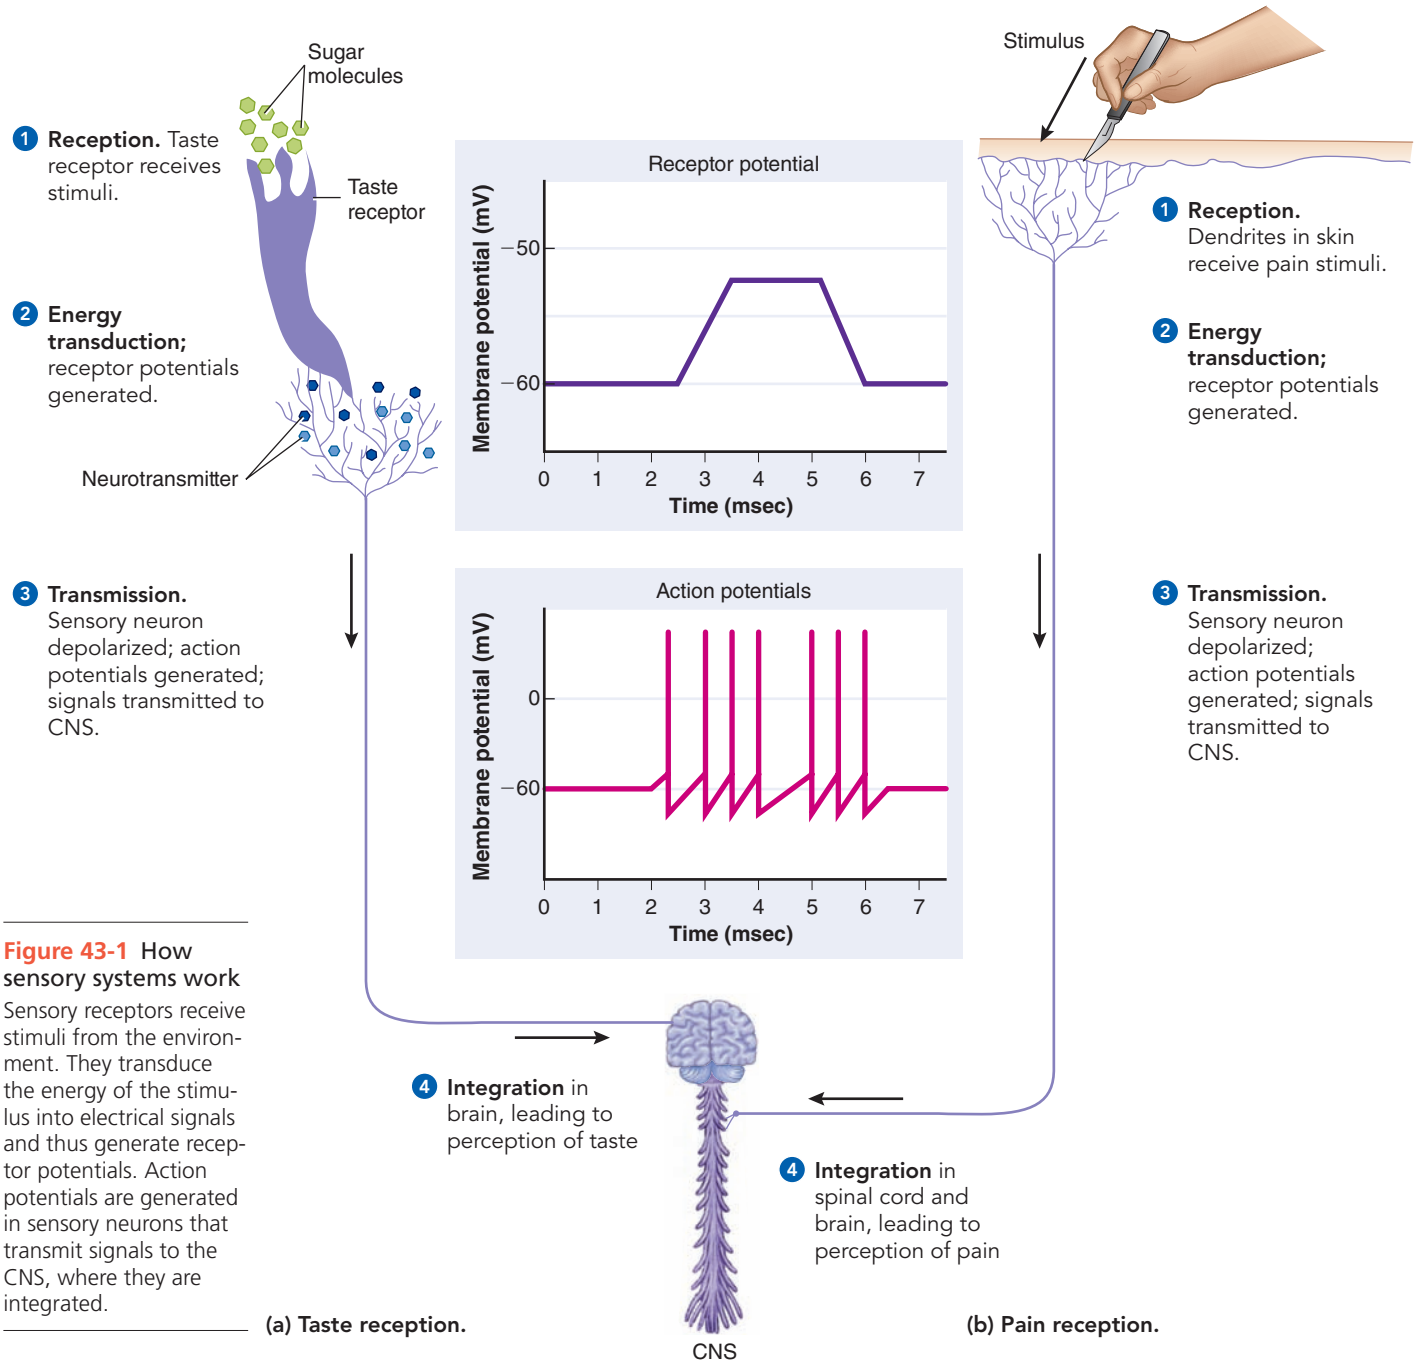

Figure 43-1 How sensory systems work

Sensory receptors receive stimuli from the environment. They transduce the energy of the stimulus into electrical signals and thus generate receptor potentials. Action potentials are generated in sensory neurons that transmit signals to the CNS, where they are integrated.

that at first seem to assault their senses. Other examples are light adaptation when you step outside into bright sunlight and dark adaptation when you step into a dimly lit room. Sensory adaptation enables an animal to discriminate between unimportant background stimuli that can be ignored and new or important stimuli that require attention.

Sensation depends on transmission of a coded message How do you know whether you are seeing a blue sky, tasting a doughnut, or hearing a note played on a piano? All action potentials are qualitatively the same. Light of the wavelength 450 nm (blue), sugar molecules (sweet), and sound waves of 440 hertz (Hz) (A above middle C) all cause transmission of similar action potentials. Our ability to differentiate stimuli depends on both the sensory receptor itself and on the brain. We can distinguish the color of a blue sky from the scent of cologne, a sweet taste from a light breeze, or the sound of a piano from the heat of the sun because cells of each sensory receptor are connected to specific neurons in particular parts of the brain. Because a receptor normally responds to only one type of stimulus (e.g., light), the brain interprets a message arriving from a particular receptor as meaning that a certain type of stimulus occurred (such as a flash of color).

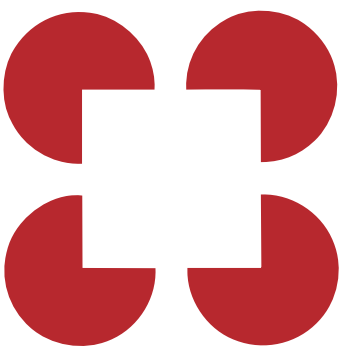
When stimulated, a sensory receptor initiates what might be considered a coded message, composed of action potentials transmitted by sensory neurons. This coded message is later decoded in the brain. Impulses from the sensory receptor may differ in the (1) total number of sensory neurons transmitting the signal, (2) specific neurons transmitting action potentials and their targets, (3) total number of action potentials transmitted by a given neuron, and (4) frequency of the action potentials transmitted by a given fiber. The intensity of a stimulus is coded by the frequency of action potentials fired by sensory neurons during the stimulus. A strong stimulus results in a greater depolarization of the receptor membrane, so the sensory neuron fires action potentials with greater frequency than would a weak stimulus. This variation is possible because, as a graded response, the receptor potential can vary in magnitude.

The difference in sound intensity between the gentle rustling of leaves and a loud clap of thunder depends on the number of neurons transmitting action potentials as well as the frequency of the action potentials transmitted by each neuron. Just how the sensory receptor initiates different codes and how the brain analyzes and interprets them to produce various sensations are not yet completely understood.



Sensation takes place in the brain. Interpretation of the message and the type of sensation depends on which interneurons receive the message. The rods and cones of the eye do not see. When stimulated, they send a message to the brain that interprets the signals and translates them into a rainbow, an elephant, or a child. Artificial (e.g., electrical) stimulation of brain centers can also result in sensation. In contrast, many sensory messages never give rise to sensations at all. For example, certain chemoreceptors sense internal changes in the body but never stir our consciousness.

Sensory perceptions are constructed by the mind

The brain interprets sensations by converting them to perceptions of stimuli. Sensory **perception** is the process of selecting, interpreting, and organizing sensory information.

(a) Your perception of the same visual input can vary. Do you see a wineglass or the profiles of two faces?

(b) Do you "see" a white square? If so, your brain is completing a familiar pattern suggested by the right-angle wedges taken out of each of the four red circles.

Figure 43-2 Visual perception

Sensory perceptions are constructed by the mind by comparing present sensory experience with our memories of past experiences. You may perceive the incoming visual and auditory input of a hissing snake very differently than does your friend who is terrified of snakes or a herpetologist who studies them. Perceptions are influenced by our state of mind at the time we receive sensory information. Optical illusions demonstrate that the brain can interpret sensory stimuli in various ways (FIG. 43-2a). The brain also modifies stimuli to make them more complete, familiar, or logical (FIG. 43-2b).

We can classify sensory receptors based on location of stimuli or on the type of energy they transduce

Sensory receptors can be classified according to the location of the stimuli to which they respond. **Exteroceptors** receive stimuli from the outside environment, enabling an animal to know and explore the world, search for food, find and attract a mate, recognize friends, and detect enemies. **Interoceptors** are sensory receptors within body organs that detect changes in pH, osmotic pressure, body temperature, and the chemical composition of the blood. You are not usually aware of messages sent to the CNS by these receptors as they work continuously to maintain homeostasis. You become aware of their activity when they signal certain internal conditions such as thirst, hunger, nausea, pain, and orgasm.

We can also classify sensory receptors based on the type of energy they transduce (TABLE 43-1). *Thermoreceptors* respond to heat and cold. *Electroreceptors* sense differences in electrical potential. *Electromagnetic receptors* are electroreceptors that are sensitive enough to detect Earth's magnetic field. *Nociceptors* (pain receptors) respond to mechanical, temperature, and other stimuli that could be damaging. *Mechanoreceptors* transduce mechanical energy—touch, pressure, gravity, stretching, and movement—and these receptors convert mechanical forces directly into electrical signals. *Chemoreceptors* transduce the energy of certain chemical compounds, and *photoreceptors* transduce light energy.

CHECKPOINT 43.1

- **CONNECT** In what way does a receptor potential differ from an action potential?
- **PREDICT** Imagine that you are hiking along a bay and notice a really strong, unpleasant odor. How might sensory adaptation be helpful?
- How is sensory information integrated?
- Identify five kinds of sensory receptors based on the type of energy they transduce. What is the specific function of each?

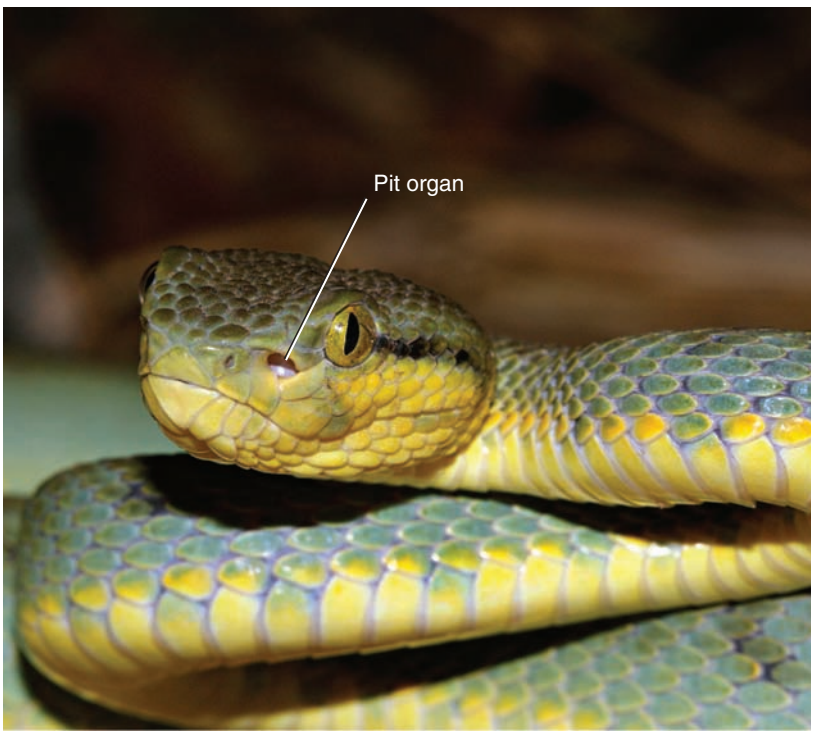
Table 43-1 Classification of Receptors by Type of Energy They Transduce

Type of Receptor	Type of Energy Transduced	Examples
Thermoreceptors	Heat	Temperature receptors in blood-sucking insects and ticks; pit organs in pit vipers; nerve endings and receptors in skin and tongues of many animals
Electroreceptors and electromagnetic receptors	Electrical; receptors detect differences in electrical potential	Electrical currents in water used to navigate by many fish and some amphibian species; some animals use magnetic fields for orientation and migration
Nociceptors (pain receptors)	Mechanical; physical force such as strong touch, pressure; heat, temperature extremes; damaging chemicals	Neuron endings in skin and other tissues
Mechanoreceptors	Mechanical; change shape as a result of being pushed or pulled	Tactile receptors (free nerve endings, Merkel cells, Meissner corpuscles, Ruffini endings, Pacinian corpuscles); respond to touch and pressure Proprioceptors respond to movement and body position Muscle spindles respond to muscle contraction Golgi tendon organs respond to stretch of a tendon Joint receptors respond to movement in ligaments Statocysts in invertebrates have hair cells that respond to gravity Lateral line organs in fish detect vibrations in the water; respond to waves and currents Vestibular apparatus Hair cells in saccule and utricle respond to gravity, linear acceleration Hair cells in semicircular canals respond to angular acceleration Hair cells in organ of Corti in cochlea; respond to pressure waves (sound)
Chemoreceptors	Specific chemical compounds	Taste buds; olfactory epithelium
Photoreceptors	Light	Eyespots; ommatidia in compound eye of arthropods; rods and cones in retina of vertebrates

43.2 Thermoreceptors



LEARNING OBJECTIVE

3 Identify three functions of thermoreceptors.

Thermoreceptors respond to heat and cold. Mosquitoes, ticks, and other blood-sucking arthropods use *thermoreception* to find endothermic hosts. Some arthropods have thermoreceptors on their antennae that are sensitive to temperature changes of less than 0.5°C.

Pit vipers (which include rattlesnakes) and some pythons and boas use thermoreceptors to locate their prey, and perhaps, to detect predators (FIG. 43-3). These thermoreceptors have heat-sensitive ion channels that detect infrared radiation.

In mammals, which are endothermic, free nerve endings (and, perhaps, specialized receptors) in the skin and tongue detect temperature changes in the outside environment. In addition, pain receptors sense extreme temperatures that pose a threat to the body. Thermoreceptors in the hypothalamus detect internal changes in temperature. They also receive and integrate information from receptors on the body surface. The hypothalamus then initiates homeostatic mechanisms that ensure a constant body temperature.

ephotocorp/Alamy Stock Photo

Figure 43-3 Thermoreception

The pit organ of the bamboo viper (*Trimeresurus gramineus*) is a sense organ located between each eye and nostril. Thermoreceptors in the pit organ can detect the heat emitted by an endothermic animal up to a distance of 1 to 2 m.

CHECKPOINT 43.2

- What are the functions of thermoreceptors in mosquitoes, snakes, and mammals?

43.3 Electroreceptors and Magnetic Reception

LEARNING OBJECTIVE

4 Describe the functions of electroreceptors and identify the functions of magnetic reception.

Electroreceptors sense differences in electrical potential. Some predatory species of sharks, rays, and bony fishes detect electric fields generated in the water by the muscle activity of their prey. Electroreception also appears important in communication, such as in recognizing a potential mate. Males and females have different frequencies of electric discharge.

Several groups of fishes have electric organs, specialized muscle or nerve cells that emit electrical signals and receive a feedback signal. In species that produce a weak electric current, electroreceptors may help in navigation. This mechanism is particularly useful in murky water, where visibility and olfaction are poor.

A few fishes, such as electric eels or electric rays, have electric organs in their heads capable of delivering powerful shocks (up to several hundred volts) that stun prey or predators. Weaker electrical signals are emitted continuously to help in assessing the environment, orienting themselves, and communicating.

Some bacteria, mollusks, crustaceans, insects, bony fishes, amphibians, reptiles, birds, and a few mammals detect Earth's magnetic fields and use this information to orient themselves. Migratory birds and sea turtles are well-known examples of animals that use magnetic fields to navigate (discussed further in Chapter 52).

Earth's magnetic fields penetrate organisms, so specialized receptors may not be required. However, certain receptors of sharks, rays, and skates appear to sense magnetic fields. For example, when a shark swims across one of Earth's magnetic field lines, *electromagnetic receptors* may detect changes that occur in electric currents. This information, which is integrated in the brain, helps the animal orient itself.

CHECKPOINT 43.3

- What are two functions of electroreceptors?
- How do animals use electromagnetic reception?

43.4 Nociceptors

LEARNING OBJECTIVE

5 Describe the functions of nociceptors and identify the roles of substance P and endorphins.

Pain receptors, called **nociceptors** (from the Latin *nocere*, meaning "to injure"), are free nerve endings (dendrites) of certain sensory neurons found in almost every tissue. Three main types of nociceptors have been identified: (1) mechanical nociceptors respond to strong tactile stimuli such as cutting, crushing, or pinching; (2) thermal nociceptors respond to temperature extremes (temperatures above 45°C or below 5°C); and (3) polymodal nociceptors respond to a variety of damaging stimuli, including certain chemicals.

When stimulated, nociceptors transmit signals through sensory neurons to interneurons in the spinal cord. These sensory neurons release the neurotransmitters *substance P* and *glutamate*. **Substance P** activates interneurons that transmit the pain message to the opposite side of the spinal cord. Ascending pathways then transmit the message upward to the brain stem and thalamus, where pain perception begins. From the thalamus, impulses are sent into the somatosensory areas that localize the pain. Signals are transmitted to the prefrontal cortex, allowing us to become fully aware of our pain and to evaluate the situation. Information is also sent from the brain stem and thalamus to the limbic system, which generates an emotional response to the injury. **Glutamate** stimulates interneurons in the spinal cord that transmit pain signals to cortical areas of the brain.

Mammals have an analgesic system that inhibits pain signals in the spinal cord. Certain interneurons release **endorphins** and **enkephalins**, neurotransmitters that bind with opiate receptors on the terminals of sensory neurons in the spinal cord. This binding inhibits release of substance P, which stops transmission of the pain signal.

CHECKPOINT 43.4

- What is the function of each main type of nociceptor?
- What is the function of substance P? of endorphins?

43.5 Mechanoreceptors

LEARNING OBJECTIVES

6 Compare the functions and mechanisms of action of the following mechanoreceptors: tactile receptors, proprioceptors, statocysts, hair cells, and lateral line organs.

7 Compare the structure and function of the saccule and utricle with that of the semicircular canals in maintaining equilibrium.

8 Trace the path taken by sound waves through the structures of the ear and explain how the organ of Corti functions as an auditory receptor.

Mechanoreceptors are activated when they change shape as a result of being mechanically pushed or pulled. They transduce mechanical energy, permitting animals to feel, hear, and maintain balance. These receptors provide information about the shape, texture, weight, and spatial relationships of objects in the external environment. Some mechanoreceptors are extremely sensitive. For example, alligators have pressure

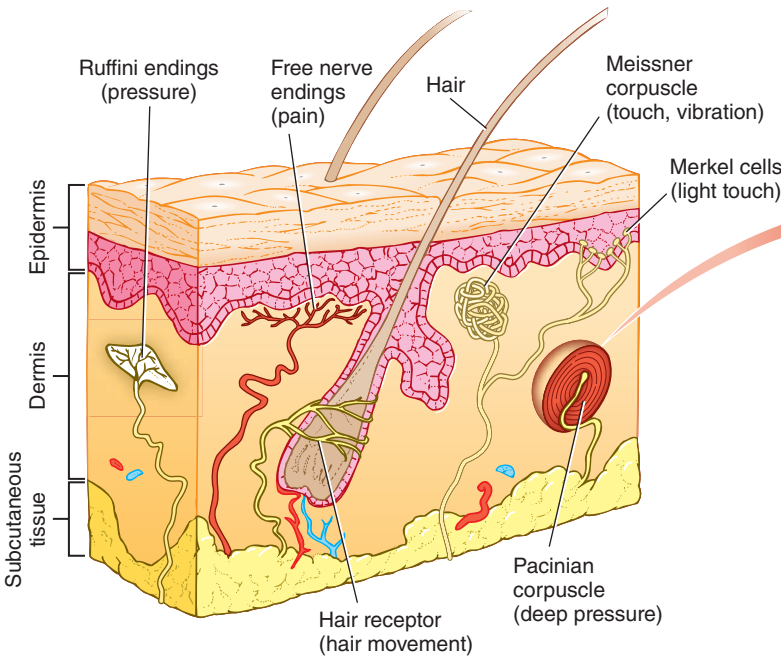
receptors on their faces that can detect the movement in the surrounding water caused by a single drop of falling water.

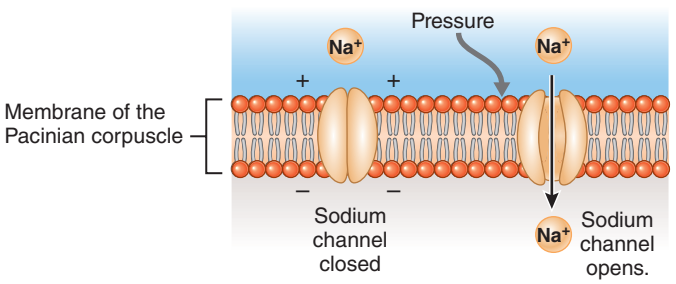


Certain mechanoreceptors enable an animal to maintain its body position with respect to gravity (for us, head up and feet down; for a dog, dorsal side up and ventral side down; for a tree sloth, ventral side up and dorsal side down). When displaced from its normal position, the animal quickly adjusts its body to return to its normal orientation. Mechanoreceptors continuously send information to the CNS regarding the position and movements of the body. These receptors also provide information about the operation of internal organs. For example, they inform us about the presence of food in the stomach, feces in the rectum, urine in the bladder, and a fetus in the uterus.

Tactile receptors are located in the skin

The simplest mechanoreceptors are free nerve endings in the skin. They detect touch, pressure, vibration, and pain when stimulated by objects that contact the body surface. In many invertebrates and vertebrates, *tactile* (touch) *receptors* lie at the base of a hair or bristle. These receptors may sense the body's orientation in space with respect to gravity. They may also detect air and water vibrations and contact with other objects. A tactile receptor is stimulated indirectly when the hair is bent or displaced. The stimulus mechanically distorts ion channel proteins in the plasma membrane of the receptor, leading to net entry of Na^+. A receptor potential develops in the afferent neuron, and action potentials may be generated. This type of receptor responds only when the hair is moving. Even though the hair may be maintained in a displaced position, the receptor is not stimulated unless there is motion.

Thousands of specialized tactile receptors are located in mammalian skin (FIG. 43-4). *Merkel cells* form discs in the deep regions of the epidermis that extend down into the dermis. Merkel cells are important in sensing light touch and enable us to distinguish among the softness of a baby's skin, the fuzziness of a peach, or the hardness of a book cover. They adapt slowly, permitting us to know that an object continues to touch the skin.



Three types of mechanoreceptors in the skin—Meissner corpuscles, Ruffini endings, and Pacinian corpuscles—have encapsulated endings. *Meissner corpuscles*, located in the upper dermis, are sensitive to light touch and vibration. They adapt quickly to a sustained stimulus. *Ruffini endings*, located in the dermis, inform us of heavy, continuous pressure and stretch

(a) Mechanoreceptors in human skin. This diagrammatic section through the human skin illustrates several types of mechanoreceptors that respond to touch and pressure. Also shown are free nerve endings that respond to pain.

(b) Pacinian corpuscle, a deep pressure receptor.

(c) Pacinian corpuscles sense mechanical forces. Pressure causes Na^+ channels to open, depolarizing the axon.

Figure 43-4 Sensory receptors in human skin

of the skin. They adapt very slowly and are thought to provide information about the position of our fingers and hand.

Pacinian corpuscles, located deep in the dermis, are sensitive to deep pressure that causes rapid movement of the tissues. They are especially sensitive to stimuli that vibrate. The Pacinian corpuscle consists of a neuron ending surrounded by concentric connective tissue layers interspersed with fluid. Compression causes displacement of the layers, which stimulates the axon. Even though the displacement is maintained under steady compression, the receptor potential rapidly falls to zero, and action potentials cease—an excellent example of sensory adaptation.

Proprioceptors help coordinate muscle movement

Proprioceptors help animals maintain the position of the body and its parts. Located within muscles, tendons, and joints, proprioceptors continuously respond to tension and movement. With their input, an animal can perceive the positions of its arms, legs, head, and other body parts along with the orientation of its body as a whole. This information is essential for all forms of locomotion and for all coordinated and skilled movements, from spinning a cocoon to completing a reverse one-and-a-half dive with a twist. With the help of proprioceptors, we carry out activities such as dressing or playing the piano even in the dark.

Vertebrates have three main types of proprioceptors: (1) **muscle spindles**, which detect muscle movement (FIG. 43-5); (2) **Golgi tendon organs**, which respond to tension in contracting muscles and in the tendons that attach muscle to bone; and (3) **joint receptors**, which detect movement in ligaments. Impulses from proprioceptors help coordinate the contractions of the several distinct muscles that may be involved in a single movement. Without such receptors, complicated, skilled acts would be impossible. Proprioceptors are also important in maintaining balance.

Proprioceptors continuously send signals to inform the brain about position. Although we are less aware of them, proprioceptors are probably more numerous and more continually active than any of the other sensory receptors. As long as a stimulus is present, receptor potentials are maintained (although not at constant magnitude) and action potentials continue to be generated. The mammalian muscle spindle, one of the more versatile stretch receptors, helps maintain muscle tone. It is a bundle of specialized muscle fibers, with a central region encircled by sensory neuron endings. These neurons continue to transmit signals for a prolonged period, in proportion to the degree of stretch.

Many invertebrates have gravity receptors called statocysts

Statocysts are the simplest organs of equilibrium. Jellyfish and crayfish are among the many aquatic invertebrates that have these gravity receptors (FIG. 43-6). A statocyst is basically an infolding of the epidermis lined with receptor cells called *sensory hair cells*. These cells are equipped with sensory hairs

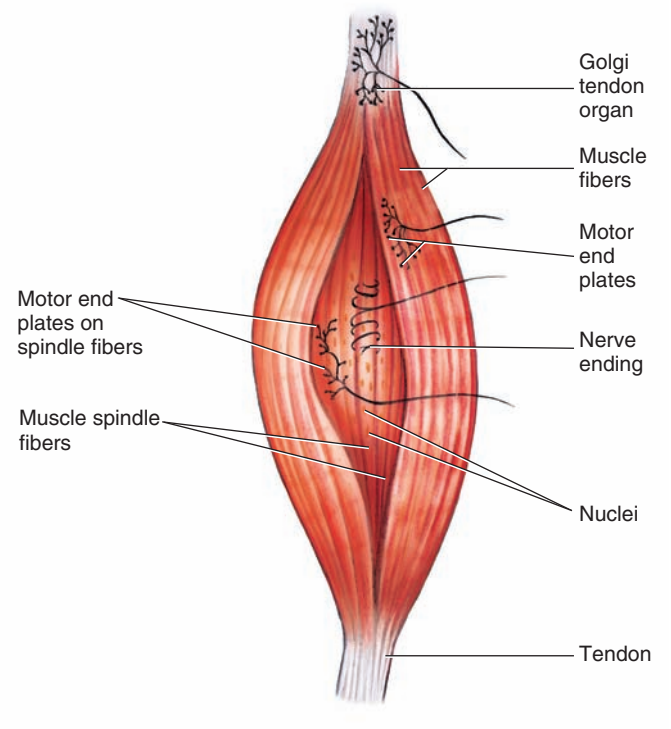

Figure 43-5 Proprioceptors
Muscle spindles detect muscle movement. A muscle spindle consists of an elongated bundle of specialized muscle fibers. Golgi tendon organs respond to tension in muscles and their associated tendons.

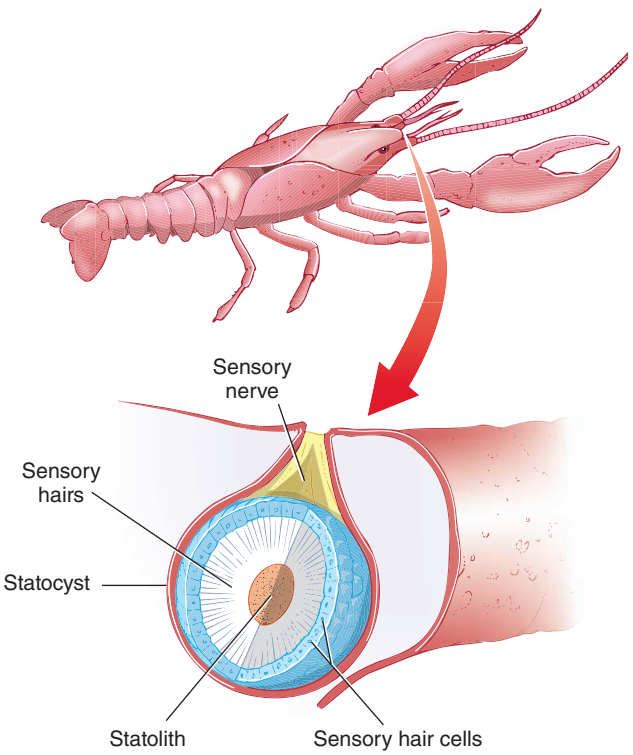

Figure 43-6 A statocyst
Many invertebrates have statocysts, receptors that sense gravitational force and provide information about orientation of the body with respect to gravity.

(not true hairs). The cavity contains one or more **statoliths**, tiny granules of loose sand grains or calcium carbonate held together by an adhesive material secreted by cells of the statocyst. Normally, the particles are pulled downward by gravity and stimulate the sensory hair cells.

When the animal changes position, the statocyst tilts, and the statolith moves in the same direction. This movement bends the sensory hairs. Each sensory hair cell responds maximally when the animal is at a particular position with respect to gravity. The mechanical displacement results in receptor potentials and action potentials that inform the nervous system of the change in position. By "knowing" which sensory cells are firing, the animal knows where "down" is and can correct any abnormal orientation.

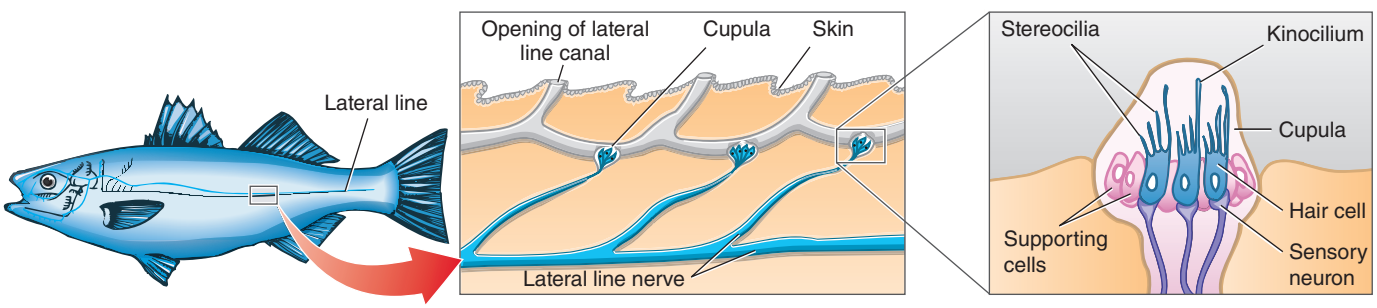
In a classic experiment, the function of the statocyst was demonstrated by replacing the sand grains with iron filings in the statocysts of crayfish. The force of gravity was overcome by holding magnets above the animals. The iron filings were attracted upward toward the magnets, and the crayfish began to swim upside down in response to the new information provided by their gravity receptors.

Hair cells are characterized by stereocilia

Vertebrate **hair cells** are mechanoreceptors that detect movement. They are the sensory receptors in the lateral line of fishes that detect water movement (FIG. 43-7). Hair cells also help maintain position and equilibrium and are important in hearing.

The surface of a vertebrate hair cell typically has a single long **kinocilium** and many shorter **stereocilia**, hairlike projections that increase in length from one side of the hair cell to the other (see Fig. 43-7c). A kinocilium is a true cilium with a 9 + 2 arrangement of microtubules (see Chapter 4). In contrast, stereocilia are not really cilia. They are microvilli that contain actin filaments.

Mechanical stimulation of the stereocilia causes voltage changes. Mechanical stimulation in one direction causes depolarization and release of neurotransmitter, whereas mechanical stimulation in the opposite direction results in hyperpolarization. However, hair cells have no axons and do not produce their own action potentials. Rather, they release neurotransmitter that depolarizes associated neurons.



Lateral line organs supplement vision in fishes

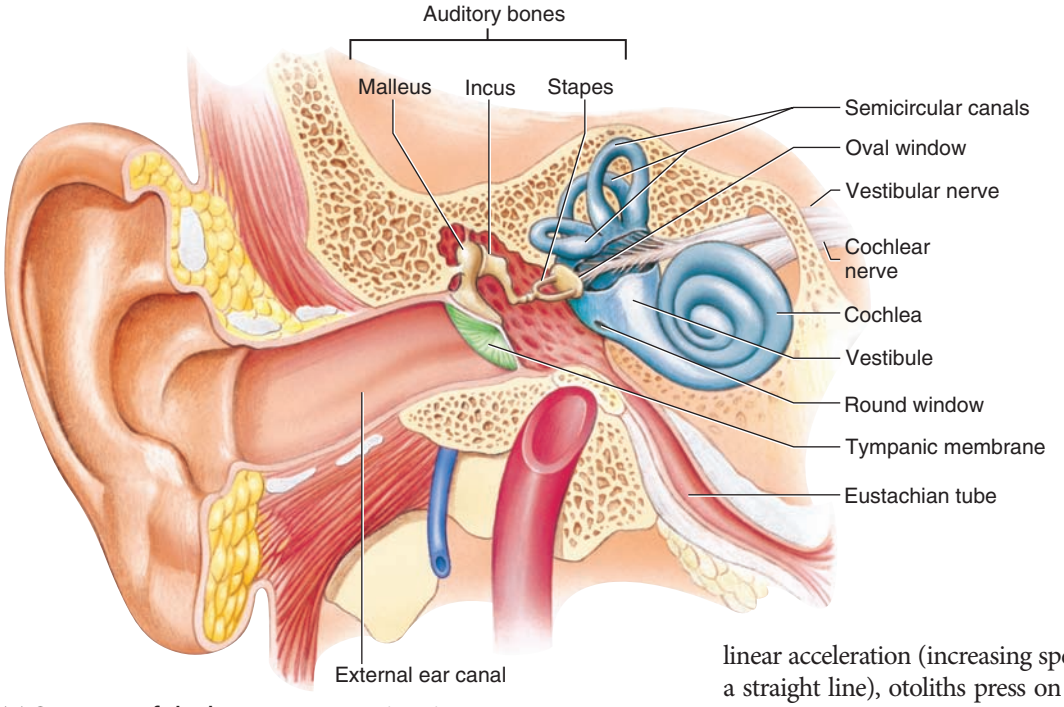
Lateral line organs of fishes and aquatic amphibians detect vibrations in the water. They inform the animal of obstacles in its way and of moving objects such as prey, enemies, and others in its school. Typically, the lateral line organ is a long canal running the length of the body and continuing into the head. The canal is lined with sensory hair cells. The tips of the stereocilia are enclosed by a **cupula**, a mass of gelatinous material secreted by the hair cells.

Pressure waves, currents, and even slight movement in the water cause vibrations in the lateral line organ. As the water moves the cupula, the stereocilia bend. This motion changes the membrane potential of the hair cell, which may then release neurotransmitter. If an associated sensory neuron is sufficiently stimulated, an action potential is dispatched to the CNS.

The vestibular apparatus maintains equilibrium

When you think of the ear, you probably think of hearing. However, in vertebrates the main function of the ear is to help maintain equilibrium. Many vertebrates do not have outer or middle ears, but all have inner ears (FIG. 43-8). In mammals the *inner ear* includes organs of equilibrium equipped with hair cells that sense the position of the body with respect to gravity.

(a) The lateral line organ is a canal that extends the length of the body.



(b) The canal has numerous groupings of hair cells and openings to the outside environment.

(c) The receptor cells are hair cells. Each hair cell has stereocilia and a kinocilium that are covered with a gelatinous cupula. The hair cells respond to waves, currents, and other disturbances in the water.

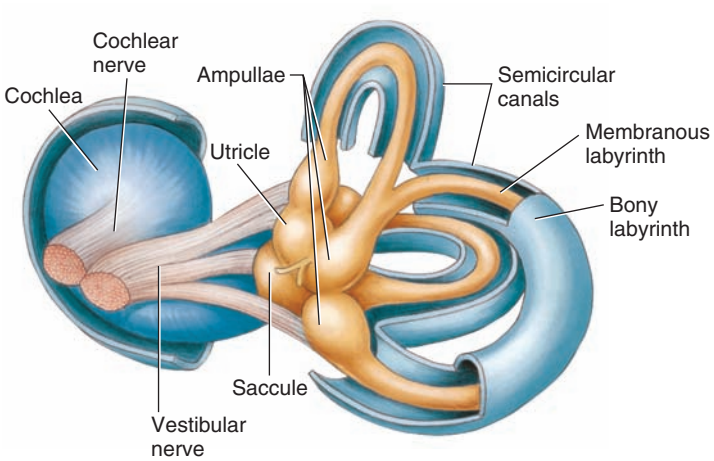


Figure 43-7 Lateral line organs of fishes
These mechanoreceptors detect vibrations in the water, informing the fish of obstacles or moving objects.

(a) Structure of the human ear, anterior view.

(b) The vestibular apparatus. The saccule, utricle, and semicircular canals together make up the vestibular apparatus. The utricle and saccule are best seen in the posterior view shown here.

Figure 43-8 The human ear: hearing and equilibrium

The inner ear is a group of interconnected canals and sacs, called the **labyrinth**, which includes a membranous labyrinth that fits inside a bony labyrinth. In mammals the membranous labyrinth has two saclike chambers—the **saccule** and the **utricle**—and three **semicircular canals**. Collectively, the saccule, utricle, and semicircular canals are called the **vestibular apparatus** (see Fig. 43-8b). Destruction of these organs leads to a considerable loss of the sense of equilibrium. A pigeon whose vestibular apparatus has been destroyed cannot fly but in time can relearn how to maintain equilibrium by using visual stimuli.

The sensory cells of the saccule and utricle are hair cells similar to those of the lateral line organ (FIG. 43-9). The stereocilia projecting from the hair cells are covered by a gelatinous cupula in which calcium carbonate ear stones, called **otoliths**, are embedded. The hair cells in the saccule and utricle lie in different planes.

Normally, the pull of gravity causes the otoliths to press against the stereocilia, stimulating them to initiate impulses. Sensory neurons at the bases of the hair cells transmit these signals to the brain. When the head is tilted or in linear acceleration (increasing speed when the body is moving in a straight line), otoliths press on the stereocilia of different cells, deflecting them. Deflection of the stereocilia toward the kinocilium depolarizes the hair cell. Deflection in the opposite direction hyperpolarizes the hair cell. Thus, depending on the direction of movement, the hair cells release more or less neurotransmitter. When the brain interprets the neural messages, the animal becomes aware of its full body position relative to the ground regardless of how its head is positioned.

Information about turning movements, referred to as angular acceleration, is provided by the three semicircular canals. Each canal, a hollow ring connected with the utricle, lies at right angles to the other two. Each canal is filled with fluid called **endolymph**. At one of the openings of each canal into the utricle there is a small, bulblike enlargement, the **ampulla**. Within each ampulla there is a clump of hair cells called a *crista* (pl., *cristae*), similar to the groups of hair cells in the utricle and saccule. No otoliths are present. The stereocilia of the hair cells of the cristae are stimulated by movements of the endolymph in the canals (FIG. 43-10).

When the head is turned, there is a lag in the movement of the fluid within the canals. The stereocilia move in relation to the fluid and are stimulated by its flow. This stimulation produces not only the consciousness of rotation but also certain reflex movements in response to it. These reflexes cause the eyes and head to move in a direction opposite that of the original rotation. Because the three canals are in three different planes, head movement in any direction stimulates fluid movement in at least one of the canals.

We humans are used to movements in the horizontal plane but not to vertical movements (parallel to the long axis of the upright body). The motion of an elevator or of a ship pitching in a rough sea stimulates the semicircular canals in an unusual way and may cause seasickness or motion sickness, with resultant nausea or vomiting. When a seasick person lies down, the movement stimulates the semicircular canals in a more familiar way, and nausea is less likely to occur.

Key Point

The utricle and saccule sense changes in the position of the head relative to gravity as well as changes in the rate of motion when moving in a straight line.

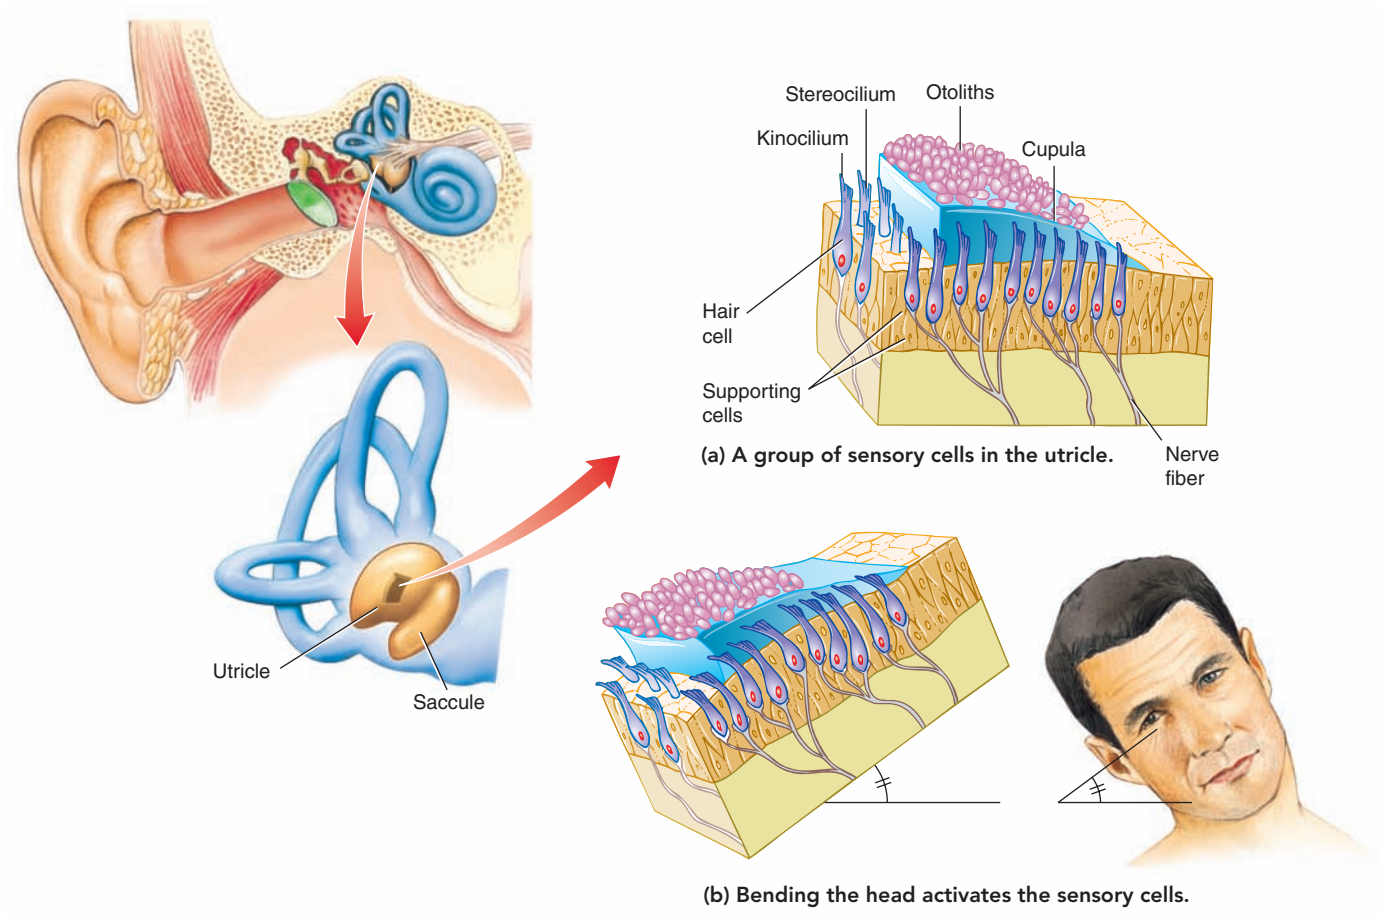

Figure 43-9 The saccule and utricle: maintaining equilibrium

The saccule and utricle sense linear acceleration, allowing us to know our position relative to the ground. Compare the positions of the otoliths and hair cells in **(a)** with those in **(b)**. Changes in head position cause the force of gravity to distort the cupula, which in turn distorts the stereocilia of the hair cells. The hair cells respond by releasing neurotransmitters. Impulses are transmitted along the vestibulocochlear nerve to the brain.

PREDICT How would the utricle and saccule function in sensing changes in head position under gravity-free (weightless) conditions?

Auditory receptors are located in the cochlea

Many arthropods and most vertebrates have sound receptors, but for many of them hearing does not seem to be a sensory priority. It is important in tetrapods, however, and both birds and mammals have a highly developed sense of hearing. Their auditory receptors are located in the **cochlea** of the inner ear. These mechanoreceptors contain hair cells that detect pressure waves.

The cochlea is a spiral tube that resembles a snail's shell (FIG. 43-11). If the cochlea were uncoiled, you would see that it consists of three canals separated from one another by thin membranes. The canals come almost to a point at the apex. Two of these canals, the *vestibular canal* and the *tympanic canal*, connect at the apex of the cochlea and are filled with a fluid called *perilymph*. The middle canal, the *cochlear duct*, is filled with endolymph. The cochlear duct contains the auditory organ, the **organ of Corti**.

The organ of Corti contains about 18,000 hair cells in rows that extend the length of the coiled cochlea. The stereocilia of each hair cell extend into the cochlear duct. The hair cells rest on the **basilar membrane**, which separates the cochlear duct from the tympanic canal. Another membrane, the **tectorial membrane**, overhangs and is in contact with the hair cells.

Sound waves are amplified in the middle ear In terrestrial vertebrates, sound waves in the air are transformed into pressure waves in the cochlear fluid. In the human ear, for example, sound waves pass through the *external auditory canal* and

Key Point

The semicircular canals detect angular acceleration or deceleration of the head (changes in the position of the head when you are turning it).

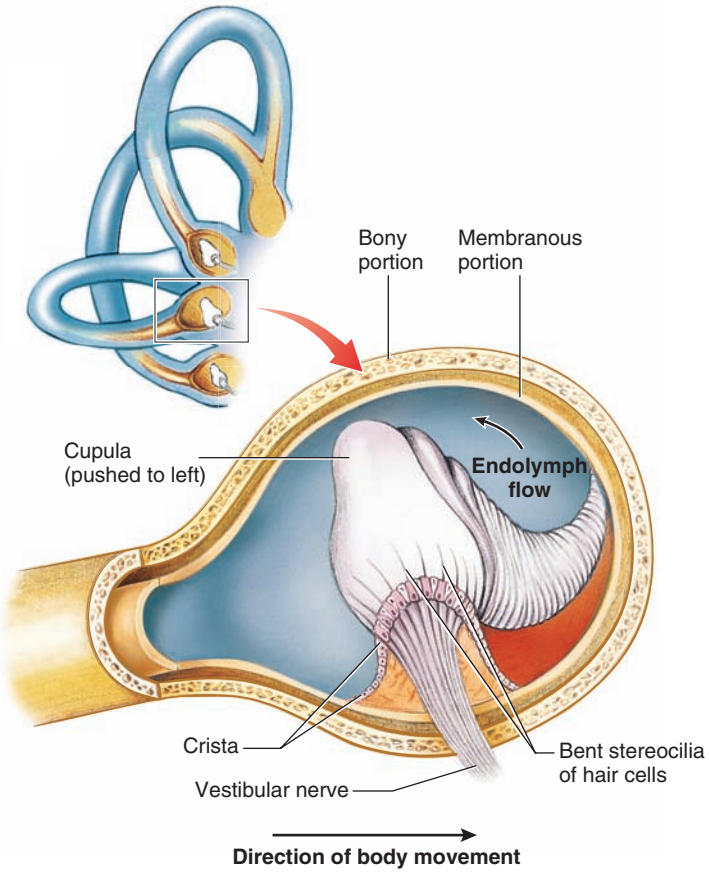

Figure 43-10 Semicircular canals and equilibrium

When the head changes its rate of rotation, endolymph within the ampulla of the semicircular canal distorts the cupula. The stereocilia of the hair cells bend, increasing the frequency of action potentials in sensory neurons. Information is transmitted to the brain via the vestibular nerve.

PREDICT A child spinning in a circle becomes dizzy. The child is advised to spin a few times in the opposite direction. What effect would this have? Explain.

vibrate the **tympanic membrane**, or eardrum, which separates the outer ear and the middle ear. The vibrations are transmitted across the middle ear by three tiny bones: the **malleus**, **incus**, and **stapes** (or hammer, anvil, and stirrup, so called because of their shapes). The malleus is in contact with the eardrum, and the stapes is in contact with a thin, membranous region of the cochlea called the *oval window*. The **eustachian tube**, which connects the middle ear with the pharynx (throat region), helps equalize pressure between the middle ear and the atmosphere.

The malleus, incus, and stapes act as three interconnected levers that amplify vibrations. A small movement in the malleus causes a larger movement in the incus and a very large movement in the stapes. The vibrations pass through the oval window to the perilymph in the vestibular canal. If sound waves were conducted directly from air to the oval window, much energy would be lost. The middle ear functions to couple sound waves in the air with the pressure waves conducted through the fluid in the cochlea.

Because liquids cannot be compressed, the oval window could not cause movement of the fluid in the vestibular canal if there were no escape valve for the pressure. This valve is provided by the membranous *round window* at the end of the tympanic canal. The pressure wave presses on the membranes separating the three ducts and is transmitted to the tympanic canal. The pressure wave makes the round window bulge. The movements of the basilar membrane produced by these pulsations cause the stereocilia of the organ of Corti to rub against the overlying tectorial membrane.

Stereocilia are bent by their contact with the tectorial membrane. As a result, ion channels in the plasma membrane of the hair cells open. Calcium ions move into the hair cell, causing the release of glutamate. This neurotransmitter binds to receptors on sensory neurons that synapse with each hair cell, leading to depolarization of these sensory neurons. Axons of the sensory neurons join to form the *cochlear nerve*, a component of the vestibulocochlear nerve (cranial nerve VIII; also referred to as the *auditory nerve*).

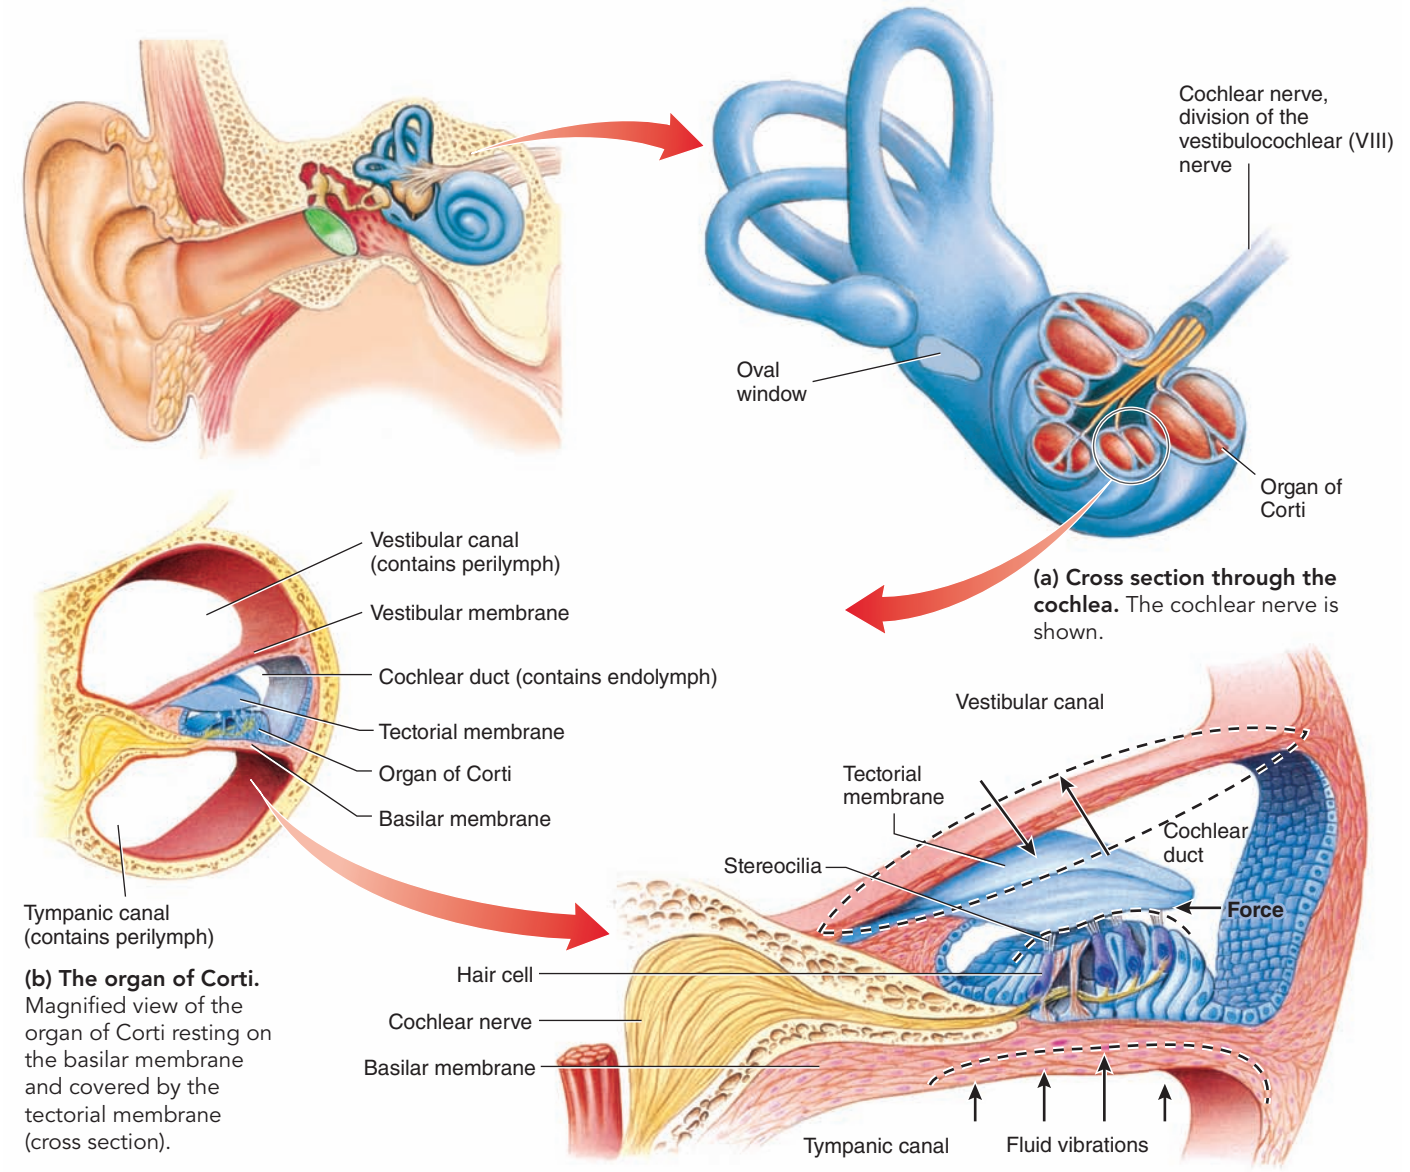
We can summarize the sequence of events involved in hearing as follows:

sound waves enter external auditory canal → tympanic membrane vibrates → malleus, incus, and stapes amplify vibrations → oval window vibrates → vibrations are conducted through fluid → basilar membrane vibrates → hair cells in organ of Corti are stimulated → cochlear nerve transmits impulses to brain

Sounds differ in pitch, loudness, and tone quality

Pitch depends on frequency of sound waves, or number of vibrations per second, and is expressed in hertz (Hz). Low-frequency vibrations result in the sensation of low pitch, whereas high-frequency vibrations result in the sensation of high pitch. Sounds of a given frequency set up resonance waves in the cochlear fluid that cause a particular section of the basilar membrane to vibrate. The brain infers the pitch of a sound from the particular hair cells that are stimulated.

The human ear typically registers sound frequencies between about 20 and 20,000 Hz (also expressed as 20 kilohertz) and is most sensitive to sounds between 1000 and 4000 Hz (FIG. 43-12). Comparing the energy of audible sound waves with the energy of visible light waves, your ear is ten times more sensitive than your eye. Dogs can hear sounds up to 40,000 Hz, and bats can detect frequencies as high as 100,000 Hz.



Loud sounds cause resonance waves of greater amplitude (height). The hair cells are more intensely stimulated, and the cochlear nerve transmits a greater number of impulses per second. Variations in tone quality (timbre)—such as when an

(b) The organ of Corti. Magnified view of the organ of Corti resting on the basilar membrane and covered by the tectorial membrane (cross section).

(c) How the organ of Corti works. Vibrations transmitted by the malleus, incus, and stapes set the fluid in the tympanic canal in motion. These vibrations (*dotted lines*) are transmitted to the basilar membrane. As the membrane vibrates, hair cells of the organ of Corti rub against the overlying tectorial membrane. This stimulation depolarizes the hair cells, generating action potentials in the sensory neurons of the cochlear nerve.

Figure 43-11 The cochlea, organ of hearing

PREDICT Imagine that the hair cells at one end of the organ of Corti were damaged and could no longer be stimulated by the tectorial membrane. How would that affect hearing?

oboe, a cornet, and a violin play the same note—depend on the number and kinds of overtones, or harmonics, produced. Many hair cells along the basilar membrane are stimulated and vibrate simultaneously in addition to the main vibration common to all three instruments. Thus, differences in tone quality are recognized in the pattern of the hair cells stimulated.

Deafness may be caused by injury to, or malformation of, either the sound-transmitting mechanism of the outer, middle, or inner ear or the sound-perceiving mechanism of the

- List the sequence of events involved in hearing.

43.6 Chemoreceptors

LEARNING OBJECTIVE

9 Compare the structure and function of the receptors of taste and smell, and describe the function of the vomeronasal organ.

The mechanisms for chemoreception have been highly conserved throughout the animal kingdom. Two highly sensitive types of **chemoreceptors** evolved: one for taste, more formally called *gustation*, and one for smell, or *olfaction*. These chemical senses, found throughout the animal kingdom, allow animals to detect chemical substances in food, water, and air. Evaluating such chemical cues allows animals to find food and mates and to avoid predators. Members of the same species use chemoreception to communicate about these critical issues.

For terrestrial vertebrates, the sense of smell involves gaseous substances, called *odorants*, that reach olfactory receptors through the air. The sense of taste depends on sensing chemicals called *tastants*, dissolved in water (or saliva) in the mouth. For aquatic animals, these distinctions blur. Does a catfish smell or taste the water?

The organs of taste and smell in insects are sensory hairs called *sensilla* (sing., *sensillum*) that project from the cuticle. Olfactory sensilla are typically found on the antennae. In some insects, including ants, bees, and wasps, taste sensilla are also located on the antennae. Taste sensilla typically project from the mouthparts. In butterflies and flies, they may also project from the end of the leg.

In the blowfly each sensillum contains four chemoreceptors (FIG. 43-13). Dendrites from each cell extend to an opening at the tip, and axons transmit sensory signals to the brain. Studies suggest that insects can distinguish among various

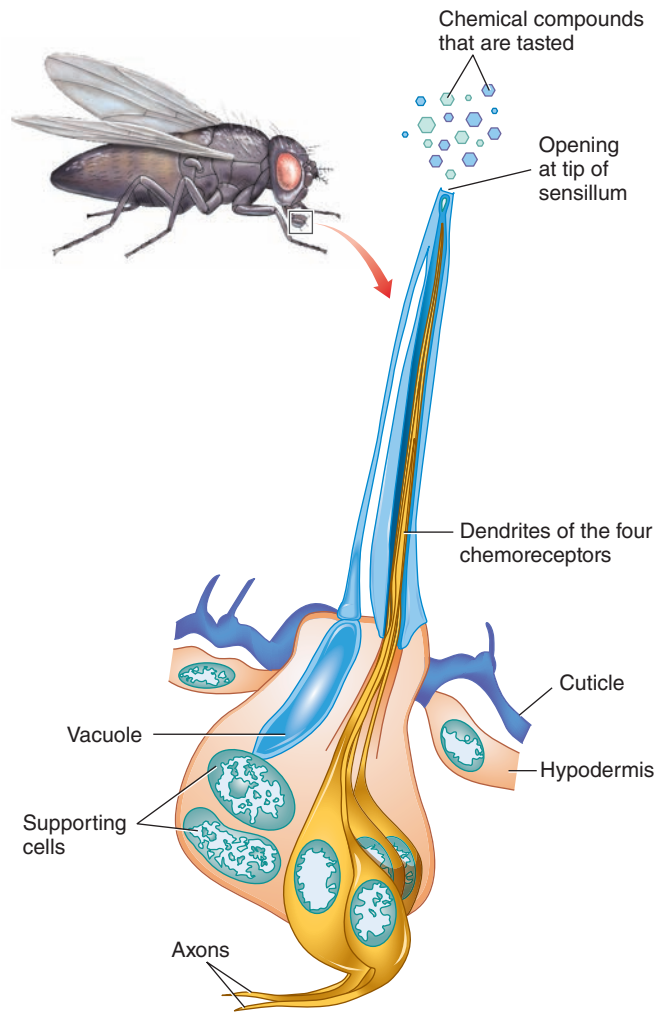

Figure 43-13 An insect taste receptor

Insects respond to a wide variety of chemical substances found in foods. Each sensillum in the blowfly contains four chemoreceptors. Dendrites that extend to an opening at the tip sense taste. The other end of each chemoreceptor is an axon that transmits sensory signals to the brain.

bitter tastes more precisely than mammals can. This ability is important in discriminating tastes associated with spoiled, bacteria-laden foods or toxins.

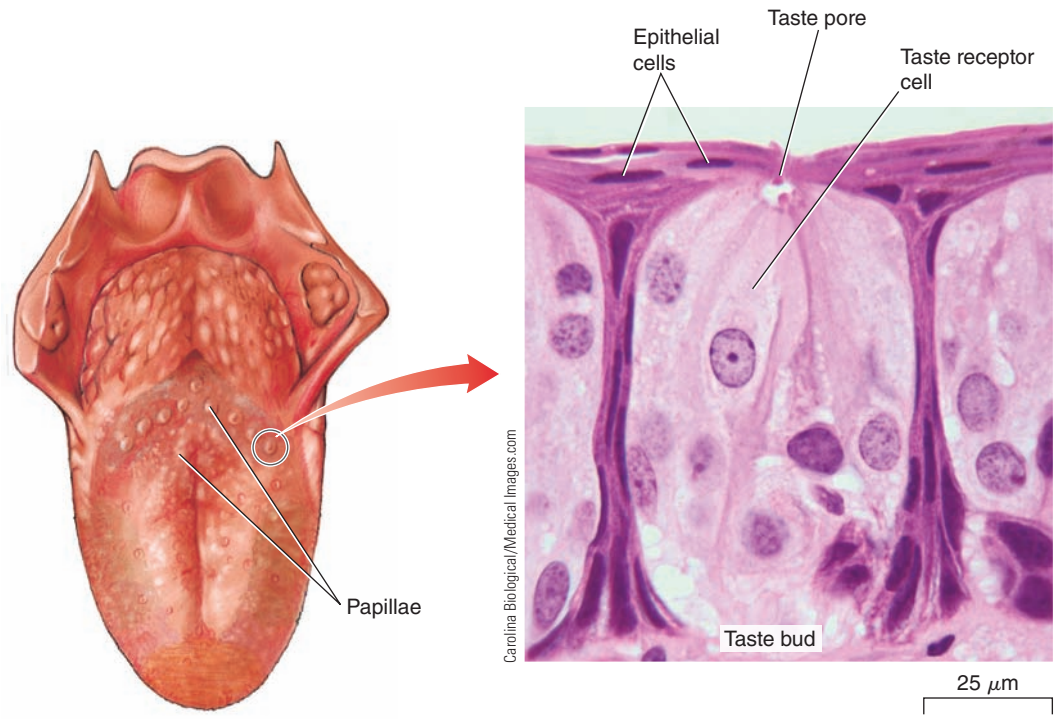
Taste receptors detect dissolved food molecules

As just described for insects, the ability to discriminate among tastes has survival value. Poisons are generally bitter. In contrast, foods with a high caloric value often taste sweet. Mammals sense taste with *taste buds* located in the mouth.

In humans, taste buds lie mainly in tiny elevations, or papillae, on the tongue. Each of the 10,000 or so taste buds is an oval epithelial capsule containing about 50 taste receptor cells interspersed with supporting cells (FIG. 43-14). Taste receptor cells are replaced about every ten days. One sensory neuron can innervate several taste buds. The plasma membrane at the tip of each taste receptor cell has microvilli that extend into a taste pore on the surface of the tongue, where they are bathed in saliva. The taste receptors detect tastants dissolved in saliva.

Although mammals can sense thousands of different tastes, most tastes are thought to be combinations of five basic tastes: sweet, sour, salty, bitter, and umami (the Japanese word for delicious). Umami is responsible for the savory flavor of certain aged cheeses, soy sauce, anchovies, and some types of seafood. The amino acid glutamate is the compound that triggers the taste. In the form of its sodium salt, monosodium glutamate, or MSG, this compound is used to flavor foods. Additional basic tastes have been proposed, including *fatty*, which is stimulated by fatty acids.

The process of tasting sweet, bitter, or umami involves a signal transduction process in which glucose, or another tastant, binds to a G protein–linked receptor that activates a second messenger system (see Chapter 6). Salty and sour tastants act directly on ion channels. In each case, action potentials are generated. Signals are transmitted (by way of the brain stem and thalamus) to the gustatory area in the parietal lobe as well as to the limbic system.



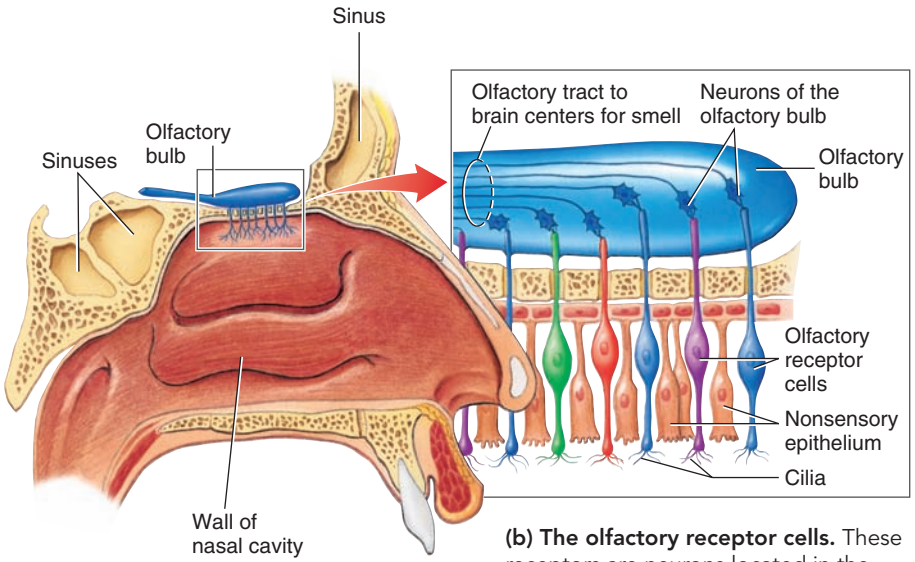
Flavor depends on the basic tastes in combination with smell, texture, and temperature. Smell affects flavor because odors pass from the nasal chamber to the mouth. You have probably observed that when your nose is congested, food seems to have little "taste." The taste buds are not affected, but the blockage of nasal passages severely reduces the participation of olfactory reception in the composite sensation of flavor.

The olfactory epithelium is responsible for the sense of smell

Most invertebrates and some vertebrates (e.g., rodents) depend on olfaction, the detection of odors, as their main sensory modality. In terrestrial vertebrates olfaction occurs in the nasal epithelium.

In humans the **olfactory epithelium** is found in the roof of the nasal cavity (FIG. 43-15). It contains about 100 million olfactory receptor cells with ciliated tips. Each receptor cell is actually an axon. The long, nonmotile cilia extend into a layer of mucus on the epithelial surface of the nasal passageway. Receptor molecules on the cilia bind with compounds dissolved in the mucus. Remarkably, the olfactory receptor cells are replaced about every two months in humans, yet another example of the generation of new neurons throughout life.

The olfactory receptor cell axons project directly to the brain. These axons make up the **olfactory nerve** (cranial nerve I), which extends to the **olfactory bulb** in the brain. From there, information is transmitted to the *olfactory cortex* in the limbic system. Recall that the limbic system is also associated



(a) Location of taste buds. Taste buds are concentrated in the papillae that cover the surface of the tongue.

(b) LM of a taste bud. Each taste bud is an epithelial capsule containing several taste receptor cells. A single taste receptor cell may respond to more than one category of taste.

Figure 43-15 Chemoreception: olfaction

Many animals communicate with pheromones

Animals within many species communicate with one another by releasing **pheromones**, small, volatile molecules that are secreted into the environment. For example, female moths release pheromones that attract males. Dogs and wolves use pheromones to mark territory.

Mammals have specialized chemoreceptor cells that detect pheromones. These cells make up the **vomeronasal organ** located in the epithelium of the nose (separate from the main olfactory epithelium). The vomeronasal sensory neurons send signals to areas of the hypothalamus, which serves as a link with the endocrine system. (We discuss pheromones further in Chapter 52.)

with emotions. Odors are often associated with feelings and memories.

When an *odorant*, a molecule that can be smelled, binds with a receptor on a cilium of an olfactory receptor cell, a signal transduction process is initiated. A G protein is activated, leading to the synthesis of cyclic AMP, which opens ion channels in the plasma membrane. These channels permit Na^+ and Ca^{2+} to enter the cell, causing depolarization. Calcium-gated chloride channels then open, and Cl^- move out of the cell, causing further depolarization. The number of odorous molecules determines the intensity, which in turn determines the magnitude of the receptor potential. The receptor potential generates action potentials in the afferent neuron.

Humans and chimps have about 400 functional olfactory genes, each coding for an olfactory receptor protein. In contrast, dogs have about 1000 functional olfactory genes.

The combination of receptors activated determines the odors perceived. Humans are capable of perceiving about 10,000 scents. Interestingly, studies have shown that dogs can be trained to detect patients with certain types of cancer based on scent.

The olfactory receptors respond to remarkably small amounts of a substance. For example, most people can detect ionone, the synthetic substitute for the odor of violets, when it is present in a concentration of only 1 part to more than 30 billion parts of air. Smell is perhaps the sense that adapts most quickly. The olfactory receptors adapt about 50% in the first second or so after stimulation, so even air that smells awful may seem odorless after only a few minutes.

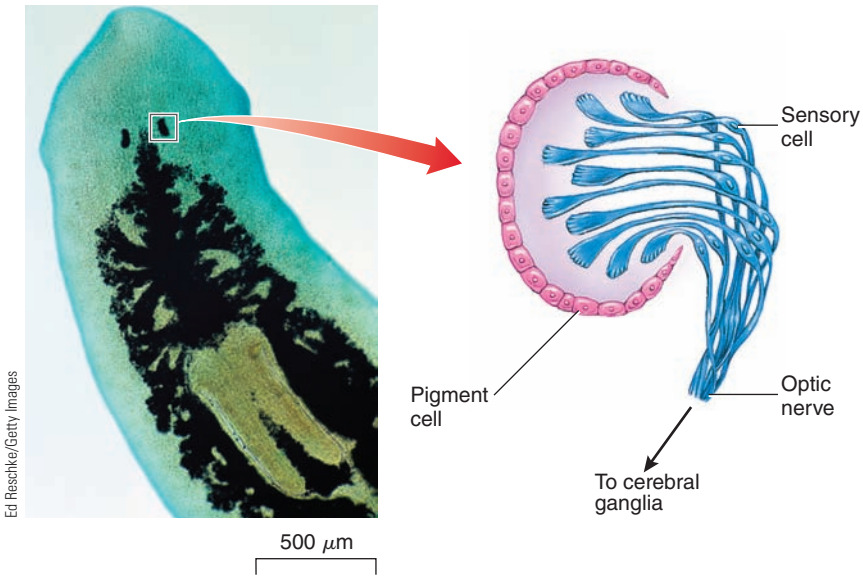
CHECKPOINT 43.6

- **CONNECT** In what ways are olfaction and gustation similar?

43.7 Photoreceptors

LEARNING OBJECTIVES

10 Contrast simple eyes, compound eyes, and vertebrate eyes.
11 Identify each structure of the vertebrate eye and describe its function.
12 Compare the two types of photoreceptors, describe the signal transduction pathway that is activated when rhodopsin responds to light, and summarize the visual pathway.



Most animals have **photoreceptors** that use pigments to absorb light energy. **Rhodopsins** are the photopigments in the eyes of cephalopod mollusks (squids and octopods), arthropods, and vertebrates. Light energy striking a light-sensitive receptor cell containing these pigments triggers chemical changes in the pigment molecules that result in receptor potentials.

Invertebrates have several types of light-sensing organs

The simplest light-sensitive structures in animals are found in certain cnidarians and flatworms (FIG. 43-16). They are *eyespots*, also called **ocelli**, which detect light but do not form images. Eyespots are often bowl-shaped clusters of light-sensitive cells within the epidermis. They may detect the direction of the light source and distinguish light intensity.

(a) Planarian flatworms have eyespots.

(b) Structure of the eyespot of a planarian flatworm.

Figure 43-16 Photoreception: eyespots

The simplest light-sensitive structures are the ocelli, or eyespots, found in certain invertebrates.

Effective image formation requires a more complex *eye*, usually with a lens. A *lens* concentrates light on a group of photoreceptors. Vision also requires a brain that can interpret the action potentials generated by the photoreceptors. The brain integrates information about movement, brightness, location, position, and shape of the visual stimulus. Two fundamentally different types of eyes evolved: the compound eye of arthropods and the camera eye of vertebrates and cephalopod mollusks.

The **compound eyes** of crustaceans and insects differ structurally and functionally from vertebrate eyes. The surface of a compound eye appears faceted, which means "having many faces," like a diamond (FIG. 43-17). Each *facet* is the convex *cornea* of one of the eye's visual units, called **ommatidia** (sing., *ommatidium*). The number of ommatidia varies with the species. For example, each eye of certain crustaceans has only 20 ommatidia, whereas the dragonfly eye has as many as 28,000!

The optical part of each ommatidium includes a biconvex lens and a *crystalline cone*. The lens and crystalline cone focus light onto photoreceptor cells called **retinular cells**. These cells have a light-sensitive membrane made up of microvilli that contain rhodopsin. The membranes of several retinular cells may fuse to form a central rod-shaped *rhabdome* that is sensitive to light.

Compound eyes do not perceive form well. Although the lens system of each ommatidium is adequate to focus a small inverted image, there is little evidence that the animal actually perceives them as images. However, all the ommatidia together produce a composite image, or *mosaic* picture. In gathering a point of light from a narrow sector of the visual field, each ommatidium is, in fact, sampling a mean intensity from that sector. All these points of light taken together form a mosaic picture (see Fig. 43-17d).

Arthropod eyes usually adapt to different intensities of light. A sheath of pigmented cells envelops each ommatidium, and screening pigments are present in *iris cells* and retinular cells. In nocturnal and crepuscular (active at dusk) insects and many crustaceans, pigment migrates proximally and distally within each pigmented cell. When the pigment is in the proximal position, each ommatidium is shielded from its neighbor, and only light entering directly along its axis can stimulate the receptors. When the pigment is in the distal position, light striking at any angle can pass through several ommatidia and stimulate many retinal units. As a result, sensitivity is increased in dim light, and the eye is protected from excessive stimulation in bright light. Pigment migration is under neural control in insects and under hormonal control in crustaceans. In some species it follows a daily rhythm.

Although the compound eye can form only coarse images, it compensates by superbly detecting movement. Flies can detect up to about 265 flickers per second. In contrast, the human eye can detect only 45 to 53 flickers per second; for us, flickering lights fuse above these values, so we see light provided by an ordinary bulb as steady and the movement in motion pictures as smooth. To an insect, both room lighting and motion pictures must flicker horribly. The insect's high critical flicker fusion threshold permits immediate detection of even slight movement by prey or enemy. The compound eye is an important adaptation to the arthropod's way of life.

Compound eyes differ from our eyes in another respect. They are sensitive to wavelengths of light in the range from red to ultraviolet (UV). Accordingly, an insect can see UV light well, and its world of color is very different from ours. Because they reflect UV light to various degrees, flowers that appear identically colored to humans may appear strikingly dissimilar to insects (see Fig. 37-4g).

Cephalod mollusks (squids and octopods) and vertebrates have eyes that work somewhat like an old-fashioned camera (described in the next section). Interestingly, the camera eye also evolved in Cubozoa (box jellyfish), a group of cnidarians.

Vertebrate eyes form sharp images

The position of the eyes in the front of the head of primates and certain birds allows both eyes to focus on the same object. The overlap in information they receive results in the same visual information striking the two retinas (light-sensitive areas) at the same time. This *binocular vision* is important in judging distance and in depth perception.

The vertebrate eye can be compared to an old-fashioned camera. An adjustable lens can be focused for different distances, and a diaphragm, called the **iris**, regulates the size of the **pupil**, an opening through which light passes (FIG. 43-18). The **retina** corresponds to the light-sensitive film used in a

Figure 43-17 Photoreception: compound eyes

camera. Outside the retina is the **choroid layer**, a sheet of cells filled with black pigment that absorbs extra light. This mechanism prevents light from being reflected back into the photoreceptors, which would cause blurring of images. (Cameras are also black on the inside.) The choroid is rich in blood vessels that supply the retina.

The outer coat of the eyeball, called the **sclera**, is a tough, opaque, curved sheet of connective tissue. The sclera protects the inner structures and helps maintain the rigidity of the eyeball. On the front surface of the eye, this sheet becomes the thinner, transparent **cornea** through which light enters. The cornea serves as a fixed *lens* that focuses light.

The **lens** of the eye is a transparent, elastic ball just behind the iris. It bends the light rays coming in and brings them to a focus on the retina. The lens is aided by the curved surface of the cornea and by the refractive properties (ability to bend light rays) of the liquids inside the eyeball. The *anterior cavity* between the cornea and the lens is filled with a watery substance, the aqueous fluid. The larger *posterior cavity* between the lens and the retina is filled with a more viscous fluid, the **vitreous body**. By providing an internal hydrostatic pressure, both fluids help maintain the shape of the eyeball.

At its anterior margin, the choroid is thick and projects medially into the eyeball, forming the *ciliary body*, which consists of ciliary processes and the ciliary muscle. The ciliary processes are glandlike folds that project toward the lens and secrete the aqueous fluid.

The eye has the ability to change focus for near or far vision by changing the shape of the lens (FIG. 43-19). This process, called **accommodation**, depends on the *ciliary muscle*, a circular muscle that is part of the ciliary body. To focus on close objects, the ciliary muscle contracts, making the elastic lens rounder. To focus on more distant objects, this muscle relaxes and the lens assumes a flattened (ovoid) shape.

The amount of light entering the eye is regulated by the iris, a ring of smooth muscle that appears as blue, green, gray, or brown depending on the amount and nature of pigment present. The iris consists of two mutually antagonistic sets of muscle fibers. One set is arranged circularly and contracts to *decrease* the size of the pupil. The other is arranged radially and contracts to *increase* the size of the pupil.

Each eye also has six muscles that extend from the surface of the eyeball to various points in the bony socket. These muscles enable the eye as a whole to move and be oriented in a given direction. Cranial nerves innervate the muscles in such a way that the eyes normally move together and focus on the same area.

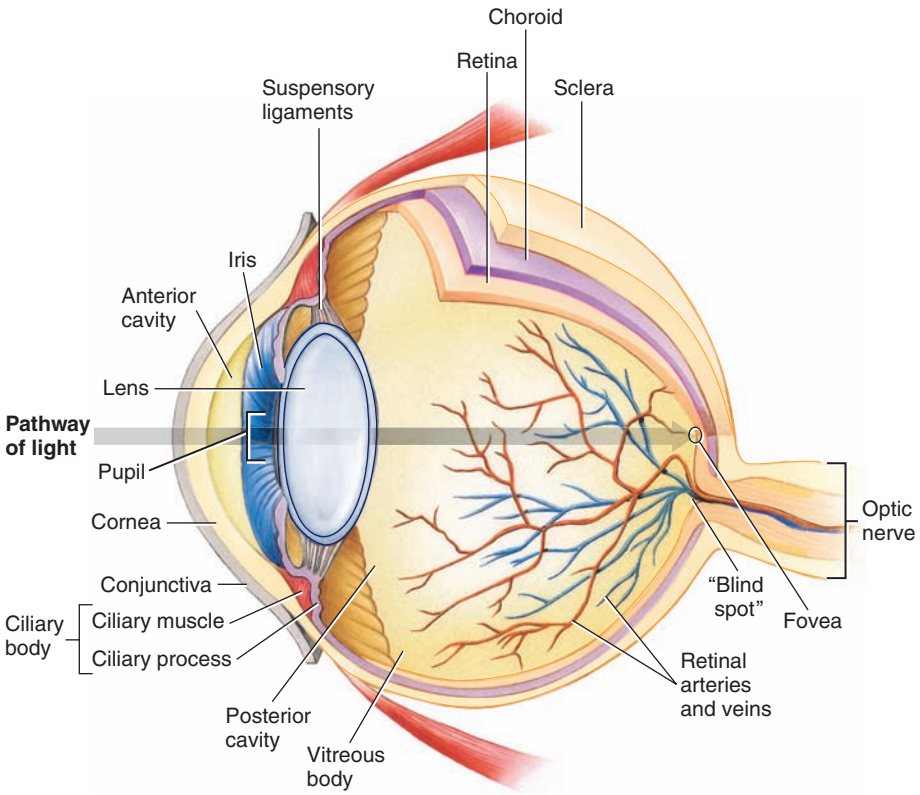

Figure 43-18 Photoreception: structure of the human eye

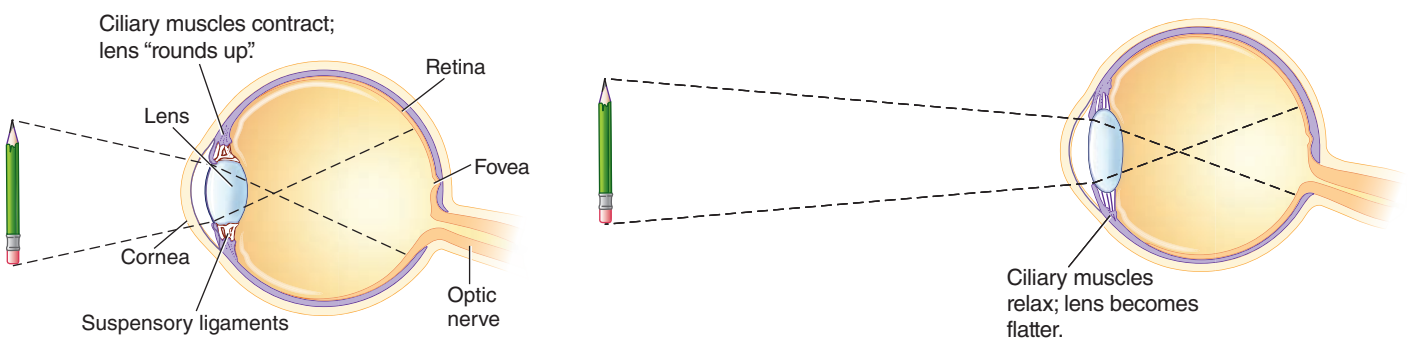
Light passes through the human eye to photoreceptor cells in the retina. In this lateral view, the eye is shown partly sectioned along the sagittal plane to expose its internal structures.



The retina contains light-sensitive rods and cones

The light-sensitive structure in the vertebrate eye is the retina, which lines the posterior two-thirds of the eyeball and covers the choroid. The retina, which is composed of ten layers, contains the photoreceptor cells called, according to shape, **rods** and **cones**. In both rod and cone cells, infoldings of the plasma membrane form stacks of membranous discs that contain the photopigments. The discs greatly increase the light-absorbing surface.

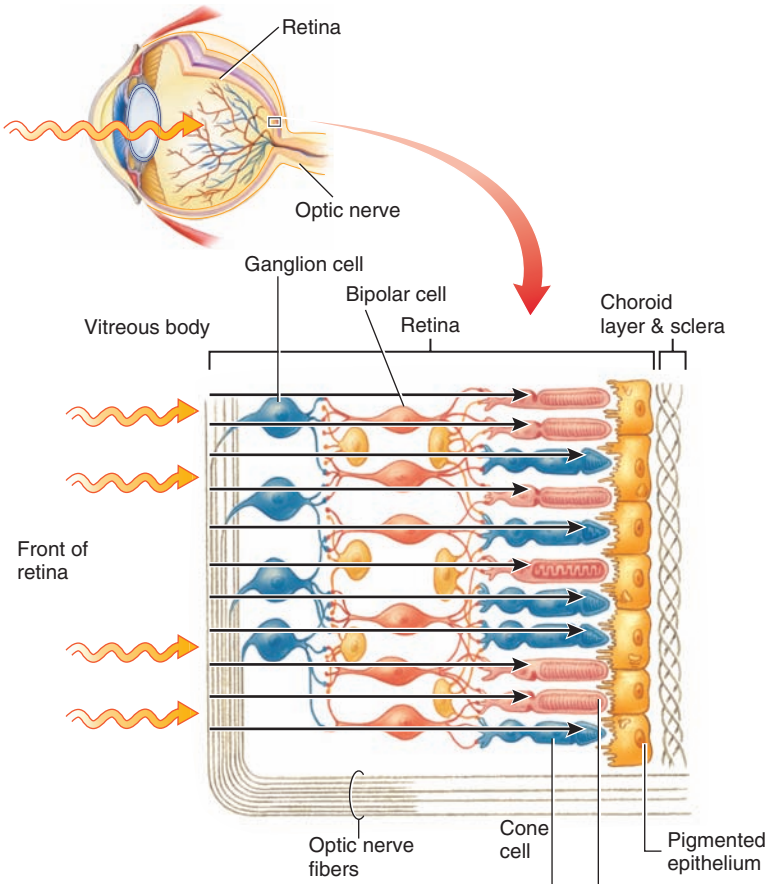
The human eye has about 125 million rods and 6.5 million cones. Rods function in dim light, allowing us to detect shape and movement. They do not discriminate among colors. Because the rods are more numerous in the periphery of the retina, you can see an object better in dim light if you look slightly to one side of it (allowing the image to fall on the rods).

Cones respond to light at higher levels of intensity, such as daylight, and they allow us to perceive fine detail. Cones are responsible for color vision; they are differentially sensitive to different wavelengths (colors) of light. In primates and certain hunting birds (such as eagles), the cones are most concentrated in the fovea, a small, depressed area in the center of the retina. The **fovea** is the region of sharpest vision because it has the greatest density of receptor cells and because the retina is thinner there.

Light must pass through several layers of connecting neurons in the retina to reach the rods and cones (FIG. 43-20). This arrangement lets the rods and cones contact a layer of pigmented epithelium that provides **retinal**, a component of rhodopsin. The retina has five main types of neurons. (1) Photoreceptors (rods and cones) synapse on (2) **bipolar cells**, which make synaptic contact with (3) **ganglion cells**. Two types of lateral interneurons are the (4) **horizontal cells**, which receive information from the photoreceptor cells and send it to bipolar cells, and the (5) **amacrine cells**, which receive messages from the bipolar cells and send signals back to them or to ganglion cells (FIG. 43-21).

(a) Near vision. (b) Distant vision.

Figure 43-19 Accommodation



How the eye changes focus for **(a)** near and **(b)** distant vision.

Key Point

The rods and cones in the retina are the photoreceptors in vertebrates.

(a) Neurons in the retina. The elaborate interconnections among the various layers of neurons in the retina allow them to interact and influence one another.

Science Photo Library/STEVE GSCHMEISSNER/Getty Images

(b) SEM of rods and cones. The *tan*, elongated structures are rods. The shorter, thicker, *green* structures are cones. The rods function in dim light and allow you to see shapes and movement. The cones allow you to view the world in color.

Horizontal and amacrine cells help process visual input within the retina. Interestingly, one group of ganglion cells *project* to (i.e., have axons that extend to) the *suprachiasmatic nucleus*, the body's main biological clock. These ganglion cells contain a light-sensitive pigment (melanopsin) that is important in nonvisual responses to light.

The axons of the ganglion cells extend across the surface of the retina and unite to form the **optic nerve**. The area where the optic nerve passes out of the eyeball, the *optic disk*, is known as the *blind spot*; because it lacks rods and cones, images falling on it cannot be perceived.

Here is a simplified summary of the visual pathway:

light passes through cornea → through aqueous fluid → through lens → through vitreous body → image forms on photoreceptor cells in retina → signal bipolar cells → signal ganglion cells → optic nerve transmits signals to thalamus → integration by visual areas of cerebral cortex

Light activates rhodopsin

How is light converted into the neural signals that transmit information about environmental stimuli into pictures in the brain? Rod cells are so sensitive to light that they can respond to a single photon. Rhodopsin in the rod cells and some very closely related photopigments in the cone cells are responsible for the ability to see. **Rhodopsin** consists of *opsin*, a large protein that is chemically joined with *retinal*, an aldehyde of vitamin A (see Fig. 3-14). Two isomers of retinal exist: the *cis* form, which is folded, and the *trans* form, which is straight.

In the dark, opsin binds to retinal in the *cis* form. Cyclic GMP (cyclic guanosine monophosphate, a molecule similar to cyclic AMP) opens nonspecific channels that permit passage of Na^+ and other cations into the rod cell (FIG. 43-22). This process depolarizes the rod cell, which then releases the neurotransmitter glutamate. The glutamate is inhibitory; it hyperpolarizes the membrane of the bipolar cell, preventing it from transmitting messages.

Note that the photoreceptor differs from other neurons in that the ion channels in its membrane are normally open; it is depolarized and continuously releases inhibitory neurotransmitter. The steady flow of ions into the cell when the environment is dark is called the *dark current*. Another unusual characteristic of photoreceptors, and of bipolar cells, is that they do not produce action potentials.

Figure 43-20 Organization of the retina

CONNECT Why is it difficult to see colors in dim light?

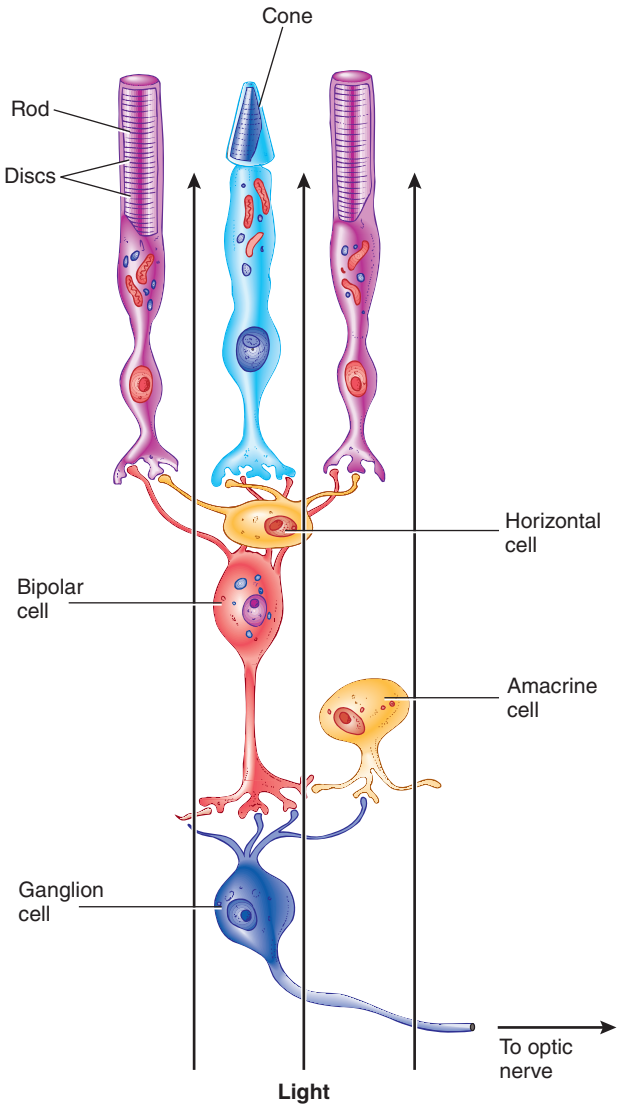

Figure 43-21 Neural pathway in the retina

The photoreceptor cells (rods and cones) are located in the back of the retina. They transmit information to bipolar cells. The bipolar cells synapse with ganglion cells. The horizontal and amacrine cells are important in local processing of visual input within the retina. Axons of ganglion cells make up the optic nerve.

Their release of neurotransmitter is graded, regulated by the extent of depolarization.

When light strikes rhodopsin, light energy is transduced. This process can be considered in three stages:

1. *Light activates rhodopsin*. Light transforms *cis*-retinal to *trans*-retinal. Rhodopsin changes shape and breaks down into its components: opsin and retinal. This sequence is the light-dependent process in vision.
2. *Rhodopsin activates a signal transduction pathway*. When it changes shape, rhodopsin binds with *transducin*, a G protein. Transducin activates an esterase that hydrolyzes cyclic GMP (cGMP) to GMP, reducing the concentration of cGMP.
3. *A decrease in concentration of cGMP in the rod causes the Na^+ channels to close*. Fewer cations pass into the rod cell, and it becomes more negative (hyperpolarized). The rod cell then releases less glutamate. Thus, light decreases the number of neural signals from the rod cells.

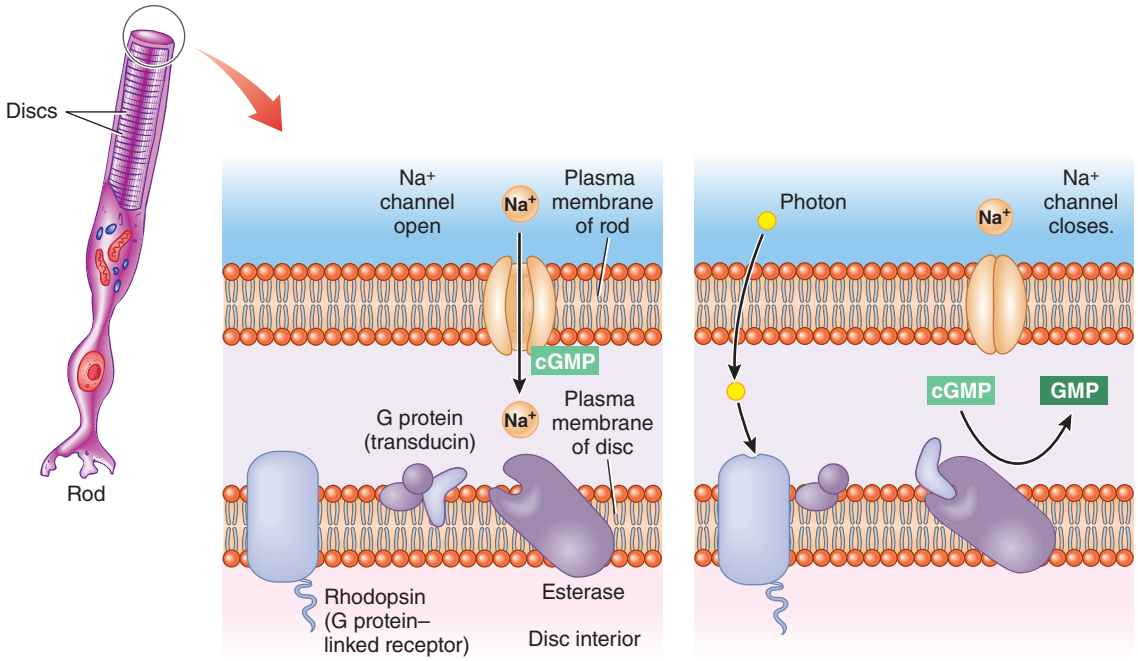
The release of glutamate normally hyperpolarizes the membrane of the bipolar cell, so a decrease in glutamate release results in depolarization of the bipolar cell. The depolarized bipolar cell increases its release of a neurotransmitter, which typically stimulates the ganglion cell.

When you move from bright daylight to a dark room, you experience "blindness" for a few moments while your eyes adapt. During exposure to bright light, rhodopsin breaks down, decreasing the sensitivity of your eyes. *Dark adaptation* occurs as enzymes restore rhodopsin to a form in which it can respond to light. In dim light, vision depends on the rods. Conversely, when you move from the dark to bright light, your eyes are very sensitive, and you may feel "blinded" by the light. *Light adaptation* occurs as some of the photopigments break down and the sensitivity of your eyes decreases.

Color vision depends on three types of cones

Many invertebrates and at least some animals in each vertebrate class have color vision. Color perception depends on cones. Most mammals have two types of cones, but humans and other primates have three types: blue, green, and red. Each contains a slightly different photopigment. Although the retinal portion of the pigment molecule is the same as in rhodopsin, the opsin protein differs slightly in each type of photoreceptor.

Each type of cone responds to light within a considerable range of wavelengths but is named for the ability of its pigment to absorb a particular wavelength more strongly than other cones do. For example, red light can be absorbed by all three types of cones, but those cones most sensitive to red act as red receptors. By comparing the relative responses of the three types of cones, the brain can detect colors of intermediate wavelengths. Color blindness occurs when there is a deficiency of one or more of the three types of cones. It is usually an inherited X-linked condition (see Fig. 11-15).



Integration of visual information begins in the retina

The size, intensity, and location of light stimuli determine initial processing in the retina. Rods and cones send signals directly to bipolar cells, and bipolar cells send signals directly to ganglion cells. However, as illustrated in Figure 43-21, photoreceptor cells can also transmit signals to horizontal cells, and bipolar cells can transmit signals to amacrine cells. Ganglion cells are inhibited by amacrine cells and can be inhibited indirectly by horizontal cells as a result of their action on bipolar cells. Thus, the horizontal and amacrine cells integrate signals laterally.

Bipolar, horizontal, and amacrine cells combine signals from several photoreceptors. Each ganglion cell has a

(a) In the dark. Sodium channels are open. The rod cell membrane is depolarized and releases the inhibitory neurotransmitter glutamate (*not shown*).

(b) In the light. When rhodopsin absorbs light, it changes shape, activating a signal transduction pathway. The concentration of cGMP is reduced. As a result cGMP-gated sodium channels close, hyperpolarizing the membrane. Hyperpolarization results in a decrease in inhibitory signals from the rod cell.

Figure 43-22 The biochemistry of vision

Inward foldings of the plasma membrane produce a series of discs in each rod cell. In the dark, the rod cell is depolarized; in the light, it becomes hyperpolarized.

receptive field, a specific group of photoreceptors that light must strike for the ganglion cell to be stimulated. Ganglion cells are activated or inhibited depending on which photoreceptor cells have been stimulated.

The pattern of neuron firing in the retina is very important. The signals sent to ganglion cells depend on spatial patterns and timing of the light striking the retina. Ganglion cells receive signals about specific types of visual stimuli, such as color, brightness, and motion, and transmit this information about the characteristics of a visual image. In contrast with rods and cones and most other neurons of the retina, which produce only graded potentials, ganglion cells produce action potentials.

The retina begins the construction of visual images, but those images are interpreted in the brain. Axons of more than one million ganglion cells form the optic nerves. These cranial nerves transmit information to the brain by complex, encoded signals. Axons from the medial half of each retina cross to the opposite side in the floor of the hypothalamus, forming an X-shaped structure, the **optic chiasm** (FIG. 43-23). The axons of the *optic nerves* that cross over extend to the opposite side of the brain.

Axons of the *optic nerves* end in the *lateral geniculate nuclei* of the thalamus. From there, neurons send signals to the *primary visual cortex* in the occipital lobe of the cerebrum. The lateral geniculate nucleus controls what information is sent to the visual cortex. Neurons in the reticular activating system are involved in this integration. Information is transmitted from the primary visual cortex to other cortical areas for further processing.

Different types of ganglion cells receive information about different aspects of a visual stimulus. As a result, information from each point in the retina is transmitted in parallel by several types of ganglion cells. These cells project to different kinds of neurons in the lateral geniculate nucleus and primary visual cortex.

Neurobiologists have not yet discovered all the mechanisms by which the brain makes sense of the visual information it receives. We know that a large part of the association areas of the cerebrum is involved in integrating visual input. The neurons of the visual cortex are organized as a map of the external visual field. They are also organized into columns. Each column of neurons receives signals originating from light entering either the right or the left eye. Columns are also organized by orientation of light. Neurons in a column receive signals originally triggered by light with the same orientation. However, these signals originate from different locations in the retina.

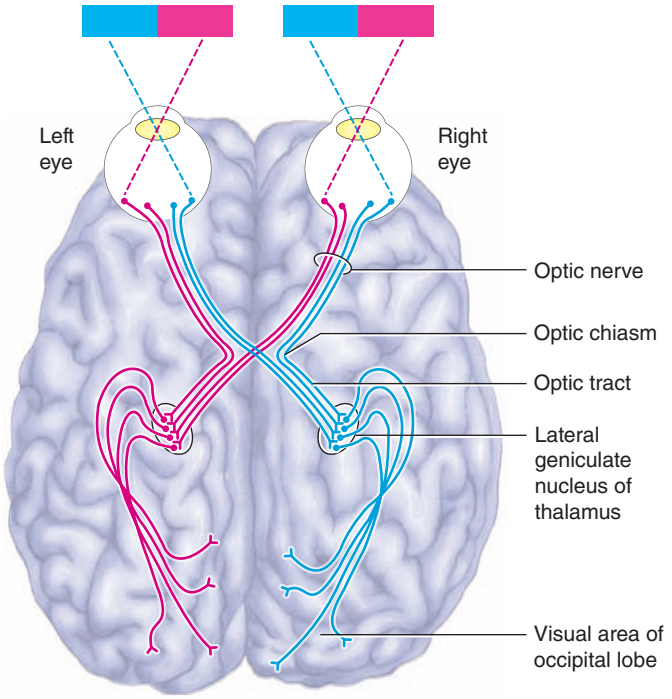

Figure 43-23 Neural pathway for transmission of visual information

Axons of ganglion cells form the optic nerves. In the brain, fibers from the medial half of each retina cross to the opposite side, forming the optic chiasm. Many optic nerve fibers end in the lateral geniculate nuclei of the thalamus. From there, signals are sent to the visual area in the occipital lobe. (Brain is viewed from above with overlying structures removed.)

CHECKPOINT 43.7

- **CONNECT** How does the insect's compound eye compare with the vertebrate eye?
- What happens when light strikes rhodopsin? (Include a description of the signal transduction pathway in your answer.)
- What is the sequence of neural signaling in the retina?
- What is meant by the statement "Vision happens mainly in the brain"?

Summary: Focus on Learning Objectives

43.1 How Sensory Systems Work *(page 912)*

1 Describe how sensory systems function; include descriptions of sensory receptors, energy transduction, receptor potential, sensory adaptation, and perception.

- **Sensory receptors** are neuron endings or specialized receptor cells in close contact with neurons. **Sense organs** consist of sensory receptors and accessory cells.
- A sensory receptor absorbs energy from a stimulus and transduces that energy—*energy transduction*—into electrical energy. In response to stimuli, a sensory receptor produces **receptor potentials**, which are depolarizations or hyperpolarizations of the membrane. Receptor potentials are **graded potentials**, local changes in electrical potential that vary in magnitude depending on the strength of the stimulus. Receptor potentials can generate action potentials in **sensory neurons**, which transmit coded signals to the CNS.
- **Sensory adaptation**, the decrease in frequency of action potentials in a sensory neuron even when the stimulus is maintained, decreases response to that stimulus.
- The brain interprets sensations by converting them to perceptions of stimuli. Sensory **perception** is the process of selecting, interpreting, and organizing sensory information.

2 Classify sensory receptors according to the location of the stimuli to which they respond and according to the types of energy they transduce.

- **Exteroceptors** receive stimuli from the outside environment. **Interoceptors** detect changes within the body, such as changes in pH, osmotic pressure, body temperature, and the chemical composition of the blood.
- Sensory receptors can be classified according to the types of energy they transduce. *Thermoreceptors* respond to heat and cold. *Electroreceptors* sense differences in electrical potential. *Nociceptors* (pain receptors) respond to mechanical stimuli, temperature, and other stimuli that could be damaging. *Mechanoreceptors* transduce mechanical energy: touch, pressure, gravity, stretching, and movement. *Chemoreceptors* transduce certain chemical compounds, and photoreceptors transduce light energy.

43.2 Thermoreceptors *(page 915)*

3 Identify three functions of thermoreceptors.

- **Thermoreceptors** transduce thermal energy; they respond to heat and cold. Some parasites use thermoreceptors to find an endothermic host. Some predators use thermoreceptors to locate endothermic prey. In endothermic animals, thermoreceptors provide cues about body temperature.

43.3 Electroreceptors and Magnetic Reception *(page 916)*

4 Describe the functions of electroreceptors and identify the functions of magnetic reception.

- **Electroreceptors** respond to electrical stimuli. Predatory fishes use electroreceptors to detect prey.
- Some animals detect and use information about Earth's magnetic fields to orient themselves. Many migratory animals use magnetic fields to navigate.

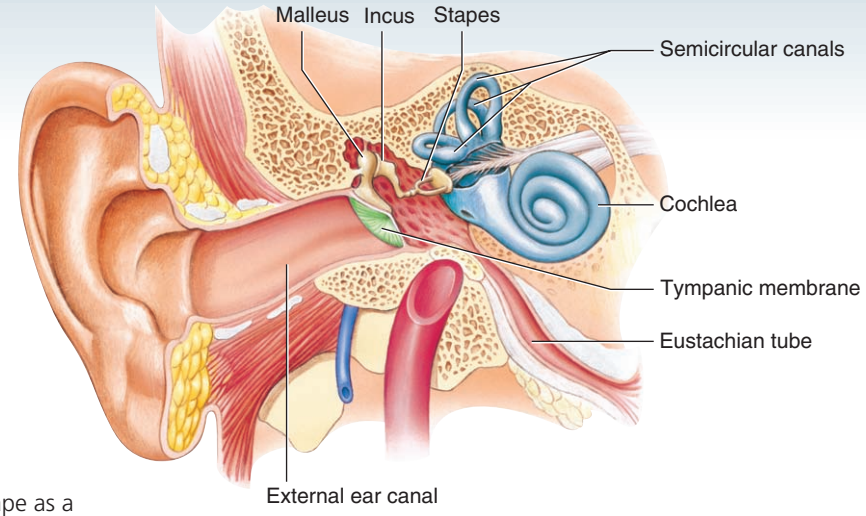
43.4 Nociceptors *(page 916)*

5 Describe the functions of nociceptors and identify the roles of substance P and endorphins.

Copyright 2019 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

- **Nociceptors** are pain receptors; they are free nerve endings of certain sensory neurons that respond to strong tactile stimuli, temperature extremes, and certain chemicals. Sensory neurons that transmit pain signals release **substance P** or **glutamate**. **Endorphins** and **enkephalins** inhibit release of substance P, ending transmission of the pain signal.

43.5 Mechanoreceptors *(page 916)*



6 Compare the functions and mechanisms of action of the following mechanoreceptors: tactile receptors, proprioceptors, statocysts, hair cells, and lateral line organs.

- **Mechanoreceptors** transduce mechanical energy, permitting animals to feel, hear, and maintain balance. Mechanoreceptors respond to touch, pressure, gravity, stretch, or movement. They are activated when they change shape as a result of being mechanically pushed or pulled.
- *Tactile receptors* in the skin respond to mechanical displacement of hairs or to displacement of the receptor cells themselves. The **Pacinian corpuscle** is a tactile receptor that responds to touch and pressure.
- **Proprioceptors** allow an animal to perceive orientation of its body and the positions of its parts. **Muscle spindles**, **Golgi tendon organs**, and **joint receptors** are proprioceptors that continuously respond to tension and movement.
- **Statocysts**, gravity receptors found in many invertebrates, are simple organs of equilibrium; they inform the CNS of change in position. A statocyst consists of a chamber lined with ciliated mechanoreceptors; the chamber contains **statoliths**, granules of sand grains or calcium carbonate that change position as the animal moves. As statoliths move, sensory hairs bend, and different sensory cells are stimulated.
- Vertebrate **hair cells** detect movement; they are found in the lateral line of fishes, the vestibular apparatus, semicircular canals, and cochlea. Each hair cell has a single **kinocilium**, which is a true cilium, and **stereocilia**, which are microvilli.
- **Lateral line organs** supplement vision in fishes and some amphibians by informing the animal of moving objects or objects in its path.

7 Compare the structure and function of the saccule and utricle with that of the semicircular canals in maintaining equilibrium.

- The vertebrate *inner ear* consists of a **labyrinth** of fluid-filled chambers and canals that help maintain equilibrium. The **vestibular apparatus** in the upper part of the labyrinth consists of the **saccule**, **utricle**, and **semicircular canals**.
- The saccule and utricle contain **otoliths**, calcium carbonate ear stones, that change position when the head is tilted or when the body is moving in a straight line. The otoliths stimulate hair cells that send signals to the brain, enabling the animal to perceive the direction of gravity.
- The semicircular canals inform the brain about turning movements. Clumps of hair cells, called *cristae*, are located within each bulblike enlargement, called an **ampulla**. Cristae are stimulated by movements of the **endolymph**, a fluid that fills each canal.

8 Trace the path taken by sound waves through the structures of the ear and explain how the organ of Corti functions as an auditory receptor.

- In terrestrial vertebrates, the **organ of Corti** within the **cochlea** contains auditory receptors.
- Sound waves pass through the *external auditory canal* and cause the **tympanic membrane** (eardrum) to vibrate. The ear bones—**malleus**, **incus**, and **stapes**—transmit and amplify the vibrations through the middle ear. Vibrations pass through the *oval window* to fluid within the vestibular canal. Pressure waves press on the membranes that separate the three ducts of the cochlea.
- The bulging of the *round window* serves as an escape valve for the pressure. The pressure waves cause movements of the **basilar membrane**. These movements stimulate the hair cells of the organ of Corti by rubbing them against the overlying **tectorial membrane**.
- Neural impulses are initiated in the dendrites of neurons that lie at the base of each hair cell and are transmitted by the *cochlear nerve* to the brain.

43.6 Chemoreceptors *(page 924)*

9 Compare the structure and function of the receptors of taste and smell, and describe the function of the vomeronasal organ.

- **Chemoreceptors** transduce certain kinds of chemical compounds, allowing *gustation*, or taste, and *olfaction*, or smell.
- In vertebrates, taste receptor cells are specialized epithelial cells in *taste buds*. The **olfactory epithelium** contains specialized olfactory receptors with axons that extend to the brain. These axons make up the **olfactory nerve**.
- Receptors that make up the **vomeronasal organ**, located in the nasal epithelium of mammals, detect **pheromones**, small, volatile signaling molecules released by animals.

43.7 Photoreceptors *(page 926)*

10 Contrast simple eyes, compound eyes, and vertebrate eyes.

- **Photoreceptors** transduce light energy and serve as the sensory receptors in eyespots and eyes. *Eyespots*, or **ocelli**, found in cnidarians and flatworms, detect light but do not form images.
- The **compound eye** of insects and crustaceans consists of visual units called **ommatidia**, which collectively produce a *mosaic* image. Each ommatidium has a transparent lens and a *crystalline cone* that focus light onto receptor cells called **retinular cells**.
- Vertebrates have camera eyes that form sharp images.

11 Identify each structure of the vertebrate eye and describe its function.

- In the human eye, light enters through the **cornea**, passes through the **pupil**, is focused by the **lens**, and produces an image on the **retina**. The **iris** regulates the amount of light that can enter. The internal surface of the eye is covered by the **choroid layer**, a black coat that prevents light rays from scattering.
- **Accommodation** is the process by which the lens changes shape, allowing the eye to focus at various distances. The lens is attached to the circular *ciliary muscle*. When the ciliary muscle contracts, the lens becomes rounder. When it relaxes, the lens flattens.

12 Compare the two types of photoreceptors, describe the signal transduction pathway that is activated when rhodopsin responds to light, and summarize the visual pathway.

- The retina contains the photoreceptor cells: **rods**, which function in dim light and form images in black and white, and **cones**, which function in bright light and permit color vision.
- Rods and cones send signals to **bipolar cells** that send signals to **ganglion cells**. Two types of lateral interneurons integrate information: **horizontal cells** receive signals from the rods and cones and send signals to bipolar cells, and **amacrine cells** receive signals from bipolar cells and send signals back to bipolar cells and to ganglion cells.
- When the environment is dark, ion channels in the plasma membranes of rod cells are open, and the cells are depolarized; they release glutamate, which hyperpolarizes the membranes of bipolar cells so that they do not send signals.
- When light strikes the photopigment **rhodopsin** in the rod cells, its retinal portion changes shape and initiates a signal transduction process that involves *transducin*. This G protein activates an esterase that hydrolyzes cGMP, reducing its concentration. As a result, ion channels close, and the membrane becomes hyperpolarized. The rod cells release less glutamate, and fewer signals are transmitted. As a result, bipolar cells become depolarized and release the neurotransmitter that stimulates ganglion cells.
- Axons of the ganglion cells extend across the retina and join to make up the **optic nerves**. The optic nerves transmit information to the *lateral geniculate nuclei* in the thalamus. From there, neurons project to the *primary visual cortex* and then to other cortical areas.

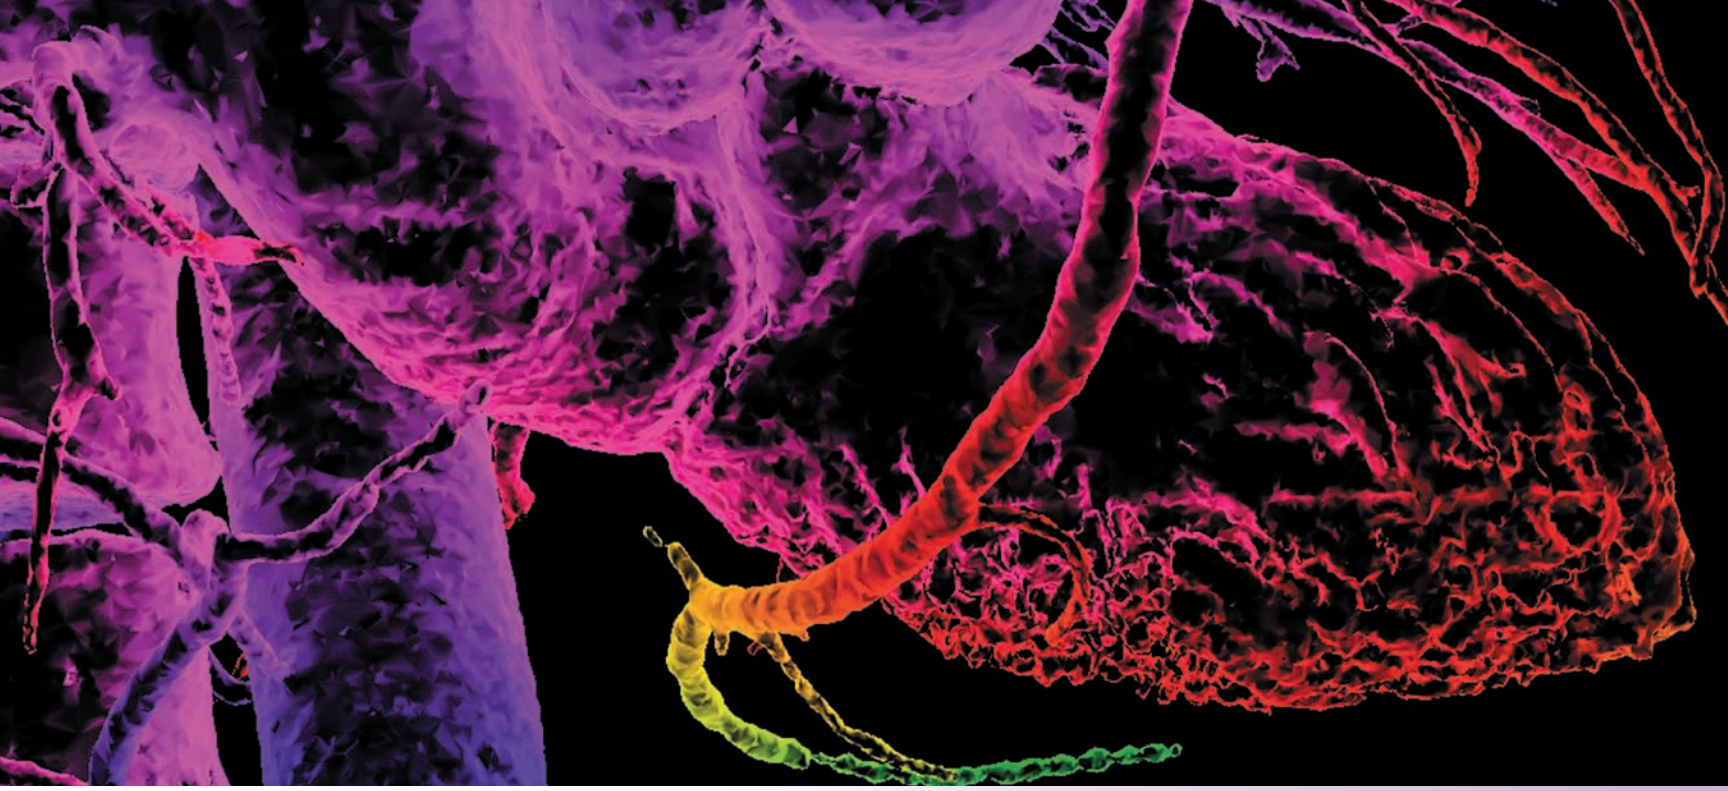
Test Your Understanding

Know and Comprehend

1. A sensory receptor absorbs energy from some stimulus. The next step is (a) release of neurotransmitter (b) transmission of an action potential (c) energy transduction (d) transmission of a receptor potential (e) sensory adaptation
2. Which of the following is *not* a correct match? (a) mechanoreceptors—touch, pressure (b) electroreceptors—voltage (c) photoreceptors—light (d) chemoreceptors—extreme temperature (e) nociceptors—pain
3. Which of the following is/are associated with informing the brain about turning movements? (a) semicircular canals (b) saccule (c) lymph (d) otoliths (e) utricle
4. In the process of hearing, the basilar membrane vibrates. Which event occurs next? (a) tympanic membrane vibrates (b) bones in middle ear amplify and conduct vibrations (c) cochlear nerve transmits impulses to organ of Corti (d) hair cells in organ of Corti are stimulated (e) vibrations are conducted to chemoreceptors
5. In the human visual pathway, after light passes through the cornea, it next (a) stimulates ganglion cells (b) passes through the lens (c) sends signals through the optic nerve (d) depolarizes horizontal cells (e) hyperpolarizes rod cells
6. When rhodopsin is activated, it (a) concentrates in bipolar cells (b) transmits more action potentials (c) binds with a G protein (d) sends signals to the lateral geniculate nuclei (e) activates substance P

Apply and Analyze

7. **VISUALIZE** In what sequence does information pass through the following structures in the vertebrate eye: optic nerve, bipolar cells, rods and cones, ganglion cells?
8. **CONNECT** Connoisseurs can recognize many varieties of cheese or wine by "tasting." How can they do so when there are only a few types of taste receptors?



Evaluate and Synthesize

9. **CONNECT** If all neurons transmit the same type of message, how do you know the difference between sound and light? How are you able to distinguish between an intense pain and a mild one? How are these discriminations adaptive?
10. **EVOLUTION LINK** Proteins known as opsins are present in the photoreceptors of all light-sensitive receptors that have been studied. What does this finding suggest about the relationships of organisms as diverse as flatworms, crayfish, and elephants?
11. **EVOLUTION LINK** Once the ability to produce images evolved, eyes evolved relatively rapidly. Hypothesize why image-forming eyes evolved quickly and are now present in most animals.
12. **SCIENCE, TECHNOLOGY, AND SOCIETY** Cochlear implants bring hearing to many children who are born deaf. The prognosis is best when the device is implanted before the child is three years old (during the early years when language is developed). Many individuals in the deaf community (which consists of individuals born deaf or who are affected by deafness) who communicate with sign language oppose cochlear implants. They do not view the inability to hear as a disability. This perspective raises ethical questions for some families with children who are deaf. Argue for and against cochlear implants for very young children.

44 Internal Transport

Most cells require a continuous supply of nutrients and oxygen and removal of waste products. In very small animals, these metabolic needs are met by simple **diffusion**, the net movement of particles from a region of higher concentration of that specific type of particle to a region of lower concentration as a result of random motion. A molecule can diffuse 1 micrometer (μm) in less than 1 millisecond (msec), so diffusion is adequate over microscopic distances. In invertebrates that are only a few cells thick, diffusion is an effective mechanism for distributing materials to and from the cells. Consequently, many small, aquatic invertebrates have no circulatory system. Fluid between the cells, called **interstitial fluid** or tissue fluid, bathes the cells and provides a medium for diffusion of oxygen, nutrients, and wastes.

The time required for diffusion increases with the square of the distance over which diffusion occurs. A cell that is 10 μm away from its oxygen (or nutrient) supply can receive oxygen by diffusion in about 50 msec, but a cell that is 1000 μm (1 mm) away from its oxygen supply would have to wait several minutes! At this distance, a cell could not survive if it had to depend on diffusion alone. The evolution of specialized **circulatory systems** allowed animals to increase in size and become many cells thick. A circulatory system reduces

PHOTO: Colored 3-D reconstructed computed tomography (CT) scan of the human heart and some of its blood vessels. The heart is the *red* oval structure extending from the center to the bottom right. KEY CONCEPTS

44.1 Arthropods and most mollusks have an open circulatory system in which blood bathes the tissues directly; some invertebrates and all vertebrates have a closed circulatory system in which a heart pumps blood that flows through a continuous circuit of blood vessels.

44.2 Vertebrate blood consists of plasma, which transports nutrients, wastes, gases, and hormones; red blood cells, which are specialized to transport oxygen; white blood cells, which defend the body against disease; and platelets, which function in blood clotting.

44.3 Three main types of vertebrate blood vessels are arteries, which carry blood away from the heart; capillaries, which are exchange vessels; and veins, which carry blood back toward the heart.

44.4 During the evolution of terrestrial vertebrates, adaptations in circulatory system structures separated oxygen-rich blood from oxygen-poor blood.

44.5 In amniotes, the pacemaker in the sinoatrial node initiates each heartbeat; one complete heartbeat makes up a cardiac cycle.

44.6 Blood pressure depends on cardiac output, blood volume, and peripheral resistance.

44.7 Along with the evolution of lungs, a double circulation evolved in vertebrates. The pulmonary circulation connects the heart and lungs, while the systemic circulation delivers oxygen-rich blood to all the tissues and organs of the body.

44.8 The vertebrate lymphatic system helps maintain fluid homeostasis by returning interstitial fluid to the blood and defends the body against disease organisms.

44.9 Several modifiable risk factors have been identified for cardiovascular disease, which is the leading cause of death in the world.

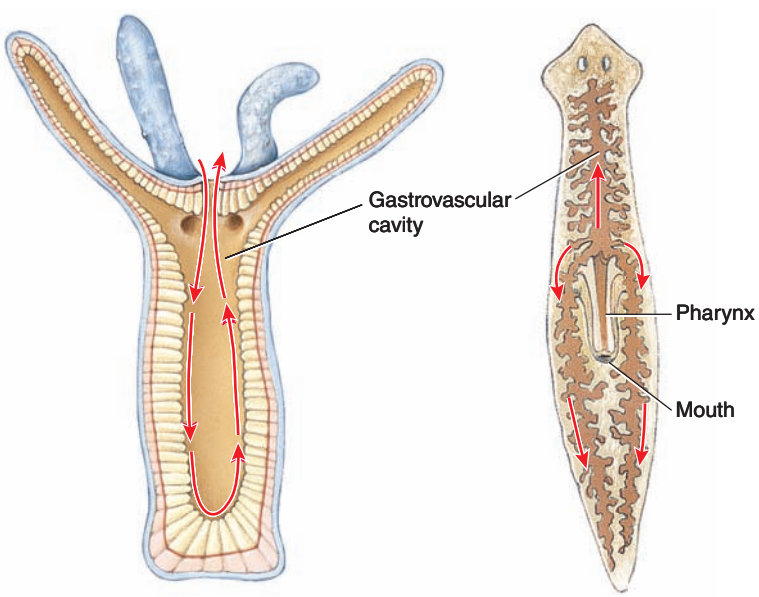
the distance that needed materials must diffuse. It transports oxygen, nutrients, hormones, and other materials to the interstitial fluid surrounding the cells and removes metabolic wastes. In most animals a circulatory system interacts with every organ system in the body.



The computed tomography (CT) scan shown in the chapter-opening photograph visualizes the human heart and several blood vessels. The human circulatory system, also known as the **cardiovascular system**, is the focus of extensive research because cardiovascular disease is the leading cause of death in the United States and throughout the world.

44.1 Types of Circulatory Systems

LEARNING OBJECTIVE

1 Contrast internal transport in animals with no circulatory system, animals with an open circulatory system, and animals with a closed circulatory system.

No specialized circulatory structures are present in sponges, cnidarians (hydras, jellyfish), ctenophores (comb jellies), flatworms, or nematodes (roundworms). In cnidarians the central gastrovascular cavity serves as a circulatory organ as well as a digestive organ (FIG. 44-1a). As the animal stretches and contracts, body movements stir up the contents of the gastrovascular cavity and help distribute nutrients.

(a) In *Hydra* and other cnidarians, nutrients circulate through the gastrovascular cavity and come in contact with the inner layer of body cells. Nutrients diffuse the short distance to the outer layer of cells.

(b) In planarian flatworms, the branched gastrovascular cavity allows nutrients to come within close proximity of most body cells.

Figure 44-1 Invertebrates with no circulatory system
Red arrows indicate the path of nutrient circulation through the gastrovascular cavity.

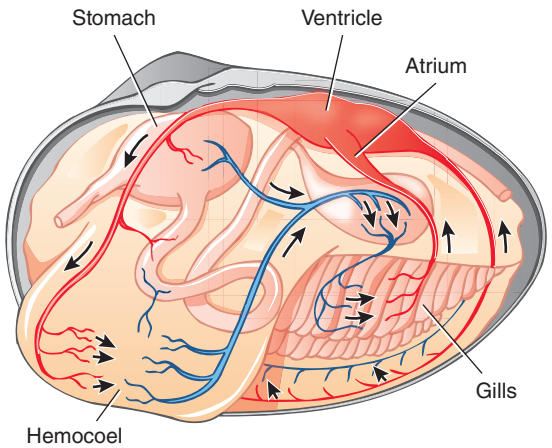
The flattened body of the flatworm permits effective gas exchange by diffusion (FIG. 44-1b). Its branched gastrovascular cavity brings nutrients close to all the cells. As in cnidarians, circulation is aided by contractions of the body wall muscles, which move the fluid throughout the gastrovascular cavity. The branching excretory system of planarians provides for transport of metabolic wastes that are then expelled from the body.

Fluid in the body cavity of nematodes and other pseudocoelomate animals helps circulate materials. Nutrients, oxygen, and wastes dissolve in this fluid and diffuse through it to and from the cells. Body movements of the animal move the fluid and thus distribute these materials.

Larger animals require a circulatory system to distribute materials efficiently. A circulatory system typically has the following components: (1) **blood**, a connective tissue consisting of cells and cell fragments dispersed in fluid, usually called *plasma*; (2) a pumping organ, generally a **heart**; and (3) a system of **blood vessels** or spaces through which blood circulates. Two main types of circulatory systems are open and closed systems.

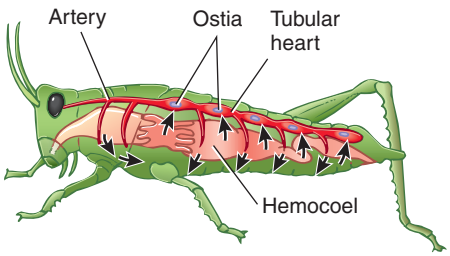
Many invertebrates have an open circulatory system

Arthropods and most mollusks have an **open circulatory system** in which the heart pumps blood into vessels that have open ends. Their blood and interstitial fluid are collectively referred to as **hemolymph**. This fluid spills out of the open ends of the blood vessels, filling large spaces called *sinuses*. The sinuses make up the **hemocoel** (blood cavity), which is not part of the coelom. (In arthropods and mollusks, the size of the coelom is reduced.) The hemolymph bathes the cells of the body directly. Hemolymph re-enters the circulatory system through openings in the heart (in arthropods) or through open-ended vessels that lead to the gills (in mollusks).



In the open circulatory system of most mollusks, the heart has three chambers (FIG. 44-2a). The two *atria* receive hemolymph from the gills. The single *ventricle* then pumps the oxygen-rich hemolymph into blood vessels that conduct it into the large sinuses of the hemocoel. After bathing the body cells, the hemolymph passes into vessels that lead to the gills, where it is recharged with oxygen. The hemolymph then returns to the heart.

Some mollusks as well as arthropods have a hemolymph pigment, **hemocyanin**, containing copper that transports oxygen. When oxygenated, hemocyanin is blue and imparts a bluish color to the hemolymph of these animals (the original blue bloods!).



In arthropods a tubular heart pumps hemolymph into arteries, blood vessels that deliver it to the sinuses of the hemocoel (FIG. 44-2b). Hemolymph then circulates through the hemocoel,

(a) In most mollusks, the heart pumps hemolymph into blood vessels that conduct it to the hemocoel. After bathing the cells, the hemolymph enters vessels that conduct it to the gills. The hemolymph is recharged with oxygen and then returned to the heart.

(b) In arthropods, a tubular heart pumps hemolymph into arteries that deliver it to the sinuses of the hemocoel. After circulating, hemolymph re-enters the heart through ostia in the heart wall.

Figure 44-2 Open circulatory systems

In mollusks and arthropods, a heart pumps the blood into arteries that end in sinuses of the hemocoel. Hemolymph circulates through the hemocoel.

eventually returning to the pericardial cavity surrounding the heart. Hemolymph enters the heart through ostia, tiny openings equipped with valves that prevent backflow. The rate of hemolymph circulation increases when the animal moves. Thus, when an animal is active and most needs nutrients for fuel, its own movement ensures effective circulation.

In crayfish and other crustaceans, gas exchange takes place as hemolymph circulates through the gills. However, an open circulatory system cannot provide enough oxygen to maintain the active lifestyle of insects. Hemolymph mainly distributes nutrients and hormones in insects. Oxygen diffuses directly to the cells through a system of air tubes (tracheae) that make up the respiratory system (see Fig. 46-2).

Some invertebrates have a closed circulatory system

Annelids, some mollusks (cephalopods), and echinoderms have a **closed circulatory system** in which blood flows through a continuous circuit of blood vessels. The walls of the smallest blood vessels, the *capillaries*, are thin enough to permit diffusion of gases, nutrients, and wastes between blood in the vessels and the interstitial fluid that bathes the cells.

Proboscis worms (phylum Nemertea) have a rudimentary closed circulatory system. Their system consists of a complete network of blood vessels but no heart. Blood flow depends on movements of the animal and on contractions in the walls of large blood vessels.

Earthworms and other annelids have a closed circulatory system in which two main blood vessels extend lengthwise in the body (FIG. 44-3). The ventral vessel conducts blood posteriorly, and the dorsal vessel conducts blood anteriorly. Dorsal and ventral vessels are connected by lateral vessels in every segment. Branches of the lateral vessels deliver blood to the surface, where it is oxygenated. In the anterior part of the worm, five pairs of contractile blood vessels (sometimes called "hearts") connect dorsal and ventral vessels. Contractions of these paired vessels and of the dorsal vessel as well as contraction of the body wall muscles circulate the blood. Earthworms have **hemoglobin**, the same red pigment that transports oxygen in vertebrate blood. However, their hemoglobin is not contained within red blood cells; rather, it is dissolved in the blood plasma.

Although other mollusks have an open circulatory system, the fast-moving cephalopods, such as the squid and octopus, require a more efficient means of internal transport. They have a closed system made even more effective by accessory "hearts" at the base of the gills, which speed passage of blood through the gills.

Vertebrates have a closed circulatory system

The vertebrate circulatory system consists of heart, blood vessels, blood, lymph, lymph vessels, and associated organs such as the thymus, spleen, and liver. All vertebrates have a ventral, muscular

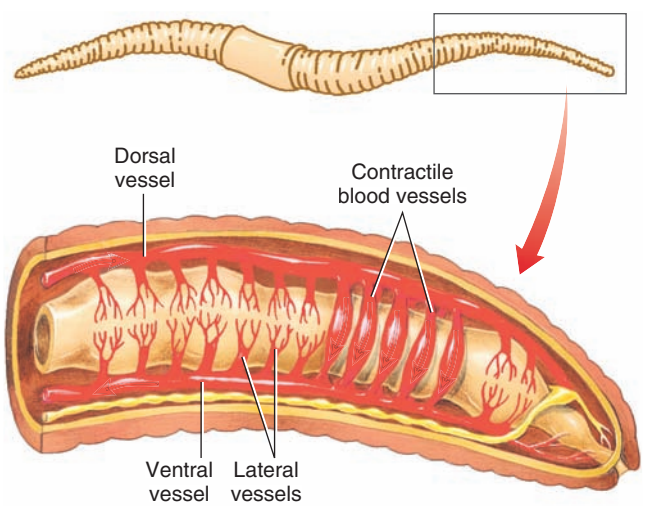

Figure 44-3 Closed circulatory system of the earthworm

Blood circulates through a continuous system of blood vessels. Five pairs of contractile blood vessels deliver blood from the dorsal vessel to the ventral vessel.

heart that pumps blood into a closed system of blood vessels. **Capillaries**, the tiniest blood vessels, have very thin walls that permit exchange of materials between blood and interstitial fluid.

The vertebrate circulatory system performs several functions:

1. Transports nutrients from the digestive system and from storage depots to each cell
2. Transports oxygen from respiratory structures (gills or lungs) to the cells
3. Transports metabolic wastes from each cell to organs that excrete them
4. Transports hormones from endocrine glands to target tissues
5. Helps maintain fluid balance
6. Helps distribute metabolic heat within the body, which helps maintain a constant body temperature in endothermic animals
7. Helps maintain appropriate pH
8. Defends the body against invading microorganisms

CHECKPOINT 44.1

- Compare how oxygen is transported to the body cells in a hydra, flatworm, earthworm, insect, and frog.
- Contrast how an open circulatory system differs from a closed circulatory system.
- What are five functions of the vertebrate circulatory system?

44.2 Vertebrate Blood

LEARNING OBJECTIVES

2 Compare the structure and function of plasma, red blood cells, white blood cells, and platelets.

3 Summarize the sequence of events involved in blood clotting.

In vertebrates, blood consists of a pale yellowish fluid called **plasma** in which red blood cells, white blood cells, and platelets are suspended (FIG. 44-4 and TABLE 44-1). In humans, the total circulating blood volume is approximately 5 L (5.3 qt) in an adult female and about 5.5 L (5.8 qt) in an adult male. About 55% of the blood volume is plasma. The remaining 45% is made up of blood cells and platelets. Because cells and platelets are heavier than plasma, they can be separated from it by centrifugation. Plasma does not separate from blood cells in the body because the blood is constantly mixed as it circulates through the blood vessels.

Plasma is the fluid component of blood

Plasma consists of water (about 92%), proteins (about 7%), salts, and a variety of materials being transported, such as dissolved gases, nutrients, wastes, and hormones. Plasma is in dynamic equilibrium with the interstitial fluid bathing the cells and with the intracellular fluid. As blood passes through the capillaries, substances continuously move into and out of the plasma. Any deviation from its normal composition signals one or more organs to restore homeostasis.

Plasma contains several kinds of **plasma proteins**, each with specific properties and functions: **fibrinogen**; alpha, beta, and gamma **globulins**; and **albumin**. Fibrinogen is one of the proteins involved in the clotting process. When the proteins involved in blood clotting have been removed from the plasma, the remaining liquid is called **serum**.

Alpha globulins include certain hormones and proteins that transport hormones; prothrombin, a protein involved in blood clotting; and high-density lipoproteins (HDL), which transport fats and cholesterol. Beta globulins include other lipoproteins that transport fats and cholesterol as well as proteins that transport certain vitamins and minerals. The *gamma globulin* fraction of plasma contains many types of antibodies that provide immunity to diseases such as measles and infectious hepatitis. Purified human gamma globulin is sometimes used to treat certain diseases or to reduce the possibility of contracting a disease.

Plasma proteins, especially albumins and globulins, help regulate distribution of fluid between plasma and interstitial fluid. These proteins are too large to pass readily through the walls of blood vessels. They contribute to the blood's osmotic pressure, which helps maintain an appropriate blood volume. Plasma proteins (along with the hemoglobin in the red blood cells) are important acid–base buffers. They help maintain the pH of the blood within a narrow range, near its normal, slightly alkaline pH of 7.4.

Red blood cells transport oxygen

Erythrocytes, informally called **red blood cells (RBCs)**, are highly specialized for transporting oxygen. In most vertebrates, circulating RBCs have nuclei. For example, birds have large, oval, nucleated RBCs. However, in mammals the nucleus is ejected as the RBC develops. Each mammalian RBC is a flexible, biconcave disc 7 to 8 μm in diameter and 1 to 2 μm thick. An internal elastic framework maintains the disc shape and permits the cell to bend and twist as it passes through blood vessels even smaller than its own diameter. Its biconcave shape provides a high ratio of surface area to volume, allowing efficient diffusion of oxygen and carbon dioxide into and out of the cell. In an adult human, about 30 trillion RBCs circulate in the blood, approximately 5 million per μL.

Erythrocytes are produced within the red bone marrow of certain bones: vertebrae, ribs, breastbone, skull bones, and long bones. As an RBC develops, it produces large quantities of **hemoglobin**, the oxygen-transporting pigment that gives vertebrate blood its red color. (Oxygen transport is discussed in Chapter 46.) The lifespan of a human RBC is about 120 days. As blood circulates through the liver and spleen, phagocytic cells remove worn-out RBCs from the circulation. These RBCs are then disassembled, and some of their components are recycled. In the human body, more than 2.4 million RBCs are destroyed every second! As you might imagine, an equal number must be produced in the bone marrow to replace them. Red blood cell production is regulated by the hormone **erythropoietin** (eh-rith″-row-poy′-ih-tin), which the kidneys release in response to a decrease in oxygen.

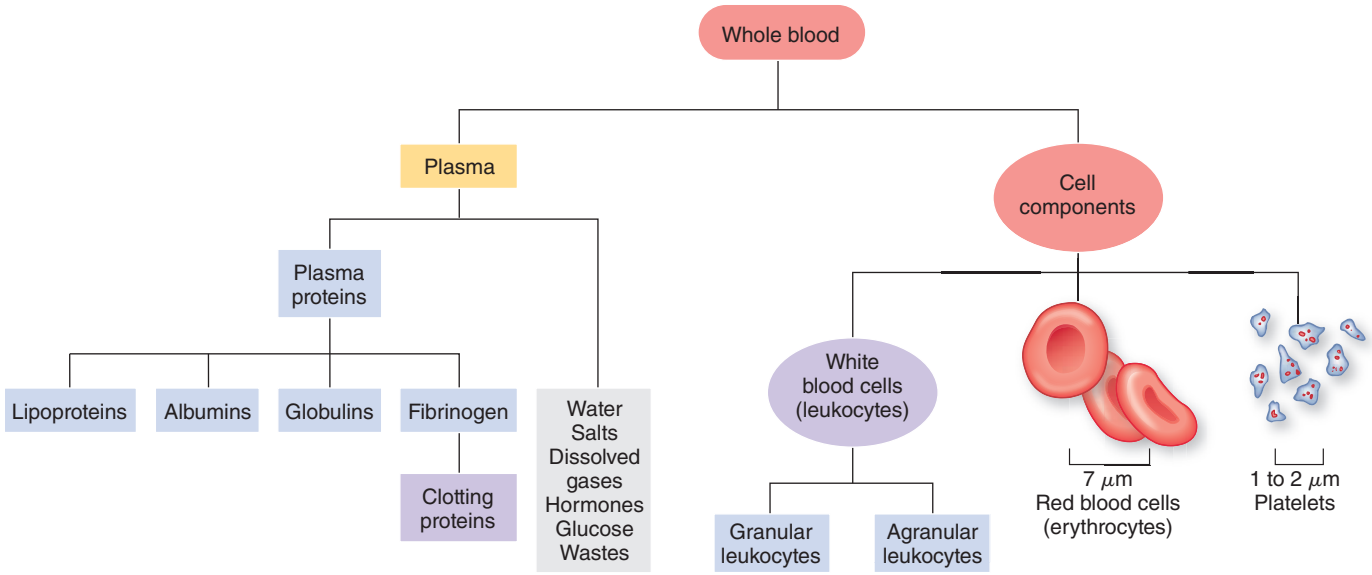

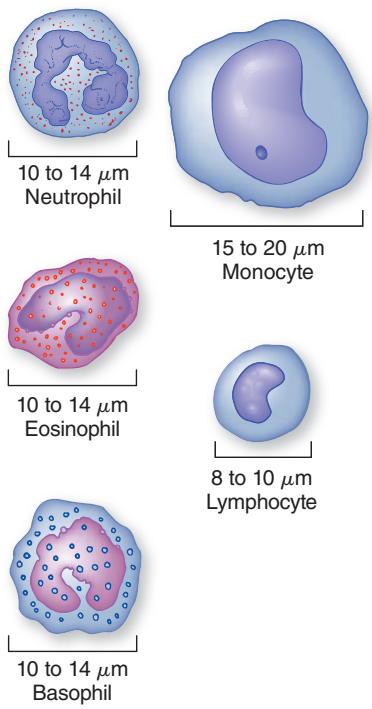

Figure 44-4 Composition of vertebrate blood

Blood consists of a fluid plasma in which white blood cells, red blood cells, and platelets are suspended.

Anemia is a deficiency in hemoglobin (often accompanied by a decrease in the number of RBCs). When hemoglobin is insufficient, the amount of oxygen transported is inadequate to supply the body's needs. An anemic person may complain of feeling weak and may become easily fatigued. Three general causes of anemia are (1) loss of blood from hemorrhage or internal bleeding; (2) decreased production of hemoglobin or red blood cells, as in iron-deficiency anemia or pernicious anemia (which can be caused by vitamin B_{12} deficiency); and (3) increased rate of RBC destruction resulting in the *hemolytic* anemias, such as sickle cell anemia (see Chapter 16).

White blood cells defend the body against disease organisms

The **leukocytes**, or **white blood cells (WBCs)**, are specialized to defend the body against harmful bacteria and other microorganisms. Leukocytes are amoeba-like cells capable of independent movement. Some types routinely slip through the walls of blood vessels and enter the tissues. Human blood contains three kinds of granular leukocytes and two types of agranular leukocytes (Table 44-1; see also Fig. 44-4). Both granular and agranular leukocytes are manufactured in the red bone marrow.

Granular leukocytes are characterized by large, lobed nuclei and distinctive granules in their cytoplasm. The three varieties of granular leukocytes are neutrophils, eosinophils, and basophils. **Neutrophils**, the principal phagocytic cells in the blood, are especially adept at seeking out and ingesting bacteria. They also phagocytose dead cells, a cleanup task that is especially demanding after injury or infection. Most granules in neutrophils contain enzymes that digest ingested material.

Eosinophils have large granules that stain bright red with eosin, an acidic dye. Eosinophils increase in number during allergic reactions and during parasitic (e.g., tapeworm) infestations. The lysosomes of these WBCs contain enzymes such as peroxidases that degrade the cell membranes of parasitic worms and protozoa. These substances can also injure normal tissue. Eosiniphils also produce substances that promote an *inflammatory response* (*inflammation*), one of the body's key responses to injury or infection (discussed in Chapter 45).

Basophils exhibit deep blue granules when stained with basic dyes. Like eosinophils, these cells play a role in allergic reactions. Basophils do not contain lysosomes. Granules in their cytoplasm contain **histamine**, a substance that dilates blood vessels and makes capillaries more permeable. Basophils release histamine in injured tissues and in allergic responses. Other basophil granules contain *heparin*, which speeds up fat removal from the blood after you eat a meal high in fat.

Table 44-1 Cell Components of Blood

	Normal Range	Function	Pathology
RED BLOOD CELLS (RBCs)	Male: 4.2–5.4 million/μL Female: 3.6–5.0 million/μL	Oxygen transport; carbon dioxide transport	Too few: anemia Too many: polycythemia
PLATELETS	150,000–400,000/μL	Essential for clotting	Clotting malfunctions; bleeding; easy bruising
WHITE BLOOD CELLS (WBCs)	5000–10,000/μL		
Neutrophils	About 60% of WBCs	Phagocytosis	Too many: may be due to bacterial infection, inflammation, myelogenous leukemia
Eosinophils	1%–3% of WBCs	Play role in allergic responses; release proteins that are toxic to parasitic worms; release compounds important in immune responses	Too many: may result from allergic reaction, parasitic infestation
Basophils	1% of WBCs	May play role in prevention of inappropriate clotting; release histamine, which is important in inflammatory responses	
Lymphocytes	25%–35% of WBCs	Produce antibodies; destroy foreign cells	Atypical lymphocytes present in infectious mononucleosis; too many may be due to lymphocytic leukemia, certain viral infections
Monocytes	6% of WBCs	Can differentiate to become macrophages and dendritic cells	May increase in monocytic leukemia and fungal infections

Heparin is an anticoagulant that may help prevent blood from clotting inappropriately within the blood vessels.

Agranular leukocytes lack large, distinctive granules, and their nuclei are rounded or kidney-shaped. Two types of agranular leukocytes are lymphocytes and monocytes. Some **lymphocytes** are specialized to produce antibodies, whereas others directly attack foreign invaders, such as bacteria or viruses (discussed in Chapter 45).

Monocytes are the largest WBCs, reaching 20 μm in diameter. During infection, monocytes migrate from the blood into the tissues. They phagocytose cells and remove toxic molecules. Monocytes can also differentiate into macrophages or dendritic cells. **Macrophages** are giant scavenger cells that voraciously engulf bacteria, dead cells, and debris. **Dendritic cells** are also important cells of the immune system. For example, some dendritic cells produce compounds that help the body fight viral infection. We discuss macrophages and dendritic cells further in Chapter 45.

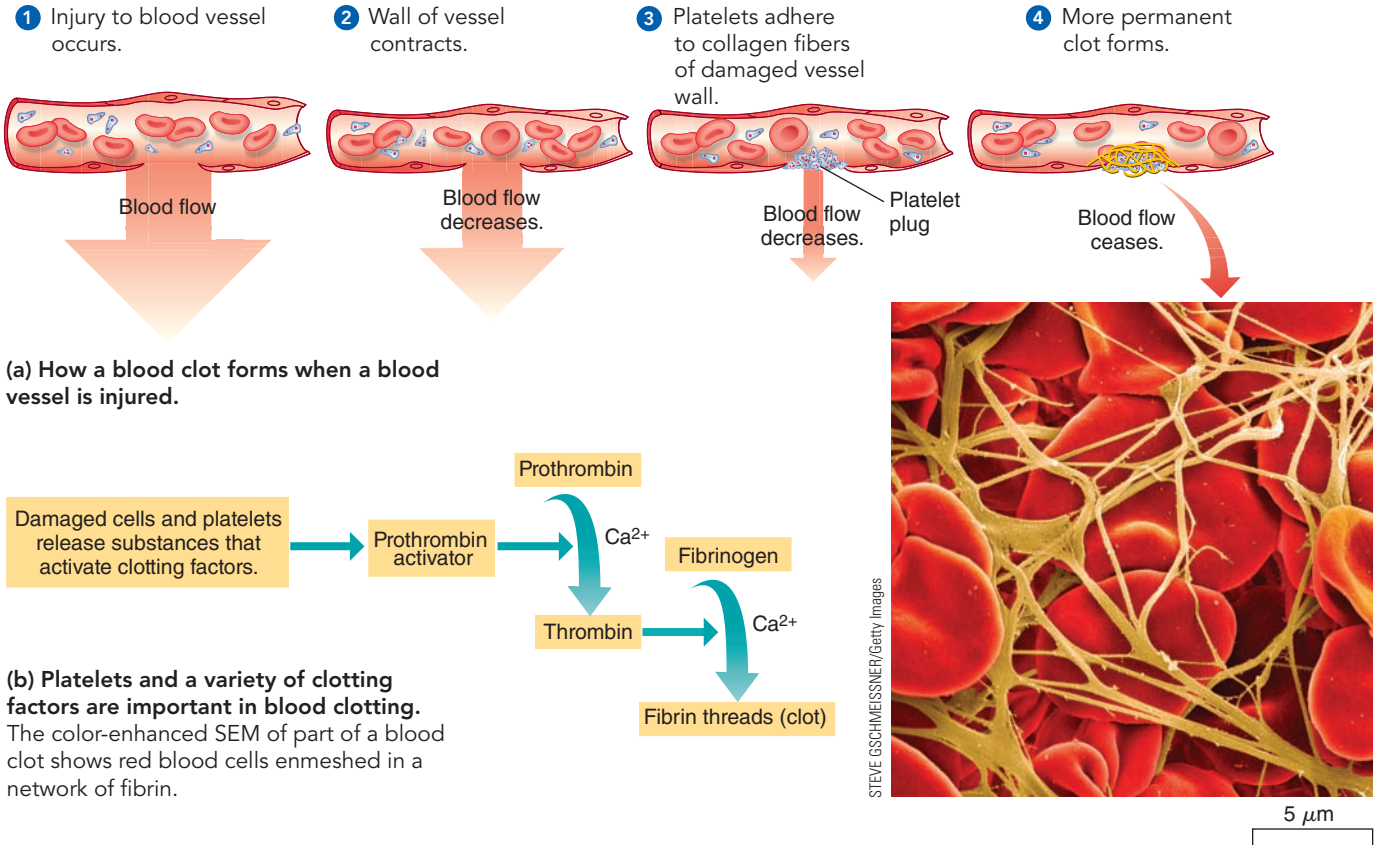
Human blood normally has about 7000 WBCs per μL of blood (only 1 for every 700 RBCs). During bacterial infections, the number may rise sharply, so a WBC count is useful in diagnosis. The proportion of each kind of WBC is determined by a differential WBC count. Table 44-1 shows a normal distribution of WBCs.

Leukemia is a form of blood cancer in which any one of the various kinds of WBCs multiplies rapidly within the bone marrow. Many of these cells do not mature, and their large numbers crowd out developing RBCs and platelets, leading to anemia and impaired clotting. A common cause of death from leukemia is internal hemorrhaging, especially in the brain. Another frequent cause of death is infection; although the WBC count may rise dramatically, the cells are immature and abnormal, and they cannot defend the body against disease organisms.

Thanks to new treatments, survival rates for individuals with leukemia and other blood cancers have recently increased sharply, particularly for children. For example, the survival rate for children younger than five years old with acute lymphocytic leukemia is now higher than 90%.

Platelets function in blood clotting

In most vertebrates other than mammals, the blood contains small, oval, nucleated cells called **thrombocytes** that function in blood clotting. Mammals have **platelets**, tiny spherical or disc-shaped bits of cytoplasm that lack nuclei. About 300,000 platelets per μL are present in human blood. Platelets are pinched off from very large cells in the bone marrow. Thus, a platelet is not a whole cell but rather is a fragment of cytoplasm enclosed by a membrane.



Platelets function in blood clotting and may also stimulate the immune system. When a blood vessel is cut, it constricts to reduce blood loss. Platelets physically patch the break by sticking to the rough, cut edges of the vessel. As platelets begin to gather, they release substances that attract other platelets. The platelets become sticky and adhere to collagen fibers in the blood vessel wall. Within about 5 minutes after injury, they form a platelet plug, or temporary clot.

At the same time that the temporary clot forms, a stronger, more permanent clot begins to develop. More than 30 chemical substances interact in this complex process. The series of reactions that leads to clotting is triggered when one of the clotting factors in the blood is activated by contact with the injured tissue. In **hemophilia** one of the clotting factors is absent as a result of an inherited genetic mutation (see Chapter 16).

Prothrombin, a plasma protein manufactured in the liver, requires vitamin K for its production. In the presence of clotting

(a) How a blood clot forms when a blood vessel is injured.

(b) Platelets and a variety of clotting factors are important in blood clotting. The color-enhanced SEM of part of a blood clot shows red blood cells enmeshed in a network of fibrin.

Figure 44-5 Blood clotting

factors, calcium ions, and compounds released from platelets, prothrombin is converted to *thrombin*. Then thrombin catalyzes the conversion of the soluble plasma protein *fibrinogen* to an insoluble protein, **fibrin**. Once formed, fibrin polymerizes, producing long threads that stick to the damaged surface of the blood vessel and form the webbing of the clot. These threads trap blood cells and platelets, which help strengthen the clot. The clotting process is summarized in FIGURE 44-5.

CHECKPOINT 44.2

- What are the functions of albumins and globulins?
- Contrast the functions of red blood cells and neutrophils.
- **PREDICT** What would happen if there were a shortage of fibrinogen in the blood?

44.3 Vertebrate Blood Vessels

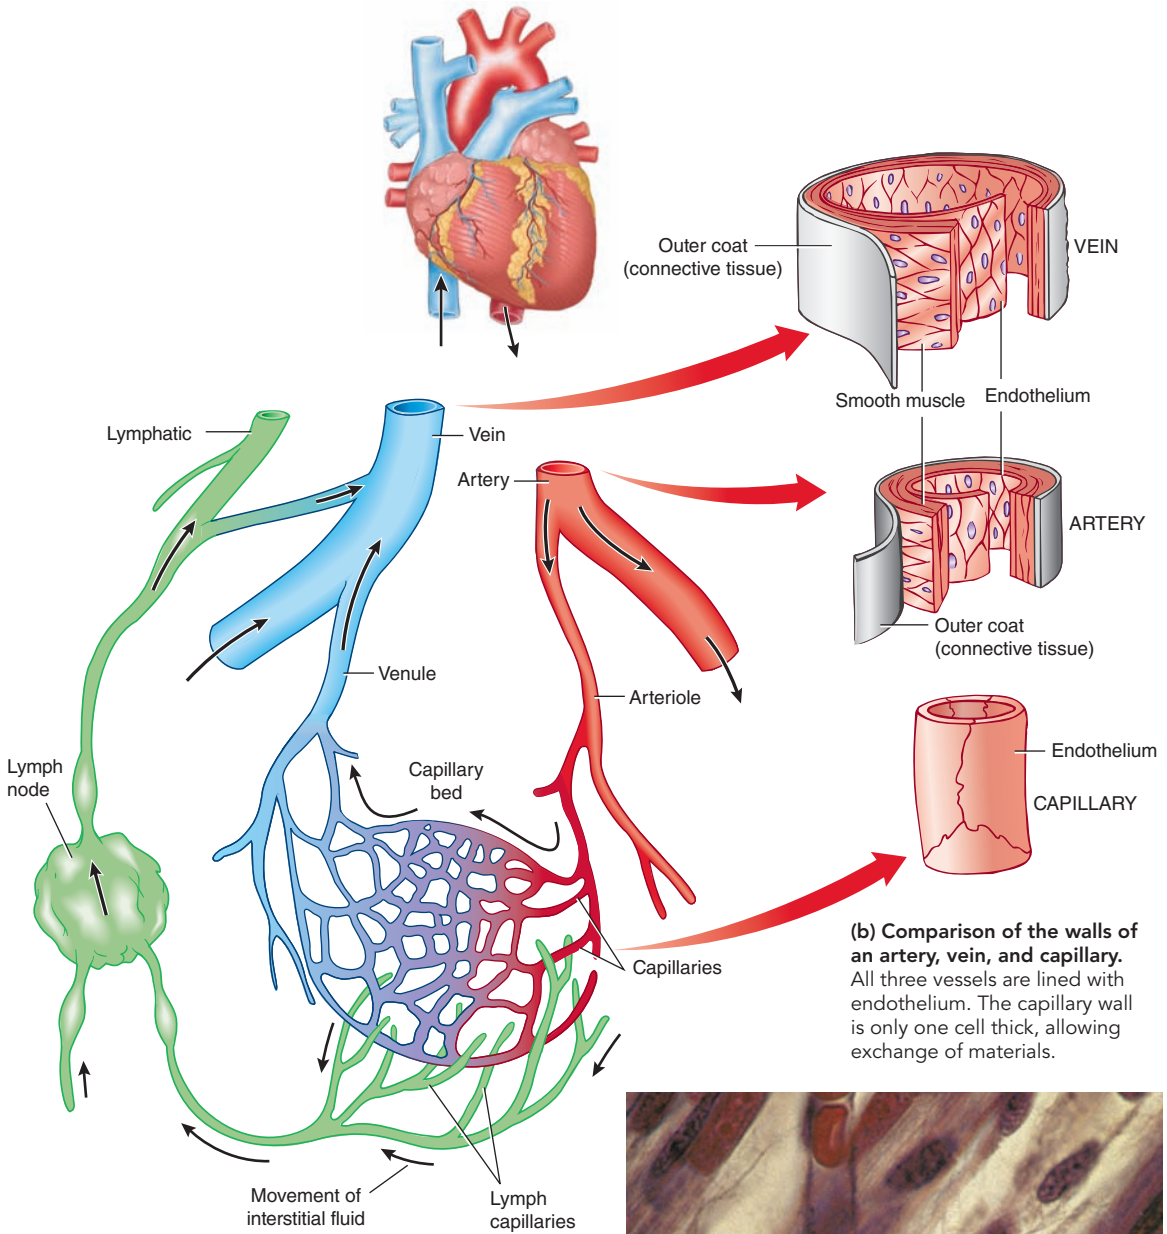
LEARNING OBJECTIVE

4 Compare the structure and function of different types of blood vessels, including arteries, arterioles, capillaries, and veins.

The vertebrate circulatory system includes three main types of blood vessels: arteries, capillaries, and veins (FIG. 44-6). An **artery** carries blood away from a heart chamber toward other tissues. When an artery enters an organ, it divides into many smaller branches called **arterioles**. The arterioles deliver blood into the microscopic **capillaries**. After blood circulates through capillary networks within tissues, capillaries merge to form **veins** that carry the blood back toward the heart.

The wall of an artery or vein has three layers (see Fig. 44-6b). The innermost layer, which lines the blood vessel, consists mainly of **endothelium**, a tissue that resembles squamous epithelium (see Chapter 39). The middle layer is made up of connective tissue and smooth muscle cells, and the outer coat consists of connective tissue rich in elastic and collagen fibers.

Gases and nutrients cannot pass through the thick walls of arteries and veins. Materials are exchanged between the blood and interstitial fluid bathing the cells through the capillary walls, which are only one cell thick. Capillary networks in the body are so extensive that at least one of these tiny vessels is located close to every cell in the body. The total length of all capillaries in the body has been estimated to be more than 96,000 km!



Smooth muscle in the arteriole wall can constrict, a process called **vasoconstriction** or relax, a process called **vasodilation**. Vasoconstriction and vasodilation change the internal diameter of the arteriole. Such changes help maintain appropriate blood pressure and help control the volume of blood passing to

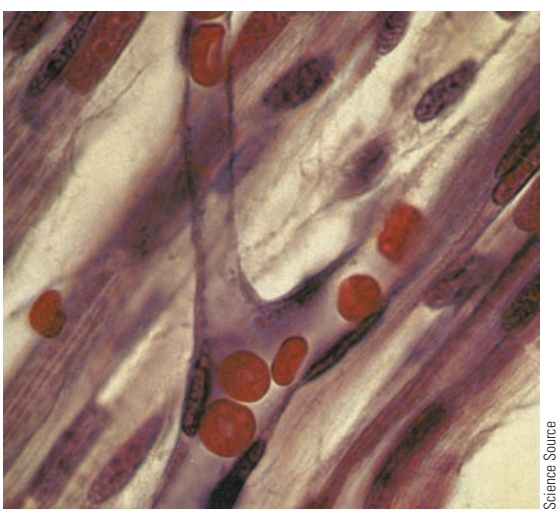
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.



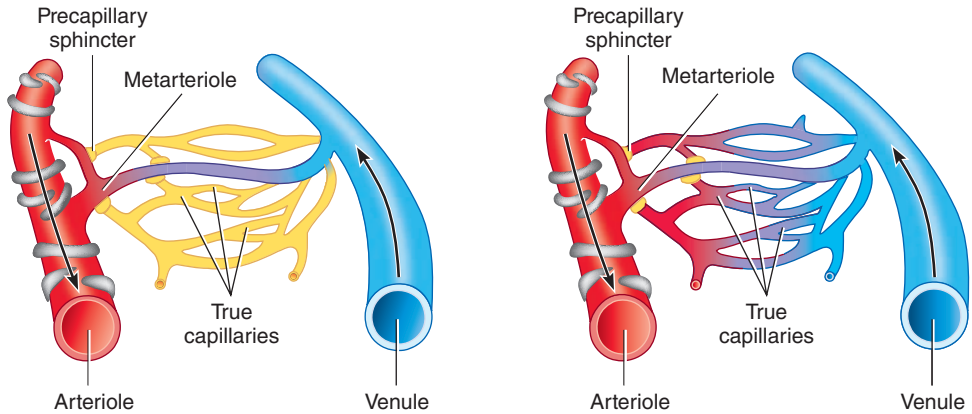
Key Point

The structure of the wall of each type of blood vessel is adapted for the particular function of the vessel; for example, materials are exchanged through the thin walls of capillaries.

(a) The heart pumps blood into arteries. Blood then flows through arterioles, capillaries, and veins, which return it to the heart. Some plasma leaves the capillaries and becomes interstitial fluid. Lymphatic vessels return excess interstitial fluid to the blood through ducts that lead into large veins in the shoulder region. Blood vessels with oxygen-rich blood are shown in *red*. Those with oxygen-poor blood are shown in *blue*.

(b) Comparison of the walls of an artery, vein, and capillary. All three vessels are lined with endothelium. The capillary wall is only one cell thick, allowing exchange of materials.

Science Source



(c) LM of red blood cells passing through capillaries almost in single file.

Figure 44-6 Blood and lymphatic vessels

CONNECT Note that lymph capillaries have dead ends. In what way is the structure of these capillaries connected with their function?

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

(a) Sphincters closed. When a tissue is inactive, only its metarterioles are open.

(b) Sphincters open. When the tissue becomes active, decreased oxygen tension in the tissue relaxes the precapillary sphincters, and the capillaries open. This process increases the blood supply and thus the delivery of nutrients and oxygen to the active tissue.

Figure 44-7 Blood flow through a capillary network
As a tissue becomes active, the pattern of blood flow through its capillary networks changes.

a particular tissue. Changes in blood flow are regulated by the nervous system in response to the metabolic needs of the tissue as well as by the demands of the body as a whole. For example, when a tissue is metabolizing rapidly, it needs more nutrients and oxygen. During exercise, arterioles within skeletal muscles dilate, increasing blood flow by more than tenfold.

If all your blood vessels dilated at the same time, you would not have enough blood to fill them completely. Normally, your liver, kidneys, and brain receive most of the blood. However, if an emergency suddenly occurred requiring rapid action, your blood would be rerouted quickly in favor of the heart and muscles. At such a time, the digestive system and kidneys can do with less blood because they are not crucial in responding to the crisis.

The small vessels that directly link arterioles with venules (small veins) are **metarterioles**. The true capillaries branch off from the metarterioles and then rejoin them (FIG. 44-7). True capillaries also interconnect with one another. Wherever a capillary branches from a metarteriole, a smooth muscle cell serves as a *precapillary sphincter* that opens and closes continuously, directing blood first to one and then to another section of tissue. These precapillary sphincters (along with the smooth muscle in the walls of arteries and arterioles) regulate the blood supply to each organ and its subdivisions.

CHECKPOINT 44.3

- Compare the functions of arteries, capillaries, and veins.
- **PREDICT** Imagine that the smooth muscle in the walls of an individual's arterioles could no longer constrict. What effect would that have on homeostasis?

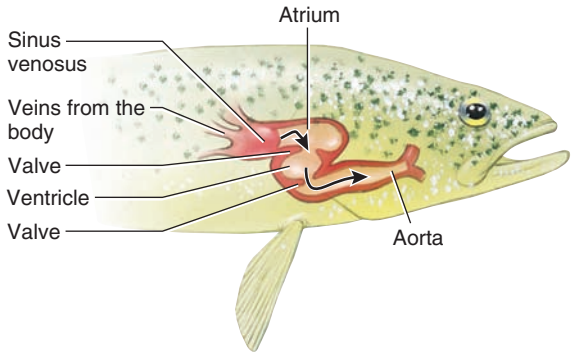
44.4 Evolution of the Vertebrate Circulatory System

LEARNING OBJECTIVE

5 Trace the evolution of the vertebrate circulatory system from fish to mammal.

The vertebrate circulatory system became modified in the course of evolution as the site of gas exchange shifted from gills to lungs and as certain vertebrates became active, endothermic animals with higher metabolic rates. The vertebrate heart has one or two **atria** (sing., *atrium*), chambers that receive blood returning from the tissues, and one or two **ventricles** that pump blood into the arteries (FIG. 44-8). Vertebrates in some groups have additional chambers.

The fish heart has one atrium and one ventricle. The atrium pumps blood into the ventricle, which pumps blood into a single circuit of blood vessels. Blood is oxygenated as it passes through capillaries in the gills. After blood circulates through the gill capillaries, its pressure is low, so blood passes very slowly to the other organs. The fish's swimming movements facilitate circulation. Blood returning to the heart has a low oxygen content. A thin-walled *sinus venosus* receives blood returning from the tissues and pumps it into the atrium.



In amphibians blood flows through a double circuit: the **pulmonary circulation** and the **systemic circulation**. Oxygen-rich blood and oxygen-poor blood are kept somewhat separate. The amphibian heart has two atria and one ventricle. A sinus venosus collects oxygen-poor blood returning

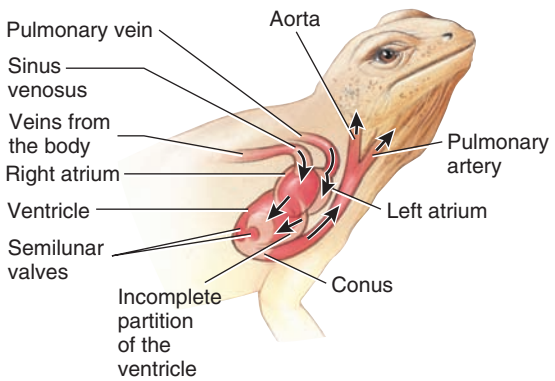
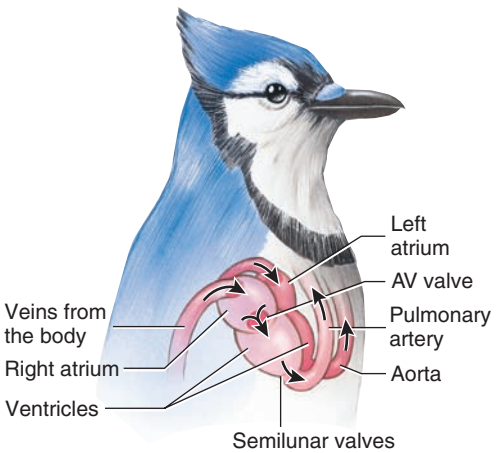
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Key Point



The four-chambered heart and double circuit that separate oxygen-rich from oxygen-poor blood are important adaptations that evolved as vertebrates diversified and some became active, terrestrial, endothermic animals.



(a) Fishes. The single atrium and ventricle of the fish heart are part of a single circuit of blood flow.

(b) Amphibians. In amphibians, the heart consists of two atria and one ventricle; blood flows through a double circuit, but oxygen-rich blood mixes with oxygen-poor blood.

(c) Reptiles (except birds). The reptilian heart has two atria and two ventricles. In most non-avian reptiles, the wall separating the ventricles is incomplete, so blood from the right and left chambers mixes to some extent. In crocodiles and alligators, the septum is complete, and the heart consists of four separate chambers.

(d) Birds and mammals. These animals have two atria and two ventricles. The interventricular septum is complete; oxygen-rich blood is separated from oxygen-poor blood.

Figure 44-8 Evolution of the vertebrate circulatory system

CONNECT How does the separation of oxygen-rich blood and oxygen-poor blood in birds and mammals affect endothermy?

from the veins and pumps it into the right atrium. Blood returning from the lungs passes directly into the left atrium.

Both atria pump into the single ventricle, but oxygen-poor blood is pumped out of the ventricle before oxygen-rich blood enters it. Blood passes into an artery, the *conus arteriosus*, equipped with a fold that helps keep the blood separate. Much of the oxygen-poor blood is directed into the pulmonary circulation, which delivers it to the lungs and skin, where it is recharged with oxygen. The systemic circulation delivers oxygen-rich blood into arteries that conduct it to the various tissues of the body.

Most non-avian reptiles also have a double circuit of blood flow, made more efficient by a wall that partly divides the ventricles. (In this discussion, birds are considered separately from other reptiles.) Mixing of oxygen-rich and oxygen-poor blood is minimized by the timing of contractions of the left

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

and right sides of the heart and by pressure differences. In crocodilians (crocodiles and alligators), the wall between the ventricles is complete, so the heart consists of two separate atria and two separate ventricles. Thus, a four-chambered heart first evolved among the non-avian reptiles. In contrast to birds and mammals, amphibians and non-avian reptiles do not ventilate their lungs continuously. Therefore, it would be inefficient to pump blood through the pulmonary circulation continuously. The shunts between the two sides of the heart allow blood to be distributed to the lungs as needed.

In all birds and mammals (and in crocodilians), the *septum* (wall) between the ventricles is complete. Biologists hypothesize that the completely divided heart evolved twice during the course of vertebrate evolution, first in the crocodilian–bird clade and then independently in mammals. The septum between the ventricles prevents oxygen-rich blood in the left chamber from mixing with oxygen-poor blood in the right chamber. The conus arteriosus has split and become the base of the **aorta** (the largest artery) and of the pulmonary artery. No sinus venosus is present as a separate chamber, but a vestige remains as the *sinoatrial node* (the pacemaker).

Complete separation of the right and left sides of the heart requires blood to pass through the heart twice each time it tours the body. The complete double circuit allows birds and mammals to maintain relatively high blood pressures in the systemic circulation and modest pressures in the pulmonary circulation. The higher pressure is necessary for efficient circulation of blood through the body. However, the delicate air sacs and capillaries of the lungs would be damaged by this pressure.

The double circulatory circuit delivers materials to the tissues rapidly and efficiently. Because their blood contains more oxygen per unit volume and circulates more rapidly than in other vertebrates, the tissues of birds and mammals receive more oxygen. As a result, these animals can maintain a higher metabolic rate than other animals and a constant high body temperature even in cold surroundings.

The pattern of blood circulation in birds and mammals can be summarized as follows :

veins (conduct blood from organs) → right atrium → right ventricle → pulmonary arteries → capillaries in the lungs → pulmonary veins → left atrium → left ventricle → aorta → arteries (conduct blood to organs) → arterioles → capillaries → veins

CHECKPOINT 44.4

- What are some of the major adaptations that occurred during the evolution of the vertebrate circulatory system?

44.5 The Human Heart

LEARNING OBJECTIVES

6 Describe how the structure and function of the human heart are inter-related; include the heart's conduction system in your answer.

7 Trace the events of the cardiac cycle and relate normal heart sounds to these events.

8 Define *cardiac output*, describe how it is regulated, and identify factors that affect it.

Not much bigger than a fist and weighing less than a pound, the human heart is a remarkable organ. It beats about 2.5 billion times during an average lifetime, pumping about 300 million L (80 million gal) of blood. To meet the body's changing needs, the heart can vary its output from 5 L to more than 20 L of blood per minute.

Your heart is a hollow, muscular organ located in the chest cavity directly under the breastbone. Its wall consists mainly of cardiac muscle attached to a framework of collagen fibers. The *pericardium*, a tough connective tissue sac, encloses the heart. A smooth layer of endothelium covers the inner surface of the pericardium and the outer surface of the heart. Between these two surfaces is a small *pericardial cavity* filled with fluid, which reduces friction to a minimum as the heart beats.

A wall, or **septum**, separates the right atrium and ventricle from the left atrium and ventricle. Between the atria, the wall is known as the *interatrial septum*; between the ventricles, it is known as the *interventricular septum*. A shallow depression, the *fossa ovalis*, on the interatrial septum marks the place where an opening, the *foramen ovale*, was located in the fetal heart. In the fetus, the foramen ovale lets the blood flow directly from the right to the left atrium, so very little passes to the nonfunctional lungs. A small muscular pouch, called an *auricle*, lies at the upper surface of each atrium.

The heart has valves that close automatically, preventing blood from flowing backward (FIG. 44-9). The valve between the right atrium and right ventricle is called the *right* **atrioventricular (AV) valve**, or **tricuspid valve**. The *left atrioventricular valve* (between the left atrium and left ventricle) is the **mitral valve**, or *bicuspid valve*. The AV valves are held in place by stout cords, or "heart-strings," the *chordae tendineae*. These cords attach the valves to the papillary muscles that project from the walls of the ventricles.

When blood returning from the tissues fills the atria, blood pressure on the AV valves forces them to open into the ventricles, filling the ventricles with blood. As the ventricles contract, blood is forced back against the AV valves, pushing them closed. Contraction of the papillary muscles and tensing of the chordae tendineae prevent the valves from opening backward into the atria. These valves are like swinging doors that open in only one direction.

Semilunar valves (named for their flaps, which are shaped like half-moons) guard the exits from the heart. The semilunar valve between the left ventricle and the aorta is the *aortic valve*, and the one between the right ventricle and the pulmonary artery is the *pulmonary valve*. When blood passes out of the

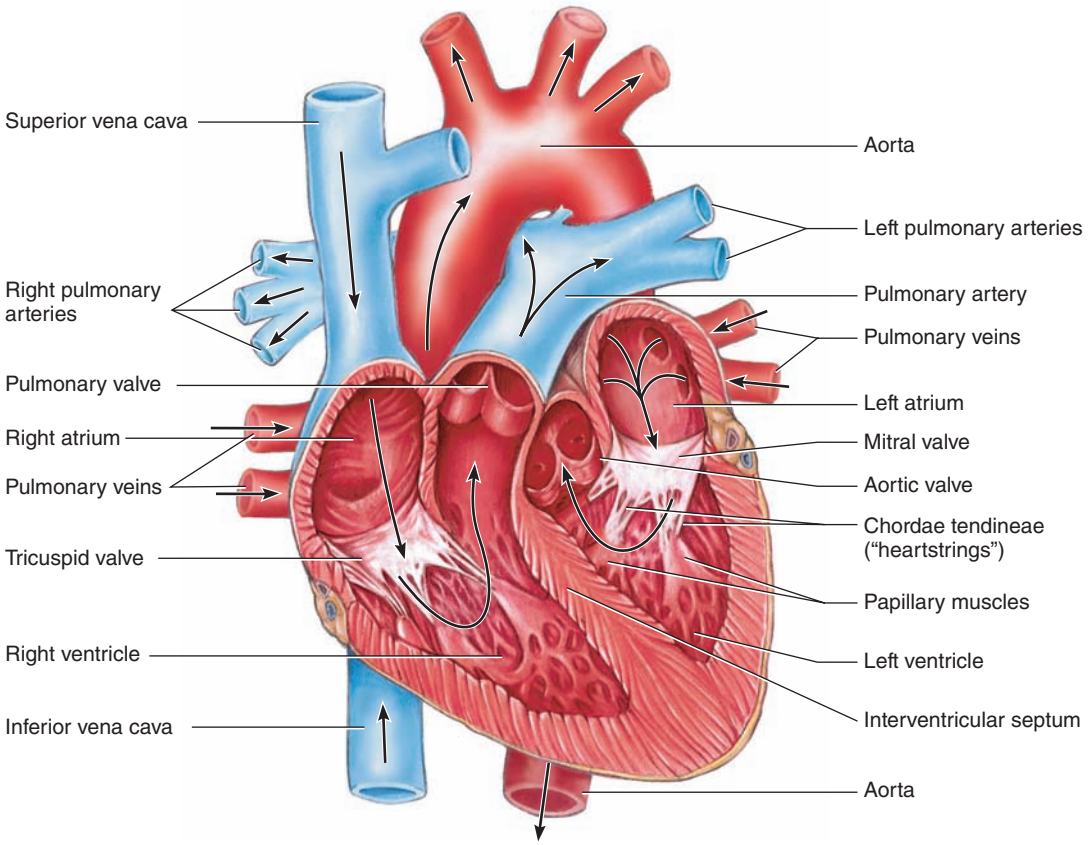

Figure 44-9 Section through the human heart showing the valves

Note the right and left atria, which receive blood, and the right and left ventricles, which pump blood into the arteries. *Arrows* indicate the direction of blood flow.

ventricles, the flaps of the semilunar valves are pushed aside and offer no resistance to blood flow. When the ventricles are relaxing and filling with blood from the atria, however, blood pressure in the arteries is higher than in the ventricles. Blood then fills the pouches of the valves, stretching them across the artery so that blood cannot flow back into the ventricle.

Each heartbeat is initiated by a pacemaker

Horror films sometimes feature a scene in which a heart cut out of a human body continues to beat. Scriptwriters of these tales actually have some factual basis for their gruesome fantasies because a heart carefully removed from the body can continue to beat for many hours if kept in a nutritive, oxygenated fluid. This is possible because the contractions of cardiac muscle begin within the muscle itself and can occur independently of any nerve supply (FIG. 44-10a).

At their ends cardiac muscle fibers (cells) are joined by dense bands called **intercalated discs** (in-ter´-kuh-lay″-ted) (FIGS. 44-10b and c). These complex junctions contain *gap junctions*. Recall from Chapter 5 that in a gap junction, two cells connect through pores. Gap junctions are of great physiological importance because they offer very little resistance to the passage of an action potential. Ions move easily through the gap junctions, allowing the entire atrial (or ventricular) muscle mass to contract as one giant cell.

Compared with skeletal muscle that has action potentials typically lasting 1 to 2 milliseconds (msec), the action potentials of cardiac muscle are much longer, several hundred msec. Voltage-activated Ca^{2+} channels open during depolarization of cardiac muscle fibers. Entry of Ca^{2+} contributes to the longer depolarization time. Another factor is a type of K^+ channel that stays open when the cell is at its resting potential but closes during depolarization, lengthening depolarization time by decreasing the permeability of the membrane to K^+. From experiments on isolated cardiac muscle fibers, investigators determined that spontaneous contraction results from the combination of a slow decrease in K^+ permeability and a slow increase in Na^+ and Ca^{2+} permeability.

A specialized conduction system ensures that the heart beats in a regular and effective rhythm. Each beat is initiated by the **pacemaker**, a small mass of specialized cardiac muscle fibers in the **sinoatrial (SA) node**. The SA node is located in the posterior wall of the right atrium near the opening of a large vein, the superior vena cava. The action potential in the

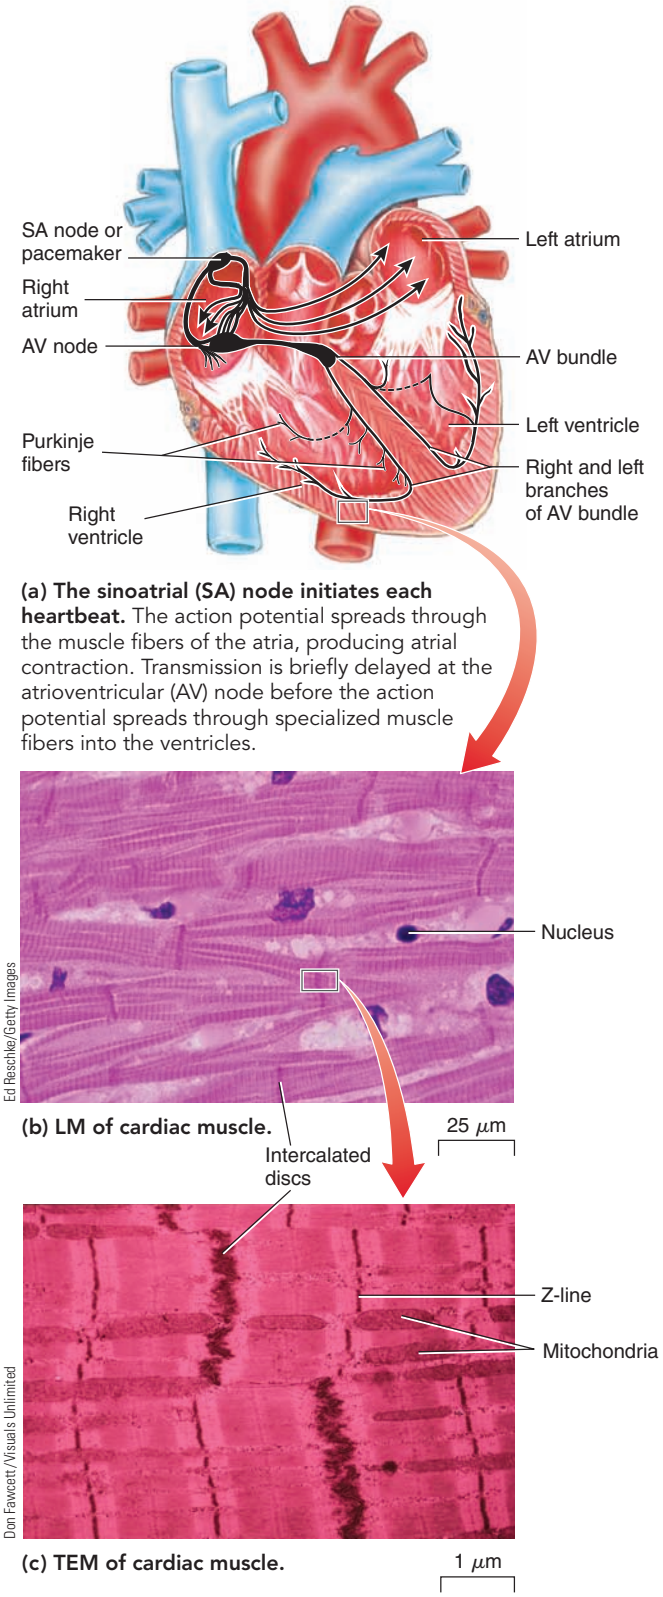

Figure 44-10 Conduction system of the heart

When action potentials are initiated by the pacemaker cells in the SA node, gap junctions within the intercalated discs allow the impulses to spread easily from one cardiac muscle fiber to the next within the atria (and within the ventricles). The atria (and then the ventricles) contract as a functional unit.

SA node is triggered mainly by the opening of Ca^{2+} channels. Ends of the SA node fibers fuse with ordinary atrial muscle fibers, so each action potential spreads through the cardiac muscle fibers of both atria, producing atrial contraction.

One group of atrial muscle fibers conducts the action potential directly to the **atrioventricular (AV) node**, located in the right atrium along the lower part of the septum. Here transmission is delayed briefly so that the atria finish contracting before the ventricles begin to contract. From the AV node, the action potential spreads into specialized muscle fibers that make up the *AV bundle*. The AV bundle divides, sending branches into each ventricle. Fibers of the bundle branches divide further, eventually forming small *Purkinje fibers*. These fibers conduct impulses to the muscle fibers of both ventricles.

In summary,

SA node → atrial muscle fibers (atria contract) → AV node → AV bundle → right and left bundle branches → Purkinje fibers → conduct impulses to muscle fibers of both ventricles → ventricles contract

As each wave of contraction spreads through the heart, electric currents flow into the tissues surrounding the heart and onto the body surface. By placing electrodes on the body surface on opposite sides of the heart, a physician can amplify and record the electrical activity. The graph produced is called an *electrocardiogram* (*EKG* or *ECG*). Abnormalities in the EKG indicate disorders in the heart or its rhythm. For example, in *heart block*, impulse transmission is delayed or blocked at some point in the conduction system. Artificial pacemakers can help patients with severe heart block. The pacemaker is implanted beneath the skin, and its electrodes are connected to the heart. This device provides continuous rhythmic impulses that avoid the block and drive the heartbeat.

The cardiac cycle consists of alternating periods of contraction and relaxation

Each minute the heart beats about 70 times. One complete heartbeat takes about 0.8 second and is referred to as a **cardiac cycle**. That portion of the cycle in which contraction occurs is known as **systole**; the period of relaxation is **diastole**. FIGURE 44-11 shows the sequence of events that occur during one cardiac cycle.

When you listen to the heartbeat with a stethoscope, you can hear two main heart sounds, "lub-dup," which repeat rhythmically. These sounds result from the heart valves closing. When the valves close, they cause turbulence in blood flow that sets up vibrations in the walls of the heart chambers. The first heart sound, "lub," is low pitched, not very loud, and fairly long lasting. It is caused mainly by the closing of the AV (mitral and tricuspid) valves and marks the beginning of ventricular systole. The "lub" sound is quickly followed by the higher-pitched, louder, sharper, and shorter "dup" sound. Heard almost as a quick snap, the "dup" marks the closing of the semilunar valves and the beginning of ventricular diastole.

The quality of these sounds tells a discerning physician much about the state of the valves. For example, when a valve

Key Point

The rhythmic changes in electrical activity of the heart are responsible for the cardiac cycle, the pattern of contraction and relaxation that takes place during each heartbeat.

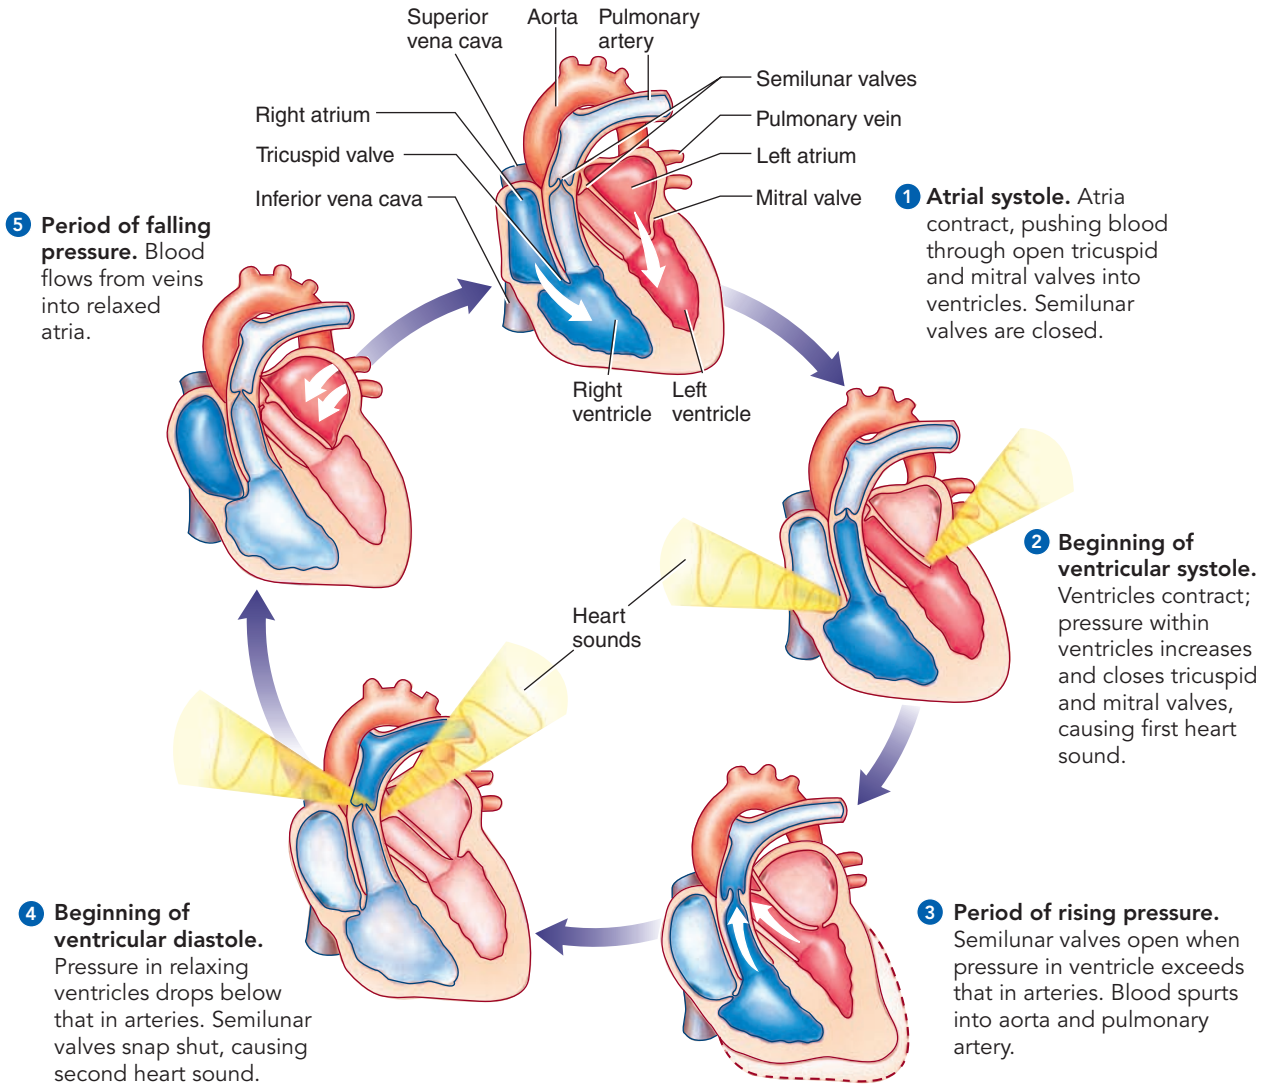

Figure 44-11 The cardiac cycle

The cycle comprises contraction of both atria followed by both ventricles. *White arrows* indicate the direction of blood flow; *dotted lines* indicate the change in size as contraction occurs.

PREDICT How is the cardiac cycle affected when the SA node increases its rate of firing?

does not close tightly, blood may flow backward. When the semilunar valves are injured, a soft, hissing noise ("lub-shhh") known as a *heart murmur* is heard in place of the normal sound. Valve deformities are sometimes present at birth, or they may result from certain diseases, such as rheumatic fever or syphilis. Diseased or deformed valves can be surgically repaired or replaced with artificial valves.

You can measure your heart rate by placing a finger over the radial artery in your wrist or the carotid artery in your neck and counting the pulsations for 1 minute. **Arterial pulse** is the alternate expansion and recoil of an artery. Each time the left ventricle pumps blood into the aorta, the elastic wall of the aorta expands to accommodate the blood. This expansion moves in a wave down the aorta and the arteries that branch from it. When the pressure wave passes, the elastic arterial wall snaps back to its normal size.

The nervous system regulates heart rate

Although the heart can beat independently, its rate is, in fact, carefully regulated by the nervous and endocrine systems (FIG. 44-12). Sensory receptors in the walls of certain blood vessels and heart chambers are sensitive to changes in blood pressure. When stimulated, the receptors send messages

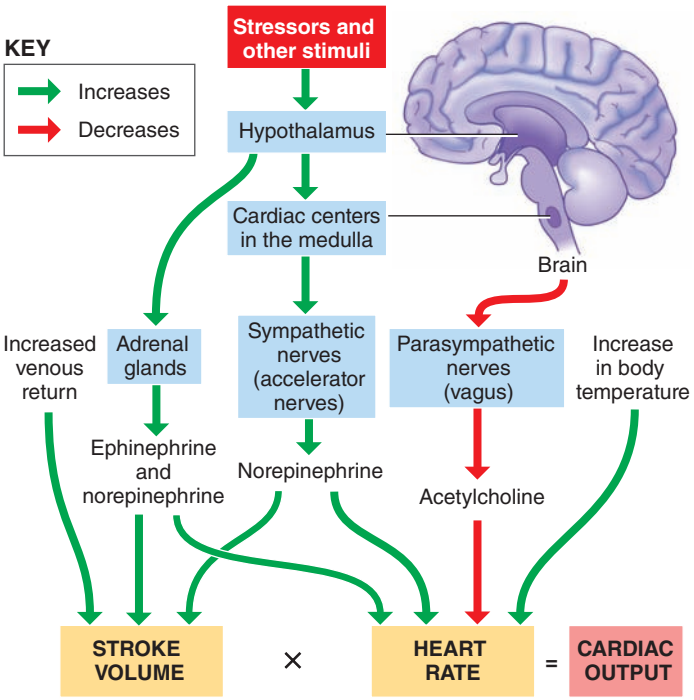

Figure 44-12 Some factors that influence cardiac output

to *cardiac centers* in the medulla of the brain. These cardiac centers govern two sets of autonomic nerves that pass to the SA node: parasympathetic nerves and sympathetic nerves. Parasympathetic and sympathetic nerves have opposite effects on heart rate (see Fig. 42-17).

Parasympathetic nerves release the neurotransmitter *acetylcholine*, which slows the heart. Acetylcholine slows the rate of depolarization by increasing the membrane's permeability to K^+ (FIG. 44-13a). Sympathetic nerves release norepinephrine, which speeds the heart rate and increases the strength of contraction. Norepinephrine stimulates Ca^{2+} channel opening during depolarization (FIG. 44-13b). Both norepinephrine and acetylcholine act indirectly on ion channels. They activate a *signal transduction* process involving a G protein (see Chapter 6).

Norepinephrine binds to *beta-adrenergic receptors*, one of the two main types of adrenergic receptors. These receptors are targeted by *beta blockers*, drugs that block the actions of norepinephrine on the heart. Beta blockers are used clinically in treating hypertension (high blood pressure) and other types of heart disease.

In response to physical and emotional stressors, the adrenal glands release epinephrine and norepinephrine, which speed the heart. An elevated body temperature also increases heart rate. During fever, the heart may beat more than 100 times per minute. When body temperature is lowered, heart rate decreases.

Stroke volume depends on venous return

The volume of blood one ventricle pumps during one beat is the **stroke volume**. Stroke volume depends mainly on **venous return**, the amount of blood the veins deliver to the heart. According to *Starling's law of the heart*, if the veins deliver more blood to the heart, the heart pumps more blood into the arteries (within physiological limits). Increased venous return stretches the cardiac muscle fibers more, and they contract with greater force, increasing stroke volume. Norepinephrine released by sympathetic nerves and both norepinephrine and epinephrine released by the adrenal glands during stress also increase the force of contraction of cardiac muscle fibers.

Cardiac output varies with the body's need

The **cardiac output (CO)** is the volume of blood pumped by the left ventricle into the aorta in 1 minute. We can compute the CO by multiplying the stroke volume by the number of times the left ventricle beats per minute. For example, in a resting adult, the heart may beat about 72 times per minute and pump about 70 mL of blood with each contraction.

$$\begin{aligned} CO &= \text{stroke volume} \times \text{heart rate (number of ventricular contractions per minute)} \\ &= 70\ \text{mL/stroke} \times 72\ \text{strokes/min} \\ &= 5040\ \text{mL/min (about 5 L/min)} \end{aligned}$$

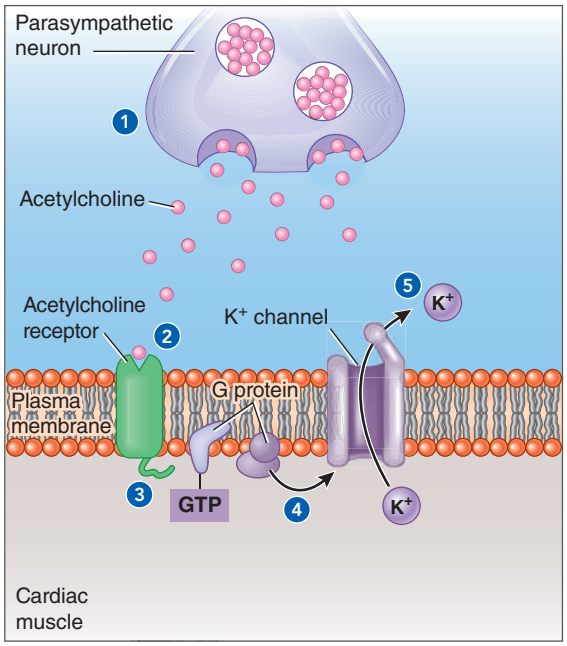
Cardiac output varies with changes in either stroke volume or heart rate (see Fig. 44-12). When stroke volume increases, CO increases. The CO varies dramatically with the changing needs of the body. During stress or heavy exercise, the normal heart can increase its CO fivefold so that it pumps 20 to 30 L of blood per minute.

CHECKPOINT 44.5

- List the sequence of events that occurs during cardiac conduction.
- **PREDICT** A patient's mitral valve (left AV valve) does not close completely at the beginning of ventricular systole. What effect would this have on the cardiac cycle?
- Imagine that you are feeling very anxious as you walk to the podium to deliver a speech. If your heart rate increases to 100 beats per minute and your stroke volume is 100 mL per stroke, what is your cardiac output?

44.6 Blood Pressure

LEARNING OBJECTIVE



9 Identify factors that determine and regulate blood pressure and compare blood pressure in different types of blood vessels.

Blood pressure is the force exerted by the blood against the inner walls of the blood vessels. It is determined by CO (cardiac output), blood volume, and resistance to blood flow

1. Parasympathetic neuron releases acetylcholine.
2. Acetylcholine binds with receptors on plasma membrane of cardiac muscle.
3. Receptor activates G protein.
4. G protein binds with K^+ channel, opening it.
5. K^+ leaves the cell, hyperpolarizing the membrane. Action potentials occur more slowly. Heart rate decreases.

(a) Parasympathetic action on cardiac muscle.

1. Sympathetic neuron releases norepinephrine.
2. Norepinephrine binds with receptors on the plasma membrane of cardiac muscle.
3. Receptor activates G protein.
4. G protein activates adenylyl cyclase, which converts ATP to cyclic AMP (cAMP).
5. Cyclic AMP activates protein kinase.
6. Protein kinase phosphorylates Ca^{2+} channels so that they open more easily when neuron is depolarized. Action potentials occur more rapidly. Heart rate increases.

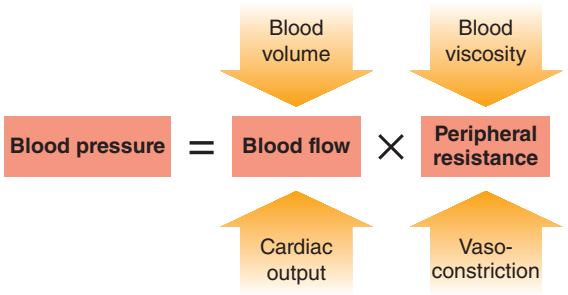
(b) Sympathetic action on cardiac muscle.

Figure 44-13 Actions of parasympathetic and sympathetic neurons on cardiac muscle
Parasympathetic neurons release acetylcholine, which slows the heart rate. Sympathetic neurons release norepinephrine, which increases both the heart rate and the strength of contraction. Each of these neurotransmitters works through a G protein and initiates a signal transduction process.

(FIG. 44-14a). When CO increases, the increased blood flow causes a rise in blood pressure. When CO decreases, the decreased blood flow causes a fall in blood pressure. If the volume of blood is reduced by hemorrhage or chronic bleeding, the blood pressure drops. In contrast, an increase in blood volume results in an increase in blood pressure. For example, a high dietary intake of salt causes water retention, which increases blood volume and raises blood pressure.

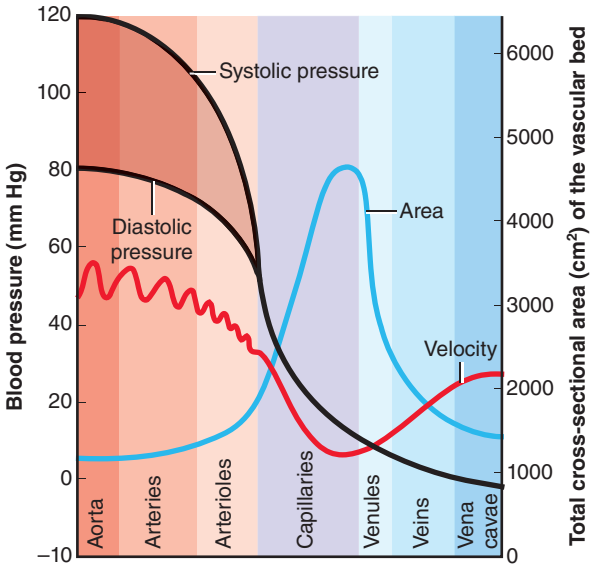
Blood flow is impeded by resistance. When the resistance to flow increases, blood pressure rises. *Peripheral resistance* is the resistance to blood flow caused by blood viscosity and by friction between blood and the blood vessel wall. In the blood of a healthy person, viscosity remains fairly constant and is only a minor influence on changes in blood pressure. More important is the friction between blood and the blood vessel wall. The length and diameter of a blood vessel determine the amount of surface area in contact with the blood. Blood vessel length does not change, but the diameter, especially of an arteriole, does. A small change in blood vessel diameter causes a big change in blood pressure. Constriction of blood vessels raises blood pressure; dilation lowers blood pressure.

Blood pressure in arteries rises during systole and falls during diastole. The National Institutes of Health defines *normal blood pressure* as a systolic pressure of less than 120 and a diastolic pressure of less than 80. An example of a normal blood pressure, measured in the upper arm with a sphygmomanometer, is 110/73 mm of mercury, abbreviated mm Hg. Systolic pressure is indicated by the first number, diastolic by the second.



If you have a blood pressure of 120 to 139 systolic over 80 to 89 diastolic, you are considered *prehypertensive*, and you need to modify your lifestyle to prevent cardiovascular disease and stroke. Lifestyle changes that will reduce your risk include exercising, losing excess weight, following a heart-healthy diet, reducing salt intake, limiting alcohol, and not smoking.

If your systolic pressure consistently measures 140 mm Hg or higher or your diastolic pressure measures 90 mm Hg or higher, you have **hypertension**, or high blood pressure. Hypertension is a risk factor for atherosclerosis and other cardiovascular disease (discussed later in this chapter).



In hypertension there is usually increased vascular resistance, especially in the arterioles and small arteries. The heart's workload increases because it must pump against this greater resistance. If this condition persists, the left ventricle

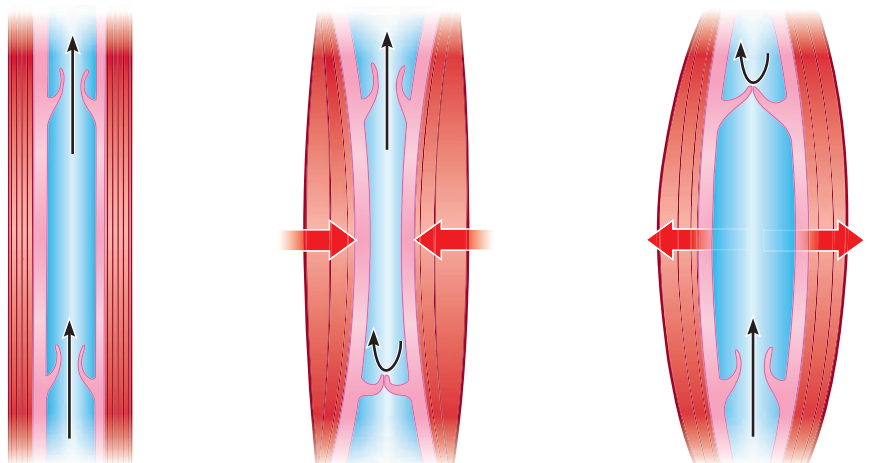
(a) Blood pressure depends on blood flow and resistance to that flow. A variety of factors affect blood flow and resistance.

(b) Blood pressure varies in different types of blood vessels. Systolic and diastolic variations in arterial blood pressures are shown. Note that the venous pressure drops below zero (below atmospheric pressure) near the heart.

Figure 44-14 Blood pressure
Area in graph refers to the surface area of blood vessels in contact with blood.

enlarges and may deteriorate in function. Heredity, aging, race, and ethnicity can increase the risk of hypertension. Modifiable risk factors include being overweight, eating too much sodium, smoking, and drinking too much alcohol.



Blood pressure varies in different blood vessels

As you might predict, blood pressure is greatest in the large arteries and decreases as blood flows away from the heart and through the smaller arteries and capillaries (FIG. 44-14b). By the time blood enters the veins, its pressure is very low, even approaching zero. Flow rate can be maintained in veins at low pressure because they are low-resistance vessels. Their diameter is larger than that of corresponding arteries, and their walls have little smooth muscle. Flow of blood through veins depends on several factors, including skeletal muscle movement, which compresses veins. Most veins larger than 2 mm (0.08 in.) in diameter that conduct blood against the force of gravity are equipped with *valves* that prevent backflow. Such valves usually consist of two cusps formed by inward extensions of the vein wall (FIG. 44-15).

When a person stands perfectly still for a long time, as when a soldier stands at attention or a store clerk stands at a cash register, blood tends to pool in the veins. When fully distended, veins can accept no more blood from the capillaries. Pressure increases in the capillaries, and large amounts of plasma are forced out of the circulation through the thin capillary walls. Within just a few minutes, as much as 20% of the blood volume can be lost from the circulation, with drastic effect. Arterial blood pressure falls dramatically, reducing blood flow to the brain. Sometimes the resulting lack of oxygen in the brain causes the person to faint. Fainting is a protective response because lying in a prone position increases blood supply to the brain. In fact, lifting a person who has fainted to an upright position can result in circulatory shock and even death.

Blood pressure is carefully regulated

Each time you get up from a horizontal position, your blood pressure changes. Several mechanisms interact to maintain normal

(a) Resting condition.

(b) Muscles contract. Muscles bulge, compressing veins and forcing blood toward the heart. The lower valve prevents backflow.

(c) Muscles relax. The vein expands and fills with blood from below. The upper valve prevents backflow.

Figure 44-15 Venous blood flow
Contraction of skeletal muscles helps move blood through the veins.

blood pressure so that you do not faint when you get out of bed each morning or change position during the day. When blood pressure decreases, sympathetic nerves to the blood vessels stimulate vasoconstriction, causing the pressure to rise again.

Baroreceptors, specialized receptors in the walls of certain arteries and in the heart wall, are sensitive to changes in blood pressure. When an increase in blood pressure stretches the baroreceptors, messages are sent to the cardiac and vasomotor centers in the medulla of the brain. The cardiac center stimulates parasympathetic nerves that slow the heart, lowering blood pressure. The vasomotor center inhibits sympathetic nerves that constrict arterioles; this action causes vasodilation, which also lowers blood pressure. These neural reflexes continuously work in a complementary way to maintain blood pressure within normal limits.

Several hormones are also involved in regulating blood pressure (discussed in more detail in Chapters 48 and 49). In response to low blood pressure, the kidneys release **renin**, which activates the *renin–angiotensin–aldosterone pathway*. Renin acts on a plasma protein (angiotensinogen), triggering a cascade of reactions that produces the hormone **angiotensin II**, a powerful vasoconstrictor. Vasoconstriction *increases* blood pressure, restoring homeostasis. Angiotensin II also acts indirectly to maintain blood pressure by increasing the synthesis and release of the hormone **aldosterone** by the adrenal glands. Aldosterone increases retention of Na^+ by the kidneys, resulting in greater fluid retention and increased blood volume.

When the body becomes dehydrated, the osmotic concentration of the blood increases. In response, the posterior lobe of the pituitary gland releases **antidiuretic hormone (ADH)**. This hormone increases reabsorption of water in the kidneys (and only a small volume of concentrated urine is produced). Blood volume increases, raising blood pressure and restoring homeostasis.

When blood volume increases, the atria of the heart release a hormone called **atrial natriuretic peptide (ANP)**. This hormone increases sodium excretion. As a result, a large volume of dilute urine is produced, and blood pressure *decreases*. Nitric oxide also helps regulate blood pressure by causing vasodilation, thus decreasing blood pressure.

CHECKPOINT 44.6

- How does constriction of arterioles affect blood pressure?
- How does blood pressure in arteries compare with blood pressure in veins?

44.7 The Pattern of Circulation

LEARNING OBJECTIVE

10 Trace a drop of blood through the pulmonary and systemic circulations, naming in sequence each structure through which it passes.

Most vertebrates other than fishes have a double circuit of blood vessels: (1) the **pulmonary circulation** connects the heart and lungs; and (2) the **systemic circulation** connects the heart with all the body tissues. You can trace this general pattern of circulation in FIGURE 44-16.

Key Point

The right side of the heart receives oxygen-poor blood returning from the tissues and pumps it into the pulmonary circulation. The left side of the heart receives oxygen-rich blood from the lungs and pumps it into the systemic circulation.

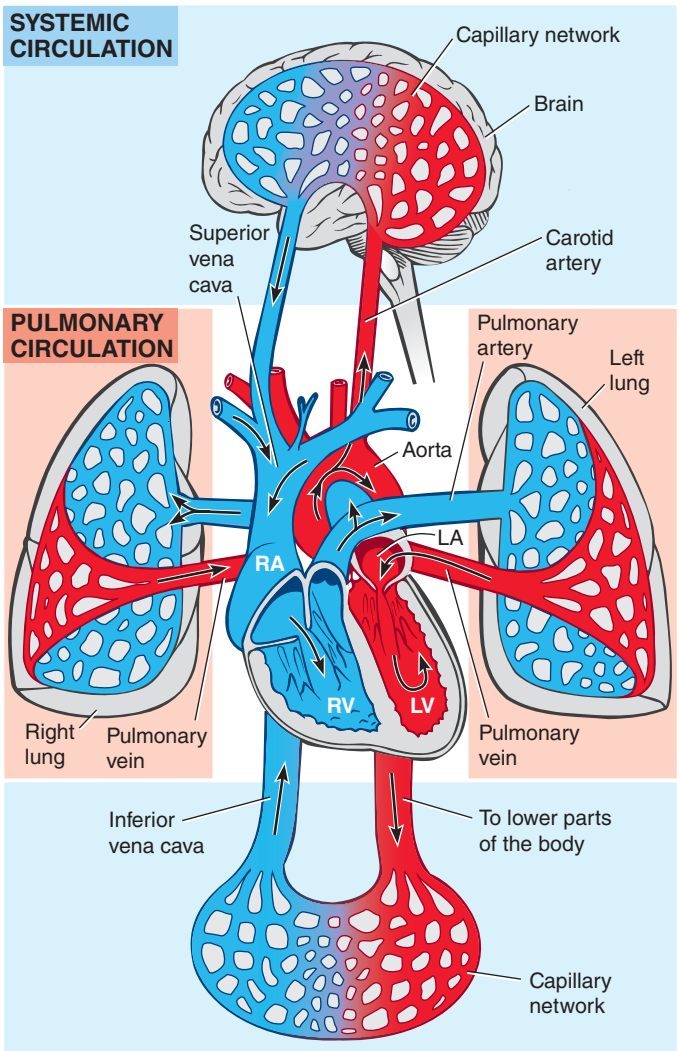

Figure 44-16 Systemic and pulmonary circulation

In this highly simplified diagram, *red* represents oxygen-rich blood, and *blue* represents oxygen-poor blood. The *light blue screens* highlight systemic circulation, and the *light pink screens* highlight pulmonary circulation.

CONNECT Although not evident in the view depicted in the illustration, the chambers of the left and right ventricles are the same size and pump equal volumes of blood. However, the muscle of the left ventricle is much thicker than that of the right ventricle. How does this difference relate to their functions?

The pulmonary circulation oxygenates the blood

Blood from the tissues returns to the right atrium of the heart. This oxygen-poor blood, loaded with carbon dioxide, is pumped by the right ventricle into the pulmonary circulation. As it emerges from the heart, the large pulmonary trunk branches to form the *pulmonary arteries* that deliver blood to the lungs. *The pulmonary arteries are the only arteries in the body that carry oxygen-poor blood.*

In the lungs the pulmonary arteries branch into smaller and smaller vessels. These blood vessels give rise to extensive networks of pulmonary capillaries that surround the air sacs of the lungs. As blood circulates through the pulmonary capillaries, carbon dioxide diffuses out of the blood and into the air sacs. Oxygen from the air sacs diffuses into the blood. By the time it enters the *pulmonary veins* leading back to the left atrium of the heart, the blood is recharged with oxygen. *Pulmonary veins are the only veins in the body that carry blood rich in oxygen*. In summary, blood flows through the pulmonary circulation in the following sequence:

right atrium → right ventricle → pulmonary arteries → pulmonary capillaries (in lungs) → pulmonary veins → left atrium

The systemic circulation delivers blood to the tissues

Blood entering the systemic circulation is pumped by the left ventricle into the **aorta**, the largest artery. Arteries that branch off from the aorta conduct blood to all regions of the body. Some of the principal branches include the *coronary arteries* to the heart wall itself, the *carotid arteries* to the brain, the *subclavian arteries* to the shoulder region, the *mesenteric artery* to the intestine, the *renal arteries* to the kidneys, and the *iliac arteries* to the legs (FIG. 44-17). Each of these arteries gives rise to smaller and smaller vessels, somewhat like branches of a tree that divide until they form tiny twigs. Eventually, blood flows into capillary networks within each tissue or organ.

Blood returning from the capillary networks within the brain passes through the *jugular veins*. Blood from the shoulders and arms drains into the *subclavian veins*. These veins and others returning blood from the upper portion of the body merge to form a very large vein that empties blood into the right atrium. In humans this vein is called the **superior vena cava**. The *renal veins* from the kidneys, *common iliac veins* from the lower limbs, *hepatic veins* from the liver, and other veins from the lower portion of the body return blood to the large **inferior vena cava**. This very large vein also delivers blood to the right atrium.

As an example of blood circulation through the systemic circuit, let us trace a drop of blood from the heart to the right leg and back to the heart:

left atrium → left ventricle → aorta → right common iliac artery → smaller arteries in leg → capillaries in leg → small veins in leg → common iliac vein → inferior vena cava → right atrium

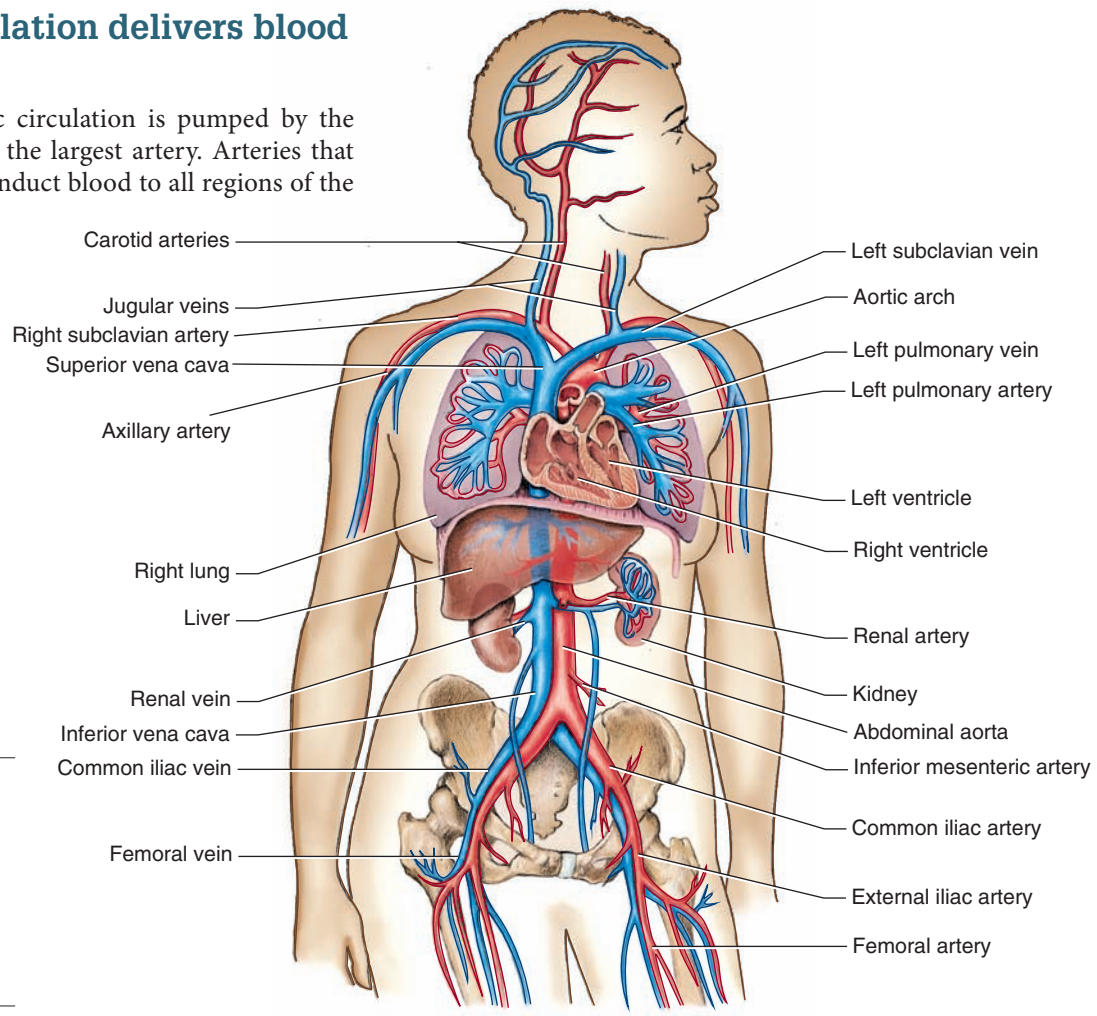

Figure 44-17 Blood circulation through some of the principal arteries and veins of the human body

Blood vessels carrying oxygen-rich blood are *red*; blood vessels carrying oxygen-poor blood are *blue*.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

In most fishes, small amphibians, and in some non-avian reptiles, the heart muscle is spongy and receives oxygen directly from the blood as it passes through the heart chambers. However, in other vertebrates, including birds and mammals, the walls of the heart are too thick for nutrients and oxygen to reach all the muscle fibers by diffusion. Instead, the cardiac muscle has its own system of blood vessels, the **coronary circulation**. In humans, *coronary arteries* give rise to a network of capillaries within the heart wall. The *coronary veins* join to form a large vein, the *coronary sinus*, which empties directly into the right atrium.

Blood almost always travels from artery to capillary to vein to the heart. An exception occurs in the **hepatic portal system**. Instead of leading directly back to the heart (as most veins do), the hepatic portal vein delivers nutrients from the intestine to the liver. Within the liver, the hepatic portal vein gives rise to an extensive network of tiny blood sinuses. As blood courses through the hepatic sinuses, liver cells remove nutrients and store them. Eventually, liver sinuses merge to form hepatic veins, which deliver blood to the inferior vena cava.

CHECKPOINT 44.7

- What sequence of blood vessels and heart chambers would a red blood cell pass through on its way (1) from the carotid artery to the superior vena cava and (2) from the renal vein to the renal artery?
- What is the function of the hepatic portal system? How does its sequence of blood vessels differ from that in most other circulatory routes?

44.8 The Lymphatic System

LEARNING OBJECTIVE

11 Describe the inter-relationship between the structures and functions of the lymphatic system.

In addition to the blood circulatory system, vertebrates have an accessory circulatory system, the **lymphatic system** (FIG. 44-18). The lymphatic system (1) collects and returns interstitial fluid to the blood, (2) launches immune responses that defend the body against disease organisms, and (3) absorbs lipids from the digestive tract. In this section we focus on the first function. We discuss immunity in Chapter 45 and lipid absorption in Chapter 47.

The lymphatic system consists of lymphatic vessels and lymph tissue

The lymphatic system consists of (1) an extensive network of *lymphatic vessels*, or simply *lymphatics*, that conduct **lymph**, the clear, watery fluid formed from interstitial fluid; and (2) *lymph tissue*, a type of connective tissue with large numbers of lymphocytes. Lymph tissue is organized into small masses of tissue called **lymph nodes** and *lymph nodules*. The tonsils, thymus gland, and spleen, which consist mainly of lymph tissue, are also part of the lymphatic system.

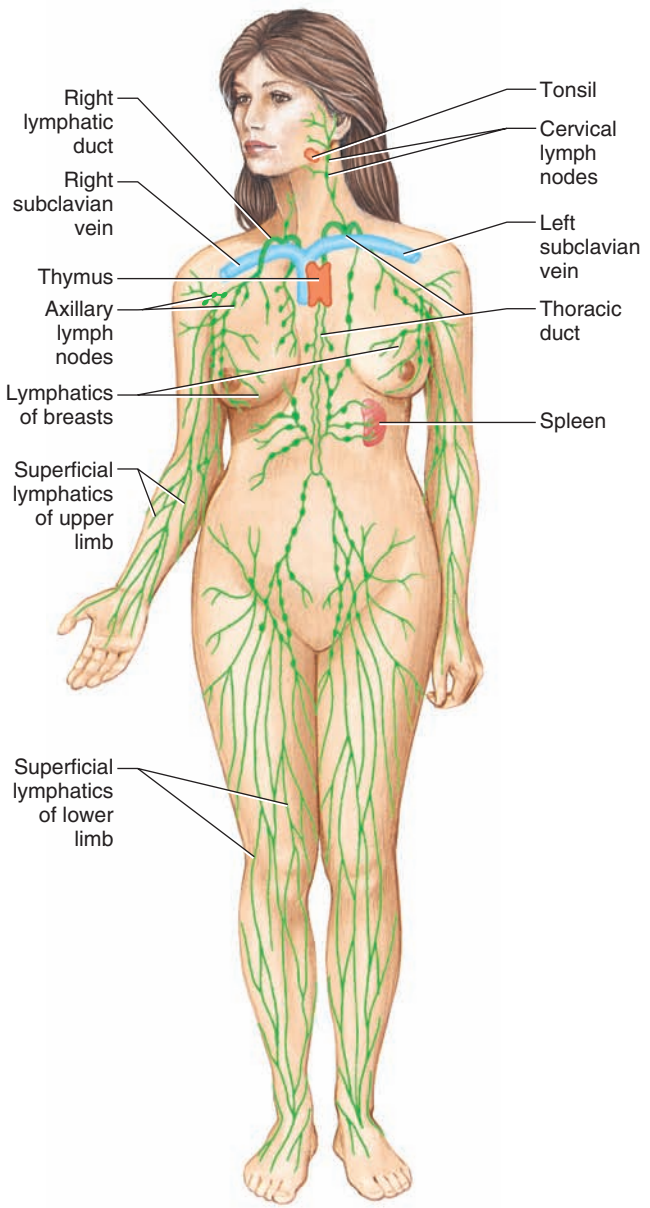

Figure 44-18 Human lymphatic system

Note that the lymphatic vessels extend into most tissues of the body, but the lymph nodes are clustered in certain regions. The right lymphatic duct drains lymph from the upper right quadrant of the body and returns fluid to the right subclavian vein. The thoracic duct drains lymph from other regions of the body and returns fluid to the left subclavian vein.

Tiny "dead-end" capillaries of the lymphatic system extend into almost all body tissues (FIG. 44-19). Interstitial fluid enters lymph capillaries, where it becomes lymph. Lymph capillaries join to form larger lymphatics (which you can think of as lymph veins). There are no lymph arteries.

Lymph passes from lymph capillaries into lymphatics, which at certain locations empty into lymph nodes. As lymph

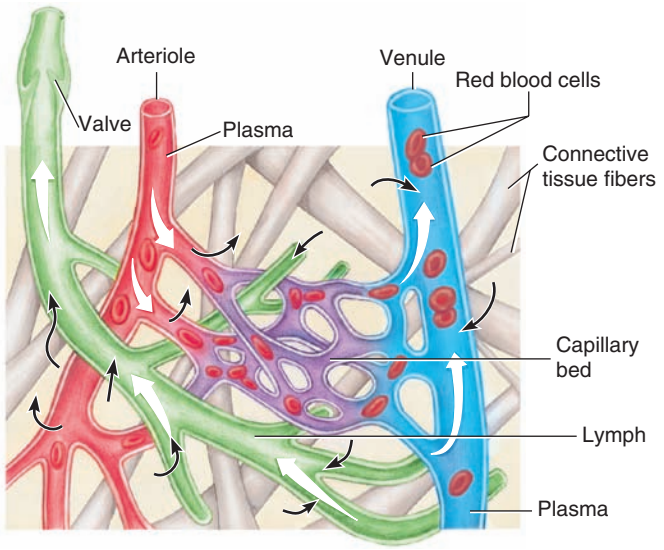

Figure 44-19 Lymph capillaries

Lymph capillaries drain excess interstitial fluid from the tissues. Note that blood capillaries are connected to vessels at both ends, whereas lymph capillaries (*shown in green*) are "dead-end streets." The *white arrows* indicate direction of blood and lymph flow. The *black arrows* indicate direction of interstitial fluid flow.

moves through the lymph nodes, phagocytes filter out bacteria and other harmful materials. The lymph then flows into lymphatics that conduct it away from the lymph node. Lymphatics from all over the body conduct lymph toward the shoulder region. These vessels join the circulatory system at the base of the subclavian veins by way of ducts: the *thoracic duct* on the left side and the *right lymphatic duct* on the right.

Tonsils are masses of lymph tissue under the lining of the oral cavity and throat. (When enlarged, the pharyngeal tonsils in back of the nose are called *adenoids*.) Tonsils help protect the respiratory system from infection by destroying bacteria and other foreign matter that enter the body through the mouth or nose. Unfortunately, tonsils are sometimes overcome by invading bacteria and become the site of frequent infection themselves.

Some vertebrates, such as frogs, have lymph "hearts," which pulsate and squeeze lymph along. However, in mammals the walls of lymphatic vessels themselves pulsate. Valves within the lymphatics prevent lymph from flowing backward. When muscles contract or when arteries pulsate, pressure on the lymphatic vessels increases lymph flow. The rate at which lymph flows is slow and variable. The total lymph flow is about 100 mL per hour, which is far slower than the 5 L per minute of blood flowing in the cardiovascular system.

The lymphatic system plays an important role in fluid homeostasis

When blood enters a capillary network, it is under rather high pressure, so some plasma is forced out of the capillaries into the tissues. Once it leaves the blood vessels, this fluid is called *interstitial fluid*, or tissue fluid. It contains no red blood cells or platelets and only a few white blood cells. Its protein content is about one-fourth that found in plasma because proteins are too large to pass easily through capillary walls. However, smaller molecules dissolved in the plasma do pass out with the fluid leaving the blood vessels. Thus, interstitial fluid contains oxygen, glucose, amino acids and other small nutrients, and a variety of salts. This nourishing fluid bathes all the cells.

Three factors are responsible for *net filtration pressure*, which is the tendency for plasma to leave the blood at the arterial end of a capillary and enter the interstitial fluid (FIG. 44-20). The main force is *hydrostatic pressure*, the blood pressure against the capillary wall. This effect is augmented by the osmotic pressure of the interstitial fluid. The principal opposing force is the osmotic pressure of the blood, which is greater than the osmotic pressure of the interstitial fluid and restrains fluid loss from the capillary.

At the venous ends of the capillaries, the blood hydrostatic pressure is much lower, and the osmotic pressure of the blood draws fluid back into the capillary. However, not as much fluid is absorbed back into the circulation at the venous ends of capillaries as is filtered out at the arterial ends. Furthermore, protein does not return effectively into the venous capillaries and instead tends to accumulate in the interstitial fluid. These potential problems are so serious that without the lymphatic system, fluid balance in the body would be significantly disturbed within a few hours, and death would occur within about 24 hours. The lymphatic system preserves fluid balance by collecting interstitial fluid, including the protein that accumulates in it, and returning it to the circulation.

The walls of the lymph capillaries consist of endothelial cells that overlap slightly. When interstitial fluid accumulates, it presses against these cells, pushing them inward like tiny swinging doors that swing in only one direction. As fluid accumulates within the lymph capillary, these cell doors are pushed closed.

Obstruction of lymphatic vessels causes *lymphedema*, swelling from excessive accumulation of interstitial fluid. Lymphatic vessels can be blocked as a result of injury, inflammation, surgery, or parasitic infection. For example, when a breast is removed (mastectomy) because of cancer, lymph nodes in the armpit are often removed to prevent the spread of cancer cells. The disrupted lymph circulation may cause the patient's arm to swell. Treatment focuses on minimizing the swelling and controlling discomfort and pain.

CHECKPOINT 44.8

- **VISUALIZE** Draw a diagram illustrating the relationships among plasma, interstitial fluid, and lymph.
- How does the lymphatic system help maintain fluid balance?

44.9 Cardiovascular Disease

LEARNING OBJECTIVE

12 Trace the progression of atherosclerosis and describe at least five risk factors for cardiovascular disease.

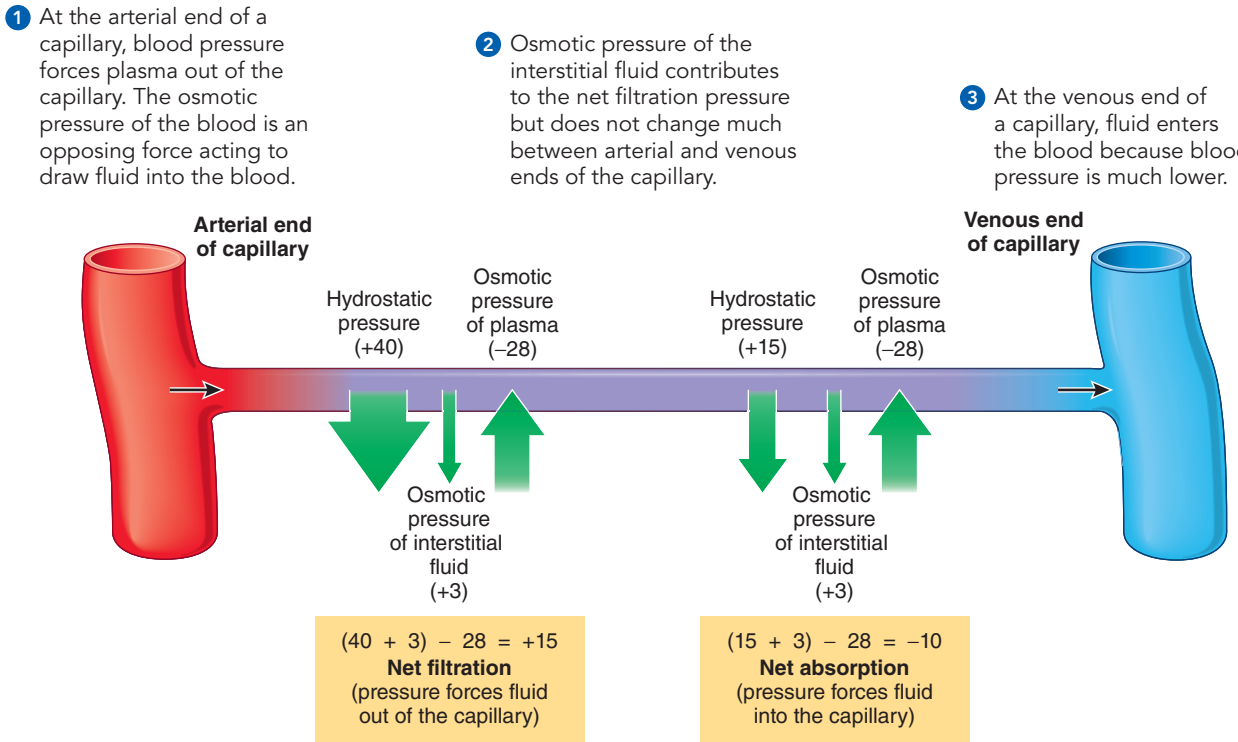

Figure 44-20 Fluid movement between blood and interstitial fluid

The exchange of dissolved materials between blood and interstitial fluid depends on fluid movement between the blood and the interstitial fluid surrounding the capillary. This fluid movement depends on the hydrostatic pressure of the blood and on osmotic pressures. More fluid leaves at the arterial end of each capillary than is returned at the venous end. The lymphatic system collects the excess interstitial fluid and returns it to the blood. The numbers given are hypothetical and represent millimeters of mercury.

Cardiovascular disease includes heart and blood vessel diseases, including cerebrovascular accidents (strokes). Cardiovascular disease is the leading cause of death for both men and women in the United States and in the world. According to the American Heart Association, cardiovascular disease causes more than 800,000 deaths (about 1 in every 3 deaths) each year in the United States. Cardiovascular disease kills more people than all types of cancer combined! Death typically results from a combination of *atherosclerosis, thrombosis* (clotting), and *hypertension* (high blood pressure).

Atherosclerosis develops progressively

Atherosclerosis is a progressive disease in which the walls of certain arteries become damaged and inflamed, and the lumen (opening) becomes narrowed as a result of lipid deposits in their walls. Although it can affect almost any artery, the disease most often develops in the aorta and in the coronary and cerebral arteries. The following sequence of events occurs in the development of atherosclerosis.

1. The earliest events in atherosclerosis begin when excess low-density lipoprotein (LDL) (known as "bad" cholesterol) in the blood enters the inner layer of blood vessels. (LDLs are discussed further in Chapter 47; uptake of LDL by cells is described in Chapter 5 and illustrated in Figure 5-22.) Recall that the inner layer of a blood vessel is made up of endothelial cells; the inner lining is the endothelium. Excess LDLs in the blood vessel wall become oxidized by **free radicals**, highly reactive, toxic compounds with unpaired electrons. (Free radicals bond with other compounds in cells and interfere with normal function.) Oxidized LDLs accumulate between and beneath the endothelial cells.
2. Endothelial cells respond to the oxidized LDLs by releasing compounds that attract monocytes. These white blood cells enter the tissues and trigger an inflammatory response. Monocytes develop into macrophages, which phagocytize the oxidized LDLs. As they become filled with LDLs, the macrophages appear foamy and are called *foam cells*.
3. Large numbers of foam cells lead to the development of fatty streaks, thought to be the initial lesion in the progression of atherosclerosis. (Interestingly, fatty streaks have been identified in the arteries of some children and adolescents.) Cells at the site of inflammation release compounds that trigger underlying smooth muscle fibers to migrate from the muscle layer of the artery and cover the fatty streaks. The smooth muscle fibers settle just below the endothelium of the artery and multiply there. The deposited lipids together with the smooth muscle fibers form the developing *atherosclerotic plaque*. Inflammation, discussed in

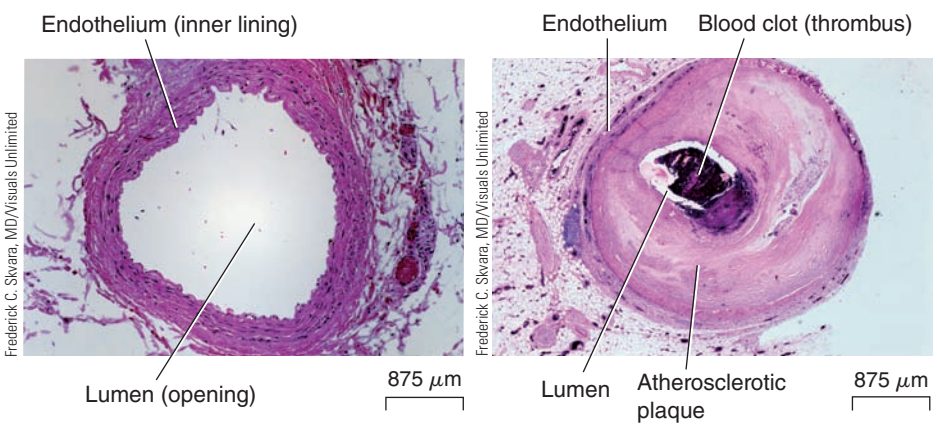
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Chapter 45, is one of the body's most important responses to infection or injury. However, inflammation can also have harmful effects and appears to be an important factor in the development of atherosclerosis.

4. Connective tissue fibers also proliferate and produce collagen, which adds to the plaque. Cells of the immune system migrate to the area and produce substances that maintain chronic inflammation in the inner layer of the arterial wall. Later, calcium may also be deposited in the plaque, hardening the wall of the artery and narrowing it.
5. Smooth muscle fibers form a protective *fibrous cap*, which walls off the plaque from the inner lining of the artery and the blood. Macrophages and other cells eventually die within the plaque, recruiting more macrophages to the area to clean up the debris.

The progression of atherosclerosis can continue for decades without causing symptoms. However, as atherosclerotic plaque builds, arteries eventually lose their ability to stretch when filled with blood. Also, as the walls thicken, the diameter of the artery decreases, and it gradually becomes occluded (blocked), as shown in **FIGURE 44-21**.

Atherosclerosis has many effects



Compared with healthy blood vessels, occluded vessels deliver less blood to the tissues. As a result, tissues become *ischemic*, or lacking in blood, which reduces their oxygen and nutrient supply. In *ischemic heart disease*, the increased need for oxygen during exercise or emotional stress results in the pain characteristic of *angina pectoris*. Nitroglycerin, in the form of pills or a patch, dilates veins, decreasing venous return. Cardiac output is lowered, so the heart is not working as hard and requires less oxygen. Nitroglycerin also dilates the coronary arteries slightly, allowing more blood to reach the heart muscle. *Calcium ion channel blockers* are drugs that slow the heart by inhibiting the passage of Ca^{2+} into cardiac muscle fibers. They also dilate the coronary arteries.

Myocardial infarction (MI), or heart attack, is a very serious, often fatal, consequence of cardiovascular disease. MI is the first symptom of cardiovascular disease for about 65% of men and almost 50% of women affected by atherosclerosis. Myocardial infarction is a leading cause of death and disability in the United States. It often results from a sudden decrease in coronary blood supply. If only a small region of cardiac muscle is affected, the heart may continue to function. Cells in the region deprived of oxygen die and are replaced by scar tissue.

The sudden decrease in blood supply associated with MI often occurs when inflammation causes the fibrous cap over the atherosclerotic plaque to break open. Platelets adhere to the roughened arterial wall and initiate clotting. A *thrombus* is a clot that forms within a blood vessel. A thrombus that migrates to a coronary artery (or develops within a coronary artery) can partially or completely block the flow of blood to part of the heart muscle. When a critical region of cardiac muscle is deprived of its blood supply, the heart may stop beating. This condition, called *cardiac arrest*, can result in death within a few minutes.

An episode of ischemia may trigger a fatal arrhythmia such as *ventricular fibrillation*, a condition in which the ventricles contract very rapidly without actually pumping blood. The pulse may stop, and blood pressure may fall precipitously. Ventricular fibrillation has been linked with 65% to 85% of cardiac arrests. The only effective treatment for fibrillation is *defibrillation* with electric shock. The shock appears to depolarize all the muscle fibers in the heart so that its timing mechanism can reset.

When atherosclerosis develops in the cerebral arteries, less blood is delivered to the brain. This condition can lead to a *cerebrovascular accident (CVA)*, commonly referred to as a *stroke*. Most CVAs are caused by ischemia, typically as a result of thrombosis. Others are caused by uncontrolled hypertension, which can cause blood vessels in the brain to leak or rupture.

(a) Normal coronary artery.

(b) This artery is almost entirely blocked by the atherosclerotic plaque that has built up within its wall. A large blood clot appears to be breaking apart. If the clot (or part of it) enters the circulation, it can block blood vessels, including coronary blood vessels, and lead to a myocardial infarction (MI).

Figure 44-21 Atherosclerosis
LMs of cross sections through two arteries showing changes that take place in atherosclerosis.

Cardiovascular disease can be treated

Current treatment for patients with progressive cardiovascular disease includes certain drugs; surgical procedures aimed at restoring and improving blood flow; and importantly, education regarding lifestyle changes that reduce risk factors. Among the many types of medications prescribed for treating cardiovascular disease are statins, medications that lower cholesterol level; aspirin, which reduces the tendency for blood clotting; beta-blockers, drugs that block the effects of epinephrine (adrenaline); and ACE inhibitors (angiotensin-converting enzyme), drugs that decrease blood pressure. By inhibiting ACE, a key

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

enzyme responsible for the synthesis of angiotensin II, these drugs decrease blood pressure. Angiotensin II is a powerful vasoconstrictor. This hormone also promotes production of aldosterone and increases sodium reabsorption in the kidneys, leading to water retention. (Angiotensin II and aldosterone are discussed further in Chapter 48.) Drugs that inhibit inflammation are also used to treat cardiovascular disease.

Surgical procedures to treat cardiovascular disease include angioplasty and stent placement, and coronary bypass surgery. *Angioplasty* involves inserting a small balloon into an occluded coronary artery. Inflating the balloon breaks up the plaque in the arterial wall and thus widens the vessel. A stent (a mesh tube) left in the artery helps keep the artery open.

In *coronary bypass surgery*, veins from another location in the patient's body are grafted around occluded coronary arteries. The newly positioned blood vessels allow blood to flow around the blocked arteries, restoring adequate blood flow to the affected area.

Future treatment for damaged hearts may include stem cell therapies. Researchers have demonstrated that patients treated with stem cells harvested from their own bone marrow (in addition to standard treatment) had better recoveries than patients who did not receive stem cell treatment.

The risk of cardiovascular disease can be lowered

Many studies have shown that a healthy lifestyle lowers the risk for cardiovascular disease. For example, exercise increases the concentration of HDLs, which protect against heart disease. A balanced diet low in sodium, cholesterol, saturated and *trans* fat, and rich in fruits and vegetables is important.

Several major *modifiable* risk factors for cardiovascular disease have been identified:

1. *Elevated LDL-cholesterol levels in the blood*. These levels are associated with diets rich in total calories, total fats, saturated fats, and cholesterol. Genetic predisposition can also be a factor.
2. *Hypertension*. The higher the blood pressure is, the greater the risk of cardiovascular disease. The hormone angiotensin II, which at abnormally high levels is thought to contribute to hypertension, also stimulates inflammation.
3. *Cigarette smoking*. The risk of developing atherosclerosis is three to six times greater in smokers than in nonsmokers and is directly proportional to the number of cigarettes smoked daily. Nicotine constricts blood vessels, and carbon monoxide in the smoke damages the inner lining of blood vessels. Components of cigarette smoke cause oxidants to form, which may contribute to the inflammation by increasing oxidation of the altered LDL in the arterial wall.
4. *Diabetes mellitus*. In this endocrine disorder, glucose is not metabolized normally. The body shifts to fat metabolism, and there is a marked increase in circulating lipids, leading to atherosclerosis. Impaired glucose tolerance is also a risk factor.
5. *Physical inactivity*. Physical inactivity contributes to more than 35% of the more than 600,000 deaths related to heart disease in the United States each year. Exercise reduces the concentrations of triacylglycerols (triglycerides) and cholesterol in the blood. (These lipids have been associated with heart disease.)
6. *Overweight and obesity*. Being overweight can affect cholesterol levels and increase the risk of hypertension and diabetes.

The risk of developing cardiovascular disease also increases with age. Other probable risk factors currently being studied are hereditary predisposition, hormone levels, stress and behavior patterns, and dietary factors.

CHECKPOINT 44.9

- **PREDICT** Over a period of years, Joe pays little attention to his diet. He eats mainly fried foods. He also smokes cigarettes. What outcome would you predict for Joe?
- **CONNECT** How might inflammation contribute to blocked arteries?

Summary: Focus on Learning Objectives

44.1 Types of Circulatory Systems *(page 937)*

1 Contrast internal transport in animals with no circulatory system, animals with an open circulatory system, and animals with a closed circulatory system.

- Small, simple invertebrates depend on **diffusion** for internal transport. Larger animals require a specialized **circulatory system**, which typically consists of **blood**, a **heart**, and a system of **blood vessels** or spaces through which blood circulates. In all animals, **interstitial fluid**, the tissue fluid between cells, brings oxygen and nutrients into contact with cells.
- Arthropods and most mollusks have an **open circulatory system** in which blood flows into a **hemocoel**, bathing the tissues directly.
- Some invertebrates and all vertebrates have a **closed circulatory system** in which blood flows through a continuous circuit of blood vessels.
- The vertebrate circulatory system consists of a muscular heart that pumps blood into a system of blood vessels. The circulatory system transports nutrients, oxygen, wastes, and hormones; helps maintain fluid balance, appropriate pH, and body temperature; and defends the body against disease.

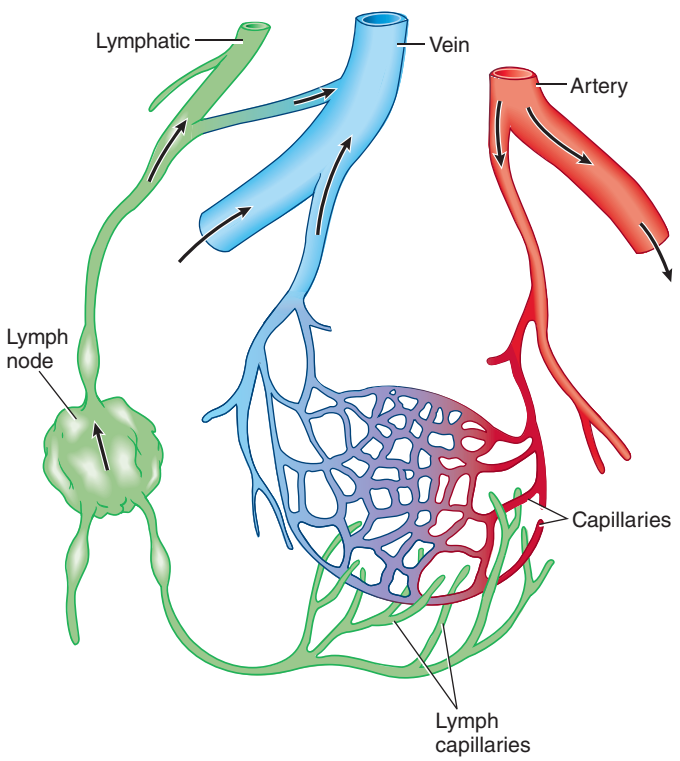
44.2 Vertebrate Blood *(page 939)*

2 Compare the structure and function of plasma, red blood cells, white blood cells, and platelets.

- **Plasma** consists of water, salts, substances in transport, and **plasma proteins**, including albumins, globulins, and fibrinogen.
- **Red blood cells (RBCs)**, also called **erythrocytes**, transport oxygen and carbon dioxide. Red blood cells produce large quantities of **hemoglobin**, a red pigment that transports oxygen.
- **White blood cells (WBCs)**, also called **leukocytes**, defend the body against disease organisms. **Lymphocytes** and **monocytes** are agranular white blood cells; **neutrophils**, **eosinophils**, and **basophils** are granular white blood cells. Monocytes can develop into **macrophages** and **dendritic cells**.
- **Platelets** patch damaged blood vessels and release substances essential for blood clotting.



3 Summarize the sequence of events involved in blood clotting.

- Damaged cells and platelets release substances that activate clotting factors. Prothrombin is converted to *thrombin*, which catalyzes the conversion of *fibrinogen* to an insoluble protein, **fibrin**. Fibrin forms long threads that make up the webbing of the clot.

44.3 Vertebrate Blood Vessels *(page 942)*

4 Compare the structure and function of different types of blood vessels, including arteries, arterioles, capillaries, and veins.

- **Arteries** carry blood away from a heart chamber. **Arterioles** are small arteries that regulate blood pressure by constricting (**vasoconstriction**) and dilating (**vasodilation**). **Capillaries** are the thin-walled exchange vessels through which blood and tissues transfer materials. **Veins** return blood to a heart chamber.

44.4 Evolution of the Vertebrate Circulatory System *(page 944)*

5 Trace the evolution of the vertebrate circulatory system from fish to mammal.

- The vertebrate heart has one or two **atria**, which receive blood, and one or two **ventricles**, which pump blood into the arteries. The fish heart consists of a single atrium and ventricle that are part of a single circuit of blood flow.
- In terrestrial vertebrates, circulatory systems separate oxygen-rich blood from oxygen-poor blood, which allows the higher metabolic rate needed to support an active terrestrial lifestyle. Amphibians have two atria and a single ventricle. Blood flows through a double circuit so that oxygen-rich blood is partly separated from oxygen-poor blood. Most non-avian reptiles have a wall that partly divides the ventricles, minimizing the mixing of oxygen-rich and oxygen-poor blood.
- The four-chambered hearts of birds and mammals separate oxygen-rich blood from oxygen-poor blood.

44.5 The Human Heart *(page 946)*

6 Describe how the structure and function of the human heart are inter-related; include the heart's conduction system in your answer.

- The heart is enclosed by a *pericardium* and has valves that prevent backflow of blood. The valve between the right atrium and ventricle is the *right* **atrioventricular (AV) valve**, or **tricuspid valve**. The valve between the left atrium and ventricle is the **mitral valve**. **Semilunar valves** guard the exits from the heart. Cardiac muscle fibers are joined by **intercalated discs**.
- The **pacemaker** in the **sinoatrial (SA) node** initiates each heartbeat. A specialized electrical conduction system coordinates heartbeats.

7 Trace the events of the cardiac cycle and relate normal heart sounds to these events.

- One complete heartbeat makes up a **cardiac cycle**. The period of contraction is called **systole**. The period of relaxation is **diastole**. At the beginning of ventricular systole, the closing of the AV valves makes a low-pitched "lub" sound. At the beginning of ventricular diastole, the closing of the semilunar valves makes a short, loud "dup" sound.

8 Define *cardiac output*, describe how it is regulated, and identify factors that affect it.

- **Cardiac output (CO)** equals **stroke volume** multiplied by heart rate. Stroke volume depends on *venous return* and on neural messages and hormones, especially epinephrine and norepinephrine. According to *Starling's law of the heart*, the more blood delivered to the heart by the veins, the more blood the heart pumps.
- Heart rate is regulated mainly by the nervous system and is influenced by hormones and body temperature.

44.6 Blood Pressure *(page 950)*

9 Identify factors that determine and regulate blood pressure and compare blood pressure in different types of blood vessels.

- **Blood pressure** is the force blood exerts against the inner walls of the blood vessel. Blood pressure is greatest in the arteries and decreases as blood flows through the capillaries.
- Blood pressure depends on cardiac output, blood volume, and resistance to blood flow. *Peripheral resistance* is the resistance to blood flow caused by blood viscosity and by friction between blood and the blood vessel wall.

Copyright 2019 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

- **Baroreceptors** are sensitive to blood pressure changes. They send messages to the cardiac and vasomotor centers in the medulla of the brain. When informed of an increase in blood pressure, the cardiac center stimulates parasympathetic nerves that slow the heart rate. The vasomotor center inhibits sympathetic nerves that constrict blood vessels. These actions reduce blood pressure.
- **Angiotensin II** is a hormone that raises blood pressure. **Aldosterone** helps regulate salt excretion, which affects blood volume and blood pressure.

44.7 The Pattern of Circulation *(page 953)*

10 Trace a drop of blood through the pulmonary and systemic circulations, naming in sequence each structure through which it passes.

- The **pulmonary circulation** connects the heart and the lungs; the **systemic circulation** connects the heart and the tissues. In the pulmonary circulation, the right ventricle pumps blood into the *pulmonary arteries*, which go to the lungs. Blood circulates through pulmonary capillaries in the lung and then is conducted to the left atrium by a *pulmonary vein*.
- In the systemic circulation, the left ventricle pumps blood into the **aorta**, which branches into arteries leading to the body organs. After flowing through capillary networks within various organs, blood flows into veins that conduct it to the **superior vena cava** or **inferior vena cava**. These large veins return blood to the right atrium.
- The **coronary circulation** supplies the heart muscle with blood. The **hepatic portal system** circulates nutrient-rich blood through the liver.

44.8 The Lymphatic System *(page 955)*

11 Describe the inter-relationship between the structures and functions of the lymphatic system.

- The **lymphatic system** helps maintain homeostasis of fluids by collecting interstitial fluid and returning it to the blood. The structure of the walls of *lymphatic vessels* allows them to collect excess interstitial fluid. **Lymph** is the clear fluid formed from interstitial fluid.
- Lymphatic vessels conduct lymph to the blood. **Lymph nodes** are small masses of tissue that filter bacteria and harmful materials out of lymph.

44.9 Cardiovascular Disease *(page 956)*

12 Trace the progression of atherosclerosis and describe at least five risk factors for cardiovascular disease.

- **Atherosclerosis** progresses as the inner walls of certain arteries become inflamed and the lumen of the artery becomes blocked by the accumulation of fatty deposits and cells that mediate inflammation. The blood supply of tissues served by these vessels becomes increasingly compromised.
- Risk factors include elevated LDL-cholesterol levels in the blood, hypertension, cigarette smoking, diabetes mellitus, physical inactivity, and being overweight.

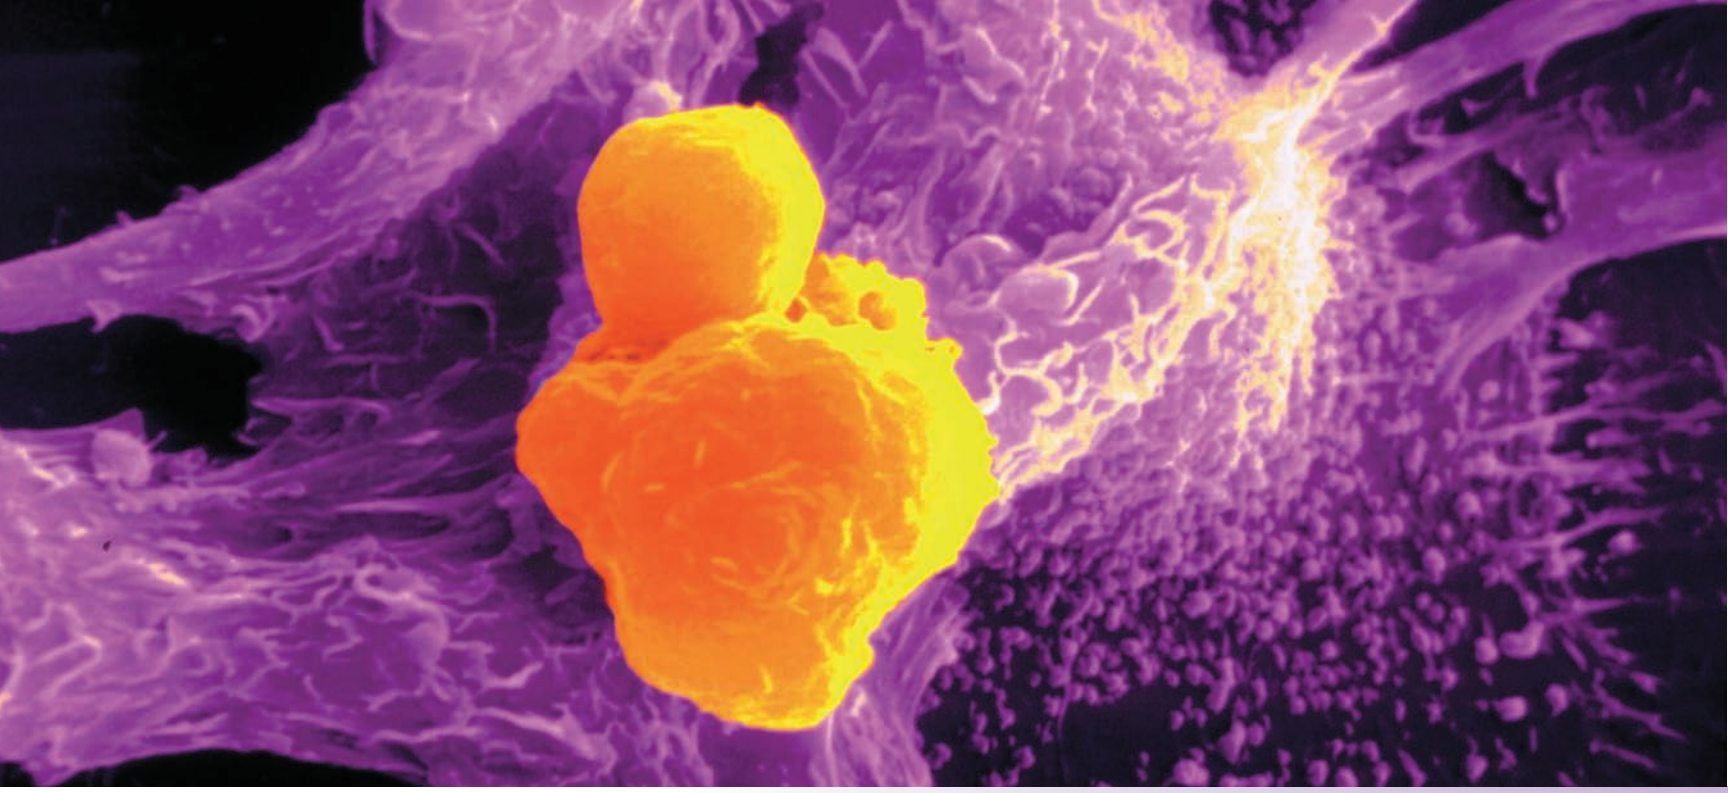
Test Your Understanding

Know and Comprehend

1. Which of the following are most closely associated with oxygen transport? (a) red blood cells (b) platelets (c) neutrophils (d) basophils (e) lymphocytes
2. The sinoatrial (SA) node (a) initiates diastole (b) conducts impulses directly to the muscle fibers of both ventricles (c) briefly delays transmission before the action potential continues into the ventricles (d) transmits action potentials directly into the atrial muscle fibers (e) consists of smooth muscle fibers
3. A cardiac cycle (a) consists of one ventricular heartbeat (b) includes a systole (c) equals stroke volume multiplied by heart rate (d) includes a diastole (e) includes a systole and a diastole
4. Blood pressure can be significantly affected by (a) cardiac output (b) peripheral resistance (c) blood volume (d) a, b, and c (e) a and b only
5. Lymph forms from (a) fluid in the lymph nodes (b) blood serum (c) plasma combined with protein (d) fluid released by lymph nodes (e) interstitial fluid
6. Norepinephrine (a) slows heart rate (b) is released in cardiac muscle by parasympathetic nerves (c) causes K^+ channels in cardiac muscle to open (d) decreases stroke volume (e) causes Ca^{2+} channels in cardiac muscle to open
7. Baroreceptors (a) stimulate renin release (b) activate the renin–angiotensin–aldosterone pathway (c) stimulate sympathetic nerves (d) are stimulated by increased blood pressure (e) send messages to cardiac centers that increase blood pressure

Apply and Analyze

8. Which sequence below describes an accurate sequence of blood flow? 1. pulmonary artery 2. pulmonary vein 3. left atrium 4. right atrium 5. pulmonary capillaries (a) 2, 1, 4, 3 (b) 3, 4, 2, 5 (c) 1, 5, 2, 3 (d) 4, 1, 5, 2 (e) 1, 5, 2, 4
9. **VISUALIZE** Draw a simple cross section of a vein, a capillary, and an artery. Label connective tissue, endothelium, and smooth muscle, if present. How does the structure of each of these vessels relate to its function?
10. When the nerves to the heart are cut, the heart rate increases to about 100 contractions per minute. What does this increase indicate about regulation of the heart rate?



Evaluate and Synthesize

11. **EVOLUTION LINK** A heart divided into four chambers independently evolved in birds and mammals. What are the benefits of this adaptation?
12. **EVOLUTION LINK** How is the heart of a fish specifically adapted to its lifestyle?
13. **SCIENCE, TECHNOLOGY, AND SOCIETY** Explain the association between atherosclerosis and ischemic heart disease. Imagine that you were the Surgeon General of the United States. What types of programs would you advocate to decrease heart disease? Do you think that as a society we should invest resources into the development of stem cell therapies for more effective treatment of myocardial infarction?

45 The Immune System: Internal Defense

KEY CONCEPTS

45.1 The immune system recognizes and destroys foreign macromolecules, including those associated with pathogens, and abnormal cells (such as cancer cells).

45.2 Innate immunity provides general and immediate protection against pathogens, some toxins, and cancer cells.

45.3 Adaptive immunity includes cell-mediated immunity and antibody-mediated immunity.

45.4 In cell-mediated immunity, specific lymphocytes called T cells are activated; they release proteins that destroy cells infected with viruses or other intracellular pathogens.

45.5 In antibody-mediated immunity, specific lymphocytes called B cells are activated; they multiply and differentiate into plasma cells, which produce antibodies.

45.6 Cancer and some other diseases and disease-causing organisms—for example, HIV (the virus that causes AIDS)—compromise or overcome the immune system. Some immune responses, such as allergic responses, have negative effects on health.

PHOTO: Immune response to cancer cells. This color-enhanced SEM shows a macrophage (*purple*) engulfing a cancer cell (*yellow*).
Microworks/Medical Images

The **immune system**, our internal defense system, is made up of the molecules and cells that protect the body against foreign macromolecules, including disease-causing organisms, certain toxins, and cancer cells. Derived from the Latin for "safe," the word *immune* refers to the early observation that when people recovered from smallpox and other serious infections, they were safe from contracting the same illness again.

Disease-causing organisms, called **pathogens**, include certain viruses, bacteria, fungi, protozoa, and worms. Pathogens enter the body with air, food, and water; during copulation; and through open wounds in the skin. The immune system recognizes pathogens and many types of toxins and rapidly responds to eliminate them. For example, *macrophages* act quickly to destroy invading bacteria. Macrophages and other cells of the immune system also destroy cancer cells (see photograph).

The immune system normally functions very effectively. However, some pathogens, and also cancer cells, sometimes evade or overcome the body's internal defenses, resulting in disease. Certain genetic mutations and some pathogens can prevent or compromise immune function. For example, HIV, the retrovirus that causes AIDS, destroys T cells, an important component of the immune system. At times, the immune system over-reacts, as in allergic reactions. At other times, immune responses are directed against our own tissues, resulting in *autoimmune disease* such as rheumatoid arthritis, ulcerative colitis, or multiple sclerosis. The immune system sometimes attacks when we would prefer it did not. For example, immune responses can destroy the cells of heart or kidney transplants.

Immunology, the study of internal defense systems of humans and other animals, is one of the most rapidly changing and exciting fields of biomedical research. The immune system is a collection of many types of cells and tissues scattered throughout the body. Effective cell signaling among these cells is critical. Cells of the immune system communicate

directly by means of their surface molecules and indirectly by releasing messenger molecules. Understanding the complex signaling systems of the immune system is a major focus of research. Investigators are also working to better understand the evolution of the immune system and how the immune system interacts with the microbiome.

One of the greatest accomplishments of immunologists has been the development of vaccines that prevent disease. Another has been developing techniques for successful tissue and organ transplantation. Sophisticated research strategies, such as gene transfer, have enabled immunologists to expand their knowledge of the cells and molecules that interact to generate immune responses. These techniques have led to the development of new approaches to the prevention and treatment of disease. Much has been learned, and many challenges lie ahead.

45.1 Evolution of Immune Responses

LEARNING OBJECTIVES

1. Distinguish between innate and adaptive immunity.
2. Compare, in general terms, the immune responses that have evolved in invertebrates and vertebrates.

Immunity is the ability to recognize and destroy foreign or dangerous macromolecules. The immune system distinguishes between *self* and *nonself*. Such recognition is possible because each individual is biochemically unique. Cells have surface proteins different from those on the cells of other species or even other individuals of the same species. An animal's immune system recognizes its own cells and can identify those of other organisms as foreign. The distinctive macromolecules of an invading pathogen stimulate the animal's defensive responses. For example, a single bacterium may have from 10 to more than 1000 distinctive macromolecules on its surface that an animal may recognize as foreign. The immune system also responds to danger signals from injured tissues, such as proteins released when cell membranes are damaged.

Two main types of immunity protect the body: innate and adaptive immunity (FIG. 45-1). **Innate immunity** consists of defenses that provide immediate, general protection against pathogens, parasites, some toxins and drugs, and cancer cells. Innate immune responses prevent most pathogens from entering the body and rapidly destroy those that do penetrate the outer defenses. For example, the cuticle or skin provides a physical barrier to pathogens that come in contact with an animal's body. *Phagocytosis* and *inflammation* are innate defenses that destroy bacteria when they manage to penetrate the outer defenses.

Adaptive immunity, also called **acquired immunity**, consists of specific defenses that target distinct macromolecules. Any molecule that cells of the immune system specifically recognize as foreign is called an **antigen**. Proteins are the most powerful antigens, but some polysaccharides and lipids are also antigenic. Adaptive immune responses are directed toward particular antigens. These responses typically include the production of **antibodies**, highly specific proteins that recognize and bind to specific antigens. An important characteristic of adaptive immune responses is **immunological memory**, which means that the adaptive immune system "remembers" foreign or dangerous molecules. Immunological memory enables the body to respond more effectively to repeated encounters with the same molecules.

Immunologists do not yet understand how the immune system is signaled to *not* destroy foreign molecules that are harmless. Animals *manage* and are managed by their **microbiome**, which includes beneficial bacteria, archaea, and fungi that live on and in the body, including on the skin surface and in the digestive tract (see Chapters 25 and 47).

Invertebrates launch innate immune responses

An animal's first line of defense is its outer covering. Tough external skeletons, such as cuticles, shells, or chitinous exoskeletons, shield the bodies of nematodes, most mollusks, arthropods, and many other invertebrates (see Chapter 31). Cells in the outer layer of many invertebrates (cnidarians, annelids, and mollusks) produce mucus that traps and kills pathogens.

Recognition of nonself depends on **pattern recognition receptors (PRRs)** in the plasma membrane. PRRs, such as *Toll receptors* in *Drosophila*, recognize certain chemical compounds (or specific parts of compounds) on the surface of bacteria and other microbes as foreign. The chemical compounds that stimulate innate immune responses are called **pathogen-associated molecular patterns**, or **PAMPs**. Each group of microbes—viruses, gram-positive bacteria, and fungi—share certain PAMPs. For example, certain viruses have double-stranded RNA, and gram-positive bacteria have peptidoglycan.

All animal species studied have *phagocytes*, cells that move through the body engulfing and destroying bacteria and other foreign matter. When PRRs on phagocytes bind with PAMPs, innate immune responses are activated. For example, phagocytes then become more effective at destroying pathogens. These receptors may also transduce signals that stimulate inflammation.

Inflammation, also referred to as the *inflammatory response*, is one of the body's key responses to injury or infection in both invertebrates and vertebrates. During inflammation the body recruits white blood cells and plasma proteins from the blood to the location of an infection. *Phagocytosis* increases at the site of inflammation. Recall that **phagocytosis** is the process by which cells engulf microorganisms, foreign matter, or other cells (see Fig. 5-20). In mollusks, substances in the hemolymph (blood) enhance phagocytosis. Annelids are the only invertebrates known to have *natural killer cells*, a type of lymphocyte that destroys tumor cells and cells infected by viruses.

Invertebrates distinguish between their own cells and those of other species. For example, sponge cells have specific glycoproteins on their surfaces that enable them to recognize their own species. When cells of two different species are mixed, they sort themselves out according to species. When two different species of sponges are forced to grow in contact with each other, tissue is destroyed along the region of contact. Cnidarians (e.g., corals), annelids (e.g., earthworms), arthropods (e.g., insects), and echinoderms (e.g., sea stars) reject tissue grafted from other animals, even from the same species.

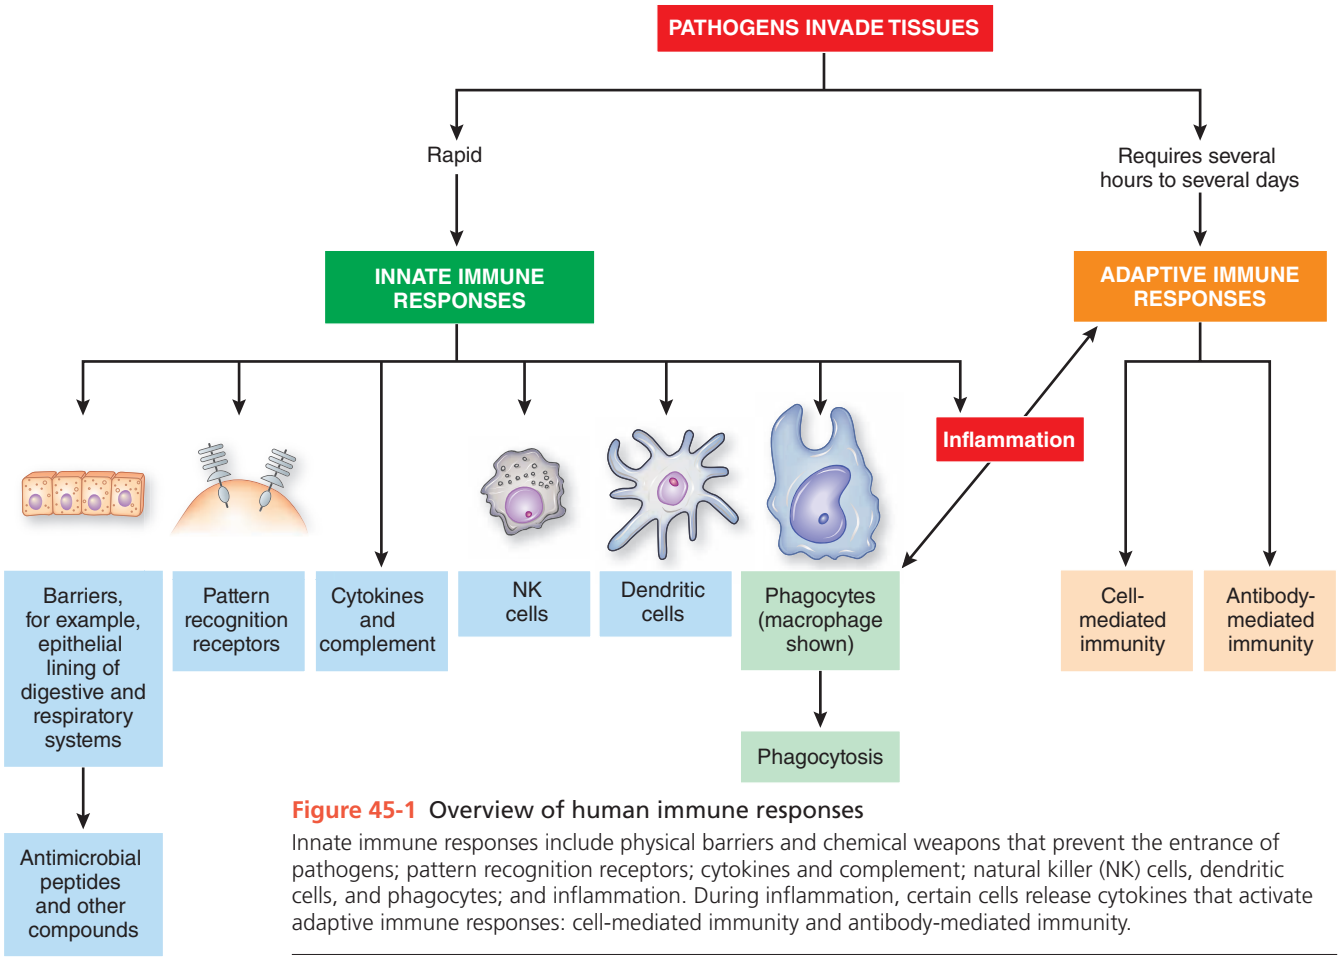

Figure 45-1 Overview of human immune responses

Innate immune responses include physical barriers and chemical weapons that prevent the entrance of pathogens; pattern recognition receptors; cytokines and complement; natural killer (NK) cells, dendritic cells, and phagocytes; and inflammation. During inflammation, certain cells release cytokines that activate adaptive immune responses: cell-mediated immunity and antibody-mediated immunity.

Pattern recognition receptors activate signal transduction pathways that lead to the production of **antimicrobial peptides**. These compounds inactivate or kill pathogens. Investigators have identified antimicrobial peptides in all eukaryotes (animals, plants, fungi) and prokaryotes (bacteria and archaea) that have been studied, suggesting an early common origin of these molecules. More than 2800 antimicrobial peptides have been described. When researchers inject an antigen into an insect, as many as 15 different antimicrobial peptides are produced within a few hours. These chemical compounds are very effective in part because of their small size (a dozen or fewer amino acids), which facilitates their rapid production and diffusion. Some antimicrobial peptides, called **defensins**, kill bacteria and fungi by punching holes in the plasma membrane. Defensins have been found in many types of animals and in some plants.

Certain cnidarians, arthropods, some echinoderms, and simple chordates (e.g., tunicates) appear to remember antigens for a short period. As mentioned earlier, immunological memory enables the body to respond more effectively when it encounters the same pathogens again. Researchers have discovered that shrimp are able to launch an adaptive immune response, called "specific immune priming." During this response, phagocytic activity increased after the animals were vaccinated with a specific pathogen. Although certain invertebrates demonstrate some specificity and memory, their immune responses are primarily innate responses.

Echinoderms and tunicates are the only invertebrates known to have differentiated white blood cells that perform limited immune functions. Investigators have identified two genes in the purple sea urchin that are very similar to vertebrate genes important in producing antibodies. Some invertebrates appear to have at least a limited capacity to launch adaptive immune responses.

Vertebrates launch both innate and adaptive immune responses

Like invertebrates, vertebrates depend on innate immunity for their initial defense against invading pathogens. However, their more recently evolved adaptive immune responses fine-tune the more general innate responses.

The lymphatic system that evolved in jawed vertebrates includes cells such as **lymphocytes**, white blood cells specialized to carry out immune responses, and organs such as lymph nodes (see Chapter 44). Very specific lymphocytes and antibodies are produced when the body is exposed to specific pathogens. Once exposed to foreign molecules, the adaptive immune system remembers them. In the discussion that follows, we focus on the vertebrate immune system.

CHECKPOINT 45.1

- What are two ways in which adaptive immunity differs from innate immunity?
- **CONNECT** In general, how are vertebrate immune responses similar to invertebrate responses? How are they different?

45.2 Innate Immune Responses in Vertebrates

LEARNING OBJECTIVE

3 Describe innate immune responses, including physical barriers; recognition by pattern recognition receptors; actions of phagocytes and other cells; actions of cytokines and complement; and the inflammatory response.

Innate immune responses include physical barriers, such as the skin; action by pattern recognition receptors; action of proteins such as *cytokines* and proteins that make up the *complement system*; actions by specialized cells, including phagocytes, dendritic cells, and natural killer (NK) cells; and the inflammatory response.

Physical barriers and chemical weapons stop most pathogens

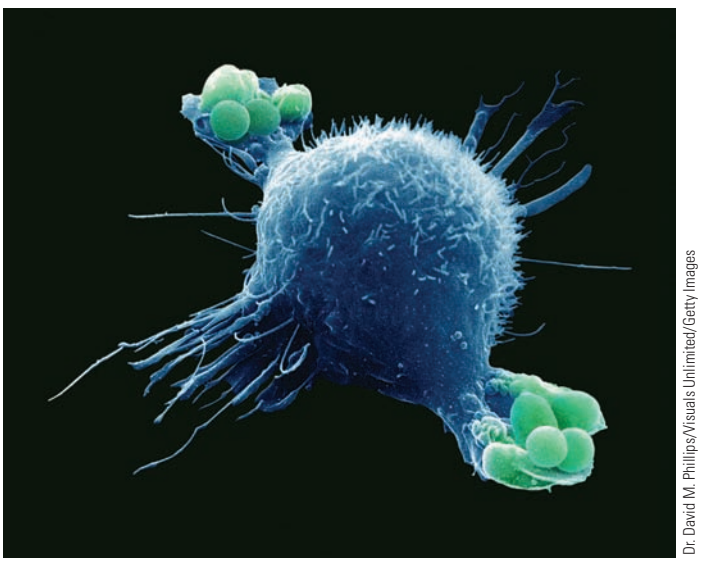
A vertebrate's first line of defense is its skin, which blocks the entry of pathogens. In some species the skin is covered by horny scales or plates. The digestive (gastrointestinal) tract, respiratory passageways, urinary tract, and reproductive tracts all open to the outside of the body. The epithelial linings of these passageways are barriers between the outside environment and the inside of the body. Various mechanisms within epithelial barriers expel, trap, or destroy pathogens. For example, pathogens that enter the body with inhaled air may be filtered out by hairs in the nose or trapped in the sticky mucous lining of the respiratory tract. Once trapped, they are destroyed by phagocytes.

Physical barriers are equipped with chemical weapons. For example, the epithelium of the skin and of the digestive tract produces defensins. These antimicrobial peptides are present in the saliva of mammals and many other types of animals. Mucus contains a substance called *mucin*, which chemically destroys invaders. **Lysozyme**, an enzyme found in tears and other body fluids, attacks the cell walls of many gram-positive bacteria.

Mucus, tears, urine, and other body fluids flush pathogens out of the body. Invading bacteria must also compete with the populations of microbes that make up the microbiome. These resident microbes are normally not harmful and are essential to good health.

Blood clotting products aid the immune system by increasing vascular permeability and producing agents that help phagocytes. Some proteins produced during clotting can lyse invading gram-positive bacteria.

Pattern recognition receptors called **Toll-like receptors** are expressed on several types of cells. (Toll-like receptors are homologous to the Toll receptors in *Drosophila*.) When activated, these receptors activate transcription factors that stimulate the expression of genes encoding important signaling molecules (e.g., cytokines).



Cells of the innate immune system destroy pathogens

Innate immune responses depend on the action of several types of cells, including phagocytes, natural killer cells, and dendritic cells. **Neutrophils**, the most common type of white blood cell (see Chapter 44), and *macrophages* are the main phagocytes in the body. A neutrophil can phagocytose about 20 bacteria before it becomes inactivated (perhaps by leaking lysosomal enzymes) and dies.

Macrophages are large phagocytes that develop from *monocytes*, a type of nongranular white blood cell. A macrophage can phagocytose about 100 bacteria during its life span (FIG. 45-2). Macrophages also release antiviral agents. Some macrophages patrol the body's tissues, engulfing damaged cells or foreign matter (including bacteria). Other macrophages stay in one place and destroy bacteria that pass by. For example, air sacs in the lungs contain large numbers of macrophages that destroy foreign matter entering with inhaled air.

Vertebrate macrophages have Toll-like receptors that recognize certain PAMPs and respond by producing cytokines. For example, a lipopolysaccharide found on gram-negative bacteria stimulates macrophages. In response, macrophages release cytokines that enhance the inflammatory response.

Can bacteria evade or counteract the phagocyte's attack? Many strategies have evolved in bacteria that protect them from their hosts. For example, the capsules of *Streptococcus pneumoniae* resist the actions of the phagocyte's lysosomal enzymes. Other bacteria

release enzymes that destroy lysosomal membranes. The powerful lysosomal enzymes then spill out into the cytoplasm and may destroy the phagocyte. Bacteria and fungi may also form biofilms (see Chapters 6 and 25), which shield them from the immune cells and proteins. Individuals diagnosed with cystic fibrosis often develop chronic bacterial infections located within biofilms in the patients' respiratory systems.

Natural killer (NK) cells are large, granular lymphocytes that originate in the bone marrow. They account for about 10% of circulating lymphocytes. NK cells are active against tumor cells and cells infected with some types of viruses. They destroy target cells by both innate and adaptive (antibody-mediated) processes.

NK cells release cytokines as well as enzymes that destroy target cells. Some of these enzymes cause pores to form in the plasma membrane of the target cell. Other enzymes enter the cell and activate reactions that cause the cell to self-destruct by **apoptosis**, programmed cell death. Several cytokines stimulate NK cell activity. When NK cell levels are high, resistance to certain cancers may be strengthened. Psychological stressors may decrease NK cell activity and thus enhance tumor growth.

Biologists first identified **dendritic cells** in 1868 and then rediscovered them in 1973, but the small numbers of these cells made them hard to study until sophisticated techniques became available in the 1990s. Their name derives from their long cytoplasmic extensions called *dendrites* (not to be confused with the dendrites of neurons). Dendritic cells develop from precursor cells in the bone marrow and from monocytes.

Dendritic cells are strategically stationed in all tissues of the body that come into contact with the environment: the skin and the epithelial linings of the digestive, respiratory, urinary, and vaginal passageways. When pathogens infect a tissue, PAMPs activate dendritic cells. One type of dendritic cell responds to viral infection. Dendritic cells produce *interferons*, cytokines that are antiviral. Certain types of activated dendritic cells capture microbial antigens by phagocytosis or by receptor-mediated endocytosis (see Chapter 5).

Cytokines are important signaling molecules

Cells of the immune system secrete a remarkable number of regulatory and antimicrobial peptides and proteins. Two major groups of molecules that are critical in innate defense responses are cytokines and complement. **Cytokines** are a large, diverse group of peptides and proteins (most are glycoproteins) that serve as important signaling molecules and perform regulatory functions. The same kinds of cytokines can be produced by many different types of cells. Also, a cytokine may affect many different kinds of cells. Just as the functions of innate and adaptive immune responses overlap, the actions of cytokines of these subsystems also overlap. For example, cytokines produced by cells such as macrophages can activate lymphocytes involved in adaptive immune responses.

Cytokines help regulate the intensity and duration of immune responses. They are also important in regulating many other biological processes, such as cell growth, repair, and cell activation. Cytokines bind to specific membrane receptors on target cells. These signaling molecules can act as *autocrine agents*, affecting the very cells that produce them, or as *paracrine agents*, regulating the activity of nearby cells (see Chapter 49). When produced in large amounts, some cytokines act as hormones that circulate in the blood and affect distant tissues. Biologists name the types of cytokines for their function or origin. We discuss several examples, including *interferons*, *tumor necrosis factors*, *interleukins*, and *chemokines*.

When infected by viruses or other intracellular parasites (some types of bacteria, fungi, and protozoa), certain cells respond by secreting cytokines called **interferons**. *Type I interferons* are produced by either macrophages or *fibroblasts*, cells that produce the fibers of connective tissues. Type I interferons inhibit viral replication and activate NK cells that have antiviral actions. Viruses produced in cells exposed to Type I interferons are not very effective at infecting other cells. Interestingly, even though Type I interferons are produced as part of the innate immune response, once released they can regulate the action of certain cells of the adaptive immune response. This interaction of innate and adaptive immune mechanisms is an example of the power and complexity of the immune system.

Type II interferon (also called IFN-gamma) is critical in both innate and adaptive immunity. In innate immunity Type II interferon stimulates macrophages to destroy tumor cells and host cells that have been infected by viruses. (The interferon activates transcription of genes that encode enzymes needed to produce antimicrobial compounds in lysosomes.)

Since their discovery in 1957, interferons have been the focus of a great deal of research. Pharmaceutical companies now use recombinant DNA techniques to produce large quantities of some interferons. The U.S. Food and Drug Administration has approved interferons for treating several diseases, including hepatitis B and hepatitis C, genital warts, several types of cancer (e.g., leukemia), a type of multiple sclerosis, and AIDS-related Kaposi's sarcoma.

In response to gram-negative bacteria, certain other pathogens, or some tumors, **tumor necrosis factor (TNF)** stimulates immune cells to initiate an inflammatory response. In fact, TNF was so named because it was first identified as a compound that destroyed tumor cells. TNF is secreted mainly by macrophages and by *T cells*, a type of lymphocyte. In severe infections, large amounts of TNF are produced. TNF is then circulated in the blood and can have widespread effects. For example, it acts on the hypothalamus, inducing fever.

Sometimes infection by gram-negative bacteria, such as *Salmonella typhi*, results in the release of large amounts of TNF and other cytokines. The result is a cascade of reactions leading to *septic shock*, a potentially fatal condition that may involve high fever and malfunction of the circulatory system. Thus, cytokines can sometimes have harmful effects.

Interleukins are a diverse group of cytokines secreted mainly by macrophages and lymphocytes. Interleukins are numbered according to their order of discovery. They regulate interactions between white blood cells, such as lymphocytes and macrophages, and other cells. *Interleukin-1 (IL-1)* functions with TNF in mediating inflammation. *Interleukin-12 (IL-12)* stimulates NK cells as well as T cells to produce IFN-gamma. Some interleukins have widespread effects. During infection, IL-1 can reset the body's thermostat in the

Key Point

During the inflammatory response, capillaries dilate and become more permeable, bringing more phagocytes to the infected area; phagocytosis increases.

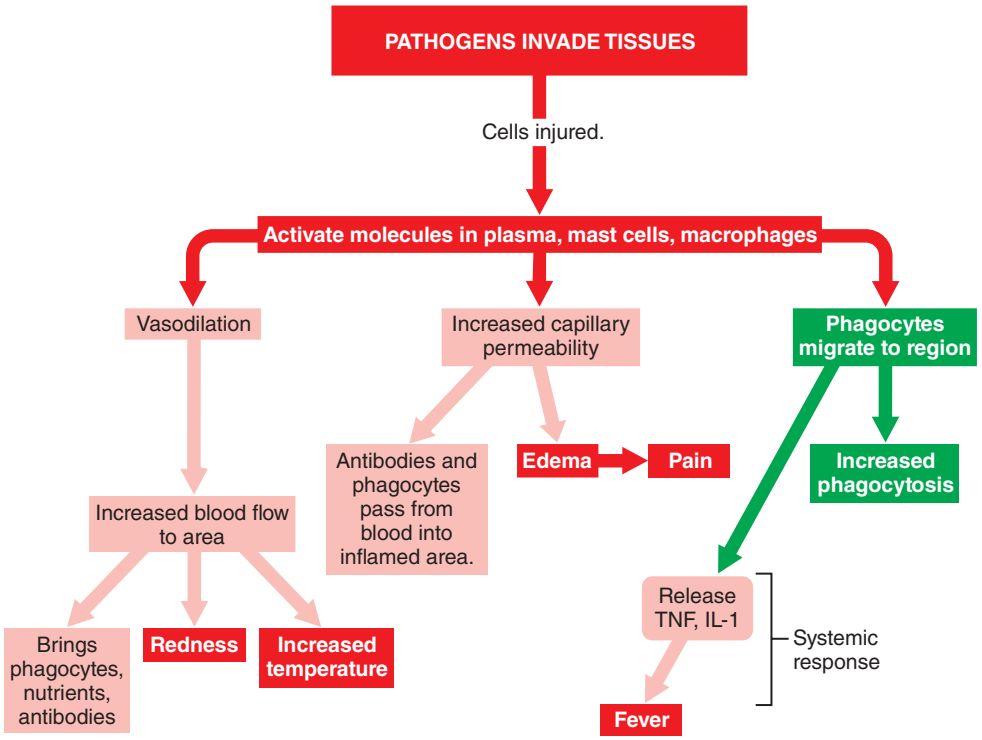

Figure 45-3 Overview of the inflammatory response

When skin is injured, bacteria (and other pathogens) enter the tissues. Tissue injury activates a clotting factor in the blood that turns on three molecular pathways in the plasma. Some of the molecules produced dilate blood vessels and increase capillary permeability.

PREDICT If left untreated, how might your foot look and feel the day after stepping on a nail?

hypothalamus, resulting in fever and its symptoms. The overproduction of certain interleukins has been associated with clinical disease, including atherosclerosis.

Chemokines, a large group of cytokines, are signaling molecules that attract, activate, and direct the movement of various cells of the immune system. For example, they regulate the migration of white blood cells from the blood to the tissues. Some chemokines are produced in response to infection and are mediators of the inflammatory response.

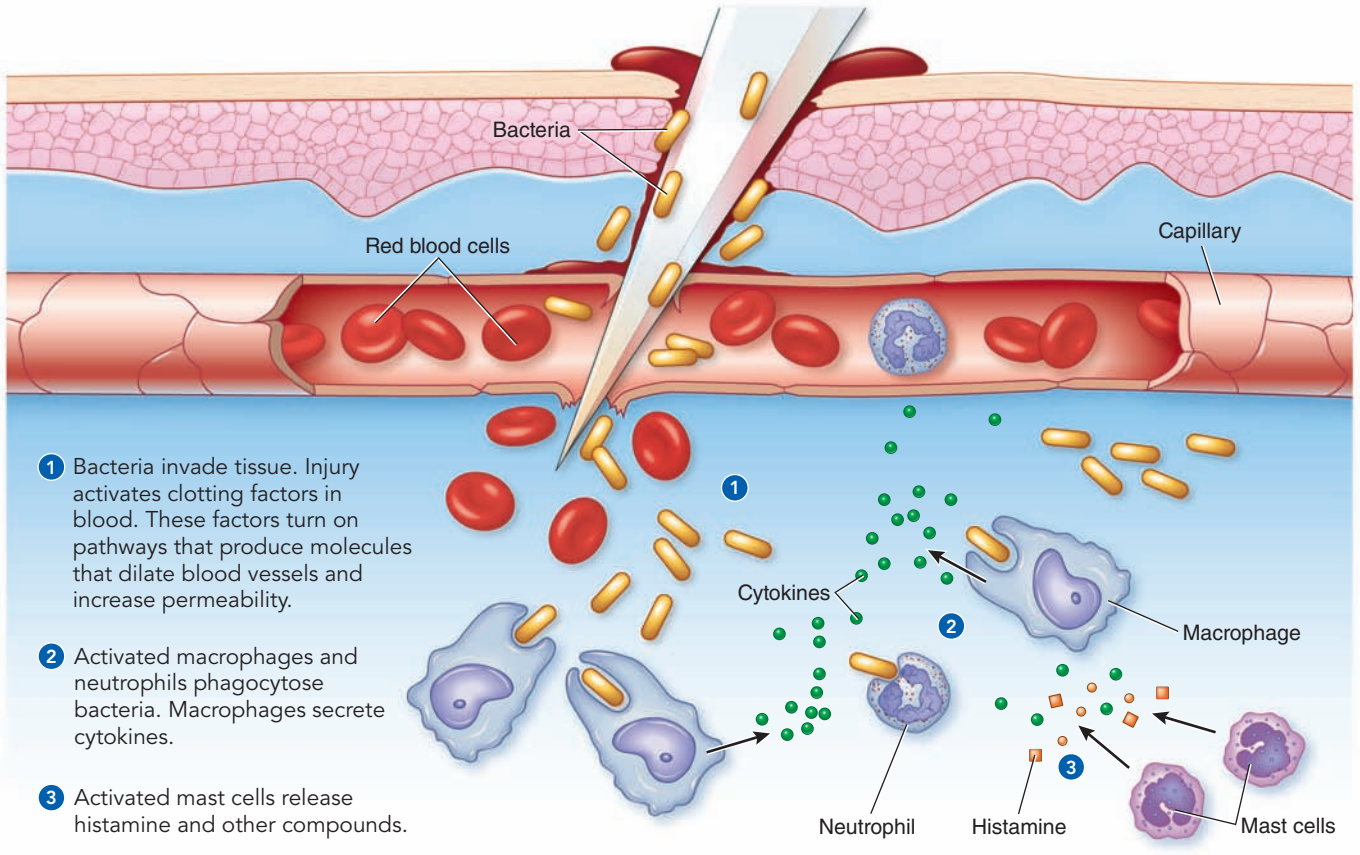
Complement promotes destruction of pathogens and enhances inflammation

Phagocytes secrete cytokines that activate the *complement system*. **Complement**, so named because it "complements" the action of other defensive responses, consists of more than 20 proteins present in plasma and other body fluids. Similarities in complement proteins in many species, including horseshoe crabs, sea urchins, tunicates, and mammals, suggest that these molecules evolved millions of years ago and have been highly conserved.

Normally, complement proteins are inactive until the body is exposed to an antigen. Certain pathogens activate the complement system directly. In other cases, the binding of an antigen and antibody stimulates activation. Complement activation involves a cascade of reactions; each component acts on the next in the series. Proteins of the complement system then work to destroy pathogens.

Complement proteins are active against many antigens, and their actions are not specific: they (1) lyse viruses, bacteria, and other cells; (2) coat pathogens, making them less "slippery" so that macrophages and neutrophils phagocytose them more easily; (3) attract white blood cells to the site of infection, a process called *chemotaxis*; and (4) bind to specific receptors on cells of the immune system, stimulating specific actions, such as secreting regulatory molecules and enhancing the inflammatory response.

Inflammation is a protective response



The **inflammatory response**, or *inflammation*, is one of the body's key responses to infection or injury. Tissue injury caused by pathogen invasion or physical injury activates a clotting factor in the blood plasma that turns on three different interconnecting molecular cascades in the plasma, including the clotting cascade. Many of these reactions generate molecules—for example, the peptide *bradykinin*—that mediate the inflammatory process. These plasma mediators dilate blood vessels and increase capillary permeability (FIGS. 45-3 and 45-4). Many cytokines signal white blood cells to launch the inflammatory response, and some cytokines help regulate the process. Inflammation also activates the complement system. The clinical characteristics of inflammation are heat, redness, edema (swelling), and pain.

The inflammatory response includes three main processes.

1. *Vasodilation*. Macrophages and **mast cells** stationed in the tissues respond rapidly to damaged tissue or infection. Mast cells, which are found in most tissues close to blood vessels, release **histamine**, cytokines, and other compounds that dilate blood vessels in the affected area. Expanded blood vessel diameter brings more blood to the

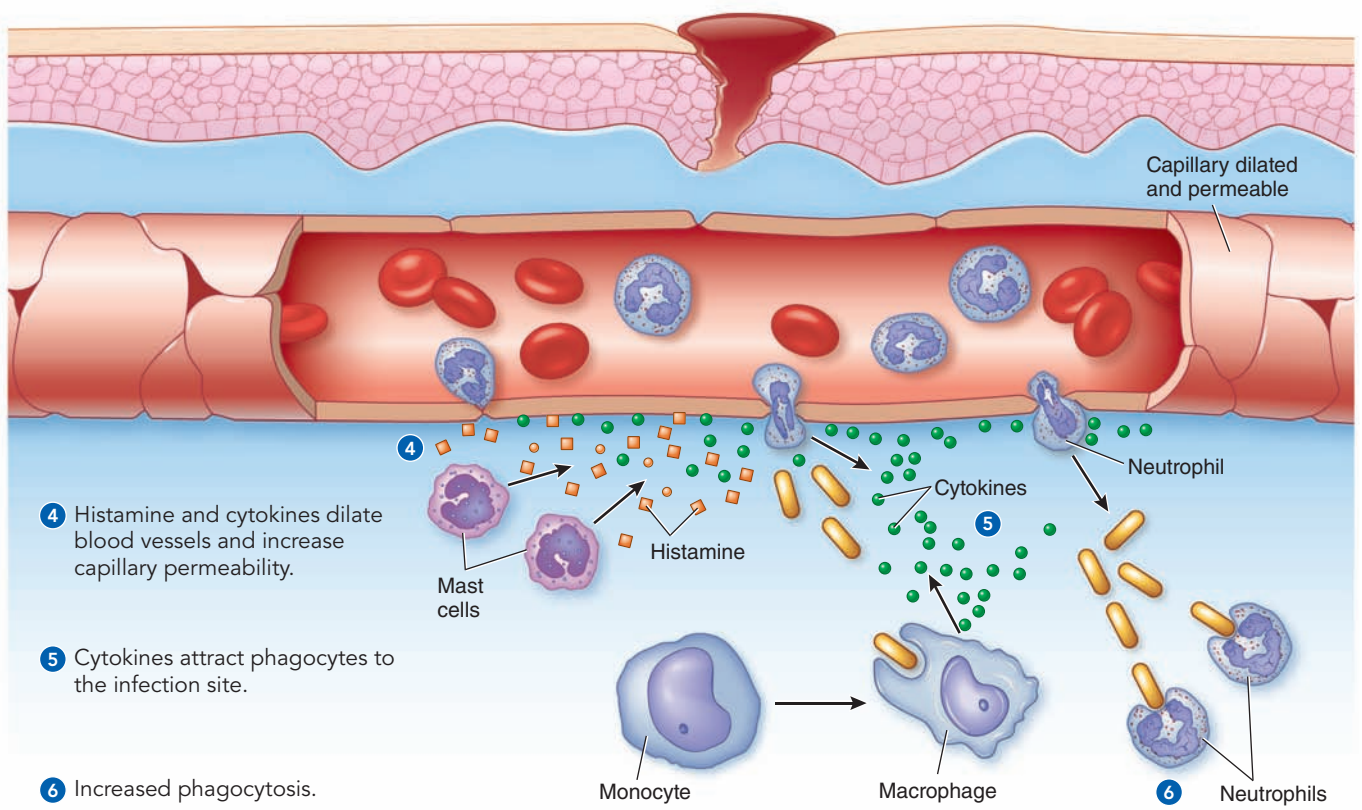
(a) Mast cells in the tissue secrete cytokines, histamine, and other compounds that increase capillary permeability and dilate blood vessels. Certain cytokines attract phagocytic cells. Macrophages and neutrophils in the infected area engulf and destroy bacteria. Macrophages also secrete cytokines that recruit additional neutrophils.

Figure 45-4 The inflammatory response

The body reacts to tissue injury, infection, or exposure to certain toxins with an inflammatory response. Bacteria are represented by *yellow rods*, cytokines by *green dots*, histamines by *orange squares*, and other mast cell secretions by *orange dots*.

area. The increased blood flow warms the skin and reddens skin that contains little pigment.



2. *Increased capillary permeability*. Histamine and other compounds released by mast cells increase capillary permeability. Fluid and antibodies leave the circulation and enter the tissues. As the volume of interstitial fluid increases, *edema* occurs. The edema, along with the action of certain enzymes in the plasma, causes the pain that characterizes inflammation.
3. *Increased phagocytosis*. Increased blood flow brings large numbers of neutrophils and other phagocytic cells to the inflamed region within a few hours of tissue injury or infection. The phagocytes migrate out of the capillaries and into the infected tissues. Macrophages secrete chemokines and other cytokines that recruit and activate additional neutrophils. One of the main functions of inflammation is increased phagocytosis.

Although the inflammatory response begins as a local response, sometimes the entire body may become involved. *Fever*, a common clinical symptom of widespread inflammation, helps the body fight infection. Elevated body temperature increases phagocytosis and interferes with the growth and replication of microorganisms. Fever breaks down lysosomes, destroying cells infected by viruses. Fever also promotes the activity of certain lymphocytes. A short-term, low fever speeds recovery.

The inflammatory response is vital in overcoming infection, but it can also cause tissue damage and disease. *Chronic inflammation* contributes to many chronic diseases. For example, inflammation has been linked with atherosclerosis, rheumatoid arthritis, Crohn's disease, diabetes, Alzheimer's disease, and cancer. Although we do not yet understand the details, chronic inflammation appears to occur when homeostatic mechanisms that normally turn off the inflammatory response do not function appropriately. Investigators have identified several risk factors for chronic inflammation, including prolonged infections, cigarette smoking, gum disease, and obesity.

45.3 Adaptive Immune Responses in Vertebrates

LEARNING OBJECTIVES

4 Contrast cell-mediated and antibody-mediated immunity and give an overview of each process.

5 Describe the functions of the specialized cells of the adaptive immune system and of the major histocompatibility complex.

Adaptive immune responses are also referred to as *acquired immunity*. In contrast to innate immune mechanisms that are always present and ready to respond to infection, adaptive immune responses develop in response to an infection and *adapt* to the specific pathogens invading the body. These immune responses are highly specific for distinct macromolecules.

While innate immune responses destroy pathogens and prevent the spread of infection, the body mobilizes its adaptive immune responses. It takes several days to activate adaptive immune responses, but once in gear, these mechanisms are extremely effective. As discussed earlier, adaptive immune responses are precisely targeted to destroy specific antigens, and they have immunological memory. Two types of adaptive immune responses are *cell-mediated immunity* and *antibody-mediated immunity*.

Many types of cells are involved in adaptive immune responses

The main types of cells of the adaptive immune system are shown in FIGURE 45-5. Two key cell types that participate in adaptive immune responses are lymphocytes and *antigen-presenting cells*. Phagocytes and many other cells important in innate immune responses also participate in specific responses. **Eosinophils**, for example, are white blood cells that release proteins, including cytokines, from their granules. Some of these cytokines are important in adaptive immune responses. Eosinophils also release proteins that are toxic to parasitic worms (the life cycles of some parasitic worms are described in Chapter 31).

Key Point

Cells important in adaptive immune responses include antigen-presenting cells (macrophages and dendritic cells) and lymphocytes (T cells and B cells). These cells interact through complex signaling.

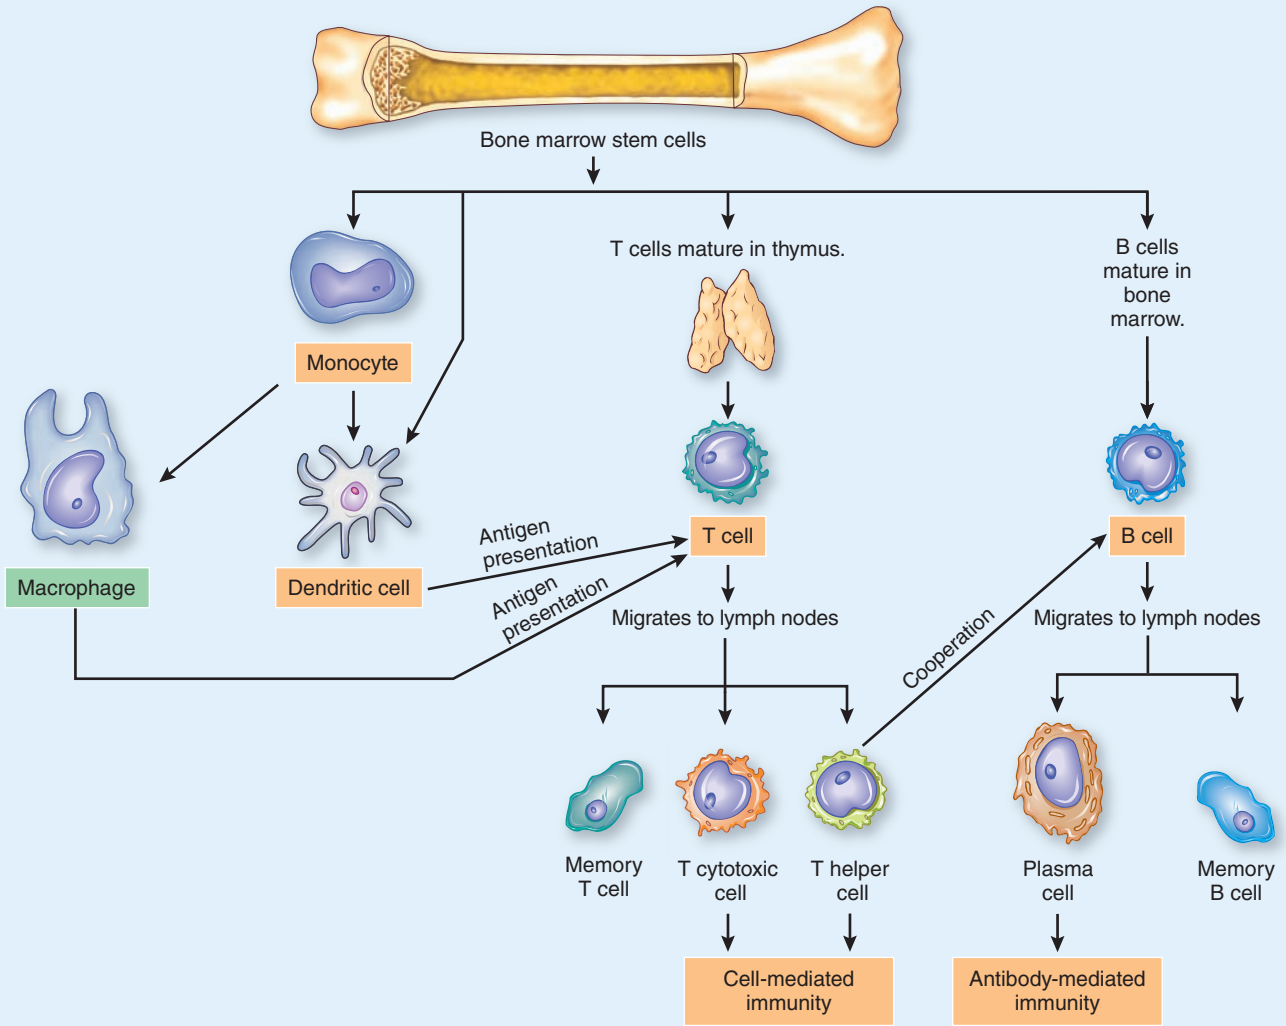

Figure 45-5 Some key cells in adaptive immune responses
Recall that macrophages and dendritic cells also have vital roles in innate immunity.

PREDICT What effect would multiple myeloma (a bone marrow cancer in which malignant plasma cells accumulate in the bone marrow) have on the production of antigen-presenting cells and lymphocytes?

Lymphocytes are important in both adaptive and innate immunity. Natural killer cells (NK cells) were discussed in the previous discussion of innate immunity. Recall that NK cells are lymphocytes that kill virally infected cells and tumor cells. **T lymphocytes**, commonly called **T cells**, and **B lymphocytes**, known as **B cells**, recognize antigens and are key cells in adaptive immunity. All lymphocytes develop from stem cells in the bone marrow. B cells complete their development in the adult bone marrow. T cells mature in the **thymus gland** (from which the *T* in their name derives). Large numbers of mature lymphocytes reside in lymph organs, including the spleen, lymph nodes, tonsils, and other lymph tissues strategically positioned throughout the body.

Although T cells and B cells are similar in appearance when viewed with a light microscope, sophisticated techniques such as fluorescence microscopy demonstrate that these cells can be differentiated by their unique cell-surface macromolecules. T cells and B cells have different functions and life histories and tend to locate in (or "home" to) separate regions of the spleen, lymph nodes, and other lymph tissues.

T cells are responsible for cell-mediated immunity

T cells are the body's cellular soldiers. T cells travel to the site of infection and attack body cells infected by invading pathogens as well as foreign cells (such as those introduced in tissue

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

grafts or organ transplants). T cells also destroy cells altered by mutation (cancer cells).

On their way from the bone marrow to the lymph tissues, T cells are processed in the thymus gland. As T cells move through the thymus, they divide many times and develop specific surface proteins with distinctive receptor sites. The thymus makes T cells *immunocompetent*, capable of producing an effective immune response after exposure to an antigen.

The T-cell population undergoes positive and negative selection. In *negative selection*, T cells in the thymus that react to self-antigens undergo apoptosis. Immunologists estimate that more than 90% of developing T cells are negatively selected in this way.

In *positive selection*, T cells are allowed to mature if they recognize self-antigens and bind with foreign antigens. These T cells differentiate and leave the thymus to take up residence in other lymph tissues or to launch immune responses in infected tissues. By selecting only appropriate T cells, the thymus gland ensures that T cells can distinguish between the body's own molecules and foreign antigens.

Most T cells in the thymus differentiate just before birth and during the first few months of postnatal life. If the thymus is removed before this processing takes place, an animal does not develop cell-mediated immunity. If the thymus is removed after that time, cell-mediated immunity is less seriously impaired.

T cells are distinguished by the **T-cell receptor (TCR)**, which recognizes specific antigens. Two main populations of T cells are T cytotoxic cells and T helper cells. **T cytotoxic (T_C) cells** are also known as *CD8 cells* because they have a glycoprotein designated CD8 on their plasma membrane surface. T_C cells recognize and destroy cells with foreign antigens on their surfaces. Their target cells include virus-infected cells, cancer cells, and foreign tissue grafts.

T helper cells (T_H cells), also known as *CD4 cells*, have a surface glycoprotein designated CD4. T_H cells secrete cytokines that activate B cells, T cells, and macrophages. **Regulatory T cells**, also known as **T_{regs}**, are a subpopulation of T_H cells. Regulatory T cells help regulate immune responses by suppressing the function of certain T cells and by interacting with mature B cells (plasma cells). After an infection, **memory T cells** (both memory T_C cells and memory T_H cells) remain in the body.

B cells are responsible for antibody-mediated immunity

B cells mature into **plasma cells**, which produce specific antibodies. Antibodies bind to specific antigens, neutralizing them or marking them for destruction. Antibody-mediated immunity is one of the body's chief chemical defense strategies.

Each B cell is genetically programmed to code for a glycoprotein receptor that can bind with a specific type of antigen. When a B cell comes into contact with an antigen that binds to its receptors, the B cell becomes activated. B-cell activation is a complex process that typically requires the participation of a T helper cell.

Once activated, a B cell divides rapidly to form a clone of identical cells. Some of the cloned B cells differentiate into plasma cells, which produce antibodies. Other activated B cells become **memory B cells**. A plasma cell can produce more than ten million molecules of antibody per hour! The antibody binds to the antigen that originally activated the B cells. Plasma cells continue to produce small amounts of antibody for months or years after the body overcomes an infection. Researchers at the University of Pennsylvania recently reported that regulatory T cells interact with and support plasma cells in the bone marrow. Without T cells, the plasma cells disappear.

Antigen-presenting cells activate T helper cells

Macrophages, dendritic cells, and B cells function as "professional" **antigen-presenting cells (APCs)** that display foreign antigens as well as their own surface proteins. APCs are inactive until their pattern recognition receptors recognize PAMPs on pathogens. Once activated, an APC ingests the pathogen. Lysosomal enzymes inside the APC degrade most bacterial antigens, but not all. The APC displays fragments of the foreign antigens on its cell surface in association with a type of self-molecule (class II MHC, discussed later). The activated APC expresses additional signaling molecules, called *co-stimulatory molecules*, along with the displayed antigen. These fully functional APCs present displayed antigens to T cells.

In addition to their function as APCs, macrophages secrete more than 100 different compounds, including cytokines and enzymes that destroy bacteria. When stimulated by bacteria, macrophages secrete interleukins that activate B cells and certain T cells. We have seen that interleukins also promote innate immune responses such as fever.

Receptors on dendritic cells bind antigens of microbes. Dendritic cells take these antigens, process them, and display antigen fragments on their cell surface. This is how they become APCs. The dendritic cells leave the epithelial lining and, guided by chemokines, migrate to the lymph nodes. Co-stimulatory molecules, along with the displayed antigen, attract and activate specific T cells capable of responding to the antigen. Thus, dendritic cells are specialized to bind, process, transport, and present antigens to T cells.

The major histocompatibility complex is responsible for recognition of self

The ability of the vertebrate immune system to distinguish self from nonself depends largely on a cluster of closely linked genes known as the **major histocompatibility complex (MHC)**. The human MHC is also referred to as **human leukocyte antigen complex (HLA)**. (We use the designations MHC and HLA interchangeably in this chapter.) The HLA consists of a group of loci on chromosome 6. The HLA genes are polymorphic (variable). Within the population there are multiple alleles for each locus. About 10,000 alleles have been identified. (Note that MHC and HLA refer to both the loci and to the membrane proteins they encode.)

The HLA genes encode HLA membrane proteins referred to as self-antigens. Because there are so many alleles, the HLA membrane proteins differ in chemical structure, function, and tissue distribution. With so many possible combinations, no two people, except identical twins, are likely to have all the same HLA proteins on their cell membranes. The more closely related two individuals are, the more HLA alleles they have in

common. You can think of your HLA proteins as a biochemical "fingerprint."

There are three main Class I HLA loci, which encode glycoproteins expressed on the surface of most nucleated cells. These antigens bind with foreign antigens from viruses or other pathogens processed within the cell to form a foreign antigen–class I HLA glycoprotein complex. The cell displays this complex on its surface and presents it to T_C cells. Thus, any infected cell can function as an antigen-presenting cell, which can activate certain T_C cells or can be instructed to self-destruct.

Six main class II HLA loci encode glycoproteins expressed primarily on "professional" APCs: dendritic cells, macrophages, and B cells. These class II HLA antigens combine with foreign antigen from bacteria, and the APC then presents the complex to T_H cells. Class III HLA loci encode many secreted proteins involved in the immune response, including components of the complement system and TNFs.

45.4 Cell-Mediated Immunity

LEARNING OBJECTIVE

6 Describe the sequence of events in cell-mediated immunity.

T cells and APCs (mainly dendritic cells and macrophages) are responsible for **cell-mediated immunity**. T cells destroy cells infected with viruses, as well as macrophages that have ingested "smart" bacteria. These bacteria escape from the vesicles in which they are enclosed during phagocytosis. They escape destruction by lysosomal enzymes by "hiding" in the cytoplasm of macrophages. T cells destroy cells that have been altered in some way, such as cancer cells. They also destroy the cells of foreign grafts such as a transplanted kidney or liver.

How do T cells know which cells to target? T cells do not recognize antigens unless they are presented properly. Recall that when a virus (or other pathogen) infects a cell, some of the viral protein is broken down to peptides and displayed with class I MHC molecules on the cell surface. Only T cells with receptors that bind to the specific antigen–MHC complex become activated.

Recall that there are two general populations of T cells: T_H cells and T_C cells. Each T_H cell expresses molecules of the glycoprotein called CD4, and each T_C cell expresses CD8 molecules. Within each general T cell population there are thousands of different antigen specificities that the T-cell receptors (TCRs) can recognize. Activation of T_H cells, for example, occurs when phagocytic cells digest antigen and parts of the antigen are placed within their surface MHC complexes. They then present these antigens to the TCR on T_H cells as part of a foreign antigen–class II MHC glycoprotein complex.

Once activated by the foreign antigen–MHC class II antigen complex displayed on the surface of APCs, the activated T_H cells secrete interleukin 2. This cytokine is a growth factor that stimulates the activated cells to proliferate. The T_H cells divide several times, giving rise to a clone of T_H cells (FIG. 45-6). This process is called **clonal expansion**.

Some of the T_H cells produced migrate to the site of infection. These cells can produce many different types of cytokines. Some attract macrophages to the site of infection and promote the destruction of intracellular pathogens. Others function mainly in promoting antibody-mediated immunity.

Each T_C cell expresses the CD8 molecule, as well as more than 50,000 identical TCRs, on its surface. The TCRs bind to one specific type of antigen. T_C cells recognize antigens presented to them as part of a foreign antigen–class I MHC glycoprotein complex. Generally, fewer than 1 in 100,000 T cells have the same antigen specificity and can respond. However, after clonal expansion as many as 1 in 10 T_C cells may be specific for the targeted antigen. T_C-cell activation requires at least two signals in addition to the presented antigen: a co-stimulatory signal and an interleukin signal. Once activated, a T_C cell increases in size and gives rise to a clone of many effector T_C cells.

Effector T_C cells make up the cell infantry. They leave the lymph nodes and make their way to the infected area, where they destroy target cells within seconds after contact. When a T_C cell combines with antigen on the surface of the target cell, it destroys the cell in much the same way that NK cells destroy their target cells. The T_C cell secretes perforins that perforate the plasma membrane of the target cell. Granzymes then induce the cell to self-destruct by apoptosis. After releasing cytotoxic substances, the T cell disengages itself from its victim cell and seeks out a new target.

The sequence of events for production and function of T_C cells in cell-mediated immunity can be summarized as follows:

virus invades body cell → infected cell displays foreign antigen–MHC class I antigen complex → specific T_C cell is activated by this complex → clone of T_C cells produced → effector T_C cells migrate to area of infection → T_C cells are stimulated by cytokines released by T_H cells → T_C cells release enzymes that destroy target cells

Key Point

T cells and APCs are responsible for cell-mediated immunity.

45.5 Antibody-Mediated Immunity

LEARNING OBJECTIVES

7 Summarize the sequence of events in antibody-mediated immunity, including the effects of antigen–antibody complexes on pathogens.

8 Describe the basic structure and function of an antibody and explain the basis of antibody diversity.

9 Describe the basis of immunological memory and contrast secondary and primary immune responses.

10 Compare active and passive immunity, and give examples of each.

We have discussed two types of molecules that recognize specific antigens: T-cell receptors and MHC molecules (HLA in humans). Here we turn our attention to the third type, antibodies. B cells are responsible for **antibody-mediated immunity**.

A given B cell can produce many copies of one specific antibody. Antibody molecules serve as cell-surface receptors that combine with antigens. Only a B cell with a receptor complementary in shape to a particular antigen can bind that antigen. The antigen enters the B cell by receptor-mediated endocytosis (see Chapter 5). The antigen is then degraded into peptide fragments, and the B cell displays peptide fragments together with MHC protein class II on its surface.

In most cases, the activation of B cells involves APCs and T_H cells (FIG. 45-7). T_H cells stimulate B cells to divide and produce antibodies. However, the T_H cell itself must first be activated. T_H cells do not recognize an antigen that is presented alone. An APC must present the antigen as part of a foreign antigen–class II MHC complex on its surface. When an APC displaying a foreign antigen–MHC complex contacts a T_H cell with complementary T-cell receptors, a complicated interaction occurs. Multiple chemical

Figure 45-6 Cell-mediated immunity

When activated by a foreign antigen–MHC complex presented by an APC and by cytokines, a T_H cell divides and gives rise to a clone of T_H cells. T_C cells are also activated by antigens presented on the surfaces of infected cells, and they also form a clone. Both types of T cells migrate to the site of infection. T_H cells release cytokines that stimulate T_C cells and activate macrophages, which then phagocytose pathogens. T_C cells release proteins that destroy infected cells. There are many receptors on the surface of each T cell and each B cell. For simplicity, only one receptor per cell is shown.

signals are sent back and forth between cells. For example, the APC secretes interleukins, such as IL-1, that activate T_H cells.

B cells serve as APCs to T cells. An activated T_H cell binds with the foreign antigen–MHC complex on the B cell. The T_H cell then releases interleukins, which together with antigen activate the B cell.

Once activated, a B cell divides by mitosis, giving rise to a clone of identical cells (FIG. 45-8). This clonal expansion in response to a specific antigen is known as *clonal selection* (discussed later). The cloned B cells mature into two types of cells: plasma cells that secrete antibodies and memory B cells. Antibodies are specific to the antigen that activated the original B cell. It is important to remember that the specificity of the clone is determined *before* the B cell encounters the antigen.

Unlike T cells, most plasma cells remain in the lymph nodes. The antibodies they secrete pass out of the lymph tissues and make their way via the lymph and blood to the infected area. The secreted antibody is a soluble form of the glycoprotein receptor of the activated B cell.

The sequence of events in antibody-mediated immunity can be summarized as follows:

> a pathogen invades the body → an APC phagocytoses the pathogen → foreign antigen–MHC complex is displayed on APC surface → T_H cell binds with foreign antigen–MHC complex → activated T_H cell interacts with a B cell that displays the same antigen → B cell is activated → clone of B cells produced → B cells differentiate, becoming plasma cells → plasma cells secrete antibodies → antibodies form complexes with pathogen → pathogen is destroyed

Some activated B cells do not differentiate into plasma cells. Instead, they become memory B cells (discussed in a later section).

A typical antibody consists of four polypeptide chains

An antibody molecule, also called **immunoglobulin (Ig)**, has several functions. It combines with antigen and activates processes that destroy the bound antigen. For example, an antibody may stimulate phagocytosis. Note that an antibody does not destroy an antigen directly; rather, it *labels* the antigen for destruction. When it is attached to the B-cell surface, an antibody molecule serves as the B-cell receptor for antigen.

In a Y-shaped antibody molecule, the tail of the Y is called the *Fc fragment* (*c* indicates that this fragment crystallizes during cold storage). The Fc fragment binds with receptors on phagocytes and other cells of the immune system. This region of the antibody molecule also binds with molecules of the complement system. The two arms of the Y are referred to as *Fab fragments* (*Fab* stands for *fragment, antigen-binding*). The tips of the Fab fragments bind with antigen (FIG. 45-9). The Y shape permits the antibody molecule to combine with two antigen molecules, resulting in the formation of *antigen–antibody complexes*.

Each antibody molecule consists of four polypeptide chains: two long chains, called *heavy chains*, and two short

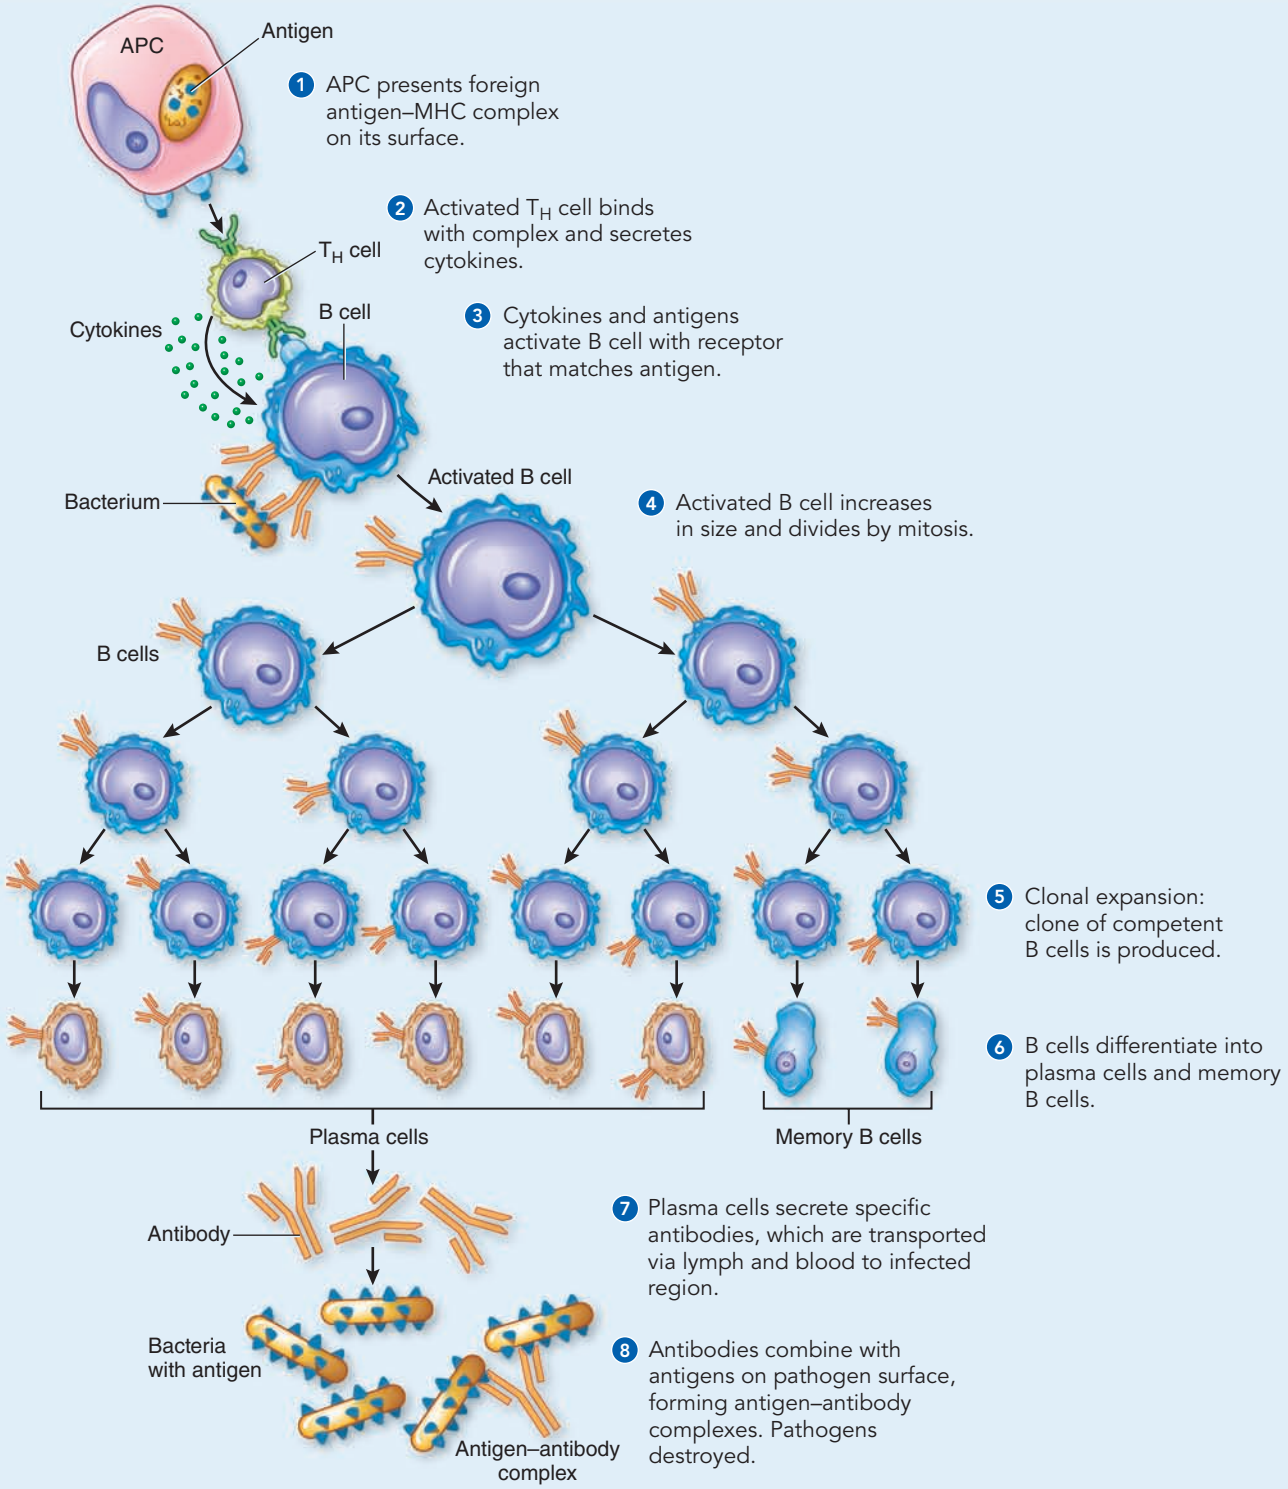
Key Point

B cells, APCs, and T_H cells are responsible for antibody-mediated immunity.



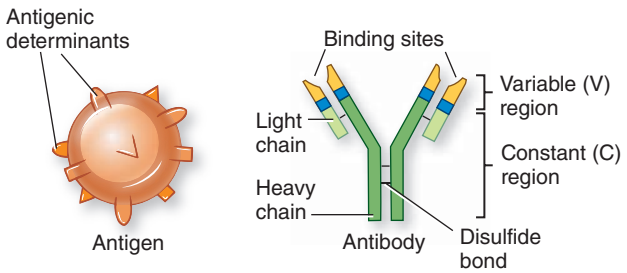


Figure 45-8 Antibody-mediated immunity

A specific B cell may be activated when a specific antigen binds to receptors on its surface. Typically, the B cell also requires cytokine stimulation from an activated T_H cell (see Fig. 45-7). Once activated, the B cell divides and produces a clone of B cells. Many of these B cells differentiate and become plasma cells that secrete antibodies. Others become memory B cells. Plasma cells remain in the lymph tissues, but the antibodies they secrete are transported to the site of infection by the blood or lymph. After the infection has been overcome, memory B cells remain in the tissues. There are many receptors on the surface of each T cell and each B cell. For simplicity, only one receptor per cell is shown.

(a) The antibody molecule is composed of two light chains and two heavy chains joined by disulfide bonds. The constant (C) and variable (V) regions of the chains are labeled.

(b) The Fab portion of the antibody binds to antigen. The Fc portion of the molecule binds to a cell of the immune system (*not shown*). Antigen–antibody complexes directly inactivate pathogens and increase phagocytosis. They also activate the complement system.

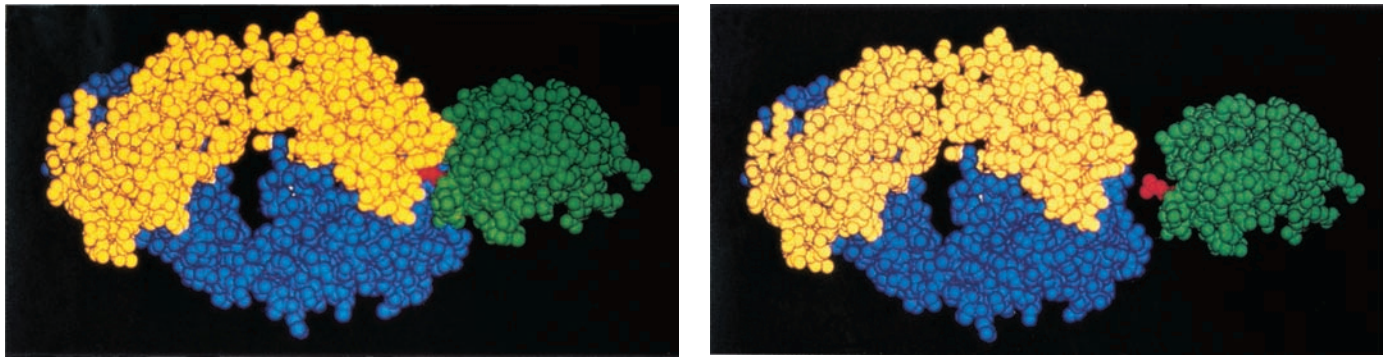
Figure 45-9 Antibody structure and function
Antibodies combine with antigens to form antigen–antibody complexes. As shown, these complexes destroy or promote the destruction of pathogens in a variety of ways.

chains, called *light chains*. Each chain has a constant region and a variable region. In the *constant (C) region* of the heavy chains, the amino acid sequence is constant within a particular immunoglobulin class. The C region of the heavy chains forms the tail of the Y part of the antibody molecule. You can think of this C region as the handle portion of a door key.

The *variable (V) region* has a unique amino acid sequence, like the pattern of bumps and notches on the part of a key that fits into a lock. At its variable regions, the antibody folds three-dimensionally, assuming a shape that enables it to combine with a specific antigen. When they meet, antigen and antibody fit together somewhat like a lock and key. They must fit in just the right way for the antibody to be effective (FIG. 45-10).

The specific part of the antigen molecule that is recognized by an antibody or T-cell receptor is called an *antigenic determinant*, or *epitope*. An antigen may have many antigenic determinants on its surface; some have hundreds. Antigenic determinants often differ from one another, so several different kinds of antibodies can combine with a single antigen. A given antibody can bind with different strengths, or *affinities*, to different antigens. In the course of an immune response, higher affinity antibodies are generated. This increase in affinity occurs because as activated B cells are replicated, mutations occur in genes that encode the antibodies. Cells with antibodies that bind more tightly are selected during the ongoing immune response—a striking example of microevolution in action.

Antibodies are grouped in five classes



Antibodies are grouped in five classes, defined by unique amino acid sequences in the C regions of the heavy chains. The classes are named using the abbreviation *Ig* for *immunoglobulin* and are designated IgG, IgM, IgA, IgD, and IgE. In humans about 75% of the circulating antibodies belong to the *IgG* class; they are part of the gamma globulin fraction of the plasma. *IgM* is the first antibody that humans make in an immune response. IgG and IgM share some functional properties. Both interact with macrophages and activate the complement system. They defend against many pathogens carried in the blood, including bacteria, viruses, and some fungi. IgG is the antibody that crosses the *placenta* (the organ of exchange between mother and developing fetus) and protects the fetus and, later, the newborn baby.

IgA, present in mucus, tears, saliva, and breast milk, prevents viruses and bacteria from attaching to epithelial surfaces. This immunoglobulin, which defends against inhaled or ingested pathogens, is strategically secreted into the respiratory, digestive, urinary, and reproductive tracts. Like IgM, *IgD* is an important immunoglobulin on the B-cell surface. It has a critical role in maturation of B cells and helps activate B cells following antigen binding. IgD has a low concentration in plasma (less than 1% of circulating antibodies).

IgE, which has an even lower plasma concentration than IgD, defends the body against invading parasitic worms. IgE also plays a role in allergic reactions. It binds to mast cells, which contain histamine and other potent signaling molecules. These chemicals are released when an antigen binds to IgE on a mast cell. Histamine triggers many allergy symptoms, including inflammation.

Figure 45-10 An antigen–antibody complex

The components of an antigen–antibody complex fit together as shown in this computer simulation of their molecular structure. Antigen lysozyme, *green*; heavy chain of the antibody, *blue*; light chain, *yellow*.

Antigen–antibody binding activates other defenses

Antibodies mark a pathogen as foreign by combining with an antigen on its surface. Generally, several antibodies bind with several antigens, creating a mass of clumped antigen–antibody complexes. The combination of antigen and antibody activates several defensive responses (see Fig. 45-9).

1. The antigen–antibody complex may inactivate the pathogen or its toxin. For example, when an antibody attaches to its surface, a virus may lose the ability to attach to a host cell.
2. The antigen–antibody complex stimulates phagocytic cells to ingest the pathogen.
3. Antibodies of the IgG and IgM groups work mainly through the complement system.

When antibodies combine with a specific antigen on a pathogen, complement proteins destroy the pathogen. IgG molecules have an Fc fragment that binds Fc receptors; these receptors are expressed on many cells, including macrophages and neutrophils. When an antibody molecule is bound to a pathogen and the Fc portion of the antibody binds with an Fc receptor on a phagocyte, the pathogen is more easily destroyed.

The immune system responds to millions of different antigens

How can the immune system recognize every possible antigen, even those produced by newly mutated viruses never before encountered during the evolution of our species? In the 1950s, Danish researcher Niels Jerne of the Basel Institute for Immunology in Basel, Switzerland; David Talmage of the University of Chicago; and Frank Macfarlane Burnet of the Walter and Eliza Hall Institute for Medical Research in Melbourne, Australia, developed the **clonal selection** hypothesis. This hypothesis proposes that before a lymphocyte ever encounters an antigen, the lymphocyte has specific receptors for that antigen on its surface. (Jerne and Burnet later were awarded Nobel Prizes in Physiology or Medicine for their work in immunology.)

When an antigen binds to a matching receptor on a lymphocyte (T cell), it activates the lymphocyte, which then gives rise to a clone of cells with identical receptors. A problem with this hypothesis, when it was initially proposed, was its suggestion that our cells must contain millions of separate antibody genes, each coding for an antibody with a different specificity. Although each human cell has a large amount of DNA, it is not enough to provide a different gene to encode each of the millions of possible specific antibody molecules.

An explanation for how the immune system could have so many different specificities came later. In 1965, W. J. Dreyer of the Institute of Biochemistry at the University of Zurich, Switzerland, and Joe Claude Bennett of the University of Alabama at Birmingham suggested that the C region and the V region of an immunoglobulin are encoded by two separate genes. Their hypothesis was at first rejected by many biologists because it contradicted the prevailing hypothesis that one gene codes for one polypeptide.

The technology needed to test Dreyer and Bennett's hypothesis was not immediately available, and it was not until 1976 that Susumu Tonegawa of the Massachusetts Institute of Technology and his colleagues demonstrated that separate genes encode the V and C regions of immunoglobulins. Tonegawa further showed that three separate families of genes code for immunoglobulins and that each gene family contains a large number of DNA segments that code for V regions. Recombination of these DNA segments during the differentiation of B cells is responsible for antibody diversity. Tonegawa was awarded the 1987 Nobel Prize in Physiology or Medicine for his work, which transformed the emerging science of immunology.

We now understand that in undifferentiated B cells, gene segments are present for a number of different V regions, for one or more junction (J) regions, and for one or more different C regions (FIG. 45-11). Rearrangement of these DNA segments produces an enormous number of potential combinations. Millions of different types of B (and T) cells are produced. By chance, one of those B cells may produce just the right antibody to destroy a pathogen that invades the body. To appreciate the capacity for antibody diversity, consider the

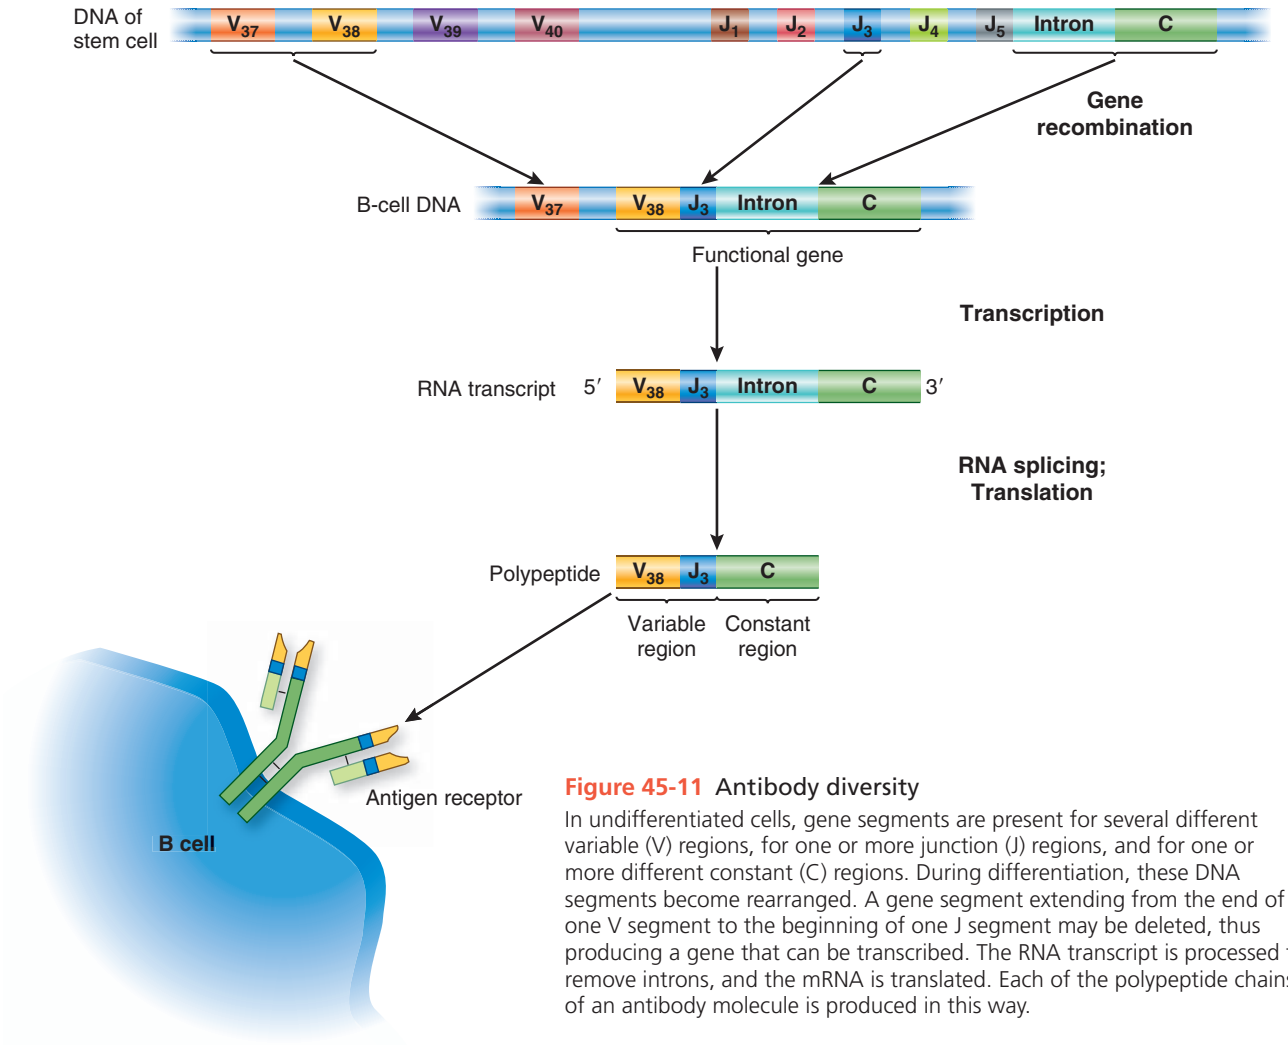

Figure 45-11 Antibody diversity

In undifferentiated cells, gene segments are present for several different variable (V) regions, for one or more junction (J) regions, and for one or more different constant (C) regions. During differentiation, these DNA segments become rearranged. A gene segment extending from the end of one V segment to the beginning of one J segment may be deleted, thus producing a gene that can be transcribed. The RNA transcript is processed to remove introns, and the mRNA is translated. Each of the polypeptide chains of an antibody molecule is produced in this way.

diverse combinations of things you create in your everyday life. A familiar example is making an ice-cream sundae. Imagine the varied combinations that are possible using 10 flavors of ice cream, 6 types of sauce, and 15 kinds of toppings.

Researchers have identified additional sources of antibody diversity. For example, the DNA of mature B cells that codes for the regions of immunoglobulins mutates very readily. These somatic mutations produce genes that code for slightly different antibodies.

We have used antibody diversity here as an example, but similar genetic mechanisms account for the diversity of T-cell receptors. Although we may actually use only a relatively few types of antibodies or T cells in a lifetime, the remarkable diversity of the immune system prepares it to attack most potentially harmful antigens that may invade the body.

Monoclonal antibodies are highly specific

Monoclonal antibodies are identical antibodies produced by cells cloned from a single cell. Each antibody reacts only with the same antigenic determinant (epitope) of the same antigen. Monoclonal antibodies are used in research and in medicine.

One way to produce monoclonal antibodies in the laboratory is to inject mice with the antigen of interest, such as an antigen from a particular bacterium. After the mice have produced antibodies to the antigen, their plasma cells are collected. However, these normal plasma cells survive in culture for only a few generations, limiting the amount of antibody that can be produced. In contrast, cancer cells live and divide in tissue culture indefinitely.

B cells can be suspended in a culture medium together with lymphoma cells from other mice. (Lymphoma is a cancer of lymphocytes.) Then the B cells and lymphoma cells are induced to fuse. They form hybrid cells, known as **hybridomas**, which have properties of the two "parent" cells. Hybridomas can be cultured indefinitely (a cancer cell property) and continue to secrete antibodies (a B-cell property). Researchers select hybrid cells that are manufacturing the specific antibody needed and then clone them in a separate cell culture. Cells of this clone secrete large amounts of the particular antibody. Antibodies produced in this way are called *monoclonal antibodies*.

Immunologists also use recombinant DNA technology to produce monoclonal antibodies. Because of their purity and specificity, monoclonal antibodies have proved to be invaluable tools in modern biology. For example, a researcher may want to detect a specific molecule present in very small amounts in a mixture. The reaction of that molecule (the antigen) with a specific monoclonal antibody makes its presence

known. Monoclonal antibodies are used in similar ways in various diagnostic tests. Home pregnancy tests make use of a monoclonal antibody that is specific for human chorionic gonadotropin (hCG), a hormone produced by a developing human embryo (see Chapters 50 and 51). A dozen monoclonal antibodies are currently being used clinically to treat cancer. The drug Herceptin is a monoclonal antibody used in treating a type of breast cancer. Other monoclonal antibodies are used to treat autoimmune diseases, such as rheumatoid arthritis.

Immunological memory is responsible for long-term immunity

Immunological memory depends on memory B cells and memory T cells. Following an immune response, memory T cells group strategically in many nonlymphatic tissues, including the lung, liver, kidney, and intestine. Many infections occur at such sites, and T cells stationed in those locations can respond quickly. In response to antigen, memory T cells rapidly become T_C cells and produce substances that kill invading cells.

Memory B cells have a "survival gene" that prevents apoptosis, the programmed cell death that is the eventual fate of plasma cells. Memory B cells continue to live and produce small amounts of antibody long after the body has overcome an infection. This circulating antibody is part of the body's arsenal of chemical weapons. If the same pathogen enters the body again, the antibody immediately targets it for destruction. At the same time, specific memory cells are stimulated to divide, producing new clones of plasma cells that produce the same antibody. The presence of circulating antibodies is used clinically to detect previous exposure to specific pathogens. For example, some HIV screening tests measure antibody to the virus that causes AIDS.

A secondary immune response is more effective than a primary response The first exposure to an antigen stimulates a **primary immune response**. An infection, or an antigen injected into an animal, causes specific antibodies to appear in the blood plasma in 3 to 14 days. After antigen injection, there is a brief *latent period* during which the antigen is recognized and appropriate lymphocytes begin to form clones. A *logarithmic phase* follows, during which the antibody concentration rises rapidly for several days until it reaches a peak (FIG. 45-12). IgM is the principal antibody synthesized during the primary immune response. Finally, there is a *decline phase*, during which the antibody concentration decreases to a very low level.

A second exposure to the same antigen, even years later, results in a **secondary immune response**. Because memory B cells bearing antibodies to that antigen (and also memory T cells with their specific T-cell receptors) persist for many years, the secondary immune response is much more rapid than the primary immune response and has a shorter latent period. Much less antigen is necessary to stimulate a secondary immune response than a primary response, and more antibodies are produced. In addition, the affinity of antibodies is generally much higher. The predominant antibody in a secondary immune response is IgG.

The body's ability to launch a rapid, effective response during a second encounter with an antigen explains why we

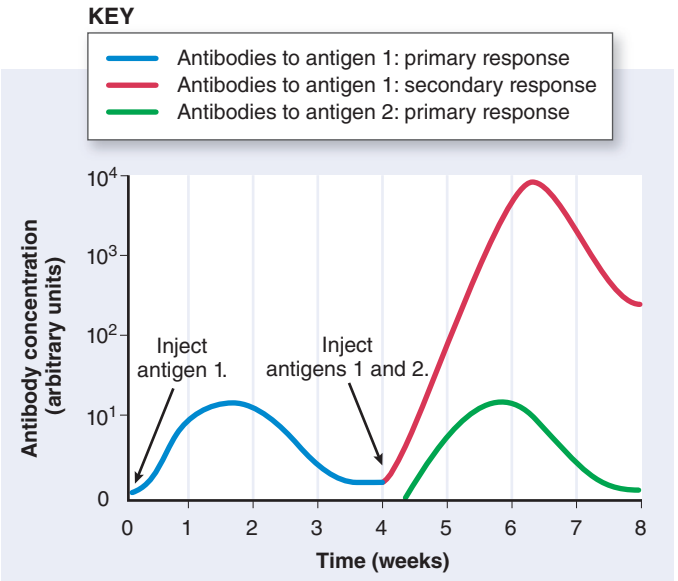

Figure 45-12 Immunological memory
Antigen 1 was injected at day 0, and the immune response was assessed by measuring levels of antibody specific for antigen 1. At week 4, the primary immune response had subsided. Antigen 1 was injected again, together with a new protein, antigen 2. The secondary immune response was greater and more rapid than the primary response. It was also specific to antigen 1. A primary immune response was made to the newly encountered antigen 2.

do not usually suffer from the same infectious disease several times. For example, a person who contracts measles or chickenpox is unlikely to become reinfected in the future. When someone is exposed a second time, the immune system responds quickly, destroying the pathogens before they have time to multiply and cause symptoms of the disease. Booster shots of vaccine are given to elicit a secondary immune response, thus reinforcing immunological memory.

You may wonder how a person can get influenza (the flu) or a cold more than once. The reason is that there are many varieties of these viral diseases, each caused by a virus with slightly different antigens. For example, more than 200 different viruses cause the common cold, and new varieties of cold and flu viruses evolve continuously by mutation (a survival mechanism for them). As viruses evolve, changes may occur in their surface antigens. Even a slight change may prevent recognition by memory cells. Because the immune system is so specific, each different antigen is treated by the body as a new immunological challenge.

Immunization induces active immunity We have been considering **active immunity**, which develops following exposure to antigens. Active immunity can be naturally or artificially induced (TABLE 45-1). If someone with influenza sneezes near you and you contract the disease, you develop active immunity naturally. Active immunity can also be artificially induced by *immunization*, that is, by exposure to antigens in a *vaccine*. When an effective vaccine is introduced into the body, the immune system actively develops clones of cells, produces antibodies, and develops memory cells.

Table 45-1 Active and Passive Immunity

Type of Immunity	When Developed	Development of Memory Cells	Duration of Immunity
ACTIVE			
Naturally induced	After pathogens enter the body through natural encounters (e.g., a person with influenza sneezes on you)	Yes	Many years
Artificially induced	After immunization with a vaccine	Yes	Many years
PASSIVE			
Naturally induced	After transfer of antibodies from mother to developing baby	No	Few months
Artificially induced	After injection with gamma globulin	No	Few months

The first vaccine was prepared in 1796 by British physician Edward Jenner against vaccinia, the cowpox virus. (The term *vaccination* was derived from the name of the cowpox virus.) Jenner's vaccine provided humans with immunity against the deadly disease smallpox, which closely resembles cowpox. Jenner had no knowledge of microorganisms or of immunology, and 100 years passed before French chemist Louis Pasteur began to develop scientific methods for preparing vaccines.

Pasteur showed that inoculations with preparations of attenuated (weakened) pathogens could be used to develop immunity against the virulent (infectious) form of the pathogen. However, not until 20th-century advances in immunology—for example, Burnet's clonal selection theory in 1957 and the discovery of T cells and B cells in 1965—did scientists gain a modern understanding of vaccines. Effective vaccination stimulates the body to launch an immune response against the antigens contained in the vaccine. Memory cells develop, and future encounters with the same pathogen are dealt with rapidly.

Microbiologists prepare effective vaccines in various ways. They can attenuate a pathogen so that it loses its ability to cause disease. When pathogens are cultured for long periods in nonhuman cells, mutations adapt the pathogens to the nonhuman host so that they no longer cause disease in humans. This method is used to produce the Sabin polio, measles, mumps, and rubella vaccines. Tetanus and diphtheria vaccines are made from toxins secreted by the respective pathogens. The toxin is altered so that it can no longer destroy tissues, but its antigenic determinants are still intact.

Researchers are developing **DNA vaccines** (or RNA vaccines) consisting of plasmids that have been genetically engineered to produce specific antigens from a pathogen. When injected into a patient, the altered DNA is taken up by cells and makes its way to the nucleus. The encoded antigens are manufactured and stimulate both cell-mediated and antibody-mediated immunity. Numerous DNA vaccines, including vaccines to prevent and treat HIV infection, are in clinical trials. Researchers are also developing DNA vaccines that could provide immunity to multiple pathogens with a single injection.

Passive immunity is borrowed immunity When individuals have been exposed to certain diseases such as measles or hepatitis A, physicians may inject them with gamma globulin containing antibodies to the pathogen. The individuals injected develop **passive immunity**, boosting the body's defenses against the disease. However, gamma globulin injections offer protection for only a few weeks. Because the body has not actively launched an immune response, it has no memory cells and cannot produce antibodies to the pathogen. Once the injected antibodies are broken down, the immunity disappears.

Pregnant women confer naturally induced passive immunity on their developing babies by manufacturing antibodies for them. These maternal antibodies, of the IgG class, pass through the placenta and provide the fetus and newborn infant with a defense system until its own immune system matures. Babies who are breast-fed continue to receive immunoglobulins, particularly IgA, in their milk during the critical months when their own immune system is developing.

Remember that passive immunity is borrowed immunity. Its effects are temporary, whether the immunity is artificially or naturally induced (see Table 45-1).

CHECKPOINT 45.5

- List the sequence of events that occur in antibody-mediated immunity.
- **VISUALIZE** Draw an antigen–antibody complex. Describe three ways that antigen–antibody complexes affect pathogens.
- What is the basis of immunological memory?
- How is passive immunity different from active immunity?

45.6 Response to Disease, Immune Failures, and Harmful Reactions

LEARNING OBJECTIVES

11 Describe the body's response to cancer cells and HIV.
12 Describe examples of hypersensitivity, including autoimmune diseases, Rh incompatibility, and allergic reactions, and summarize the immunological basis of graft rejection.

The immune system is generally very effective in defending the body against invading pathogens. However, many

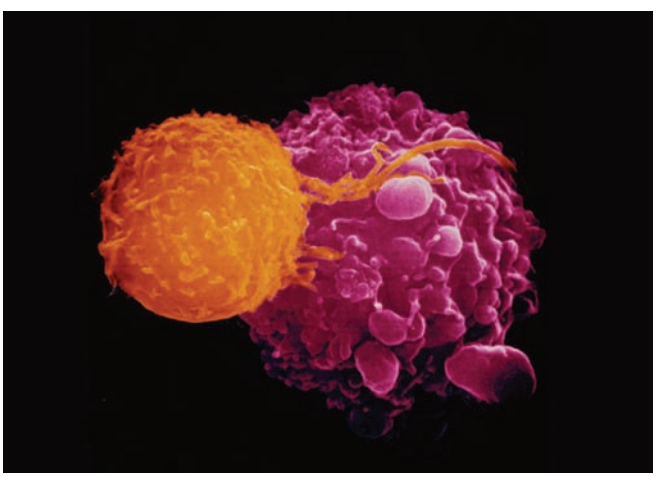
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.



factors can impair immune function, including genetic mutations, malnutrition, sleep deprivation, pre-existing disease, stress, and virulent pathogens. Ineffective or inappropriately directed immune responses can also result in disease states.

Exaggerated, damaging immune responses are referred to as *hypersensitivity*. For example, sometimes the immune system malfunctions and attacks its own tissues, causing *autoimmune disease*. In allergic reactions, individuals are over-responsive to mild environmental antigens. The immune system's ability to distinguish self from nonself sometimes interferes with clinical interventions. Physicians must carefully consider immune system responses when employing such life-saving procedures as blood transfusions or organ transplants.

Cancer cells evade the immune system

Cancer is a leading cause of death worldwide and the second-leading cause of death in Western countries. An estimated one person in three in the United States will develop cancer, and one in five will die of cancer. Worldwide, lung cancer in men and breast cancer in women are the main types of cancer resulting in death. In our earlier discussions of cancer in Chapters 17 and 39, we explained that cancer is actually a complex group of diseases characterized by dysregulation of normal control mechanisms for cellular growth. Here we focus on the interaction between cancer cells and cells of the immune system and on new treatment strategies based on immune mechanisms.

Cancer cells are body cells that have been transformed in a way that alters their normal growth-regulating mechanisms. Every day a few normal cells may be transformed into precancer cells in each of us in response to the sun's UV rays, X-rays, certain viruses, tobacco smoke, asbestos, and other chemical carcinogens in the environment as well as other unknown factors.

DR ANDREJS LIEPINS/Science Source

Figure 45-13 A cytotoxic T cell destroying a cancer cell
This color-enhanced SEM shows a cytotoxic T_C cell (*orange*) attacking a cancer cell (*pink*). When a T_C cell attaches to a cancer cell, it releases compounds that induce the cancer cell to undergo apoptosis (programmed cell death).

How does the immune system respond? And why are immune responses sometimes ineffective?

Cancer cell antigens are classified according to their molecular structure and their source. Some cancer cell antigens are produced by mutant genes that are associated with cancer cells. T cells may respond to them because these antigens are not found in normal cells. Other cancer cell antigens are normal proteins that may stimulate immune responses because they are expressed in abnormally large quantities.

The human papillomavirus (HPV), which has been linked to several types of cancer (including cervical cancer and head and neck cancer), produces antigens that stimulate T cells to respond. Adaptive immune responses sometimes prevent the development of such DNA virus-induced cancers.

Cancer cell antigens induce both cell-mediated and antibody-mediated immunity NK cells and macrophages destroy cancer cells. Macrophages produce cytokines, including TNFs that inhibit tumor growth. Dendritic cells present antigens to T cells, stimulating them to produce interferons, which have an antitumor effect. T_C cells attack cancer cells directly and also produce interleukins, which attract and activate macrophages and NK cells (**FIG. 45-13**). Although the immune system recognizes many cancer cell antigens, these antigens often stimulate only weak immune responses that are not effective.

Sometimes cancer cells evade the immune system and multiply unchecked. Some types of cancer cells can block T_C cells. Others dramatically decrease their expression of class I MHC molecules. Recall that T_C cells recognize only antigens associated with class I MHC, so a low level of these molecules prevents tumor destruction. Some cancer cells do not produce co-stimulatory molecules needed to activate T_C cells.

Future cancer treatment will be more targeted Cancer treatments, such as chemotherapy and radiation, are designed to kill cells that are rapidly dividing. However, these treatments destroy normal cells as well as cancer cells. To treat cancer effectively, treatment strategies must be more specific, or even customized to the particular cancer. For example, cancer researchers are genetically engineering cancer cells to secrete cytokines that would stimulate the patient's immune response.

A few cancer drugs, such as Herceptin, are monoclonal antibodies. Herceptin binds with a growth-factor receptor that is present in excessive numbers on the cells of about 30% of metastatic breast cancers. Herceptin blocks the growth factors that would stimulate proliferation of the cells.

The spread of cancer typically depends on the development of blood vessels that bring nutrients and oxygen to the tumor. *Angiogenesis inhibitors* slow the development of blood vessels and thereby slow the spread of cancer. Many studies under way are attempting to optimize the clinical benefits of these drugs.

Researchers are developing DNA vaccines made from bits of DNA from a patient's cancer cells. When injected into the patient, the vaccine stimulates increased production of the target antigens. In response, the patient's immune system launches cell-mediated responses to tumor-associated antigens. These vaccines differ from traditional vaccines that

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

are used to destroy pathogens *before* they cause disease. Effective new treatment protocols for cancer will use a systems approach and combinations of medications. Cellular mechanisms are complex, and when a drug blocks one signaling pathway, cancer cells often work around the blocked reaction or take advantage of a redundant pathway. When combinations of drugs are used, more than one signaling pathway, or different parts of the same pathway, can be targeted.

Gene therapy research is another rapidly expanding area of study that is targeting cancer and other immune diseases. A new gene can be added or a faulty gene replaced to strengthen the body's defenses or cure cancer. Medical researchers are using CRISPR/Cas9 technology to change a human cell line to represent the disease genetically and functionally. Using recently developed research tools, cancer research is moving ahead rapidly and at lower cost.

Immunodeficiency disease can be acquired or inherited

The absence or failure of some component of the immune system can result in **immunodeficiency disease**, a condition that increases susceptibility to infection. Worldwide, the leading cause of *acquired* immunodeficiency in children is protein malnutrition. Lack of protein decreases T-cell numbers and decreases the ability to manufacture antibodies, which impairs the immune system. This condition increases the risk of contracting *opportunistic infections*, infections by microbes that do not typically cause disease. Another important cause of acquired immunodeficiency is chemotherapy administered to cancer patients because chemotherapy is most damaging to cells that divide rapidly, including blood stem cells and activated lymphocytes.

Inherited immunodeficiencies have an estimated incidence of 1 per 10,000 births. *Severe combined immunodeficiency syndromes (SCIDs)* are X-linked and autosomal recessive disorders that profoundly affect both cell-mediated immunity and antibody-mediated immunity, resulting in multiple infections. Babies born with SCID typically die by two years of age unless they are maintained in a protective bubble until they can be effectively treated, typically with bone marrow transplants.

In *DiGeorge syndrome*, the thymus is reduced or absent, and the patient is deficient in T cells. Children born with this disorder are prone to serious viral infections. Treatment involves transplanting bone marrow or fetal thymus tissue. Other tissues may take over T-cell production, and function typically improves by age five.

Researchers use several animal models to study immunodeficiency. For example, the nude mouse (a hairless mutant mouse) does not develop a functional thymus. Because nude mice are deficient in mature T cells, they are used to study the effects of compromised cell-mediated immunity as well as possible treatments. *Stem cell research* and advances in genetic engineering, including CRISPR/Cas9, suggest new approaches to treating immunodeficiency (see Chapters 16 and 17).

HIV is the major cause of acquired immunodeficiency in adults

The **human immunodeficiency virus (HIV)** was first isolated in 1983 and was shown to be the cause of **acquired immunodeficiency syndrome (AIDS)** in 1984. HIV, which is a retrovirus, has been studied more than any other virus. (Recall from Chapter 24 that a retrovirus is an RNA virus that uses its RNA as a template to make DNA with the help of reverse transcriptase.) Several different strains of the virus are known; HIV-1 is the most virulent form in humans (see Fig. 23-12).

The AIDS pandemic has claimed more than 35 million lives and has infected more than 78 million people since 1981. HIV kills approximately 1 million people every year. Epidemiologists estimate that more than 37 million people worldwide, including nearly 3 million children, are now infected with HIV. More than 2 million people are newly infected with HIV each year. Unfortunately, due to extreme poverty, less than half of the people diagnosed with AIDS receive antiretroviral therapy. The General Assembly of the United Nations has called AIDS a "global emergency" and has outlined measures for mobilizing world resources to combat this disease. HIV/AIDS is more than a medical issue; it is a political, economic, and human rights threat.

HIV is transmitted through body fluids from infected individuals, including semen, vaginal secretions, blood, and breast milk. Transmission occurs mainly during sexual intercourse with an infected person or by direct exposure to infected blood or blood products. Sharing needles and/or syringes (usually for drug injection) with an infected person is a major risk factor. The virus is not spread by casual contact. People do not contract HIV by hugging, casual kissing, sharing food or water, or using the same bathroom facilities. Friends and family members who have contact with AIDS patients are not more likely to become infected than those who do not have such contact.

In the United States, more than 39,000 new HIV infections occur each year. Of these new infections, almost 70% occur in men. Sexual contact with persons who have HIV infection is a risk factor that can be modified. Use of a latex condom during sexual intercourse provides some protection against HIV transmission, and use of a spermicide containing nonoxynol-9 may provide additional protection.

As many as one-third of untreated pregnant women infected with HIV will transmit the virus to their babies during pregnancy, childbirth, or breast-feeding. Recent drug treatment protocols have reduced the rate of HIV transmission between mother and fetus. Clinical studies are ongoing to confirm reports that beginning treatment (using triple antiretroviral drugs) of HIV-infected infants within the first 30 hours of life may lead to a cure after about 18 months.

In high-income countries, effective blood-screening procedures now safeguard blood bank supplies, markedly reducing the risk of infection by blood transfusion. In low- and middle-income countries, HIV continues to be a health threat, particularly to women and newborns. As treatment, prevention, and education programs are implemented, the incidence of new infections in many parts of the world is decreasing.

HIV destroys the host immune system HIV typically enters the body through the mucosa that lines passageways into the body. A protein on the outer envelope of the virus attaches to CD4 on the surface of T_H cells, the main target (FIG. 45-14). The virus also binds to a co-receptor that normally binds a chemokine. HIV enters the T_H cell and is reverse transcribed to form DNA. Its DNA is then incorporated into the host genome. The virus reproduces itself, causing death of the host cell. The first phase of HIV infection is the *acute* phase of the infection. Within two weeks of infection, large numbers of T_H and memory T cells are destroyed. HIV also infects dendritic cells and macrophages. Dendritic cells in the mucous membranes transport HIV from their point of entry to the lymph nodes. The virus further spreads through the blood.

The body launches an immune response following HIV infection. Innate responses include production of antimicrobial peptides and action by NK cells, dendritic cells, and the complement system. Adaptive immune responses include activation and mobilization of T_C cells.

An estimated 13% of HIV-infected individuals in the United States do not know that they are infected. During the first few weeks after infection, some people experience mild flulike symptoms (fever, headache, sore throat, aching muscles). However, some individuals have no symptoms.

The acute phase transitions into the latent period, a *chronic* phase, as the immune system decreases HIV in the blood. Some cells infected by HIV are not destroyed, and the virus may continue to replicate slowly for many years. T_C cells appear to be the main cells that attack HIV, limiting viral replication and delaying the progress of the disease. However, over time HIV continues to destroy T_H cells, resulting in a dramatic decrease in the T_H-cell population. This decrease severely impairs the body's ability to resist infection because T_H cells are needed to release the cytokines that activate T_C cells and B cells. After a time, a progression of symptoms occurs, including swollen lymph glands, night sweats, fever, and weight loss (FIG. 45-15). Too often, the virus eventually wins the battle.

In most HIV-infected individuals, the disease eventually progresses to AIDS, the final, and often lethal, stage. This process can take more than ten years, and antiretroviral drugs

NIBSC/Science Source

Figure 45-14 HIV infecting T helper cell (color-enhanced SEM)
HIV (*red particles*) attack and destroy T_H cell (*green*). Depletion of T_H is the main reason for the failure of the immune system in HIV infection.

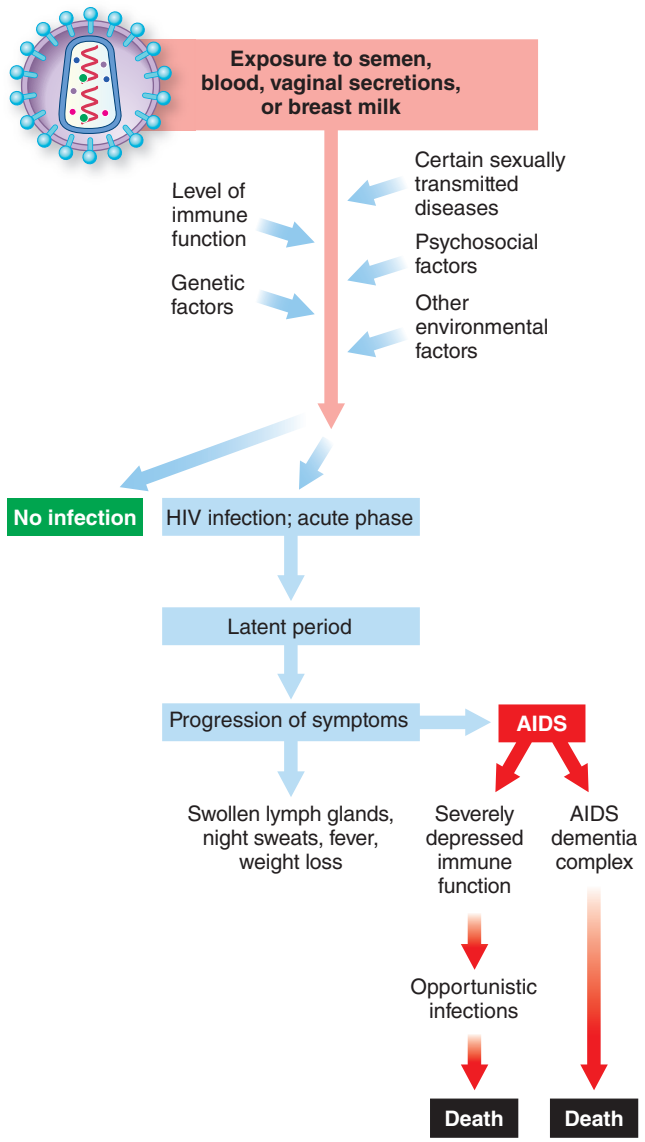

Figure 45-15 The course of HIV infection
Exposure to semen, blood, vaginal secretions, or breast milk containing HIV can lead to HIV infection. The acute (early) infection begins in lymph nodes and other lymph tissues associated with epithelial linings. Most T_H cells may be destroyed within two weeks of infection. During the latent period, chronic infection develops, and the virus replicates at a low level. Eventually, viral replication may increase and lead to a progression of symptoms and to AIDS. Although some exposed individuals apparently do not become infected, the risk increases with multiple exposures. Many factors determine whether a person exposed to HIV will develop AIDS.

slow the process. By the time the disease progresses to AIDS, lymph tissue has been destroyed and the blood T_H cell count has dropped below a critical level of 200 cells/μL. As a consequence of this immunosuppression, many AIDS patients develop serious opportunistic infections, such as tuberculosis, or cancers, such as lymphomas and Kaposi's sarcoma (a tumor of the endothelial cells lining blood vessels that causes purplish spots on the skin). In about one-third of AIDS patients, the virus infects the nervous system and causes *AIDS dementia complex*. These patients exhibit progressive cognitive, motor, and behavioral dysfunction that typically ends in coma and death.

Researchers are searching for effective treatments

Researchers throughout the world are searching for anti-retroviral drugs that will successfully combat the AIDS virus. Because HIV often infects the central nervous system, an effective drug must cross the blood–brain barrier. **Azidothymidine (AZT)**, the first anti-retroviral drug developed to treat HIV infection, can prolong the period prior to the onset of AIDS symptoms. AZT inhibits the action of reverse transcriptase, the enzyme the retrovirus uses to synthesize DNA. As a result, AZT blocks HIV replication. Without producing DNA, the virus cannot incorporate itself into the host cell's DNA. Unfortunately, the reverse transcriptase that HIV uses to synthesize DNA makes many mistakes: about 1 in every 2000 nucleotides it incorporates is incorrect. By mutating in this way, viral strains resistant to AZT have evolved.

Protease inhibitors block the viral enzyme protease, resulting in viral copies that cannot infect new cells. Protease inhibitors are used in combination with AZT and other reverse transcriptase inhibitors. Triple-combination treatment has been very effective for many AIDS patients, preventing opportunistic infections and prolonging life. In fact, combination treatment has led to a decline in AIDS incidence and mortality in the United States. Preliminary studies suggest that new regimens using a combination of two newly developed, more powerful drugs may replace the triple-combination treatment.

Unfortunately, people in many parts of the world cannot afford these expensive drugs. According to the World Health Organization, more than 50% of HIV-infected individuals are not receiving treatment. As a result, the AIDS epidemic continues to grow.

Another serious problem has been the emergence of drug-resistant HIV viruses. Worldwide containment of the AIDS epidemic will require an effective vaccine that prevents the spread of HIV. Developing such a vaccine remains a daunting challenge for immunologists. About 60 vaccines have been developed and tested clinically, but none has proved effective. An effective vaccine would have to counteract HIV's destruction of the key cells needed to launch an immune response. Also, because mutations arise at a very high rate, new viral strains with new antigens evolve quickly. A vaccine might quickly become obsolete. Some optimism has been generated by a combination of vaccine and gene therapy that has been tested in simian monkeys.

While immunologists work to develop a successful vaccine and more effective drugs to treat infected patients, massive educational programs have been launched to control, or slow, the spread of HIV. Educating the public that having multiple sexual partners increases the risk of HIV and teaching sexually active individuals the importance of "safe sex" help contain the pandemic. In some countries public health facilities provide free condoms to those who are sexually active and free needles and syringes to those addicted to intravenous drugs. Some HIV prevention programs now provide male circumcision, which reduces the risk of HIV infection through sexual contact. The cost of these measures is far less than the cost of medical care for increased numbers of HIV patients.

In an autoimmune disease, the body attacks its own tissues

Self-tolerance, the ability to recognize self, is established during lymphocyte development. Lymphocytes do not normally attack cells and tissues of their own body. However, some lymphocytes do have the potential to be *autoreactive*, that is, to launch an immune response against self-tissues. In about 5% of adults in high-income countries, such autoreactivity can lead to a form of hypersensitivity known as *autoimmunity*, or **autoimmune disease**, in which immune cells react against the body's own cells. Some of the diseases that result from such failure in self-tolerance are rheumatoid arthritis, systemic lupus erythematosus, insulin-dependent diabetes, scleroderma, and multiple sclerosis.

In autoimmune diseases, antibodies and T cells attack the body's own tissues. In *rheumatoid arthritis*, T cells in the area of inflammation produce a cytokine that promotes inflammation. In addition, antibodies to a joint protein may generate antigen–antibody complexes that are deposited in the small joints. In *multiple sclerosis*, an autoimmune disease of the central nervous system, T_H cells attack an individual's own myelin antigens. MRI scans show the loss of myelin sheaths in multiple areas around axons in the brain and spinal cord that are normally myelinated. Scar tissue forms and compromises the ability of these damaged neurons to transmit signals.

Multiple genes, including MHC alleles, contribute to the development of autoimmune disease. Mutations that cause abnormal apoptosis or inadequate clearing of dead cells may result in danger signals that activate the immune system. Another important factor is that viral or bacterial infection often precedes the onset of an autoimmune disease. A tactic known as *molecular mimicry* has evolved in some pathogens. They trick the body by producing molecules that look like self-molecules. For example, an adenovirus that causes respiratory and intestinal illness produces a peptide that mimics myelin protein. When the body launches responses to the adenovirus peptide, it may also begin to attack the similar self-molecule, myelin.

As we have discussed, the numerous types of cells, regulatory and signaling molecules, and the complex actions of the immune system must be carefully regulated to maintain health. For example, specific T cells and B cells proliferate and respond to challenges by pathogens, but after an effective immune response, the expanded populations of T cells and B cells must be decreased to normal numbers. Cells that are no longer needed die by apoptosis. Overactivation of critical components can result in inflammation and autoimmune disease. Underactivation allows pathogens to cause serious disease. Either situation can be fatal.

Rh incompatibility can result in hypersensitivity

Named for the rhesus monkeys in whose blood it was first found, the Rh system consists of more than 40 kinds of Rh antigens, each referred to as an **Rh factor**. By far the most important of these factors is *antigen D*. About 85% of U.S. residents who are of Western European descent are Rh positive, meaning that they have antigen D on the surfaces of their red blood cells (in addition to the antigens of the ABO system and other blood group antigens). The 15% or so of this population who are Rh negative have no antigen D.

Unlike the situation discussed in Chapter 11 for the ABO blood group, Rh-negative individuals do not routinely produce antibodies against antigen D (anti-D). However, they do produce anti-D antibodies when they are exposed to Rh-positive blood. The allele coding for antigen D is dominant to the allele for the absence of antigen D. For this reason, Rh-negative people are homozygous recessive, and Rh-positive people are heterozygous or homozygous dominant.

Although several kinds of maternal–fetal blood type incompatibilities are known, **Rh incompatibility** is the most serious (FIG. 45-16). If a woman is Rh negative and the father of the fetus she is carrying is Rh positive, the fetus may also be Rh positive, having inherited the D allele from the father. Ordinarily, the maternal and fetal blood do not mix; nutrients, oxygen, and other substances are exchanged between the two circulatory systems across the placenta. However, late in pregnancy or during the birth process, a few drops of blood from the fetus may pass through a defect in the placenta.

When maternal blood mixes with fetal blood, fetal red blood cells, which bear antigen D, activate the mother's immune system. The mother's B cells then produce antibodies to antigen D. If the woman becomes pregnant again, anti-D antibodies cross the placenta and enter the fetal blood. They combine with antigen D molecules on the surface of the fetal red blood cells, causing hemolysis (cells rupture and release hemoglobin into the circulation). The ability to transport oxygen is reduced, and breakdown products of the released hemoglobin damage organs, including the brain. In extreme cases of this disease, known as *erythroblastosis fetalis*, so many fetal red blood cells are destroyed that the fetus may die.

When Rh-incompatibility problems are suspected, fetal blood can be exchanged by transfusion before birth, but it is a risky procedure. More commonly, Rh-negative women are treated just after childbirth (or at termination of pregnancy by miscarriage or abortion) with a preparation of anti-D antibodies known as RhoGAM. These antibodies clear the Rh-positive fetal red blood cells from the mother's blood very quickly, minimizing the chance for her own white blood cells to become sensitized and develop memory cells. The antibodies are also soon eliminated from her body. As a result, if she becomes pregnant again, her blood does not contain the anti-D that could harm the developing fetus.

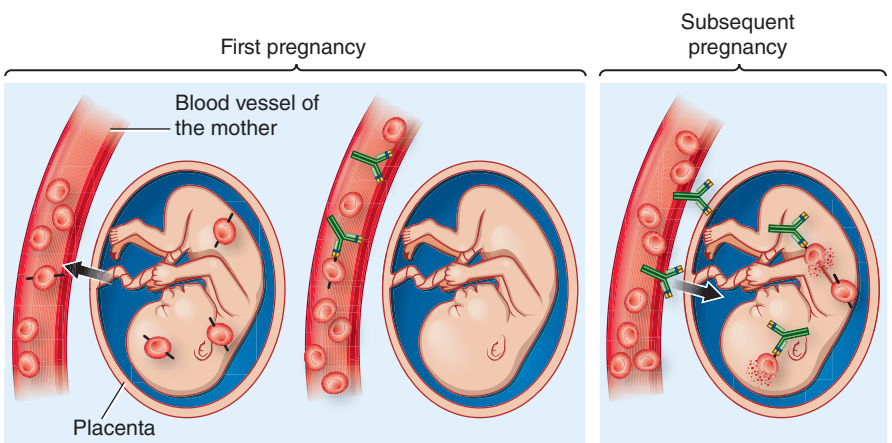

Figure 45-16 Rh incompatibility

When an Rh-negative woman produces Rh-positive offspring, her immune system may become sensitized. In subsequent pregnancies, she may produce anti-D antibodies that cross the placenta and destroy fetal red blood cells.

Allergic reactions are directed against ordinary environmental antigens

About 20% of the U.S. population is plagued by an allergic disorder, such as allergic asthma or hay fever. A predisposition toward these disorders appears to be inherited. In *allergic reactions* hypersensitivity results in the manufacture of antibodies against mild antigens, called **allergens**, which normally do not stimulate an immune response. Common environmental agents, such as pollen, house-dust mites, roach feces, and pet dander, can trigger allergic reactions in some individuals. In many kinds of allergic reactions, distinctive IgE immunoglobulins are produced.

Let us examine a common allergic reaction, *allergic rhinitis*, commonly known as hay fever. This allergic response is triggered in some individuals by breathing pollen (FIG. 45-17). Exposure to pollen causes *sensitization*. Macrophages degrade the allergen and present fragments of it to T cells. The activated T cells then stimulate B cells to become plasma cells and produce pollen-specific IgE. These antibodies attach to receptors on mast cells. The Fc end of each IgE molecule attaches to a mast cell receptor; its V region is free to combine with the pollen allergen.

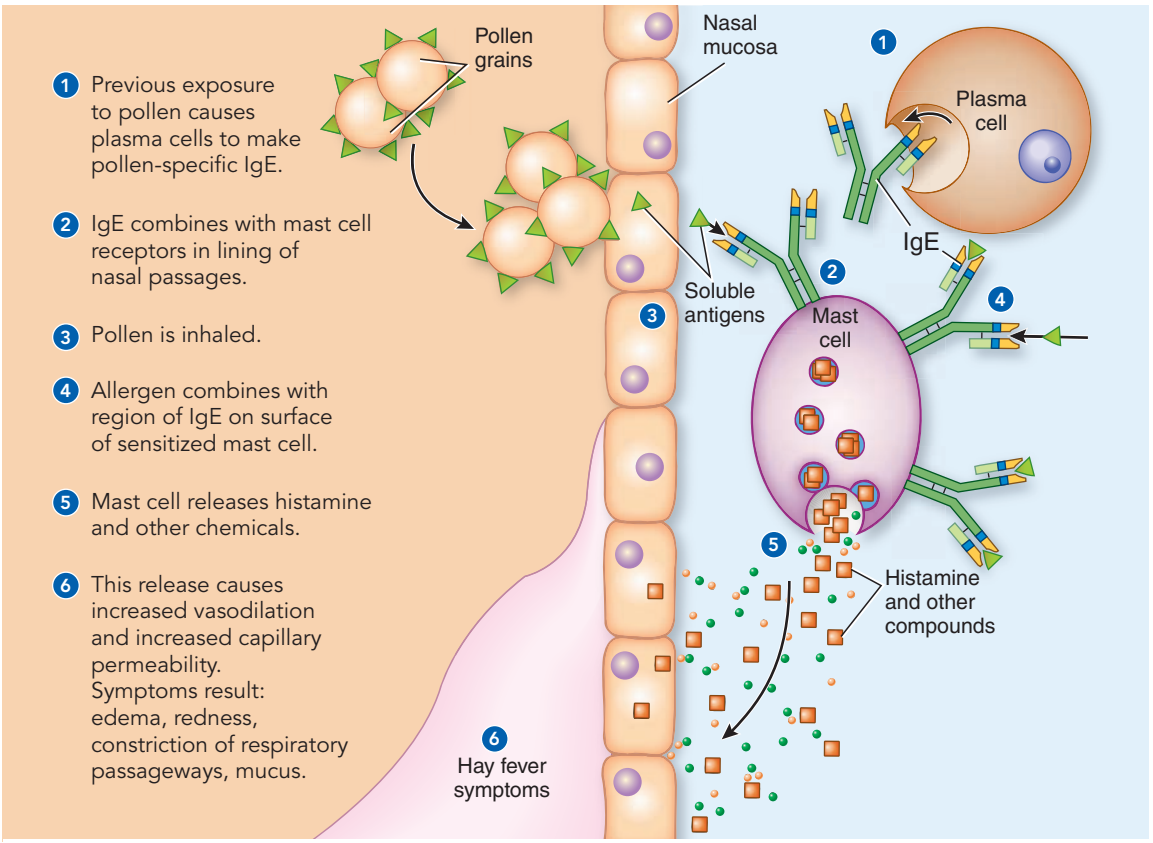

Figure 45-17 An allergic reaction

Many people respond to breathing pollen by exhibiting symptoms of allergic rhinitis (hay fever), a common type of allergic reaction.

When a sensitized, allergic person inhales the microscopic pollen, allergen molecules rapidly attach to the IgE on sensitized mast cells. The IgE antibody then binds with the allergen. In response, mast cells release granules filled with histamine and other molecules that stimulate inflammation. Blood vessels dilate, and capillaries become more permeable, leading to edema and redness. Such responses cause the nasal passages to become swollen and irritated. A runny nose, sneezing, watery eyes, and a general feeling of discomfort are common.

A prolonged allergic response occurs when neutrophils are attracted by chemical compounds released by the mast cells. Neutrophils migrate to the inflamed area and release compounds that lengthen the allergic reaction.

In **allergic asthma**, an allergen–IgE response occurs in the bronchioles of the lungs. Mast cells release substances that cause smooth muscle to contract, and the airways in the lungs sometimes constrict for several hours, making breathing difficult. Mast cells also secrete compounds that cause inflammation. Allergic asthma is treated with steroids, which block cytokine production and reduce inflammation. Monoclonal antibodies to IgE are also useful in treating allergic asthma because they reduce IgE levels in the blood.

Certain foods or drugs act as allergens in some people, causing a reaction in the walls of the digestive tract that leads to discomfort and diarrhea. When allergens are absorbed, they can cause mast cells to release granules elsewhere in the body. When the allergen–IgE reaction takes place in the skin, the histamine released by mast cells causes the swollen red welts known as urticaria, or hives.

Systemic anaphylaxis is a dangerous allergic reaction that can occur when a person develops an allergy to a specific drug, such as penicillin; to compounds in the venom injected by a stinging insect; or even to certain foods. Within minutes after the substance enters the body, a widespread allergic reaction takes place. Mast cells release large amounts of histamine and other compounds into the circulation, causing extreme vasodilation and capillary permeability. So much plasma may be lost from the blood that circulatory shock and death can occur within a few minutes. Epinephrine (adrenaline) must be rapidly injected to reverse anaphylactic symptoms.

The symptoms of allergic reactions are often treated with corticosteroids and antihistamines, drugs that block the effects of histamine. These drugs compete for the same receptors on cells targeted by histamine. When the antihistamine combines with the receptor, it blocks the histamine from binding, thus preventing its harmful effects. Antihistamines are useful clinically in relieving the symptoms of hives and hay fever. They are not completely effective because mast cells release molecules other than histamine that also cause allergic symptoms.

Graft rejection is an immune response against transplanted tissue

Skin can be successfully transplanted from one part of the same body to another or from one identical twin to another. However, when skin is taken from one person and grafted onto the body of a non-twin, it is rejected and sloughs off. Why? Recall that tissues from the same individual or from identical twins have identical HLA alleles and thus the same HLA antigens. Such tissues are compatible. Because there are many alleles for each of the HLA genes, it is difficult to find identical matches among individuals who are not identical twins.

When a tissue or organ is taken from a donor and transplanted to the body of another person, several of the HLA antigens are likely to be different. The recipient's immune system regards the graft as foreign and launches an immune response known as **graft rejection**. In the first stage of rejection, the *sensitization stage*, T_H cells and T_C cells recognize the foreign antigens. In the second stage, the *effector stage*, T_C cells, the complement system, and cytokines secreted by T_H cells attack the transplanted tissue and can destroy it within a week. The sequence of events in graft rejection can be summarized as follows:

tissue from donor transplanted into body of recipient → T_H cells and T_C cells recognize HLA antigens on transplant cells as foreign → T_H cells secrete cytokines, complement system is activated, and T_C cells destroy transplant cells

To avoid graft rejection, tissues from the patient and from potential donors must be typed and matched as closely as possible. Cell typing is somewhat similar to blood typing but is more complex. If all the HLA antigens are matched, the graft has about a 95% chance of surviving the first year. Unfortunately, not many people are lucky enough to have an identical twin to supply spare parts, so perfect matches are difficult to find. Furthermore, some organs, such as the heart, cannot be spared. Most transplanted organs therefore come from unrelated donors, often from patients who have just died.

To prevent graft rejection in less compatible matches, physicians use antirejection drugs such as cyclosporine to suppress the immune system. Cyclosporine prevents T cells from producing cytokines. Unfortunately, immunosuppression makes the transplant patient more vulnerable to pneumonia or other infections and increases the risk of certain types of cancer. After the first few months, immunosuppressant drug dosages may be reduced. Researchers are working to develop more effective immunosuppression techniques involving gene therapy and CRISPR/Cas9 technology.

In the United States, thousands of patients are in need of organ transplants. Because the number of human donors does not meet this need, investigators are developing techniques for culturing stem cells as replacement tissues. Current research is promising for successful human tissue and organ replacement in the future using a patient's own stem cells. Medical engineers also continue to develop effective artificial organs.

Some researchers are working on more effective methods for transplanting animal tissues and organs to humans. Other investigators plan to introduce human stem cells into animal embryos in order to produce human organs in animals. These organs would eventually be harvested and implanted in humans.

The body has a few immunologically privileged locations where foreign tissue is accepted. For example, corneal transplants are highly successful because the cornea has almost no associated blood or lymphatic vessels and is thus out of reach of most lymphocytes. Furthermore, antigens in the corneal graft probably would not find their way into the circulatory system and therefore could not stimulate an immune response.

CHECKPOINT 45.6

- How do cancer cells evade the immune system?
- How does HIV infect the body? How does the immune system respond?
- How does an autoimmune disease develop?
- **VISUALIZE** Draw the sequence of immunological events that take place in a common type of allergic reaction, such as hay fever.
- **CONNECT** What is the immunological basis for graft rejection?

Summary: Focus on Learning Objectives

45.1 Evolution of Immune Responses *(page 963)*

1 Distinguish between innate and adaptive immunity.

- The **immune system** is the internal defense system; it consists of the cells and molecules that recognize foreign or dangerous macromolecules and respond to eliminate them. **Immune responses** are the body's defensive responses against foreign macromolecules, including **pathogens** (disease-causing organisms), cancer cells, toxins, and other harmful agents.
- **Innate immunity** provides general and immediate protection against foreign macromolecules, including pathogens, some toxins and drugs, and cancer cells.
- **Adaptive immunity** targets distinct **antigens**, molecules recognized as foreign or dangerous by cells of the immune system. The adaptive immune system produces **antibodies**, highly specific proteins that recognize and bind to specific antigens.
- Another defining feature of adaptive immunity is **immunological memory**; that is, the system "remembers" foreign or dangerous molecules and responds more strongly to repeated encounters with the same molecules.

2 Compare, in general terms, the immune responses that have evolved in invertebrates and vertebrates.

- Invertebrates depend mainly on innate immune responses, such as physical barriers; **phagocytosis** (engulfing and destroying pathogens); receptors that recognize molecular patterns associated with pathogens; and **antimicrobial peptides** (soluble molecules that destroy pathogens).
- Vertebrates use both innate and adaptive immune responses.

45.2 Innate Immune Responses in Vertebrates *(page 965)*

3 Describe innate immune responses, including physical barriers; recognition by pattern recognition receptors; actions of phagocytes and other cells; actions of cytokines and complement; and the inflammatory response.

- Innate immune responses include physical barriers, such as the skin and the epithelial linings of the respiratory and digestive tracts. Antimicrobial peptides are produced by epithelial membranes.
- When pathogens break through the first-line defenses, **pathogen-associated molecular patterns**, or **PAMPs**, bind with **pattern recognition receptors (PRRs)**; this binding activates other innate defenses. PAMPs are sets of common molecular features that are characteristic of each class of pathogen. The best known pattern recognition receptors are **Toll-like receptors**, receptors on phagocytes and certain other types of cells.
- *Phagocytes*, including **neutrophils** and **macrophages**, destroy bacteria. **Natural killer (NK) cells** destroy cells infected with viruses and foreign or altered cells such as tumor cells. **Dendritic cells** release antiviral proteins called **interferons**.
- **Cytokines** are signaling proteins that regulate interactions between cells. Important groups include interferons, tumor necrosis factors, interleukins, and chemokines. Interferons inhibit viral replication and activate natural killer cells. **Tumor necrosis factor (TNF)** stimulates immune cells to initiate an inflammatory response. **Interleukins** help regulate interactions between lymphocytes and other cells of the body, help mediate inflammation, and can mediate fever. *Chemokines* attract, activate, and direct the movement of certain cells of the immune system.
- **Complement** proteins lyse the cell walls of pathogens; coat pathogens, thereby enhancing phagocytosis; and attract white blood cells to the site of infection. These actions enhance the inflammatory response.
- When pathogens invade tissues, they trigger an **inflammatory response**, which includes three main processes: vasodilation, which brings more blood to the area of infection; increased capillary permeability, which allows fluid and antibodies to leave the circulation and enter the tissues; and increased phagocytosis. In response to infection, **mast cells** release **histamine** and other compounds that cause vasodilation and increased capillary permeability.

45.3 Adaptive Immune Responses in Vertebrates *(page 969)*

4 Contrast cell-mediated and antibody-mediated immunity and give an overview of each process.

- In **cell-mediated immunity**, specific T cells are activated; T cells release proteins that destroy cells infected with viruses or other intracellular pathogens.
- In **antibody-mediated immunity**, specific B cells are activated; B cells multiply and differentiate into plasma cells, which produce antibodies.

5 Describe the functions of the specialized cells of the adaptive immune system and of the major histocompatibility complex.

- Two main types of cells important in adaptive immune responses are lymphocytes and antigen-presenting cells. Lymphocytes develop from stem cells in the bone marrow. **T cells** are lymphocytes responsible for cell-mediated immunity. The **thymus gland** confers immunocompetence on T cells by making them capable of distinguishing between self and nonself. The types of T cells include **T cytotoxic cells (T_C cells)**, **T helper cells (T_H)**, **memory T_C cells, memory T_H cells**, and **regulatory T cells (T_{regs})**. T cells are distinguished by their **T-cell receptors (TCRs)**.
- **B cells** are lymphocytes responsible for antibody-mediated immunity. B cells differentiate into **plasma cells**, which produce antibodies. Some activated B cells become **memory B cells**, which continue to produce antibodies after the body overcomes the infection.
- **Antigen-presenting cells (APCs)**, including dendritic cells, macrophages, and B cells, display foreign antigens as

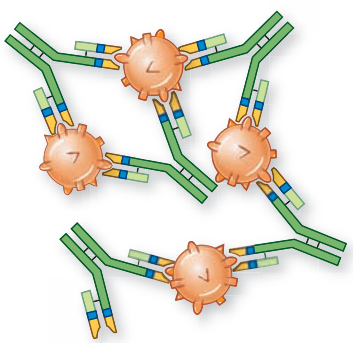
well as their own surface proteins. Dendritic cells are specialized to process, transport, and present antigens.

- Immune responses depend on the **major histocompatibility complex (MHC)**, a group of genes that encode MHC proteins. In humans the MHC is called the **human leukocyte antigen complex (HLA)**.

45.4 Cell-Mediated Immunity *(page 972)*

6 Describe the sequence of events in cell-mediated immunity.

- In cell-mediated immunity, specific T cells are activated by a foreign antigen–MHC complex on the surface of an infected cell. A *co-stimulatory molecule* and interleukins are also required.
- Activated T_C cells multiply and give rise to a clone, a process called **clonal expansion**. These differentiated cells migrate to the site of infection and destroy pathogen-infected cells. Activated T_H cells give rise to a clone of T_H cells, which secrete cytokines that activate B cells and macrophages.



45.5 Antibody-Mediated Immunity *(page 973)*

7 Summarize the sequence of events in antibody-mediated immunity, including the effects of antigen–antibody complexes on pathogens.

- In antibody-mediated immunity, B cells are activated when they combine with antigen. Activation requires both an APC (such as a dendritic cell or macrophage) that has a foreign antigen–MHC complex displayed on its surface and a T_H cell that secretes interleukins.
- When activated B cells multiply, they give rise to clones of cells. The cloned cells differentiate and form plasma cells. Plasma cells produce specific antibodies, called **immunoglobulins (Ig)**, in response to the specific antigens that activated them.
- An antibody combines with a specific antigen to form an *antigen–antibody complex*, which may inactivate the pathogen, stimulate phagocytosis, or activate the complement system.

8 Describe the basic structure and function of an antibody and explain the basis of antibody diversity.

- An antibody molecule consists of four polypeptide chains: two identical heavy chains and two shorter light chains. Each chain has a *constant (C) region* and a *variable (V) region*. In a Y-shaped antibody, the two arms combine with antigen.

- Rearrangement of DNA segments during the differentiation of B cells is the main factor responsible for antibody diversity; millions of different types of B (and T) cells are produced.

9 Describe the basis of immunological memory and contrast secondary and primary immune responses.

- After an infection, memory B cells and memory T cells remain in the body. These cells are responsible for long-term immunity.
- The first exposure to an antigen stimulates a **primary immune response**. A second exposure to the same antigen evokes a **secondary immune response**, which is more rapid and more intense than the primary response.

10 Compare active and passive immunity, and give examples of each.

- **Active immunity** develops as a result of exposure to antigens; it may occur naturally after recovery from a disease or can be artificially induced by immunization with a vaccine.
- **Passive immunity** is a temporary condition that develops when an individual receives antibodies produced by another person or animal.

45.6 Response to Disease, Immune Failures, and Harmful Reactions *(page 980)*

11 Describe the body's response to cancer cells and HIV.

- NK cells, macrophages, T cells, and other cells of the immune system recognize antigens on cancer cells and launch an immune response against them. Cancer cells evade the immune system by blocking T_C directly or by decreasing the class I MHC molecules on T_C cells.
- **Acquired immunodeficiency syndrome (AIDS)** is caused by the **human immunodeficiency virus (HIV)**, a retrovirus. HIV destroys T helper cells, severely impairing immunity and placing the patient at risk for opportunistic infections.

12 Describe examples of hypersensitivity, including autoimmune diseases, Rh incompatibility, and allergic reactions, and summarize the immunological basis of graft rejection.

- In **autoimmune diseases**, the body reacts immunologically against its own tissues.
- When an Rh-negative woman gives birth to an Rh-positive baby, she may develop anti-D antibodies. Rh incompatibility can then occur in future pregnancies.
- In an *allergic reaction*, an **allergen** stimulates the production of IgE, which combines with receptors on mast cells. The mast cells release histamine and other molecules that cause inflammation and other symptoms of allergy. **Systemic anaphylaxis** is a rapid, widespread allergic reaction that can lead to death.
- Transplanted tissues have HLA antigens that stimulate **graft rejection**, an immune response in which T cells destroy the transplant.

Test Your Understanding

Know and Comprehend

1. Innate immune responses include all but (a) inflammation (b) antigen–antibody complexes (c) binding of PAMPs with pattern recognition receptors (d) complement (e) phagocytosis
2. Cytokines (a) are regulatory Toll-like receptors (b) prevent the inflammatory response (c) include interferons and interleukins (d) are immunoglobulins (e) b and c are correct
3. Which of the following is *not* an action of complement? (a) enhances phagocytosis (b) enhances inflammatory response (c) coats pathogens (d) lyses viruses (e) stimulates production of memory T cells
4. Which of the following cells are antigen-presenting cells? (a) NK cells and monocytes (b) macrophages and plasma cells (c) dendritic cells and macrophages (d) mast cells and B cells (e) memory T cells and plasma cells
5. Which of the following cells are especially adept at destroying tumor cells? (a) NK cells (b) plasma cells (c) neutrophils (d) B cytotoxic cells (e) mast cells
6. The major histocompatibility complex (MHC) (a) consists of Y-shaped molecules (b) encodes certain antibodies (c) encodes Toll-like receptors (d) inhibits complement release from macrophages (e) encodes a group of cell-surface proteins.
7. Immunoglobulin A (a) recognizes pathogen-associated molecular patterns (b) binds with NK cells (c) prevents pathogens from attaching to epithelial surfaces (d) is found mainly on dendritic cell surfaces (e) is found mainly on T-cell surfaces
8. When a person is exposed to the same antigen a second time, the response is (a) less specific than the first time (b) more rapid than the first time (c) mediated by dendritic cells (d) likely to lead to development of an autoimmune disease (e) a hypersensitivity reaction
9. In an allergic reaction, (a) an allergen binds with IgE (b) the body is immunodeficient (c) T helper cells release histamine (d) allergens are produced by plasma cells (e) mast cells are deactivated

Apply and Analyze

10. Which sequence most accurately describes antibody-mediated immunity? 1. B cell divides and gives rise to clone 2. antibodies produced 3. cells differentiate and form plasma cells 4. activated T helper cell interacts with B cell displaying same antigen complex 5. B cell activated (a) 1, 2, 3, 4, 5 (b) 3, 2, 1, 4, 5 (c) 4, 5, 3, 2, 1 (d) 4, 5, 1, 3, 2 (e) 4, 3, 1, 2, 5
11. **VISUALIZE** Label the following diagram and explain what this diagram illustrates.

12. Specificity, diversity, and memory are key features of the immune system. Giving specific examples, explain how each of these features is important.
13. **PREDICT** What would be the effects of a significant reduction of macrophages in the body? Which do you think would have a greater effect on the immune system: significant decrease of macrophages or of memory B cells?
14. **PREDICT** A playmate in kindergarten exposes John and Jack to measles. John has been immunized against measles, but Jack has not received the measles vaccine. How are their immune responses different? Five years later, John and Jack are playing together when Judy, who is coming down with measles, sneezes on both of them. Is it probable that either John or Jack will become ill with measles?

Evaluate and Synthesize

15. **EVOLUTION LINK** The enzymes Rag1 and Rag2 cut and rearrange DNA, producing millions of specific antibodies and T-cell receptors. Immunologists thought that the genes (*Rag1* and *Rag2*) that encode these enzymes were found only in jawed vertebrates. However, investigators have found similar genes in the purple sea urchin. What does this finding suggest about the evolution of the adaptive immune system?
16. **SCIENCE, TECHNOLOGY, AND SOCIETY** Imagine that you are a researcher developing new HIV treatments. What approaches might you take? What public policy decisions would you recommend that might help slow the spread of HIV while new treatments or vaccines are being developed? What role might technology play in slowing the spread of HIV?

46 Gas Exchange

To stay alive, animals must take in oxygen and release excess carbon dioxide. Most animal cells require a continuous supply of oxygen for cellular respiration. Brain cells may be seriously damaged if their oxygen supply is cut off for only a few minutes. The exchange of gases between an organism and its environment is called **respiration**.

There are two phases of respiration. During **organismic respiration**, oxygen from the environment is taken up by the animal and delivered to its individual cells. At the same time, carbon dioxide generated during *cellular respiration* is excreted into the environment. **Aerobic cellular respiration** takes place in mitochondria. Oxygen is essential because it serves as the final electron acceptor in the mitochondrial electron transport chain (see Chapter 8). Recall that carbon dioxide is a metabolic waste product of cellular respiration.

Sponges, hydras, flatworms, and many other small, aquatic organisms exchange gases entirely by simple diffusion. Recall that **diffusion** is the passive movement of particles (atoms, ions, or molecules) from a region of higher concentration of a particular kind of particle to a region of lower concentration of that particle, that is, down its concentration gradient (see Chapter 5). In these animals most cells are in direct contact with the environment. Dissolved oxygen from the surrounding water diffuses into the cells, while carbon dioxide diffuses out of the cells and into the water. No specialized respiratory structures are needed.

In an animal more than about 1 mm thick, oxygen cannot diffuse quickly enough through the layers of cells to support life. Specialized respiratory structures, such as gills or lungs, deliver oxygen to the cells or to a transport system. These structures also facilitate excretion

KEY CONCEPTS

46.1 Air has a higher concentration of molecular oxygen than water does, and animals require less energy to move air than to move water over a gas exchange surface; however, animals that respire in air must have adaptations that reduce water loss so that their respiratory surfaces do not dry out.

46.2 Adaptations for gas exchange include a thin, moist body surface; gills in aquatic animals; and tracheal tubes and lungs in terrestrial animals.

46.3 In mammals, oxygen and carbon dioxide are exchanged between alveoli and blood by diffusion; the pressure of a particular gas determines its direction and rate of diffusion. Respiratory pigments combine with oxygen and transport it; carbon dioxide is transported mainly as bicarbonate ions.

46.4 Several defense mechanisms protect the lungs from harmful substances that are inhaled; tobacco smoke and other air pollutants are major causes of disease, disability, and death.

PHOTO: **Elephant seal (*Mirounga leonina*) releasing its warm breath into freezing air.** The water vapor in the exhaled air condenses into liquid water and ice; it can be seen as a small cloud. Photographed at Gold Bay, South Georgia Island, Antarctic Ocean, Antarctica. John Bryant/Getty Images

of carbon dioxide. Lungs are an adaptation for gas exchange in terrestrial environments (see photograph).

In many animal groups, including vertebrates, respiratory systems and circulatory systems are functionally connected. They work together to provide efficient intake and transport of oxygen. Such systems provide sufficient oxygen to support high metabolic rates. As we will discuss, different strategies for gas exchange have evolved in the arthropods.

In this chapter we will examine adaptations for gas exchange in air and water and describe various types of respiratory surfaces. We will then focus on the structure and function of the mammalian respiratory system. We end the chapter with a discussion of the effects of breathing polluted air, including cigarette smoke.

46.1 Adaptations for Gas Exchange in Air or Water

LEARNING OBJECTIVE

1 Compare the advantages and disadvantages of air and water as mediums for gas exchange and describe adaptations for gas exchange in air.

Gas exchange in air has certain advantages over gas exchange in water. Air contains a much higher concentration of molecular oxygen (at least 20 times more) than water does. In addition, oxygen diffuses about 10,000 times faster through air than through water. Another advantage is that less energy is needed to move air than to move water over a gas exchange surface because air is less dense and less viscous. A mammal uses less than 2% of its energy budget to breathe compared to a fish, which must spend as much as 20% of its energy to obtain its oxygen from water.

Gas exchange in air presents a major challenge: the threat of desiccation (becoming extremely dry). Animals that respire in air struggle continuously with water loss. Respiratory surfaces must be kept moist because oxygen and carbon dioxide are dissolved in the fluid that bathes the cells of these surfaces. Whether an animal makes its home on land or water, gas exchange takes place across a moist surface.

Adaptations have evolved that keep respiratory surfaces moist and minimize desiccation. For example, the lungs of air-breathing vertebrates are located deep within the body, not exposed as gills are. Air is humidified and brought to body temperature as it passes through the moist upper respiratory passageways. Expired air must again pass through these airways (providing opportunity for retaining water) before leaving the body. These adaptations protect the lungs from the drying and cooling effects of air.

CHECKPOINT 46.1

- What are some advantages of gas exchange in air over gas exchange in water?

46.2 Types of Respiratory Surfaces

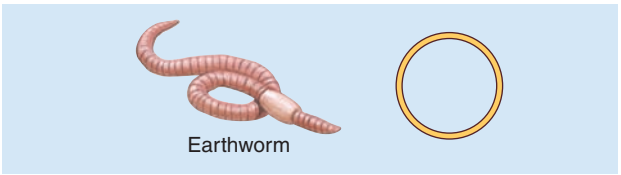
LEARNING OBJECTIVE

2 Describe the following adaptations for gas exchange: body surface, tracheal tubes, gills, and lungs.

Respiratory structures must be moist and must also have thin walls through which diffusion can easily occur. Four main types of respiratory surfaces have evolved in animals: the animal's own body surface, tracheal tubes, gills, and lungs (FIG. 46-1). Some animals use a combination of these adaptations. Gills are adapted for gas exchange in water, and the tracheal tubes of insects and lungs of vertebrates are respiratory structures adapted for gas exchange in air. With the important exception of insect tracheal tubes, respiratory structures are richly supplied with blood vessels that facilitate exchange and transport of respiratory gases.

Most animals carry on **ventilation**; that is, they actively move air or water over their respiratory surfaces. If the air or water supplying oxygen to the cells can be continuously renewed, more oxygen will be available. Sponges use their flagella to set up a current of water through the channels of their bodies. Most fishes gulp water, which then passes over their gills. Terrestrial vertebrates have lungs and breathe air. When mammals breathe, the diaphragm and other muscles move air in and out of the lungs.

The body surface may be adapted for gas exchange



Gas exchange occurs through the entire body surface in many animals, including nudibranch mollusks, most annelids, and some amphibians. These animals are small, with a high ratio of surface area to volume. They also have a low metabolic rate that requires smaller quantities of oxygen per cell. In aquatic animals, the body surface is kept moist by the surrounding water. In some terrestrial animals, the body secretes fluids that keep its surface moist. Many animals that exchange gases across the body surface also have gills or lungs.

Tracheal tube systems deliver air directly to the cells

In insects and some other arthropods (such as centipedes and millipedes, some mites, and some spiders), the respiratory system is a network of **tracheal tubes**, also called **tracheae** (FIG. 46-2). This very efficient respiratory system delivers air directly to the cells. Air enters the tracheal tubes through a series of as many as 20 tiny openings called **spiracles** along the body surface. In some insects, especially large, active ones, muscles help ventilate the tracheae by pumping air in and out of the spiracles. For example, the grasshopper draws air in through the first four pairs of spiracles when the abdomen expands. Then the abdomen contracts, forcing air out through the last six pairs of spiracles.

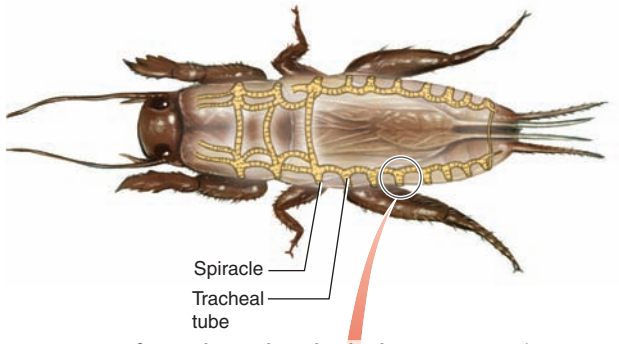
(a) Body surface. Some small, multicellular animals exchange gases through the body surface.

(b) Tracheal tubes. Insects and some other arthropods exchange gases through a system of tracheal tubes, or tracheae.

(c) Gills. Most aquatic animals exchange gases through gills, thin structures that extend from the body surface. Gills can be internal or external.



(d) Lungs. Lungs are adaptations for gas exchange in terrestrial habitats.

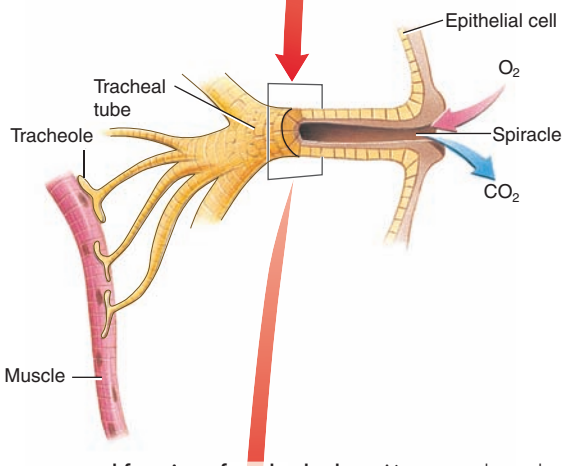


Figure 46-1 Adaptations for gas exchange

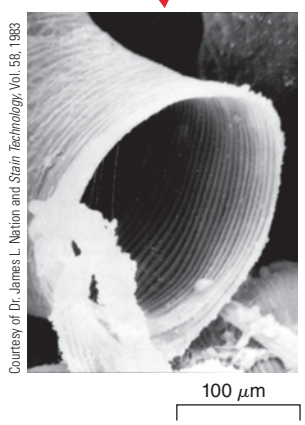
Key Point



The efficient tracheal tube system of insects delivers air directly to the cells.

(a) Location of spiracles and tracheal tubes. Air enters the system of tracheal tubes through openings called spiracles.

(b) Structure and function of tracheal tubes. Air passes through a system of branching tracheal tubes that conduct oxygen to all cells of the insect.

(c) SEM of a mole cricket trachea. Rings of chitin reinforce the tubes of the tracheal system, preventing their collapse.

Figure 46-2 Gas exchange in insects: tracheal tubes

CONNECT In contrast to vertebrate gas exchange, blood does not play an essential role in insect gas exchange. Why?

Once inside the body, the air passes through a system of branching tracheal tubes, which extend to all parts of the animal. The tracheal tubes terminate in microscopic, fluid-filled tracheoles. Gases are exchanged between this fluid and the body cells. The tracheal system supplies enough oxygen to support the high metabolic rates required by many insects.

Gills are the respiratory surfaces in many aquatic animals

Found mainly in aquatic animals, **gills** are moist, thin structures that extend outward from the body surface. They are supported by the buoyancy of water but tend to collapse in air. In many animals, the outer surface of the gills is exposed to water, whereas the inner side is in close contact with networks of blood vessels.

Sea stars and sea urchins have *dermal gills* that project from the body wall. Their ciliated epidermal cells ventilate the gills by beating a stream of water over them. Gases are exchanged between the water and the fluid inside the coelom by diffusion through the gills.

Various types of gills are found in some annelids, aquatic mollusks, crustaceans, fishes, and amphibians. Mollusk gills are folded, providing a large surface for respiration. In clams and other bivalve mollusks and in simple chordates, gills may also be adapted for trapping and sorting food. The rhythmic beating of cilia draws water over the gill area, and food is filtered out of the water while gases are exchanged. In mollusks, gas exchange also takes place through the mantle.

In chordates, gills are usually internal. A series of slits perforates the pharynx, and the gills lie along the edges of these gill slits (see Fig. 32-4). In bony fishes, the fragile gills are protected by an external bony plate, the **operculum**. In some fishes, movements of the jaw and operculum help pump water rich in oxygen through the mouth and across the gills. The water leaves through the gill slits.

Each gill in the bony fish consists of many *gill filaments*, which provide an extensive surface for gas exchange (FIGS. 46-3a and b). The filaments extend out into the water, which continuously flows over them. A capillary network delivers blood to the gill filaments, facilitating diffusion of oxygen and carbon dioxide between blood and water. This system is extremely efficient because blood flows in a direction opposite to the movement of the water. This arrangement, called a **countercurrent exchange system**, maximizes the difference in oxygen concentration between blood and water throughout the area where the two remain in contact (FIG. 46-3c).

If blood and water flowed in the *same* direction—that is, *concurrent exchange*—the difference between the oxygen concentrations in blood (low) and water (high) would be very large initially and then very small at the end (FIG. 46-3d). The oxygen concentration in the water would decrease as the concentration in the blood increased. When the concentrations in the two fluids became equal, equilibrium would be reached, and the net diffusion of oxygen would stop. Only about 50% of the oxygen dissolved in the water could diffuse into the blood.

In the countercurrent exchange system, however, blood low in oxygen comes in contact with water that is partly depleted of oxygen. Then, as the blood flowing through the capillaries becomes progressively richer in oxygen, the blood comes in contact with water with an increasingly higher concentration of oxygen. Thus, all along the capillaries, the diffusion gradient favors passage of oxygen from the water into the gill. A high rate of diffusion is maintained, ensuring that a very high percentage (more than 80%) of the available oxygen in the water diffuses into the blood.

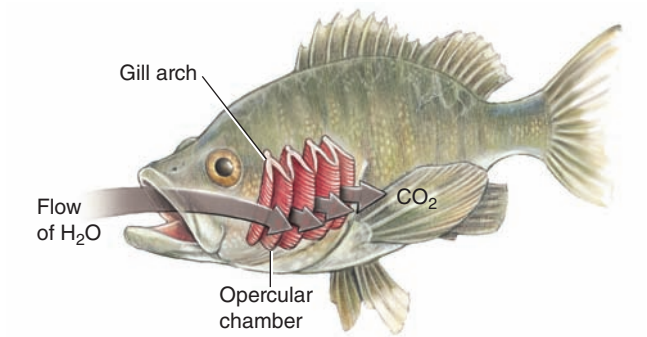
Oxygen and carbon dioxide do not interfere with each other's diffusion, and they simultaneously diffuse in opposite directions. The reason is that oxygen is more concentrated outside the gills than inside but carbon dioxide is more concentrated inside the gills than outside. Thus, the same countercurrent exchange mechanism that ensures efficient inflow of oxygen also results in equally efficient outflow of carbon dioxide.

Terrestrial vertebrates exchange gases through lungs

Lungs are respiratory structures that develop as ingrowths of the body surface or from the wall of a body cavity such as the pharynx (throat region). For example, the *book lungs* of spiders are enclosed in an inpocketing of the abdominal wall. These lungs consist of a series of thin, parallel plates of tissue (like the pages of a book) filled with hemolymph (see Fig. 46-1d). The plates of tissue are separated by air spaces that receive oxygen from the outside environment through a spiracle. A different type of lung evolved in land snails and slugs. (These terrestrial mollusks lack gills.) Gas exchange takes place through a lung, which is a vascular region of the mantle.

Fossil evidence suggests that early lobe-finned fishes had lungs somewhat similar to those of modern lungfishes. The Australian lungfish can use either its gills or its lungs, depending on the conditions in its environment. The gills of African and South American lungfishes degenerate with age, so adults must rise to the surface and exchange gases entirely through their lungs. Some paleontologists hypothesize that all early bony fishes had lungs or lunglike structures. Most modern bony fishes have no lungs, but nearly all have homologous **swim bladders** (see Chapter 32). By adjusting the amount of gas in its swim bladder, the fish can control its buoyancy.

Most amphibians have lungs (FIG. 46-4). However, most of their gas exchange takes place across the body surface. The lungs of salamanders are two long, simple sacs richly supplied with capillaries. Frogs and toads have ridges containing connective tissue on the inside of the lungs, which increases the respiratory surface. Some amphibians do not have lungs. Among plethodontid (lungless) salamanders, for example, gas exchange takes place across the thin, wet skin and through the moist, vascular walls of the mouth and pharynx.



Non-avian reptile lungs are more developed than amphibian lungs. The respiratory surface of each lung is divided into large sacs that increase the surface for gas exchange. In some turtles, lizards, and crocodiles, the lungs have many subdivisions that give them a spongy texture. Non-avian reptiles ventilate their lungs by drawing air into the lungs, but the muscles

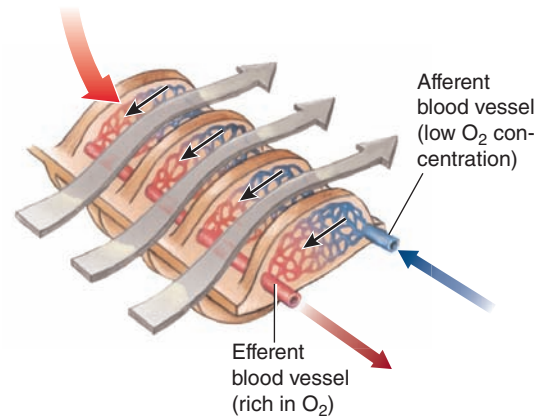
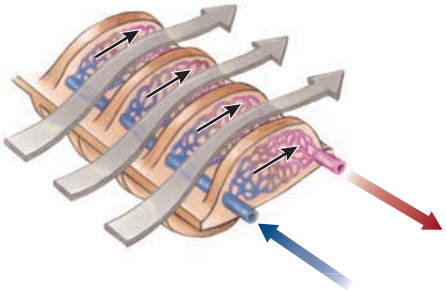
Key Point



Countercurrent flow efficiently oxygenates blood circulating through the gill filaments.



(a) Location of gills. The gills form the lateral wall of the pharyngeal cavity. They lie under a bony plate, the operculum, which has been removed in this side view.

(b) Structure of a gill. Each gill consists of a cartilaginous gill arch to which two rows of leaflike gill filaments attach. Each gill filament has many smaller extensions rich in capillaries. As water flows past the gill filament, oxygen passes from the water into blood circulating through the capillaries.

(c) Countercurrent flow. Blood entering the capillaries of the gill filament is deficient in oxygen. The blood flows through the capillaries in a direction opposite to that taken by the water. This countercurrent exchange system efficiently charges the blood with oxygen.

(d) Concurrent flow (hypothetical). If the system were concurrent—that is, if blood flowed through the capillaries in the same direction as the flow of the water—much less of the oxygen dissolved in the water could diffuse into the blood.

Bernard Photo Production / Animals Animals

PREDICT In what way would you expect the countercurrent mechanism to affect the removal of CO_2 from the blood?

involved differ in the various reptile groups. Gas exchange is not very efficient and does not supply enough oxygen to sustain long periods of activity.

Birds have the most efficient respiratory system of any living vertebrate. Very active, endothermic animals with high metabolic rates, birds require large amounts of oxygen to sustain flight and other activities. Their small, bright red lungs have extensions (usually nine) called *air sacs*, which reach into all parts of the body and even connect with air spaces in some of the bones. The air sacs act as bellows, drawing air into

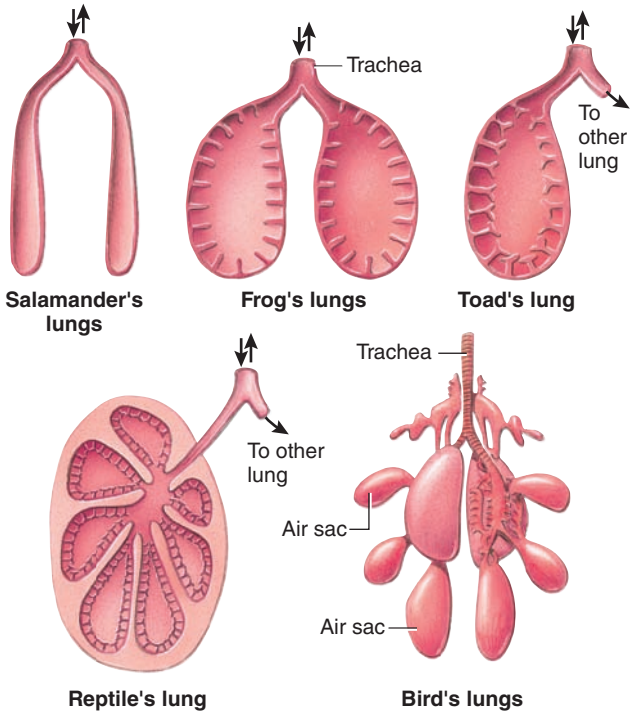

Figure 46-4 Evolution of vertebrate lungs

During vertebrate evolution, the surface area of the lung increased. Salamander lungs are simple sacs. Other amphibians and reptiles have lungs with small ridges or folds that increase surface area. Birds have an elaborate system of lungs and air sacs. Mammalian lungs have millions of air sacs (alveoli) that increase the surface available for gas exchange (see Fig. 46-7).

the system. Collapse of the air sacs during exhalation forces air out. In birds, gas exchange does not take place across the walls of the air sacs.

The high-performance bird respiratory system is arranged so that air flows in one direction through the lungs and is renewed during a two-cycle process (FIG. 46-5). Air entering the body passes into the posterior air sacs and the part of the lungs closest to these air sacs. The posterior air sacs are reservoirs for fresh air. When the bird exhales, that air flows into the lungs. At the second breath, the air flows from the lungs to the anterior air sacs. Finally, at the second exhalation, the air leaves the body as another breath of air enters the lungs. Thus, a bird gets fresh air across its lungs through both inhalation and exhalation.

In birds, the narrowest branches of the airway end in tiny, thin-walled tubes called **parabronchi**. In contrast to the saclike alveoli of mammals, parabronchi are open at both ends and air continuously flows through them. Gas exchange takes place across the walls of these tubes, which are rich in capillaries. Chickens and other weak-flying birds have about 400 parabronchi per lung; pigeons and other strong-flying birds have about 1800 parabronchi per lung.

The direction of blood flow in the lungs is in a different direction from that of airflow through the parabronchi. This arrangement, similar in principle to the countercurrent exchange in the gills of fishes, increases the amount of oxygen that enters the blood. However, in birds, the capillaries are oriented at right angles to the parabronchi rather than along their length. For this reason, this arrangement is referred to as *crosscurrent* rather than countercurrent.

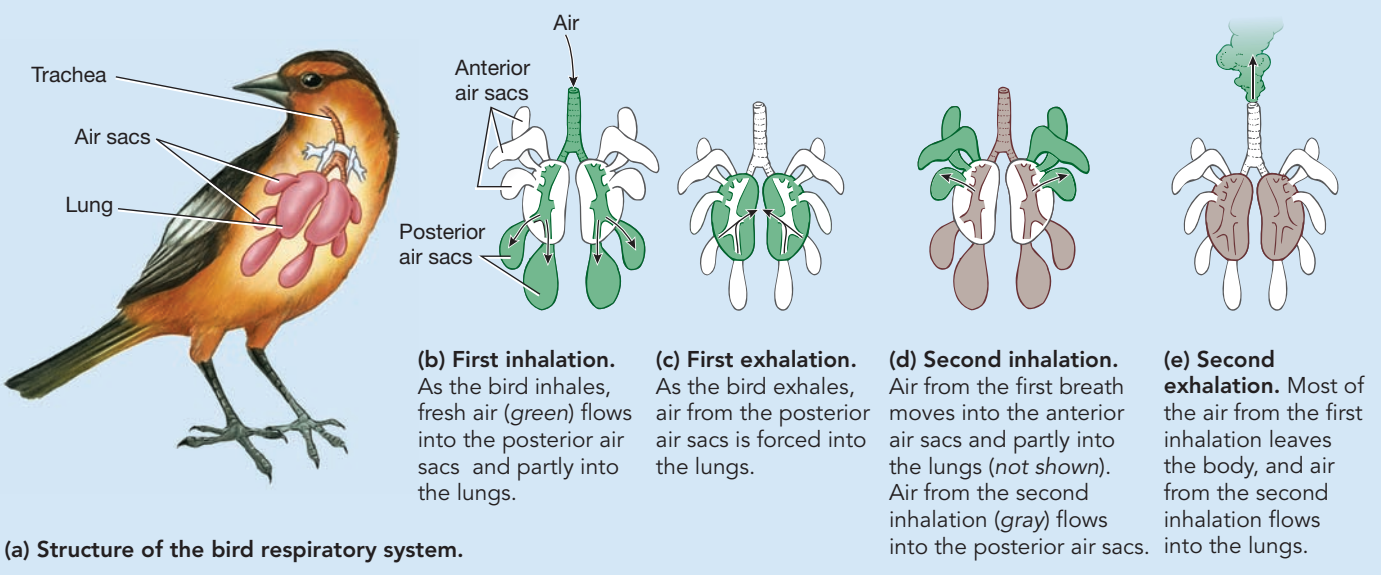

Figure 46-5 Gas exchange in birds

The bird respiratory system includes lungs and air sacs. The bird's breathing process requires two cycles of inhalation and exhalation to support a one-way flow of air through the lungs.

CHECKPOINT 46.2

- **CONNECT** Why are specialized respiratory structures necessary in a tadpole but not in a flatworm?
- How does gas exchange differ among the following animals: earthworm, grasshopper, fish, and bird?
- How does the countercurrent exchange system increase the efficiency of gas exchange between a fish's gills and blood?

46.3 The Mammalian Respiratory System

LEARNING OBJECTIVES

3 Trace the passage of oxygen through the human respiratory system from nostrils to alveoli.

4 Summarize the mechanics of breathing in humans and describe gas exchange in the lungs and tissues.

5 Summarize the mechanisms by which oxygen and carbon dioxide are transported in the blood and identify factors that determine the oxygen–hemoglobin dissociation curve.

6 Describe the regulation of breathing in humans and summarize the physiological effects of hyperventilation and of sudden decompression when a diver surfaces too quickly from deep water.

The respiratory system of mammals consists of the lungs and a series of tubes through which air passes on its journey from the nostrils to the lungs and back (FIG. 46-6). The lungs have an enormous surface area. As in all vertebrates, the respiratory and circulatory systems are functionally connected. The circulatory system delivers oxygen-rich blood to all the cells in the body. In the following sections, we focus mainly on the human respiratory system.

The airway conducts air into the lungs

A breath of air enters the body through the *nostrils* and flows through the *nasal cavities*. Air passing through the nose is filtered, moistened, and brought to body temperature. The nasal cavities are lined with a moist, ciliated epithelium rich in blood vessels. Inhaled dirt, bacteria, and other foreign particles are trapped in the stream of mucus produced by cells within the epithelium and pushed along toward the throat by the cilia. In this way, foreign particles are delivered to the digestive system, which can more effectively dispose of such materials than can the delicate lungs. We normally swallow more than a pint of nasal mucus each day, and even more during an infection or allergic reaction.

The back of the nasal cavities is continuous with the throat region, or **pharynx**. Air finds its way into the pharynx whether we breathe through the nose or mouth. An opening in the floor of the pharynx leads into the **larynx**. Because the larynx contains the vocal cords, it is also referred to as the "voice box." Cartilage embedded in its wall prevents the larynx from collapsing and makes it hard to the touch when felt through the neck.

During swallowing, a flap of tissue called the **epiglottis** automatically closes off the larynx so that food and liquid enter the esophagus rather than the lower airway. If this mechanism fails and foreign matter enters the sensitive larynx, a cough reflex expels the material. Despite these mechanisms, choking sometimes occurs.

From the larynx, air passes into the **trachea**, or windpipe, which is kept from collapsing by rings of cartilage in its wall. The trachea divides into two branches, the **bronchi** (sing., *bronchus*); one bronchus connects to each lung. Both trachea and bronchi are lined by a mucous membrane containing ciliated cells. These cells trap medium-sized particles that escape the cleansing mechanisms of the nose and larynx. Mucus containing these particles is constantly beaten upward by the cilia to the pharynx, where it is periodically swallowed. This mechanism, functioning as a cilia-propelled elevator of mucus, helps keep foreign material out of the lungs.

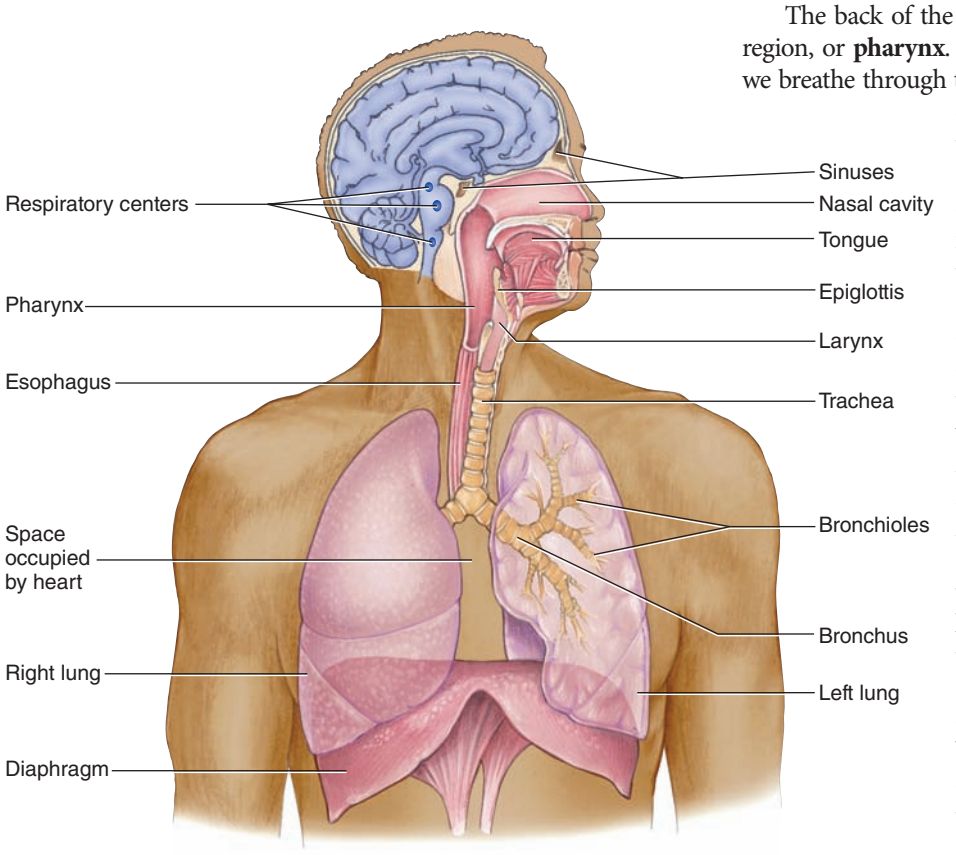

Figure 46-6 The human respiratory system
The internal view of one lung illustrates a small portion of its extensive system of air passageways. The muscular diaphragm forms the floor of the thoracic cavity. The respiratory centers in the brain (medulla and pons) regulate the rate of respiration.

Gas exchange occurs in the alveoli of the lungs

The lungs are large, paired, spongy organs occupying the *thoracic* (chest) cavity. The right lung is divided into three lobes, the left lung into two lobes. Each lung is covered with a **pleural membrane**, which forms a continuous sac that encloses the lung and extends outward to become the lining of the thoracic cavity. The *pleural cavity* is the space between the pleural membranes. A film of fluid in the pleural cavity provides lubrication between the lungs and the chest wall.

Because the lung consists largely of air tubes and elastic connective tissue, it is a spongy, elastic organ with a very large internal surface area for gas exchange. Within each lung the bronchi branch and become progressively shorter, narrower, and more numerous, similar to the branching of a tree. Small branches give rise to the even smaller **bronchioles** in each lung. Each bronchiole ends in a cluster of tiny air sacs, the **alveoli** (sing., *alveolus*) (FIG. 46-7). Each human lung contains more than 200 million alveoli, which provide an internal surface area the approximate size of a tennis court!

Each alveolus is lined by an extremely thin, single layer of epithelial cells. Gases diffuse freely through the wall of the alveolus and into the capillaries that surround it. Only two thin cell layers—the endothelium of the alveolar wall and the epithelium of the capillary wall—separate the air in the alveolus from the blood.

In summary, air passes through the following sequence of structures after it enters the body:

nostrils → nasal cavities → pharynx → larynx → trachea → bronchi → bronchioles → alveoli

Ventilation is accomplished by breathing

Breathing is the mechanical process of moving air from the environment into the lungs and of expelling air from the lungs. Inhaling air is called **inhalation** or *inspiration*; exhaling air is **exhalation** or *expiration*. The thoracic cavity is closed so that air can enter only through the trachea. (When the chest wall is punctured, for example, by a fractured rib or gunshot wound, air enters the pleural space and the lung collapses.)

During inhalation, the volume of the thoracic cavity is increased by the contraction of the **diaphragm**, the dome-shaped muscle that forms its floor. When the diaphragm contracts, it moves downward, increasing the volume of the thoracic cavity (FIG. 46-8). The lungs adhere to the walls of the thoracic cavity, so when the volume of the thoracic cavity increases, the space within each lung also increases. The air in the lungs now has more space in which to move about. As a result, air pressure in the lungs falls by 2 or 3 millimeters of mercury (mm Hg) below the air pressure outside the body. Because of this pressure difference, air from the outside rushes in through the respiratory passageways and fills the lungs until the two pressures are equal once again.

During deep or forced inhalation, the *external intercostal muscles* also contract, pulling the rib cage upward and outward. This action further increases the volume of the thoracic cavity, and more air moves into the lungs.

Exhalation occurs when the diaphragm relaxes. The volume of the thoracic cavity decreases, raising the pressure in the lungs to 2 to 3 mm Hg above atmospheric pressure. The millions of distended air sacs partially deflate and expel the inhaled air. The pressure then returns to normal, and the lung is ready for another inhalation. To summarize: during inhalation, the millions of alveoli fill with air like so many tiny balloons. Then, during exhalation, the air rushes out of the alveoli, partially deflating them.

During forced exhalation, muscles of the abdominal wall and the *internal intercostal muscles* contract, pushing the diaphragm up and the ribs down. This action decreases the volume of the thoracic cavity, pushing air out of the lungs.

Some of the work required to stretch the thorax and the lungs is necessary to stretch their elastic connective tissue. Work is also required to overcome the cohesive force of water molecules associated with the pleural membranes. The forces between the water molecules produce a surface tension that resists stretching.

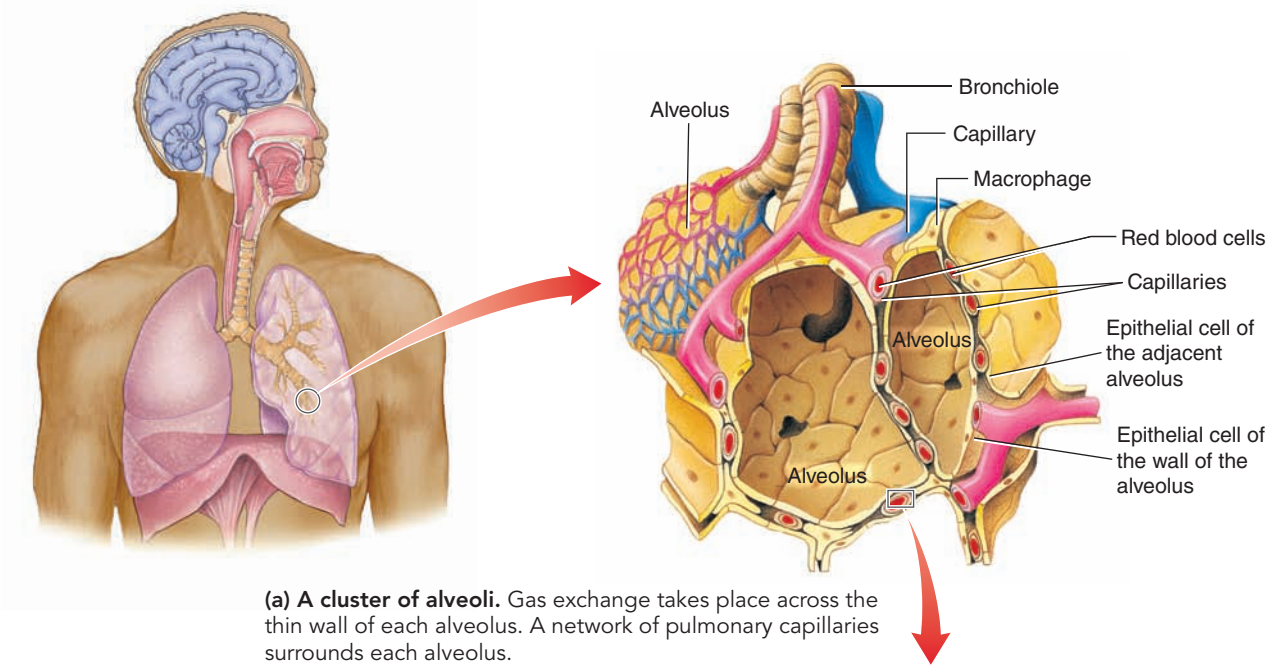
The work of breathing is reduced by *pulmonary surfactant*, a detergent-like phospholipid mixture secreted by specialized epithelial cells in the lining of the alveoli. Pulmonary surfactant intersperses between the water molecules, reducing their cohesive force. This action markedly reduces the surface tension of the water, prevents the alveoli from collapsing, and reduces the energy required to stretch the lungs. Premature infants often cannot produce enough surfactant, which causes respiratory distress syndrome. In these infants, high surface tension makes it difficult to inflate the lungs, and the alveoli collapse during expiration. Breathing is labored. Respiratory failure as a result of surfactant deficiency is a leading cause of morbidity and mortality in premature infants. Surfactant deficiency can be treated with surfactant replacement therapy in which artificial surfactant is delivered through the trachea.

The quantity of respired air can be measured

The amount of air moved into and out of the lungs with each normal resting breath is called the **tidal volume**. The normal tidal volume is about 500 mL. A great deal of stale air remains in the lungs during normal resting breathing. The volume of air that remains in the lungs at the end of a maximal expiration is the **residual volume** (about 1200 mL).

The **vital capacity** is the maximum amount of air a person can exhale after filling the lungs to the maximum extent (about 4500 mL). Vital capacity is a useful measure of the functional capacity of the lungs.

Gas exchange takes place in the alveoli



The respiratory system delivers oxygen to the alveoli, but if oxygen remained in the lungs, all the other body cells would soon die. The vital link between alveoli and body cells is the circulatory system. Clusters of pulmonary capillaries surround the alveoli, bringing blood close to the alveolar air. Each alveolus serves as a tiny depot from which oxygen diffuses into the blood (FIG. 46-9).

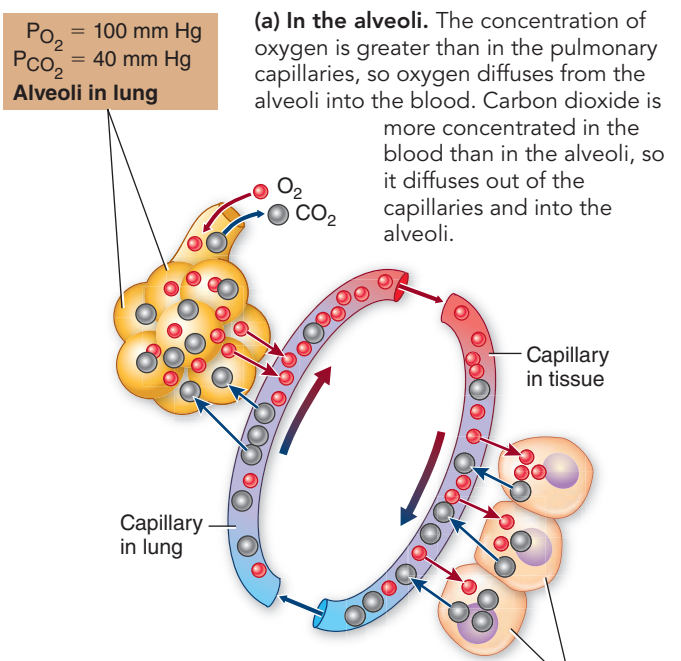
(a) Inhalation. The diaphragm contracts, increasing the volume of the thoracic cavity. Air moves into the lungs.

(b) Exhalation. The diaphragm relaxes, decreasing the volume of the thoracic cavity. Air moves out of the lungs.

(c) Forced inhalation. The external intercostal muscles contract, pulling the rib cage upward and outward. This action increases the front-to-back dimension of the chest and correspondingly increases the volume of the thoracic cavity.

(d) Forced exhalation. The internal intercostal muscles contract, pulling the rib cage downward and inward. The volume of the thoracic cavity decreases.

Figure 46-8 Mechanics of breathing
During inhalation and exhalation, the position of the diaphragm and of the external and internal intercostal muscles changes. These changes increase or decrease the volume of the thoracic cavity.



Oxygen molecules efficiently pass by simple diffusion from the alveoli, where they are more concentrated, into the blood in the pulmonary capillaries, where they are less concentrated. At the same time, carbon dioxide moves from the blood, where it is more concentrated, to the alveoli, where it is less concentrated. Each gas diffuses through the single layer of cells lining the alveoli and the single layer of cells lining the capillaries.

Recall that in aerobic respiration, oxygen is the final electron acceptor; it accepts two electrons, which are added to two protons to produce water (see Chapter 8). Inhaled (atmospheric) air contains about 20.9% oxygen, but because oxygen is used during cellular respiration, exhaled (alveolar) air contains only 14% oxygen. Carbon dioxide is produced during aerobic respiration. For this reason, exhaled air contains more than one hundred times as much (5.6%) carbon dioxide as inhaled air (about 0.04% carbon dioxide).

The concentration of oxygen in the cells is lower than in the capillaries entering the tissues, and the concentration of carbon dioxide is higher in the cells than in the capillaries. As blood circulates through capillaries of a tissue such as brain or muscle, oxygen moves by simple diffusion from the blood to the cells, and carbon dioxide moves from the cells into the blood.

The factor that determines the direction and rate of diffusion is the pressure or tension of the particular gas. According to *Dalton's law of partial pressures*, in a mixture of gases, the total pressure of the mixture is the sum of the pressures of the individual gases. Each gas exerts, independently of the others, a **partial pressure**, the same pressure it would exert if it were present alone. At sea level, the barometric pressure (the pressure of Earth's atmosphere) typically supports a column of mercury 760 mm high. Because oxygen makes up about 21% of the atmosphere, oxygen's share of that pressure is $0.21 \times 760 = 160$ mm Hg. Thus, 160 mm Hg is the partial pressure of atmospheric O_2, abbreviated P_{O_2}. In contrast, the partial pressure of atmospheric CO_2 is 0.23 mm Hg, abbreviated P_{CO_2}.

Fick's law of diffusion explains that the amount of oxygen or carbon dioxide that diffuses across the membrane of an alveolus depends both on the differences in partial pressure on the two sides of the membrane and on the surface area of

(a) In the alveoli. The concentration of oxygen is greater than in the pulmonary capillaries, so oxygen diffuses from the alveoli into the blood. Carbon dioxide is more concentrated in the blood than in the alveoli, so it diffuses out of the capillaries and into the alveoli.

(b) In the tissues. Oxygen is more concentrated in the blood than in the body cells; it diffuses out of the capillaries into the cells. Carbon dioxide is more concentrated in the cells, so it diffuses out of the cells and moves into the blood.

Figure 46-9 Gas exchange in the lungs and tissues
Note the differences in partial pressures of oxygen and carbon dioxide before and after gases are exchanged in the tissues.

the membrane. The gas diffuses faster if the difference in pressure or the surface area increases.

Gas exchange takes place in the tissues

The partial pressure of oxygen in arterial blood is about 100 mm Hg. The P_{O_2} in the tissues is still lower, averaging about 40 mm Hg. Consequently, oxygen diffuses out of the capillaries and into the tissues. Not all the oxygen leaves the blood, however. The blood passes through the tissue capillaries too rapidly for equilibrium to be reached. As a result, the partial pressure of oxygen in venous blood returning to the lungs is about 40 mm Hg. Thus, exhaled air has had only part of its oxygen removed, which is a good thing for those in need of mouth-to-mouth resuscitation!

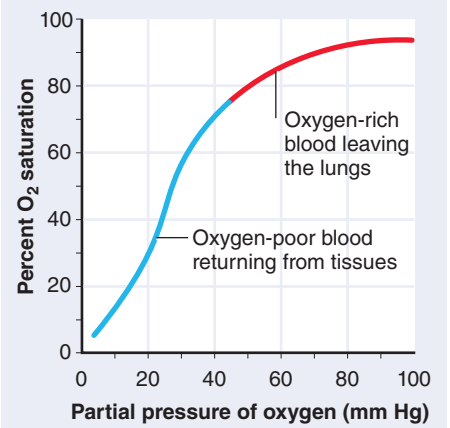
Respiratory pigments increase capacity for oxygen transport

Respiratory pigments greatly increase the quantity of oxygen that blood can transport. These molecules combine reversibly with oxygen. **Hemocyanins** are copper-containing proteins dispersed in the hemolymph of many species of mollusks and arthropods. Without oxygen, these pigments are colorless. When oxygen combines with the copper, hemocyanins are blue.

Hemoglobin and **myoglobin** are the most common respiratory pigments in animals. Hemoglobin is the pigment found in the blood of vertebrates. It is also present in many invertebrate species, including annelids, nematodes, mollusks, and arthropods. In some of these animals, the hemoglobin is dispersed in the plasma rather than confined to blood cells. Recall that myoglobin is a form of hemoglobin found in muscle fibers (see Chapter 40).

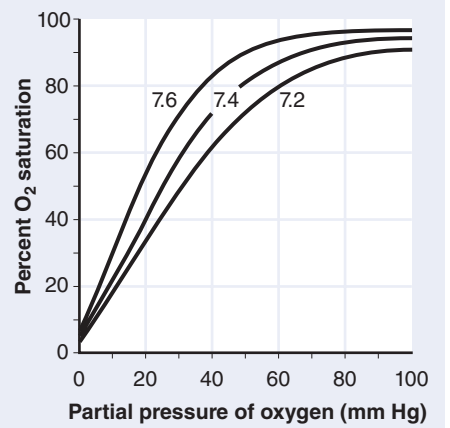
In humans and other mammals, inhaled oxygen diffuses out of the alveoli and enters the pulmonary capillaries. Plasma in equilibrium with alveolar air can take up only 0.25 mL of oxygen per 100 mL. However, oxygen diffuses into red blood cells (RBCs) and combines with hemoglobin. The properties of hemoglobin permit whole blood to carry some 20 mL of oxygen per 100 mL. Hemoglobin transports almost 99% of the oxygen. The rest is dissolved in the plasma.

The term *hemoglobin* is actually a general name for a group of related compounds. These compounds consist of an iron–porphyrin, or heme, group bound to a protein known as a *globin*. The protein portion of the molecule varies in size, amino acid composition, and physical properties among various species.



The protein portion of hemoglobin is composed of four peptide chains, typically two alpha and two beta chains, each attached to a heme (iron–porphyrin) ring (see Fig. 3-23a). An iron atom is bound in the center of each heme ring. Hemoglobin has the remarkable property of forming a weak chemical bond with oxygen. An oxygen molecule can attach to the iron atom in each heme. In the lung (or gill), oxygen diffuses into the RBCs and combines with hemoglobin (Hb) to form **oxyhemoglobin (HbO_2)**. When combined with oxygen, hemoglobin is bright red; without oxygen, it appears dark red, imparting a purplish color to venous blood.

Because the chemical bond formed between the oxygen and the hemoglobin is weak, the reaction is readily reversible. As blood circulates through tissues where the oxygen concentration is low, the reaction proceeds to the left. Hemoglobin releases oxygen, which diffuses out of the blood and into the cells of the tissues.



$$Hb + O_2 \rightleftharpoons HbO_2$$

The maximum amount of oxygen that hemoglobin can transport is its **oxygen-carrying capacity**. The *actual* amount of oxygen bound to hemoglobin is the *oxygen content*. The ratio of O_2 content to oxygen-carrying capacity is the *percent O_2 saturation* of the hemoglobin. The percent O_2 saturation is highest in the pulmonary capillaries, where the concentration of oxygen is greatest. In the capillaries of the tissues, where there is less oxygen, oxyhemoglobin dissociates, releasing oxygen. There, the percent saturation of hemoglobin is correspondingly lower.

The *oxygen–hemoglobin dissociation curve* shown in FIGURE 46-10a illustrates the relationship between partial pressure

(a) Normal oxygen–hemoglobin dissociation curve. Look at the relationship between the partial pressure of oxygen and the percent O_2 saturation of hemoglobin. Oxygen binds to hemoglobin in the lungs and unloads from hemoglobin in the tissues.

(b) Effect of pH on the oxygen–hemoglobin curve (Bohr effect). The normal pH of human blood is 7.4. Find the location on the horizontal axis where the partial pressure of oxygen is 40, and follow the line up through the curves. Notice that the saturation of hemoglobin with oxygen differs among the three curves, even though the partial pressure of oxygen is the same. Oxygen loading increases at higher pH (7.6). At lower pH (7.2), hemoglobin unloads more oxygen.

Figure 46-10 Oxygen–hemoglobin dissociation curves

of oxygen and percent saturation of hemoglobin. As oxygen concentration increases, there is a progressive increase in the percentage of hemoglobin that is combined with oxygen. The ability of oxygen to combine with hemoglobin and be released from oxyhemoglobin is influenced by several factors in addition to percent O_2 saturation. These factors include pH, carbon dioxide concentration, and temperature.

Carbon dioxide produced in respiring tissue reacts with water in the plasma to form carbonic acid, H_2CO_3. For this reason, any increase in carbon dioxide concentration also increases the acidity (lowers the pH) of the blood. Oxyhemoglobin unloads oxygen more readily in an acidic environment than in an environment with normal pH. Displacement of the oxygen–hemoglobin dissociation curve by a change in pH is known as the **Bohr effect** (FIG. 46-10b). Lactic acid released from active muscles also lowers blood pH and has a similar effect on the oxygen–hemoglobin dissociation curve: more oxygen is unloaded and available for muscle contraction.

Some carbon dioxide is transported by the hemoglobin molecule. Although carbon dioxide attaches to the hemoglobin molecule in a different way and at a different site than oxygen does, the attachment of a carbon dioxide molecule releases an oxygen molecule from the hemoglobin. This effect of carbon dioxide concentration on the oxygen–hemoglobin dissociation curve is important. In the capillaries of the lungs (or gills in fishes), carbon dioxide concentration is relatively low and oxygen concentration is high, so oxygen combines with a very high percentage of hemoglobin. In the capillaries of the tissues, carbon dioxide concentration is high and oxygen concentration is low, so hemoglobin readily unloads oxygen.

The oxygen and carbon dioxide bound to hemoglobin in RBCs do not contribute to the partial pressures that govern diffusion. Loading and unloading of gases onto hemoglobin depend on partial pressures of the plasma and interstitial fluid (which is determined by the gases dissolved in these fluids).

Carbon dioxide is transported mainly as bicarbonate ions

Blood transports carbon dioxide in three forms. About 10% of carbon dioxide dissolves in plasma. Another 30% enters the RBCs and combines with hemoglobin. Because the bond between the hemoglobin and carbon dioxide is very weak, the reaction is readily reversible. Most carbon dioxide (about 60%) moves through plasma as *bicarbonate ions* (HCO_3^-).

In plasma, carbon dioxide slowly combines with water to form carbonic acid. This reaction proceeds much more rapidly inside RBCs as a result of the action of the enzyme *carbonic anhydrase* (FIG. 46-11). Carbonic acid dissociates, forming hydrogen ions and bicarbonate ions.

$$\underset{\text{Carbon dioxide}}{CO_2} + \underset{\text{Water}}{H_2O} \xrightarrow{\text{Carbonic anhydrase}} \underset{\text{Carbonic acid}}{H_2CO_3} \longrightarrow \underset{\text{Hydrogen ion}}{H^+} + \underset{\text{Bicarbonate ion}}{HCO_3^-}$$

Most hydrogen ions released from carbonic acid combine with hemoglobin, which is a very effective buffer. Many of the bicarbonate ions diffuse into the plasma. The action of carbonic anhydrase in the RBCs maintains a diffusion gradient for carbon dioxide to move into and then out of RBCs. As the negatively charged bicarbonate ions move out of RBCs, chloride ions (Cl^-) in the plasma diffuse into the RBCs to replace them, a process known as the *chloride shift*. In the alveolar capillaries, CO_2 diffuses out of the plasma and into the alveoli. As the CO_2 concentration decreases, the reaction sequence just described reverses.

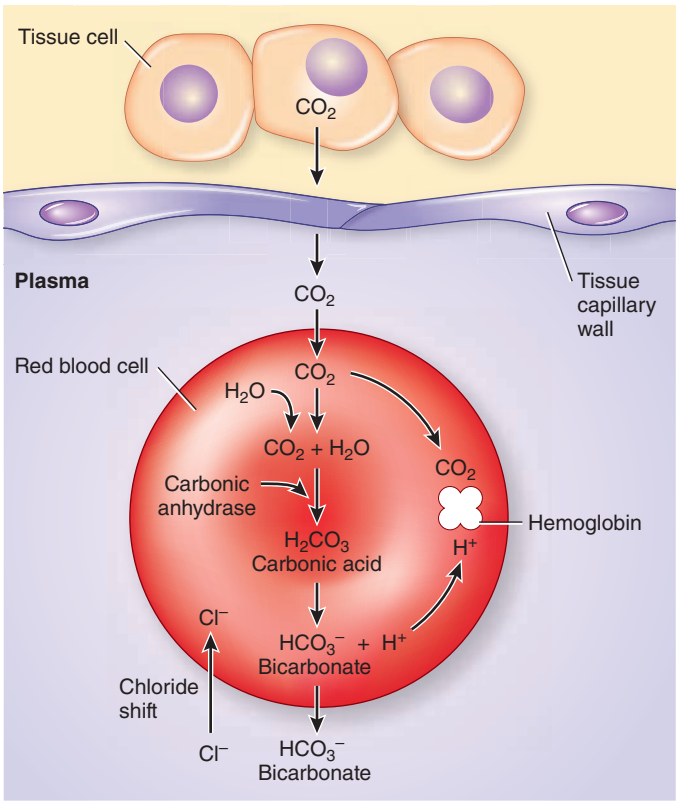
Any condition (such as emphysema) that interferes with the removal of carbon dioxide by the lungs can lead to *respiratory acidosis*. In this situation, carbon dioxide is produced more rapidly than it is excreted by the lungs. As a result, the concentration of carbonic acid in the blood increases. When blood pH falls below 7, the central nervous system becomes depressed, and the individual becomes disoriented. Untreated respiratory acidosis can cause coma and death.

Breathing is regulated by respiratory centers in the brain

Breathing is a rhythmic, involuntary process regulated by **respiratory centers** in the brain stem (see Fig. 46-6). Groups of neurons in the medulla regulate the basic rhythm of breathing. These neurons send a burst of impulses to the diaphragm and external intercostal muscles, which causes them to contract. After several seconds, these neurons become inactive, the muscles relax, and exhalation occurs. Respiratory centers in the pons help control the transition from inspiration to exhalation. These centers can stimulate or inhibit the respiratory centers in the medulla. The cycle of activity and inactivity repeats itself so that at rest you breathe about 14 times per minute. Overdose of certain medications, such as barbiturates, depresses the respiratory centers and may lead to respiratory failure.

The basic rhythm of respiration changes in response to the body's needs. When you are playing a fast game of tennis, you need more oxygen than when you are studying biology. During exercise, the rate of aerobic cellular respiration increases, producing more carbon dioxide. Your body must dispose of this carbon dioxide through increased ventilation.

Carbon dioxide concentration is the most important chemical stimulus for regulating the rate of respiration. Specialized **chemoreceptors** in the medulla and in the walls of the aorta and carotid arteries are sensitive to changes in arterial carbon dioxide concentration. When stimulated, they send impulses to the respiratory centers, which increase breathing rate.



The chemoreceptors in the walls of the aorta, called *aortic bodies*, and those in the walls of the carotid arteries, the *carotid bodies*, are sensitive to changes in hydrogen ion concentration and oxygen concentration as well as to carbon dioxide levels. Recall that an increase in carbon dioxide concentration increases hydrogen ions (from carbonic acid) and lowers blood pH. Even a slight decrease in pH stimulates these chemoreceptors, leading to faster breathing. As the lungs remove carbon dioxide, the hydrogen ion concentration in the blood and other body fluids decreases, and homeostasis is re-established.

Key Point

The enzyme carbonic anhydrase (in red blood cells) converts carbon dioxide to carbonic acid; carbonic acid dissociates, producing hydrogen ions and bicarbonate ions. About 60% of carbon dioxide is transported in the plasma as bicarbonate ions.

(a) In the tissues, carbon dioxide diffuses from cells into the plasma. Most of the carbon dioxide enters red blood cells, where the enzyme carbonic anhydrase rapidly converts it to carbonic acid. Carbonic acid dissociates, producing bicarbonate ions (HCO_3^-) and H^+. As bicarbonate ions move out into the plasma, chloride ions replace them. Hemoglobin combines with H^+, preventing a decrease in pH.

(b) In the lungs, carbon dioxide diffuses out of the plasma and into the alveoli. The reactions described in **(a)** are reversed. Bicarbonate ions diffuse from the plasma into the red blood cells. H^+ released from hemoglobin combines with bicarbonate ions, producing carbonic acid. Carbon dioxide produced from the carbonic acid diffuses out of the blood and into the alveoli.

Figure 46-11 Carbon dioxide transport

PREDICT In what way would diffusion of CO_2 into the red blood cells be affected if the carbonic anhydrase enzyme were inhibited?

Interestingly, oxygen concentration generally does not play an important role in regulating respiration. Only if the partial pressure of oxygen falls markedly do the chemoreceptors in the aorta and carotid arteries become stimulated to send messages to the respiratory centers.

Shallow breathing, which occurs in anxiety and in many respiratory diseases, causes *hypoxia*, a deficiency of oxygen. Even *rapid*, shallow breathing results in hypoxia because we do not clear out the stale air in the airway and ventilate the lungs. Hypoxia causes drowsiness, mental fatigue, headache, and sometimes euphoria. The ability to think and make judgments is impaired, as is the ability to perform tasks requiring coordination.

Although breathing is involuntary, the action of the respiratory centers can be consciously influenced for a short time by stimulating or inhibiting them. For example, you can inhibit respiration by holding your breath. You cannot hold your breath indefinitely, however, because eventually you feel a strong urge to breathe. Even if you could ignore this urge, you would eventually pass out and resume breathing.

People who have stopped breathing because of drowning, smoke inhalation, electric shock, or cardiac arrest can sometimes be sustained by mouth-to-mouth resuscitation until their own breathing reflexes return. **Cardiopulmonary resuscitation (CPR)** is a method for aiding victims who have suffered respiratory and cardiac arrest. CPR must be started immediately because irreversible brain damage occurs within about 4 minutes of oxygen deprivation. A number of organizations offer training in CPR to the general public. You can

also learn to save a life with Hands-Only CPR. Free online instructional materials, including videos, are provided by the American Heart Association and other organizations.

Hyperventilation reduces carbon dioxide concentration

Underwater swimmers and some Asian pearl divers intentionally *hyperventilate* before going underwater. By making a series of deep inhalations and exhalations, they "blow off" CO_2, markedly reducing the CO_2 content of the alveolar air and of the blood. *Hyperventilation* allows the divers to remain underwater longer before the urge to breathe becomes irresistible.

When hyperventilation continues for a long period, dizziness and sometimes unconsciousness may result. These responses occur because a certain concentration of carbon dioxide is needed in the blood to maintain normal blood pressure. (This mechanism operates by way of the vasoconstrictor center in the brain, which maintains the muscle tone of blood vessel walls.) Furthermore, if divers hold their breath too long, the low concentration of oxygen may result in unconsciousness and drowning.

High flying or deep diving can disrupt homeostasis

The barometric pressure decreases at progressively higher altitudes. Because the concentration of oxygen in the air remains at 21%, the partial pressure of oxygen decreases along with the barometric pressure. When a person moves to a high altitude, his or her body adjusts over time by producing a greater number of RBCs.

Getting sufficient oxygen from the air becomes an ever-increasing problem as we ascend to progressively higher altitudes. All high-flying jets have airtight cabins pressurized to the equivalent of the barometric pressure at an altitude of about 2000 m (6600 ft). If a jet flying at 11,700 m (more than 38,000 ft) suddenly decompressed, the pilot would lose consciousness in about 30 seconds and become comatose in about 1 minute.

In addition to the problems of hypoxia, a rapid decrease in barometric pressure causes *decompression sickness* (commonly known as the "bends" because those suffering from it bend over in pain). When the barometric pressure drops below the total pressure of all gases dissolved in the blood and other body fluids, the dissolved gases tend to come out of solution and form gas bubbles. A familiar example occurs each time you uncap a bottle of soda, reducing pressure in the bottle. Carbon dioxide is released from solution and bubbles out into the air. In the body, nitrogen has a low solubility in blood and tissues. When it comes out of solution, the bubbles produced may damage tissues and block capillaries, interfering with blood flow. The clinical effects of decompression sickness are pain, dizziness, paralysis, unconsciousness, and even death.

Decompression sickness is more common in scuba diving than in high-altitude flying. As a diver descends, the surrounding pressure increases tremendously at a rate of 1 atmosphere (the atmospheric pressure at sea level, which equals 760 mm Hg) for each 10 m (about 32 ft). To prevent lung collapse, a diver must be supplied with air under pressure, exposing the lungs to very high alveolar gas pressures.

At sea level an adult human has about 1 L of nitrogen dissolved in the body, with about half in the fat and half in the body fluids. After a diver's body has become saturated with nitrogen at a depth of 100 m (325 ft), the body fluids contain about 10 L of nitrogen. To prevent this nitrogen from rapidly bubbling out of solution and causing decompression sickness, the diver must rise to the surface gradually, with stops at certain levels on the way up. These pauses allow nitrogen to be expelled slowly through the lungs.

Some mammals are adapted for diving

Some air-breathing mammals can spend long periods underwater without coming up for air. Dolphins, whales, seals, and beavers have structural and physiological adaptations that allow them to dive for food or to elude their enemies. With their streamlined bodies and forelimbs modified as fins or flippers, diving mammals perform impressive aquatic feats. The Weddell seal can swim under the ice at a depth of 596 m (1955 ft) for more than an hour without coming up for air. The enormous elephant seal, which measures about 5 m (16 to 18 ft) in length and weighs 2 to 4 tons, can plunge even deeper (FIG. 46-12). A female elephant seal can dive to depths of more than 1500 m (almost 5000 ft) in less than 20 minutes and stay beneath the surface for more than an hour.

Bruce Watkins/Animals Animals

Figure 46-12 Deep diver
Elephant seals, like this northern elephant seal (*Mirounga angustirostris*), may be the deepest divers on Earth. Researchers have recorded their dives at depths of more than 1500 m (almost 5000 ft).

Physiological adaptations, including ways to distribute and store oxygen, permit some mammals to dive deeply and remain underwater for long periods. Turtles and birds that dive depend on oxygen stored in their lungs. However, diving mammals do not take in and store extra air before a dive. In fact, seals exhale before they dive. With less air in their lungs, they are less buoyant. Their lungs collapse at about 50 to 70 m into their dive and then reinflate as they ascend, so their lungs do not function for most of the dive. These adaptations are thought to reduce the chance of decompression sickness because with less air in the lungs there is less nitrogen in the blood to dissolve during the dive.

Seals have about twice the volume of blood, relative to their body weight, as nondiving mammals. Diving mammals also have high concentrations of myoglobin, which stores oxygen in muscles. These animals have up to ten times as much myoglobin as do terrestrial mammals. The very large spleen typical of many diving mammals stores oxygen-rich red blood cells. During a dive, the increased pressure squeezes the spleen, releasing the stored red blood cells into the circulation.

Diving mammals markedly reduce the energy expended in deep diving (more than 200 m) by gliding. Filmed video sequences of diving seals and whales show that they glide most of the way down. Gliding is possible because the animal's buoyancy decreases as the lungs gradually collapse and the amount of air in the lungs is reduced. Gravity then pulls the animal downward.

When a mammal dives to its limit, physiological mechanisms known collectively as the **diving reflex** are activated. Metabolic rate decreases by about 20%, which conserves oxygen. Breathing stops, and bradycardia (slowing of the heart rate) occurs. The heart rate may decrease to one-tenth the normal rate, reducing the body's consumption of oxygen and energy. Blood is redistributed so that the heart and brain receive the greatest share; skin, muscles, digestive organs, and other internal organs can survive with less oxygen, and less blood is directed to these organs while an animal is submerged.

The diving reflex is present to some extent in humans, where it may act as a protective mechanism during birth, when an infant may be deprived of oxygen for several minutes. Cases of near drownings, especially of young children, have been documented in which the victim was submerged for as long as 45 minutes in very cold water before being rescued and resuscitated. Some of these survivors showed no brain damage. The shock of icy water slows heart rate, increases blood pressure, and shunts blood to internal organs of the body that most need oxygen (blood flow in arms and legs decreases). Metabolic rate decreases, so less oxygen is required.

CHECKPOINT 46.3

- What is the sequence of inhaled airflow through the respiratory structures in a mammal?
- What happens in the alveoli? Why does alveolar air differ in composition from atmospheric air? Explain.
- **CONNECT** How does carbon dioxide concentration affect the oxygen–hemoglobin dissociation curve?
- **CONNECT** Imagine that you are playing basketball. How would your breathing be affected? What mechanisms are activated to restore homeostasis?

46.4 Breathing Polluted Air

LEARNING OBJECTIVE

7 Describe the defense mechanisms that protect the lungs and describe the effects of polluted air and cigarette smoking on the respiratory system.

Several defense mechanisms protect the delicate lungs from the harmful substances we breathe (FIG. 46-13). Hairs in the nostrils, the ciliated mucous lining in the nose and pharynx, and the cilia–mucus elevator of the trachea and bronchi trap foreign particles that enter the body in inspired air. Cilia on epithelial cells lining the human airway have chemoreceptors that sense taste. Researchers have shown that when potentially toxic bitter substances are inhaled, the cilia beat more rapidly. This mechanism appears to remove harmful compounds from the airway.

One of the body's most rapid defense responses to breathing dirty air is **bronchial constriction**. In this process, the bronchial tubes narrow, increasing the chance that inhaled particles will land on the sticky mucous lining. Unfortunately, bronchial constriction narrows the airway. Less air can reach the lungs, decreasing the amount of oxygen available to body cells. Fifteen puffs on a cigarette during a 5-minute period increases airway resistance as much as three times, and this added resistance to breathing lasts more than 30 minutes. Chain-smokers and those who breathe heavily polluted air are in a state of chronic bronchial constriction.

David Nunuk/Science Source

Figure 46-13 Urban air pollution
Industry continues to spew tons of pollutants into the atmosphere. Despite modern technology, air pollution still poses a significant health risk.

Inquiring About

The Effects of Smoking

Tobacco use is the leading cause of preventable and premature death in the United States. Cigarette smoking kills more people than alcohol, car accidents, suicide, AIDS, homicide, and illegal drugs combined. An estimated 480,000 people die prematurely each year from smoking or exposure to secondhand smoke. More than 16 million Americans have a serious illness caused by smoking. On average, tobacco smokers die ten years earlier than nonsmokers.[1]

Tobacco smoke is by far the most important risk factor for lung cancer, the most common lethal cancer worldwide. It is also associated with many other types of cancer and accounts for at least 30% of all cancer deaths. Tobacco smoke is also an important risk factor for cardiovascular disease, chronic obstructive pulmonary disease (COPD), and many other diseases. Despite these grim facts, 9.3% of high school students and about 20% of adults in the United States continue to smoke cigarettes.

Secondhand tobacco smoke is smoke from a burning cigarette, cigar, or pipe, or smoke that has been exhaled by a smoker. Secondhand smoke contains hundreds of toxic chemical compounds, including about 70 known human carcinogens. It causes the deaths of an estimated 49,000 individuals each year in the United States alone. Millions of children and adults are exposed to secondhand smoke in their homes and workplaces. This exposure causes disease and premature death in children and adults who do not smoke. Babies and children exposed to secondhand smoke are at increased risk for sudden infant death syndrome (SIDS), acute respiratory infections, pneumonia, bronchitis, ear infections, and asthma. In adults, secondhand smoke causes cardiovascular disease and lung cancer. About 60% of *nonsmokers* in the United States have biological symptoms of exposure to secondhand smoke. Laws passed during the past 25 or so years that ban smoking in workplaces and public places and increased awareness of the dangers of secondhand smoke have led to a decrease in exposure.

Nicotine dependence is the most common type of chemical dependence in the United States. Studies indicate that nicotine may be as addictive as alcohol, cocaine, or heroin. Like cocaine, morphine, and amphetamines, nicotine increases dopamine concentration in the limbic system. This region of the brain helps integrate emotion, and dopamine may facilitate learning an association between the pleasurable effects of the drug and other stimuli, such as the smell of smoke. Nicotine, like cocaine and other abused drugs, causes long-lasting changes in the brain. Cell signaling and other mechanisms underlying drug addiction are very similar to those of learning and memory.

An estimated 70% of smokers (more than 33 million) want to quit, but only a small number each year succeed in quitting permanently. Nicotine replacement with gum, patches, nasal spray, inhalers, or lozenges has been shown to be effective as an aid to smoking cessation, especially when used with behavioral therapy. Certain antidepressants are used to reduce the craving for nicotine. One prescription medication (Chantix) works by blocking nicotine receptors in the brain. It reduces symptoms of nicotine withdrawal and also decreases the pleasurable effects of smoking. The Tips From Former Smokers Campaign is credited with helping thousands of smokers in the United States to quit smoking permanently.

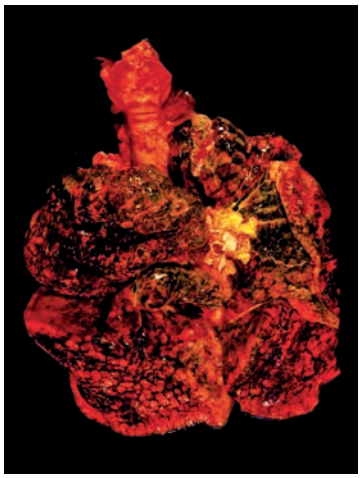
Use of electronic cigarettes (also known as e-cigarettes or electronic nicotine delivery systems) is growing rapidly. Electronic cigarettes are battery-powered devices that provide a heated aerosol containing nicotine. The effects of e-cigarettes have not yet been thoroughly studied. Brands vary in the amounts of nicotine they deliver and in their toxin content. However, they are not "harmless" replacements for cigarettes. Also, many individuals who use e-cigarettes become smokers of traditional cigarettes.

Here are some facts about smoking:

- Almost everyone who takes up smoking in the U.S. is a teenager, and every day nearly 4000 teens smoke their first cigarette. About one-third of these teens will die prematurely from a smoking-related disease. The younger you are when you begin to smoke, the more likely you are to be an adult smoker.
- Smoking shortens the life of an adult male smoker by an average of 13.2 years and shortens the life of an adult female smoker by an average of 14.5 years.
- If you smoke more than one pack of cigarettes per day, you are about 20 times as likely as a nonsmoker to develop lung cancer. Cigarette smoking causes almost nine out of ten lung cancer deaths.
- If you smoke, you double your chances of dying from cardiovascular disease.
- If you smoke, you are 20 times more likely as a nonsmoker to develop chronic bronchitis and emphysema. About 90% of all deaths from chronic obstructive pulmonary disease are caused by cigarette smoking.
- If you smoke, you have about 5% less oxygen circulating in your blood (because carbon monoxide binds to hemoglobin) than does a nonsmoker.
- If you smoke when you are pregnant, your baby will weigh about 6 ounces less at birth, and there is a higher risk of miscarriage, premature birth (early delivery), stillbirth, and sudden infant death syndrome.
- Infants whose parents smoke have double the risk of contracting pneumonia or bronchitis in their first year of life.
- There is no risk-free level of exposure to secondhand smoke. Nonsmokers who are exposed to secondhand smoke increase their risk of developing heart disease by 25% to 30% and lung cancer by 20% to 30%.
- When smokers quit smoking, their risk of dying from chronic obstructive pulmonary disease, cardiovascular disease, or cancer gradually decreases. (Precise changes in risk depend on the number of years the person smoked, the number of cigarettes smoked per day, the age of starting to smoke, and the number of years since quitting.)
- The direct medical costs of tobacco use in the U.S. amount to more than $96 billion annually.
- Smokeless tobacco products (snuff, chewing tobacco) are not a safe alternative to tobacco smoking. All forms of these products contain chemicals that cause cancer.

[1] Statistics quoted are from the Centers for Disease Control and the American Cancer Society.

Neither the smallest bronchioles nor the alveoli are equipped with mucus or ciliated cells. Foreign particles that get through other respiratory defenses and find their way into the alveoli may be engulfed by macrophages. The macrophages may then accumulate in the lymph tissue of the lungs. Lung tissues of cigarette smokers and those who work in dirty industries burning fossil fuel contain large blackened areas where carbon particles have been deposited (FIG. 46-14).



Continued insult to the respiratory system results in disease. Chronic bronchitis, pulmonary emphysema, and lung cancer have been linked to cigarette smoking and breathing polluted air. More than 75% of patients with *chronic bronchitis* have a history of heavy cigarette smoking (see *Inquiring About: The Effects of Smoking*). People with chronic bronchitis often develop **pulmonary emphysema**, a disease also most common in cigarette smokers. In this disorder, alveoli lose their

(a) Lungs of a nonsmoker.

(b) Lungs of a cigarette smoker. The dark spots in the lung tissue are particles of carbon, tar, and other substances that passed through the respiratory defenses and lodged in the lungs.

Figure 46-14 Effects of cigarette smoking

Most patients with *chronic obstructive pulmonary disease (COPD)*, a condition characterized by obstructed airflow, have both chronic bronchitis and emphysema. Asthma also contributes to COPD. People with asthma respond to inhaled stimuli with exaggerated bronchial constriction, and the airway is typically inflamed.

Cigarette smoking is also the main cause of *lung cancer*. At least 70 of the 4800 chemical compounds in tobacco smoke cause cancer in animals, including humans. These carcinogenic substances irritate the cells lining the respiratory passages and alter their metabolic balance. Normal cells are transformed into cancer cells, which may multiply rapidly and invade surrounding tissues.

elasticity, and walls between adjacent alveoli are destroyed. The surface area of the lung is so reduced that gas exchange is seriously impaired. Air is not expelled effectively, and stale air accumulates in the lungs.

The emphysema victim struggles for every breath, and still the body does not get enough oxygen. To compensate, the right ventricle of the heart pumps harder and becomes enlarged. Emphysema patients frequently die of heart failure.

CHECKPOINT 46.4

- What mechanisms does the human respiratory system have for getting rid of inhaled particles?
- **CONNECT** What happens when so much dirty air is inhaled that the respiratory system's defense mechanisms cannot function effectively?

Summary: Focus on Learning Objectives

46.1 Adaptations for Gas Exchange in Air or Water *(page 992)*

1 Compare the advantages and disadvantages of air and water as mediums for gas exchange and describe adaptations for gas exchange in air.

- Air contains a higher concentration of molecular oxygen than water, and oxygen diffuses more rapidly through air than through water. Air is less dense and less viscous than water, so less energy is needed to move air over a gas exchange surface.
- Terrestrial animals have adaptations that protect their respiratory surfaces from drying, including location deep in the body. Also, air is humidified as it passes through the moist upper airway.

46.2 Types of Respiratory Surfaces *(page 992)*

2 Describe the following adaptations for gas exchange: body surface, tracheal tubes, gills, and lungs.

- Small aquatic animals exchange gases by diffusion; they require no specialized respiratory structures. Some invertebrates, including most annelids, and a few vertebrates (many amphibians) exchange gases across the body surface.
- In insects and some other arthropods, air enters a network of **tracheal tubes**, or **tracheae**, through openings, called **spiracles**, along the body surface. Tracheal tubes branch and extend to all regions of the body.
- **Gills** are moist, thin projections of the body surface found mainly in aquatic animals. In chordates, gills are usually internal, located along the edges of the gill slits. In bony fishes, an **operculum** protects the gills. A **countercurrent exchange system** maximizes diffusion of oxygen into the blood and diffusion of carbon dioxide out of blood.
- Animals carry on **ventilation**, the process of actively moving air or water over respiratory surfaces. Terrestrial vertebrates have **lungs** and some means of ventilating them.

Copyright 2019 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

- In birds, the lungs have extensions, called *air sacs*, that act as bellows, drawing air into the system. Two cycles of inhalation and exhalation support a one-way flow of air through the lungs. Air from the outside flows into the posterior air sacs, to the lung, through the anterior air sacs, and then out of the body. Gas exchange takes place through the walls of the **parabronchi**, small, open tubes in the lungs. A crosscurrent arrangement, in which blood flow is at right angles to the parabronchi, increases the amount of oxygen that enters the blood.

46.3 The Mammalian Respiratory System *(page 997)*

3 Trace the passage of oxygen through the human respiratory system from nostrils to alveoli.

- The human respiratory system includes the lungs and a system of airways. Each breath of air passes in sequence through the *nostrils*, *nasal cavities*, **pharynx**, **larynx**, **trachea**, **bronchi**, **bronchioles**, and **alveoli**. Each lung occupies a pleural cavity and is covered with a **pleural membrane**.

4 Summarize the mechanics of breathing in humans and describe gas exchange in the lungs and tissues.

- During breathing, the **diaphragm** contracts, expanding the chest cavity. The membranous walls of the lungs move outward along with the chest walls, lowering pressure within the lungs. Air from outside the body rushes in through the air passageways and fills the lungs until the pressure equals atmospheric pressure.
- **Tidal volume** is the amount of air moved into and out of the lungs with each normal breath. The volume of air that remains in the lungs at the end of a maximal expiration is the **residual volume**. **Vital capacity** is the maximum volume of air that can be exhaled after the lungs fill to the maximum extent.
- Oxygen and carbon dioxide are exchanged between alveoli and blood by diffusion. The pressure of a particular gas determines its direction and rate of diffusion.
- *Dalton's law of partial pressures* explains that in a mixture of gases, the total pressure of the mixture is the sum of the pressures of the individual gases. Thus, each gas in a mixture of gases exerts a **partial pressure**, the same pressure it would exert if it were present alone. The partial pressure of atmospheric oxygen, P_{O_2}, is 160 mm Hg at sea level.
- According to **Fick's law of diffusion**, the greater the difference in pressure on the two sides of a membrane and the larger the surface area, the faster the gas diffuses across the membrane.

5 Summarize the mechanisms by which oxygen and carbon dioxide are transported in the blood and identify factors that determine the oxygen–hemoglobin dissociation curve.

- **Hemoglobin** is the respiratory pigment in the blood of vertebrates. Almost 99% of the oxygen in human blood is transported as **oxyhemoglobin (HbO_2)**.
- The maximum amount of oxygen that hemoglobin can transport is the **oxygen-carrying capacity**. The actual amount of oxygen bound to hemoglobin is the *oxygen content*. The *percent O_2 saturation*, the ratio of oxygen content to oxygen-carrying capacity, is highest in pulmonary capillaries, where oxygen concentration is greatest.
- *The oxygen–hemoglobin dissociation curve* shows that as oxygen concentration increases, there is a progressive increase in the amount of hemoglobin that combines with oxygen. The curve is affected by pH, temperature, and CO_2 concentration.
- Oxyhemoglobin dissociates more readily as carbon dioxide concentration increases because carbon dioxide combines with water and produces carbonic acid, which lowers the pH. Displacement of the oxygen–hemoglobin dissociation curve by a change in pH is called the **Bohr effect**.
- About 60% of the carbon dioxide in the blood is transported as bicarbonate ions. About 30% combines with hemoglobin, and another 10% is dissolved in plasma.
- *Carbonic anhydrase* catalyzes the production of carbonic acid from carbon dioxide and water. Carbonic acid dissociates, producing bicarbonate ions (HCO_3^-) and hydrogen ions (H^+).
- Hemoglobin combines with H^+, which buffers the blood. Many bicarbonate ions diffuse from red blood cells into the plasma; they are replaced by Cl^-. This exchange is known as the *chloride shift*.

6 Describe the regulation of breathing in humans and summarize the physiological effects of hyperventilation and of sudden decompression when a diver surfaces too quickly from deep water.

- **Respiratory centers** in the medulla and pons regulate respiration. These centers are stimulated by **chemoreceptors** sensitive to an increase in carbon dioxide concentration. They also respond to an increase in hydrogen ions and to very low oxygen concentration.
- *Hyperventilation* reduces the concentration of carbon dioxide in the alveolar air and in the blood.
- As altitude increases, barometric pressure falls, and less oxygen enters the blood. This situation can lead to *hypoxia*, or oxygen deficiency, which in turn can lead to loss of consciousness and death. Rapid decrease in barometric pressure can also cause *decompression sickness*, especially common among divers who ascend too rapidly from a dive.

Copyright 2019 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

- Diving mammals have unusually high concentrations of **myoglobin**, a pigment that stores oxygen, in their muscles. The **diving reflex**, a group of physiological mechanisms that includes a decrease in metabolic rate, is activated when a mammal dives to its limit.

46.4 Breathing Polluted Air *(page 1005)*

7 **Describe the defense mechanisms that protect the lungs and describe the effects of polluted air and cigarette smoking on the respiratory system.**

- The ciliated mucous lining of the airway traps inhaled particles. Inhaling polluted air results in *bronchial constriction*, increased mucus secretion, damage to ciliated cells, and coughing.
- Breathing polluted air or inhaling cigarette smoke can cause many diseases, including *chronic bronchitis*, *pulmonary emphysema*, and *lung cancer*.

Test Your Understanding

Know and Comprehend

1. Which of the following is a benefit of gas exchange in air compared with gas exchange in water? (a) air has a higher concentration of molecular oxygen (b) oxygen diffuses more slowly in air (c) no energy is required for ventilation (d) moist respiratory surface is not needed (e) air is denser than water
2. Which of the following are accurately matched? (a) bony fish—operculum (b) insect—alveoli (c) bird—spiracles (d) aquatic mammal—gill filaments (e) shark—dermal gills
3. The most efficient vertebrate respiratory system is that of (a) amphibians (b) birds (c) reptiles (d) mammals (e) humans
4. In a bird, the correct sequence for a breath of air is: 1. anterior air sacs 2. posterior air sacs 3. parabronchi 4. alveoli (a) 1, 2, 4 (b) 2, 1, 3 (c) 2, 3, 1 (d) 2, 4, 1 (e) 1, 3, 2
5. Which sequence most accurately describes the flow of air in the human respiratory system? 1. pharynx 2. bronchus 3. trachea 4. larynx 5. alveolus 6. bronchiole (a) 4, 1, 3, 2, 5, 6 (b) 1, 4, 3, 2, 5, 6 (c) 4, 1, 3, 2, 6, 5 (d) 1, 4, 3, 2, 6, 5 (e) 1, 3, 4, 2, 6, 5
6. The amount of air moved in and out of the lungs with each normal resting breath is the (a) vital capacity (b) residual volume (c) vital volume (d) partial pressure (e) tidal volume
7. According to Fick's law of diffusion, a gas will diffuse faster if the (a) surface is reduced (b) difference in pressure is decreased (c) difference in pressure is increased (d) pH is lowered (e) a and c
8. The concentration of which substance is most important in regulating the rate of respiration? (a) chloride ions (b) oxygen (c) bicarbonate ions (d) nitrogen (e) carbon dioxide
9. When a diver ascends too rapidly, (a) bronchial constriction occurs (b) a diving reflex is activated (c) nitrogen rapidly bubbles out of solution in the body fluids (d) nitrogen hypoxia occurs (e) carbon dioxide bubbles damage the alveoli
10. Which of the following is *not* true of the diving reflex? (a) breathing stops (b) the heart slows (c) less blood is distributed to the muscles (d) metabolic rate increases by about 20% (e) energy consumption decreases

Apply and Analyze

11. **VISUALIZE** Draw and label a diagram illustrating the sequence of structures through which inhaled air travels to reach the alveoli.
12. **EVOLUTION LINK** What are the advantages of having millions of alveoli rather than a pair of simple, balloonlike lungs?
13. **INTERPRET DATA** Look at Figure 46-10b. How would strenuous muscle activity affect the oxygen–hemoglobin dissociation curve? (*Hint:* How does muscular activity affect pH? See Chapter 40 if you need to review this concept.)
14. **PREDICT** What problems would be faced by a terrestrial animal having gills instead of lungs?

Evaluate and Synthesize

15. **EVOLUTION LINK** Under what conditions might it be advantageous for a fish to have lungs as well as gills? What function do the "lungs" of modern fishes serve?
16. **EVOLUTION LINK** Aquatic mammals such as whales and dolphins use lungs rather than gills for gas exchange. Propose a hypothesis to explain why.
17. **SCIENCE, TECHNOLOGY, AND SOCIETY** Tobacco smoking is extremely expensive to our society in economic and health costs as well as in human suffering. How would you solve the tobacco smoking problem? How would you specifically target young people?

47 Processing Food and Nutrition

KEY CONCEPTS

47.1 Food processing includes ingestion, digestion, absorption, and elimination; many animal adaptations are associated with mode of nutrition.

47.2 Various parts of the vertebrate digestive system are specialized to perform specific functions; accessory glands (liver, pancreas, and salivary glands) secrete fluids and enzymes that are important in digestion.

47.3 Most animals require the same basic nutrients: carbohydrates, lipids, proteins, vitamins, and minerals.

47.4 Basal metabolic rate is the body's cost of metabolic living; energy metabolism is regulated by complex signaling pathways. Both overnutrition and undernutrition can result in malnutrition.

PHOTO: Atlantic wolffish (*Anarhichas lupus*) snatching a sea star (*Asterias rubens*). Also known as the seawolf, this predator hunts hard-shelled prey, such as echinoderms, mollusks, and crustaceans. The Atlantic wolffish, which can weigh up to 18 kg (40 lb), helps control the density and distribution of populations of sea urchins and certain other invertebrates. The wolffish population has decreased drastically as a result of overfishing, unintentional harm by fishermen (bycatch), and habitat damage. Photographed in the North Sea off St Abbs, Berwickshire, Scotland. Nature Picture Library/Alamy Stock Photo

Animals as diverse as sponges and baleen whales feed on food particles suspended in oceans. Giraffes eat leaves, and antelope graze on grasses. Frogs, lions, and some snakes and insects capture other animals. Although their choices of food and feeding mechanisms are diverse, all animals are **heterotrophs**, organisms that must obtain their energy and nourishment from the organic molecules manufactured by other organisms. What they eat, how they obtain food, and how they process and use food are the focus of this chapter.

Nutrients are substances in food that are used as energy sources to power the systems of the body, as ingredients to make compounds needed for metabolic processes, and as building blocks in the growth and repair of tissues. Obtaining nutrients is of such vital importance that both individual organisms and ecosystems are structured around the central theme of **nutrition**, the process of taking in and using food.

An animal's body plan and its lifestyle are adapted to its particular mode of obtaining food—the most effective mode for its survival. For example, the Atlantic wolffish lives on the ocean floor at depths of up to 120 m (400 ft). Its body is adapted for hunting and eating clams, crabs, sea stars, and sea urchins (see photograph). Both its upper and lower jaws have four to six fanglike teeth that stab and tear its prey. Behind these fangs are three rows of teeth that crush the hard shells of its prey. It also has serrated teeth in its throat.

Nutrition has been an important force in human evolution. Through natural selection, the human diet became more varied than the diets of other primates. Humans also became very efficient at obtaining and modifying (e.g., cooking) food. Their higher-quality diet supported the evolution of a larger, more complex brain.

With only slight variations, all animals require the same basic nutrients: carbohydrates, lipids, proteins, vitamins, and minerals. Carbohydrates, lipids, and proteins are used as energy sources. Eating too much of any of these nutrients can result in weight gain, whereas

eating too few nutrients or an unbalanced diet can result in malnutrition and death. **Malnutrition**, or poor nutritional status, results from dietary intake that is either below or above required needs. In human populations both undernutrition (particularly protein deficiency) and obesity (which results from overnutrition) are serious health problems. Food processing and nutrition are active areas of research.

47.1 Nutritional Styles and Adaptations

LEARNING OBJECTIVE

1 Describe food processing and modes of nutrition, and compare the digestive systems of a cnidarian (such as *Hydra*), a flatworm, an earthworm, and a vertebrate.

Feeding is the selection, acquisition, and ingestion of food. Most animals have a specialized digestive system that processes the food they eat. **Ingestion** is the process of taking food into the digestive cavity. In many animals, including vertebrates, ingestion includes taking food into the mouth and swallowing it.

Digestion is the process of breaking down food. Because animals eat the macromolecules made by and for other organisms, they must break down these molecules and synthesize new macromolecules for their own needs. For example, we humans cannot incorporate the proteins and other organic compounds from a hamburger directly into our own cells. We must *mechanically digest* the meat and then *chemically digest* it by enzymatic hydrolysis (see Chapter 3). During digestion, complex organic compounds are degraded into smaller molecular components. For example, proteins are broken down into their component amino acids. These amino acids are then used to synthesize proteins tailored for the needs of that individual at that particular time.

Amino acids and other nutrients pass through the lining of the digestive tract and into the blood by **absorption**. Then the circulatory system transports the nutrients to all the cells of the body. Cells use nutrients to synthesize proteins and other organic compounds or as fuel for cellular respiration. Food that is not digested and absorbed is discharged from the body, a process called *egestion* or **elimination**.

Animals are adapted to their mode of nutrition

We can classify animals based on the type of food they typically eat and on how they obtain food (FIG. 47-1). Many adaptations have evolved for each type of feeding. For example, the beaks of birds and the teeth of many vertebrates are specialized for cutting, tearing, crushing, or chewing food.

Animals that feed directly on producers are **herbivores**, or **primary consumers**. Most of what an herbivore eats is not efficiently digested and is eliminated from the body, almost unchanged, as waste. Herbivores must therefore eat large quantities of food to obtain the nourishment they need. Many herbivores—grasshoppers, manatees, elephants, and cattle, for example—spend a major part of their lives eating.

Animals cannot digest the cellulose of plant cell walls, and many adaptations have evolved for extracting nutrients from the plant material they eat. Many herbivores, including termites, cows, and horses, have a symbiotic relationship with bacteria, fungi, and other microorganisms that inhabit their digestive tracts. *Ruminants* (cattle, sheep, deer, giraffes) are hoofed animals with a stomach divided into four chambers. Symbiotic bacteria and protists living in the first two chambers digest cellulose, splitting some of the molecule into sugars, which are then used by the host and by the bacteria themselves. The bacteria produce fatty acids during their metabolism, some of which are absorbed by the animal and serve as an important energy source.

Solid bits of food clump together to form a cud. The cud is regurgitated into the animal's mouth, where it is mixed with saliva and chewed again. When the cud is reswallowed, the partly digested food is further broken down. Partially digested food passes into the third chamber, where water and minerals are absorbed into the blood. Digestion is completed in the fourth chamber, which corresponds to the stomach of humans and other animals with a single stomach.

Herbivores are sometimes eaten by secondary and higher-level consumers. These **predators** are adapted for capturing and killing prey. Some predators seize their victims and swallow them alive and whole (see Fig. 47-1d). Others paralyze, crush, or shred their prey before ingesting it. Adaptations for this type of feeding include tentacles, claws, fangs, poison glands, and teeth. (Predators, which may also eat one another, are sometimes referred to as *carnivores*.)

Carnivorous mammals have well-developed canine teeth for stabbing their prey during combat. For example, spotted hyenas, which are formidable predators as well as scavengers, have massive jaws that allow them to consume an entire elephant carcass, including bones and hide. Few nutrients are wasted. Meat is more easily digested than plant food, and carnivore digestive tracts are shorter than those of herbivores.

Omnivores, such as pigs, humans, most bears, and some fishes, consume both plants and animals. Earthworms ingest large amounts of soil containing both animal and plant material. The blue whale, which is the largest animal, filters out tiny algae and animals from the water as it swims. Omnivores often have adaptations that help them distinguish among a wide range of smells and tastes and thereby select a variety of foods.

Animals can also be classified according to the mechanisms they use to feed. Many omnivores are **filter feeders** that remove suspended food particles from the water they inhabit. For example, clams and oysters trap suspended food particles in mucus secreted by their gills. Some echinoderms trap food particles along their tentacles, which are coated with mucus. Baleen whales use rows of hard plates (baleen) suspended from the roof of the mouth to filter small crustaceans.

Some animals feed on fluids by piercing and sucking. Mosquitoes have highly adapted structures for piercing skin and sucking blood. Bats that feed on nectar have a long tongue and a reduced number of teeth. Birds that feed on pollen and nectar have long bills and tongues. The shape, size, and curve of the beak may be specialized for feeding on or capturing a particular type of food (see Fig. 1-13).

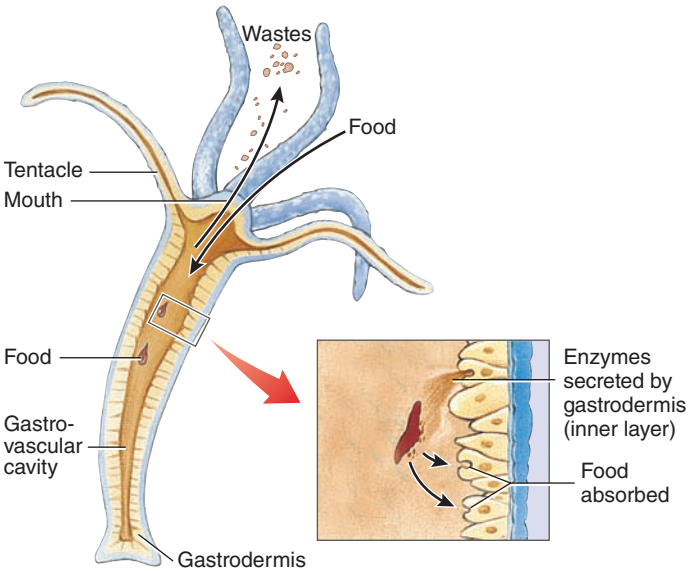
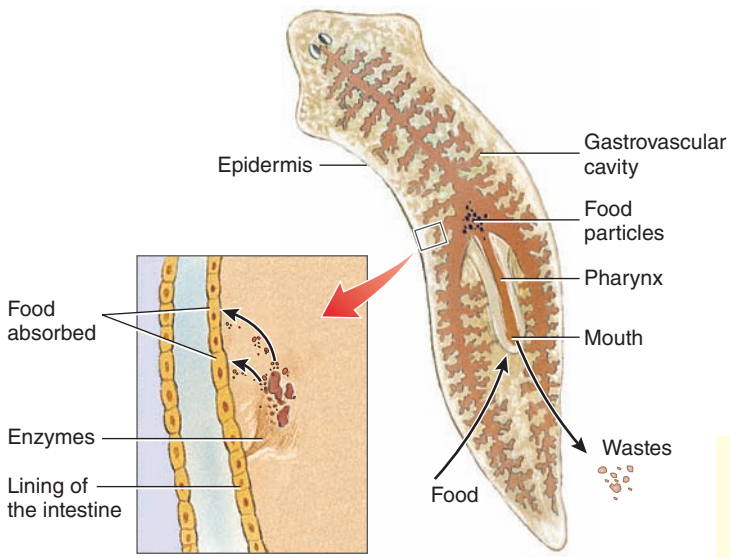
Figure 47-1 Adaptations for obtaining and processing food

Deposit feeders, such as earthworms, fiddler crabs, and sea cucumbers, consume nutrients in soil or sediments. For example, earthworms eat their way through the soil, digesting and absorbing organic material.



Some invertebrates have a digestive cavity with a single opening

Sponges, which are very simple invertebrates, obtain food by filtering microscopic organisms from the surrounding water. Individual cells phagocytose the food particles, and digestion is *intracellular* within food vacuoles. Wastes are egested into the water that continuously circulates through the sponge body.



Most animals have a digestive cavity. Digestion within a cavity is more efficient than intracellular digestion because digestive enzymes can be released into one confined space. Less surface area is required. Cnidarians (such as hydras and jellyfish) and flatworms have a **gastrovascular cavity**, a central digestive cavity with a single opening. Cnidarians capture small aquatic animals with the help of their stinging cells and tentacles (FIG. 47-2a). The mouth opens into the gastrovascular cavity. Cells lining this digestive cavity secrete enzymes that break down proteins.

(a) Digestive system of a hydra.

(b) Digestive system of a flatworm.

Figure 47-2 Simple invertebrate digestive systems
(a) Hydras and **(b)** flatworms (planarians) have a gastrovascular cavity, a digestive tract with a single opening that serves as both mouth and anus.

Digestion continues intracellularly within food vacuoles, and digested nutrients diffuse into other cells. Body contractions promote egestion of undigested food particles through the mouth.

Free-living flatworms begin to digest their prey even before ingesting it. They extend the pharynx out through their mouth and secrete digestive enzymes onto their prey (FIG. 47-2b). After it is ingested, the food enters the branched gastrovascular cavity, where enzymes continue to digest it. Cells lining the gastrovascular cavity phagocytose partly digested food fragments, and digestion is completed within food vacuoles. As in cnidarians, the flatworm digestive cavity has only one opening, so undigested wastes are egested through the mouth.

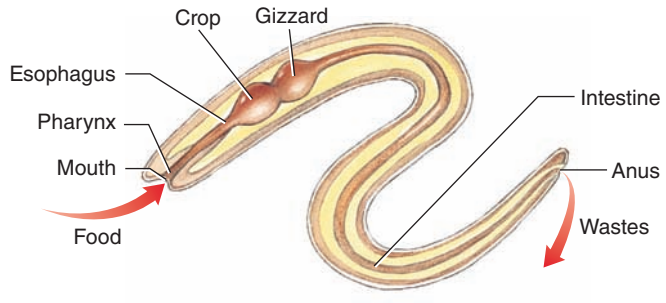

Figure 47-3 Digestive tract with two openings
The earthworm, like most animals, has a complete digestive tract extending from mouth to anus. Various regions of the digestive tract are specialized to perform different food-processing functions.

Most animal digestive systems have two openings

Most invertebrates, and all vertebrates, have a tube-within-a-tube body plan. The body wall forms the outer tube. The inner tube is a digestive tract with two openings, sometimes referred to as a complete digestive system (FIG. 47-3). Food enters through the mouth, and undigested food is eliminated through the anus. The mixing and propulsive movements of the digestive tract are referred to as **motility**. The propulsive activity characteristic of most regions of the digestive tract is **peristalsis**, waves of muscular contraction that push the food in one direction. More food can be taken in while previously eaten food is being digested and absorbed farther down the digestive tract. In a digestive tract with two openings, various regions of the tube are adapted to perform specific functions.

CHECKPOINT 47.1

- **CONNECT** How have predators adapted to their mode of nutrition?
- How does food processing differ in earthworms and flatworms?
- What are the benefits of a digestive tract with two openings?

47.2 The Vertebrate Digestive System

LEARNING OBJECTIVES

2 Trace the pathway traveled by an ingested meal through the human digestive system and describe the structure and function of each structure involved.
3 Trace the step-by-step digestion of carbohydrate, protein, and lipid.
4 Describe the structural adaptations that increase the surface area of the digestive tract.
5 Compare lipid absorption with absorption of other nutrients.

Key Point

Various regions of the digestive tract are specialized to perform specific functions. More food can be ingested while the stomach and duodenum are digesting food that was previously swallowed; and food ingested hours earlier is being absorbed.

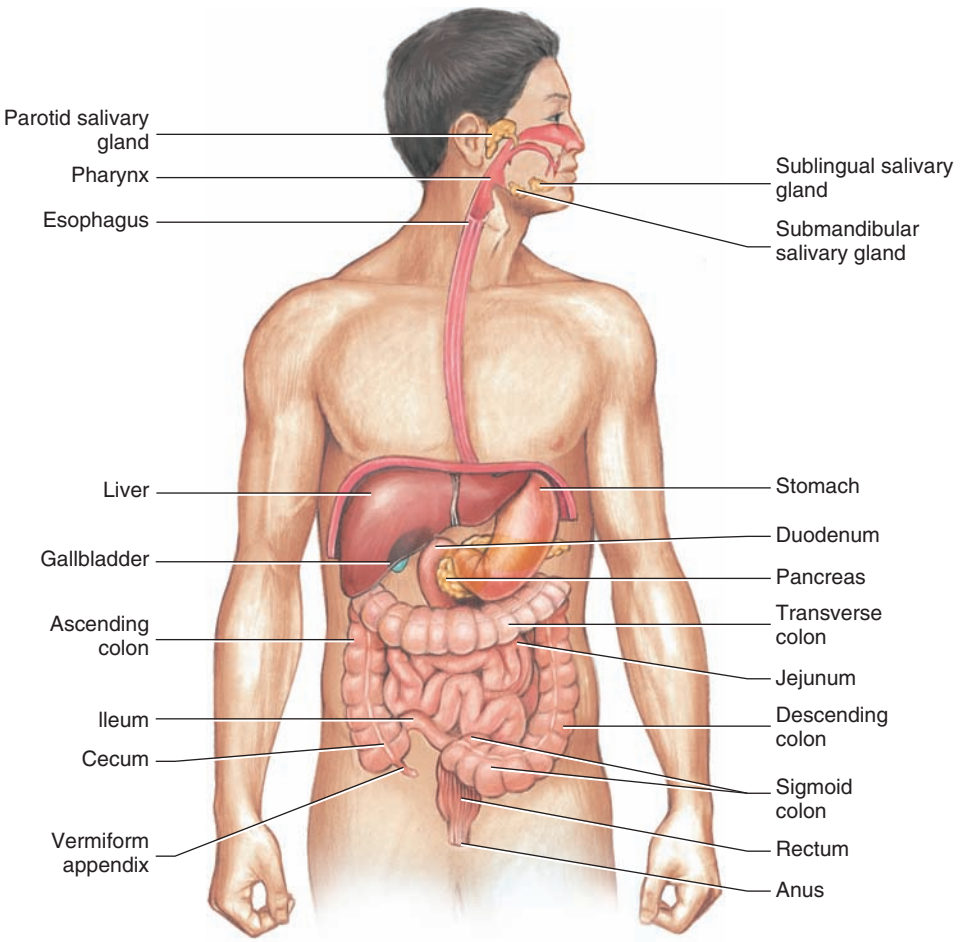

Figure 47-4 Human digestive system

The human digestive tract is a long, coiled tube extending from mouth to anus. Food passes from the mouth, through the pharynx and esophagus, and into the stomach. After being partially digested in the stomach, food passes into the small intestine. Digestion continues in the first part of the small intestine. Absorption takes place mainly in the small intestine, which consists of the duodenum, jejunum, and ileum. The large intestine absorbs water and minerals. The large intestine includes the cecum, colon, rectum, and anus. Locate the three types of accessory glands: the liver, pancreas, and salivary glands.

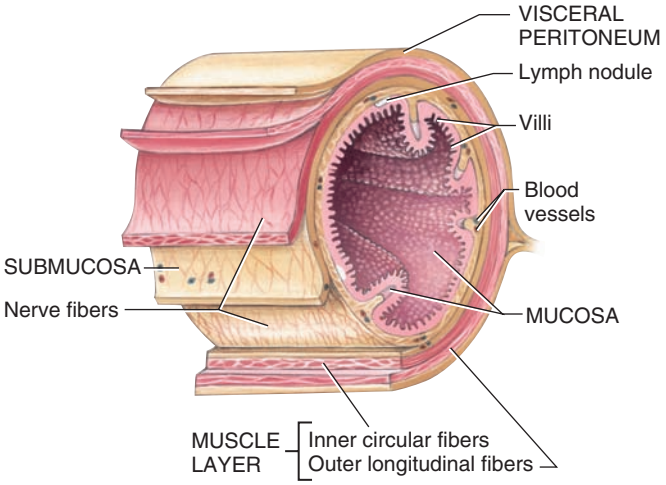
PREDICT A surgeon removes the stomach of a cancer patient. What would the surgeon do to ensure that the patient could continue to digest and absorb food?

Various regions of the vertebrate digestive tract are specialized to perform specific functions (FIG. 47-4). Food passes in sequence through the following specialized regions:

mouth → pharynx (throat) → esophagus → stomach → small intestine → large intestine → anus

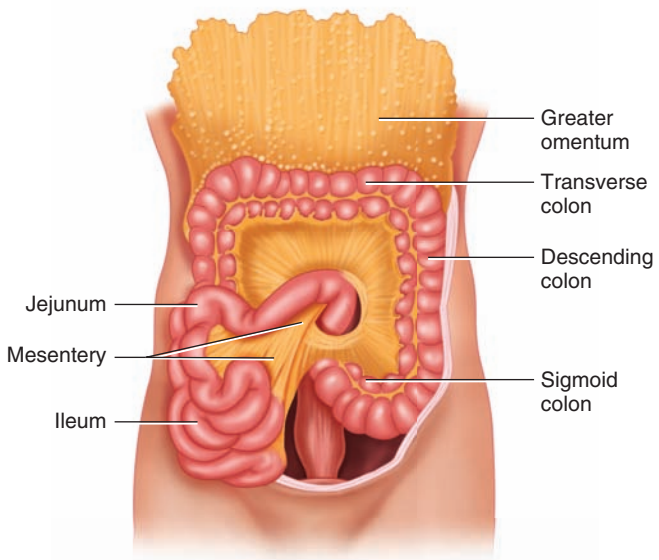
The liver, pancreas, and salivary glands (in terrestrial vertebrates) are accessory glands that secrete digestive juices into the digestive tract.

The wall of the digestive tract has four layers. Although various regions differ somewhat in structure, the layers are basically similar throughout the digestive tract (FIG. 47-5a). The **mucosa**, which consists of a layer of epithelial tissue and underlying connective tissue, lines the **lumen** (inner space) of the digestive tract. In the stomach and intestine, the mucosa is greatly folded to increase the secreting and absorbing surface.



Surrounding the mucosa is the *submucosa*, a connective tissue layer rich in blood vessels, lymphatic vessels, and nerves.

A *muscle layer*, consisting of two sublayers of smooth muscle, surrounds the submucosa. In the inner sublayer, the muscle fibers are arranged circularly around the digestive tube. In the outer sublayer, the muscle fibers are arranged longitudinally. Below the level of the diaphragm, the outer connective tissue coat of the digestive tract is called the *visceral peritoneum* (per″-ih-tow-nee′-um). By various folds, it is connected to the *parietal peritoneum*, a sheet of connective tissue that lines the walls of the abdominal and pelvic cavities. The visceral and parietal peritonea enclose part of the coelom, the *peritoneal cavity*. Inflammation of the peritoneum, called *peritonitis*, can be very serious because infection can spread along the peritoneum to most of the abdominal organs.



A double fold of peritoneal tissue, called the **mesentery** (mez′-en-ter-ee), fans outward from the parietal peritoneum to the wall of the intestine (FIG. 47-5b). The mesentery is loosely

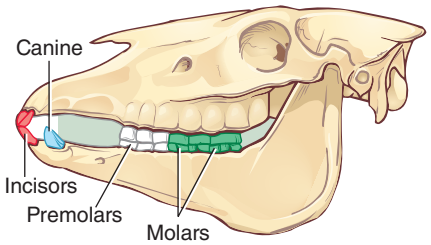
(a) Wall of digestive tract. From inside out, the layers of the wall are the mucosa, submucosa, muscle layer, and visceral peritoneum.



(b) The mesentery. The mesentery is a large, double fold of peritoneal tissue. The greater omentum and transverse colon have been lifted to expose the mesentery.

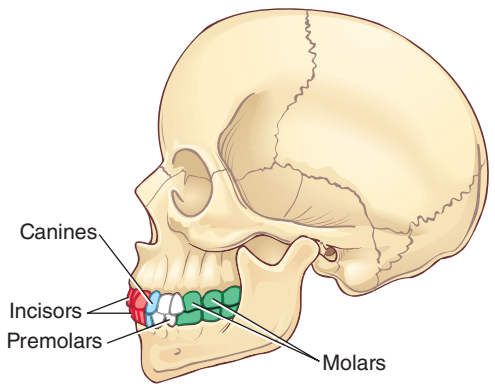


Figure 47-5 Wall of the digestive tract and mesentery

(a) Predator. The skull of a coyote shows the pointed incisors and canines, adaptations for ripping flesh.

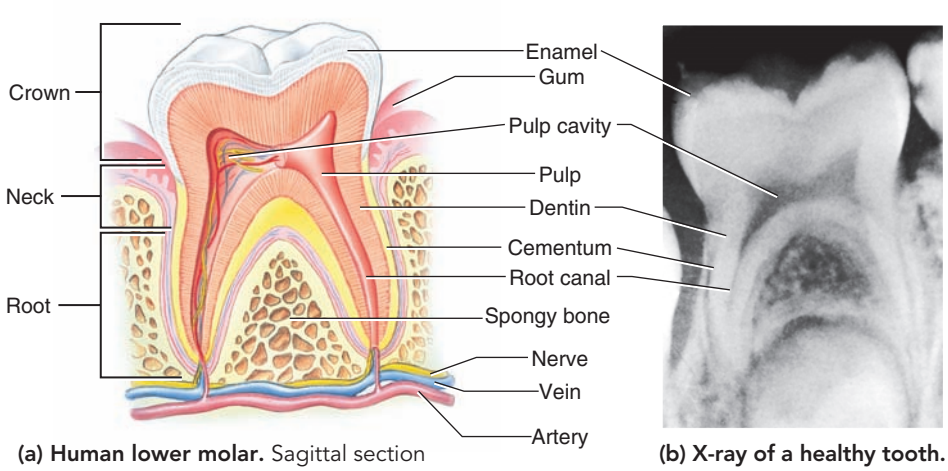
(b) Herbivore. Horses and other herbivores have incisors (and sometimes canines) adapted for cutting off bits of vegetation. Canines are absent in some herbivores. The broad, ridged surfaces of the molars are adapted for grinding plant material.

(c) Omnivore. The teeth of humans and other omnivores are adapted for chewing a variety of foods.

Figure 47-6 Teeth and diet
An animal's teeth are adapted for its mode of nutrition.

attached to the outer edge of the small intestine, allowing each coil of the intestine to move freely. Until recently, the mesentery was thought to consist of several separate structures. We now know that the mesentery is a continuous structure, extending from the parietal peritoneum to the wall of the intestine. The mesentery extends along most of the length of the intestine. The **greater omentum**, which develops from the mesentery, hangs down over the intestine like a *fatty apron*.

Although described more than 100 years ago, scientists have only recently begun to understand the importance of the mesentery. It has recently been recognized as an organ—the 79th known human organ! Investigators are just beginning to learn about the mesentery's role in health and disease, including cardiovascular disease, obesity, metabolic syndrome, diabetes, colorectal cancer, and Crohn's disease.



Food processing begins in the mouth

Imagine that you have just taken a big bite of a hamburger in a bun. The mouth is specialized for ingestion and for beginning the digestive process. Mechanical digestion begins as you bite, grind, and chew the meat and bun with your teeth. Unlike the simple, pointed teeth of fish, amphibians, and non-avian reptiles, the teeth of mammals vary in size and shape and are specialized to perform specific functions. The chisel-shaped **incisors** are used for biting and cutting food, whereas the long, pointed **canines** are adapted for piercing prey and tearing food (FIG. 47-6). The flattened surfaces of the **premolars** and **molars** are specialized for crushing and grinding.

Each tooth is covered by *enamel*, the hardest substance in the body (FIG. 47-7). Most of the tooth consists of *dentin*,

(b) X-ray of a healthy tooth.

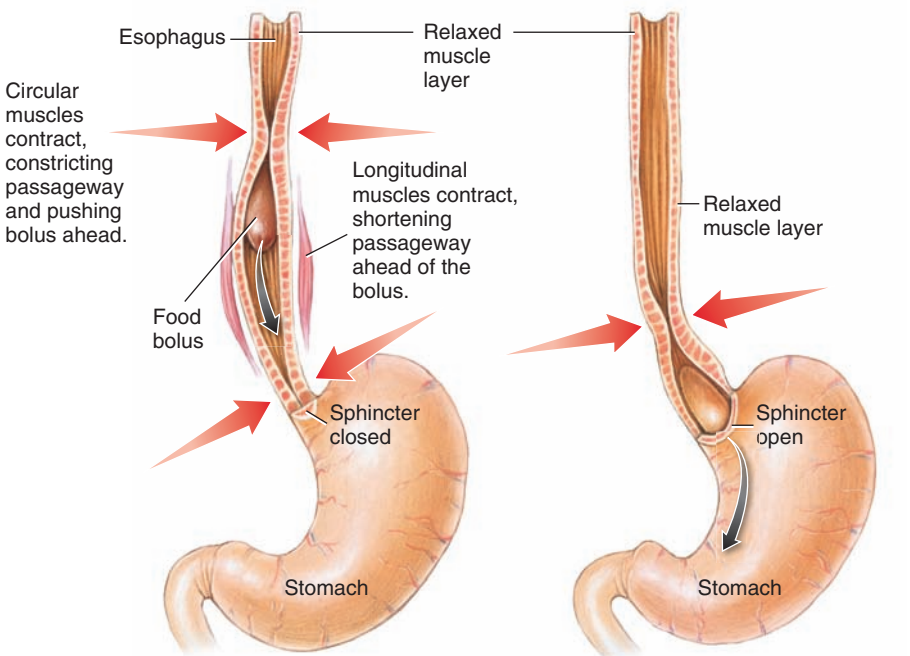
Figure 47-7 Tooth structure

which resembles bone in composition and hardness. The *pulp cavity*, which lies beneath the dentin, is a soft connective tissue containing blood vessels, lymph vessels, and nerves.

While food is being mechanically disassembled by the teeth, it is moistened by saliva. As some of the food molecules dissolve, you can taste the food. (Recall from Chapter 43 that taste buds are located on the tongue and other surfaces of the mouth.) Three pairs of **salivary glands** secrete about a liter of saliva into the mouth cavity each day. Saliva contains an enzyme, **salivary amylase**, which begins the chemical digestion of starch into sugar.

The pharynx and esophagus conduct food to the stomach

After being chewed and fashioned into a lump called a *bolus*, the bite of food is swallowed, moving through the **pharynx** into the **esophagus**. The pharynx, or throat, is a muscular tube that serves as the hallway of both the respiratory system and the digestive system. During swallowing, a small flap of tissue, the **epiglottis**, closes the opening to the airway.



Waves of peristalsis sweep the bolus through the pharynx and esophagus toward the stomach (FIG. 47-8). Circular muscle fibers in the wall of the esophagus contract around the top of the bolus and push it downward. Almost at the same time, longitudinal muscles around the bottom of the bolus and below it contract, which shortens the tube.

When the body is in an upright position, gravity helps move the food through the esophagus, but gravity is not essential. Astronauts eat in its absence, and even if you are standing on your head, food will reach your stomach.

Food is mechanically and enzymatically digested in the stomach

The entrance to the large, muscular **stomach** is normally closed by a ring of muscle at the lower end of the esophagus. When a peristaltic wave passes down the esophagus, the muscle relaxes, and the bolus then enters the stomach (FIG. 47-9). When empty, the stomach is collapsed and shaped almost like a hot dog. Folds of the stomach wall, called **rugae**, give the inner lining a wrinkled appearance. As food enters, the rugae gradually smooth out, which expands the capacity of the stomach to more than a liter.

The stomach is lined with a simple, columnar epithelium that secretes large amounts of mucus. Tiny pits mark the entrances to the millions of **gastric glands**, which extend deep into the stomach wall. *Parietal cells* in the gastric glands secrete hydrochloric acid and *intrinsic factor*, a substance needed for adequate absorption of vitamin B_{12}. *Chief cells* in the gastric glands secrete **pepsinogen**, an inactive enzyme precursor. When it comes in contact with the acidic gastric juice in the stomach, pepsinogen is converted to pepsin, the main digestive enzyme of the stomach. **Pepsin** hydrolyzes proteins, converting them to short polypeptides.

1 A bolus is moved through the esophagus by peristaltic contractions.

2 When the sphincter (ring of muscle) at the entrance of the stomach opens, food enters the stomach.

Figure 47-8 Peristalsis

Key Point

The structure of the stomach is adapted for digesting food; gastric glands in its mucosa secrete digestive juices, and the three layers of muscle in the stomach wall are important in mechanically digesting food.

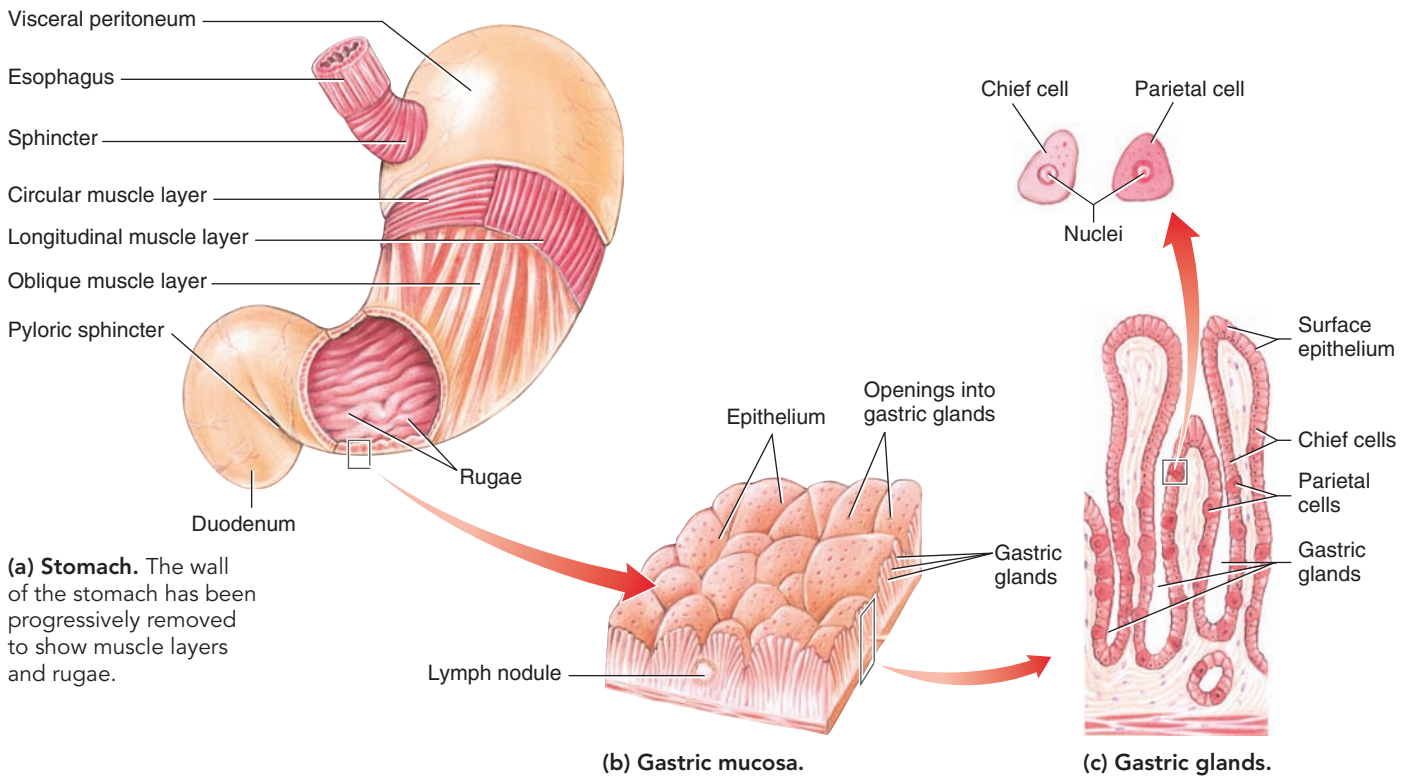

Figure 47-9 Structure of the stomach

The stomach is adapted for digesting food mechanically and enzymatically.

CONNECT What is the benefit of having lymph nodules within the gastric mucosa?

Several protective mechanisms prevent the gastric juice from digesting the wall of the stomach. Cells of the gastric mucosa secrete alkaline mucus that coats the stomach wall and neutralizes the acidity of the gastric juice along its lining. In addition, the epithelial cells of the lining fit tightly together, preventing gastric juice from leaking between them and into the tissue beneath. If some of the epithelial cells become damaged, they are quickly replaced. In fact, about a half million of these cells are shed and replaced every minute!

Sometimes, the part of the stomach lining is digested, leaving an open sore, or *peptic ulcer*. Such ulcers also occur in the duodenum and sometimes in the lower part of the esophagus. The bacterium *Helicobacter pylori* is the cause of about 80% of peptic ulcers (see Fig. 25-13). *Helicobacter pylori* infects the mucus-secreting cells of the stomach lining, decreasing the protective mucus, which can lead to peptic ulcers or cancer. This type of infection responds to antibiotic therapy.

What changes occur in a bite of hamburger during its 3- to 4-hour stay in the stomach? The stomach churns and chemically degrades the food so that it assumes the consistency of a thick soup; this partially digested food is called *chyme*. Digestion of the starch in the bun to small polysaccharides and maltose continues until salivary amylase is inactivated by the acidic pH of the stomach. Protein digestion degrades much of the hamburger protein to polypeptides. Over a period of several hours, peristaltic waves release the chyme in spurts through the stomach exit, the *pylorus*, and into the small intestine.

Most enzymatic digestion takes place in the small intestine

Digestion of food is completed in the **small intestine**, and nutrients are absorbed through its wall. The small intestine, which is 5 to 6 m (about 17 ft) in length, has three regions: the **duodenum**, *jejunum*, and *ileum*. Most chemical digestion takes place in the duodenum, the first portion of the small intestine, not in the stomach. Bile from the liver and enzymes from the pancreas are released into the duodenum and act on the chyme. Then enzymes produced by the epithelial cells lining the duodenum catalyze the final steps in the digestion of the major types of nutrients.

The lining of the small intestine appears velvety because of its millions of tiny fingerlike projections, the intestinal

Key Point

The digestive and absorptive surface area of the small intestine is vastly increased by millions of fingerlike villi; the surface area is further increased by microvilli of the epithelial cells of the villi.

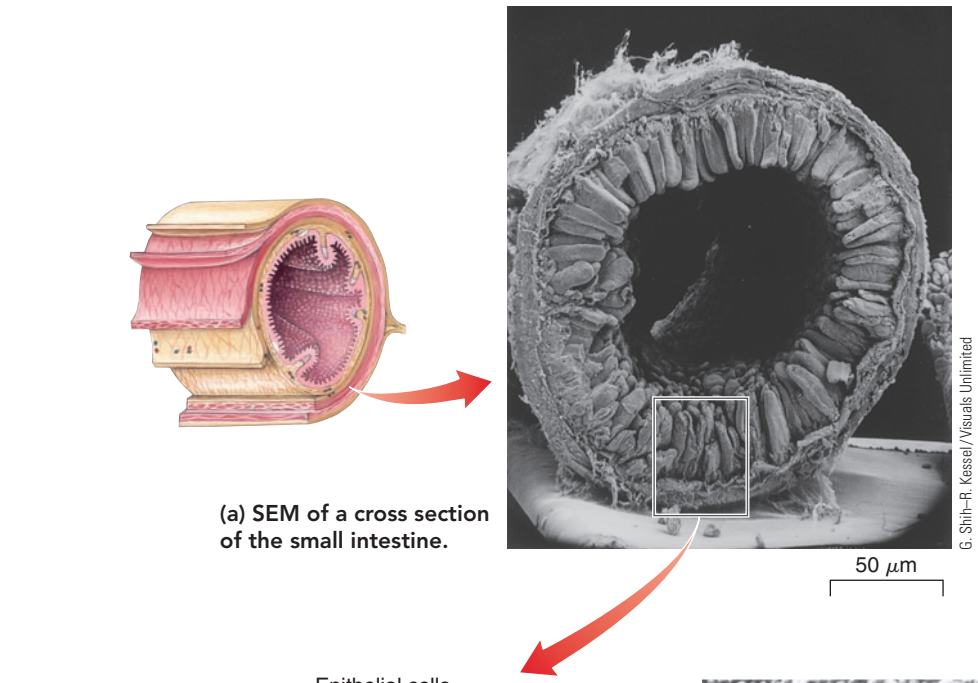

Figure 47-10 Villi and microvilli

CONNECT In celiac disease, the body launches an immune response to gluten, a protein found in wheat, rye, and barley. How could this disease lead to malnutrition?

villi (sing., *villus*) (FIG. 47-10). The villi increase the surface area of the small intestine for digestion and absorption of nutrients. The intestinal surface is further expanded by **microvilli**, projections of the plasma membrane of the simple columnar epithelial cells of the villi. About 600 microvilli protrude from the exposed surface of each cell, giving the epithelial lining a fuzzy appearance when viewed with the light microscope.

If the intestinal lining were smooth, like the inside of a water pipe, food would zip right through the intestine, and many valuable nutrients would not be digested or absorbed. Folds in the wall of the intestine, the villi, and microvilli together increase the surface area of the small intestine by about 600 times. If we could unfold and spread out the lining of the small intestine of an adult human, its surface would approximate the size of a tennis court.

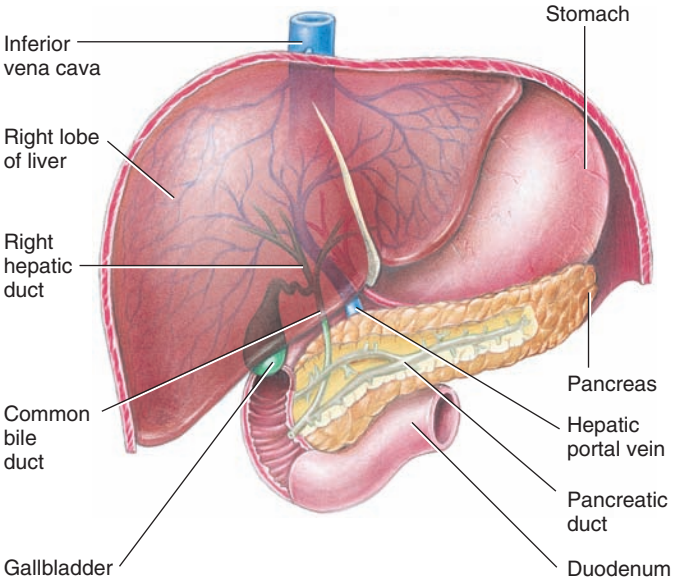

Figure 47-11 The liver and pancreas

The gallbladder stores bile from the liver. Note the ducts that conduct bile to the gallbladder and the duodenum. The stomach has been displaced to expose the pancreas, which secretes several digestive enzymes into the duodenum.

The liver secretes bile

The **liver**, the largest internal organ and also one of the most complex organs in the body, lies in the upper-right part of the abdomen just under the diaphragm (FIG. 47-11). The liver secretes **bile**, which mechanically digests fats by a detergent-like action (discussed in a later section). Bile consists of water, bile salts, bile pigments, cholesterol, salts, and lecithin (a phospholipid). Because it contains no digestive enzymes, bile does not enzymatically digest food. The pear-shaped **gallbladder** stores and concentrates bile and releases it into the duodenum as needed.

A single liver cell can carry on more than 500 separate, specialized metabolic activities! The liver performs these vital functions:

1. Secretes bile that mechanically digests fats
2. Helps maintain homeostasis by removing or adding nutrients to the blood
3. Converts excess glucose to glycogen and stores it
4. Converts excess amino acids to fatty acids and urea
5. Stores iron and certain vitamins
6. Detoxifies alcohol and other drugs and poisons

The pancreas secretes digestive enzymes

The **pancreas** is an elongated gland that secretes both digestive enzymes and hormones that help regulate the level of glucose in the blood. The cells that line the pancreatic ducts secrete an alkaline solution rich in bicarbonate ions. This pancreatic juice neutralizes the stomach acid in the duodenum and provides the optimal pH for action of the pancreatic enzymes. Pancreatic enzymes include **trypsin** and *chymotrypsin*, which digest polypeptides to short peptides; *pancreatic* **lipase**, which degrades fats; *pancreatic amylase*, which breaks down almost all types of complex carbohydrates, except cellulose, to disaccharides; and *ribonuclease* and *deoxyribonuclease*, which split the nucleic acids ribonucleic acid (RNA) and deoxyribonucleic acid (DNA) into free nucleotides.

Nutrients are digested as they move through the digestive tract

Chyme moves through the digestive tract by peristalsis, mixing contractions, and motions of the villi. As nutrients in the chyme move through the small intestine, they come into contact with enzymes that digest them (TABLE 47-1).

Table 47-1 Summary of Digestion

	Carbohydrates	Proteins	Lipids
Mouth	Polysaccharides ↓ **Salivary amylase** Maltose and small polysaccharides		
Stomach	Action continues until acidic pH inactivates salivary amylase	Protein ↓ **Pepsin** Short polypeptides	
Small intestine	Undigested polysaccharides ↓ **Pancreatic amylase** Maltose and other disaccharides ↓ **Maltase, sucrase, lactase** Monosaccharides	Polypeptides ↓ **Trypsin, chymotrypsin** Short peptides ↓ **Carboxypeptidase, peptidases, dipeptidases** Amino acids	Glob of fat ↓ **Bile salts** Emulsified fat droplets ↓ **Pancreatic lipase** Fatty acids and glycerol

Carbohydrates are digested to monosaccharides Polysaccharides, such as starch and glycogen, are important components of the food ingested by most animals. The glucose units of these large molecules are connected by glycosidic bonds linking carbon 4 (or 6) of one glucose molecule with carbon 1 of the adjacent glucose molecule. These bonds are hydrolyzed (broken down through the addition of water molecules; see Chapter 3) by *amylases* that digest polysaccharides to the disaccharide maltose. Although amylase can split the α-glycosidic linkages present in starch and glycogen, it cannot split the β-glycosidic linkages present in cellulose (see Figs. 3-9 and 3-10).

Enzymes produced by the cells lining the small intestine break down disaccharides such as maltose to monosaccharides. *Maltase*, for example, splits maltose into two glucose molecules (see Fig. 3-8a). Hydrolysis occurs while the disaccharides are being absorbed through the epithelium of the small intestine.

Proteins are digested to amino acids Several proteolytic enzymes are secreted into the digestive tract. Each enzyme breaks peptide bonds at one or more specific locations in a polypeptide chain. Trypsin, secreted in an inactive form by the pancreas, is activated by an enzyme called *enterokinase*. The trypsin then activates chymotrypsin and carboxypeptidase as well as additional trypsin.

Carboxypeptidase removes amino acids with free terminal carboxyl groups from the end of polypeptide chains. Pepsin, trypsin, and chymotrypsin break certain internal peptide bonds of proteins and polypeptides. *Dipeptidases* released by the duodenum then split the small peptides into amino acids.

Fats are digested to fatty acids and monoacylglycerols Lipids are usually ingested as large masses of triacylglycerols (also called triglycerides; recall from Chapter 3 that a triacylglycerol is a glycerol molecule chemically combined with three fatty acids; see Fig. 3-12b). They are digested mainly within the duodenum by pancreatic lipase. Like many other proteins, lipase is water soluble, but its substrates are not. Thus, the enzyme can attack only the fat molecules at the surface of a mass of fat.

Bile salts act like detergents, reducing the surface tension of fats. Their action, called *emulsification*, breaks large masses of fat into smaller droplets. Emulsification greatly increases the surface area of fat exposed to the action of pancreatic lipase. In this way, bile salts increase the rate of lipid digestion.

Conditions in the intestine are usually not optimal for the complete hydrolysis of lipids to glycerol and fatty acids. Consequently, the products of lipid digestion include monoacylglycerols (monoglycerides) and diacylglycerols (diglycerides) as well as glycerol and fatty acids. Undigested triacylglycerols also remain, some of which are absorbed without digestion.

Nerves and hormones regulate digestion

Most digestive enzymes are produced only when food is present in the digestive tract. Salivary gland secretion is controlled entirely by the nervous system, but secretion of other digestive juices is regulated by both nerves and hormones. The wall of the digestive tract contains dense networks of neurons. This *enteric nervous system* continues to regulate many motor and secretory activities of the digestive system even if sympathetic and parasympathetic nerves to these organs are cut. Many neuropeptides present in the brain are also released by neurons in the digestive tract and help regulate digestion. For example, *substance P* stimulates smooth muscle contraction of the digestive tract, and *enkephalin* inhibits it (see Table 41-2).

Several hormones, including **gastrin**, *secretin*, *cholecystokinin (CCK)*, and *glucose-dependent insulinotropic peptide (GIP)*, help regulate the digestive system (TABLE 47-2). These hormones are small polypeptides secreted by endocrine cells in the mucosa of certain regions of the digestive tract. Investigators are studying several other messenger peptides that are important in regulating digestive activity.

As an example of the regulation of the digestive system, consider the secretion of gastric juice. Seeing, smelling, tasting, or even thinking about food causes the brain to send neural signals to the gastric glands in the stomach. These signals stimulate these glands to secrete gastric juice. In addition, when food

Table 47-2 Some Hormones That Regulate Digestion

Hormone	Source	Target Tissue	Actions	Factors That Stimulate Release
Gastrin	Stomach (mucosa)	Stomach (gastric glands)	Stimulates gastric glands to secrete pepsinogen and HCl; stimulates gastric motility	Distention of the stomach by food; certain substances such as partially digested proteins and caffeine
Secretin	Duodenum (mucosa)	Pancreas	Stimulates pancreas to secrete sodium bicarbonate, which neutralizes acid in duodenum	Acidic chyme acting on mucosa of duodenum
		Liver	Stimulates bile secretion	
		Stomach	Inhibits gastric secretion and gastric emptying	
Cholecystokinin (CCK)	Duodenum (mucosa)	Pancreas	Stimulates release of digestive enzymes	Presence of fatty acids and partially digested proteins in duodenum
		Gallbladder	Stimulates emptying of bile	
		Brain	Helps regulate food intake by signaling satiety	
Glucose-dependent insulinotropic peptide (GIP)	Duodenum (mucosa)	Pancreas	Stimulates insulin secretion	Presence of glucose in duodenum

distends the stomach, stretch receptors send neural messages to the medulla. The medulla then sends messages to endocrine cells in the stomach wall that secrete gastrin. After being transported by the circulatory system, gastrin returns to the stomach, where it stimulates the stomach to release gastric juice. Gastrin also stimulates gastric and intestinal motility, and gastric emptying.

Absorption takes place mainly through the villi of the small intestine

Only a few substances—water, simple sugars, salts, alcohol, and certain drugs—are small enough to be absorbed through the stomach wall. Absorption of nutrients is primarily the job of the intestinal villi. As illustrated in Figure 47-10, the wall of a villus is a single layer of epithelial cells. Inside each villus is a network of capillaries and a central lymph vessel, called a **lacteal**.

To reach the blood (or lymph), a nutrient molecule must pass through an epithelial cell lining the intestine and through a cell lining a blood or lymph vessel. Absorption occurs by a combination of simple diffusion, facilitated diffusion, and active transport. Because glucose and amino acids cannot diffuse through the intestinal lining, they must be absorbed by active transport. Absorption of these nutrients is coupled with the active transport of sodium (see Chapter 5). Fructose is absorbed by facilitated diffusion.

Amino acids and glucose are transported directly to the liver by the *hepatic portal vein*. In the liver this vein divides into a vast network of tiny blood sinuses, vessels similar to capillaries. As the nutrient-rich blood moves slowly through the liver, nutrients and certain toxic substances are removed from the circulation.

The products of lipid digestion are absorbed by a different process and different route. After free fatty acids and monoacylglycerols enter an epithelial cell in the intestinal lining, they are reassembled as triacylglycerols in the smooth endoplasmic reticulum. The triacylglycerols, along with absorbed cholesterol and phospholipids, are packaged into protein-covered fat droplets, called **chylomicrons**.

After they are released into the interstitial fluid, chylomicrons enter the lacteal (lymph vessel) of the villus. Chylomicrons are transported in the lymph to the subclavian veins, where the lymph and its contents enter the blood. About 90% of absorbed fat enters the blood circulation in this indirect way. The rest, mainly short-chain fatty acids such as those in butter, are absorbed directly into the blood. After a meal rich in fats, the great number of chylomicrons in the blood may give the plasma a turbid, milky appearance for a few hours. Chylomicrons transport fats to the liver and other tissues.

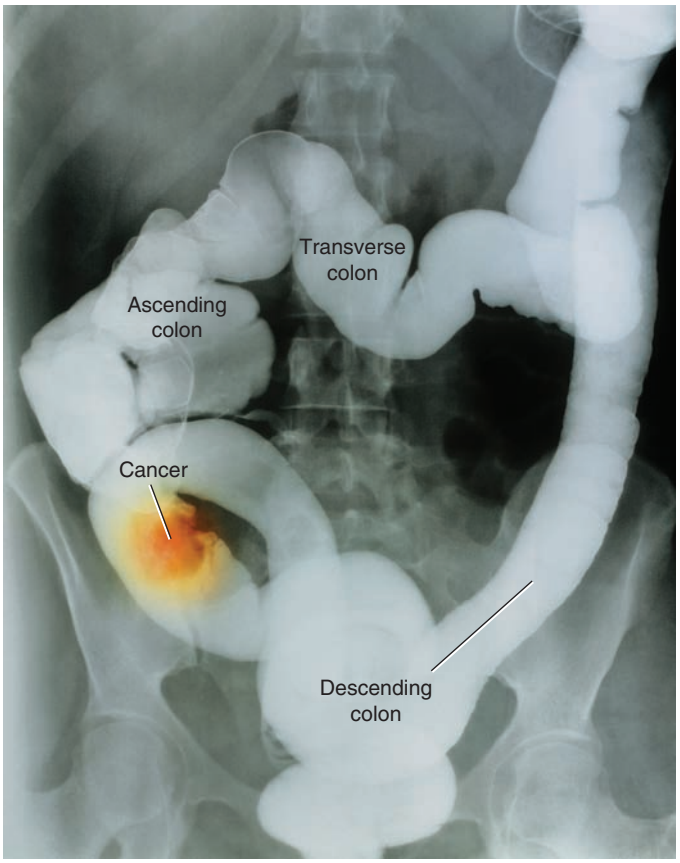
Most of the nutrients in the chyme are absorbed by the time it reaches the end of the small intestine. What is left (mainly waste) passes through a sphincter, the *ileocecal valve*, into the large intestine.

The large intestine eliminates waste

Undigested material, such as the cellulose of plant foods, along with unabsorbed chyme passes into the **large intestine** (see Fig. 47-4). Although only about 1.3 m (about 4 ft) long, this part of the digestive tract is referred to as "large" because its diameter is greater than that of the small intestine. The small intestine joins the large intestine about 7 cm (2.8 in.) from the end of the large intestine, forming a blind pouch, the **cecum**. Herbivores such as rabbits have a large, functional cecum that holds food while bacteria digest its cellulose. The *vermiform appendix* projects from the end of the cecum. (Appendicitis is an inflammation of the appendix.) Until recently, the appendix was considered a vestigial organ. Researchers have recently discovered that the appendix plays an important role in immune functions.

From the cecum to the **rectum** (the last portion of the large intestine), the large intestine is known as the **colon**. The regions of the large intestine are the cecum; ascending colon; transverse colon; descending colon; sigmoid colon; rectum; and **anus**, the opening for the elimination of wastes.

As chyme passes slowly through the large intestine, water and sodium are absorbed from it, and it gradually assumes the consistency of normal feces. Members of the intestinal **microbiome** (also referred to as the gut microbiome) that inhabit the large intestine are nourished by the last remnants of the meal. In exchange, certain bacteria of the microbiome produce large amounts of vitamin K and certain B vitamins (biotin, thiamine, and riboflavin) that can be absorbed and used. (The intestinal microbiome is part of the human microbiome, described in Chapter 25.)



Researchers are currently studying the relationship of the intestinal microbiome with many important health issues, including obesity, cancer, and mental health. For example, members of the intestinal microbiome produce a high percentage of the serotonin that the brain uses to regulate mood. Insufficient serotonin in the brain is associated with depression and anxiety. The microbiome also works with the immune system to keep the body healthy. For example, it helps prevent infection from pathogenic organisms (see *Inquiring About: The Human Microbiota: Our Many Symbionts* in Chapter 54).

A distinction should be made between elimination and excretion. *Elimination* is the process of getting rid of digestive wastes, materials that have not been absorbed from the digestive tract and did not participate in metabolic activities. In contrast, *excretion* is the process of getting rid of metabolic wastes, which in mammals is mainly the function of the kidneys and lungs. The large intestine, however, does *excrete* bile pigments, as well as potassium and chloride ions.

When chyme passes through the intestine too rapidly, *defecation* (expulsion of feces) becomes more frequent, and the feces are watery. This condition, called *diarrhea*, may be caused by anxiety, certain foods, or pathogens that irritate the intestinal lining. Prolonged diarrhea results in loss of water and salts and leads to dehydration, which can be a serious condition, especially in infants. *Constipation* results when chyme passes through the intestine too slowly. Because more water than usual is removed from the chyme, the feces may be hard and dry. Constipation is often caused by a diet deficient in fiber. Colorectal cancer occurs in the colon or rectum (FIG. 47-12). In Western countries, colorectal cancer is the second most common cancer, and in the United States, it is the second leading cancer killer. Several factors contribute to the risk of developing colon cancer, including certain genetic factors and family history, smoking, heavy use of alcohol, physical inactivity, and obesity. A diet high in red meat

Figure 47-12 Colon cancer

In this radiographic view of the large intestine, cancer is evident as a mass that projects into the lumen of the colon. (The cancer has been color-enhanced.) The large intestine has been filled with a suspension of barium sulfate, which makes irregularities in the wall visible.

and processed meat and low in fresh fruit, vegetables, poultry, and fish increases the risk. Self-examination and screening are important because they allow early diagnosis. Cancer can be prevented by detecting and removing polyps (benign growths that can become malignant) early. Both men and women should be screened for colorectal cancer beginning at age 50.

CHECKPOINT 47.2

- Imagine that you have just taken a bite of a chicken sandwich. List in sequence the structures through which that food passes in its journey through the digestive system. What happens in each structure?
- **CONNECT** How are villi in the small intestine functionally related to rugae in the stomach?
- What are the functions of each of the following: trypsin, bile salts, gastrin, lacteals?
- **VISUALIZE** Draw a sketch of the large intestine and label the cecum, transverse colon, descending colon, vermiform appendix, ascending colon, sigmoid colon, and rectum.

47.3 Required Nutrients

LEARNING OBJECTIVES

6 Summarize the nutritional requirements for dietary carbohydrates, lipids, and proteins, and trace the fate of glucose, lipids, and amino acids after their absorption.

7 Describe the nutritional functions of vitamins, minerals, and phytochemicals.

Adequate amounts of nutrients are necessary for metabolic processes. Animals require carbohydrates, lipids, proteins, vitamins, minerals, and water. Nutritionists are also investigating plant compounds called *phytochemicals* that are important in nutrition. Water is a necessary dietary component because water is the medium in which all the body's biochemical processes take place. Sufficient water must be ingested to replace water lost in urine, sweat, feces, and breath.

Nutritionists continually consider new data and re-examine the *relative* amounts of various types of nutrients recommended for a healthy diet. Current dietary guidelines in the United States suggest that 50% to 60% of our calories should come from carbohydrates, about 30% from fat, and 12% to 20% from protein.

Recall from Chapter 1 that **metabolism** includes all the chemical processes that take place in the body. Metabolism includes anabolic and catabolic processes. **Anabolism** includes the synthetic aspects of metabolism, such as the production of proteins and nucleic acids. **Catabolism** includes breakdown processes, such as hydrolysis. Nutritionists measure the energy value of food in kilocalories, or simply Calories. A Calorie, spelled with a capital *C*, denotes a **kilocalorie (kcal)**, defined as the amount of heat required to raise the temperature of 1 kilogram of water 1°C.

Carbohydrates provide energy

Sugars and starches are important sources of energy in the human diet. Most carbohydrates are ingested in the form of starch and cellulose, both polysaccharides composed of long chains of glucose subunits. (You may want to review the discussion of carbohydrates in Chapter 3.) Nutritionists refer to *polysaccharides* as *complex carbohydrates*. Foods rich in complex carbohydrates include rice, potatoes, corn, and other cereal grains.

When we eat an excess of carbohydrate-rich food, the liver cells become fully packed with glycogen and convert excess glucose to fatty acids and glycerol. Liver cells convert these compounds to triacylglycerols and send them to the fat deposits of the body for storage.

Refined carbohydrates, such as white bread and white rice, are unhealthy because the refining process removes fiber and many vitamins and minerals. The refining process also produces a form of starch that the digestive system rapidly breaks down to glucose. The resulting rapid increase in glucose concentration in the blood stimulates the pancreas to release a large amount of insulin. This hormone lowers blood glucose level by signaling the liver and muscles to remove glucose from

the blood. When glucose and insulin levels are high, two things happen: triacylglycerol levels increase, and high-density lipoprotein (HDL; the good cholesterol) concentration decreases. These metabolic events can lead to cardiovascular disease and increase the risk of type 2 diabetes (discussed in Chapter 49).

Dietary fiber decreases cholesterol concentration in the blood and is associated with a lower risk for cardiovascular disease and diabetes. *Fiber* is mainly a mixture of cellulose and other indigestible carbohydrates. We obtain dietary fiber by eating fruits, vegetables, and whole grains. The U.S. diet is low in fiber because of low intake of fruits and vegetables and the use of refined flour. Increasing fiber in the diet has a variety of health benefits. For instance, fiber stimulates the feeling of being satisfied (satiety) after food intake and thus is useful in treating obesity.

Lipids provide energy and are used to make biological molecules

Cells use ingested lipids as a source of energy and to make a variety of lipid compounds, including components of cell membranes, steroid hormones, and bile salts. We ingest about 98% of our dietary lipids in the form of triacylglycerols (triglycerides). Triacylglycerols may be saturated—that is, fully loaded with hydrogen atoms—or their fatty acids may be monounsaturated (containing one double bond) or polyunsaturated (containing two or more double bonds).

Three polyunsaturated fatty acids (linoleic, linolenic, and arachidonic acids) are essential fatty acids that humans must obtain from food. Given these and sufficient nonlipid nutrients, the body can make all the lipid compounds (including fats, cholesterol, phospholipids, and prostaglandins) it needs. The average U.S. diet provides far more cholesterol than the recommended daily maximum of 300 mg. High-cholesterol sources include egg yolks, butter, ice cream, and meat.

How are lipids transported? Recall that chylomicrons transport lipids from the intestine to the liver and to other tissues. As chylomicrons circulate in the blood, the enzyme *lipoprotein lipase* breaks down triacylglycerols. The fatty acids and glycerol can then be taken up by the cells. What is left of the chylomicron, a remnant made up mainly of cholesterol and protein, is taken up by the liver.

Liver cells repackage cholesterol and triacylglycerols. These lipids are bound to proteins and transported as large molecular complexes, called **lipoproteins**. Some plasma cholesterol is transported by **high-density lipoproteins**, or **HDLs** ("good" cholesterol), but most is transported by **low-density lipoproteins**, or **LDLs** ("bad" cholesterol). LDLs deliver cholesterol to the cells. For cells to take in LDLs, a protein (apolipoprotein B) on the LDL surface must bind with a protein *LDL receptor* on the plasma membrane (see Fig. 5-22). After binding, the LDL enters the cell, and its cholesterol and other components are used. When cholesterol levels are high, HDLs collect the excess cholesterol and transport it to the liver. HDLs decrease risk for cardiovascular disease.

When needed, stored fats are hydrolyzed to fatty acids and released into the blood. Before cells can use these fatty acids as fuel, they are broken down into smaller compounds and combined with coenzyme A to form molecules of acetyl coenzyme A (acetyl CoA; FIG. 47-13). Acetyl CoA enters the citric acid cycle (see discussion of cellular respiration in Chapter 8). The conversion of fatty acids to acetyl CoA is accomplished in the liver by a process known as *β-oxidation*.

For transport to the cells, acetyl coenzyme A is converted into one of three types of *ketone bodies* (four-carbon ketones). Normally, the level of ketone bodies in the blood is low, but in certain abnormal conditions, such as starvation and diabetes mellitus, fat metabolism is tremendously increased. Ketone bodies are then produced so rapidly that their level in the blood becomes excessive, which may make the blood too acidic to function normally. Such disrupted pH balance can lead to death.

What is the relationship between fat and cholesterol intake and cardiovascular disease? Lipids play a key role in the development of atherosclerosis, a progressive disease in which the arteries become clogged with fatty material (see Chapter 44). Low-density lipoproteins are the main source of the cholesterol that builds up in the walls of arteries. The type of fat consumed—as well as other dietary and lifestyle factors—is important. You can promote a healthy proportion of HDL to LDL by exercising regularly, following a healthy diet, maintaining appropriate body weight (obesity raises LDL and triacylglycerol levels), and by not smoking cigarettes.

In general, animal foods are rich in both saturated fats and cholesterol, whereas most plant foods contain unsaturated fats and no cholesterol. Butter contains mainly saturated fats. Commonly used polyunsaturated vegetable oils are corn,

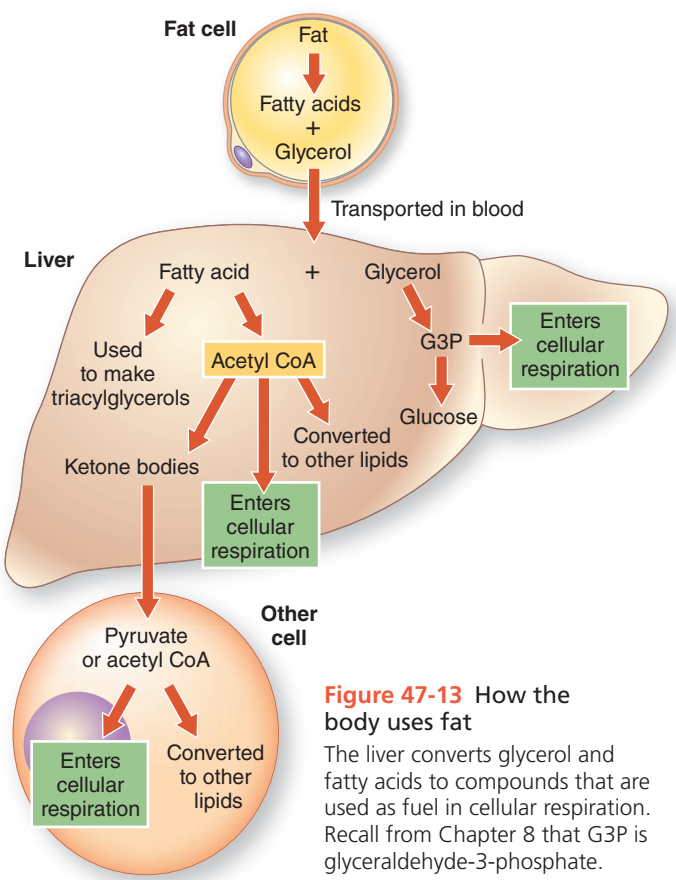

Figure 47-13 How the body uses fat

The liver converts glycerol and fatty acids to compounds that are used as fuel in cellular respiration. Recall from Chapter 8 that G3P is glyceraldehyde-3-phosphate.

soybean, and safflower oils. Monounsaturated fats raise HDL level, as does stearic acid, the saturated fat in chocolate. Olive, canola, and peanut oils contain large amounts of monounsaturated fats. A few plant oils, including palm oil and coconut oil, are high in saturated fats. Their effects on blood lipids and their role in causing cardiovascular disease are the focus of ongoing investigation. **Omega-3 fatty acids** (found in fish and some plant oils) decrease LDL levels and play other protective roles in decreasing the risk for coronary heart disease.

A diet high in saturated fats and cholesterol increases the cholesterol concentration in the blood by as much as 25%. Because polyunsaturated fats decrease the blood cholesterol level, many people cook with vegetable oils rather than with butter and lard, drink skim milk rather than whole milk, and eat low-fat ice cream. Some use margarine instead of butter. However, during production of many margarines, vegetable oils are partially hydrogenated (some of the carbons accept hydrogen to become fully saturated). During hydrogenation, some double bonds are transformed from a *cis* arrangement to a *trans* arrangement (see Fig. 3-3b), forming *trans fatty acids*; the harder the margarine, the higher the *trans* fatty acid content. Health concerns have been raised because *trans* fatty acids increase LDL cholesterol in the blood and lower HDL. In response there has been a decrease in the use of *trans* fatty acids in commercial products. However, some fast foods, baked goods, and snack foods still contain *trans* fatty acids.

Although some fats, such as *trans* fatty acids and saturated fats, are unhealthy, others, such as omega-3 fatty acids and monounsaturated fat, promote health. The Inuits in Greenland have diets extremely high in fat. However, because their dietary fat is rich in omega-3 fatty acids, they have a low incidence of heart disease.

Proteins serve as enzymes and as structural components of cells

Proteins are essential building blocks of cells, serve as enzymes, and are used to make essential compounds such as receptors, hemoglobin and myosin. Protein consumption is an index of a country's (or an individual's) economic status because high-quality protein tends to be the most expensive and least available of the nutrients. In many parts of the world, protein poverty is one of the most pressing health problems.

Ingested proteins are degraded in the digestive tract to small peptides and amino acids. Of the 20 or so amino acids important in nutrition, approximately 9 (10 in children) cannot be synthesized by humans at all, or at least not in sufficient quantities to meet the body's needs. The diet must provide these **essential amino acids** (see Chapter 3).

Complete proteins, those that contain the most appropriate distribution of amino acids for human nutrition, are found in fish, meat, nuts, eggs, and milk. Some foods, such as gelatin and legumes (soybeans, beans, peas, peanuts), contain a high proportion of protein. However, they either do not contain all the essential amino acids or do not contain them in proper nutritional proportions. Most plant proteins are deficient in one or more essential amino acids. The healthiest sources of protein are fish, chicken, nuts, and legumes.

Amino acids circulating in the blood are taken up by cells and used for the synthesis of proteins. The liver removes excess amino acids from the circulation. Liver cells deaminate amino acids; that is, they remove the amino group (FIG. 47-14). During deamination, ammonia is produced from the amino group. Ammonia, which is toxic at high concentrations, is converted to urea and excreted from the body. The remaining carbon chain of the amino acid (called a *keto acid*) may be converted into carbohydrate or lipid and used as fuel or stored. For this reason, people who eat high-protein diets can gain weight if they eat too much.

Vitamins are organic compounds essential for normal metabolism

Vitamins are organic compounds required in the diet in relatively small amounts for normal biochemical functioning. Many are components of coenzymes (see Chapter 7). Nutritionists divide vitamins into two main groups. *Fat-soluble vitamins* include vitamins A, D, E, and K. *Water-soluble vitamins* are the B and C vitamins. Fruit and vegetables are rich sources of vitamins. TABLE 47-3 provides the sources, functions, and consequences of deficiency for the vitamins.

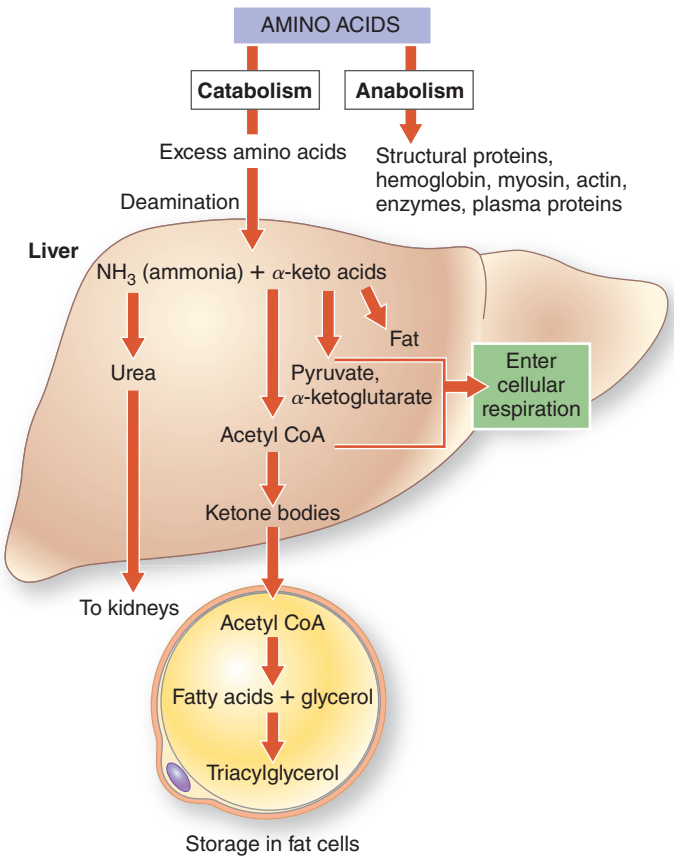

Figure 47-14 How the body uses protein

The liver plays a central role in protein metabolism. Deamination of amino acids and conversion of the amino groups to urea take place there. In addition, many proteins are synthesized in the liver. Note that you can gain weight on a high-protein diet because excess amino acids can be converted to fat.

Table 47-3 The Vitamins

Vitamins and U.S. RDA	Actions	Effects of Deficiency	Sources
FAT-SOLUBLE VITAMINS			
Vitamin A (retinal)	Converted to retinal; essential for normal vision; essential for normal growth and differentiation of cells; reproduction; immunity	Retarded growth; night blindness; worldwide millions of children are at risk of blindness from vitamin A deficiency; decrease in blood stem cells; increased risk of infections	Liver; fortified milk and dairy products; orange, yellow, and green vegetables and fruit, such as carrots, broccoli, and cantaloupe
Vitamin D (calciferol) Two major forms: vitamin D_2 is derived mainly from plant foods in diet; vitamin D_3 is derived from animal foods in diet and synthesis in skin	Promotes calcium and phosphorus absorption from digestive tract; essential to normal growth and maintenance of bone	Weak bones; bone deformities; rickets in children, softening of the bones (osteomalacia) in adults; affects immune function	Fish oils, egg yolk, fortified milk, butter, margarine, salmon; synthesized in the skin through action of sunlight
Vitamin E (tocopherols)	Antioxidant; protects unsaturated fatty acids and cell membranes	Increased catabolism of unsaturated fatty acids so that not enough are available for maintenance of cell membranes; prevention of normal growth; nerve damage	Polyunsaturated plant oils, nuts, leafy greens, whole-grain products
Vitamin K	Synthesis of proteins necessary for blood-clotting; important in bone function	Prolonged blood-clotting time; hemorrhage	Synthesized by bacteria of the intestinal microbiome; leafy greens, legumes
WATER-SOLUBLE VITAMINS			
Vitamin C (ascorbic acid)	Synthesis of collagen, some hormones, and neurotransmitters; antioxidant; important in immune function	Scurvy (wounds heal very slowly, and scars become weak and split open; capillaries become fragile; bone does not grow or heal properly); impaired immunity	Citrus fruit, strawberries, tomatoes, leafy vegetables, cabbage-type vegetables
Thiamine (vitamin B_1)	Active form is a coenzyme in many enzyme systems; important in carbohydrate and amino acid metabolism	Beriberi (weakened heart muscle, enlarged right side of heart, nervous system and digestive tract disorders); deficiency common in alcoholics	Liver, meat, fish, yeast, whole-grain or enriched breads, green leafy vegetables; also produced by bacteria of the intestinal microbiome
Riboflavin (vitamin B_2)	Used to make coenzymes (e.g., FAD) essential in energy metabolism	Dermatitis, inflammation of mouth	Liver, dairy products, meat, green leafy vegetables, whole-grain or enriched breads; also produced by bacteria of the intestinal microbiome
Niacin	Component of important coenzymes (NAD^+ and $NADP^+$); essential to energy metabolism	Pellagra (dermatitis, diarrhea, dementia, weakness, fatigue)	Meat, fish, dairy products, nuts, whole-grain or enriched breads
Vitamin B_6 (pyridoxine)	Part of coenzyme needed in amino acid and fatty acid metabolism	Dermatitis, anemia, depression, convulsions	Meat, fish, whole grains, legumes, soy, green leafy vegetables
Pantothenic acid	Component of coenzyme A (important in energy metabolism)	Deficiency rare; sleep disturbances, fatigue	Widespread in foods; meat, eggs, whole grains, legumes
Folate (folic acid)	Coenzyme needed for nucleic acid synthesis and maturation of red blood cells	Anemia; neural tube birth defects; increased risk of cardiovascular disease and certain cancers; deficiency common in alcoholics	Liver, legumes, dark green leafy vegetables, citrus fruit and juices, whole grains
Biotin	Coenzyme important in metabolism	Deficiency uncommon; anemia, dermatitis	Produced by bacteria of the intestinal microbiome; liver, chocolate, egg yolks
Vitamin B_{12} (cobalamin)	Coenzyme important in DNA synthesis and metabolism; works with folate in production of red blood cells	A type of anemia, fatigue	Liver, meat, fish, dairy products

Health professionals debate the advisability of taking large amounts of certain specific vitamins, such as vitamin C to prevent colds or vitamin E to protect against vascular disease. Some studies suggest that vitamin A (found in yellow and green vegetables) and vitamin C (found in citrus fruits and tomatoes) help protect against certain forms of cancer. We do not yet understand all the biochemical roles played by vitamins or the interactions among various vitamins and other nutrients. We do know, however, that, like vitamin deficiency, large overdoses of some vitamins can be harmful. Moderate overdoses of the B and C vitamins are excreted in the urine, but surpluses of the fat-soluble vitamins are not easily excreted and can accumulate to harmful levels.

Minerals are inorganic nutrients

Minerals are inorganic nutrients ingested in the form of salts dissolved in food and water (TABLE 47-4). We need certain minerals, including sodium, chloride, potassium, calcium, phosphorus, magnesium, manganese, and sulfur, in amounts of 100 mg or more daily. These nutrients are referred to as *major minerals*. Several others, such as iron, copper, iodide, fluoride, and selenium, are **trace elements**, minerals that we require in minute amounts (less than 100 mg per day).

Minerals are necessary components of body tissues and fluids. Salt content (about 0.9% in plasma) is vital in maintaining the fluid balance of the body, and because salts are lost from the body daily in sweat, urine, and feces, they must be replaced by dietary intake. Sodium chloride (common table salt) is the salt needed in largest quantity in blood and other body fluids. Deficiency results in dehydration. Iron is the mineral most often deficient in the diet. In fact, iron deficiency is one of the most widespread nutritional problems in the world.

Antioxidants inactivate reactive molecules

Normal cell processes that require oxygen produce **oxidants**, highly reactive molecules such as free radicals, peroxides, and superoxides. **Free radicals**, molecules or ions with one or more unpaired electrons, are also generated by ionizing radiation, alcohol, tobacco smoke, and other forms of air pollution. Oxidants damage DNA, proteins, and unsaturated fatty acids by snatching electrons. Damage to DNA causes mutations that may lead to cancer, and injury to unsaturated fatty

Table 47-4 Some Important Minerals and Their Functions

Mineral	Functions	Sources	Effects of Deficiency; Comments
Calcium	Main mineral of bones and teeth; essential for normal blood clotting, muscle contraction, nerve function, and regulation of cell activities	Milk and other dairy products, fish, green leafy vegetables; bones serve as calcium reservoir	Stunted growth; osteoporosis in adults
Phosphorus	Performs more functions than any other mineral; structural component of bone; component of ATP, DNA, RNA, and phospholipids	Meat, fish, dairy products, cereals	Muscle weakness
Sulfur	Component of many proteins and certain vitamins	High-protein foods such as meat, fish, legumes, nuts	None known
Potassium	Principal positive ion within cells; important in muscle contraction, nerve function, and fluid balance	Meat, milk, fruits, vegetables, grains	Deficiency caused by dehydration; muscle weakness; paralysis; confusion; can cause cardiac arrest
Sodium	Principal positive ion in interstitial fluid; important in fluid balance and acid–base balance; neural transmission	Many foods, table salt; too much ingested in average American diet	Muscle cramps, apathy; excessive amounts may contribute to high blood pressure
Chloride	Principal negative ion of interstitial fluid; important in fluid balance and in acid–base balance; component of hydrochloric acid in stomach	Many foods, table salt	Stunted growth in children; muscle cramps
Magnesium	Needed for normal muscle and nerve function	Nuts, whole grains, legumes, green leafy vegetables, seafood, chocolate	Stunted growth in children; weakness; muscle spasms, confusion
Copper	Component of several enzymes; essential for hemoglobin synthesis	Meats, seafood, whole grains, legumes, seeds	Anemia
Iodine	Component of thyroid hormones (help regulate metabolic rate, growth, and development)	Seafood, iodized salt, vegetables grown in iodine-rich soils	Underactive thyroid gland, goiter (abnormal enlargement of thyroid gland); in children, deficiency affects mental and physical development
Manganese	Activates many enzymes; bone formation	Whole grains, nuts, leafy green vegetables; tea	Poorly absorbed from intestine, but deficiency symptoms rare
Iron	Component of hemoglobin, myoglobin, important respiratory enzymes (cytochromes), and other enzymes essential to oxygen transport and cellular respiration	Good sources: meat (especially liver), fish, nuts, egg yolk, legumes, dried fruit	Iron-deficiency anemia; weakness, fatigue, may impair cognitive function; impaired immunity; mineral most likely to be deficient in diet
Fluoride	Component of bones and teeth; makes teeth resistant to decay	Fluoridated water; seafood; tea	Risk of tooth decay; excess causes tooth mottling
Zinc	Cofactor for at least 70 enzymes; helps regulate synthesis of certain proteins; needed for growth and repair of tissues	Meat, fish, dairy products, whole grains, vegetables	Slowed growth in children; loss of appetite; impaired immune function
Selenium	Antioxidant (cofactor for a peroxidase that protects against oxidation by breaking down peroxides)	Seafood, meat, whole grains	Deficiency is rare

acids can damage cell membranes. Free radicals are thought to contribute to atherosclerosis by causing oxidation of LDL cholesterol. Free radicals also lead to chronic inflammation, rheumatoid arthritis, cardiovascular disease, and aging.

Cells have **antioxidants** that inactivate free radicals and other reactive molecules by donating an electron. Antioxidants in tissues include certain enzymes, such as catalase and peroxidase. Their action requires certain minerals, such as selenium, zinc, manganese, and copper. Vitamins C and E, beta-carotene, and coenzyme Q have strong antioxidant activity. A variety of *phytochemicals* are also potent antioxidants (discussed in next section).

Nutritionists recommend that we increase the antioxidants in our diet by eating fruits, vegetables, and other foods high in antioxidants. Studies indicate that antioxidant compounds decrease inflammation, bacterial and viral activity, and the risk of atherosclerosis, mutations, and cancer.

Phytochemicals play important roles in maintaining health

A diet that includes all the essential nutrients does not provide the same health benefits as one also rich in fruit and vegetables. The missing ingredients are **phytochemicals**, biologically active plant compounds that promote health. Many phytochemicals are antioxidants. For example, *lycopenes*, which are responsible for the red color of tomatoes, are powerful antioxidants. *Flavonoids*, found in cocoa and especially in dark chocolate, are antioxidants that also appear to lower blood pressure, lower cholesterol, and improve cardiovascular health in other ways.

Some important classes of phytochemicals are *carotenoids* (which include vitamin A and lycopene) in deeply pigmented fruits and vegetables such as carrots and tomatoes; *flavonoids* in berries, herbs, vegetables, barley, soy, black and green teas, and cocoa; *isothiocyanates* and indoles in broccoli and other cruciferous vegetables; and *organosulfur compounds* in garlic and onions. In Asian countries where diets are low in fat and high in soy and green tea, the incidence of breast, prostate, and colorectal cancer is low.

Diets rich in fruits and vegetables lower the incidence of heart disease and of certain types of cancer. Studies comparing diets in various countries suggest that intake of fruits and vegetables may be more important than differences in dietary fat. Yet nutritionists estimate that in the United States only about 1 person in 10 eats the daily recommended 2 to 6.5 cups of fruits and vegetables a day (the equivalent of 4 to 13 servings).

CHECKPOINT 47.3

- What are the major categories of required nutrients?
- What is the function of glucose? of essential amino acids?
- **CONNECT** How are low-density lipoproteins (LDLs) related to cardiovascular disease?

47.4 Energy Metabolism

LEARNING OBJECTIVES

8 Contrast basal metabolic rate with total metabolic rate; write the basic energy equation for maintaining body weight and describe the consequences of altering it in either direction.

9 Identify components of the regulatory pathways that regulate food intake and energy homeostasis.

10 In general terms, describe the effects of malnutrition, including both overnutrition and undernutrition.

The amount of energy liberated by the body per unit time is a measure of its **metabolic rate**. Much of the energy expended by the body is ultimately converted to heat. Metabolic rate may be expressed either in kilocalories of heat energy expended per day or as a percentage above or below a standard normal level.

The **basal metabolic rate (BMR)** is the rate at which the body releases heat as a result of breaking down fuel molecules. BMR is the body's basic cost of living; that is, it is the rate of energy use during resting conditions. This energy is required to maintain body functions such as heart contraction, breathing, and kidney function. *Total metabolic rate* is the sum of the BMR and the energy used to carry on daily activities. A professional athlete has a greater total metabolic rate than a computer programmer who is inactive most of the day and who does not exercise regularly.

An average-sized man who does not exercise and who sits at a desk all day expends about 2100 kcal daily (women expend less energy). If the food the individual eats each day also contains about the same number of kilocalories, the body will be in a state of energy balance; that is, energy input will equal energy output. This concept is important because body weight remains constant when

$$\text{energy input} = \text{energy output}$$

When people take in less energy in food than they expend in daily activity, the body burns stored fat, and they lose weight. In this case,

$$\text{energy input} < \text{energy output}$$

When people take in more energy in food than they expend in daily activity, they gain weight. In this case,

$$\text{energy input} > \text{energy output}$$

Body mass index (BMI), used worldwide as a measure of body size, is an index of weight in relation to height. It is calculated by dividing the square of a person's weight (in kilograms) by height (in meters). The equivalent in the United States is 4.89 times the weight (in pounds) divided by the square of the height (in feet). An adult with a BMI between 18.5 and 24.9 typically has a healthy weight. Although it is still widely used, BMI is no longer considered a valid measure of obesity because it does not consider important factors such as differences in body composition between males and females, between the average adult and a muscular athlete, or among various races.

Energy metabolism is regulated by complex signaling

The hypothalamus regulates energy metabolism and food intake. Biologists have identified signaling molecules that form complex pathways involving the hypothalamus, digestive system, and adipose tissue. Several appetite regulators, including a family of peptides, signal us to eat or to stop eating. For example, when the stomach is empty, it secretes the peptide hormone **ghrelin** (grell´-in), which stimulates appetite. Ghrelin stimulates a set of neurons in the hypothalamus to produce the appetite-stimulating neurotransmitter **neuropeptide Y (NPY)**.

Several compounds send "stop eating" signals following a meal. The gastrointestinal tract releases peptides that signal satiety and suppress food intake. For example, **peptide YY**, secreted by the small and large intestine, signals the hypothalamus to stop secreting NPY. The decrease in NPY slows gastric emptying, suppressing appetite. *Cholecystokinin (CCK)*, released by the duodenum, signals satiety and suppresses appetite. After a meal, the pancreas rapidly releases pancreatic polypeptide (PP), which stays elevated for about 5 hours. PP also appears to signal satiety.

Another set of neurons in the hypothalamus release **melanocortins**, which suppress appetite, resulting in decreased food intake and weight loss. NPY and melanocortins also act on other parts of the brain that regulate food intake.

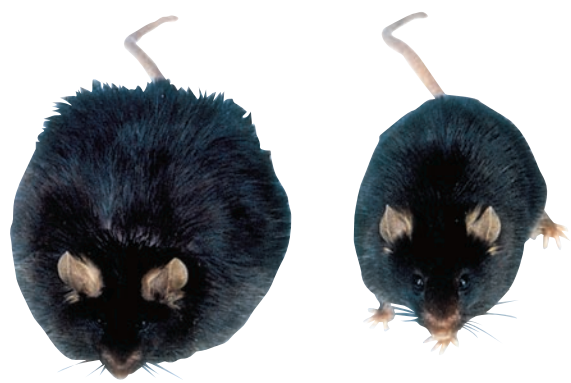
Fat cells in adipose tissue secrete hormones called *adipokines* that are critical in regulating energy metabolism. **Leptin** (from the Greek word *leptos*, "thin") is an adipokine that helps regulate normal body weight. Leptin signals the hypothalamus about the status of energy stores in adipose tissue. As more fat is stored, more leptin is released. Leptin both slows the release of NPY, which stimulates appetite, and stimulates the release of melanocortins, which decrease appetite.

Another important molecular player in the regulation of energy metabolism is **insulin**. This pancreatic hormone is secreted when the concentration of glucose and other nutrients increases after we eat. Insulin stimulates cells, especially liver, muscle, and fat cells, to take in glucose from the blood and use or store it. The actions of insulin inhibit the hypothalamus from secreting NPY. Thus, insulin inhibits further food intake.

The hypothalamus integrates input from these (and other) signaling molecules with other information, such as the concentration of nutrients circulating in the blood. The brain then sends signals that adjust feeding behavior and metabolism so that homeostasis of stored fat and fuel metabolism is maintained. When food is available and energy stores are adequate, energy use increases, fat stores are mobilized, and food (energy) intake is inhibited. Glucose production in the liver is also inhibited.

In contrast, when food intake is low, as during dieting or starvation, the hypothalamus increases secretion of neuropeptide Y. Appetite increases and metabolism slows, two actions that help restore energy homeostasis. The regulation of food intake and energy metabolism continues to be an important focus of research.

Obesity is a serious nutritional problem



Overnutrition causes **obesity**, the excess accumulation of body fat. More than 65% of U.S. adults are overweight, and more than 35% of U.S. adults (more than 78 million) are obese. An estimated 32% of U.S. children and adolescents (2 to 19 years old) are overweight.

Obesity is a serious form of malnutrition that has become a problem of epidemic proportions in affluent societies. The World Health Organization considers obesity to be one of the most important global health problems, and the American Medical Association now considers obesity a disease. Obesity contributes to 1 in 5 deaths annually in the United States and is the second leading preventable cause of death (second only to smoking). It is a major risk factor for heart disease, diabetes mellitus, certain types of cancer (including breast and colon cancers), hypertension, osteoarthritis, and liver and gallbladder diseases. In the well-known Framingham study of more than 2000 men, those who were 20% overweight had a significantly higher mortality rate from all causes than those who were not overweight.

Each of us appears to have a **set point**, or steady state, around which body weight is regulated. Dieting can be difficult because when weight decreases below an individual's set point, energy-conserving mechanisms are activated, causing energy expenditure to decrease.

Many factors affect weight In addition to the array of signaling molecules that affect energy metabolism and body weight, researchers have identified several gene mutations that affect food intake and energy homeostasis. For example, the normal *ob* gene product is leptin. Mice with a mutated allele at the *ob* locus become grossly obese. When researchers inject leptin into grossly obese mice, the appetites of the mice decrease and their energy use increases. They lose weight, mainly from loss of body fat (FIG. 47-15). Unfortunately, most obese humans are resistant to the actions of leptin.

The number of fat cells in the adult is apparently determined mainly by the amount of fat stored during infancy and childhood. When we are overfed early in life, abnormally large numbers of fat cells are produced. Later in life, these fat cells may be fully stocked with excess lipids or may shrink in size, but they are always there. People with such increased numbers of fat cells are thought to be at greater risk for obesity than are those with normal numbers.

Eating activates the dopamine reward circuit in the brain. (Recall that this circuit is also activated in drug addiction.) The amount of dopamine released corresponds to the intensity of pleasure experienced by eating the food. High-calorie foods rich in fats and sugars strongly stimulate the reward system. These foods also stimulate regions of the brain to produce endorphins. In some people, the pleasurable feelings apparently overpower leptin, insulin, and other hormones that normally interact to suppress appetite and inhibit overeating. As an individual gains weight, more insulin and leptin are released. However, the body apparently develops tolerance to these hormones. As with alcohol, cocaine, and other addictive drugs, the more food the addicted individual consumes, the harder it is to satisfy the craving. One hypothesis holds that some obese individuals may have an underactive dopamine reward system. They overeat to compensate and develop a food addiction in the process.

Although some factors involved in obesity are inherited, behavior is critically important. High-calorie diets, overeating, and underexercising lead to obesity, and psychosocial factors influence these behaviors. A sedentary lifestyle combined with the ready availability of high-energy foods contributes to the problem. One researcher cleverly described the roots of the obesity problem as the combination of "computer chips and potato chips." For every 9.3 kcal of excess food taken into the body, about 1 g of fat is stored. (An excess of about 140 kcal, less than a typical candy bar, per day for one month results in a 1-lb weight gain.)

Researchers have identified targets for obesity treatment As researchers discover the genetic and biochemical mechanisms that regulate energy metabolism, they provide potential targets for the development of pharmacological treatments for obesity. The following are among the many targets for drug action that are the focus of research: (1) reduce appetite so that food intake is decreased, (2) block absorption of fat, (3) uncouple metabolism from energy production so that food is dissipated as heat (see *Inquiring About: Electron Transport and Heat* in Chapter 8), and (4) block receptors for molecules that send signals leading to increased energy storage.

Undernutrition can cause serious health problems

Billions of people do not have enough to eat or do not eat a balanced diet. Individuals suffering from *undernutrition* are malnourished. Essential amino acids, iron, calcium, iodine, zinc, and vitamin A are nutrients commonly deficient in the diet. Malnutrition results in poor health and lowered resistance to disease.

Worldwide, more than two billion people suffer from nutritional deficiencies. According to the World Health Organization, more than one-third of the world's children suffer from malnutrition. One half of children (age 6 months to 5 years) have nutritional deficiencies. Inadequate amounts of protein and other essential nutrients severely affect physical growth and mental development. Because children suffering from malnutrition cannot manufacture antibodies (which are proteins) or cells needed to fight infection, they often die from infectious diseases. Globally, malnutrition is the leading cause of death among children.

P. Pittet/United Nations Food and Agricultural Organization

Figure 47-16 Protein deficiency
Millions of children suffer from kwashiorkor, a disease caused by severe protein deficiency. Note the characteristic swollen belly, which results from fluid imbalance.

In young children severe malnutrition results in the condition known as *kwashiorkor*. This Ashanti (West African) word means "first-second" and refers to the situation in which a first child is displaced from its mother's breast when a younger sibling is born. The older child is then given a diet of starchy cereal or cassava that is deficient in protein. Growth becomes stunted, muscles are wasted, and edema develops (as displayed by a swollen belly); the child is anemic and suffers from apathy and impaired metabolism (FIG. 47-16). Without essential amino acids, digestive enzymes cannot be manufactured, so what little protein is ingested cannot be digested. Recent studies suggest that certain gut bacteria may increase the risk for kwashiorkor among malnourished children. In the future, antibiotics may play a role in treatment and recovery.

CHECKPOINT 47.4

- **VISUALIZE** Write an equation to describe energy balance and explain what happens when the equation is altered in either direction.
- What is body mass index (BMI)?
- **CONNECT** How do melanocortins, neuropeptides Y (NPY), ghrelin, and leptin function to maintain energy balance?

Summary: Focus on Learning Objectives

47.1 Nutritional Styles and Adaptations *(page 1011)*

1 Describe food processing and modes of nutrition, and compare the digestive systems of a cnidarian (such as *Hydra*), a flatworm, an earthworm, and a vertebrate.

- **Nutrition** is the process of taking in and using food. *Feeding* is the selection, acquisition, and **ingestion** of food, that is, taking food into the body. **Digestion** is the process of breaking down food mechanically and chemically. Nutrients pass through the lining of the digestive tract and into the blood by **absorption**. Food that is not digested and absorbed is discharged from the body by *egestion* or **elimination**.
- **Herbivores**, or **primary consumers**, are adapted to feed directly on producers. **Predators** are secondary and higher level consumers adapted for capturing and killing prey. **Omnivores** consume both plants and animals.
- In cnidarians and flatworms, food is digested in the **gastrovascular cavity**. This cavity has a single opening that serves as both mouth and anus. In more complex invertebrates and in all vertebrates, the digestive tract is a complete tube with an opening at each end. Digestion takes place as food passes through the tube. Various parts of the digestive tract are specialized to perform specific functions.

47.2 The Vertebrate Digestive System *(page 1013)*

2 Trace the pathway traveled by an ingested meal through the human digestive system and describe the structure and function of each structure involved.

- Mechanical and enzymatic digestion of carbohydrates begins in the mouth. Mammalian teeth include **incisors**, which are adapted for biting and cutting food; **canines** adapted for tearing food; and **premolars** and **molars** adapted for crushing and grinding. Three pairs of **salivary glands** secrete saliva, which contains the enzyme **salivary amylase** that digests starch.
- As food is swallowed, it is propelled through the **pharynx** and **esophagus**. A *bolus* of food is moved along through the digestive tract by **peristalsis**, waves of muscular contraction that push food along.
- In the **stomach** food is mechanically digested by vigorous churning, and proteins are enzymatically digested by the action of **pepsin** in the gastric juice. **Rugae** are folds in the stomach wall that expand as the stomach fills with food. **Gastric glands** secrete hydrochloric acid and **pepsinogen**, the precursor of pepsin.
- After several hours, a soup of partly digested food, called *chyme*, leaves the stomach through the *pylorus* and enters the **small intestine** in spurts. Most enzymatic digestion takes place in the **duodenum**, which produces several digestive enzymes and receives secretions from the liver and pancreas.
- The **liver** produces **bile**, which emulsifies fats. The **pancreas** releases enzymes that digest carbohydrate, lipid, and protein as well as RNA and DNA. *Pancreatic amylase* digests complex carbohydrates. *Pancreatic* **lipase** degrades fats, and **trypsin** and *chymotrypsin* digest polypeptides to small peptides.
- The **large intestine**, which consists of the **cecum**, **colon**, **rectum**, and **anus**, is responsible for eliminating undigested wastes. Bacteria that are part of the intestinal **microbiome** produce vitamin K and certain B vitamins, and have immune functions.

3 Trace the step-by-step digestion of carbohydrate, protein, and lipid.

- Nutrients in chyme are enzymatically digested as they move through the digestive tract. Polysaccharides are digested to the disaccharide maltose by salivary and pancreatic amylases. *Maltase* in the small intestine splits maltose into glucose, the main product of carbohydrate digestion.
- Proteins are split by pepsin in the stomach and by proteolytic enzymes in the pancreatic juice. *Dipeptidases* split small peptides to amino acids.
- Lipids are emulsified by bile salts and then hydrolyzed by pancreatic lipase.

4 Describe the structural adaptations that increase the surface area of the digestive tract.

- The surface area of the small intestine is greatly expanded by folds in its wall; by the intestinal **villi**, elongated projections of the mucosa; and by **microvilli**, projections of the plasma membrane of the epithelial cells of the villi.

5 Compare lipid absorption with absorption of other nutrients.

- Nutrients are absorbed through the thin walls of intestinal villi. The *hepatic portal vein* transports amino acids and glucose to the liver.
- Fatty acids and monoacylglycerols enter epithelial cells in the intestinal lining, where they are reassembled into triacylglycerols. They are packaged into **chylomicrons**, droplets that also contain cholesterol and phospholipids and are covered with a protein coat. The lymphatic system transports chylomicrons to the blood circulation.

47.3 Required Nutrients *(page 1022)*

6 Summarize the nutritional requirements for dietary carbohydrates, lipids, and proteins, and trace the fate of glucose, lipids, and amino acids after their absorption.

- Most carbohydrates are ingested in the form of polysaccharides: starch and cellulose. Polysaccharides are referred to as *complex carbohydrates*. *Fiber* is mainly a mixture of cellulose and other indigestible carbohydrates. Carbohydrates are used mainly as an energy source. Glucose concentration in the blood is carefully regulated. Excess glucose is stored as glycogen and can also be converted to fat.
- Lipids are used to provide energy, to form components of cell membranes, and to synthesize steroid hormones and other lipid substances. Most lipids are ingested in the form of triacylglycerols. Fatty acids are converted to molecules of acetyl coenzyme A, which enter the citric acid cycle. Excess fatty acids are converted to triacylglycerol and stored as fat.
- Lipids are transported as large molecular complexes called **lipoproteins**. **Low-density lipoproteins (LDLs)** deliver cholesterol to the cells. **High-density lipoproteins (HDLs)** collect excess cholesterol and transport it to the liver.
- Proteins serve as enzymes and are essential structural components of cells. The best distribution of **essential amino acids** is found in the complete proteins of animal foods. Excess amino acids are deaminated by liver cells. Amino groups are converted to urea and excreted in urine; the remaining keto acids are converted to

Copyright 2019 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

carbohydrate and used as fuel or are converted to lipid and stored in fat cells.

7 Describe the nutritional functions of vitamins, minerals, and phytochemicals.

- **Vitamins** are organic compounds required in small amounts for many biochemical processes. Many serve as components of coenzymes. *Fat-soluble vitamins* include vitamins A, D, E, and K. *Water-soluble vitamins* are the B and C vitamins.
- **Minerals** are inorganic nutrients ingested as salts dissolved in food and water. **Trace elements** are minerals required in amounts less than 100 mg per day.
- *Phytochemicals* are plant compounds that promote health. Many phytochemicals are **antioxidants** that destroy **oxidants**, reactive molecules such as **free radicals**. Oxidants damage DNA, proteins, and unsaturated fatty acids by snatching electrons.

47.4 Energy Metabolism *(page 1027)*

8 Contrast basal metabolic rate with total metabolic rate; write the basic energy equation for maintaining body weight and describe the consequences of altering it in either direction.

- **Basal metabolic rate (BMR)** is the body's cost of metabolic living. *Total metabolic rate* is the BMR plus the energy used to carry on daily activities.
- When energy (kilocalories) input equals energy output, body weight remains constant. When energy output is greater than energy input, body weight decreases. When energy input exceeds energy output, body weight increases.

9 Identify components of the regulatory pathways that regulate food intake and energy homeostasis.

- The hypothalamus, digestive system, and adipose tissue release signaling molecules that help regulate food intake and energy metabolism.
- When empty, the stomach secretes the hormone **ghrelin**, which stimulates appetite. Ghrelin also stimulates the hypothalamus to release **neuropeptide Y (NPY)**, which stimulates appetite.
- After a meal, the intestine secretes **peptide YY** and *cholecystokinin (CCK)*, which signal satiety and decrease appetite. The hypothalamus releases **melanocortins**, which also suppress appetite.
- Adipose tissue secretes *adipokines* that are important in regulating energy metabolism. The adipokine **leptin** signals the brain about the status of energy stores in adipose tissue. Leptin and the pancreatic hormone **insulin** inhibit food intake.

10 In general terms, describe the effects of malnutrition, including both overnutrition and undernutrition.

- In **obesity**, an excess amount of fat accumulates in adipose tissues. Obesity is a major risk factor for several major disorders, including heart disease and diabetes mellitus. A person gains weight by taking in more energy, in the form of kilocalories, than is expended in activity.
- Undernutrition can be caused by not eating enough food or by not eating a balanced diet. Nutrients commonly deficient in the diet include essential amino acids, iron, calcium, iodine, zinc, and vitamin A. Malnourishment prevents normal physical and mental development. In severe malnutrition, death often results from infectious disease, and in children, by conditions such as *kwashiorkor*.

Test Your Understanding

Know and Comprehend

1. Teeth adapted for crushing and grinding are (a) incisors (b) canines (c) premolars and molars (d) incisors and premolars (e) canines and molars
2. The layer of tissue that lines the lumen of the digestive tract is the (a) muscle layer (b) visceral peritoneum (c) parietal peritoneum (d) mucosa (e) submucosa
3. Which of the following are accessory digestive glands? (a) salivary glands (b) pancreas (c) liver (d) a, b, and c (e) a and b
4. Arrange the following into the correct sequence. 1. stomach 2. esophagus 3. pharynx 4. small intestine 5. colon (a) 2, 3, 1, 4, 5 (b) 3, 2, 1, 5, 4 (c) 3, 2, 5, 1, 4 (d) 2, 3, 1, 5, 4 (e) 3, 2, 1, 4, 5
5. Which sequence most accurately describes the digestion of protein? 1. small peptides 2. amino acid 3. protein 4. polypeptide 5. glycerol (a) 4, 3, 1, 2 (b) 3, 4, 1, 2 (c) 3, 4, 1, 5 (d) 4, 3, 5, 1, 2 (e) 2, 1, 4, 5
6. The surface area of the small intestine is increased by (a) folds in its wall (b) villi (c) microvilli (d) a, b, and c (e) a and b
7. Lipids are transported from the intestine to the liver by (a) chylomicrons (b) HDLs (c) LDLs (d) glycerol transporters (e) leptin
8. Most vitamins are (a) inorganic compounds (b) components of coenzymes (c) used as fuel (d) electrolytes (e) required by herbivores and carnivores but not omnivores
9. When energy input is greater than energy output, (a) weight loss occurs (b) weight remains stable (c) weight gain occurs (d) leptin secretion is inhibited (e) the *ob* gene is deactivated
10. A hormone that stimulates gastric glands to secrete pepsinogen is (a) secretin (b) GIP (c) gastrin (d) cholecystokinin (CCK) (e) Peptide YY

Apply and Analyze

11. **VISUALIZE** Sketch a small area of the lining of the small intestine. Label intestinal glands, lacteal, capillary network of villus, and epithelial cells of villus.
12. Design an experiment to test the hypothesis that the B vitamin pyridoxine is an essential nutrient in mice.
13. Proteolytic enzymes are produced in an inactive form. What, if any, benefit might that have?

Evaluate and Synthesize

14. **EVOLUTION LINK** If you were presented with an unfamiliar animal and asked to determine its nutritional lifestyle, how would you do so? (*Hint:* Consider adaptations.)
15. **SCIENCE, TECHNOLOGY, AND SOCIETY** Investigators are unraveling the biochemical pathways that help regulate body weight. How might their work lead to a cure for obesity? How might a cure for obesity affect our society?

48 Osmoregulation and Disposal of Metabolic Wastes

KEY CONCEPTS

48.1 Osmoregulation is the process by which animals regulate the concentration of water and salts in the body, allowing them to maintain their body fluids within homeostatic limits.

48.2 During metabolism, most animals produce water, carbon dioxide, and nitrogenous wastes, including ammonia, uric acid, and urea.

48.3 Many invertebrates have nephridial organs that carry on osmoregulation and excretion; insects and spiders have Malpighian tubules that excrete metabolic wastes and conserve water.

48.4 Freshwater, marine, and terrestrial animals have different adaptations for osmoregulation that meet the challenges of these diverse environments.

48.5 The vertebrate kidney maintains water and electrolyte balance and excretes metabolic wastes; the nephron is the functional unit of the vertebrate kidney. Several hormones interact to regulate kidney function.

PHOTO: Most terrestrial animals inhabit areas near water sources. Zebras, giraffes, and a variety of antelopes drink at a waterhole in Etosha National Park, Namibia. Clem Haagner/Science Source

Water, the most abundant molecule both in the cell and on Earth's surface, shapes life and is a critical factor in the distribution of organisms on our planet. Most animals need a dependable source of water with which to replenish their body fluids (see photograph). For this reason, animals often inhabit areas near water sources.

Ions are dissolved in water, the medium in which most metabolic reactions take place. The volume and ionic composition of an animal's body fluids must be maintained within homeostatic limits. Through natural selection, a variety of homeostatic mechanisms have evolved that regulate the volume and composition of fluids in the internal environment.

Many small animals live in the ocean and get their food and oxygen directly from the sea water that surrounds them; they release waste products into the sea water. In larger animals and in most terrestrial animals, an *internal* sea of fluid bathes the cells. Terrestrial animals have a continuous need to conserve water. Water loss from the body must be carefully regulated, and water lost must be replaced. Water is taken in with food and drink, and it is also produced in metabolic reactions.

Two processes that help maintain fluid and electrolyte (salt) homeostasis in animals are *osmoregulation* and *excretion*, the disposal of metabolic wastes. In this chapter we discuss these processes in both invertebrates and vertebrates inhabiting various environments. Then we focus on the structure and functions of the mammalian kidney. We end the chapter with a description of the hormones that regulate kidney function.

48.1 Maintaining Fluid and Electrolyte Balance

LEARNING OBJECTIVE

1 Describe how the processes of *osmoregulation* and *excretion* contribute to fluid and electrolyte homeostasis.

Intracellular fluid, the fluid within cells, accounts for most of the body fluid. *Extracellular fluid*, the fluid outside the cells, includes interstitial fluid (the fluid between cells), lymph, and blood plasma (or hemolymph). In vertebrates, blood plasma, which is mainly water, transports nutrients, gases, waste products, and other materials throughout the body. **Interstitial fluid**, also called *tissue fluid*, forms from the blood plasma and bathes all the cells. Excess water evaporates from the body surface or is excreted by specialized structures.

Electrolytes are compounds such as inorganic salts, acids, and bases that form ions in solution. Electrolytes are very important solutes in body fluids. Many homeostatic mechanisms regulate fluid and electrolyte balance.

Recall from Chapter 5 that *osmosis* is the diffusion of water through a selectively permeable membrane. The net flow of water is from a more dilute solution (one with a lower solute concentration) to a less dilute solution (one with a higher solute concentration). If the solute concentrations of two solutions are equal, they are *isotonic* to each other. If solution A has a greater solute concentration than solution B, solution A is *hypertonic* to solution B. Solution B, with a lower solute concentration relative to solution A, is *hypotonic* to solution A. Remember that the total solute concentration of a solution is responsible for the direction of water movement. The *osmotic pressure* of a solution is the pressure that must be exerted on the hypertonic side of a selectively permeable membrane to prevent net movement of water from the hypotonic side.

An **osmole** is related to a mole (see Chapter 2), but takes into account the number of particles produced when a solute dissolves. For example, glucose dissolves to give only one kind of particle, so a mole of glucose in solution is one osmole. A mole of NaCl in solution produces two kinds of particles (Na^+ and Cl^-), so a mole of NaCl is two osmoles. Both types of ions affect the osmotic pressure of the solution. One *milliosmole* is 1/1000 of an osmole.

Osmolarity is a measure of the number of osmoles of solute per liter of solution. Solutions with the same osmolarity are described as *iso-osmotic*. If solution X has a higher osmolarity than solution Y, it is described as *hyperosmotic*. Solution Y would be described as *hypo-osmotic* relative to solution X.

Osmoregulation is the process by which animals regulate the concentration of water and salt in the body, allowing them to maintain their body fluids within homeostatic limits. **Excretion** is the process of discharging metabolic wastes from the body. **Excretory systems** have evolved that function in both osmoregulation and in disposal of metabolic wastes. Excretory systems rid the body of excess water and ions, metabolic wastes, and harmful substances. As we will discuss, hormones are important signaling molecules in these regulatory processes.

CHECKPOINT 48.1

- **CONNECT** How does osmoregulation contribute to homeostasis?
- What are the functions of excretory systems?

48.2 Metabolic Waste Products

LEARNING OBJECTIVE

2 Contrast the benefits and costs of excreting each of the following: ammonia, uric acid, or urea.

Metabolic wastes must be excreted so that they do not accumulate and reach concentrations that would disrupt homeostasis. The principal metabolic waste products produced by most animals are water, carbon dioxide, and *nitrogenous wastes*, those that contain nitrogen. Carbon dioxide is excreted mainly by respiratory structures (see Chapter 46). In terrestrial animals some water is also lost from respiratory surfaces. However, specialized excretory organs, such as kidneys, remove and excrete most of the water and nitrogenous wastes.

Nitrogenous wastes include ammonia, uric acid, and urea. Recall that amino acids and nucleic acids contain nitrogen. During the metabolism of amino acids, the nitrogen-containing amino group is removed (in a process known as deamination) and converted to *ammonia* (FIG. 48-1). However, ammonia is highly toxic. Some aquatic animals excrete ammonia into the surrounding water before it can build up to toxic concentrations in their tissues. A few terrestrial animals, including some snails and wood lice, vent it directly into the air. But many animals, humans included, convert ammonia to some less toxic nitrogenous waste such as uric acid or urea.

Uric acid is produced both from ammonia and by the breakdown of nucleotides from nucleic acids. Uric acid is insoluble in water and forms crystals that are excreted as a crystalline paste, so little fluid loss results. This excretion is an important water-conserving adaptation in many terrestrial animals, including insects, certain reptiles, and birds. Also, because uric acid is not toxic and can be safely stored, its excretion is an adaptive advantage for species whose young begin their development enclosed in eggs.

Urea, the principal nitrogenous waste product of amphibians and mammals, is synthesized in the liver from ammonia and carbon dioxide by a sequence of reactions known as the urea cycle. As in the production of uric acid, these reactions require specific enzymes and the input of energy by the cells. Compared with the energy cost of producing ammonia, the cost of producing urea and uric acid is high.

Urea has the advantage of being far less toxic than ammonia and can accumulate in higher concentrations without causing tissue damage; thus, it can be excreted in more concentrated form. Because urea is highly soluble, however, it is dissolved in water, and more water is needed to excrete urea than to excrete uric acid.

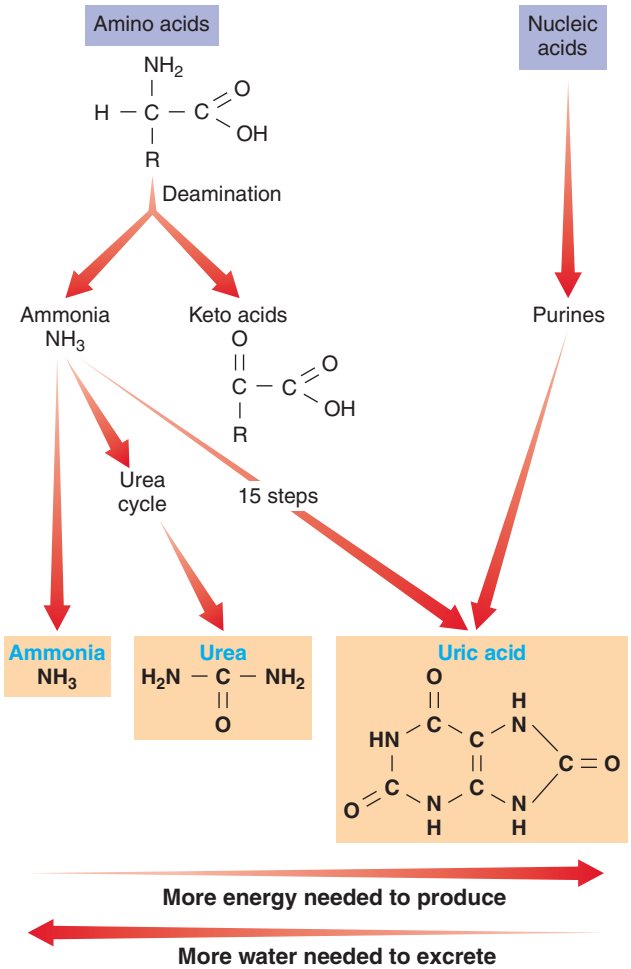

Figure 48-1 Formation of nitrogenous wastes

Deamination of amino acids and metabolism of nucleic acids produce nitrogenous wastes. Ammonia is the first metabolic product of deamination. Many aquatic animals excrete ammonia, but terrestrial animals convert it to urea and uric acid, which are less toxic than ammonia. Most amphibians and mammals convert ammonia to urea via the urea cycle. Insects and many reptiles, including birds, convert ammonia to uric acid. Energy is required to convert ammonia to urea and uric acid, but less water is required to excrete these wastes.

CHECKPOINT 48.2

- **CONNECT** Give examples of animals that excrete each of the principal types of nitrogenous wastes.
- What are the benefits of excreting nitrogenous wastes in the form of uric acid? in the form of urea?

48.3 Osmoregulation and Excretion in Invertebrates

LEARNING OBJECTIVES

3 Contrast osmoconformers and osmoregulators.

4 Compare the structure and function of protonephridia, metanephridia, and Malpighian tubules.

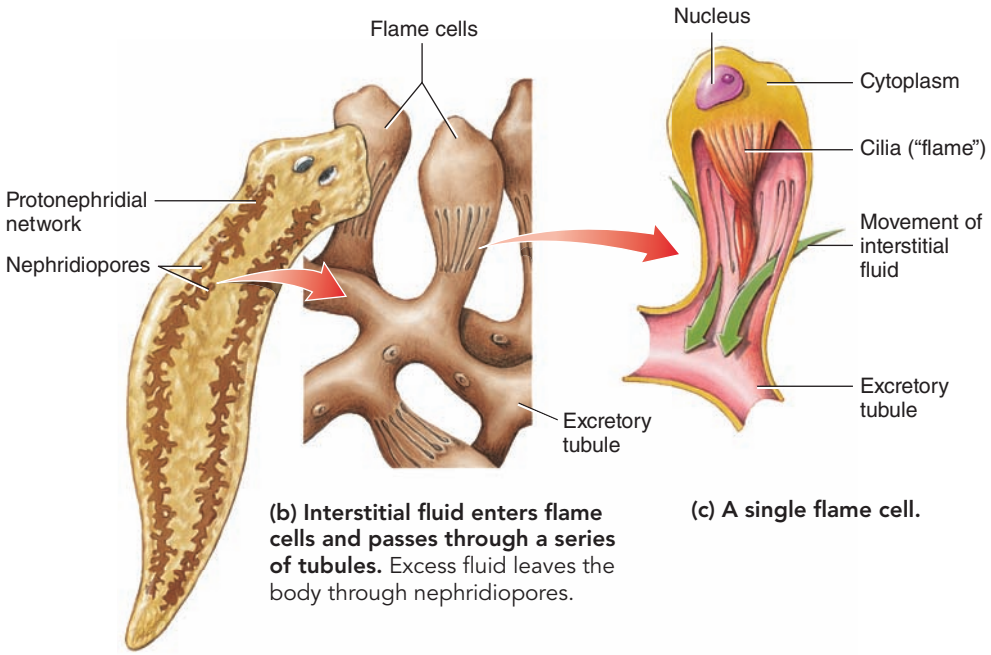
The ocean is a stable environment, and its salt concentration does not vary much. The electrolyte concentration in the cells and body fluids of marine sponges and cnidarians is very similar to sea water, so these animals do not require specialized excretory structures. They expend little or no energy in excreting wastes because wastes simply diffuse from their cells to the external environment and are washed away by water currents. When water stagnates and currents do not wash away wastes, aquatic environments, such as coral reefs, are damaged by the waste accumulation.

The body fluids of most marine invertebrates are in osmotic equilibrium with the surrounding sea water. These animals are known as **osmoconformers** because the concentration of their body fluids varies along with changes in the sea water. However, many osmoconforming marine animals still regulate some ions in their body fluids.

Coastal habitats, such as estuaries that contain brackish water, are much less stable environments than is the open ocean. Salt concentrations change frequently with shifting tides. Many invertebrates and vertebrates that inhabit coastal environments are **osmoregulators**. These animals have homeostatic mechanisms that maintain an optimal salt concentration in their tissues regardless of changes in the salt concentration of their surroundings.

In a coastal environment where fresh water enters the ocean, the water may have a lower salt concentration than the body fluids of an animal. Water osmotically moves into the animal's body, and salt diffuses out. An animal adapted to this environment has excretory structures that remove the excess water. Certain polychaete worms and the blue crab are among the animals that can be either osmoconformers or osmoregulators, depending on environmental conditions.

Dehydration is a constant threat to terrestrial animals. Because their fluid concentration is higher than that of the air around them, they tend to lose water by evaporation from both the body surface and respiratory surfaces. Terrestrial animals may also lose water as wastes are excreted. As animals moved onto the land, natural selection favored the evolution of structures and processes that conserve water.



Excretory systems help maintain fluid and electrolyte homeostasis by selectively adjusting the concentrations of salts and other substances in blood and other body fluids. Typically, an excretory system collects fluid, generally from the blood or interstitial fluid. It then adjusts the composition of this fluid by selectively returning needed substances to the body fluid. Finally, the body releases the adjusted excretory product containing excess or potentially toxic substances.

Nephridial organs are specialized for osmoregulation and/or excretion

Nephridial organs, or nephridia, are structures that function in osmoregulation and excretion in many invertebrates, including flatworms, nemerteans, rotifers, annelids, mollusks, and lancelets. Each nephridial organ consists of simple or branching tubes that typically open to the outside of the body through pores, called *nephridiopores*. Two types of nephridial organs are protonephridia and metanephridia.

(b) Interstitial fluid enters flame cells and passes through a series of tubules. Excess fluid leaves the body through nephridiopores.

(c) A single flame cell.

(a) The protonephridia of a planarian function mainly in osmoregulation. These organs form a system of branching tubules.

Figure 48-2 Protonephridia of a flatworm

In flatworms and nemerteans, metabolic wastes pass through the body surface by diffusion, but these animals also have **protonephridia** (FIG. 48-2). The protonephridia are composed of tubules with no internal openings. Their enlarged blind ends consist of **flame cells** with brushes of cilia, so named because their constant motion reminded early biologists of flickering flames. The flame cells lie in the interstitial fluid that bathes the body cells. Fluid enters the flame cells, and the beating of the cilia propels the fluid through the tubules. Excess fluid leaves the body through nephridiopores.

Most annelids and mollusks have more complex nephridial organs called **metanephridia** (FIG. 48-3). Each segment of an earthworm has a pair of metanephridia. A metanephridium is a tubule open at both ends. The inner end opens into the coelom as a ciliated funnel, and the outer end opens to the outside through a nephridiopore. A network of capillaries surrounds each tubule. Fluid from the coelom passes into the tubule, bringing with it whatever it contains: glucose, salts, or wastes.

As fluid moves through the tubule, needed materials (e.g., water and glucose) are removed from the fluid by the tubule and are reabsorbed by the capillaries, leaving the wastes behind. In this way, urine that contains concentrated wastes is produced.

Malpighian tubules conserve water

The excretory system of insects and spiders consists of several hundred **Malpighian tubules** (FIG. 48-4). Malpighian tubules are slender extensions of the gut wall. Their blind ends lie in the hemocoel (blood cavity) and are bathed in hemolymph. Cells of the tubule wall actively transport uric acid, potassium ions, and some other substances from the hemolymph into the tubule lumen. Other solutes and water follow by diffusion.

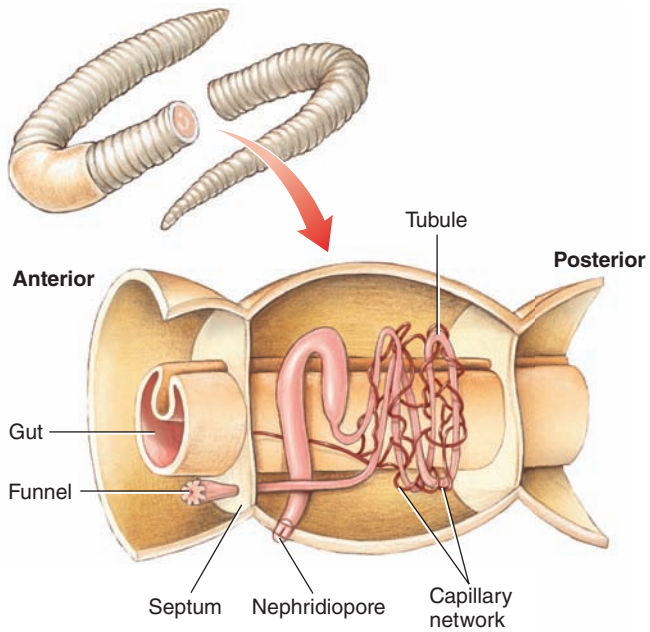

Figure 48-3 Metanephridium of an earthworm

Each metanephridium consists of a ciliated funnel opening into the coelom, a coiled tubule, and a nephridiopore opening to the outside. This 3-D internal view shows parts of three segments of the earthworm body.

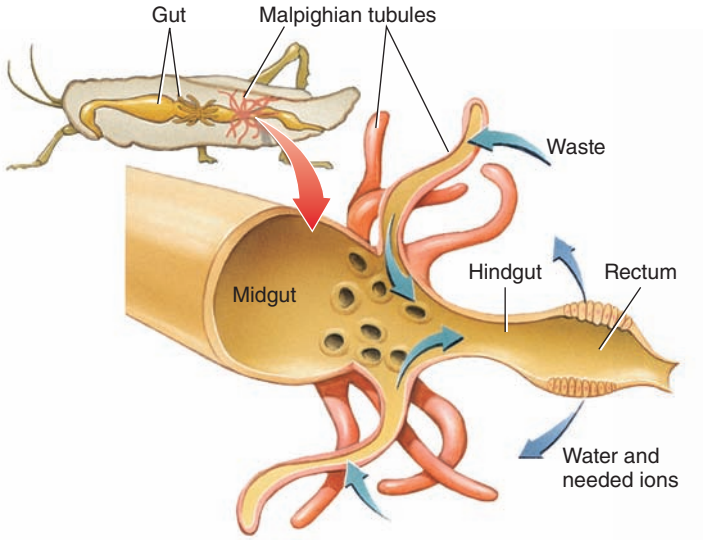

Figure 48-4 Malpighian tubules of an insect

The slender Malpighian tubules have blind ends that extend into the hemocoel. Their cells transfer uric acid and some ions from the hemolymph into the tubule. Water follows by diffusion. The wastes are discharged into the gut. The epithelium that lines the rectum (part of the hindgut) actively reabsorbs most of the water and needed ions.

The Malpighian tubules empty into the gut. Water, some salts, and other solutes are reabsorbed into the hemolymph by a specialized epithelium in the rectum.

Uric acid, the major waste product, is excreted as a semidry paste with a minimum of water loss. Because Malpighian tubules effectively conserve body fluids, they have contributed to the success of insects in terrestrial environments.

CHECKPOINT 48.3

- **CONNECT** How are nephridial organs and Malpighian tubules alike? How are they different? (*Hint*: Consider both structure and function.)

48.4 Osmoregulation and Excretion in Vertebrates

LEARNING OBJECTIVES

5 Relate the function of the vertebrate kidney to the success of vertebrates in a wide variety of habitats.

6 Compare adaptations for osmoregulation in freshwater fishes, marine bony fishes, sharks, marine mammals, and terrestrial vertebrates.

Vertebrates live successfully in a wide range of habitats: in fresh water; in the ocean and tidal regions; and on land, even in extreme environments such as deserts. In response to the requirements of these diverse environments, adaptations have evolved for regulating salt and water content and for excreting wastes. The main osmoregulatory and excretory organ in most vertebrates is the kidney. The **kidney** excretes most nitrogenous wastes and helps maintain fluid balance by adjusting the salt and water content of the urine. The skin, lungs or gills, and digestive system also help maintain fluid balance and dispose of metabolic wastes.

Freshwater vertebrates must rid themselves of excess water

As fishes began to move into freshwater habitats about 470 million years ago (mya), there must have been strong selection for adaptations that promoted effective osmoregulation. The evolution of body fluids more dilute than sea water was a major adaptation. However, the salt concentration of the body fluids of these fishes is still higher than that of the fresh water that surrounds them. They are hypertonic to their watery environment. As a result, water moves into the body, and they are in constant danger of becoming waterlogged.

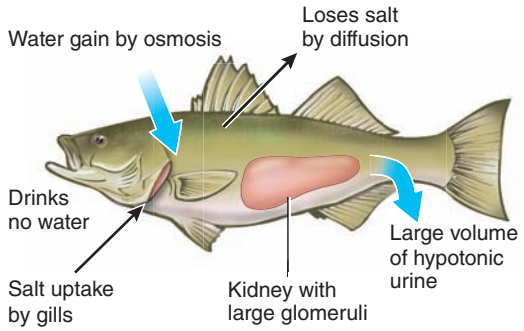
Freshwater fishes are covered by scales and a mucous secretion that retard the passage of water into the body. However, water constantly enters through the gills and through the mouth (with food). How do these animals meet this challenge? The kidneys of freshwater fishes are adapted to excrete large amounts of very dilute urine (FIG. 48-5a). The kidneys have large *glomeruli*, capillary clusters that filter the blood in the first step in producing urine.

Water entry is only part of the challenge of osmoregulation in freshwater fishes. These animals also tend to lose salts by diffusion through the gills into the surrounding water. To compensate, special gill cells have evolved that actively transport salts (mainly sodium chloride) from the water into the body.

The gills of freshwater fishes excrete ammonia, their principal nitrogenous wastes. About 10% of nitrogenous wastes are excreted as urea.

Most amphibians are at least semi-aquatic, and their mechanisms of osmoregulation are similar to those of freshwater fishes. They, too, produce large amounts of dilute urine. In its urine and through its skin, a frog can lose an amount of water equivalent to one-third of its body weight in one day. Active transport of salt into the body by special cells in the skin compensates for loss of salt through skin and in urine. Adult amphibians generally inhabit moist environments. They excrete urea and reabsorb some water from the urinary bladder. When dehydrated, terrestrial frogs can dramatically decrease the process of urine production.

Marine vertebrates must replace lost fluid



Freshwater fishes adapted very successfully to their aquatic habitats. Thus, when some freshwater fishes returned to the sea about 200 mya, their blood and body fluids were less salty than their surroundings; that is, they were hypoosmotic to their environment. These fishes lose water osmotically and take in salt through their gills and with their food. To compensate for fluid loss, many marine bony fishes drink sea water (FIG. 48-5b). They retain the water and excrete salt by the action of specialized cells in their gills.

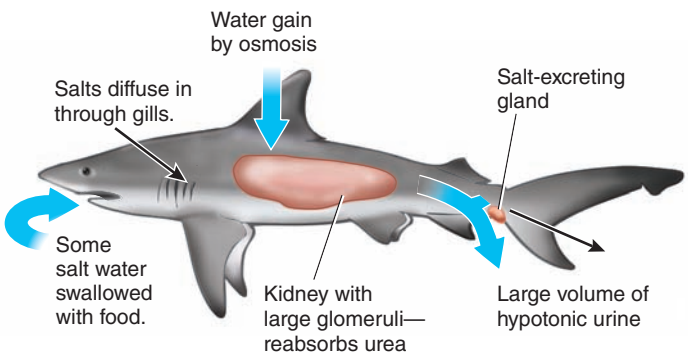
Key Point



Adaptations for regulating water and salt concentration allow fishes to inhabit diverse environments, from freshwater lakes to salty oceans.

(a) Freshwater fishes live in a hypotonic medium. Water continuously enters the body, and salts diffuse out. These fishes excrete large quantities of dilute urine and actively transport salts in through the gills.

(b) Marine fishes live in a hypertonic medium. They lose water by osmosis. They gain salts from the sea water they drink and by diffusion. To compensate, the fish drinks water, excretes the salt, and produces a small volume of urine.

(c) Cartilaginous fishes (sharks and rays). The shark kidney reabsorbs urea in high enough concentration that its tissues become hypertonic to the surrounding medium. As a result, water enters the shark by osmosis. The shark excretes a large quantity of dilute urine.

Figure 48-5 Osmoregulation in fishes

PREDICT A marine shark is spotted swimming in fresh water. How might this shark's kidney function be affected?

The gills are also responsible for ammonia excretion. Very little urine is excreted by the kidneys, which have only small (or no) glomeruli. The kidneys excrete certain excess ions (e.g., Mg^{2+}).

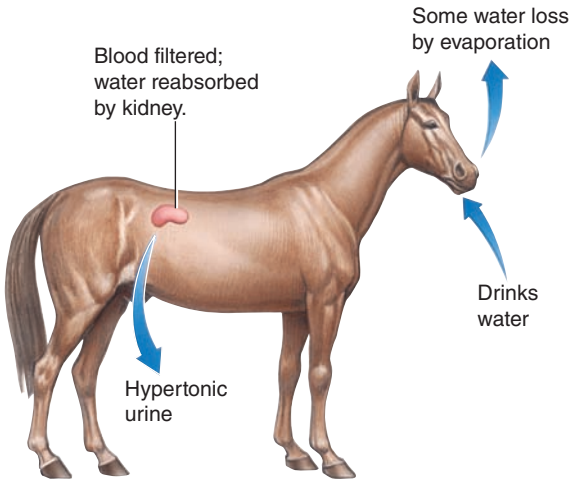
Marine cartilaginous fishes (sharks and rays) have different osmoregulatory adaptations that allow them to tolerate the salt concentrations of their environment. These animals accumulate and tolerate urea (FIG. 48-5c). Their tissues are adapted to function at concentrations of urea that would be toxic to most other animals. The high urea concentration makes the body fluids slightly hypertonic to sea water, resulting in a net inflow of water. Marine cartilaginous fishes have well-developed kidneys that excrete a large volume of urine. Excess salt is excreted by the kidneys and, in many species, by a rectal gland.

Certain non-avian reptiles and marine birds ingest sea water and take in a lot of salt in their food. Glands in their heads excrete salt. These salt glands are usually inactive; they function in response to osmotic stress. Non-avian reptiles and birds excrete uric acid, which conserves water.

Whales, dolphins, and other marine mammals ingest sea water along with their food. Their kidneys produce concentrated urine, much saltier than sea water. This physiological adaptation is important, especially for marine carnivores. The high-protein diet of these animals results in the production of large amounts of urea, which must be excreted in urine without losing much water.

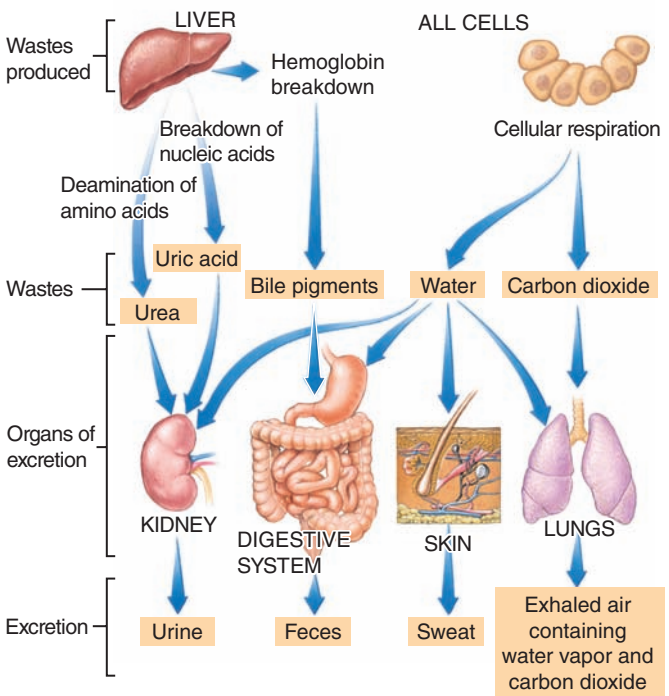
Terrestrial vertebrates must conserve water

Amniotes (non-avian reptiles, birds, and mammals) have effective adaptations for life on land. Their skin minimizes water loss by evaporation, and many amniotes excrete uric acid, which requires very little water.



Because birds and mammals are endothermic (maintain a constant body temperature) and have a high rate of metabolism, they produce a relatively large volume of nitrogenous wastes. They have numerous adaptations, including very efficient kidneys, for conserving water. An extreme example is the desert-dwelling kangaroo rat, which obtains most of its water from its own metabolism. (Recall from Chapter 8 that aerobic respiration produces water. The kangaroo rat's kidneys are so efficient that it loses little fluid as urine.)

Birds conserve water by excreting nitrogen as uric acid and by efficiently reabsorbing water from the cloaca and intestine. Mammals excrete urea. Their kidneys produce very concentrated (hypertonic) urine.



In terrestrial vertebrates, the lungs, skin, and digestive system are important in osmoregulation and waste disposal (FIG. 48-6). Most carbon dioxide is excreted by the lungs. In birds and mammals, some water is lost from the body as water vapor in exhaled air. Although primarily concerned with the regulation of body temperature, the sweat glands of humans and some other mammals excrete 5% to 10% of all metabolic wastes.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

(a) The kidney of terrestrial vertebrates conserves water by reabsorbing it. Birds and mammals can produce concentrated urine.

(b) Disposal of metabolic wastes in humans and other terrestrial mammals. Nitrogenous wastes are produced by the liver and transported to the kidneys. To conserve water, mammals produce a small amount of hypertonic urine. All cells produce carbon dioxide and some water during cellular respiration. These waste products are excreted by the lungs.

Figure 48-6 Excretory organs in terrestrial vertebrates

The liver produces both urea and uric acid, which are transported by the blood to the kidneys. Most of the bile pigments produced by the breakdown of red blood cells are excreted by the liver into the intestine. From the intestine they pass out of the body with the feces.

CHECKPOINT 48.4

- **CONNECT** What type of osmoregulatory challenge is faced by marine fishes? by freshwater fishes? What mechanisms have evolved to meet these challenges?
- **CONNECT** What adaptations in aquatic birds and mammals help meet the challenges of osmoregulation and metabolic waste disposal? in terrestrial birds and mammals?

48.5 The Urinary System of Mammals

LEARNING OBJECTIVES

7 Describe (and label on a diagram) the organs of the mammalian urinary system and give the functions of each.
8 Describe (and label on a diagram) the structures of a nephron (including associated blood vessels) and give the functions of each structure.
9 Trace a drop of glomerular filtrate from Bowman's capsule to its release from the body as urine.
10 Describe regulation of fluid and electrolyte balance by antidiuretic hormone (ADH), the renin–angiotensin–aldosterone system, and atrial natriuretic peptide (ANP).

The mammalian **urinary system** consists of the kidneys, the urinary bladder, and associated ducts. The overall structure of the human urinary system is shown in FIGURE 48-7. Located just below the diaphragm in the "small of the back," the kidneys look like a pair of giant, dark red lima beans, each about the size of a fist. Each kidney is covered by a connective tissue capsule (FIG. 48-8). The outer region of the kidney is the **renal cortex**, and the inner region is the **renal medulla**. The renal medulla contains eight to ten cone-shaped structures called *renal pyramids*. The tip of each pyramid is a *renal papilla*. Each papilla has several pores, the openings of **collecting ducts**.

As urine is produced, it flows from collecting ducts through a renal papilla and into the **renal pelvis**, a funnel-shaped chamber. Urine then flows into one of the paired **ureters**, ducts that connect each kidney with the **urinary bladder**. The urinary bladder is a remarkable organ capable of holding (with practice) up to 800 mL (about a pint and a half) of urine. Emptying the bladder changes it from the size of a small melon to that of a pecan. This feat is made possible by the smooth muscle and specialized epithelium of the bladder wall, which is capable of great shrinkage and stretching.

During *urination*, urine is released from the bladder and flows through the **urethra**, a duct leading to the outside of the body. In the male the urethra is lengthy and passes through the penis. Semen as well as urine passes through the male urethra. In the female the urethra is short and transports only urine. Its opening to the outside is just above the opening of the vagina. The length of the male urethra discourages bacterial invasions of the bladder. This length difference helps explain why bladder

Figure 48-9 Nephron structure

infections are more common in females than in males. In summary, urine flows through the following structures:

kidney (through renal pelvis) → ureter→ urinary bladder → urethra

The nephron is the functional unit of the kidney

The principal function of the kidneys is to help maintain homeostasis by regulating fluid balance and excreting metabolic wastes. However, the kidneys also have other functions. They produce the enzyme *renin*, which helps regulate fluid balance and blood pressure (discussed later in the chapter), and at least two hormones: *erythropoietin*, which stimulates red blood cell production, and *1,25-dihydroxy-vitamin D_3*, which stimulates calcium absorption by the intestine.

Each kidney has up to one million functional units called **nephrons**. A nephron consists of a cuplike **Bowman's capsule** connected to a long, partially coiled **renal tubule** (FIG. 48-9). Positioned within Bowman's capsule is a cluster of capillaries called a **glomerulus**. Three main regions of the renal tubule are (1) the **proximal convoluted tubule** (or simply, *proximal tubule*), which conducts the *glomerular filtrate* (the fluid filtered from the blood) from Bowman's capsule; (2) the **loop of Henle**, an elongated, hairpin-shaped portion; and (3) the **distal convoluted tubule** (or *distal tubule*), which conducts the glomerular filtrate to a collecting duct. Thus, the glomerular filtrate passes through the following structures:

Bowman's capsule → proximal convoluted tubule → loop of Henle → distal convoluted tubule → collecting duct

The human kidney has two types of nephrons: the more numerous (85%) cortical nephrons and the more internal juxtamedullary nephrons (see Fig. 48-8b). *Cortical nephrons* have relatively small glomeruli and are located almost entirely within the cortex or outer medulla. *Juxtamedullary nephrons* have large glomeruli, and their very long loops of Henle extend deep into the medulla. The loop of Henle consists of a *descending limb* that receives glomerular filtrate from the proximal convoluted tubule and an *ascending limb*, through which the filtrate passes on its way to the distal convoluted tubule. The juxtamedullary nephrons contribute to the ability of the mammalian kidney to concentrate urine. Excretion of urine that is hypertonic to body fluids is an important mechanism for conserving water.

Key Point

The glomerulus filters blood. As the glomerular filtrate moves through the renal tubule, its composition is adjusted by selective reabsorption and tubular secretion. The adjusted filtrate is urine.

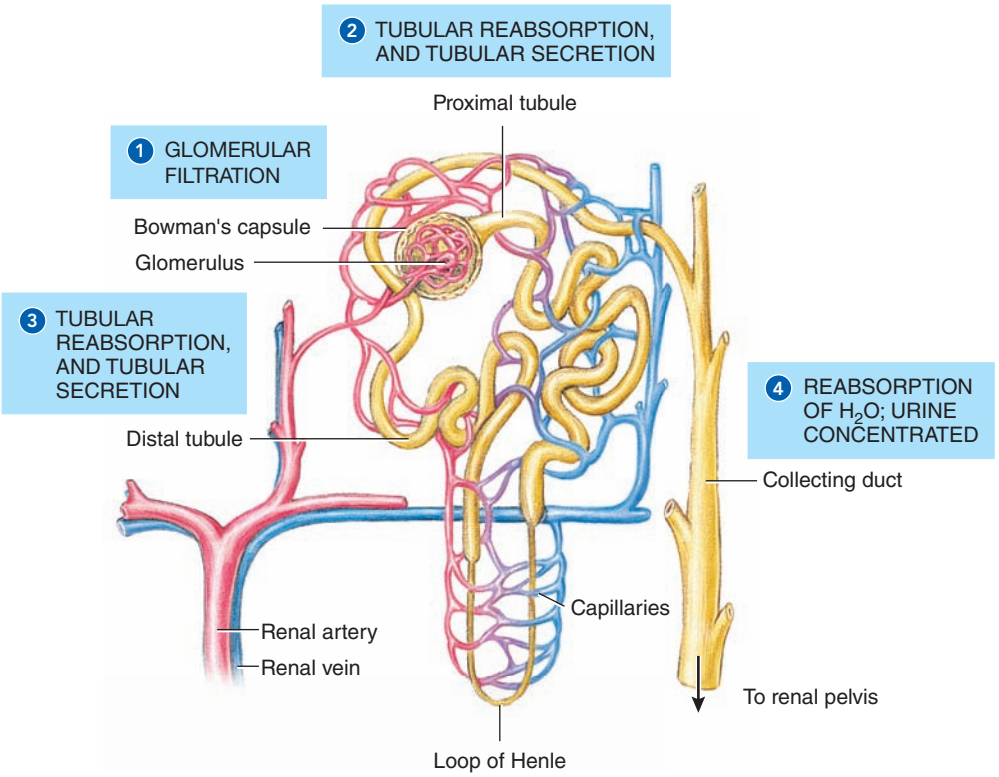

Figure 48-10 General regions of glomerular filtration, tubular reabsorption, and tubular secretion

PREDICT How would mild dehydration affect kidney function?

Blood is delivered to the kidney by the **renal artery**. Small branches of the renal artery give rise to **afferent arterioles** (*afferent* means "to carry toward"). An afferent arteriole conducts blood into the capillaries that make up each glomerulus. As blood flows through the glomerulus, some of the plasma is forced into Bowman's capsule.

You may recall that in a typical circulatory route, capillaries deliver blood into veins. Circulation in the kidneys is an exception because blood flowing from the glomerular capillaries next passes into an **efferent arteriole**. Each efferent arteriole conducts blood *away* from a glomerulus. The efferent arteriole delivers blood to a second capillary network, the **peritubular capillaries** surrounding the renal tubule.

Blood is filtered as it flows through the first set of capillaries, those of the glomerulus. The peritubular capillaries receive blood containing materials reabsorbed from the renal tubule. Blood from the peritubular capillaries enters small veins that eventually lead to the **renal vein**. In summary, blood circulates through the kidney in the following sequence:

renal artery → an afferent arteriole → capillaries of a glomerulus → an efferent arteriole → peritubular capillaries → small veins → renal vein

Urine is produced by glomerular filtration, tubular reabsorption, and tubular secretion

Urine, the watery discharge of the urinary system, is produced by a combination of three processes: glomerular filtration, tubular reabsorption, and tubular secretion (FIG. 48-10).

Glomerular filtration is not selective with regard to ions and small molecules

Blood flows through the glomerular capillaries under high pressure, forcing more than 10% of the plasma out of the capillaries and into Bowman's capsule. **Glomerular filtration** is similar to the mechanism whereby interstitial fluid is formed as blood flows through other capillary networks in the body. However, blood flow through glomerular capillaries is at much higher pressure, so more plasma is filtered in the kidney.

Several factors contribute to the production of a large amount of *glomerular filtrate*. First, the hydrostatic blood pressure in the glomerular capillaries is higher than in other capillaries. This high pressure is mainly due to the high resistance to outflow presented by the efferent arteriole, which is

Copyright 2019 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in

Copyright 2019 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

smaller in diameter than the afferent arteriole. A second factor contributing to the large amount of glomerular filtrate is the large surface area for filtration provided by the highly coiled glomerular capillaries. A third factor is the great permeability of the glomerular capillaries. Numerous small pores between the endothelial cells that form their walls make the glomerular capillaries more porous than typical capillaries.

The wall of Bowman's capsule in contact with the capillaries consists of specialized epithelial cells called *podocytes*. These cells have numerous cytoplasmic extensions called *foot processes* that cover most of the surfaces of the glomerular capillaries (FIG. 48-11). Foot processes of adjacent podocytes are separated by narrow gaps called *filtration slits*. The porous walls of the glomerular capillaries and the filtration slits of the podocytes form a *filtration membrane* that permits fluid and small solutes dissolved in the plasma (including glucose, amino acids, sodium, potassium, chloride, bicarbonate, other salts, and urea) to pass through and become part of the glomerular filtrate. This filtration membrane holds back blood cells, platelets, and most of the plasma proteins.

The total volume of blood passing through the kidneys is about 1200 mL per minute, or about one-fourth of the entire cardiac output. As plasma passes through the glomerulus, it loses more than 10% of its volume to the glomerular filtrate.

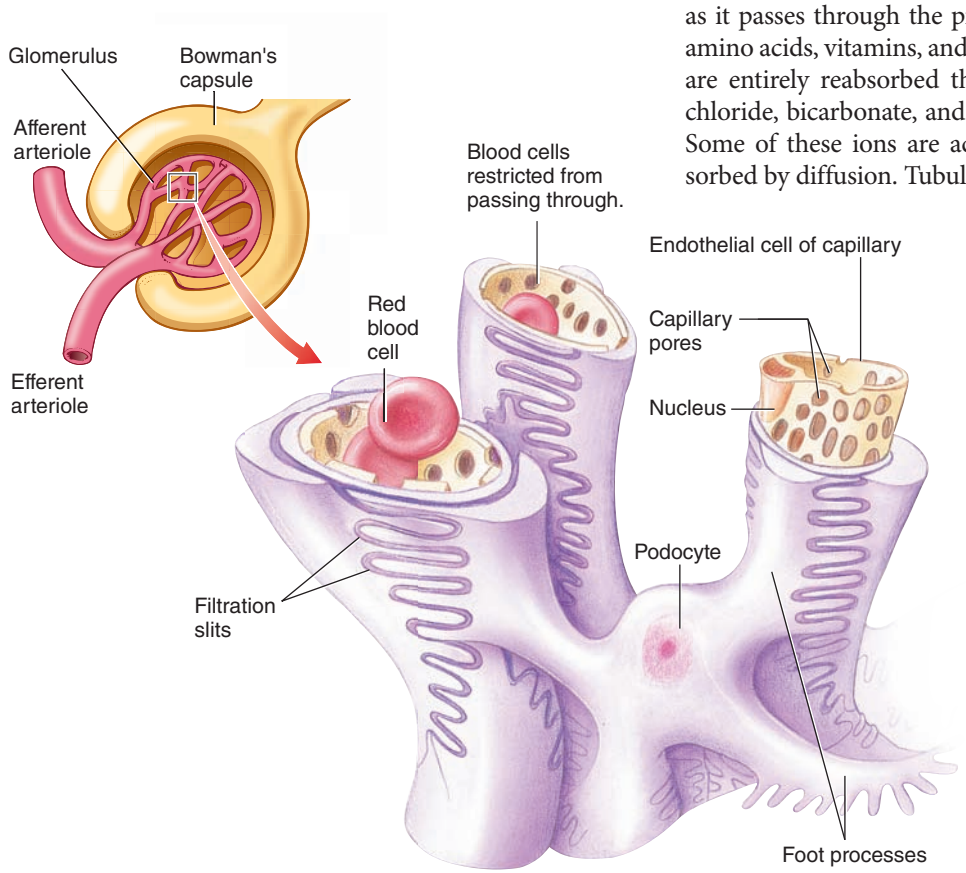

Figure 48-11 Filtration membrane of the kidney

The porous walls of the glomerular capillaries and the filtration slits between podocytes form a filtration membrane. This membrane is highly permeable to water, small molecules, and ions but restricts the passage of blood cells and large molecules.

The normal glomerular filtration rate amounts to about 180 L (about 45 gallons) each 24 hours, which is four and a half times the amount of fluid in the entire body! Common sense tells us that urine could not be excreted at that rate. Within a few moments, dehydration would become life-threatening.

Tubular reabsorption is highly selective The threat to homeostasis posed by the vast amounts of fluid filtered by the kidneys is avoided by **tubular reabsorption**. The renal tubules reabsorb about 99% of the glomerular filtrate into the blood, leaving only about 1.5 L to be excreted as urine during a 24-hour period. Tubular reabsorption permits precise regulation of blood chemistry by the kidneys. Wastes, excess salts, and other materials remain in the filtrate and are excreted in the urine, whereas needed substances such as glucose and amino acids are returned to the blood. Each day the tubules reabsorb more than 178 L of water, 1200 g (2.6 lb) of salt, and about 250 g (0.5 lb) of glucose. Most of it, of course, is reabsorbed many times over.

The simple epithelial cells lining the renal tubule are well adapted for reabsorbing materials. Their abundant microvilli increase the surface area for tubular reabsorption. These epithelial cells contain numerous mitochondria that provide the energy for running the cell pumps that actively transport materials.

Most (about 65%) of the glomerular filtrate is reabsorbed as it passes through the proximal convoluted tubule. Glucose, amino acids, vitamins, and other substances of nutritional value are entirely reabsorbed there. Many ions, including sodium, chloride, bicarbonate, and potassium, are partially reabsorbed. Some of these ions are actively transported; others are reabsorbed by diffusion. Tubular reabsorption continues as the glomerular filtrate passes through the loop of Henle and the distal convoluted tubule. Then the filtrate is further concentrated as it passes through the collecting duct that leads to the renal pelvis.

Substances that are useful to the body, such as glucose and amino acids, are normally reabsorbed from the renal tubules. If the concentration of a particular substance in the blood is high, however, the tubules may not be able to reabsorb it all. The maximum rate at which a substance can be reabsorbed is its **tubular transport maximum (Tm)**. When that rate is reached, the binding sites are saturated on the membrane proteins that transport the substance. For example, the tubular load of glucose is about 125 mg per minute, and almost all of it is normally reabsorbed. However, in a person with uncontrolled diabetes mellitus, the concentration of glucose in the blood exceeds its Tm

(glucose concentration in excess of 320 mg per minute). The excess glucose cannot be reabsorbed and is excreted in the urine (glucosuria), a symptom of diabetes (discussed in Chapter 49).

Some substances are actively secreted from the blood into the glomerular filtrate **Tubular secretion** is the selective transfer of substances from the blood in the peritubular capillaries into the renal tubule. Note that in tubular secretion ions and other substances are moved across the tubule epithelium in the opposite direction of tubular reabsorption. Potassium, hydrogen ions, and ammonium ions as well as some organic ions, such as creatinine (a metabolic waste), are secreted into the glomerular filtrate. Certain drugs, such as penicillin, are also removed from the blood by secretion. Secretion occurs mainly in the region of the distal convoluted tubule.

Secretion of hydrogen ions by the collecting ducts is an important homeostatic mechanism for regulating the pH of the blood. Carbon dioxide, which diffuses from the blood into the cells of the distal tubules and collecting ducts, combines with water, which produces carbonic acid. This acid then dissociates to form hydrogen ions and bicarbonate ions. When the blood becomes too acidic, the collecting ducts secrete more hydrogen ions into the urine:

$$CO_2 + H_2O \rightleftharpoons H_2CO_3 \rightleftharpoons H^+ + HCO_3^-$$

Potassium ion secretion is another important homeostatic mechanism. When K^+ concentration is too high, nerve impulses are not effectively transmitted, and the strength of muscle contraction decreases. The heart rhythm becomes irregular, and cardiac arrest can occur. When K^+ concentration exceeds its homeostatic level, K^+ are secreted from the blood into the renal tubules and then excreted in the urine. Secretion results partly from a direct effect of the K^+ on the tubules. In addition, the adrenal cortex (a region of the adrenal gland) increases its output of the hormone *aldosterone*, which further stimulates secretion of K^+.

Urine becomes concentrated as it passes through the renal tubule

We can survive with limited fluid intake because the kidneys can produce highly concentrated urine, more than four times as concentrated as blood. The osmolarity of human blood is about 300 milliosmoles per liter (mOsm/L). The kidneys can produce urine with an osmolarity of about 1200 mOsm/L.

As the glomerular filtrate passes through various regions of the renal tubule, salt (NaCl) is reabsorbed, establishing a salt concentration gradient in the interstitial fluid (FIGS. 48-12 and 48-13). The gradient is used to produce concentrated urine.

When glomerular filtrate flows from Bowman's capsule to the proximal tubule, its osmolarity is the same as that of blood (about 300 mOsm/L). Water and salt are reabsorbed from the proximal tubule. Sodium ions are actively transported out of the proximal tubule, and chloride follows passively. As salt passes into the interstitial fluid, water follows osmotically.

The walls of the descending limb of the loop of Henle are relatively permeable to water but relatively impermeable to sodium and urea. The interstitial fluid has a high concentration of Na^+, so as the glomerular filtrate passes down the loop of Henle, water moves out by osmosis. This process concentrates the filtrate inside the loop of Henle.

The loop of Henle is specialized to highly concentrate sodium chloride in the interstitial fluid of the medulla. It maintains a highly hypertonic interstitial fluid in the medulla near the bottom of the loop, which in turn lets the kidneys produce concentrated urine. At the turn of the loop of Henle, the walls become more permeable to salt and less permeable to water. As the concentrated glomerular filtrate begins to move up the ascending limb (the thin region), salt diffuses out into the interstitial fluid. This diffusion contributes to the high salt concentration of the interstitial fluid in the medulla surrounding the loop of Henle. Farther along the ascending limb (the thick region), sodium is actively transported out of the tubule.

Because water passes out of the descending limb of the loop of Henle, the glomerular filtrate at the bottom of the loop has a high salt concentration. However, because salt (but not water) is removed in the ascending limb, by the time the filtrate moves into the distal tubule, its osmolarity may be the same as or even lower than that of blood.

As it passes through the distal tubule, the filtrate may become even more dilute. The distal tubule is relatively impermeable to water but actively transports salt out into the interstitial fluid. The filtrate passes from the renal tubule into a larger collecting duct that eventually empties into the renal pelvis.

Note the *counterflow* of fluid through the two limbs of the loop of Henle. Glomerular filtrate passing down through the descending limb is flowing in a direction opposite that of the filtrate moving upward through the ascending limb. The filtrate becomes concentrated as it moves down the descending limb and diluted as it moves up the ascending limb. This countercurrent mechanism helps maintain a high salt concentration in the interstitial fluid of the medulla. The hypertonic interstitial fluid draws water osmotically from the filtrate in the collecting ducts.

The inner medullary collecting ducts are permeable to urea, so some of the concentrated urea in the filtrate can diffuse out into the interstitial fluid. The urea contributes to the high solute concentration of the inner medulla. This process helps concentrate urine.

The collecting ducts pass through the zone of very salty interstitial fluid. As the glomerular filtrate moves through the collecting duct, water passes osmotically into the interstitial fluid. Excess interstitial fluid continuously enters capillaries and becomes part of the blood. Sufficient water can leave the collecting ducts to produce a highly concentrated urine. Remember that a hypertonic urine conserves water.

Some of the water that diffuses from the filtrate into the interstitial fluid is removed by the *vasa recta*, which are long, straight capillaries that extend from the efferent arterioles of the juxtamedullary nephrons. The vasa recta extend deep into the medulla, only to negotiate a hairpin curve and return to the cortical venous drainage of the kidney. These capillaries parallel the renal tubules.

Blood flows in opposite directions in the ascending and descending regions of the vasa recta, just as glomerular filtrate flows in opposite directions in the ascending and descending

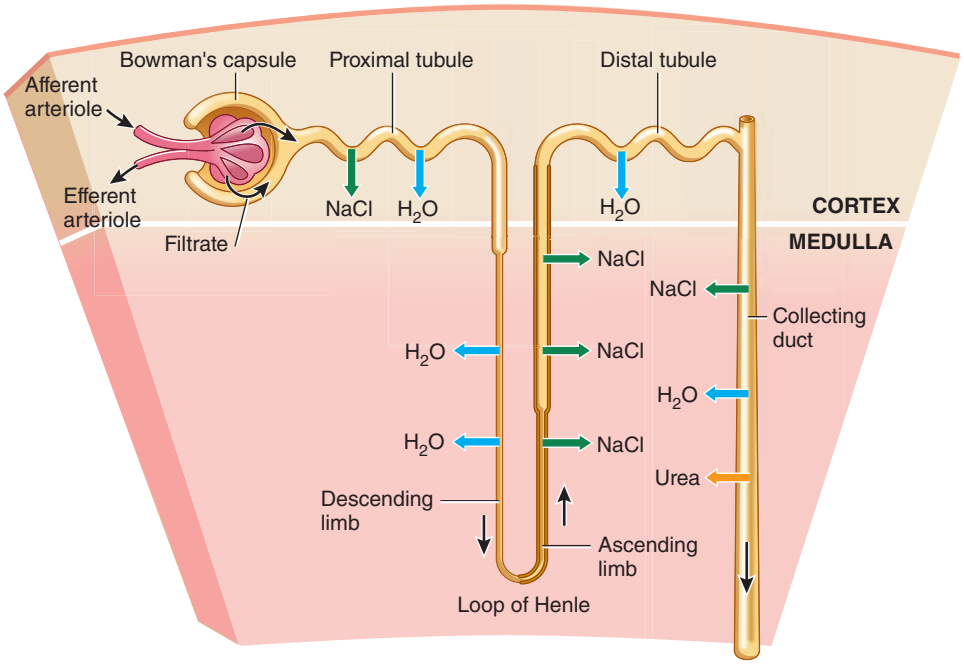

Figure 48-12 Movement of water, ions, and urea through the renal tubule and collecting duct

Water passes out of the descending limb of the loop of Henle, leaving a more concentrated filtrate inside. The heavy outline along the ascending limb indicates that this region is relatively impermeable to water. NaCl diffuses out from the lower (*thin*) part of the ascending limb. In the upper (*thick*) part of the ascending limb, NaCl is actively transported into the interstitial fluid. The saltier the interstitial fluid becomes, the more water moves out of the descending limb. This process leaves a concentrated filtrate inside, so more salt passes out. Note that this is a positive feedback system. Some urea also moves out into the interstitial fluid through the collecting ducts, contributing to its osmolarity. Water from the collecting ducts moves osmotically out into the hypertonic interstitial fluid and is carried away by capillaries. The concentrated solutes (NaCl and urea) are excreted in the urine.

limbs of the loop of Henle. As a consequence of this countercurrent flow, much of the salt and urea that enter the blood through the descending region of the vasa recta leave again from the ascending region. As a result, the solute concentration of the blood leaving the vasa recta is only slightly higher than that of the blood entering. This mechanism helps maintain the high solute concentration of the interstitial fluid in the renal medulla.

Urine consists of water, nitrogenous wastes, and salts

By the time the glomerular filtrate reaches the renal pelvis, its composition has been precisely adjusted. The adjusted filtrate, called *urine*, consists of approximately 96% water, 2.5% nitrogenous wastes (mainly urea), 1.5% salts, and traces of other substances, such as bile pigments, that may contribute to the characteristic color and odor. Healthy urine is sterile and has been used to wash battlefield wounds when clean water was not available. However, when exposed to bacterial action, urine swiftly decomposes and forms ammonia and other products. Ammonia produces the diaper rash of infants.

The composition of urine yields many clues to body function and malfunction. *Urinalysis*, the physical, chemical, and microscopic examination of urine, is a very important diagnostic tool that has been used to monitor diabetes mellitus and many other disorders. Urinalysis is also extensively used in drug testing because breakdown products of some drugs can be identified in the urine for several days or weeks after the drugs are ingested.

Hormones regulate kidney function

As we have discussed, the kidneys are vital in maintaining the body's fluid volume and electrolyte concentration. They help maintain the concentration of Na^+ and K^+ in the blood within narrow limits and also regulate blood pH. The endocrine system regulates these homeostatic functions of the kidneys. Hormones involved include antidiuretic hormone (ADH), aldosterone, angiotensin II, and atrial natriuretic peptide (ANP) (TABLE 48-1).

ADH increases water reabsorption The amount of urine produced depends on the body's need to retain or rid itself of water. When fluid intake is low, the body begins to dehydrate, and the blood volume decreases. As blood volume decreases, the concentration of salts dissolved in the blood becomes greater, causing an increase in osmotic pressure. Certain receptors in the hypothalamus are sensitive to this osmotic change. They signal the posterior lobe of the pituitary gland to release **antidiuretic hormone (ADH)**. This hormone is actually produced in the hypothalamus, but it is stored in the posterior pituitary gland and is released as needed. A thirst center in the hypothalamus also responds to dehydration, stimulating an increase in fluid intake.

ADH makes the collecting ducts more permeable to water so that more water is reabsorbed. ADH temporarily increases the number of gated water channels in the plasma membranes of the collecting ducts. These channels allow water to pass rapidly through the plasma membrane. As a result, a small volume of concentrated urine is produced (FIG. 48-14).

When you drink a large volume of water, your blood becomes diluted, and its osmotic pressure falls. Release of ADH by the pituitary gland decreases, lessening the amount of water reabsorbed from the collecting ducts. The kidneys produce a large volume of dilute urine.

In the disorder *diabetes insipidus* (not to be confused with the more common disorder, diabetes mellitus), water is not efficiently reabsorbed from the ducts, so the body produces a large volume of urine. A person with severe diabetes insipidus may excrete up to 25 quarts of urine each day, a serious water loss. The affected individual becomes dehydrated and must drink almost continually to offset fluid loss. Diabetes insipidus results when the pituitary gland does not release enough

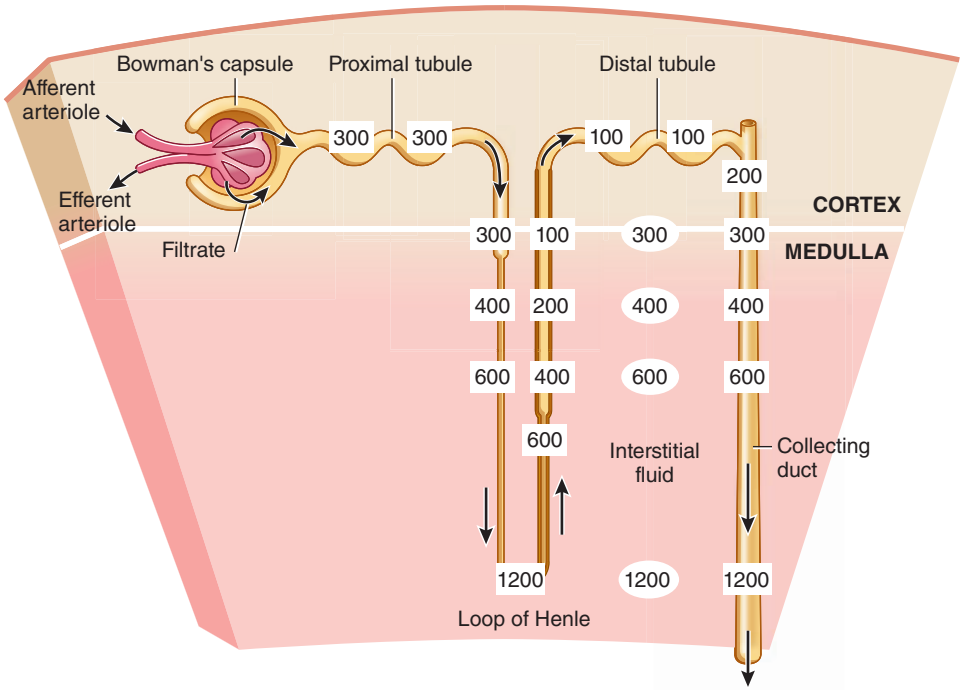

Figure 48-13 Concentration of the glomerular filtrate as it moves through the nephron

This figure shows the relative concentration of ions, mainly Na^+ and Cl^-, during production of a very concentrated urine. Numbers indicate the concentration of salt in the glomerular filtrate and interstitial fluid expressed in milliosmoles per liter. The more hypertonic a solution is, the higher its osmotic pressure. The very hypertonic interstitial fluid near the renal pelvis draws water osmotically from the filtrate in the collecting ducts. The heavy outline along the ascending loop indicates that this region is relatively impermeable to water.

ADH. This type of diabetes insipidus can be treated with a synthetic hormone (desmopressin). Diabetes insipidus can also develop from an acquired insensitivity of the kidney to ADH.

The renin–angiotensin–aldosterone pathway increases sodium reabsorption Sodium is the most abundant extracellular ion, accounting for about 90% of all positive ions in the extracellular fluid. Several hormones work together to regulate sodium concentration. **Aldosterone**, which is secreted by the cortex of the adrenal glands, stimulates the distal tubules and collecting ducts to increase sodium reabsorption. When researchers remove the adrenal glands of experimental animals, too much sodium is excreted, leading to serious depletion of the extracellular fluid.

Aldosterone secretion is stimulated both by hormones and by a decrease in blood pressure (caused by a decrease in volume of blood and interstitial fluid). When blood pressure falls, cells of the **juxtaglomerular apparatus** secrete the enzyme **renin**, which activates the *renin–angiotensin–aldosterone pathway*. The juxtaglomerular apparatus is a small group of cells in the region where the renal tubule contacts the afferent and efferent arterioles (see Fig. 48-9b). Renin converts the plasma protein angiotensinogen to **angiotensin I**. *Angiotensin-converting enzyme (ACE)* converts angiotensin I into its active form, **angiotensin II**, which is a peptide hormone. Angiotensin II stimulates aldosterone secretion. ACE is produced by the endothelial cells in the walls of pulmonary capillaries.

Table 48-1 Endocrine Regulation of Kidney Function

Hormone	Source	Target Tissue	Actions	Factors That Stimulate Release
Antidiuretic hormone (ADH)	Produced in hypothalamus; released by posterior pituitary gland	Collecting ducts	Increases permeability of collecting ducts to water, which increases tubular reabsorption and decreases water excretion	Low fluid intake decreases blood volume, which increases osmotic pressure of blood; receptors in hypothalamus stimulate posterior pituitary
Angiotensin II	Produced from angiotensin I	Blood vessels and adrenal glands	Constricts blood vessels, which raises blood pressure; stimulates aldosterone secretion; stimulates thirst	Decrease in blood pressure causes renin secretion; renin catalyzes conversion of angiotensinogen to angiotensin I, which is then converted to angiotensin II by ACE
Aldosterone	Adrenal glands (cortex)	Distal tubules and collecting ducts	Increases sodium reabsorption, which raises blood pressure	Angiotensin II; decrease in blood pressure
Atrial natriuretic peptide (ANP)	Atrium of heart	Afferent arterioles; collecting ducts	Dilates afferent arterioles; inhibits sodium reabsorption by collecting ducts; inhibits aldosterone secretion; decreases blood pressure	Stretching of atria due to increased blood volume

Key Point

When the body is dehydrated, the hormone ADH increases the permeability of the collecting ducts to water. More water is reabsorbed, which increases blood volume and decreases osmotic pressure.

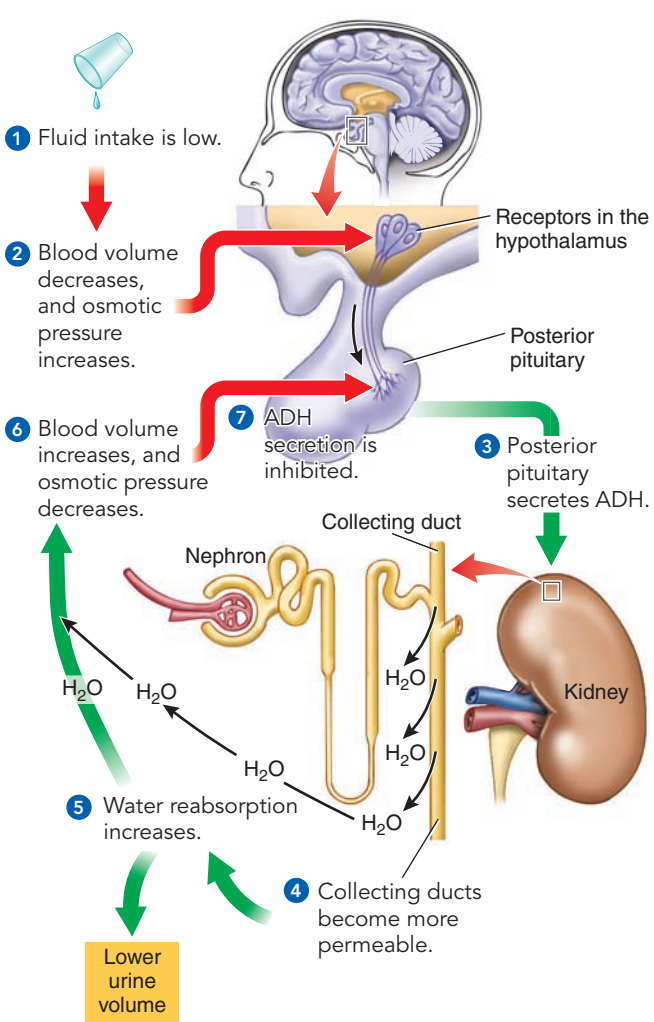

Figure 48-14 Regulation of urine volume by antidiuretic hormone (ADH)

The hormone ADH helps maintain fluid homeostasis.

CONNECT What effect does ADH have on arterial blood pressure?

Angiotensin II increases the synthesis and release of aldosterone. Angiotensin II also raises blood pressure directly by constricting blood vessels. In addition, this hormone stimulates the posterior pituitary to release ADH and stimulates thirst. These actions help increase extracellular fluid volume, which raises blood pressure. In individuals with hypertension, *ACE inhibitors* are sometimes used to block the production of angiotensin II. We can summarize the renin–angiotensin–aldosterone pathway as follows:

blood volume decreases → blood pressure decreases → cells of juxtaglomerular apparatus secrete renin → renin catalyzes conversion of angiotensinogen to angiotensin I → ACE catalyzes conversion of angiotensin I to angiotensin II → angiotensin II constricts blood vessels, which increases blood pressure, and stimulates aldosterone secretion → aldosterone increases sodium reabsorption → blood pressure increases

Atrial natriuretic peptide inhibits sodium reabsorption **Atrial natriuretic peptide (ANP)**, a hormone produced by the heart, increases sodium excretion and decreases blood pressure. ANP is stored in granules in atrial muscle cells. When Na^+ concentration increases, fluid is retained, and blood volume increases. As atrial muscle cells are stretched, they respond by releasing ANP into the circulation.

ANP dilates afferent arterioles, which increases the glomerular filtration rate. This hormone directly inhibits sodium reabsorption by the collecting ducts. ANP also acts indirectly by inhibiting aldosterone secretion. (Recall that aldosterone increases sodium reabsorption.) ANP reduces plasma aldosterone concentration by inhibiting renin release. These actions of ANP increase sodium excretion and urine output, which decreases blood volume and blood pressure. Note that the renin–angiotensin–aldosterone pathway works antagonistically with ANP in regulating fluid balance, electrolyte balance, and blood pressure.

blood volume increases → blood pressure increases → atria of heart stretched → atria release ANP → ANP directly inhibits sodium reabsorption and inhibits aldosterone secretion (which also inhibits sodium reabsorption) → urine volume increases → blood volume decreases → blood pressure decreases

CHECKPOINT 48.5

- **CONNECT** Which structure(s) is/are associated with each of the following functions: urea formation, urine formation, temporary storage of urine, and conduction of urine out of the body?
- **CONNECT** Which part(s) of the nephron is/are associated with each of the following processes: filtration, reabsorption, and secretion?
- **VISUALIZE** Draw a diagram showing the sequence of structures that a drop of glomerular filtrate passes through as it moves from Bowman's capsule to the urinary bladder.
- What are the main actions of the renin–angiotensin–aldosterone pathway? Compare the actions of this pathway with the actions of ANP.

Summary: Focus on Learning Objectives

48.1 Maintaining Fluid and Electrolyte Balance *(page 1033)*

1 Describe how the processes of *osmoregulation* and *excretion* contribute to fluid and electrolyte homeostasis.

- **Osmoregulation** is the active regulation of osmotic pressure of body fluids so that fluid and electrolyte homeostasis is maintained. **Excretion** is the process of disposing of metabolic wastes.

48.2 Metabolic Waste Products *(page 1033)*

2 Contrast the benefits and costs of excreting each of the following: ammonia, uric acid, or urea.

- The principal waste products of animal metabolism are water; carbon dioxide; and *nitrogenous wastes*, including ammonia, uric acid, and urea. *Ammonia*, which is toxic, is excreted mainly by aquatic animals.
- **Uric acid** and **urea** are far less toxic than ammonia, but their synthesis requires energy. Uric acid can be excreted as a semisolid paste, a water-conserving adaptation. Urea excretion requires water.

48.3 Osmoregulation and Excretion in Invertebrates *(page 1034)*

3 Contrast osmoconformers and osmoregulators.

- Most marine invertebrates are **osmoconformers**, meaning that the salt concentration of their body fluids varies with changes in the sea water. Some marine invertebrates, especially those inhabiting coastal habitats, are **osmoregulators** that maintain an optimal salt concentration despite changes in salinity of their surroundings.

4 Compare the structure and function of protonephridia, metanephridia, and Malpighian tubules.

- **Nephridial organs** help maintain homeostasis by regulating the concentration of body fluids through osmoregulation and excretion of metabolic wastes.
- **Protonephridia**, nephridial organs found in flatworms and nemerteans, are tubules with no internal openings. Interstitial fluid enters their blind ends, which consist of **flame cells**, cells with brushes of cilia. The cilia propel fluid through the tubules, and excess fluid exits through nephridiopores.
- Most annelids and mollusks have nephridial organs called **metanephridia**, which are tubules open at both ends. As fluid from the coelom moves through the tubule, needed materials are reabsorbed by capillaries. Urine, containing wastes, exits the body through nephridiopores.
- **Malpighian tubules**, extensions of the insect gut wall, have blind ends that lie in the hemocoel. Cells of the tubule actively transport uric acid and some other substances from the hemolymph into the tubule. Water follows by diffusion. The contents of the tubule pass into the gut. Water and some solutes are reabsorbed in the rectum. Malpighian tubules have contributed to the success of insects as terrestrial animals.

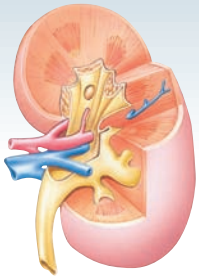
48.4 Osmoregulation and Excretion in Vertebrates *(page 1036)*

5 Relate the function of the vertebrate kidney to the success of vertebrates in a wide variety of habitats.

- The vertebrate **kidney** excretes nitrogenous wastes and helps maintain fluid balance by adjusting the salt and water content of the urine.
- Freshwater, marine, and terrestrial habitats present different problems for maintaining internal fluid balance and for the excretion of nitrogenous wastes. The structure and function of the vertebrate kidney have adapted to meet the various osmotic challenges presented by these different habitats.

6 Compare adaptations for osmoregulation in freshwater fishes, marine bony fishes, sharks, marine mammals, and terrestrial vertebrates.

- Freshwater fishes take in water osmotically, and they excrete a large volume of hypotonic urine.
- Marine bony fishes lose water osmotically. They compensate by drinking sea water and excreting salt through their gills; they produce only a small volume of isotonic urine. Sharks and other marine cartilaginous fishes retain large amounts of urea, allowing them to take in water osmotically through the gills. They excrete a large volume of hypotonic urine. Marine mammals ingest sea water with their food. They produce concentrated urine.
- Terrestrial vertebrates must conserve water. Endotherms have a high metabolic rate and produce a large volume of nitrogenous wastes. They have numerous adaptations for conserving water, including efficient kidneys.



48.5 The Urinary System of Mammals *(page 1038)*

7 Describe (and label on a diagram) the organs of the mammalian urinary system and give the functions of each.

- The **urinary system** is the principal excretory system in mammals. The kidneys produce urine, which passes through the **ureters** to the **urinary bladder** for storage. During urination, the urine is released from the body through the **urethra**.
- The outer portion of each kidney is the **renal cortex**, and the inner portion is the **renal medulla**. The renal medulla contains eight to ten *renal pyramids*. The tip of each pyramid is a *renal papilla*. As urine is produced, it flows into **collecting ducts**, which empty through a renal papilla into a funnel-shaped chamber, the **renal pelvis**. Each kidney has more than one million functional units called **nephrons**.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

8 Describe (and label on a diagram) the structures of a nephron (including associated blood vessels) and give the functions of each structure.

- Each nephron consists of a cluster of capillaries called a **glomerulus**, which is surrounded by a **Bowman's capsule** that opens into a long, coiled **renal tubule**. The renal tubule consists of a **proximal convoluted tubule**, **loop of Henle**, and **distal convoluted tubule**.
- *Cortical nephrons*, located almost entirely within the cortex, have small glomeruli. *Juxtamedullary nephrons* have large glomeruli and long loops of Henle that extend deep into the medulla. These nephrons are important in concentrating urine.
- Blood flows from small branches of the **renal artery** to **afferent arterioles** and then to glomerular capillaries. Blood then flows into an **efferent arteriole** that delivers blood into a second set of capillaries, the **peritubular capillaries** that surround the renal tubule. Blood leaves the kidney through the *renal vein*.

9 Trace a drop of glomerular filtrate from Bowman's capsule to its release from the body as urine.

- Urine is produced by **glomerular filtration** of plasma, **tubular reabsorption** of needed materials, and **tubular secretion** of a few substances, such as potassium and hydrogen ions, into the renal tubule.
- Plasma filters through the glomerular capillaries and into Bowman's capsule. The permeable walls of the capillaries and *filtration slits* between *podocytes*, specialized epithelial cells that make up the inner wall of Bowman's capsule, serve as a *filtration membrane*.
- Glomerular filtration is nonselective with regard to small molecules. In addition to metabolic wastes, glucose and other needed substances become part of the filtrate.
- Tubular reabsorption is a highly selective process that returns usable materials to the blood, but leaves wastes and excesses of other substances to be excreted in the urine. The maximum rate at which a substance can be reabsorbed is its **tubular transport maximum (Tm)**.
- In tubular secretion, hydrogen ions, certain other ions, and some drugs are actively transported into the renal tubule to become part of the urine.
- Production of concentrated urine depends on a high salt and urea concentration in the interstitial fluid of the kidney medulla. The interstitial fluid in the medulla has a concentration gradient in which the salt is most concentrated around the bottom of the loop of Henle. This gradient is maintained, in part, by salt reabsorption from various parts of the renal tubule.
- A counterflow of fluid through the two limbs of the loop of Henle concentrates filtrate as it moves down the descending loop and dilutes it as it moves up the ascending loop.
- Water is drawn by osmosis from the filtrate as it passes through the collecting ducts. This process concentrates urine in the collecting ducts.
- Some of the water that diffuses from the filtrate into the interstitial fluid is removed by the *vasa recta*, a system of capillaries that extend from the efferent arterioles.
- *Urine* is a watery solution of nitrogenous wastes, excess salts, and other unneeded substances.

10 Describe regulation of fluid and electrolyte balance by antidiuretic hormone (ADH), the renin–angiotensin–aldosterone system, and atrial natriuretic peptide (ANP).

- When the body needs to conserve water, the posterior pituitary gland increases its release of **antidiuretic hormone (ADH)**. The pituitary gland responds to an increase in osmotic concentration of the blood (caused by dehydration). ADH increases the permeability of the collecting ducts to water. As a result, more water is reabsorbed, and only a small volume of urine is produced.
- The renin–angiotensin–aldosterone pathway and atrial natriuretic peptide work antagonistically. When blood pressure decreases, cells of the **juxtaglomerular apparatus** secrete the enzyme **renin**, which activates a pathway leading to production of **angiotensin II**. This hormone stimulates aldosterone release. **Aldosterone** increases sodium reabsorption, and angiotensin II constricts arterioles; both actions raise blood pressure.
- When blood pressure increases, **atrial natriuretic peptide (ANP)** increases sodium excretion and inhibits aldosterone secretion. These actions increase urine output and lower blood pressure.

Test Your Understanding

Know and Comprehend

1. The process that maintains homeostasis of body fluids by keeping them from becoming too dilute or too concentrated is (a) excretion (b) elimination (c) osmoregulation (d) glomerular filtration (e) tubular secretion
2. Which of the following is *not* a correct pair? (a) protonephridia; flatworm (b) metanephridia; annelid (c) flame cell; flatworm (d) Malpighian tubule; mollusk (e) kidney; vertebrate
3. To compensate for fluid loss, many marine bony fishes (a) accumulate urea (b) have glands that excrete glucose (c) eat a low-protein diet (d) excrete a large volume of hypertonic urine (e) drink sea water
4. The afferent arteriole delivers blood to the (a) renal artery (b) efferent arteriole (c) renal vein (d) capillaries of the glomerulus (e) peritubular capillaries
5. Which of the following does *not* contribute to the process of filtration? (a) active transport by epithelial cells lining renal

tubules (b) large surface area for filtration (c) low permeability of glomerular capillaries (d) high hydrostatic blood pressure in glomerular capillaries (e) podocytes

6. Tubular transport maximum (Tm) is (a) the maximum rate at which a substance in the filtrate can be reabsorbed into the blood from the renal tubules (b) the most rapid rate at which urine can be transported through the ureter (c) the maximum rate at which a substance can be reabsorbed by the glomerulus (d) the maximum rate at which a substance can pass through the loop of Henle (e) the maximum amount of a substance that can be secreted into the filtrate
7. Which of the following does *not* contribute to the high salt concentration in the interstitial fluid of the kidney medulla? (a) active transport of sodium from the upper part of the ascending limb (b) diffusion of salt from the ascending limb of the loop of Henle (c) reabsorption of salt from various regions of Bowman's capsule (d) counterflow of fluid through the two limbs of the loop of Henle (e) diffusion of urea out of the collecting duct
8. Which is *not* true of ADH? (a) released by posterior lobe of the pituitary gland (b) increases water reabsorption (c) secretion increases when osmotic pressure in body increases (d) increases urine volume (e) secretion decreases when you drink a lot of water
9. Aldosterone (a) is released by the posterior pituitary gland (b) decreases sodium reabsorption (c) secretion is stimulated by an increase in blood pressure (d) is an enzyme that converts angiotensin into angiotensin II (e) secretion increases in response to angiotensin II

Apply and Analyze

10. Arrange the following structures into an accurate sequence through which urine passes. 1. urethra 2. urinary bladder 3. kidney 4. ureter (a) 4, 3, 2, 1 (b) 3, 4, 2, 1 (c) 1, 2, 3, 4 (d) 4, 2, 1, 3 (e) 3, 1, 2, 4
11. Arrange the following structures into an accurate sequence through which glomerular filtrate passes. 1. proximal convoluted tubule 2. loop of Henle 3. collecting duct 4. distal convoluted tubule 5. Bowman's capsule (a) 5, 4, 3, 2, 1 (b) 3, 4, 2, 5, 1 (c) 1, 5, 2, 3, 4 (d) 5, 4, 2, 3, 1 (e) 5, 1, 2, 4, 3
12. **VISUALIZE** Label the diagram.

13. **CONNECT** Glucose is normally present in the glomerular filtrate, but not in the urine. Persons with uncontrolled diabetes mellitus are an exception. They have glucose in their urine, as well as increased urine output. Develop a hypothesis to explain these exceptions.
14. What types of osmoregulatory challenges do humans experience? Explain. What mechanisms do we have to meet these challenges?

Evaluate and Synthesize

15. **EVOLUTION LINK** The number of protonephridia in a planarian is related to the salinity of its environment. Planaria inhabiting slightly salty water develop fewer protonephridia than those inhabiting less salty water, but the number of protonephridia quickly increases when the concentration of salt in the environment is lower. How is this increase adaptive? Explain.
16. **EVOLUTION LINK** The kangaroo rat's diet consists of dry seeds, and it drinks no water. What types of osmoregulatory adaptations might help this animal survive?
17. **EVOLUTION LINK** Although the kidney is basically similar in all vertebrates, its structure and function vary somewhat among vertebrate taxa. What are some of the adaptations that have occurred during the evolution of the vertebrate kidney?
18. **SCIENCE, TECHNOLOGY, AND SOCIETY** A person with kidney disease lives 10 to 15 years longer with a kidney transplant than on continued dialysis. However, in the United States many individuals have difficulty being accepted by a transplant program because they do not have adequate insurance or other resources. The immunosuppressive drugs and other medications required after the surgery are also very expensive, costing about $2500 per month. Should economic status be a deciding factor about whether a person lives or dies? or about quality of life?

49 Endocrine Regulation

KEY CONCEPTS

49.1 Endocrine glands and tissues secrete hormones, chemical messengers that bind to specific receptors on (or in) target cells and regulate physiological processes. Endocrine regulation depends mainly on negative feedback systems.

49.2 Several types of endocrine signaling are known: in classical endocrine signaling, endocrine glands secrete hormones that are transported to target cells by the blood; in neuroendocrine signaling, neuroendocrine cells produce hormones that are transported down axons and released into interstitial fluid; in autocrine signaling, a hormone acts on the very cells that produce it; and in paracrine signaling, a hormone acts on nearby cells.

49.3 Receptors are responsible for the specificity of the endocrine system. Small, lipid-soluble hormones enter target cells, bind to receptors inside the cell, and then activate or repress specific genes; hydrophilic hormones bind to cell-surface receptors and initiate signal transduction, leading to changes in cell processes.

49.4 Many invertebrate hormones are neurohormones secreted by neuroendocrine cells. Invertebrate hormones regulate metabolism, growth, and development, including molting and metamorphosis.

49.5 In vertebrates, many organs and tissues secrete hormones that interact to regulate growth and development, metabolism, fluid balance, response to stress, reproduction, and many other processes.

A caterpillar becomes a butterfly. A crustacean changes color to blend with its background (see photograph). A young girl develops into a woman. An adult copes with chronic stress. The **endocrine system** regulates these physiological processes and many more, including growth and development; metabolism; fluid balance and concentrations of specific ions and chemical compounds in the blood, urine, and other body fluids; reproduction; and response to stress. The tissues and organs of the endocrine system secrete *hormones*, chemical messengers that signal other cells.

Endocrinology, the study of endocrine activity, is an active, exciting field of biomedical research. This branch of biology has its roots in experiments performed by German physiologist A.A. Berthold in the 1840s. Berthold removed the testes from young roosters and observed that the roosters' combs (a male secondary sex characteristic) did not grow as large as those in normal roosters. He then transplanted testes into some of the birds and observed that the combs grew to normal size. Berthold's methods became a model for subsequent studies in endocrinology and are still used by researchers today.

Investigators are actively studying mechanisms of hormone action, including characterizing receptors and identifying the molecules involved in *signal transduction*. Some endocrinologists use a reverse strategy for discovering new hormones and signaling pathways within the cell. They focus on "orphan" nuclear receptors, those for which ligands (the molecules that bind with them) are not yet known. Some of these "orphan" receptors are receptors for hormones that have not yet been identified. Using this strategy,

researchers have identified intracellular signaling pathways for steroids, fatty acids, and several other compounds. Interestingly, many signaling pathways share the same molecules even though they respond to different stimuli and activate different responses. Much remains to be learned about how similar pathways lead to many different, and very specific, cell actions.

In this chapter we discuss how the endocrine system regulates life processes. We focus on how hormones maintain homeostasis, and we examine how overproduction or deficiency of various hormones interferes with normal functioning.

49.1 An Overview of Endocrine Regulation

LEARNING OBJECTIVES

1. Compare endocrine system function with nervous system function and describe how these systems work together to regulate body processes.
2. Summarize the regulation of endocrine action by negative feedback systems.
3. Identify four main chemical groups to which hormones are assigned and give two examples for each group.

The endocrine system is a diverse collection of cells, tissues, and organs including specialized **endocrine glands** that produce and secrete **hormones**, chemical messengers that regulate many physiological processes. The term *hormone* is derived from a Greek word meaning "to excite." Hormones excite, or stimulate, changes in specific tissues. Endocrine glands differ from **exocrine glands** (such as sweat glands and gastric glands) that release their secretions into ducts. Endocrine glands have no ducts and secrete their hormones into the surrounding interstitial fluid or blood.

Endocrinologists have identified about ten discrete endocrine glands. They have also discovered specialized cells in the digestive tract, heart, kidneys, and many other parts of the body that release hormones or hormone-like substances. As a result of these discoveries, the scope of endocrinology now includes the production and actions of chemical messengers produced by a wide variety of organs, tissues, and cells.[1]

Hormones are typically transported by the blood. They produce a characteristic response only after they bind with specific receptors on **target cells**, the cells influenced by a particular hormone. Target cells may be in another endocrine gland or in an entirely different type of organ, such as a bone or kidney. Target cells may be located far from the endocrine gland. For example, the vertebrate thyroid gland secretes hormones that stimulate metabolism in tissues throughout the body.

[1] Pheromones are chemical messengers that animals release to communicate with other animals of the same species. Most biologists do not classify pheromones as hormones because pheromones are generally produced by exocrine glands and do not regulate metabolic activities within the animal that produces them. Their role in regulating behavior is discussed in Chapter 52.

Several types of hormones may be involved in regulating the metabolic activities of a particular type of cell. In fact, many hormones produce a synergistic effect in which the presence of one hormone enhances the effects of another.

The endocrine system and nervous system interact to regulate the body

The endocrine system works closely with the nervous system to maintain **homeostasis**, the balanced internal environment of the body. Recall from Chapters 41 and 42 that the nervous system responds rapidly to stimuli by transmitting electrical and chemical signals. Neurons signal muscle and gland cells, including endocrine cells. The endocrine system signals a much wider range of target cell types than the nervous system does.

In general, the endocrine system responds more slowly than the nervous system, but its responses may be longer-lasting. As we will learn, the nervous system helps regulate many endocrine responses. For example, when the body is threatened, the hypothalamus signals the adrenal glands to secrete the hormone epinephrine. The hypothalamus, which is the link between the nervous and endocrine systems, also produces several hormones (neurohormones), including hormones that regulate the pituitary gland.

Nervous system and endocrine function further blur when we consider that the same signal molecule can function as either a neurotransmitter or a hormone, depending on its source. (You may recall from Chapters 41 and 42 that norepinephrine is secreted at synapses by neurons in the brain and by the sympathetic system.) Norepinephrine is also secreted as a hormone by the adrenal medulla, an endocrine organ.

Negative feedback systems regulate endocrine activity

Although present in minute amounts, more than 50 different hormones may be circulating in the blood of a vertebrate at any given time. Hormone molecules continuously move out of the circulation and bind with target cells. They are also removed from the blood by the liver, which inactivates some hormones, and by the kidneys, which excrete them.

Most endocrine action is regulated by **negative feedback systems**, discussed in Chapter 39. The parathyroid glands, located in the neck of tetrapod vertebrates, provide a good example of how negative feedback works in endocrine regulation (FIG. 49-1). The parathyroid glands regulate the calcium concentration of the blood. When the calcium concentration is not within homeostatic limits, nerves and muscles cannot function properly. For instance, when too few calcium ions are present, neurons fire spontaneously, causing muscle spasms. When calcium concentration varies too far from the steady state (either too high or too low), negative feedback systems restore homeostasis.

A decrease in calcium concentration in the plasma signals the parathyroid glands to release more parathyroid hormone. This hormone increases the concentration of calcium in the blood. When the calcium concentration rises above normal

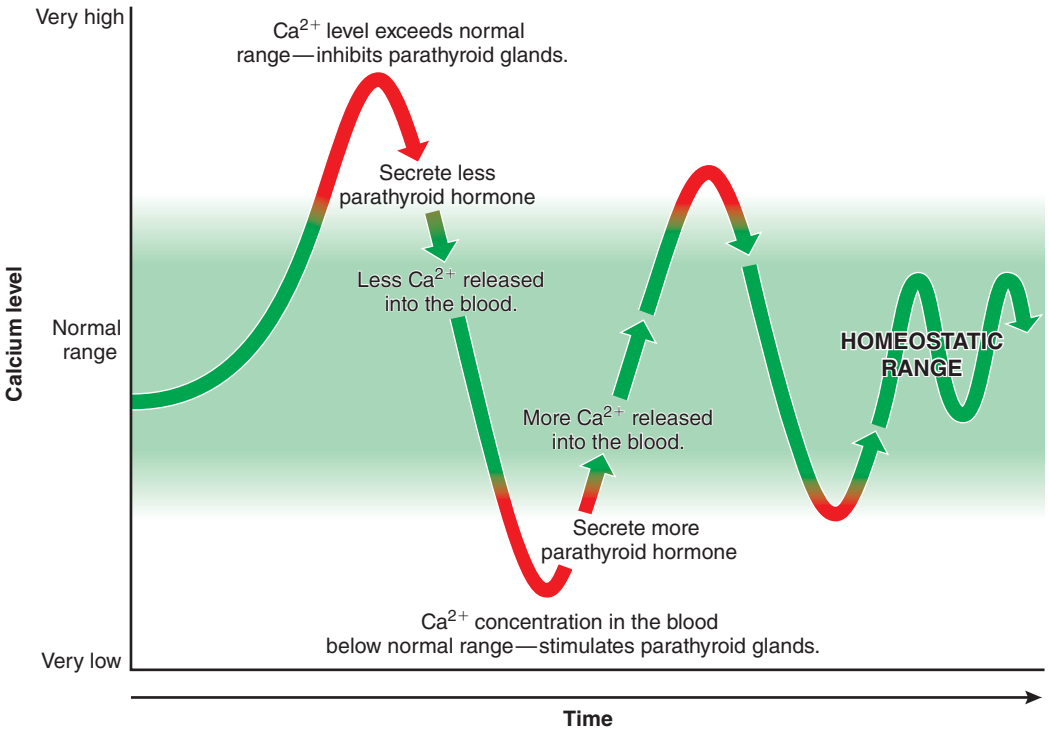

Figure 49-1 Regulation by negative feedback

Whether the calcium concentration in the blood is too high or too low, negative feedback mechanisms restore homeostasis. Parathyroid hormone increases calcium concentration by stimulating calcium release from bones and calcium reabsorption from the kidney tubules. The *green area* represents the homeostatic range. (See Figure 49-11 for more detailed diagrams of parathyroid hormone regulation.)

limits, the parathyroid glands slow their output of hormone. Both responses are negative feedback systems. An increase in calcium concentration results in decreased release of parathyroid hormone, whereas a decrease in calcium leads to increased hormone secretion. In each case, the response counteracts the inappropriate change, restoring the steady state. (Parathyroid action is discussed in greater detail later in the chapter.)

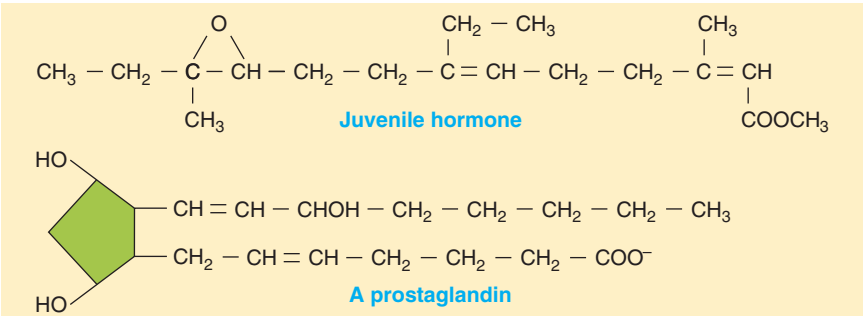
Hormones are assigned to four chemical groups

Although hormones are chemically diverse, they generally belong to one of four chemical groups: (1) fatty acid derivatives, (2) steroids, (3) amino acid derivatives, or (4) peptides or proteins. *Prostaglandins* and the juvenile hormones of insects are **fatty acid derivatives** (FIG. 49-2a). Prostaglandins are synthesized from arachidonic acid, a 20-carbon fatty acid. A prostaglandin has a 5-carbon ring in its structure.

The molting hormone of insects is a **steroid hormone** (FIG. 49-2b). In vertebrates, the adrenal cortex, testis, ovary, and placenta secrete steroid hormones synthesized from cholesterol. Examples of steroid hormones are cortisol, secreted by the adrenal cortex; the male reproductive hormone testosterone secreted by the testis; and the female reproductive hormones progesterone and estrogen produced by the ovary. Athletes (and others) sometimes abuse synthetic hormones known as anabolic steroids (see *Inquiring About: Anabolic Steroids and Other Performance-Enhancing Drugs*).

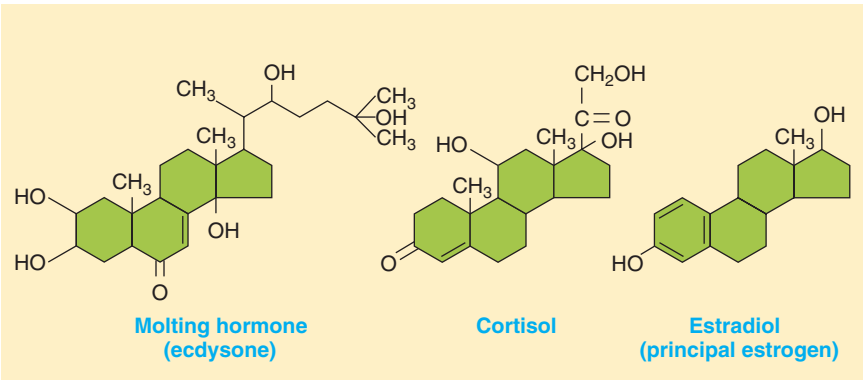
Chemically, the simplest hormones are **amino acid derivatives** (FIG. 49-2c). The thyroid hormones (T_3 and T_4) are synthesized from the amino acid tyrosine and iodide. Epinephrine (also known as adrenaline) and norepinephrine (also known as noradrenaline), produced by the medulla of the adrenal gland, are also derived from tyrosine. Melatonin is synthesized from the amino acid tryptophan.

The water-soluble **peptide hormones** are the largest hormone group. (Many endocrinologists include protein hormones in this group.) **Neuropeptides** are a large group of signaling molecules produced by neurons. Oxytocin and antidiuretic hormone (ADH), produced in the hypothalamus, are short neuropeptides, each composed of nine amino acids (FIG. 49-2d). Seven of the amino acids are identical in the two hormones, but the actions of these hormones are quite different. The hormones glucagon (see Fig. 3-19), secretin, adrenocorticotropic hormone (ACTH), and calcitonin are somewhat longer peptides that each consist of about 30 amino acids.



Insulin is a small protein that consists of two peptide chains joined by disulfide bonds. Growth hormone, thyroid-stimulating hormone, and the gonadotropic hormones, all secreted by the anterior pituitary gland, are large proteins with molecular weights of 25,000 or more.

CHECKPOINT 49.1



- What are target cells?
- **CONNECT** How do the nervous and endocrine systems work together?
- **PREDICT** The concentration of calcium in the blood decreases below the homeostatic level. How does the body respond?
- What are four major chemical groups of hormones? Give an example of each.

49.2 Types of Endocrine Signaling

LEARNING OBJECTIVE

4 Compare four types of endocrine signaling.

Hormones signal their target cells by classical endocrine signaling, neuroendocrine signaling, autocrine signaling, and paracrine signaling. In *classical endocrine signaling*, hormones are secreted by endocrine glands and are transported by the blood to target cells (FIG. 49-3a). Steroid hormones and thyroid hormones are transported bound to plasma proteins. The water-soluble peptide hormones are dissolved in the plasma. Hormones move out of the blood with plasma and are present in interstitial fluid.

Neurohormones are transported in the blood

Certain neurons, known as **neuroendocrine cells**, are an important link between the nervous and endocrine systems. In *neuroendocrine signaling*, neuroendocrine cells produce **neurohormones** that are transported down axons and released into the interstitial fluid. They typically diffuse into capillaries and are transported by the blood (FIG. 49-3b). Invertebrate endocrine systems are largely neuroendocrine. In vertebrates, the hypothalamus produces neurohormones that link the nervous system with the pituitary gland, an endocrine gland that secretes several hormones.

Some local regulators are considered hormones

A **local regulator** is a signaling molecule that diffuses through the interstitial fluid and acts on nearby cells. Most endocrinologists include at least certain local regulators as hormones. Also, some chemical compounds that act as classical hormones (transported by the blood) function as local regulators under some conditions.

Local regulators use *autocrine* or *paracrine* signaling. In *autocrine signaling*, a hormone or other regulator acts on the very cells that produce it (FIG. 49-3c). For example, the female hormone estrogen, which

Inquiring About

Anabolic Steroids and Other Performance-Enhancing Drugs

Why are anabolic steroids and some other performance-enhancing drugs abused? An estimated one million people in the United States, half of them adolescents, abuse certain hormones so as to enhance their physical performance. Anabolic steroids, a group of synthetic hormones, are officially called anabolic-androgenic steroids. Anabolic steroids are synthetic androgens (male reproductive hormones) that were developed in the 1930s to prevent muscle atrophy in patients with diseases that prevented them from moving.

In the 1950s, anabolic steroids became popular with professional athletes, who used them to increase muscle mass, physical strength, endurance, and aggressiveness. In truth, their athletic performance was probably enhanced, at least in part, by drug-induced euphoria and increased enthusiasm for training. The term *doping* refers to the use of banned performance-enhancing drugs.

As with other hormones, the concentration of steroids circulating in the body is precisely regulated, so use of anabolic steroids interferes with normal physiological processes. These drugs remain in the body for a long time. Their metabolites (breakdown products) can be detected in the urine for up to six months.

Even during short-term use and at relatively low doses, anabolic steroids have a significant effect on mood and behavior. At higher doses users experience disturbed thought processes, forgetfulness, and confusion and often find themselves easily distracted. The term *roid rage* refers to the mood swings, unpredictable anger, increased aggressiveness, and irrational behavior exhibited by many users.

Misuse of anabolic steroids poses many health hazards. These drugs increase the risk of cardiovascular disease by elevating blood pressure and decreasing the concentration of high-density lipoproteins (HDL, or "good" cholesterol). Anabolic steroids cause kidney and liver damage as well as increase the risk of liver cancer. Abuse of these hormones also reduces sexual function. In males, testosterone secretion decreases and the testes shrink, leading to sterility. In females, abuse of anabolic steroids can cause infertility as well as masculine features such as facial hair and decreased breast size. In adolescents, these steroids cause severe acne and stunt growth by prematurely closing the growth plates in bones.

Anabolic steroids are both injected and taken in pill form. Steroid abusers who share needles or use nonsterile techniques when they inject steroids are at risk for contracting hepatitis, HIV, and other serious infections.

When their serious side effects became known in the 1960s, anabolic steroid use became controversial, and in 1973 the Olympic Committee banned their use. They are now prohibited worldwide by amateur and professional sports organizations. In the United States, possession of anabolic steroids without a prescription is a federal offense. However, despite the risks, the black market for these synthetic hormones is estimated at more than $1 billion per year.

A recent analysis determined that almost one-third of anabolic steroids purchased illegally did not contain the drugs listed on their labels. Almost 50% of anabolic steroids that did contain the promised drug were delivered in much lower or much higher dosage. In addition, illegally purchased drugs are often contaminated with toxic heavy metals (e.g., lead and arsenic).

The typical anabolic steroid user is a male (95%) athlete (65%), most often a football player, weight lifter, or wrestler. Surprisingly, though, about 10% of male high school students have used anabolic steroids, and about one-third of these students are not even on a high school team. These adolescents use the hormone only to change their physical appearance—to pump up their muscles ("bulk up")—and increase endurance. Many anabolic steroid users have difficulty realistically perceiving their body images. They remain unhappy even after dramatic increases in muscle mass.

Some people also abuse other hormones, including human growth hormone (HGH) and erythropoietin, to enhance performance. HGH, like anabolic steroids, helps build muscle mass but also causes acromegaly, a condition in which certain bones thicken abnormally. HGH can also cause diabetes and increase heart size, which can lead to heart failure.

Erythropoietin, a hormone produced by the kidney, increases the concentration of red blood cells, which increases oxygen transport. This hormone can enhance the performance of an endurance athlete by as much as 10% for short periods. However, abnormally high concentrations of red blood cells can cause serious cardiovascular problems. Erythropoietin abuse has caused the deaths of several athletes.

functions as a classical hormone, can also exert an autocrine effect that stimulates additional estrogen secretion. At times, estrogen acts on nearby cells, a type of local regulation known as *paracrine signaling* (FIG. 49-3d).

Local regulators include chemical mediators such as growth factors, histamine, nitric oxide, and prostaglandins. More than 50 **growth factors**, typically peptides, stimulate cell division and normal development in specific types of cells. Recall from Chapter 45 that **histamine** is stored in mast cells and is released in response to allergic reactions, injury, or infection. Histamine causes blood vessels to dilate and capillaries to become more permeable. **Nitric oxide (NO)**, another local regulator, is a gas produced by many types of cells, including those lining blood vessels. NO relaxes smooth muscle fibers in the blood vessel wall, causing the blood vessel to dilate. (See discussion of nitric oxide in Chapter 6.)

Prostaglandins are modified fatty acids released continuously by the cells of most tissues. These local hormones use paracrine signaling. Although present in very small quantities, prostaglandins affect a wide range of physiological processes. They modify cyclic AMP levels and interact with other hormones to regulate various metabolic activities.

The major prostaglandin target is smooth muscle. Some prostaglandins stimulate smooth muscle to contract, whereas others cause relaxation. Thus, some reduce blood pressure, whereas others raise it. Prostaglandins synthesized in the temperature-regulating center of the hypothalamus cause fever. In fact, nonsteroidal anti-inflammatory drugs (NSAIDs), such as aspirin and ibuprofen, reduce fever and decrease inflammation and pain by inhibiting prostaglandin synthesis.

Because prostaglandins are involved in the regulation of so many metabolic processes, they have great potential for a variety of clinical uses. Physicians use them to induce labor in pregnant women, to induce abortion, and to promote the healing of ulcers in the stomach and duodenum. Prostaglandins may someday be used to treat a variety of illnesses, including asthma, arthritis, kidney disease, certain cardiovascular disorders, and some forms of cancer.

Endocrine cells secrete hormones that signal target cells, leading to a change in one or more cell processes.

CHECKPOINT 49.2

- **VISUALIZE** Draw diagrams to contrast neuroendocrine signaling with classical endocrine signaling.
- How are autocrine and paracrine signaling different?
- What are two functions of prostaglandins?

49.3 Mechanisms of Hormone Action

LEARNING OBJECTIVE

5 Compare the mechanism of action of small, lipid-soluble hormones with that of hydrophilic hormones; include the role of second messengers, such as cyclic AMP.

A hormone present in the interstitial fluid remains "unnoticed" until it comes in contact with its target cells and binds to specific receptors on the cell surface or inside the cell. Recall that the receptor site is somewhat similar to a lock, and the hormones are like different keys. Only the hormone that fits the specific receptor can influence the metabolic machinery of the cell (see Chapter 6). Receptors are responsible for the specificity of the endocrine system.

Receptors are continuously synthesized and degraded. Their numbers are decreased or increased by **receptor down-regulation** and **receptor up-regulation**. For example, when the concentration of a hormone is too high for an extended period, cells decrease the number of receptors for that hormone. Down-regulation decreases the sensitivity of target cells to the hormone, so it dampens the hormone's ability to carry out its function. Up-regulation occurs when the concentration of a particular hormone is too low. Increasing the number of receptors on the plasma membrane increases the hormone's effect on the cell.

Lipid-soluble hormones enter target cells and activate genes

Steroid hormones and thyroid hormones are relatively small, lipid-soluble (hydrophobic) molecules that easily pass through the plasma membrane of the target cell. Specific protein receptors in the cytoplasm or in the nucleus bind with the hormone to form a hormone–receptor complex (FIG. 49-4). For example, thyroid hormones bind with receptors in the nucleus that are transcription factors. When activated by the hormone, they activate or repress transcription of messenger RNA coding for specific proteins. Proteins that are synthesized produce changes in structure or metabolic activity.

Gene activation and protein synthesis may take several hours. However, steroid hormones may also have more

Key Point

Steroid and thyroid hormones are small, lipid-soluble molecules that pass through the plasma membrane; they pass into the nucleus where they activate or repress specific genes. Specific proteins are synthesized, leading to the changes we recognize as the hormone's actions.

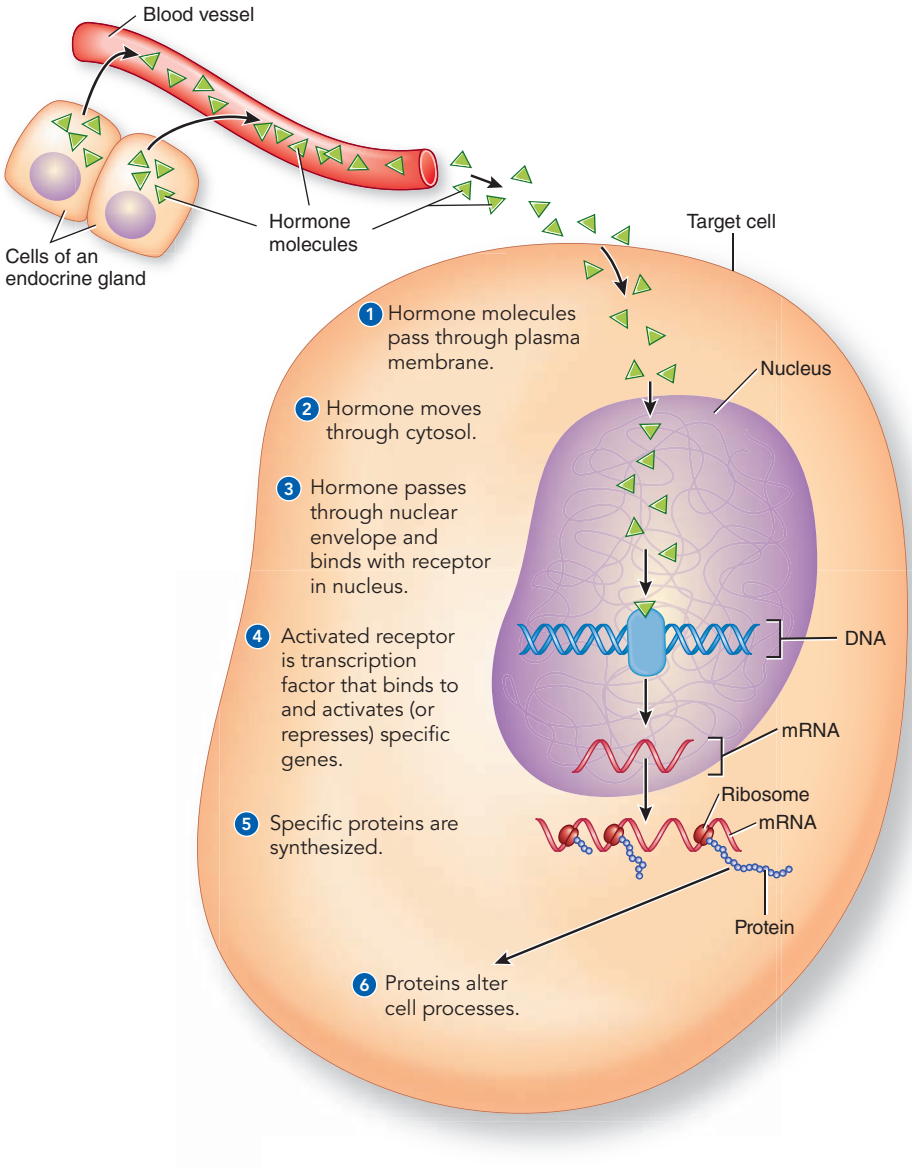

Figure 49-4 Mechanism of action of steroid and thyroid hormones

PREDICT What would happen if the number of receptors in the nucleus were severely decreased?

rapid mechanisms of action that do not require protein synthesis. For example, when an estrogen receptor in the membrane of the endoplasmic reticulum is activated by estrogen binding, it initiates rapid signaling that leads to changes in the cell within minutes or even seconds. Plasma membrane receptors have been described for at least two steroid hormones.

Water-soluble hormones bind to cell-surface receptors

Because peptide hormones are hydrophilic, they are not soluble in the lipid layer of the plasma membrane and do not enter the target cell. Instead, they bind to specific cell-surface receptors in the plasma membrane. Two main types of cell-surface receptors that bind hormones are G protein–linked receptors and enzyme-linked receptors. These receptors were discussed in Chapter 6. Here we will review some basic concepts.

G protein–linked receptors initiate signal transduction

G protein–linked receptors are transmembrane proteins that initiate **signal transduction**; they convert an extracellular hormone signal into an intracellular signal that affects some cell process. The hormone does not enter the cell. It serves as the **first messenger** and relays information to a **second messenger**, or intracellular signal. The second messenger then signals effector molecules that carry out the action.

G protein–linked receptors activate **G proteins**, a group of integral regulatory proteins (FIG. 49-5). The G indicates that they bind *guanosine triphosphate (GTP)*, which, like ATP, is an important molecule in energy reactions. When the system is inactive, G protein binds to *guanosine diphosphate (GDP)*, which is similar to ADP, the hydrolyzed form of ATP. G proteins shuttle a signal between the receptor and a second messenger.

When a hormone-bound receptor binds to it, a stimulatory G protein releases GDP and replaces it with GTP. The G protein undergoes a change in shape that allows it to bind with and activate the enzyme **adenylyl cyclase** on the cytoplasmic side of the plasma membrane. Once activated, adenylyl cyclase catalyzes the conversion of ATP to **cyclic AMP (cAMP)**. By coupling the hormone–receptor complex to an enzyme that generates a signal, G proteins amplify

Key Point

Peptide hormones bind with receptors on the plasma membrane. The receptor is a signal transducer that converts the hormone signal to an intracellular signal.

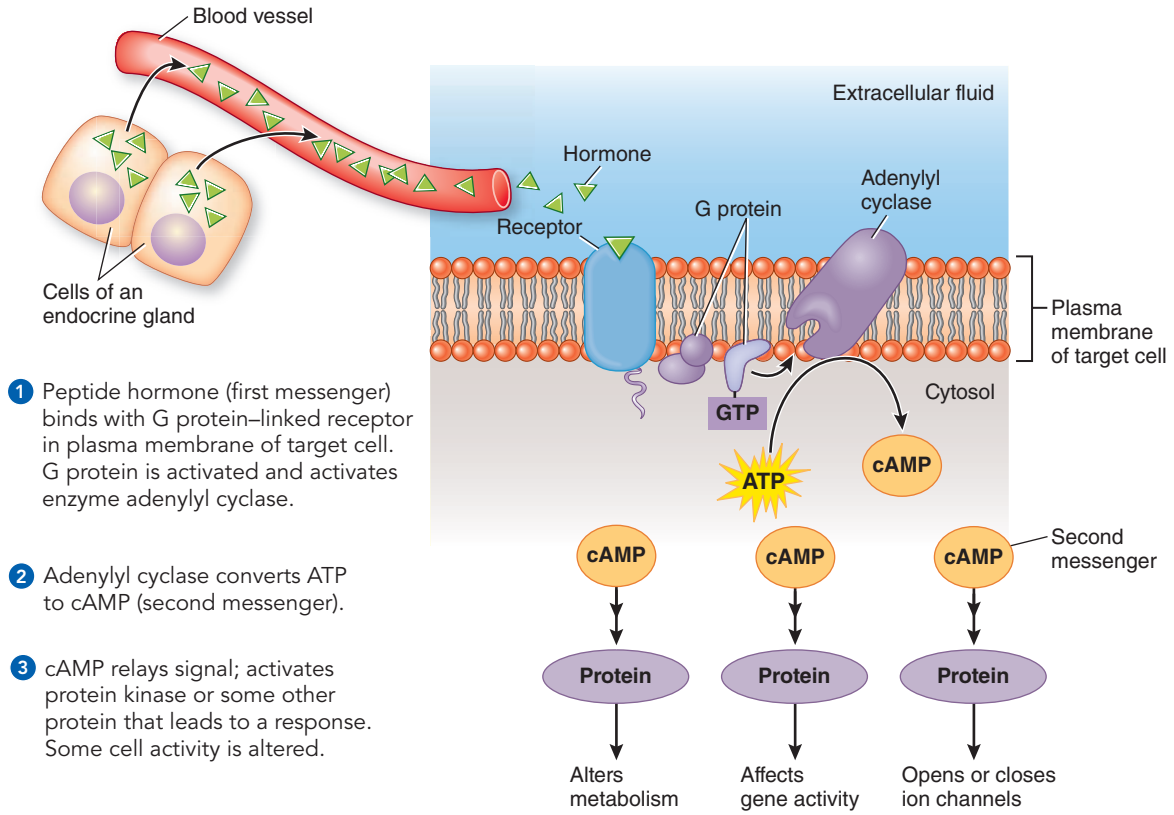

Figure 49-5 Mechanism of action of peptide hormones

Many peptide hormones signal target cells by way of a G protein–linked receptor. Cyclic AMP, or some other second messenger, relays the signal by activating a cascade of phosphorylation reactions. The final protein in the pathway changes some cell process.

PREDICT What would happen if adenylyl cyclase were inhibited?

hormone effects, and many second-messenger molecules are rapidly produced. One type of G protein, G_s, stimulates adenylyl cyclase, and another, G_i, inhibits it.

Cyclic AMP activates **protein kinases**, enzymes that phosphorylate (add a phosphate group to) specific proteins. When phosphorylated, protein kinase is activated and may phosphorylate the next protein in the pathway. A chain of reactions leads to some metabolic change. The substrates for protein kinases are different in various cell types, so the effect of cAMP varies. In skeletal muscle cells, a protein kinase triggers the breakdown of glycogen to glucose, whereas in cells of the hypothalamus, a protein kinase activates the gene that encodes a growth-inhibiting hormone.

Recall from Chapter 6 that some G proteins use phospholipids as second messengers. Certain hormone–receptor complexes activate a G protein that then activates phospholipase C, a membrane-bound enzyme (see Fig. 6-9). This enzyme splits a membrane phospholipid into two products: *inositol trisphosphate (IP_3)* and *diacylglycerol (DAG)*. Both act as second messengers. DAG (in combination with calcium ions) activates a protein kinase that phosphorylates a variety of proteins, and IP_3 opens calcium channels in the endoplasmic reticulum, releasing calcium ions into the cytosol. Calcium ions bind to certain proteins, such as *calmodulin*. The activated calmodulin then activates other proteins.

Enzyme-linked receptors function directly **Enzyme-linked receptors** are transmembrane proteins with a hormone-binding site outside the cell and an enzyme site inside the cell (see Fig. 6-5c). These receptors are not linked to G proteins. They function directly as enzymes or are directly linked to enzymes. Most enzyme-linked receptors are **tyrosine kinase receptors** that bind growth factors and other signal molecules, including insulin. When the receptor is activated, it phosphorylates the amino acid tyrosine in specific signaling proteins inside the cell.

CHECKPOINT 49.3

- **CONNECT** What are the roles of receptors and second messengers in hormone action?
- How do steroid and peptide hormones differ in their mechanisms of action?
- What is the mechanism of action of a hormone that uses cyclic AMP as a second messenger?

49.4 Neuroendocrine Regulation in Invertebrates

LEARNING OBJECTIVE

6 Identify four functions of invertebrate neurohormones and describe the regulation of insect development.

Among invertebrates, hormones are secreted mainly by neurons rather than by endocrine glands. These *neurohormones* regulate regeneration in hydras, flatworms, and annelids as well as color changes in crustaceans. Invertebrate neurohormones regulate growth, development, metabolism, gamete production, and reproduction (including reproductive behavior) in many groups. Trends in the evolution of invertebrate endocrine systems include an increasing number of both neurohormones and hormones secreted by endocrine glands and a greater role of hormones in physiological processes.

Insects have endocrine glands and neuroendocrine cells. Their various hormones and neurohormones interact with one another to regulate metabolism, growth, and development, including molting and metamorphosis. Hormonal control of development in insects varies among species. Generally, some environmental factor (e.g., temperature change) activates neuroendocrine cells in the brain. These cells then produce a neurohormone referred to as *brain hormone (BH)*, which is transported down axons and stored in the paired *corpora cardiaca* (sing., *corpus cardiacum*; FIG. 49-6). When released from the corpora cardiaca, BH stimulates the *prothoracic glands*, endocrine glands in the prothorax, to produce *molting hormone (MH)*, also called *ecdysone* (see Fig. 49-2b). MH is a steroid hormone that stimulates growth and molting.

In the immature insect, paired endocrine glands called *corpora allata* (sing., *corpus allatum*) secrete *juvenile hormone (JH)*. This hormone suppresses metamorphosis at each larval molt so that the insect increases in size while remaining in its immature state. After the molt, the insect is still in a larval stage. When the concentration of JH decreases below some critical level, metamorphosis occurs, and the insect is transformed into a pupa (see Chapter 31). In the absence of JH, the pupa molts and becomes an adult. The nervous system regulates the secretory activity of the corpora allata, and the amount of JH decreases with successive molts.

CHECKPOINT 49.4

- What are four actions of hormones in invertebrates?
- **CONNECT** How does juvenile hormone affect metamorphosis in insects?

49.5 Endocrine Regulation in Vertebrates

LEARNING OBJECTIVES

7 Identify the classical vertebrate endocrine glands and describe the actions of their hormones; describe the effects of hypersecretion and hyposecretion on homeostasis.

8 Describe the mechanisms by which the hypothalamus and pituitary gland integrate regulatory functions; summarize the actions of the hypothalamic and pituitary hormones.

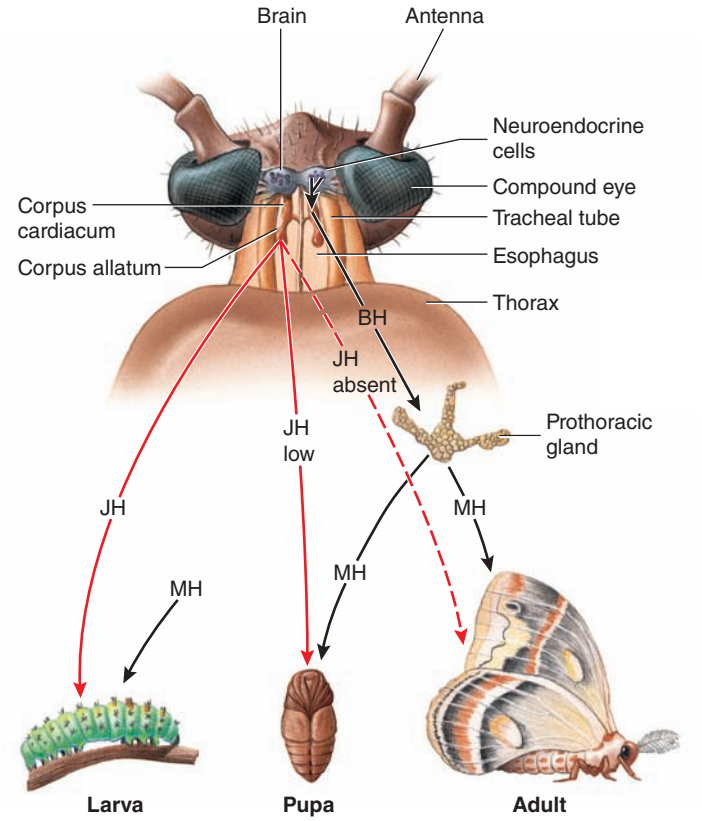
9 Describe the actions of the thyroid and parathyroid hormones, their regulation, and the effects of malfunction.

10 Contrast the actions of insulin and glucagon, and describe diabetes mellitus and hypoglycemia, including the metabolic effects of these disorders.

11 Describe the actions and regulation of the adrenal hormones, including their role in the body's response to stress.

Vertebrate hormones regulate such diverse activities as growth and development, reproduction, metabolic rate, fluid balance, blood homeostasis, and response to stress. Most vertebrates have similar endocrine glands, although the actions of some hormones may be different in various vertebrate groups. TABLE 49-1 gives the sources, target tissues, and principal physiological actions of some of the major vertebrate hormones. The hypothalamus and pituitary gland regulate many of these hormones. The principal human endocrine glands are illustrated in FIGURE 49-7.

Homeostasis depends on normal concentrations of hormones



When a disorder or disease process affects an endocrine gland, the rate of secretion may become abnormal. If **hyposecretion**, abnormally reduced output, occurs, target cells are deprived of needed stimulation. If **hypersecretion**, abnormally increased output, occurs, the target cells may be overstimulated. In some endocrine disorders, an appropriate amount of hormone is secreted, but the target cell receptors do not function properly. As a result, the target cells cannot respond to the hormone. These failures in regulation threaten homeostasis and can lead to predictable metabolic malfunctions and clinical symptoms (TABLE 49-2).

The hypothalamus regulates the pituitary gland

Most endocrine activity is controlled directly or indirectly by the **hypothalamus**, which links the nervous and endocrine

1. Neuroendocrine cells secrete brain hormone (BH), which is stored in corpora cardiaca.
2. When released, BH stimulates prothoracic glands to secrete molting hormone (MH), which stimulates growth and molting.
3. In immature insect, corpora allata secrete juvenile hormone (JH), which suppresses metamorphosis at each larval molt.
4. Metamorphosis to adult form occurs when MH acts in absence of JH.

FIGURE 49-6 Regulation of growth and molting in insects

Hormones regulate insect development. Most insects go through a series of larval stages and then undergo metamorphosis to the adult form. This dissection of an insect head shows the brain, paired corpora allata, and paired corpora cardiaca.

systems both anatomically and physiologically. The **pituitary gland** is connected to the hypothalamus by the pituitary stalk. The hypothalamus receives input from other areas of the brain and from hormones in the blood. In response, neurons of the hypothalamus secrete neurohormones that regulate specific physiological processes.

Because secretions of the pituitary gland control the activities of several other endocrine glands, biologists sometimes refer to it as the master gland of the body. Although it is the size of a large pea and weighs only about 0.5 g (0.02 oz), the pituitary gland produces six peptide hormones that exert far-reaching influence over growth, metabolism, reproduction, and many other body activities. The human pituitary gland consists of two main parts: the *anterior pituitary* and the *posterior pituitary*. In some vertebrates, an intermediate lobe is present.

The posterior pituitary gland releases hormones produced by the hypothalamus

The **posterior pituitary**, also called the posterior lobe of the pituitary gland, develops from brain tissue. This neuroendocrine organ *secretes* two peptide hormones, **oxytocin** and **antidiuretic hormone (ADH)**, also known as *vasopressin*. Oxytocin and ADH are actually *produced* by neuroendocrine cells in two distinct areas of the hypothalamus. These hormones are enclosed within vesicles and transported down the axons of the neuroendocrine cells into the posterior pituitary gland (FIG. 49-8 on page 1062). The vesicles are stored in the axon terminals until the neuron is stimulated. Then the hormones are released and diffuse into surrounding capillaries.

We discussed the function of ADH in Chapter 48. Recall that ADH stimulates reabsorption of water in the kidneys. Oxytocin concentration in the blood rises toward the end of pregnancy, stimulating the strong contractions of the uterus needed to expel a baby. Synthetic oxytocin is sometimes administered clinically to initiate or speed labor.

After birth, when an infant sucks at its mother's breast, sensory neurons signal the pituitary to release oxytocin. The hormone stimulates contraction of smooth muscle cells surrounding the milk glands so that milk is let down into the ducts, making it available to the nursing infant. Because oxytocin also stimulates the uterus to contract, breast-feeding promotes recovery of the uterus to nonpregnant size.

Oxytocin also plays a role in social behavior. In voles, for example, males with higher concentrations of oxytocin are more likely to be monogamous (have a single sexual partner) than those with lower concentrations. In humans, oxytocin affects maternal behavior. Of critical importance, this hormone facilitates attachment between mother and infant. It appears that oxytocin continues to play a role in social behavior throughout the lifespan. This hormone appears to help us recognize familiar faces and promote trust and cooperation. Oxytocin may also help us notice social cues.

The anterior pituitary gland regulates growth and other endocrine glands

The **anterior pituitary**, also called the anterior lobe of the pituitary, develops from epithelial cells rather than neural cells. The anterior pituitary functions like a classical endocrine gland: it receives signals by way of the blood and releases its hormones into the blood. The hypothalamus produces several **releasing hormones** and **inhibiting hormones** that regulate the production and secretion of specific hormones by the anterior pituitary.

Table 49-1 Some Vertebrate Endocrine Glands and Their Hormones

Gland	Hormone	Target Tissue	Principal Actions
Hypothalamus	Releasing and inhibiting hormones	Anterior pituitary	Regulate secretion of hormones by the anterior pituitary
Posterior pituitary (storage and release of hormones produced by hypothalamus)	Oxytocin	Uterus Mammary glands	Stimulates contraction Stimulates ejection of milk into ducts
	Antidiuretic hormone (ADH)	Kidneys (collecting ducts)	Stimulates reabsorption of water
Anterior pituitary	Growth hormone (GH)	General	Stimulates growth of skeleton and muscle
	Prolactin	Mammary glands	Stimulates milk production
	Melanocyte-stimulating hormones (MSH); belong to a group of hormones known as melanocortins	Pigment cells in skin	Stimulate melanin production in some animals; in humans, help regulate food intake
	Thyroid-stimulating hormone (TSH)	Thyroid gland	Stimulates secretion of thyroid hormones; helps regulate bone remodeling
	Adrenocorticotropic hormone (ACTH)	Adrenal cortex	Stimulates secretion of adrenal cortical hormones
	Gonadotropic hormones* (follicle-stimulating hormone [FSH]; luteinizing hormone [LH])	Gonads	Stimulate gonad function and growth
Thyroid gland	Thyroxine (T_4) and triiodothyronine (T_3)	General	Stimulate metabolic rate; regulate energy metabolism
	Calcitonin	Bone	Decreases blood calcium concentration
Parathyroid glands	Parathyroid hormone	Bone, kidneys, digestive tract	Increases blood calcium concentration
Pancreas	Insulin	General	Decreases blood glucose concentration
	Glucagon	Liver, adipose tissue	Increases blood glucose concentration
Adrenal medulla	Epinephrine and norepinephrine	Muscle; blood vessels; liver; adipose tissue	Help body cope with stress; increase metabolic rate; increase blood glucose concentration; increase heart rate and blood pressure
Adrenal cortex	Mineralocorticoids	Kidney tubules	Maintain sodium and potassium balance
	Glucocorticoids	General	Help body cope with long-term stress; increase blood glucose concentration
Pineal gland	Melatonin	Hypothalamus	Regulates biological rhythms
Ovary*	Estrogens	General; uterus	Develop and maintain sex characteristics in females; stimulate growth of uterine lining
	Progesterone	Uterus; breast	Stimulates development of uterine lining
Testis*	Testosterone	General; reproductive structures	Develops and maintains sex characteristics in males; promotes spermatogenesis

* Reproductive hormones are discussed in Chapter 50; see Tables 50-1 and 50-2.

Releasing and inhibiting hormones are produced by specific endocrine cells in the hypothalamus and are stored in vesicles in the axon terminals. When signaled to do so, the cells secrete a particular releasing (or inhibiting) hormone, which then enters a capillary. The hormone is transported in the blood through special portal veins that connect the hypothalamus with the anterior lobe of the pituitary. Within the anterior pituitary, the portal veins divide into a second set of capillaries. Thus, these portal veins, like the hepatic portal vein, do not deliver blood to a larger vein directly; they connect two sets of capillaries.

Releasing and inhibiting hormones pass through the capillary walls into the tissue of the anterior lobe of the pituitary. These hormones control the secretion of anterior pituitary hormones. For example, when the body is stressed, the hypothalamus secretes *corticotropin-releasing factor*. This releasing factor stimulates the anterior pituitary to secrete *adrenocorticotropic hormone (ACTH)*.

The anterior lobe secretes prolactin, melanocyte-stimulating hormones, growth hormone, and several **tropic hormones** that stimulate other endocrine glands (FIG. 49-9). **Prolactin** stimulates the cells of the mammary glands to produce milk in a nursing mother. This hormone has diverse roles in various vertebrate groups. In fishes and amphibians, for example, it helps maintain water and electrolyte balance by decreasing Na^+ and K^+ loss in the urine. Prolactin also inhibits metamorphosis in amphibians and stimulates molting in reptiles. This versatile hormone appears to have a role in immune function and in the formation of new blood vessels.

Melanocyte-stimulating hormones (MSH) (a group of **melanocortins**; see Chapter 47) are a group of peptide hormones secreted by the anterior pituitary gland and also by certain neurons in the hypothalamus. In some fishes, amphibians, and reptiles, MSH causes the skin to darken, facilitating camouflage. In

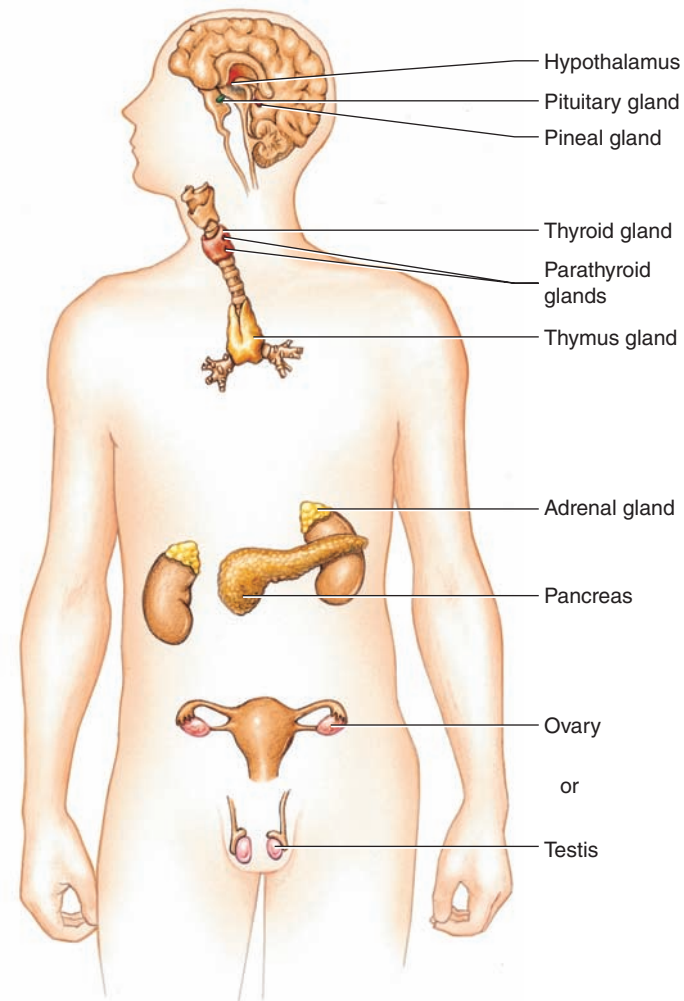

Figure 49-7 The principal human endocrine glands
Many of the hormones produced by these glands and their actions are discussed in this chapter.

humans, it suppresses appetite, leading to weight loss, and thus is important in regulating body weight and energy.

Growth hormone stimulates protein synthesis Whether someone is tall or short depends on many factors, including genes, diet, and hormone balance. **Growth hormone** (also called *somatotropin*) is referred to as an **anabolic hormone** because it promotes tissue growth. (The general acronym for vertebrate growth hormone is GH; human growth hormone is referred to as HGH or hGH.) Many of the effects of GH on skeletal growth are indirect. GH stimulates liver cells (and cells of many other tissues) to produce peptides called **insulin-like growth factors (IGFs)**. These growth factors (1) promote the linear growth of the skeleton by stimulating cartilage formation in growth areas of bones and (2) promote protein synthesis and other anabolic processes, which stimulates general tissue growth and increases organ size.

In adults as well as in growing children, GH is secreted in pulses throughout the day. The hypothalamus regulates GH secretion by secreting a **growth hormone–releasing hormone (GHRH)** and a **growth hormone–inhibiting hormone (GHIH)**, which is also called *somatostatin*. A high level of GH in the blood signals the hypothalamus to secrete GHIH; in response, the pituitary slows its release of GH. In contrast, a low level of GH in the blood stimulates the hypothalamus to secrete GHRH, which stimulates the pituitary gland to release more GH. Many other factors, including blood sugar level, amino acid concentration, and stress, influence GH secretion.

For children to grow, research supports the age-old notions that they need plenty of sleep, a proper diet, and regular exercise. GH is secreted about 1 hour after the onset of deep sleep and in a series of pulses 2 to 4 hours after a meal. Secretion of GH increases during exercise, probably because rapid metabolism by muscle cells lowers the blood glucose level.

Emotional support is also necessary for proper growth. Growth is retarded in children who are deprived of cuddling, playing, and other forms of nurture, even when their needs for food and shelter are met. In extreme cases, childhood stress can produce a form of retarded development known as *psychosocial dwarfism*. Some emotionally deprived children exhibit abnormal sleep patterns, which may be the basis for decreased secretion of GH.

Other hormones also influence growth. Thyroid hormones appear necessary for normal GH secretion and function and for normal tissue response to IGFs. Sex hormones must be present for the adolescent growth spurt to occur. However, the presence of sex hormones eventually causes the growth centers within the long bones to ossify so that no further increase in height can occur even when GH is present.

Table 49-2 Consequences of Endocrine Malfunction

Hormone	Hyposecretion	Hypersecretion
Growth hormone	Pituitary dwarfism	Gigantism if malfunction occurs in childhood; acromegaly in adult
Thyroid hormones	Cretinism (in children); myxedema, a condition of pronounced adult hypothyroidism; dietary iodine deficiency leads to hyposecretion and goiter	Hyperthyroidism; increased metabolic rate, nervousness, irritability; goiter; Graves' disease
Parathyroid hormone	Spontaneous discharge of nerves; spasms; tetany; death	Weak, brittle bones; kidney stones
Insulin	Diabetes mellitus	Hypoglycemia
Hormones of adrenal cortex	Adrenal insufficiency (Addison's disease)	Cushing's syndrome

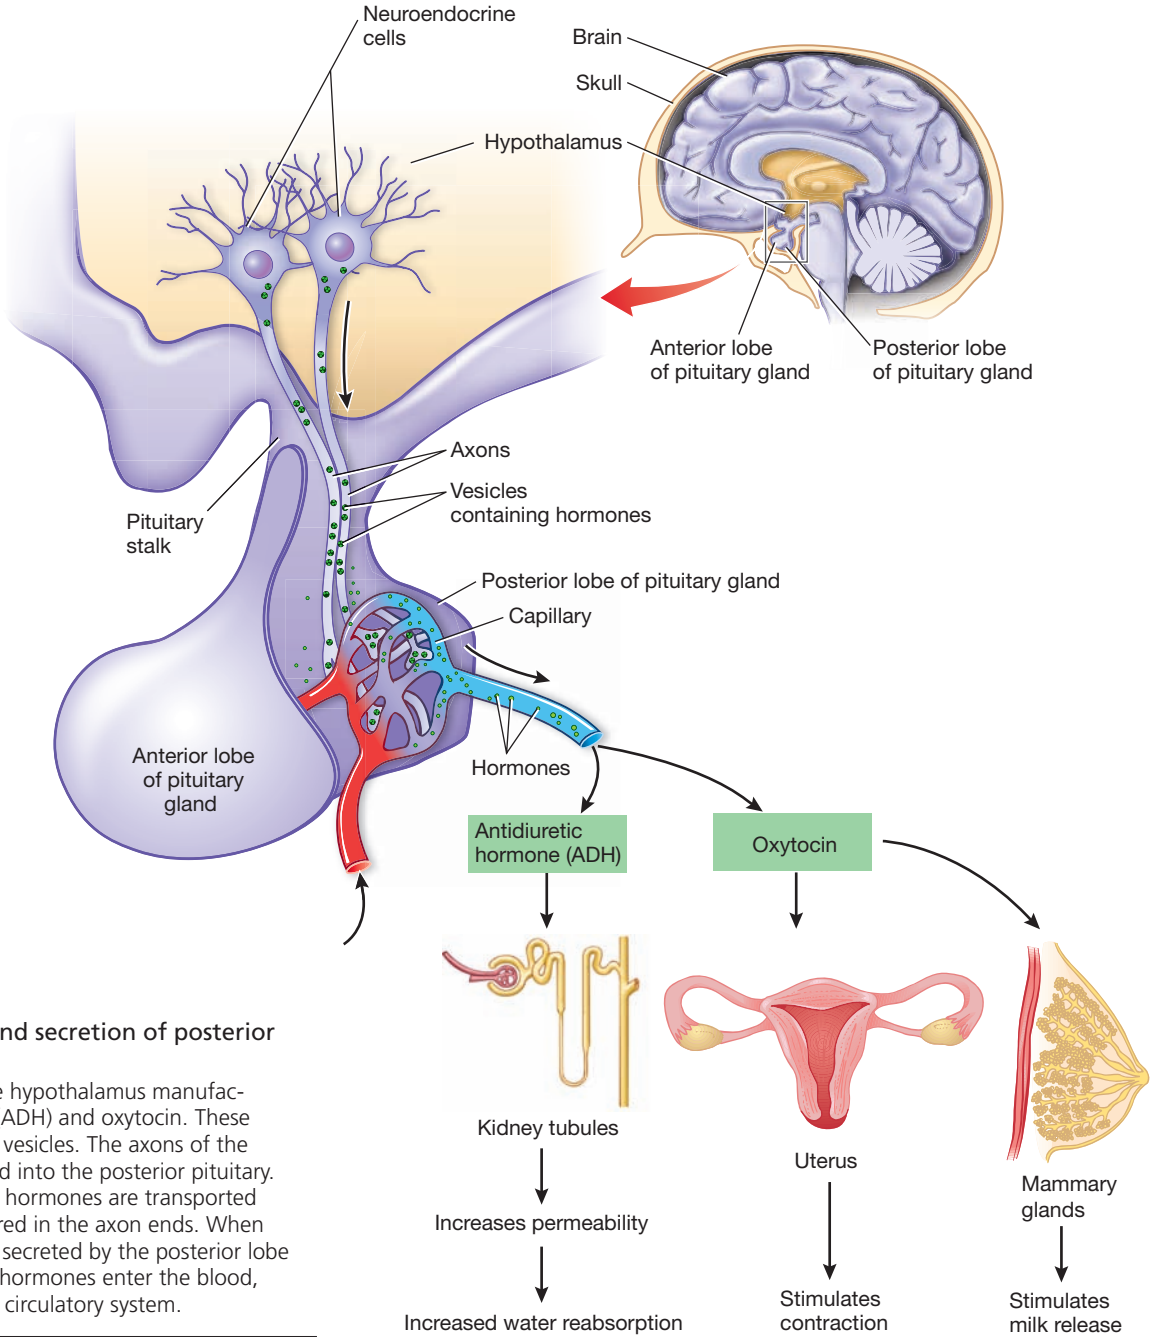

Figure 49-8 Synthesis and secretion of posterior pituitary hormones

Neuroendocrine cells in the hypothalamus manufacture antidiuretic hormone (ADH) and oxytocin. These hormones are packaged in vesicles. The axons of the neuroendocrine cells extend into the posterior pituitary. The vesicles containing the hormones are transported through the axons and stored in the axon ends. When needed, the hormones are secreted by the posterior lobe of the pituitary gland. The hormones enter the blood, and are transported by the circulatory system.

Inappropriate amounts of growth hormone secretion result in abnormal growth Have you ever wondered why some people fail to grow normally? Extreme deficiency in GH during childhood causes pituitary dwarfism. This condition is usually caused by insufficient production of GH by the pituitary gland. However, dwarfism also occurs when the liver produces insufficient IGF or when target tissues do not respond to IGF. Although miniature, a pituitary dwarf has normal intelligence and is usually well-proportioned. If the growth centers in the long bones are still active when this condition is diagnosed, it can often be effectively treated by HGH injection. Human GH can be synthesized by recombinant DNA technology.

A person grows abnormally tall when the anterior pituitary secretes excessive amounts of HGH during childhood. This condition is called **gigantism**. If hypersecretion of HGH occurs during adulthood, the individual cannot grow taller. Instead, connective tissue thickens, and bones in the hands, feet, and face may increase in diameter. This condition is known as **acromegaly** (*acromegaly* means "large extremities").

Thyroid hormones increase metabolic rate

The **thyroid gland** is located in the neck region, in front of the trachea and below the larynx. The **thyroid hormones—thyroxine**,

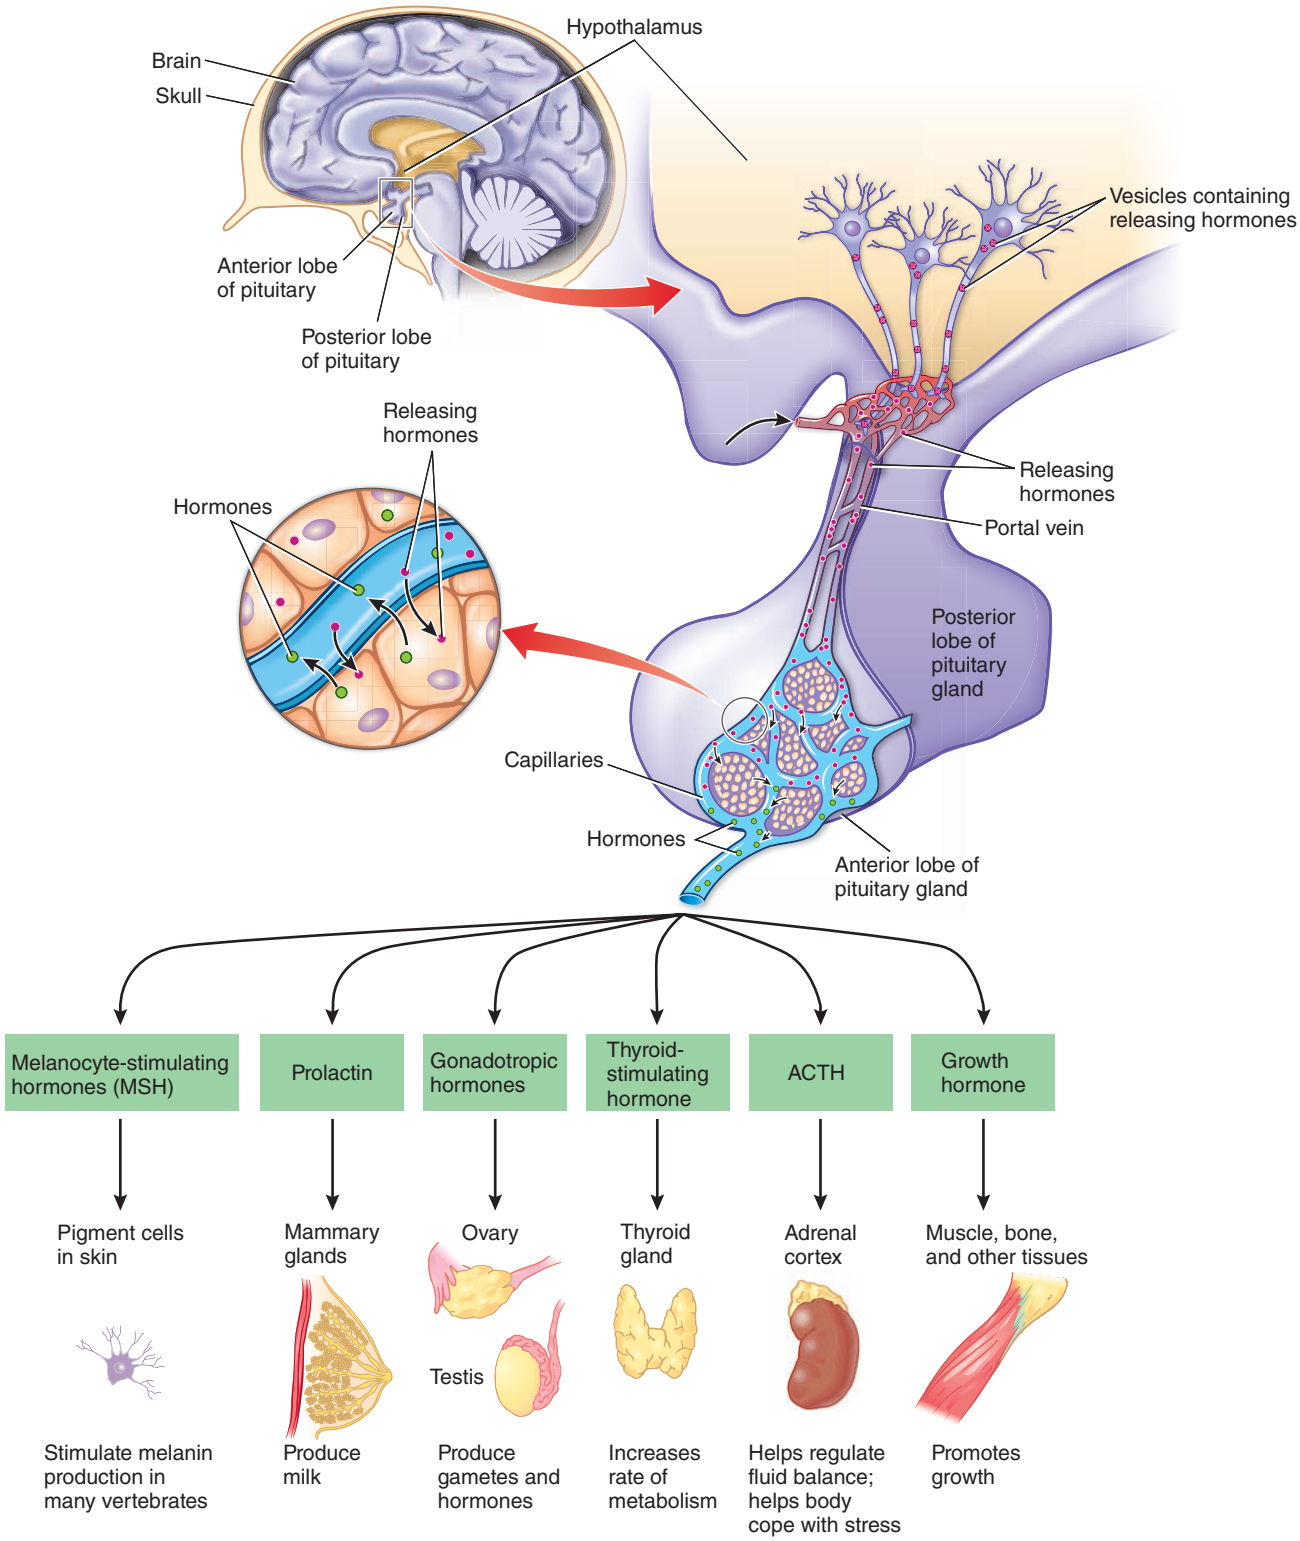

Figure 49-9 Synthesis and secretion of anterior pituitary hormones

The hypothalamus secretes several specific releasing and inhibiting hormones. The hormones are transported to the anterior lobe of the pituitary gland by way of portal veins. These regulatory hormones stimulate or inhibit the release of specific hormones by cells of the anterior pituitary. The anterior pituitary hormones act on a wide variety of target tissues. (ACTH, adrenocorticotropic hormone)

also known as T_4, and **triiodothyronine**, or T_3—are synthesized from the amino acid tyrosine and iodine. Thyroxine has four iodine atoms attached to each molecule, and T_3 has three. In most target tissues, T_4 is converted to T_3, the more active form (see Fig. 49-2c). We describe the actions of calcitonin, another hormone secreted by the thyroid gland, when we discuss the parathyroid glands.

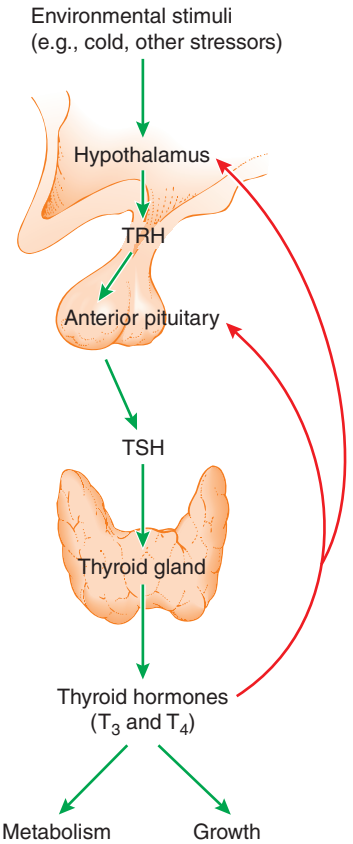
In vertebrates, thyroid hormones are essential for normal growth and development. These hormones increase the rate of metabolism in most body tissues. After T_3 binds with its receptor in the nucleus of a target cell, the T_3 receptor complex induces or suppresses synthesis of specific enzymes and other proteins. Thyroid hormones also help regulate the synthesis of proteins necessary for cell differentiation. For example, tadpoles cannot develop into adult frogs without thyroxine.

Negative feedback systems regulate thyroid secretion

The regulation of thyroid hormone secretion depends on a negative feedback loop between the anterior pituitary and the thyroid gland (FIG. 49-10). When the concentration of thyroid hormones in the blood rises above normal, the anterior pituitary secretes less **thyroid-stimulating hormone (TSH)**:

> thyroid hormone concentration high → inhibits anterior pituitary → secretes less TSH → thyroid gland secretes less hormone → homeostasis



When the concentration of thyroid hormones decreases, the anterior pituitary secretes more TSH. TSH acts by way of cAMP to promote synthesis and secretion of thyroid hormones and also to promote increased size of the thyroid gland itself. The effect of TSH can be summarized as follows:

> thyroid hormone concentration low → anterior pituitary secretes more TSH → thyroid gland secretes more hormone → homeostasis

In some mammals, changes in weather affect the hypothalamus. Exposure to very cold temperature stimulates the hypothalamus to increase secretion of **TSH-releasing hormone (TRH)**. This action causes a dramatic increase in thyroid hormone secretion. Metabolic rate increases, which also increases heat production, so the body temperature rises. Increased body temperature has a negative feedback effect, limiting further secretion of thyroid hormones.

Malfunction of the thyroid gland leads to specific disorders Extreme hypothyroidism during infancy and childhood results in low metabolic rate and can lead to **cretinism**, a condition characterized by intellectual disability and impaired physical development. When diagnosed early enough, hypothyroidism can be treated with thyroid hormones, and cretinism can be prevented.

An adult who feels like sleeping all the time, has little energy, and is mentally slow or confused may be suffering from hypothyroidism. When there is almost no thyroid function, the basal metabolic rate is reduced by about 40% and the patient develops **myxedema**, characterized by a slowing down of physical and mental activity. Hypothyroidism is treated by oral administration of the missing hormone.

(a) Regulation of thyroid hormone secretion by negative feedback. An increase in concentration of thyroid hormones above normal levels signals the anterior pituitary to slow thyroid-stimulating hormone (TSH) production. Thus, thyroid hormones limit their own production by negative feedback. *Green arrows* indicate stimulation; *red arrows* indicate inhibition. (TRH, TSH-releasing hormone)

Mike Goldwater/Alamy Stock Photo

(b) Iodine deficiency is a common cause of goiter, enlargement of the thyroid gland.

Figure 49-10 Regulation of thyroid hormone secretion

Hyperthyroidism does not cause abnormal growth but does increase metabolic rate by 60% or even more. This increase in metabolism results in the rapid use of nutrients, causing the individual to be hungry and to eat more. Increased food intake is not sufficient to meet the demands of the rapidly metabolizing cells, however, and people with this condition often lose weight. They also tend to be nervous, irritable, and emotionally unstable. The most common form of hyperthyroidism is **Graves' disease**, an autoimmune disease. Abnormal antibodies bind to TSH receptors and activate them. Production of thyroid hormones increases.

An abnormal enlargement of the thyroid gland, or **goiter**, may be associated with either hypersecretion or hyposecretion (see Fig. 49-10b). In Graves' disease the abnormal antibodies that activate TSH receptors can cause the development of a goiter. Worldwide, more than 90% of goiters are caused by iodine deficiency. Without iodine the gland cannot make thyroid hormones, resulting in hyposecretion. When the concentration of thyroid hormones in the blood decreases, the anterior pituitary secretes large amounts of TSH. The TSH stimulates growth of

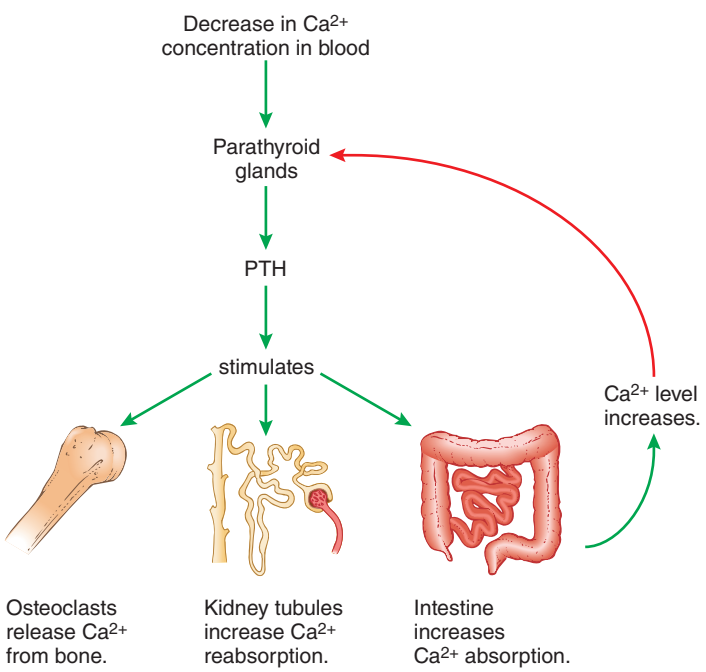
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

the thyroid gland, sometimes to gigantic proportions. However, enlargement of the gland does not increase production of the hormones because the needed ingredient—iodine—is still missing.

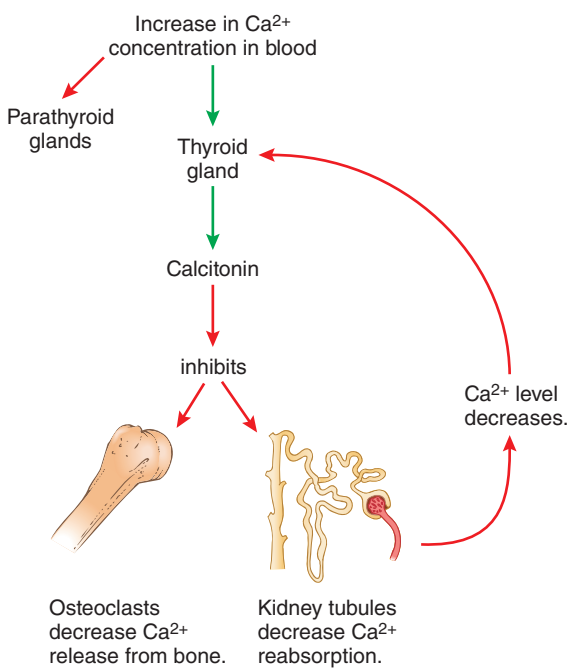
Seafood is a rich source of iodine, and iodine is also added to table salt as a nutritional supplement. In fact, thanks to iodized salt, goiter is no longer common in the United States and other highly developed countries. In other parts of the world, however, hundreds of thousands of people still suffer from this easily preventable disorder. Because it results in hypothyroidism, iodine deficiency has a negative effect on intellectual and physical development. *Lancet*, a well-respected British medical journal, has referred to iodine deficiency as "the single greatest preventable cause of mental retardation."

The parathyroid glands regulate calcium concentration



The **parathyroid glands** are typically embedded in the connective tissue surrounding the thyroid gland. These glands secrete **parathyroid hormone (PTH)**, a polypeptide that helps regulate the calcium level of the blood and interstitial fluid (FIG. 49-11a). Parathyroid hormone acts by way of a G protein–linked receptor and cAMP to stimulate calcium release from bones and to increase calcium reabsorption from the kidney tubules. It also activates vitamin D, which then increases the amount of calcium absorbed from the intestine.

Calcitonin, a peptide hormone secreted by the thyroid gland, works antagonistically to parathyroid hormone (FIG. 49-11b). When the concentration of calcium rises above homeostatic levels, calcitonin is released and rapidly inhibits removal of calcium from bone.



The islets of the pancreas regulate blood glucose concentration

In addition to secreting digestive enzymes (see Chapter 47), the pancreas is an important endocrine gland. Its hormones, insulin and glucagon, are secreted by cells that occur in little clusters, the **islets of Langerhans**, throughout the pancreas (FIG. 49-12). About one million islets are present in the human pancreas. They consist mainly of **beta cells**, which secrete insulin, and **alpha cells**, which secrete glucagon.

Insulin lowers the concentration of glucose in the blood **Insulin** is an anabolic hormone that regulates the use and storage of nutrients. Insulin stimulates cells of many tissues, including liver, muscle, and fat cells, to take up glucose from the blood by facilitated diffusion (see Chapter 5). Once glucose enters muscle cells, it is either used immediately as

(a) Calcium concentration too low. When calcium concentration decreases below the normal range, the parathyroid glands secrete parathyroid hormone (PTH). PTH stimulates homeostatic mechanisms that restore appropriate calcium concentration.

(b) Calcium concentration too high. When calcium concentration increases above its set point, the parathyroid glands are inhibited. The thyroid gland secretes calcitonin, which inhibits Ca^{2+} release from bone and decreases Ca^{2+} reabsorption in the kidneys.

Figure 49-11 Regulation of calcium homeostasis
Green arrows indicate stimulation; *red arrows* indicate inhibition.

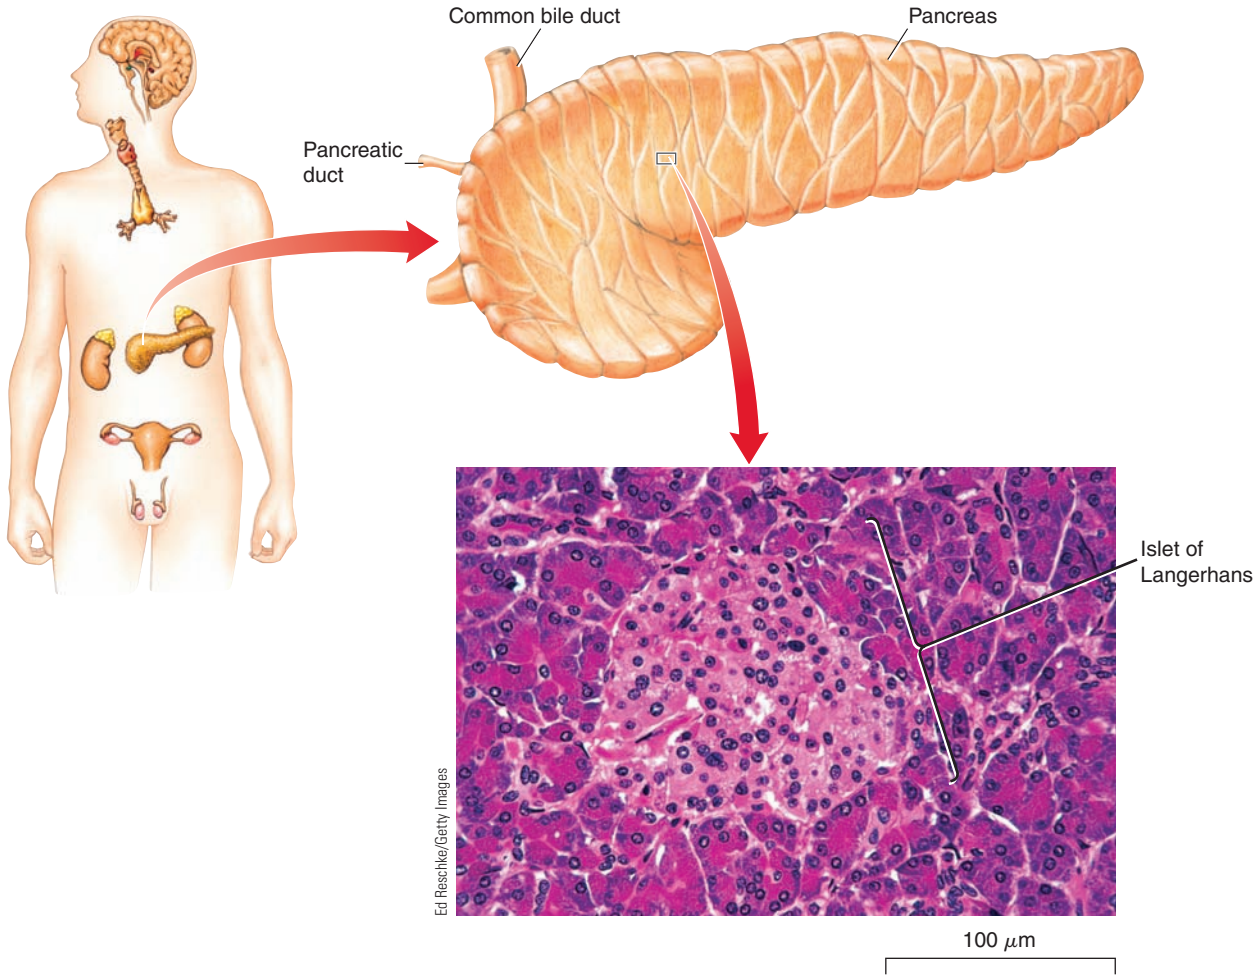

Figure 49-12 An islet of Langerhans in the pancreas

Scattered throughout the pancreas, clusters of endocrine cells (such as the one shown in this LM) secrete insulin and glucagon.

fuel or stored as glycogen. Insulin also inhibits liver cells from releasing glucose. Thus, insulin activity *lowers* the glucose level in the blood.

Insulin also helps regulate fat and protein metabolism. It reduces the use of fatty acids as fuel and instead stimulates their storage in adipose tissue. Insulin has an anabolic effect on protein metabolism, resulting in a net increase in protein in cells. It promotes protein synthesis by increasing the number of amino acid transporters in the plasma membrane, thus stimulating the transport of certain amino acids into cells. Insulin also promotes transcription and translation.

Glucagon raises the concentration of glucose in the blood The effects of **glucagon** are opposite to those of insulin. Glucagon's main action is to raise blood glucose level. It does so by stimulating liver cells to convert glycogen to glucose. Glucagon also stimulates *gluconeogenesis* (glu-ko-nee-oh-gen′-eh-sis), the production of glucose from noncarbohydrates. Glucagon mobilizes fatty acids by promoting breakdown of fat and inhibiting triacylglycerol synthesis. This hormone also stimulates the liver to degrade proteins and inhibits protein synthesis.

Glucose concentration regulates insulin and glucagon secretion The concentration of glucose in the blood directly controls insulin and glucagon secretion (FIG. 49-13). After a meal, when the blood glucose level rises as a result of intestinal absorption, beta cells are stimulated to increase insulin secretion. Then, as cells remove glucose from the blood, decreasing its concentration, insulin secretion decreases.

high blood glucose concentration → beta cells secrete insulin → blood glucose concentration decreases → homeostasis

Key Point

Insulin and glucagon work antagonistically to regulate the concentration of glucose in the blood.

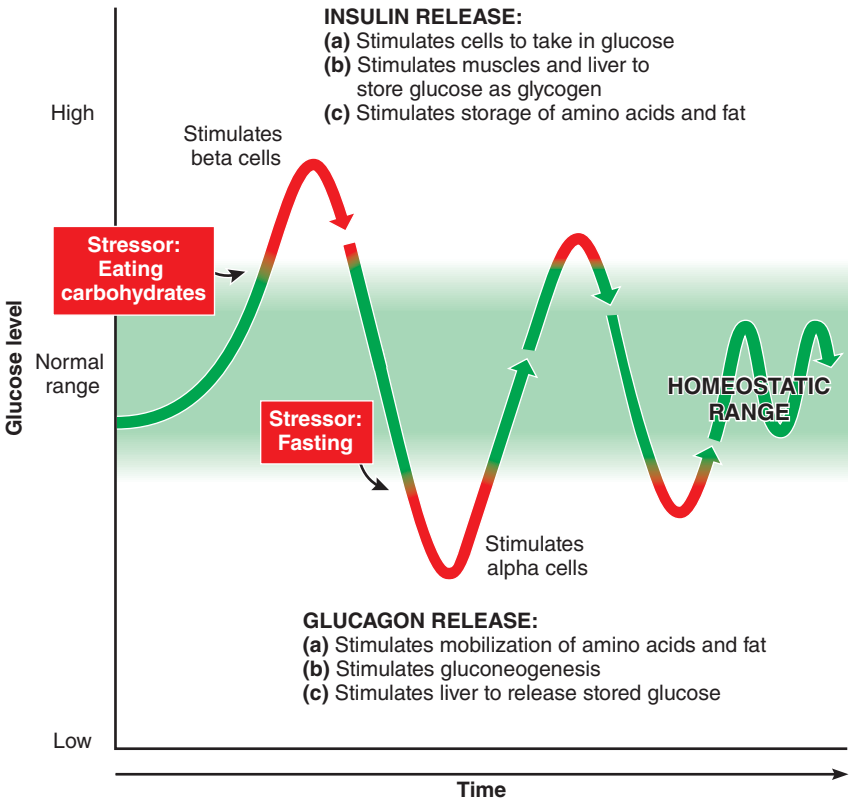

Figure 49-13 Regulation of blood glucose concentration

When the concentration of glucose in the blood increases above normal, beta cells secrete insulin. This hormone lowers blood glucose concentration, thus restoring homeostasis. When the concentration of glucose in the blood decreases below normal, alpha cells secrete glucagon. This hormone increases blood glucose concentration, restoring homeostasis.

PREDICT What would happen if an autoimmune disease sharply reduced the number of functional alpha cells?

When you have not eaten for several hours, the concentration of glucose in your blood begins to fall. When it decreases from its normal fasting level of about 90 mg of glucose per 100 mL of blood to about 70 mg of glucose, the alpha cells of the islets increase their secretion of glucagon. Glucose is mobilized from storage in the liver cells, returning blood glucose concentration to normal:

low blood glucose concentration → alpha cells secrete glucagon → blood glucose concentration increases → homeostasis

Alpha cells respond to the glucose concentration within their own cytoplasm, which reflects the blood glucose level. When blood glucose level is high, there is generally a high level of glucose within the alpha cells, and glucagon secretion is inhibited.

Note that in these negative feedback systems, insulin and glucagon work antagonistically to keep blood glucose concentration within homeostatic limits. When the glucose level rises, insulin release brings it back to normal; when the glucose concentration falls, glucagon acts to raise it again. The insulin–glucagon system is a powerful, fast-acting mechanism for keeping blood glucose level within normal limits. Why is it important to maintain a constant blood glucose level? Recall that brain cells ordinarily are unable to use other nutrients as fuel, so they depend on a continuous supply of glucose. As we will discuss, several other hormones also affect blood glucose concentration.

Diabetes mellitus is a serious disorder of carbohydrate metabolism

Diabetes mellitus, the most common endocrine disorder, is a serious health problem, and according to the World Health Organization, its global prevalence is increasing rapidly. More than 422 million people worldwide have this disorder. (Note that diabetes mellitus is an entirely different disorder from diabetes insipidus, which was discussed in Chapter 48.) According to the Centers for Disease Control and Prevention (CDC), diabetes is the leading cause of kidney failure, nontraumatic lower limb amputations, and new cases of blindness. Diabetes is also a major risk factor for cardiovascular disease, neurological disease, and premature death. Approximately one-half of the people suffering from diabetes are unaware that they have this disorder; consequently, they do not receive treatment and are at high risk for its serious effects.

Diabetes mellitus is actually a group of related disorders characterized by high blood glucose concentrations. Two main types of diabetes are type 1 and type 2. *Type 1 diabetes* is an autoimmune disease in which antibodies mark the beta cells for destruction. T cells destroy the beta cells, resulting in insulin deficiency. Insulin injections are needed to correct the carbohydrate imbalance that results. This disorder usually develops before age 30, often during childhood. Type 1 diabetes is caused by a combination of genetic predisposition and environmental factors, possibly including infection by a virus.

More than 90% of diabetics have *type 2 diabetes*. This disorder develops gradually, typically in overweight people. **Metabolic syndrome** often precedes type 2 diabetes. The symptoms of metabolic syndrome include obesity, large waist circumference ("apple shape"), elevated blood glucose concentration, high triacylglycerol (triglyceride) and low HDL ("good" cholesterol) concentrations in the blood, and high blood pressure.

More than 20% of obese children have impaired glucose tolerance, an early warning sign of diabetes. Impaired glucose tolerance, which affects more than 200 million people worldwide, is defined as *hyperglycemia* (a blood glucose concentration that is abnormally high) following ingestion of a large amount of glucose (a glucose load).

Type 2 diabetes typically begins as **insulin resistance**, a condition in which cells cannot use insulin effectively. In type 2 diabetes, normal (or greater than normal) concentrations of insulin are present in the blood, but target cells cannot use it. You can decrease your risk of type 2 diabetes with a healthy diet, regular physical activity (at least 30 minutes of moderate-intensity exercise each day), and by avoiding tobacco use.

Similar metabolic disturbances occur in both types of diabetes mellitus: disruption of carbohydrate, fat, and protein metabolism and electrolyte imbalance.

1. *Glucose use decreases*. In a diabetic, the cells have difficulty taking up glucose from the blood, and its accumulation causes hyperglycemia. Instead of the normal fasting concentration of about 90 mg of glucose per 100 mL of blood, the level may exceed 140 mg per 100 mL and may reach concentrations of more than 500 mg per 100 mL. Recall from Chapter 48 that when glucose concentration exceeds its **tubular transport maximum (Tm)**, the maximum rate at which it can be reabsorbed, glucose is excreted in the urine. Despite the large quantities of glucose in the blood, insulin-dependent cells in a diabetic can take in only about 25% of the glucose they require for fuel.
2. *Fat mobilization increases*. Cells turn to fat and protein for energy. The absence of insulin promotes the mobilization of fat stores to provide nutrients for cellular respiration. Unfortunately, however, the blood lipid level may reach five times the normal level, leading to the development of atherosclerosis (see Chapter 44). Increased fat metabolism also increases the formation of ketone bodies, which build up in the blood. This accumulation can cause *ketoacidosis*, a condition in which the body fluids and blood become too acidic. When the ketone level in the blood rises, ketones appear in the urine, another clinical indication of diabetes mellitus. If severe, ketoacidosis can lead to coma and death.
3. *Protein use increases*. Lack of insulin also results in increased protein breakdown relative to protein synthesis, so the untreated diabetic becomes thin and emaciated.
4. *Electrolyte imbalance*. When ketone bodies and glucose are excreted in the urine, water follows by osmosis; as a result, urine volume increases. The resulting dehydration causes thirst and challenges electrolyte homeostasis. When ketones are excreted, they also take sodium, potassium, and some other cations with them, contributing to electrolyte imbalance.

Many type 2 diabetics can keep their blood glucose levels within normal range by diet management, weight loss, and regular exercise. When this treatment approach is not effective, the disorder is treated with oral drugs that stimulate insulin secretion and promote its actions. Approximately one-third of type 2 diabetics eventually need insulin injections.

The dramatic increase in type 2 diabetes is a public health problem resulting from increased prevalence of obesity, rapid increases in people becoming overweight, and lack of physical activity. Because type 2 diabetes is associated with insulin resistance, researchers are studying this metabolic problem in their search for causes of and cures for diabetes. Researchers have found a strong association between increased fat tissue and insulin resistance. When insulin-resistant individuals lose weight, they become more sensitive to insulin.

In hypoglycemia the blood glucose concentration is too low Low blood glucose concentration, or *hypoglycemia*, sometimes occurs in people who later develop diabetes. These individuals may have impaired glucose tolerance in which the islets overreact to glucose challenge. When carbohydrates are ingested, there is a delayed insulin response, followed after about 3 hours by too much insulin secretion. This hypersecretion causes glucose levels to fall, and the individual feels drowsy. If this reaction is severe, the person may become uncoordinated or even unconscious.

Serious hypoglycemia can develop if diabetics receive injections of too much insulin or if the islets, because of a tumor, secrete too much insulin. The blood glucose concentration may then fall drastically, depriving brain cells of their needed fuel supply. These events can lead to **insulin shock**, a condition in which the patient may appear drunk or may become unconscious, suffer convulsions, and even die.

The adrenal glands help the body respond to stress

The paired **adrenal glands** are small, yellow masses of tissue that lie in contact with the upper ends of the kidneys (FIG. 49-14). Each gland consists of a central portion, the **adrenal medulla**, and a larger outer section, the **adrenal cortex**. Although joined anatomically, the adrenal medulla and cortex develop from different types of tissue in the embryo and function as distinctly different glands. However, both secrete hormones that help regulate metabolism and help the body respond to stress.

The adrenal medulla initiates an alarm reaction The adrenal medulla is a neuroendocrine gland that is coupled to the sympathetic nervous system. It develops from neural tissue, and its secretion is controlled by sympathetic nerves. The adrenal medulla secretes **epinephrine** and **norepinephrine**. Chemically, these hormones are very similar; they are amino acid derivatives that belong to the chemical group known as **catecholamines** (see Fig. 49-2c). Most of the hormone output of the adrenal medulla is epinephrine. Recall that

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

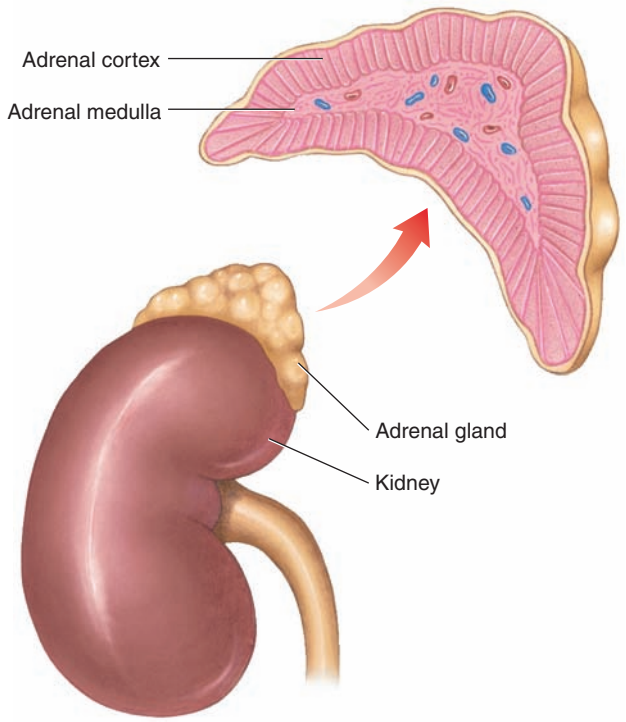

Figure 49-14 Adrenal gland

The adrenal glands are located above the kidneys. Each gland consists of a central adrenal medulla surrounded by an adrenal cortex.

norepinephrine also serves as a neurotransmitter released by sympathetic neurons and by some neurons in the central nervous system (see Chapter 41).

Under normal conditions, the adrenal medulla continuously secretes small amounts of both epinephrine and norepinephrine. Their secretion is under neural control. When anxiety is aroused, the hypothalamus sends signals via sympathetic nerves to the adrenal medulla. Sympathetic neurons release acetylcholine, which triggers the adrenal medulla to release larger amounts of epinephrine and norepinephrine.

During a stressful situation, adrenal medullary hormones initiate an *alarm reaction* that enables you to think more quickly, fight harder, or run faster than usual. Metabolic rate increases by as much as 100%. Blood is rerouted to those organs essential for emergency action (FIG. 49-15). Blood vessels going to the brain, muscles, and heart are dilated, whereas those to the skin and kidneys are constricted. Constriction of blood vessels serving the skin has the added advantage of decreasing blood loss in case of hemorrhage (and explains the sudden paling that comes with fear). At the same time, the heart beats faster. Strength of muscle contraction increases. Thresholds in the reticular activating system of the brain are lowered, so you become more alert (see Chapter 42). The adrenal medullary hormones also raise fatty acid and glucose levels in the blood, ensuring needed fuel for extra energy.

The adrenal cortex helps the body deal with chronic stress The adrenal cortex synthesizes steroid hormones from cholesterol (which in turn is made in the liver from acetyl coenzyme A). Although the adrenal cortex produces more than 30 types of steroids, it secretes only three types of hormones in significant amounts: sex hormone precursors, mineralocorticoids, and glucocorticoids.

In both sexes the adrenal cortex secretes sex hormone precursors, such as androgens (masculinizing hormones). Certain tissues convert sex hormone precursors to **testosterone**, the principal male sex hormone, and **estradiol**, the principal female sex hormone. In males, androgen production by the adrenal cortex is not significant because the testes produce testosterone. However, in females, the adrenal cortex secretes the androgen used to produce most of the testosterone circulating in the blood.

The principal **mineralocorticoid** is **aldosterone**. (Recall from Chapter 48 that aldosterone helps regulate fluid balance by regulating salt balance.) In response to aldosterone, the kidneys reabsorb more sodium and excrete more potassium. As a result of increased sodium, extracellular fluid volume increases, which results in greater blood volume and elevated blood pressure.

When the adrenal glands do not produce enough aldosterone, large amounts of sodium are excreted in the urine. Water leaves the body with the sodium (because of osmotic pressure), and the blood volume may be so markedly reduced that the patient dies of low blood pressure.

Cortisol, also called *hydrocortisone*, accounts for about 95% of the **glucocorticoid** activity of the human adrenal cortex (see Fig. 49-2b). Cortisol helps ensure adequate fuel supplies for the cells when the body is under stress. Its principal action is to stimulate production of glucose from other nutrients in liver cells.

Cortisol helps provide nutrients for glucose production by stimulating amino acid transport into liver cells (see Fig. 49-15). It also promotes mobilization of fats so that glycerol from triacylglycerol molecules is available for conversion to glucose. These actions ensure that glucose and glycogen are produced in the liver, and the concentration of glucose in the blood rises. Thus, the adrenal cortex provides an important backup system for the adrenal medulla, ensuring adequate glucose supplies when the body is under stress and in need of extra energy.

During stress, the brain and the adrenal glands work together to help the body respond effectively (see Fig. 49-15; also see *Inquiring About: The Neurobiology of Traumatic Experience* in Chapter 42). Almost any type of stress stimulates the hypothalamus to secrete **corticotropin-releasing factor (CRF)**, which stimulates the anterior pituitary to secrete **adrenocorticotropic hormone (ACTH)**. ACTH regulates both glucocorticoid and aldosterone secretion. It is so potent that it can result in a 20-fold increase in cortisol secretion within minutes. When the body is not under stress, high levels of cortisol in the blood inhibit both CRF secretion by the hypothalamus and ACTH secretion by the pituitary.

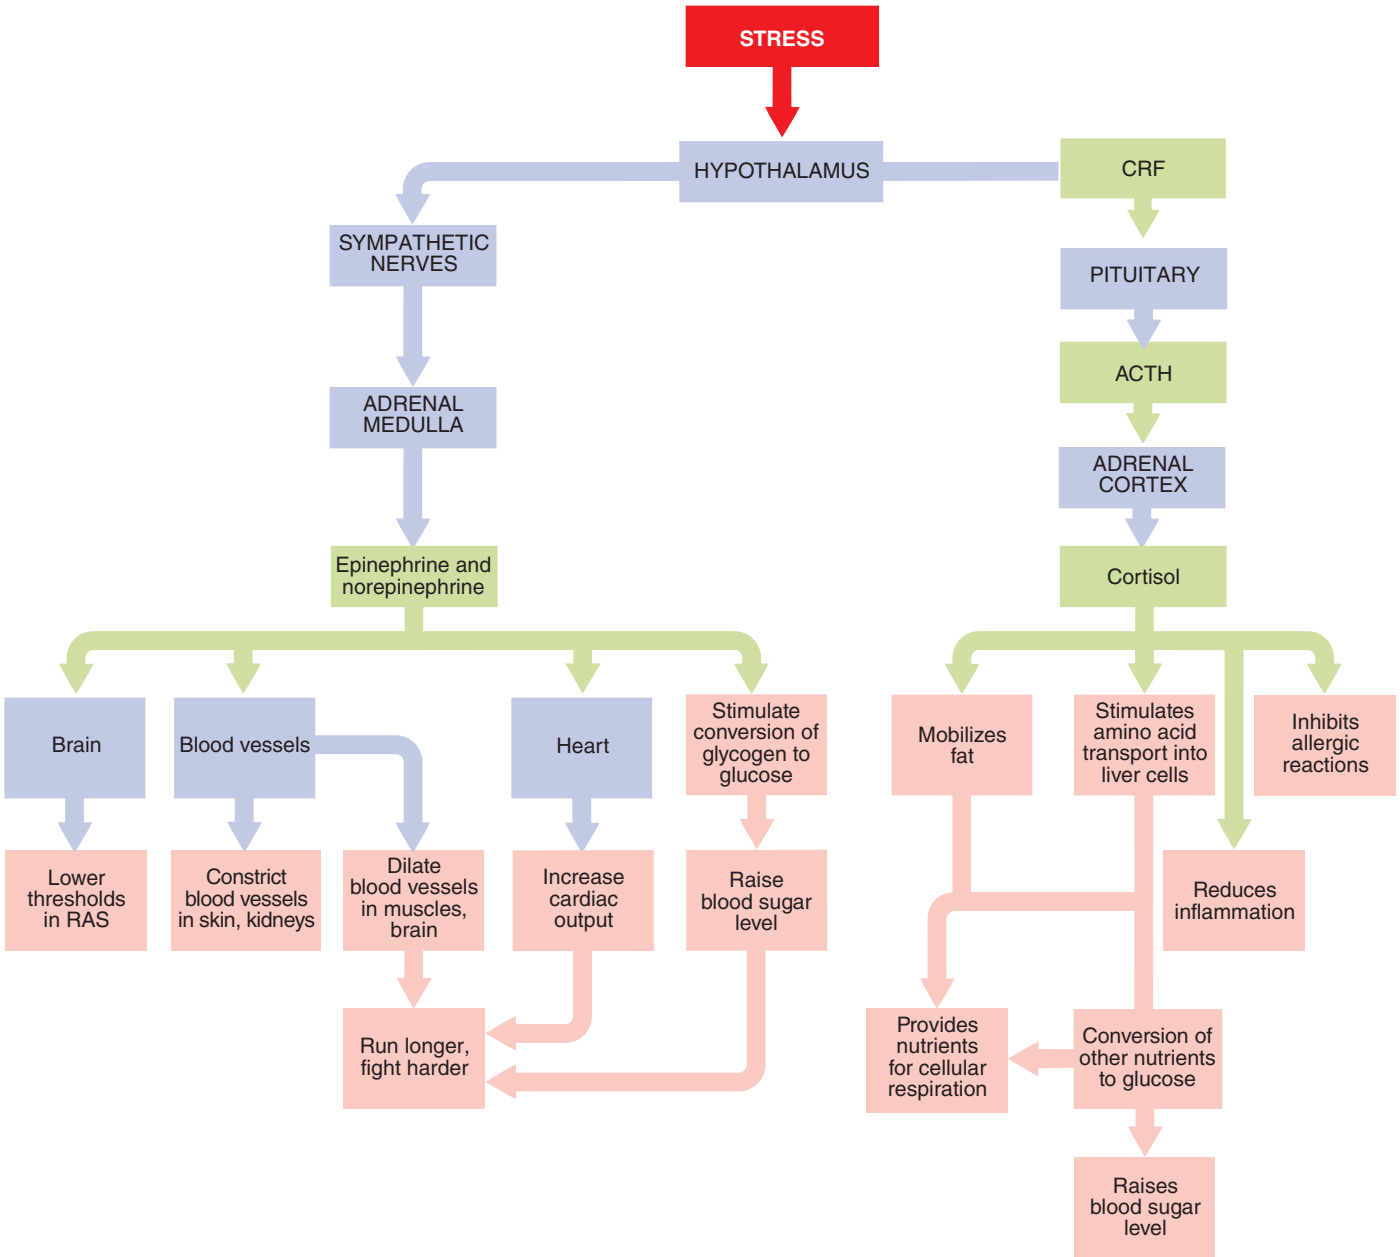

Figure 49-15 Response to stress

The adrenal glands release hormones that prepare the body to respond to stressful experiences. (RAS, reticular activating system; CRF, corticotropin-releasing factor; ACTH, adrenocorticotropic hormone)

Glucocorticoids are used clinically to reduce inflammation in allergic reactions, infections, arthritis, and certain types of cancer. These hormones inhibit production of prostaglandins (which are mediators of inflammation). Glucocorticoids also reduce inflammation by decreasing capillary permeability, which reduces swelling. In addition, they reduce the effects of histamine and so are used to treat allergic symptoms.

When used in large amounts over long periods, glucocorticoids can cause serious side effects. Although they help stabilize lysosome membranes so that they do not destroy tissues with their potent enzymes, the ability of lysosomes to degrade foreign molecules is also decreased. Glucocorticoids decrease interleukin-1 production, blocking cell-mediated immunity and reducing the patient's ability to fight infections. Other side effects include ulcers, hypertension, diabetes mellitus, and atherosclerosis.

Abnormally large amounts of glucocorticoids, whether due to disease or steroid medication, can result in **Cushing's syndrome**. In this condition, excess glucose is converted to fat and deposited about the trunk. Edema gives the patient's face a full-moon appearance. Blood glucose level may increase by as much as 50% above normal, causing *adrenal diabetes*. If this condition persists for several months, the beta cells in the pancreas may "burn out" from secreting excessive amounts of insulin, leading to permanent diabetes mellitus. Reduction

in protein synthesis causes weakness and decreased immune responses.

Many other hormones help regulate life processes

Many other tissues of the body secrete hormones. The **pineal gland**, located in the brain, produces **melatonin**, which is derived from the amino acid tryptophan. Melatonin influences biological rhythms and the onset of sexual maturity. In humans, melatonin facilitates the onset of sleep. Interestingly, exposure to light suppresses melatonin secretion.

As we have discussed, several hormones secreted by the digestive tract and by adipose tissue regulate digestive processes (see Chapter 47). The **thymus gland** produces **thymosin**, a hormone that plays a role in immune responses. **Atrial natriuretic peptide**, secreted by the atrium of the heart, promotes sodium excretion and lowers blood pressure (see Chapter 48). We discuss reproductive hormones in Chapter 50.

CHECKPOINT 49.5

- **CONNECT** Why is the hypothalamus considered the link between the nervous and endocrine systems? What is the role of the anterior pituitary gland? of the posterior pituitary?
- **VISUALIZE** Draw a diagram illustrating how thyroid hormone secretion is regulated.
- **PREDICT** Imagine that you eat a hot fudge sundae. What would be the response of your pancreas? What are the antagonistic actions of insulin and glucagon in regulating blood glucose level?
- **PREDICT** Imagine that you are being chased by an alligator. How would your adrenal glands respond? How would that help? (Be specific.)
- How is regulation of the adrenal medulla different from regulation of the adrenal cortex?

Summary: Focus on Learning Objectives

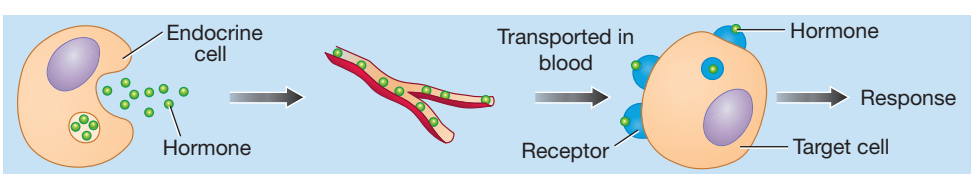
49.1 An Overview of Endocrine Regulation *(page 1051)*

1 Compare endocrine system function with nervous system function and describe how these systems work together to regulate body processes.

- The **endocrine system** consists of endocrine glands, cells, and tissues that secrete **hormones**, chemical signals that regulate physiological processes. Most endocrine responses are slow but long-lasting. The endocrine system signals a wide range of **target cells**.
- The nervous system responds rapidly to stimuli by transmitting electrical and chemical signals. Neurons signal other neurons, muscle cells, and gland cells, including endocrine cells. The nervous system helps regulate many endocrine responses.

2 Summarize the regulation of endocrine action by negative feedback systems.

- Hormone secretion is typically regulated by **negative feedback systems**. A hormone is released in response to some change in a steady state. The hormone triggers a response that counteracts the changed condition. This process restores homeostasis.



3 Identify four main chemical groups to which hormones are assigned and give two examples for each group.

- Prostaglandins and the juvenile hormone of insects are **fatty acid derivatives**. Hormones secreted by the adrenal cortex, ovary, and testis, as well as the molting hormone of insects, are **steroid hormones**.
- Thyroid hormones and epinephrine are **amino acid derivatives**. Antidiuretic hormone (ADH) and glucagon are examples of **peptide hormones**. Insulin is a small protein.

49.2 Types of Endocrine Signaling *(page 1053)*

4 Compare four types of endocrine signaling.

- In *classical endocrine signaling*, discrete **endocrine glands**, glands without ducts, secrete hormones into the interstitial fluid. Hormones are transported by the blood. They bind with receptors on or in specific target cells.
- In *neuroendocrine signaling*, neurons secrete **neurohormones**. These hormones are transported down axons and then secreted; they are typically transported by the blood.
- In *autocrine signaling*, a hormone (or other signal molecule) is secreted into the interstitial fluid and then acts on the very cell that produced it.
- In *paracrine signaling*, a hormone (or other signal molecule) diffuses through interstitial fluid and acts on nearby target cells.
- Some **local regulators** are considered hormones; they use autocrine or paracrine signaling. Local regulators include **growth factors**, peptides that stimulate cell division and development, and **prostaglandins**, a group of local hormones that help regulate many metabolic processes.

49.3 Mechanisms of Hormone Action *(page 1055)*

5 Compare the mechanism of action of small, lipid-soluble hormones with that of hydrophilic hormones; include the role of second messengers, such as cyclic AMP.

- Steroid hormones and thyroid hormones are small, lipid-soluble molecules that pass through the plasma membrane and combine with receptors within the target cell; the hormone–receptor complex may activate or repress transcription of messenger RNA coding for specific proteins.
- Peptide hormones are hydrophilic and do not enter target cells. They combine with receptors on the plasma membrane of target cells. Many hormones bind to **G protein–linked receptors** that act via **signal transduction**. An extracellular hormone signal is transduced into an intracellular signal by the receptor.
- Most peptide hormones are first messengers that carry out their actions by way of **second messengers**, such as **cyclic AMP (cAMP)**. The G protein–linked receptor activates a **G protein**. The G protein either stimulates or inhibits an enzyme that affects the second messenger. For example, G proteins stimulate or inhibit **adenylyl cyclase**, the enzyme that catalyzes the conversion of ATP to cAMP.
- Many second messengers stimulate the activity of *protein kinases*, enzymes that phosphorylate specific proteins that affect some cell process.
- Some G proteins use phospholipid derivatives as second messengers. *Inositol trisphosphate (IP_3)* and *diacylglycerol (DAG)* are second messengers that increase calcium concentration and activate enzymes. Calcium ions bind with *calmodulin*, which activates certain enzymes.
- **Tyrosine kinase receptors** are **enzyme-linked receptors** that bind growth factors, including insulin and nerve growth factor.

49.4 Neuroendocrine Regulation in Invertebrates *(page 1058)*

6 Identify four functions of invertebrate neurohormones and describe the regulation of insect development.

- Invertebrate hormones and neurohormones help regulate metabolism, growth and development, regeneration, color changes, molting, metamorphosis, reproduction, and behavior.
- Hormones control development in insects. When stimulated by some environmental factor, neuroendocrine cells in the insect brain secrete *brain hormone (BH)*. BH stimulates the prothoracic glands to produce *molting hormone (MH)*, which stimulates growth and molting.
- In the immature insect, the *corpora allata* secrete *juvenile hormone (JH)*, which suppresses metamorphosis at each larval molt. The amount of JH decreases with successive molts.

49.5 Endocrine Regulation in Vertebrates *(page 1058)*

7 Identify the classical vertebrate endocrine glands and describe the actions of their hormones; describe the effects of hypersecretion and hyposecretion on homeostasis.

- Consult Table 49-1 for a description of the main endocrine glands and their actions. Vertebrate hormones regulate growth and development, reproduction, salt and fluid balance, and many aspects of metabolism and behavior.
- **Hyposecretion** (abnormally reduced output) or **hypersecretion** (abnormally increased output) of hormones leads to disruption of homeostasis and specific endocrine disorders.

8 Describe the mechanisms by which the hypothalamus and pituitary gland integrate regulatory functions; summarize the actions of the hypothalamic and pituitary hormones.

- Nervous and endocrine regulation is integrated in the **hypothalamus**, which regulates the activity of the **pituitary gland**.
- The neurohormones **oxytocin** and **antidiuretic hormone (ADH)** are produced by the hypothalamus and released by the **posterior pituitary** of the pituitary gland. Oxytocin stimulates contraction of the uterus and stimulates ejection of milk by the mammary glands. ADH stimulates reabsorption of water by the kidney tubules.
- The hypothalamus secretes **releasing hormones** and **inhibiting hormones** that regulate the hormone output of the **anterior pituitary gland**.
- The anterior pituitary secretes prolactin, melanocyte-stimulating hormones, growth hormone, and several **tropic hormones** that stimulate other endocrine glands. **Melanocyte-stimulating hormones (MSH)** suppress appetite and are important in regulating energy and body weight. **Prolactin** stimulates the mammary glands to produce milk.
- **Growth hormone (GH)** is an **anabolic hormone** that stimulates body growth by promoting protein synthesis. GH stimulates the liver to produce **insulin-like growth factors (IGFs)**, which promote skeletal growth and general tissue growth.

9 Describe the actions of the thyroid and parathyroid hormones, their regulation, and the effects of malfunction.

- The **thyroid gland** secretes thyroid hormones: **thyroxine**, or **T_4**, and **triiodothyronine**, or **T_3**. Thyroid hormones stimulate the rate of metabolism.
- Regulation of thyroid secretion depends mainly on a negative feedback system between the anterior pituitary gland and the thyroid gland.
- Hyposecretion of thyroxine during childhood may lead to **cretinism**; during adulthood it may result in **myxedema**. **Goiter**, an abnormal enlargement of the thyroid gland, is associated with both hyposecretion and hypersecretion. The most common cause of hyperthyroidism is **Graves' disease**, an autoimmune disease.
- The **parathyroid glands** secrete **parathyroid hormone (PTH)**, which regulates the calcium level in the blood. PTH increases calcium concentration by stimulating calcium release from bones, increasing calcium reabsorption by kidney tubules, and increasing calcium reabsorption from the intestine.
- **Calcitonin**, secreted by the thyroid gland, acts antagonistically to parathyroid hormone.

10 Contrast the actions of insulin and glucagon, and describe diabetes mellitus and hypoglycemia, including the metabolic effects of these disorders.

- The **islets of Langerhans** in the pancreas secrete **insulin** and **glucagon**. Insulin and glucagon secretion is regulated directly by glucose concentration. Insulin stimulates cells to take up glucose from the blood, so it lowers blood glucose concentration. Glucagon raises blood glucose concentration by stimulating conversion of glycogen to glucose and by stimulating production of glucose from other nutrients.

Copyright 2019 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

- In **diabetes mellitus**, either insulin deficiency or **insulin resistance** results in decreased use of glucose, increased fat mobilization, increased protein use, and electrolyte imbalance. In *hypoglycemia*, impaired glucose tolerance results in a delayed insulin response followed by hypersecretion of insulin. The glucose concentration falls, causing drowsiness.

11 Describe the actions and regulation of the adrenal hormones, including their role in the body's response to stress.

- Each **adrenal gland** consists of an inner adrenal medulla and an outer adrenal cortex. The **adrenal medulla** secretes **epinephrine** and **norepinephrine**, hormones that help the body cope with stress. These hormones increase heart rate, metabolic rate, and strength of muscle contraction. They reroute blood to organs needed for fight or flight. The adrenal medulla is regulated by the nervous system.
- The **adrenal cortex** secretes sex hormones; **mineralocorticoids**, such as **aldosterone**; and **glucocorticoids**, such as **cortisol**. Aldosterone increases the rate of sodium reabsorption and potassium excretion by the kidneys.
- During stress, the adrenal cortex ensures adequate fuel supplies for the rapidly metabolizing cells. Cortisol promotes glucose synthesis from other nutrients. During stress, the hypothalamus secretes **corticotropin-releasing factor (CRF)**, which stimulates the anterior pituitary gland to secrete **adrenocorticotropic hormone (ACTH)**. ACTH regulates both aldosterone and cortisol secretion.

Test Your Understanding

Know and Comprehend

1. A cell secretes a product that diffuses through the interstitial fluid and acts on nearby cells. This process is an example of (a) neuroendocrine secretion (b) autocrine signaling (c) paracrine signaling (d) classical endocrine regulation (e) peptide hormone function
2. Which of the following is/are *true* of steroid hormones? (a) hydrophilic (b) secreted by the posterior pituitary (c) typically work through G proteins and cyclic AMP (d) typically bind with receptor in nucleus and affect transcription (e) a and c are correct
3. Which of the following is *not* a correct pair? (a) neurohormone; insect brain hormone (b) calcium; calmodulin (c) posterior pituitary; releasing hormone (d) anterior pituitary; growth hormone (e) thyroid hyposecretion; cretinism
4. Growth hormone (a) signals the hypothalamus to produce a releasing hormone (b) is regulated mainly by calcium level (c) is a catabolic hormone (d) stimulates metabolic rate (e) stimulates the liver to produce insulin-like growth factors
5. Which of the following occurs in diabetes mellitus? (a) decreased use of glucose (b) decreased fat metabolism (c) decreased protein use (d) increased concentration of TSH-releasing hormone (e) b and c are correct
6. Which of the following is an action of epinephrine? (a) decreases glucose use (b) increases cardiac output (c) constricts blood vessels in brain (d) reduces inflammation (e) mobilizes fat
7. Aldosterone (a) is released by posterior pituitary (b) is an androgen (c) secretion is stimulated by an increase in thyroid-stimulating hormone (d) is an enzyme that converts epinephrine to norepinephrine (e) increases sodium reabsorption

Apply and Analyze

8. Arrange the following events into an appropriate sequence. 1. high thyroid hormone concentration 2. anterior pituitary inhibited 3. homeostasis 4. lower level of thyroid-stimulating hormone 5. thyroid gland secretes less thyroid hormone (a) 1, 2, 4, 5, 3 (b) 5, 4, 3, 2, 1 (c) 1, 2, 5, 4, 3 (d) 4, 5, 2, 3, 1 (e) 1, 4, 2, 5, 3
9. Arrange the following events into an appropriate sequence. 1. blood glucose concentration increases 2. alpha cells in islets stimulated 3. homeostasis 4. low blood glucose concentration 5. glucagon secretion increases (a) 1, 2, 3, 5, 4 (b) 5, 4, 2, 1, 3 (c) 1, 2, 5, 4, 3 (d) 4, 2, 5, 1, 3 (e) 4, 5, 1, 2, 3
10. **VISUALIZE** Draw a diagram illustrating the regulation of blood glucose concentration.
11. Why is it important to maintain a constant blood glucose level? Several hormones discussed in this chapter affect carbohydrate metabolism. Why is it important to have more than one? How do they interact?
12. An injection of too much insulin may cause a diabetic to go into insulin shock, in which the person may appear drunk or may become unconscious, suffer convulsions, and even die. From what you know about the actions of insulin, explain the physiological causes of insulin shock.

Evaluate and Synthesize

13. How do receptors impart specificity within the endocrine system? What might be some advantages of having complex mechanisms for hormone action (such as second messengers)?
14. **EVOLUTION LINK** The receptor for aldosterone appears to have evolved much earlier than aldosterone itself. Propose a hypothesis to explain how that might have occurred.
15. **SCIENCE, TECHNOLOGY, AND SOCIETY** The "thrifty gene" hypothesis holds that the genes that increase risk for type 2 diabetes allow efficient utilization of food (and fat accumulation) when food is available. In times of food scarcity, this efficiency increases chances of survival. Use this hypothesis to explain the rising rate of diabetes in the United States and suggest how science and technology may partner with society to reduce incidence of the disease.

50 Reproduction

KEY CONCEPTS

50.1 Most animals reproduce sexually by fusion of sperm and egg; some animals reproduce asexually; and others can reproduce either way, depending on conditions.

50.2 In male vertebrates, testes produce sperm and reproductive hormones. In humans and other mammals, reproduction is regulated by hormones produced by the hypothalamus, pituitary gland, and gonads.

50.3 In female vertebrates, ovaries produce ova and reproductive hormones. In human females, hormones maintain a monthly menstrual cycle that prepares the body for possible pregnancy.

50.4 When a secondary oocyte is fertilized, development begins, and the embryo implants in the wall of the uterus; hormones from the developing embryo, from the corpus luteum, and later from the placenta maintain the pregnancy.

50.5 In both human males and females, sexual response includes four physiological stages: excitement phase, plateau phase, orgasmic phase, and resolution phase.

50.6 A variety of highly reliable contraceptives are available; most hormonal contraceptives prevent ovulation.

50.7 Sexually transmitted infections (STIs) are communicable diseases; the most common STIs in the United States include chlamydia (which can lead to pelvic inflammatory disease), human papillomavirus (HPV), and genital herpes.

The survival of each species requires that its members produce new individuals to replace those that die. The ability to reproduce and perpetuate its species is a basic characteristic of living things. To paraphrase U.S. sociobiologist E.O. Wilson, animal reproduction is an animal's way of making more copies of its genes. How this process is accomplished depends on the relative benefits (and costs) of the reproductive strategies available in any given situation.

The mating nudibranchs (marine slugs) in the photograph are *hermaphrodites*. Each animal has both male and female organs and produces both sperm and eggs. However, they do not self-fertilize. Two nudibranchs come together to mate and exchange sperm through a tube near the head. Each then goes its own way and lays masses containing millions of eggs.

In this chapter we summarize some major features of animal reproduction and discuss the evolutionary advantages of sexual reproduction. We then focus on the process of human reproduction and on the hormones that regulate reproduction. We limit our discussion to a binary (that is, female/male) consideration of the sexes. As you read, remember that sex and gender in humans have many aspects that are the focus of ongoing scientific research. Among these aspects are genetic and chromosomal factors (see Chapters 11 and 16), developmental processes (see Chapter 51 and Fig. 51-16), gender identification, and sexual orientation. We conclude the chapter with discussions of contraception and sexually transmitted infections.

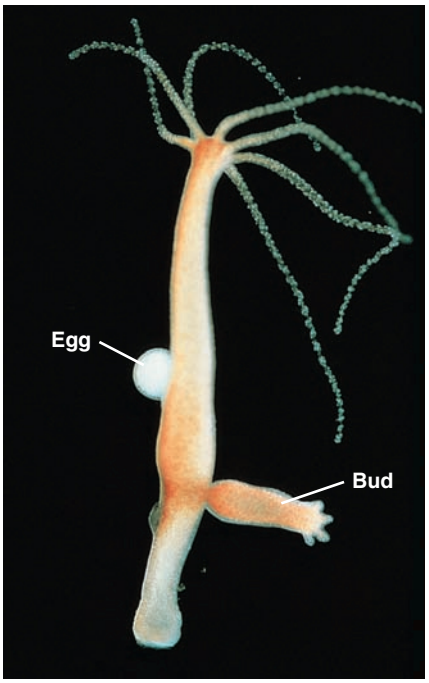
50.1 Asexual and Sexual Reproduction

LEARNING OBJECTIVE

1 Compare the benefits of asexual and sexual reproduction, and describe each mode of reproduction, giving specific examples.

Most animals carry on *sexual reproduction*, and some carry on *asexual reproduction*. Some animals reproduce asexually under some conditions and sexually at other times. As we will discuss, many variations of both asexual and sexual reproduction have evolved.

Asexual reproduction is an efficient strategy



In **asexual reproduction**, a single parent gives rise to offspring that are genetically identical to the parent (with the exception of mutations). Many invertebrates, including sponges, cnidarians, and some rotifers, flatworms, and annelids, can reproduce asexually. Some vertebrates also reproduce asexually under certain conditions. Asexual reproduction is an adaptation of some sessile animals that cannot move about to search for mates. For animals that do move about, asexual reproduction can be advantageous when the population density is low and mates are not readily available.

In asexual reproduction, a single parent may split, bud, or fragment to give rise to two or more offspring. Sponges and cnidarians are among the animals that can reproduce by **budding**. A small part of the parent's body separates from the rest and develops into a new individual (FIG. 50-1). Sometimes the buds remain attached and become more or less independent members of a colony.

Oyster farmers learned long ago that when they tried to kill sea stars by chopping them in half and throwing the pieces back into the sea, the number of sea stars preying on the oyster bed doubled! In some flatworms, nemerteans, and annelids, this ability to regenerate is part of a method of reproduction known as **fragmentation**. The body of the parent breaks into several pieces; each piece then regenerates the missing parts and develops into a whole animal.

Parthenogenesis ("virgin development") is a form of asexual reproduction in which an unfertilized egg develops into an adult animal. The adult is typically haploid. Parthenogenesis is common among insects (especially honeybees and wasps) and crustaceans; it also occurs among some other invertebrate and vertebrate groups, including some species of nematodes, gastropods, fishes, amphibians, and reptiles.

Although a few species appear to reproduce solely by parthenogenesis, in most species episodes of parthenogenesis alternate with periods of sexual reproduction. Parthenogenesis may occur for several generations, followed at some point by sexual reproduction in which males develop, produce sperm, and mate with the females to fertilize their eggs. In some species, parthenogenesis is a means of rapidly producing individuals when conditions are favorable.

Cabisco/Visuals Unlimited, Inc.

Figure 50-1 Asexual reproduction by budding
A part of the *Hydra's* body grows outward (*right*), then it separates and develops into a new individual. The region of the parent body that buds is not specialized exclusively for reproduction. The *Hydra* shown here is also reproducing sexually, as evidenced by the egg (*left*).

Most animals reproduce sexually

Sexual reproduction in animals involves the production and fusion of two types of **gametes**: sperm and eggs. Typically, two different individuals are required. A male parent contributes a **sperm**, and a female parent contributes an egg, or **ovum** (pl., *ova*). The sperm provides genes coding for some of the male parent's traits, and the egg contributes genes coding for some of the female parent's traits. The egg is typically large and nonmotile, with a store of nutrients that supports the development of the embryo. The sperm is usually small and motile, and is adapted to propel itself by beating its long, whiplike flagellum.

When sperm and egg unite, a **zygote**, or fertilized egg, is produced. The zygote develops into a new animal, similar to both parents but not identical to either. Sexual reproduction typically involves remarkably complex structural, functional, and behavioral processes. In vertebrates, hormones secreted by the hypothalamus, pituitary gland, and gonads regulate these processes.

Many aquatic animals practice **external fertilization** in which the gametes meet outside the body (FIG. 50-2a). Mating partners usually release eggs and sperm into the water simultaneously. Gametes live for only a short time, and many are lost in the water; some are eaten by predators. However, so many gametes are released that sufficient numbers of sperm and egg cells meet to perpetuate the species.

In **internal fertilization**, matters are left less to chance. The male generally delivers sperm cells directly into the body of the female. Her moist tissues provide the watery medium required

for the movement of sperm, and the gametes fuse inside the body. Most terrestrial animals, sharks, and aquatic reptiles, birds, and mammals practice internal fertilization (FIG. 50-2b).

Hermaphroditism is a form of sexual reproduction in which a single individual produces both eggs and sperm. A few hermaphrodites, such as the tapeworm, are capable of self-fertilization. More typically, two animals come together and fertilize each other's eggs (see the chapter-opening photograph of mating nudibranchs). The common earthworm is also a hermaphrodite. Two animals copulate, and mutual cross-fertilization occurs. Each earthworm inseminates the other. In some hermaphroditic species, self-fertilization is prevented by the development of testes and ovaries at different times.

Sexual reproduction increases genetic variability

Asexual reproduction is the fastest and most efficient way to reproduce. Each cell can produce two new cells. Sexual reproduction is less efficient than asexual reproduction because two cells, rather than just one, are required to make a new organism. (Two parents are typically required.) Sexual reproduction is also more expensive in terms of energy than asexual reproduction because the animal must produce gametes and find mates. If asexual reproduction has so many advantages, you may wonder why most animals reproduce sexually.

A major benefit of sexual reproduction is that it has the potential to increase the *fitness* (reproductive success) of some of the offspring. In contrast to asexual reproduction, in which an animal passes all its genes to its offspring, sexual reproduction has the biological advantage of promoting genetic variety among the members of a species. Each offspring is the product of a particular combination of genes contributed by both parents rather than a genetic copy of a single individual. By combining inherited traits of two parents, sexual reproduction gives rise to at least some offspring that may be better able to survive than either parent. Also, because the offspring are diploid, they have a backup copy of their genes in case one copy gets damaged by mutation.

Although they agree that sexual reproduction has some selective advantage, biologists do not agree on the details. They are exploring several hypotheses. One hypothesis holds that sexual reproduction provides a mechanism for beneficial mutations from each parent to come together in offspring that can reproduce and spread these mutations through the population. For example, certain beneficial mutations may permit animals to protect themselves from predators or resist parasites.

Another hypothesis holds that sexual reproduction is more efficient than asexual reproduction at removing harmful mutations from a population. As you have learned in earlier chapters, mutations occur constantly, and most mutations are harmful. When animals reproduce asexually, all the offspring inherit all the harmful mutations. As mutations accumulate in a population, individuals carry a bigger and bigger load of harmful genes. In contrast, when animals with different mutations mate, offspring inherit varying numbers and combinations of mutations. Offspring that inherit too many harmful mutations are selected against. They may not live to reproduce, so their harmful mutations are removed from the population.

(a) External fertilization. Like many aquatic animals, these spawning frogs (*Rana temporaria*) release their gametes into the water. The female lays a mass of eggs, while the male mounts her and simultaneously deposits his sperm in the water.

Stuart G Porter/Shutterstock.com

(b) Internal fertilization. In most terrestrial animals, such as these lions (*Panthera leo*), the male deposits sperm inside the female body. Internal fertilization is also practiced by some fishes and some aquatic reptiles and mammals.

Wayne Getz, an applied mathematician at the University of California, Berkeley, developed a mathematical model that predicts whether asexual reproduction or sexual reproduction will exist within a population. According to his model, clones of animals produced by asexual reproduction would be favored in an unchanging environment. The model further predicts that sexual reproduction will be adaptive in an unstable, changing environment and that both types of reproduction can coexist under conditions of moderate change.

Competing hypotheses are an expected part of the scientific process because scientific discovery is rarely a straightforward, linear sequence of question–answer, question–answer. In fact, as scientific knowledge expands, many creative hypotheses are falsified or discarded as dead ends. Sometimes researchers show that competing hypotheses may each explain part of the problem under scrutiny.

CHECKPOINT 50.1

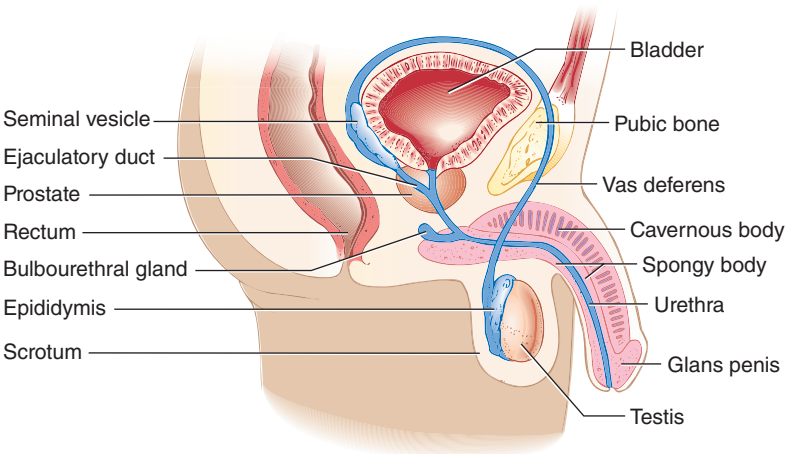
- Distinguish among budding, fragmentation, and parthenogenesis.
- What are the advantages and disadvantages of asexual reproduction compared with sexual reproduction?

50.2 Human Reproduction: The Male

LEARNING OBJECTIVES

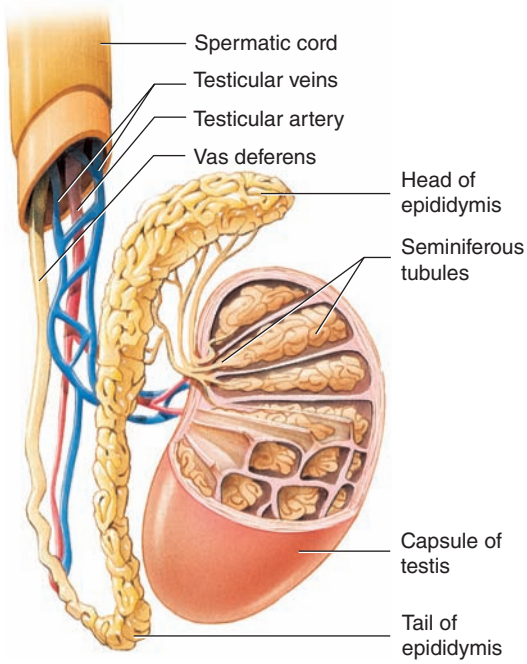
2 Relate the structure of each organ of the human male reproductive system to its function.

3 Trace the passage of sperm cells through the human male reproductive system from their origin in the seminiferous tubules to their expulsion from the body in the semen; include a description of spermatogenesis.



4 Describe endocrine regulation of reproduction in the human male.

The human male, like other male mammals, has the reproductive role of producing sperm cells and delivering them into the female reproductive tract. When a sperm combines with an egg, the sperm contributes its genes and determines the sex of the offspring.

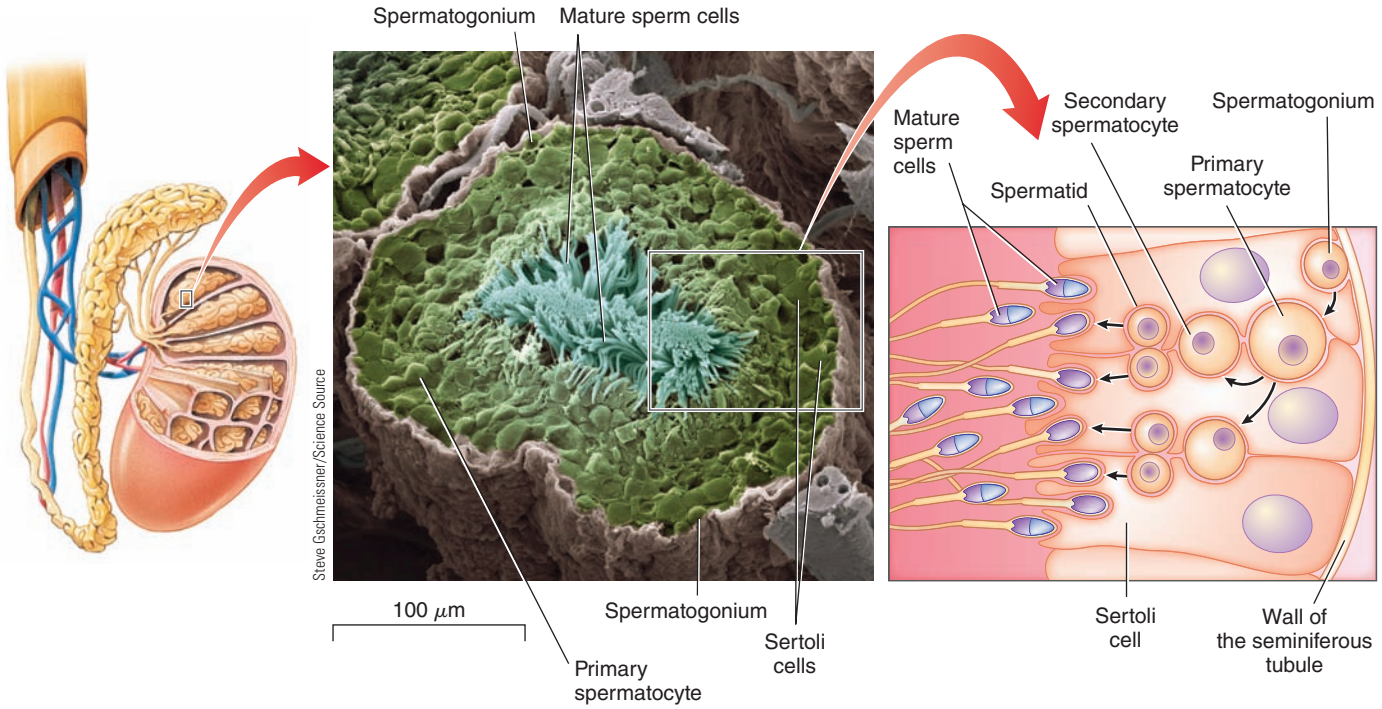


The testes produce gametes and hormones

In humans and other vertebrates, **spermatogenesis**, the process of sperm cell production, occurs in the paired male gonads, or **testes** (sing., *testis*) (FIG. 50-3a). More specifically, spermatogenesis takes place within a vast tangle of hollow tubules, the **seminiferous tubules**, within each testis (FIG. 50-3b). Spermatogenesis begins with undifferentiated cells, the **spermatogonia** (sing., *spermatogonium*) in the walls of the tubules (FIG. 50-4).

The spermatogonia, which are diploid cells, divide by mitosis and produce more spermatogonia. Some enlarge and become **primary spermatocytes**, which undergo **meiosis**. (You may want to review the discussion of meiosis in Chapter 10.) In many animals, gamete production occurs only in the spring or fall, but humans have no special breeding season. In the human adult male, spermatogenesis proceeds continuously, and millions of sperm are produced each day.

(a) Male reproductive anatomy. The scrotum, penis, and pelvic region of the human male are shown in sagittal section to illustrate their internal structure.



(b) Structures that produce and transport sperm. The testis, epididymis, and spermatic cord are shown partly dissected and exposed. The testis is shown in sagittal section to illustrate the arrangement of the seminiferous tubules.

(a) Color-enhanced SEM of a cross section through a seminiferous tubule. Flagella (*blue*) of maturing sperm are visible in the center. Developing sperm are nourished by large Sertoli cells (both *green*). A connective tissue sheath (*gray*) surrounds each tubule.

(b) Sperm cells in various stages of development. Developing sperm cells lie among the large, nutritive Sertoli cells.

Figure 50-4
Spermatogenesis in the seminiferous tubules

Each primary spermatocyte undergoes a first meiotic division, which produces two haploid **secondary spermatocytes** (FIG. 50-5). During the second meiotic division, each of the two secondary spermatocytes gives rise to two haploid **spermatids**. Four spermatids are produced from the original primary spermatocyte. Each spermatid differentiates into a mature sperm. The sequence is as follows:

spermatogonium (diploid) → primary spermatocyte (diploid) → two secondary spermatocytes (haploid) → four spermatids (haploid) → four mature sperm (haploid)

Each mature sperm consists of a head, midpiece, and flagellum (FIG. 50-6). The head consists almost entirely of the nucleus. Part of the nucleus is covered by the *acrosome*, a large vesicle that differentiates from the Golgi complex. The acrosome contains enzymes that help the sperm penetrate the egg.

Mitochondria, located in the midpiece of the sperm, provide the energy for movement of the flagellum. The sperm flagellum has the typical eukaryotic 9 + 2 arrangement of microtubules. During its development, most of the sperm's cytoplasm is discarded and is phagocytosed by the large **Sertoli cells** that ring the fluid-filled lumen of the seminiferous tubule. These cells provide nutrients for the developing sperm cells. Sertoli cells also secrete hormones and other signaling molecules.

Each Sertoli cell extends from the outer membrane of the seminiferous tubule to its lumen. Sertoli cells are joined to one another by *tight junctions* at a place just within the outer membrane of the tubule (see Chapter 5 for discussion of tight junctions). Together, Sertoli cells form a blood–testis barrier that prevents harmful substances from entering the tubule and interfering with spermatogenesis. This barrier also prevents sperm from passing out of the tubule into the blood, where they could stimulate an immune response. The tight junctions between Sertoli cells also form compartments that separate sperm cells in various stages of development.

Human sperm cells cannot develop at body temperature. Although the testes develop within the abdominal cavity of the male embryo, about two months before birth they descend into the **scrotum**, a skin-covered sac suspended from the groin. The scrotum serves as a cooling unit, maintaining sperm below body temperature. In rare cases, the testes do not descend. If this condition is not corrected by surgery or hormone treatment, the seminiferous tubules eventually degenerate and the male becomes *sterile*, unable to produce offspring.

The scrotum is an outpocketing of the pelvic cavity and is connected to it by the *inguinal canals*. As they descend, the testes pull their blood vessels, nerves, and conducting tubes after them. The inguinal region is a weak place in the abdominal wall. Straining the abdominal muscles by lifting heavy objects sometimes tears the inguinal tissue. A loop of intestine can then bulge into the scrotum through the tear, a condition known as an *inguinal hernia*.

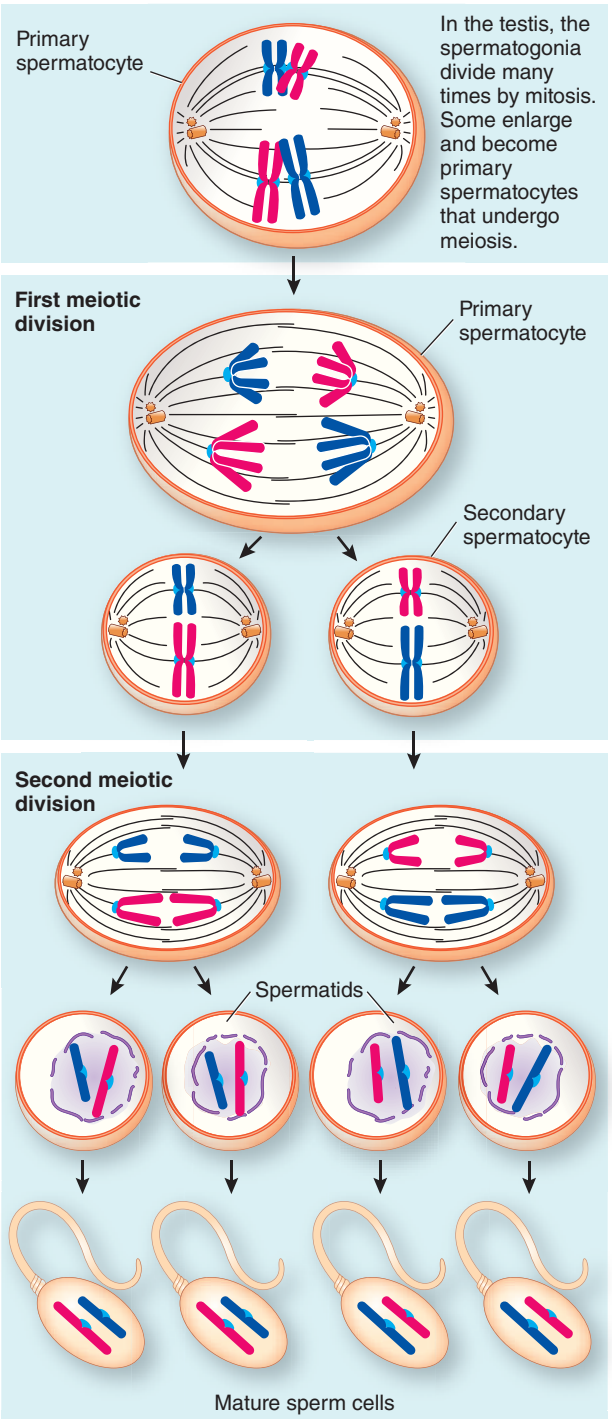

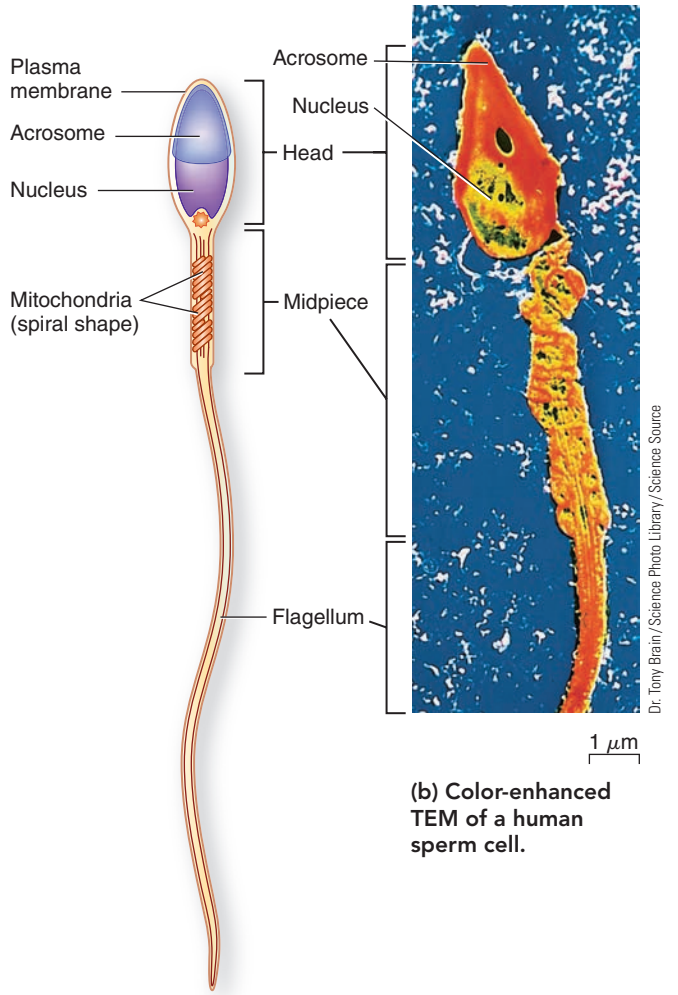

Figure 50-5 Spermatogenesis

Note in this example that four chromosomes are present in the primary spermatocyte ($2n$) and that meiosis produces the haploid (n) number (2) in the secondary spermatocytes. The spermatids and mature sperm cells are also haploid.

(a) A mature sperm has a head, midpiece, and flagellum. The acrosome contains enzymes important in penetrating the egg.

(b) Color-enhanced TEM of a human sperm cell.

Figure 50-6 Structure of a mature sperm

A series of ducts store and transport sperm

Sperm cells leave the seminiferous tubules of each testis and pass into a larger coiled tube, the **epididymis**. There, sperm finish maturing and are stored. During **ejaculation**, sperm pass from each epididymis into a sperm duct, the **vas deferens** (pl., *vasa deferentia*). The vas deferens extends from the scrotum through the inguinal canal and into the pelvic cavity.

Each vas deferens empties into a short **ejaculatory duct**, which passes through the prostate gland and then opens into the single **urethra**. The urethra, which at different times conducts urine and semen, passes through the penis to the outside of the body. Thus, the sperm pass through the following structures:

seminiferous tubules → epididymis → vas deferens → ejaculatory duct → urethra → release from body

The accessory glands produce the fluid portion of semen

As sperm travel through the conducting tubes, they mix with secretions from three types of accessory glands. **Semen** consists

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

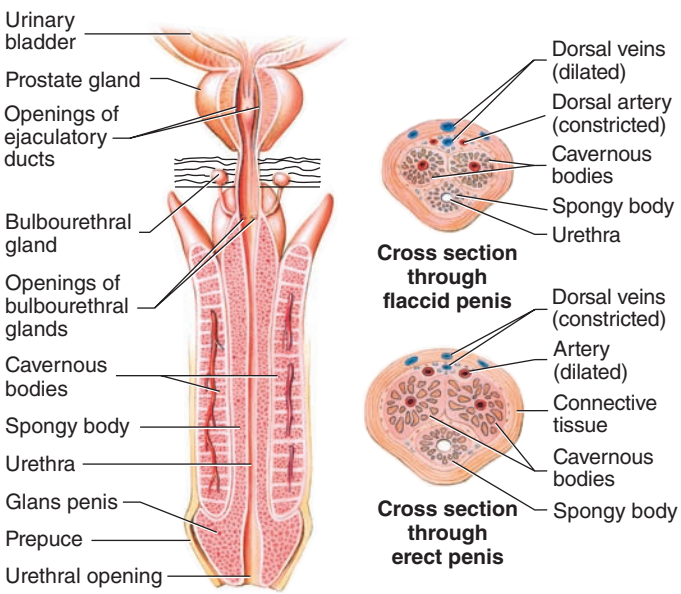
of about 200 million sperm cells suspended in these secretions. Approximately 3 mL of semen is ejaculated during sexual climax.

The paired **seminal vesicles** secrete a fluid rich in fructose and prostaglandins into the vasa deferentia (see Fig. 50-3). The fructose provides energy for the sperm after they are ejaculated. Prostaglandins stimulate contractions of smooth muscle in both male and female reproductive tracts. These contractions help transport the sperm down the male reproductive tract and up the female tract to the oviduct where fertilization occurs. The seminal vesicles also secrete fibrinogen, which clots the semen. The fluid secreted by the seminal vesicles accounts for about 60% of the semen volume.

The single **prostate gland** secretes an alkaline fluid that neutralizes the acidic secretions of the vagina. This process is important because sperm are more active and survive longer in a slightly alkaline environment. Prostate gland secretion also contains clotting enzymes and *prostate-specific antigen (PSA)*. The clotting enzymes act on fibrinogen from the seminal vesicles, producing fibrin. You may recall from Chapter 44 that fibrin threads form blood clots. In this case, fibrin clots the semen. When semen is ejaculated, the clotted semen helps keep the sperm in the female reproductive tract while the penis is withdrawn. The clot is then broken down by PSA, and mobile sperm make their way through the female reproductive tract to the ovum.

Except for skin cancer, prostate cancer is the most common cancer in males and is also one of the leading causes of cancer death among males in the United States. According to national guidelines, doctors should talk to their patients about the benefits and risks of PSA-based screening for prostate cancer for men without symptoms. Screening tests for prostate cancer include the digital rectal exam and the prostate specific antigen blood test (PSA). The PSA measures the concentration of PSA in the blood. Elevated concentrations of PSA are associated with prostate cancer, prostate infection, and certain benign changes in the prostate. An elevated PSA indicates a need for further evaluation, typically a prostate biopsy. Prostate cancer can be treated with surgery, hormone therapy, or radiation treatment.

During sexual arousal, the paired *bulbourethral glands*, located on each side of the urethra, release a mucous secretion. This fluid lubricates the penis, facilitating its penetration into the vagina.



A major cause of male infertility is insufficient sperm production. When sperm counts drop below 35 million per milliliter of semen, fertility is impaired, and males with a sperm count lower than 20 million per milliliter are usually considered sterile. When a couple's attempts to produce a child are unsuccessful, a sperm count and analysis may be performed in a clinical laboratory. Sometimes semen is found to contain large numbers of abnormal sperm or, occasionally, no sperm at all.

In the United States in the 1970s, an average healthy young man produced about 100 million sperm per milliliter of semen. Today that average has dropped to about 60 million. Although the cause of this decrease is not known, low sperm counts have been linked to a variety of environmental factors, including chronic marijuana use, alcohol abuse, and cigarette smoking. Studies also show that men who smoke tobacco are more likely than nonsmokers to produce abnormal sperm. Exposure to industrial and environmental toxins such as PCBs (polychlorinated biphenyls) may contribute to low sperm count and sterility. The use of anabolic steroids by athletes to accelerate muscle development can cause sterility in both males and females (see *Inquiring About: Anabolic Steroids and Other Performance-Enhancing Drugs* in Chapter 49). A recent study identified two potentially modifiable factors that might lead to an increase in sperm count: increased exercise and decreased television viewing.

The penis transfers sperm to the female

The **penis** is an erectile copulatory organ that delivers sperm into the female reproductive tract. It is a long shaft that enlarges to form an expanded tip, the *glans*. Part of the loose-fitting skin of the penis folds down and covers the proximal portion of the glans, forming a cuff called the *prepuce*, or *foreskin*. The foreskin is removed during circumcision, a procedure commonly performed on male babies either for hygienic or religious reasons. Studies have documented that male circumcision significantly reduces a man's risk of acquiring **human immounodeficiency virus (HIV)** and other sexually transmitted infections during vaginal sexual intercourse.

Under the skin, the penis consists of three parallel columns of *erectile tissue*: two *cavernous bodies* and one *spongy body* (FIG. 50-7). The spongy body surrounds the portion of the urethra that passes through the penis. Erectile tissue contains numerous blood vessels. When the male is sexually stimulated, parasympathetic neurons dilate the arteries in the penis. As

(a) Longitudinal section through the prostate gland and penis. Note the three parallel columns of erectile tissue in the penis: the two cavernous bodies and the spongy body.

(b) Cross sections through a flaccid and an erect penis. The erectile tissues become engorged with blood in the erect penis.

blood fills the blood vessels of the erectile tissue, the tissue swells. This swelling compresses veins that conduct blood away from the penis, slowing the outflow of blood. Thus, more blood enters the penis than can leave, further engorging the erectile tissue with blood. Erection of the penis occurs as the penis increases in length, diameter, and firmness. Although the human penis contains no bone, penis bones do occur in some other mammals, such as bats, rodents, and some primates.

Erectile dysfunction, the chronic inability to sustain an erection, prevents effective sexual intercourse. Associated with a variety of physical causes and psychological issues, this common disorder is treated with medication, such as sildenafil (Viagra) and related drugs (Levitra, Cialis). These drugs block the action of an enzyme that breaks down the signaling molecule that sustains erection.

Testosterone has multiple effects

Testosterone is the principal **androgen**, or male sex hormone. It is a steroid produced by the **interstitial cells** between the seminiferous tubules in the testes. Testosterone has many functions, beginning during early embryonic development when it stimulates development of the primary male reproductive organs (TABLE 50-1). Later during development, testosterone stimulates descent of the testes into the scrotum.

Puberty is the period of sexual maturation during which the secondary sex characteristics begin to develop and the individual becomes capable of reproducing. In males, puberty typically begins between ages 10 and 12 and continues until ages 16 to 18. Testosterone directly affects muscle and bone and stimulates the adolescent growth spurt in males at puberty. It produces the male's *primary sex characteristics*: growth of the reproductive organs and spermatogenesis. Testosterone also stimulates the development of the **secondary sex characteristics** at puberty, including growth of facial and body hair, muscle development, and the increase in vocal cord length and thickness that causes the voice to deepen. Testosterone is necessary for normal sex drive.

In some of its target tissues, testosterone is converted to other steroids. Interestingly, in brain cells testosterone is converted to *estradiol*, the principal female sex hormone. The implications of this transformation are not yet understood.

The hypothalamus, pituitary gland, and testes regulate male reproduction

As you read the following description of male hormone action and regulation, follow the steps in FIGURE 50-8. When a boy is about 10 years old, the hypothalamus begins to secrete **gonadotropin-releasing hormone (GnRH)**. GnRH stimulates the anterior pituitary to secrete the *gonadotropic hormones* **follicle-stimulating hormone (FSH)** and **luteinizing hormone (LH)**. Both FSH and LH are glycoproteins that use cyclic AMP as a second messenger (see Chapter 49). FSH stimulates Sertoli cells to secrete **androgen-binding protein (ABP)** and other signaling molecules that are necessary for spermatogenesis. LH stimulates the interstitial cells to secrete testosterone.

FSH, LH, and testosterone all directly or indirectly stimulate testosterone secretion and spermatogenesis. A high concentration of testosterone in the testes is required for spermatogenesis. Testosterone and FSH stimulate Sertoli cells to produce ABP, which binds to testosterone and concentrates it in the tubules. Testosterone also maintains the male secondary sex characteristics.

Reproductive hormone concentrations are regulated by negative feedback mechanisms (see Fig. 50-8b). Testosterone acts on the hypothalamus, decreasing its secretion of GnRH, which decreases FSH and LH secretion by the pituitary. Testosterone also directly inhibits the anterior lobe of the pituitary by blocking the normal actions of GnRH on LH synthesis and release.

FSH secretion is inhibited mainly by **inhibin**, a peptide hormone secreted by Sertoli cells. FSH itself stimulates inhibin secretion. The endocrine regulation of reproductive function is complex, and it is likely that other hormones and signaling molecules will be identified.

Table 50-1 Principal Male Reproductive Hormones

Endocrine Gland and Hormones	Principal Target Tissue	Principal Action
HYPOTHALAMUS		
Gonadotropin-releasing hormone (GnRH)	Anterior pituitary	Stimulates release of FSH and LH
ANTERIOR PITUITARY		
Follicle-stimulating hormone (FSH)	Testes	Stimulates development of seminiferous tubules; stimulates spermatogenesis
Luteinizing hormone (LH)	Testes	Stimulates interstitial cells to secrete testosterone
TESTES		
Testosterone	General	**Before birth:** stimulates development of primary sex organs and descent of testes into scrotum **At puberty:** responsible for growth spurt; stimulates development of reproductive structures and secondary sex characteristics **In adult:** maintains secondary sex characteristics; stimulates spermatogenesis
Inhibin	Anterior pituitary	Inhibits FSH secretion

Key Point

Hormones from the hypothalamus, anterior pituitary gland, and testes regulate male reproduction by negative feedback systems.

1. Hypothalamus secretes GnRH, which stimulates anterior pituitary.
2. Pituitary secretes FSH and LH.
3. FSH stimulates Sertoli cells to secrete ABP and other signaling molecules necessary for spermatogenesis. LH stimulates interstitial cells to secrete testosterone.
4. Testosterone stimulates Sertoli cells, leading to stimulation of spermatogenesis.
5. Testosterone maintains secondary sex characteristics.

6. Testosterone inhibits GnRH secretion by hypothalamus and FSH and LH secretion by pituitary.
7. Inhibin inhibits FSH secretion.

Figure 50-8 Regulation of male reproduction

Several hormones interact to maintain male characteristics and reproductive function. *Green arrows* indicate stimulation; *red arrows* indicate inhibition. (GnRH, gonadotropin-releasing hormone; FSH, follicle-stimulating hormone; LH, luteinizing hormone; ABP, androgen-binding protein)

PREDICT Imagine that a man's anterior pituitary stopped producing LH. How would that affect him?

Insufficient testosterone results in sterility. If a male is *castrated*—that is, the testes are removed—before puberty, he is deprived of testosterone and becomes a eunuch. He retains childlike sexual organs and does not develop secondary sexual characteristics. If castration occurs after puberty, increased secretion of male hormones by the adrenal glands helps maintain masculinity.

CHECKPOINT 50.2

- What are the functions of the testes?
- **VISUALIZE** Draw a diagram showing the structures through which a sperm passes in its journey from a seminiferous tubule until it leaves the male body during ejaculation.
- What are the actions of testosterone?
- **VISUALIZE** Draw and label a diagram illustrating the endocrine regulation of male reproduction. (Include LH, FSH, GnRH, ABP, testosterone, and inhibin.)

50.3 Human Reproduction: The Female

LEARNING OBJECTIVES

5. Relate the structure of each organ of the human female reproductive system to its function.
6. Trace the development of a human egg and trace its passage through the female reproductive system until it is fertilized.
7. Describe the endocrine regulation of reproduction in the human female and identify key events of the menstrual cycle, such as ovulation and menstruation.

The female reproductive system produces ova (gametes), receives the penis and sperm released from it during heterosexual intercourse, houses and nourishes the embryo during prenatal development, gives birth, and produces milk for the young (lactation). Hormones secreted by the hypothalamus, pituitary gland, and ovaries interact to regulate and coordinate these processes.

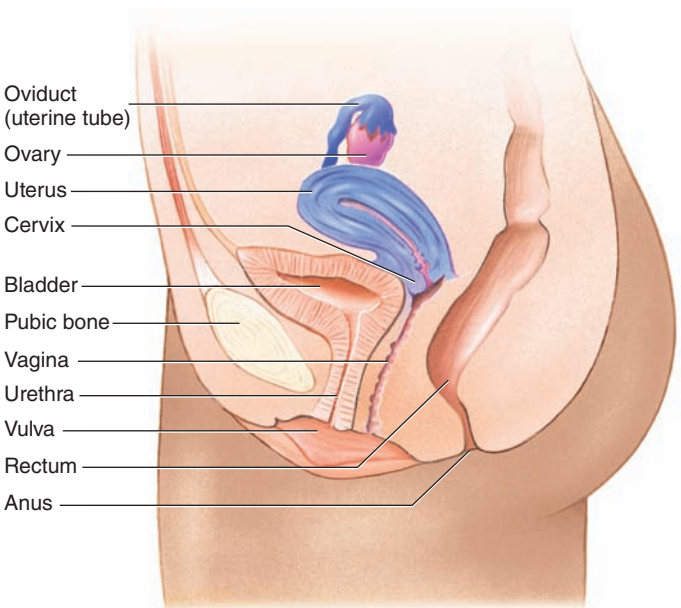
The ovaries produce gametes and sex hormones

Like the male gonads, the female gonads, or **ovaries**, produce both gametes and sex hormones. About the size and shape of large almonds, the ovaries lie close to the lateral walls of the pelvic cavity and are held in position by several connective tissue ligaments (FIG. 50-9). Internally, the ovary consists mainly of connective tissue containing scattered ova in various stages of maturation.

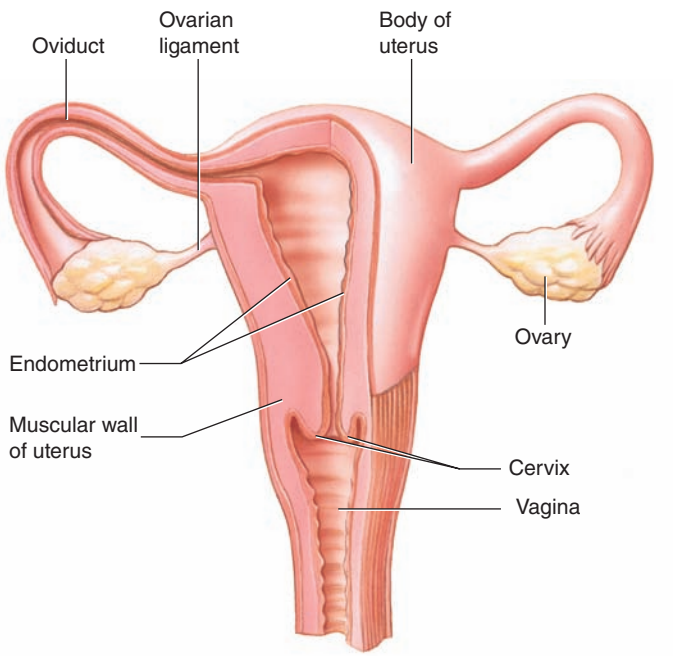
The process of ovum production, called **oogenesis**, begins in the ovaries. Before birth, hundreds of thousands of **oogonia** are present in the ovaries. For more than 50 years, biologists agreed that all a female's oogonia were produced during embryonic development and that no new oogonia were produced after birth. Recently, a research team challenged this view, claiming that stem cells in the ovaries of women (and mice) continue to differentiate into ova throughout adulthood, until menopause.

During prenatal development, the oogonia increase in size and become **primary oocytes**. By the time of birth, they are in the prophase of the first meiotic division. At this stage, they enter a resting phase that lasts throughout childhood and into adult life.



A primary oocyte and the **granulosa cells** surrounding it together make up a **follicle** (FIG. 50-10). The granulosa cells are connected by tight junctions that form a protective barrier around the oocyte. With the onset of puberty, a few follicles begin to mature each month in response to FSH secreted by the anterior pituitary gland. As a follicle grows, the granulosa cells proliferate, forming several layers. Connective tissue cells surrounding the granulosa cells differentiate to form a layer of **theca cells**.

As the follicle matures, the primary oocyte completes its first meiotic division. The two haploid cells produced differ in size (FIG. 50-11). The smaller one, the first **polar body**, may later divide, forming two polar bodies, but these cells eventually disintegrate. The larger cell, the **secondary oocyte**, proceeds to the second meiotic division but remains in metaphase II until it is fertilized. When meiosis continues, the second meiotic division gives rise to a single ovum and a second polar body. The polar bodies are small and apparently dispose of unneeded chromosomes with a minimal amount of cytoplasm. The sequence is as follows:



oogonium (diploid) → primary oocyte (diploid) → secondary oocyte + first polar body (both haploid) → (after fertilization) ovum + second polar body (both haploid)

Recall that in the male, each primary spermatocyte gives rise to four functional sperm cells. In contrast, each primary oocyte generates only one ovum.

As an oocyte develops, it becomes separated from its surrounding follicle cells by a layer of glycoproteins called the **zona pellucida**. As the follicle develops, follicle cells secrete fluid, which collects in the antrum (space) between them (see Fig. 50-10). The follicle cells also secrete **estrogens**, female sex hormones. The principal estrogen is *estradiol* (see Fig. 49-2b). Typically, only one follicle fully

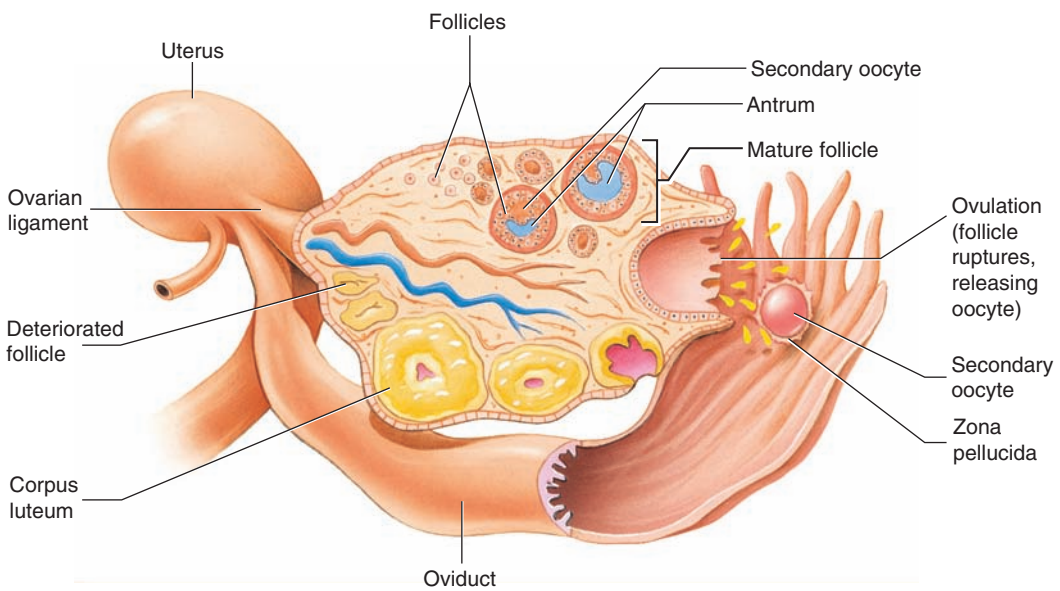
matures each month. Several others may develop for a while and then deteriorate by apoptosis.

As a follicle matures, it moves closer to the surface of the ovary, eventually resembling a fluid-filled bulge on the ovarian surface. Follicle cells secrete proteolytic enzymes that break down a small area of the ovary wall. During **ovulation**, the secondary oocyte ejects through the ovary wall and into the pelvic cavity. The portion of the follicle that remains in the ovary develops into the **corpus luteum**, a temporary endocrine gland that secretes estrogen and **progesterone**.

(a) LM of a developing follicle. The secondary oocyte is surrounded by the zona pellucida (a layer of glycoproteins) and by granulosa cells. Connective tissue cells surrounding the granulosa cells form a layer of theca cells.



The oviducts transport the secondary oocyte

Almost immediately after ovulation, the secondary oocyte is swept into the funnel-shaped opening of the **oviduct**, also called the **uterine tube** or *fallopian tube*. Ciliated epithelial cells lining the oviduct sweep the secondary oocyte into the oviduct and move it along toward the uterus. Fertilization takes place within the oviduct. If fertilization does not occur, the secondary oocyte degenerates there.

Scarring of the oviducts (e.g., by *pelvic inflammatory disease*, caused by a sexually transmitted infection) can block the tubes so that the fertilized ovum cannot pass to the uterus. Women with blocked oviducts may be infertile. Sometimes partial constriction of the oviduct results in *tubal pregnancy*. The embryo cannot progress to the uterus, and it begins to develop in the wall of the oviduct. Because oviducts are not adapted to bear the burden of a developing embryo, the oviduct and the embryo it contains must be surgically removed before it ruptures and endangers the life of the mother.

The uterus incubates the embryo

The oviducts open into the upper corners of the pear-shaped **uterus** (see Fig. 50-9b). About the size of a fist, the uterus (or womb) occupies a central position in the pelvic cavity. It has thick walls of smooth muscle and an epithelial lining, the **endometrium**, which thickens each month in preparation

(b) Follicles in the ovary. This drawing is a composite; all these stages of development would not be present at the same time.

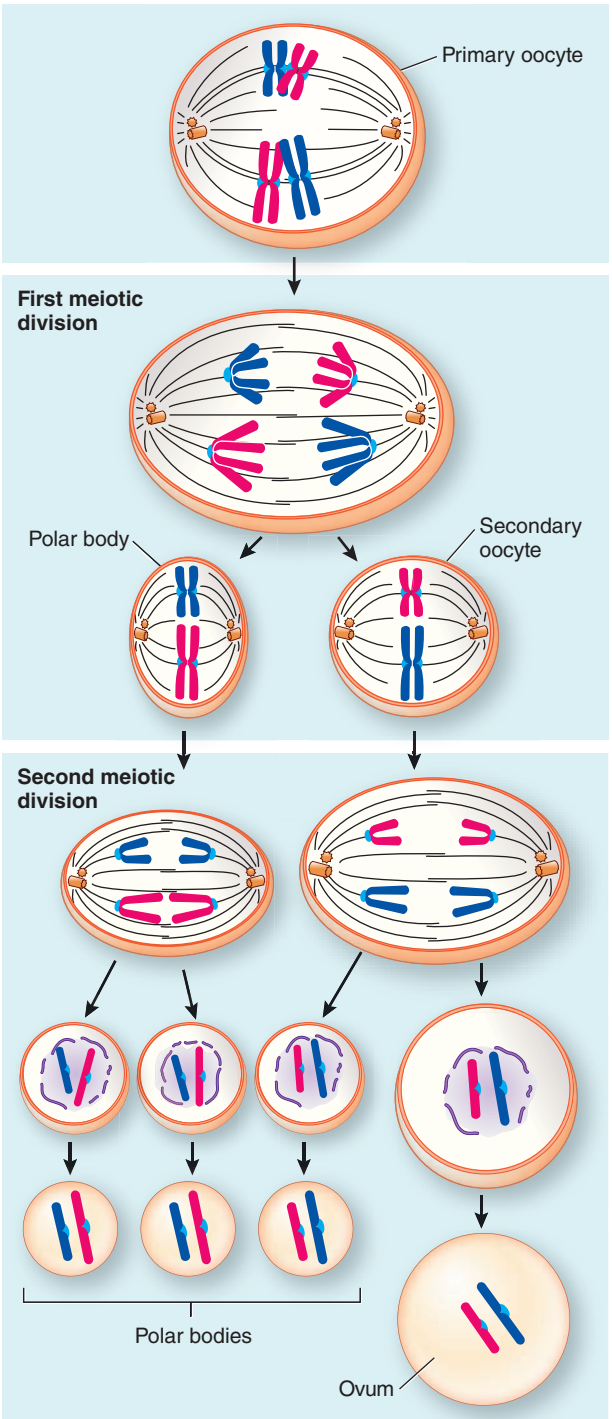

Figure 50-11 Oogenesis

Before birth, oogonia (*not shown*) divide many times by mitosis. Some oogonia differentiate to become primary oocytes that undergo meiosis. Only one functional ovum is produced from each primary oocyte. The other cells produced are polar bodies that degenerate. The first polar body sometimes divides as shown but often just deteriorates. The second meiotic division is completed after fertilization. Note in this example that four chromosomes are present in the primary oocyte ($2n$) and that meiosis produces the haploid (n) number (two chromosomes) in the polar bodies, secondary oocyte, and mature ovum.

for possible pregnancy. About 10% of women (more than ten million women in the United States alone) are affected by *endometriosis* during their reproductive years. In this painful disorder, fragments of the endometrium migrate to other areas, such as the oviducts or ovaries. Like pelvic inflammatory disease, endometriosis causes scarring that can lead to infertility.

If a secondary oocyte is fertilized, the tiny embryo enters the uterus and implants in the endometrium. As it grows and develops, it is sustained by nutrients and oxygen delivered by surrounding maternal blood vessels. If fertilization does not occur during the monthly cycle, the endometrium sloughs off and is discharged in the process known as **menstruation**.

The lower portion of the uterus, called the **cervix**, extends slightly into the vagina. Cervical cancer is the third most common type of cancer for females in the world. Almost all cases of cervical cancer are linked to infection with human papillomavirus (HPV). (Vaccines against HPV are described later in this chapter.) Detection of cervical cancer is usually possible by the routine Papanicolaou test (Pap smear), in which a few cells are scraped from the cervix during a regular gynecological examination and studied microscopically. When cervical cancer is detected at an early stage, there is a good chance that the patient can be cured. (Interestingly, researchers have reported that in the future, Pap smears may also be used to detect mutations that put women at high risk for developing ovarian cancer or uterine cancer.)

The vagina receives sperm

The **vagina** is an elastic, muscular tube that extends from the uterus to the exterior of the body. The vaginal opening is located in the *perineal region* between the opening of the urethra (anteriorly) and the opening of the anus (posteriorly). The vagina serves as a receptacle for sperm during heterosexual intercourse and as part of the birth canal (see Fig. 50-9).

The vulva are external genital structures

The female external genitalia, collectively known as the **vulva**, include several structures. Liplike folds, the *labia minora*, surround the vaginal and urethral openings (FIG. 50-12). The area enclosed by the labia minora is the *vestibule* of the vagina. Vestibular glands secrete a lubricating mucus into the vestibule. The *hymen* is a thin ring of tissue that forms a border around the entrance to the vagina.

Anteriorly, the labia minora merge to form the prepuce of the **clitoris**, a small erectile structure homologous to the male glans penis. Like the penis, the clitoris contains erectile tissue that becomes engorged with blood during sexual excitement. Rich in nerve endings, the clitoris is highly sensitive to touch, pressure, and temperature, and serves as the main center of sexual sensation in the female.

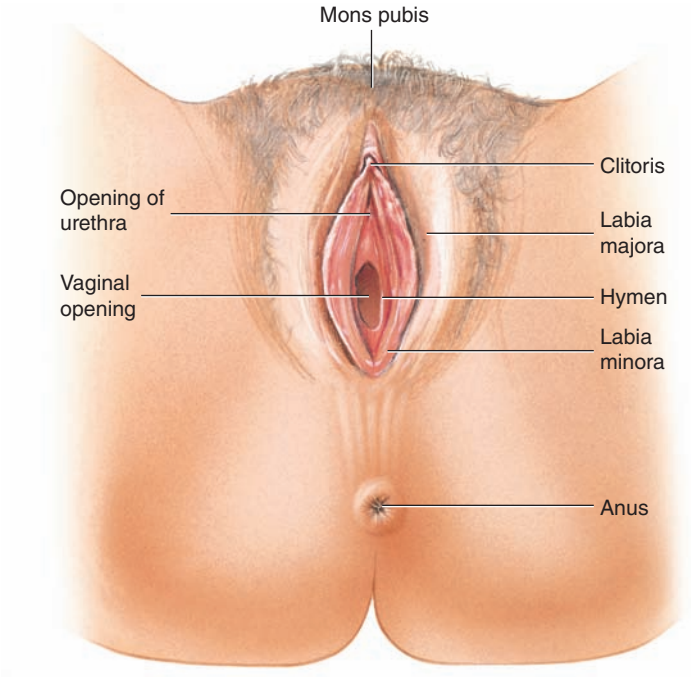

Figure 50-12 External female genital structures
Collectively, the structures shown (excluding the anus) are referred to as the vulva.

External to the delicate labia minora are the thicker *labia majora*. The *mons pubis* is the mound of fatty tissue just above the clitoris at the junction of the thighs and torso. At puberty the mons pubis and labia majora become covered by coarse pubic hair.

Breasts function in lactation

Each breast consists of 15 to 20 lobes of glandular tissue. The amount of adipose tissue around these lobes determines the size of the breasts and accounts for their softness. Gland cells are arranged in grapelike clusters called **alveoli** (FIG. 50-13). Ducts from each cluster join to form a single duct from each lobe, producing 15 to 20 tiny openings on the surface of each nipple. The breasts are the most common site of cancer in women, except for the skin (see *Inquiring About: Breast Cancer*).

Lactation is the production of milk for nourishing the young. During pregnancy, high concentrations of the female reproductive hormones, estrogen and progesterone, stimulate the breasts to increase in size. For the first few days after childbirth, the mammary glands produce a fluid called *colostrum*, which contains proteins and antibodies, but little fat. When the baby suckles, the hormone **prolactin**, secreted by the anterior pituitary gland, stimulates milk production. Nursing also stimulates the posterior pituitary gland to release **oxytocin**. This hormone stimulates ejection of milk from the alveoli into the ducts.

Breast-feeding promotes recovery of the uterus because oxytocin released during breast-feeding stimulates the uterus to contract to nonpregnant size. Breast-feeding offers advantages to the baby as well. It promotes bonding between mother and child, and provides milk tailored to the nutritional needs of the human infant. Breast milk contains a variety of immune cells (B cells, T cells, neutrophils, and macrophages) and antibodies. As a result, breast-fed infants have a lower incidence of diarrhea, ear and respiratory infections, and hospital admissions than do formula-fed babies. According to the U.S. Surgeon General's Office, breast-fed babies also have a lower lifetime risk of asthma, obesity, type 2 diabetes, and other health problems.

The hypothalamus, pituitary gland, and ovaries regulate female reproduction

As in the male, regulation of female reproduction involves many hormones and other signaling molecules. In the male, concentration of sex hormones is kept within a narrow range. In contrast, concentrations of female sex hormones change dramatically during the course of each monthly cycle. TABLE 50-2 lists the actions of the principal female reproductive hormones.

Like testosterone in the male, *estrogens* are responsible for growth of the sex organs at puberty, for body growth, and for the development of secondary sexual characteristics. In the female, these characteristics include development of the breasts, broadening of the pelvis, and the development and distribution of muscle and fat responsible for the female body shape. In females, *puberty* typically begins between ages 10 and 12 and continues until ages 14 to 16.

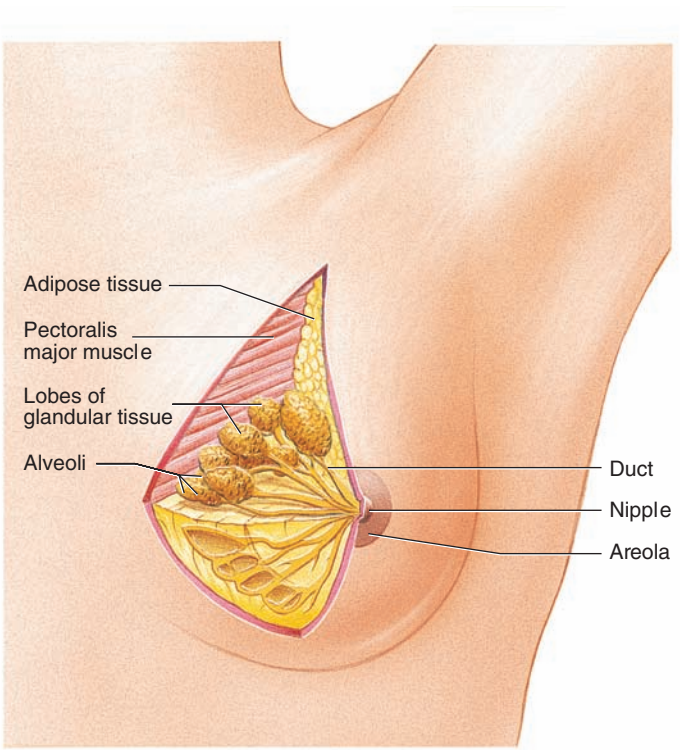

Figure 50-13 Structure of the mature female breast
The breast contains lobes of glandular tissue. This tissue consists of alveoli, clusters of gland cells.

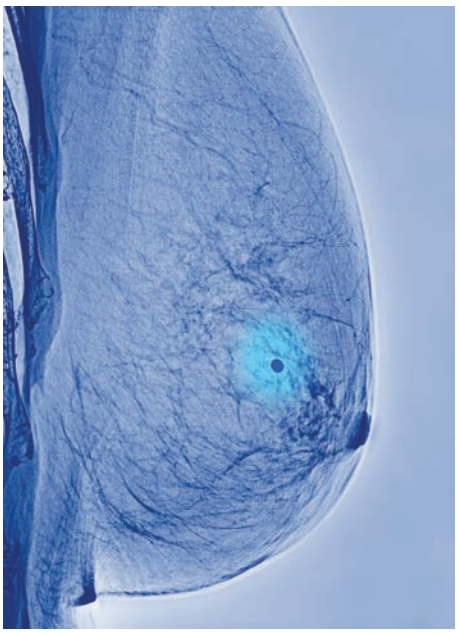
Inquiring About

Breast Cancer

How common is breast cancer? According to the American Cancer Society, breast cancer is the most common type of cancer in the United States (exceeded only by skin cancer). More than 250,000 new cases of invasive breast cancer are diagnosed each year, and more than 40,000 women die from breast cancer every year. Breast cancer is the second leading cause of cancer deaths (exceeded only by lung cancer). Risk factors for breast cancer include being overweight (especially after menopause), alcohol use (more than two drinks per day), and lack of exercise. Some studies show that cigarette smoking is also a risk factor.

About 25 genetic mutations have been linked to breast and ovarian cancer. Women with a family history of breast cancer are at higher risk than those without such family history. An estimated 10% of breast cancers are familial, and about half of these patients have mutations in a tumor suppressor gene, either *BRCA1* or *BRCA2* (see Fig. 17-21). When the normal protein product of the *BRCA1* gene is phosphorylated by a specific protein kinase, it interacts with the normal protein product of the *BRCA2* gene and certain other compounds to repair DNA damage. Women with a family history of breast (or ovarian) cancer should seek genetic counseling and consider genetic testing. For those who test positive, there are now drugs available (such as tamoxifen) that decrease the risk of cancer. Some women choose preventive surgery.

About 50% of breast cancers begin in the upper, outer quadrant of the breast. As a malignant tumor grows, it may adhere to the deep tissue of the chest wall. Sometimes it extends to the skin, causing dimpling. Eventually, the cancer spreads to the lymphatic system. About two-thirds of breast cancers have metastasized (spread) to the lymph nodes by the time they are first diagnosed. When diagnosis and treatment begin early, about 86% of patients survive for five years, and 65% survive for 20 years or longer. Untreated patients have a 5-year survival rate of only 20%.



Common methods of treating breast cancer include mastectomy (surgical removal of the breast), chemotherapy, and radiation treatment. Lumpectomy (surgical removal of only the affected portion of the breast) in conjunction with radiation treatment appears to be as effective as mastectomy in some cases. *Chemotherapy* (chemo) is treatment with drugs that kill cancer cells. Chemotherapy is often administered after surgery to destroy any cancer cells that may have broken away from the main tumor and escaped surgical removal. Even in the early stages of cancer, *metastasis* can occur: Cancer cells may move away from the primary tumor and establish new tumors in other parts of the body.

Targeted therapy involves the use of newer drugs that specifically target certain changes in cancer cells. Targeted therapy is often used along with chemotherapy. For example, in about one in five individuals with breast cancer, HER2, a protein that promotes growth, is present in abnormally large amounts on the surface of cancer cells. Cancer cells with HER2 spread more aggressively than other cancer cells. Monoclonal antibodies, such as Herceptin, have been developed that slow the growth of these cells. These drugs may also stimulate the immune system to more effectively destroy the cancer.

To grow, tumors must stimulate growth of new blood vessels. A monoclonal antibody has been developed that targets the growth of new blood vessels that supply the tumors. New drugs are being developed that target specific proteins that promote tumor growth.

About two-thirds of breast cancers have estrogen or progesterone receptors. Growth of these cancers is enhanced by circulating estrogens and progesterone. Removing the ovaries in patients with these tumors relieves the symptoms and may cause remission of the disease for months or even years. Drugs (e.g., tamoxifen and aromatase inhibitors) have been developed that antagonize the action of estrogen receptors.

According to the American Cancer Society, when breast cancer is confined to the breast, the 5-year survival rate is almost 100%. Because early detection of breast cancer greatly increases the chances of cure and survival, self-examination and screening are important. The American Cancer Society recommends that women in their 20s and 30s should have a clinical breast exam by a health professional about every three years. After age 40, women should have an annual breast exam by a health professional. Women age 40 and older should have a screening mammogram annually. *Mammography*, a soft-tissue radiological study of the breast, is helpful in detecting very small lesions that might not be identified by routine examination. In mammography, lesions show on an X-ray plate as areas of increased density (see figure). Tomosynthesis, which is 3-D mammography, is increasing in use and appears to be a more effective way to image the breast, especially when it is dense.

Deco/Alamy Stock Photo

Mammogram showing area of breast cancer. Cancer is seen as a dense mass (*blue*) in this colorized mammogram. The healthy fibrous tissue (*lavender*) supports the glandular structures.

Hormones of the hypothalamus, anterior pituitary, and ovaries regulate the **menstrual cycle**, the monthly sequence of events that prepares the body for possible pregnancy. (The term *menstrual cycle* is sometimes used more narrowly to refer to the changes that occur in the uterus; we use the term here to include both the ovarian and uterine cycles.) The menstrual cycle runs its course every month from puberty until *menopause*, which occurs at about age 50. Although wide variations exist, a typical menstrual cycle is 28 days long (FIG. 50-14).

The first two weeks of the menstrual cycle make up the *preovulatory phase*. Ovulation occurs on about the 14th day of the cycle. The third and fourth weeks of the menstrual cycle are the *postovulatory phase*. As you read the following description of the menstrual cycle, follow the steps illustrated in FIGURE 50-15 on page 1090.

The preovulatory phase spans the first two weeks of the cycle The first day of the menstrual cycle is marked by the onset of *menstruation*, the monthly discharge through the vagina of blood and tissue from the endometrium. Accordingly, the first five days or so of the preovulatory phase are known as the *menstrual phase*. During the first part of the preovulatory phase,

Table 50-2 Principal Female Reproductive Hormones

Endocrine Gland and Hormones	Principal Target Tissue	Principal Actions
HYPOTHALAMUS		
Gonadotropin-releasing hormone (GnRH)	Anterior pituitary	Stimulates release of FSH and LH
ANTERIOR PITUITARY		
Follicle-stimulating hormone (FSH)	Ovary	Stimulates development of follicles and secretion of estrogen
Luteinizing hormone (LH)	Ovary	Stimulates ovulation and development of corpus luteum
Prolactin	Breast	Stimulates milk production (after breast has been prepared by estrogen and progesterone)
POSTERIOR PITUITARY		
Oxytocin	Uterus	Stimulates contraction and stimulates prostaglandin release
	Mammary glands	Stimulates ejection of milk into ducts
OVARIES		
Estrogens (estradiol)	General	Stimulates growth of sex organs at puberty and development of secondary sex characteristics
	Reproductive structures	Induces maturation; stimulates monthly preparation of endometrium for pregnancy; makes cervical mucus thinner and more alkaline
Progesterone	Uterus	Completes preparation of endometrium for pregnancy
Inhibin	Anterior pituitary	Inhibits secretion of FSH

the hypothalamus releases *gonadotropin-releasing hormone (GnRH)*. This hormone stimulates the anterior pituitary to release gonadotropic hormones: *follicle-stimulating hormone (FSH)* and *luteinizing hormone (LH)*. GnRH, FSH, and LH are the same hormones that help regulate reproduction in the male.

The preovulatory phase is also called the *follicular phase* because during this period, FSH stimulates a few follicles to begin to develop in the ovary. FSH also stimulates the granulosa cells of the follicle to multiply and produce estrogen. Some estrogen diffuses into the blood, but estrogen also has an *autocrine* action on the granulosa cells that produce it and a *paracrine* effect on nearby granulosa cells (see Chapter 49 for a discussion of autocrine and paracrine regulation). The amount of estrogen secreted by the granulosa cells is enhanced by the action of LH on the theca cells. LH stimulates the theca cells to proliferate and produce androgens. The androgens diffuse into the granulosa cells, where they are converted to estrogen. Estrogen stimulates growth of the endometrium, which begins to thicken and develop new blood vessels and glands.

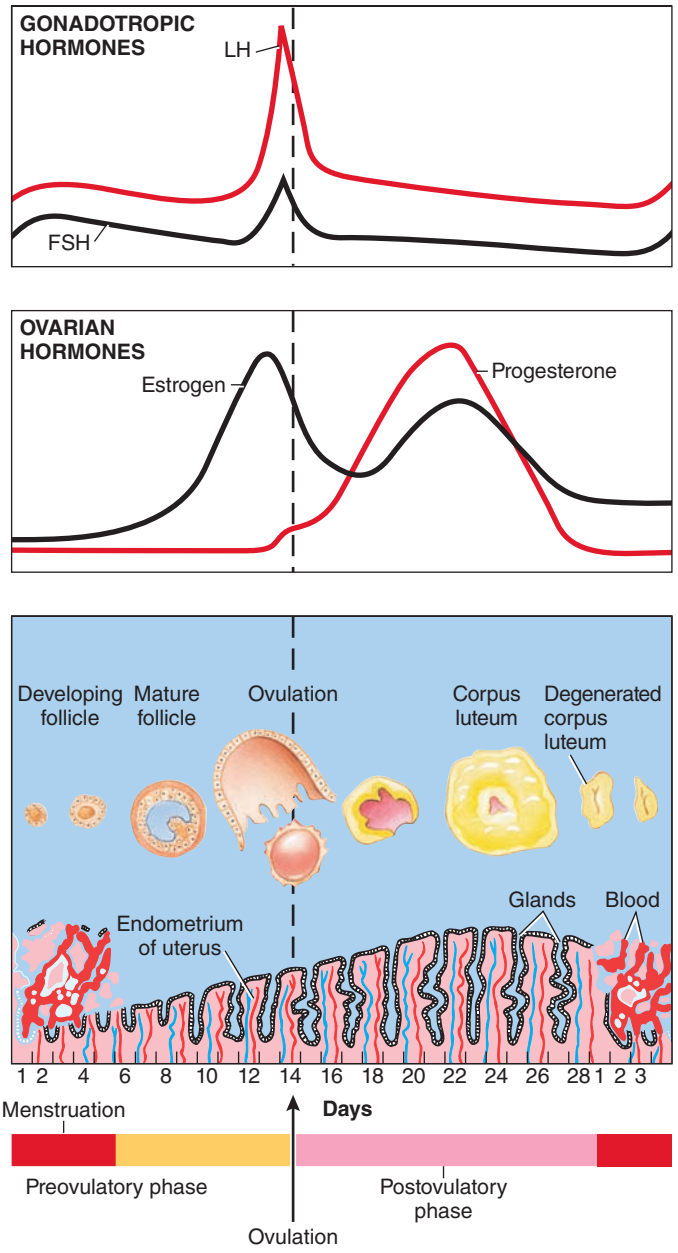
Typically, after the first week of the menstrual cycle, only one follicle continues to develop. Its granulosa cells become sensitive to LH as well as to FSH. This dominant follicle now secretes enough estrogen to cause a rise in the concentration of estrogen in the blood. *Although still at relatively low concentration*, estrogen inhibits secretion of FSH from the pituitary. Estrogen also acts directly on certain neurons in the hypothalamus, which inhibit secretion of GnRH. In addition, the granulosa cells secrete *inhibin*, a hormone that mainly inhibits FSH secretion. As a result of these negative feedback signals, FSH concentration decreases.

As its concentration in the blood peaks during the late preovulatory phase, estrogen signals a different set of neurons in the hypothalamus to stimulate GnRH secretion. The GnRH stimulates the anterior pituitary to secrete LH, which increases estrogen production by the follicle. This is a positive feedback mechanism. *The high estrogen concentration stimulates a surge in LH secretion*.

The surge of LH secreted at the middle of the menstrual cycle stimulates the final maturation of the follicle. The LH surge also stimulates *ovulation*, the ejection of the secondary oocyte from the ovary. The granulosa cells of the follicle decrease their estrogen output, resulting in a temporary decrease in estrogen concentration.

The corpus luteum develops during the postovulatory phase The postovulatory phase, also called the *luteal phase*, begins after ovulation. LH stimulates development of the corpus luteum, which secretes a large amount of progesterone and estrogen as well as inhibin. These hormones stimulate the uterus to continue its preparation for pregnancy. Progesterone stimulates tiny glands in the endometrium to secrete a fluid rich in nutrients.

During the postovulatory phase, the high concentration of progesterone in the blood, along with estrogen, inhibits secretion of GnRH, FSH, and LH. Progesterone acts on the hypothalamus and the anterior pituitary. Inhibin acts on the anterior pituitary to further inhibit FSH secretion. As a result of these negative feedback systems, FSH and LH concentrations are low during the postovulatory phase, and no new follicles develop.



If the secondary oocyte is not fertilized, the corpus luteum begins to degenerate after about eight days. Although the mechanism responsible for corpus luteum degeneration is not completely understood, the decrease in LH is an important factor. When the corpus luteum stops secreting progesterone and estrogen, the concentrations of these hormones in the blood fall markedly. As a result, small arteries in the endometrium constrict, reducing the oxygen supply. Menstruation,

Key Point

Gonadotropic hormones and ovarian hormones regulate the monthly sequence of events that take place within the ovary and uterus. The preovulatory phase begins with menstruation; the postovulatory phase begins after ovulation.

(a) Concentrations of pituitary gonadotropic hormones. Note that the concentrations of both FSH and LH peak just prior to ovulation (*dotted line*).

(b) Concentrations of ovarian hormones. Estrogen concentration peaks during the late preovulatory phase. Progesterone, secreted mainly by the corpus luteum, reaches its peak concentration during the postovulatory phase.

(c) Ovarian and uterine cycles. Hormone concentrations correlate with changes that take place in the ovaries and uterus. If fertilization occurs, the corpus luteum continues to secrete estrogen and progesterone, and menstruation does not occur.

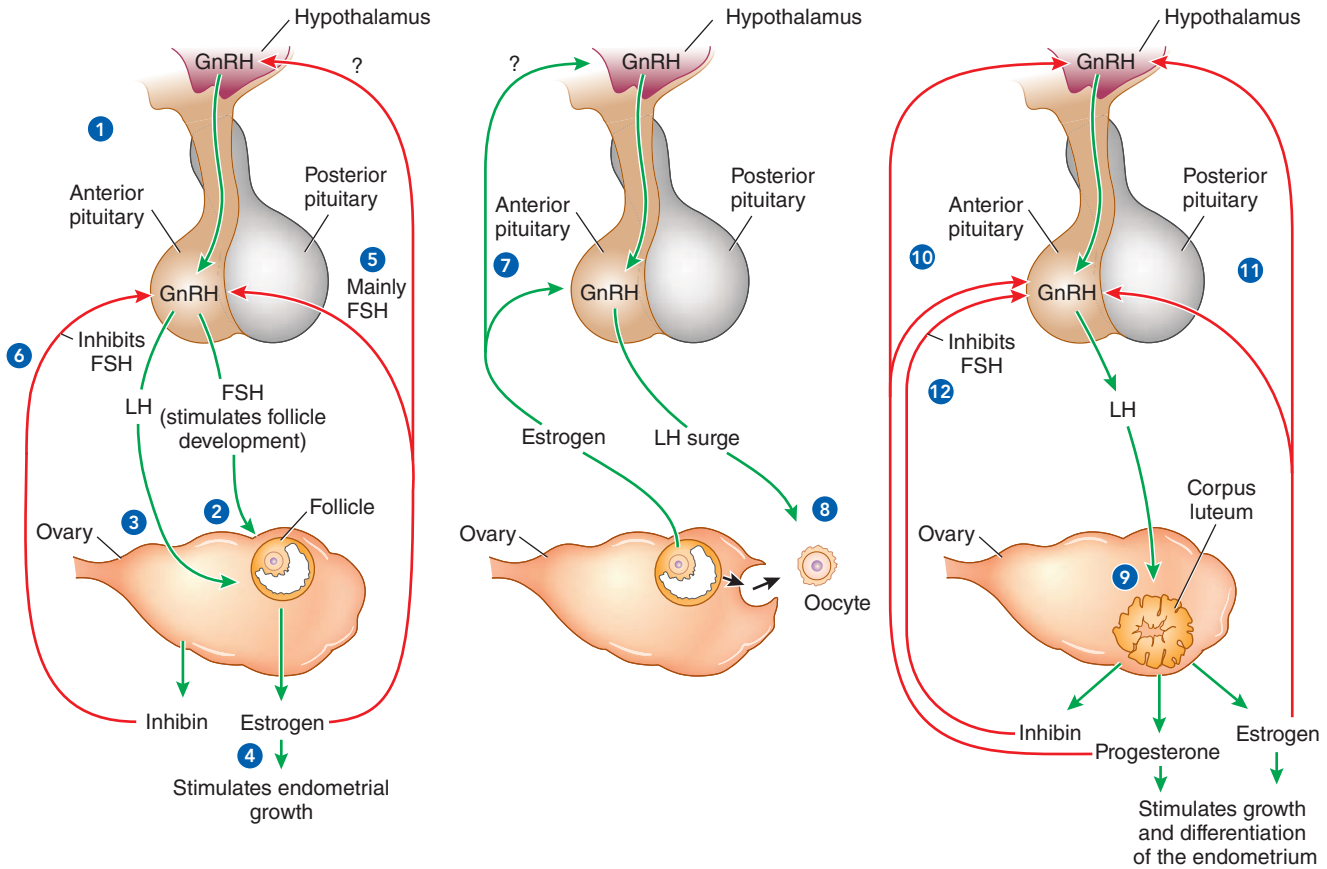
Figure 50-14 Endocrine regulation of the menstrual cycle

When fertilization does not occur, the menstrual cycle repeats about every 28 days. Note the changes in hormone concentrations that regulate the menstrual cycle. (FSH, follicle-stimulating hormone; LH, luteinizing hormone)

PREDICT What happens when a woman's ovaries produce a very low amount of estrogen?

which marks the beginning of a new cycle, begins as cells die and damaged blood vessels rupture and bleed. The concentrations of estrogen and progesterone are now too low to inhibit the anterior pituitary, and secretion of FSH and LH increases once again.

Menstrual cycles stop at menopause



At about age 50, a woman enters **menopause**, a period when ova are no longer produced and the woman becomes infertile. Apparently, a change in the hypothalamus triggers menopause.

Key Point

The hypothalamus, anterior pituitary, and ovary secrete hormones that regulate the menstrual cycle through feedback systems.

(a) Preovulatory phase.

1. Hypothalamus releases GnRH.
2. FSH stimulates follicle development.
3. LH indirectly stimulates estrogen production.
4. Estrogen stimulates thickening of endometrium.
5. Estrogen has a negative feedback effect on the pituitary and hypothalamus.
6. Inhibin inhibits FSH secretion by pituitary.

(b) Late preovulatory phase.

7. High concentration of estrogen has a positive feedback effect on the pituitary and hypothalamus.
8. Surge of LH stimulates ovulation.

(c) Postovulatory phase.

9. LH stimulates development of corpus luteum.
10. High concentration of progesterone strongly inhibits hypothalamus and anterior pituitary. FSH and LH secretion decreases.
11. Estrogen has a negative feedback effect on the hypothalamus and anterior pituitary.
12. Inhibin inhibits FSH secretion by pituitary.

Figure 50-15 Feedback mechanisms in endocrine regulation of female reproduction

The secretion and interaction of hormones changes during the phases of the menstrual cycle. *Green arrows* indicate stimulation; *red arrows* indicate inhibition. (GnRH, gonadotropin-releasing hormone; FSH, follicle-stimulating hormone; LH, luteinizing hormone)

PREDICT Imagine that the anterior pituitary no longer responded to inhibin. How would that affect the ovary?

Although gonadotropic hormones are produced, the ovaries become less responsive to them, and the oocytes in the ovaries begin to degenerate. The ovaries secrete less estrogen and progesterone than previously, and the menstrual cycle becomes irregular and eventually halts.

Women in menopause sometimes experience a sensation of heat ("hot flashes"), probably because of less stable regulation of blood flow through blood vessels in the skin. Periodic increases of warm blood through these blood vessels may cause the sensation of a hot flash. Other physiological changes associated with menopause include night sweats, mood swings, and weight gain. Although its use is controversial, hormone replacement therapy with estrogen and progesterone relieves symptoms of menopause for many women.

Progesterone is needed to protect the uterus from uterine cancer. If the uterus has been removed by hysterectomy, estrogen alone is used to alleviate menopause symptoms.

In contrast to humans, females of other species maintain their ability to reproduce throughout the lifespan. They do not experience menopause. Researchers have suggested that the infertile postmenopausal period allows older women to help their daughters with grandchildren, increasing their survival rate. This practice may help ensure that the older woman's genes will be transmitted to future generations.

Most mammals have estrous cycles

Only humans and some other primates have menstrual cycles. Most other mammals have *estrous cycles*. Although their reproductive organs and hormones are generally similar, there are some important differences. In animals with estrous cycles, the uterus reabsorbs the thickened lining of the endometrium if conception does not occur. As we have just learned, in animals with a menstrual cycle, the endometrium is expelled during menstruation.

Female animals with estrous cycles are sexually receptive ("in heat") only during the *estrus phase* of the cycle. The frequency and length of the estrus phase vary. In dogs, the estrus phase typically occurs twice a year and lasts 4 to 13 days. Estrus occurs every 4 to 5 days in rodents. In cats, cycles can occur about every three weeks, and the estrus phase averages 7 days. The resting phase of the cycle is prolonged in the fall and early winter. (Why might that be advantageous?) Animals with estrous cycles typically display physiological and behavioral changes that signal sexual readiness to potential mates.

CHECKPOINT 50.3

- How is oogenesis different from spermatogenesis?
- **PREDICT** What would happen if ovulation occurred but no corpus luteum developed?
- **VISUALIZE** Draw a diagram illustrating hormone interactions during the preovulatory phase. What are the specific actions of FSH? of estrogens?

50.4 Fertilization, Pregnancy, and Birth

LEARNING OBJECTIVE

8 Describe the process of human fertilization and summarize the actions of hormones that regulate pregnancy and birth.

Hormones play key roles in preparing the body for fertilization and pregnancy. These signaling molecules are also critical in initiating the birth process.

Fertilization is the fusion of sperm and egg

Fertilization and establishing pregnancy together are referred to as *conception*. After ejaculation into the female reproductive tract, sperm typically remain alive and retain their ability to fertilize an ovum for about 48 hours. However, sperm can survive up to five days in the female reproductive tract. The ovum remains fertile for 12 to 24 hours after ovulation. Therefore, in a very regular 28-day menstrual cycle, heterosexual intercourse during the middle of the cycle is most likely to result in fertilization. However, many women do not have regular menstrual cycles, and many factors can cause an irregular cycle even in women who are generally regular.

When conditions in the vagina and cervix are favorable, sperm begin to arrive at the site of fertilization in the upper oviduct within 30 minutes after ejaculation. At the time of ovulation, when estrogen concentration is high, the cervical mucus has a thin consistency that permits passage of sperm from the vagina into the uterus. During the rest of the menstrual cycle, the cervical mucus is too thick and sticky for sperm to penetrate.

Once sperm enter the uterus, contractions of the muscular uterine wall help transport them. When they reach the oviduct, contractions of smooth muscle in the wall of the oviduct help move sperm toward the egg. The uterine and oviduct contractions are induced by the high estrogen concentration present just before ovulation. Prostaglandins in the semen contribute to this muscle contraction. The sperm's own motility is important, especially in approaching and fertilizing the secondary oocyte. Also, the secondary oocyte is thought to release a compound that attracts the sperm.

When a sperm encounters an egg, openings develop in the sperm acrosome, exposing enzymes that digest a path through the zona pellucida surrounding the secondary oocyte. As soon as one sperm enters the secondary oocyte, changes occur that prevent the entrance of other sperm. As the fertilizing sperm enters, it usually loses its flagellum (FIG. 50-16). Sperm entry stimulates the secondary oocyte to complete its second meiotic division. The head of the haploid sperm then swells to form the *male pronucleus* and fuses with the *female pronucleus* to form the diploid nucleus of the zygote. The process of fertilization is described in more detail in Chapter 51 (also see *Inquiring About: Novel Origins*).

If only one sperm is needed to fertilize a secondary oocyte, why are more than a million sperm ejaculated? First, many die as a result of unfavorable pH or phagocytosis by white blood cells and macrophages in the female tract. Only a few hundred succeed in making their way up the correct oviduct and reaching the vicinity of the secondary oocyte. Second, the enzymes released by the acrosomes of many sperm are needed to break down the barriers that surround the secondary oocyte.

When the secondary oocyte is fertilized, development begins while the embryo is still in the oviduct. After three or four days, the progesterone concentration is sufficiently high to induce changes that permit the oviduct to move the embryo to the uterus. The embryo is moved along by muscle

Inquiring About

Novel Origins

What are some benefits of reproductive technology? About six million couples of reproductive age in the United States are affected by infertility, the inability to achieve conception after using no contraception for at least one year. More than three million infertile couples consult health care professionals each year. Some are helped with conventional treatment, such as with hormone therapy that regulates ovulation or with fertility drugs.

About 30% of infertility cases involve both male and female factors. Male infertility is often attributed to low sperm count. Sperm can be concentrated; alternatively, sperm from a donor can be used to fertilize an egg. Although the sperm donor usually remains anonymous to the prospective birth parents, his genetic qualifications are screened by physicians.

Among the common causes of female infertility are failure to ovulate, production of infertile eggs (common in older women), and oviduct scarring (often caused by pelvic inflammatory disease). Women with blocked oviducts can usually ovulate and incubate an embryo normally but need clinical assistance in getting the young embryo to the uterus.

Many couples are helped with **artificial insemination**, in which a catheter is used to inject sperm directly into the cervix or uterus. Transfer into the uterus is called *intrauterine insemination (IUI)*. More than 600,000 IUI procedures are performed annually, with a success rate of about 10%.

More than 40,000 couples need more sophisticated clinical help. They turn to high-tech, *assisted reproductive techniques (ART)* that have been developed through reproduction and human embryo research. Currently, these techniques are expensive, and the success rate is low, less than one-third. According to the Centers for Disease Control and Prevention (CDC), more than 1% of all infants born in the United States are conceived using ART, including in vitro fertilization, gamete intrafallopian transfer, and zygote intrafallopian transfer.

Using **in vitro fertilization (IVF)** , a woman takes a fertility drug that induces ovulation of several eggs. The eggs are retrieved by needle aspiration through the vagina. These eggs are placed in a dish with sperm, and fertilization takes place in vitro (outside the patient's body). Embryos are cultured for three to five days and then screened for chromosome or gene abnormalities. Healthy ones are transferred into the uterus through the vagina. IVF was first used in England in 1978 to help a couple who had tried unsuccessfully for several years to have a child. Since that time, thousands of babies have been conceived and born in this way. The success rate of in vitro fertilization is more than 30%; women younger than 35 years have the highest rate of pregnancy, and the rate declines with age.

In *gamete intrafallopian transfer (GIFT)*, a laparoscope (a fiber-optic instrument) is used to guide the transfer of eggs and sperm into a woman's oviduct through a small incision in her abdomen. More than 4000 of these expensive procedures are performed each year, with a success rate of about 28%.

In *zygote intrafallopian transfer (ZIFT)*, the woman's own ova may be used. However, if she does not produce fertile eggs, they can be contributed by a donor (oocyte donation). The ova are fertilized in the laboratory. A laparoscope is used to guide the transfer of the resulting zygotes into the oviduct. The fertilized eggs move through the oviduct into the uterus.

Another novel procedure is **host mothering**. An embryo is removed from its natural mother and implanted into a female substitute. The foster mother can support the developing embryo either until birth or temporarily until it is implanted again into the original mother or another host. This technique has proved useful to animal breeders. For example, embryos from prize sheep can be temporarily implanted into rabbits for easy shipping by air and then implanted into a host ewe, perhaps one of inferior quality. Host mothering allows an animal with superior genetic traits to produce more offspring than would be naturally possible. This procedure is also used to increase the populations of certain endangered species (see photograph).

Technology is available to freeze the gametes or embryos of many species, including humans, and then transplant them into their donors or into host mothers. Freezing eggs can be an effective strategy for women with cancer who must undergo chemotherapy or for women not yet ready to become parents but who want to preserve young eggs with lower risk for chromosome abnormality. These eggs can be implanted at a later time.

Newborn bongo with its surrogate mother, an eland. As a young embryo, the bongo was transplanted into the eland's uterus, where it implanted and developed. Bongos are a rare and elusive species that inhabits dense forests in Africa. The larger and more common elands inhabit open areas.

contractions and by the cilia lining the oviduct. By the time it enters the uterus, cleavage has occurred and the embryo consists of a ball of about 32 cells. After floating free in the uterus for another three to four days, the embryo (which has developed into a *blastocyst*) begins to implant in the thick endometrium. Implantation occurs on about the seventh day after fertilization (FIG. 50-17). (See Chapter 51 for a discussion of development.)

Figure 50-16 Fertilization

Hormones are necessary to maintain pregnancy

Estrogen and progesterone are necessary to maintain conditions required for pregnancy. Estrogen stimulates development of the uterine wall, including the muscle needed to expel the fetus during delivery. Progesterone inhibits uterine contractions so that the fetus is not expelled too soon. Because these hormones also inhibit FSH and LH, new follicles do not develop, and the menstrual cycle stops during pregnancy.

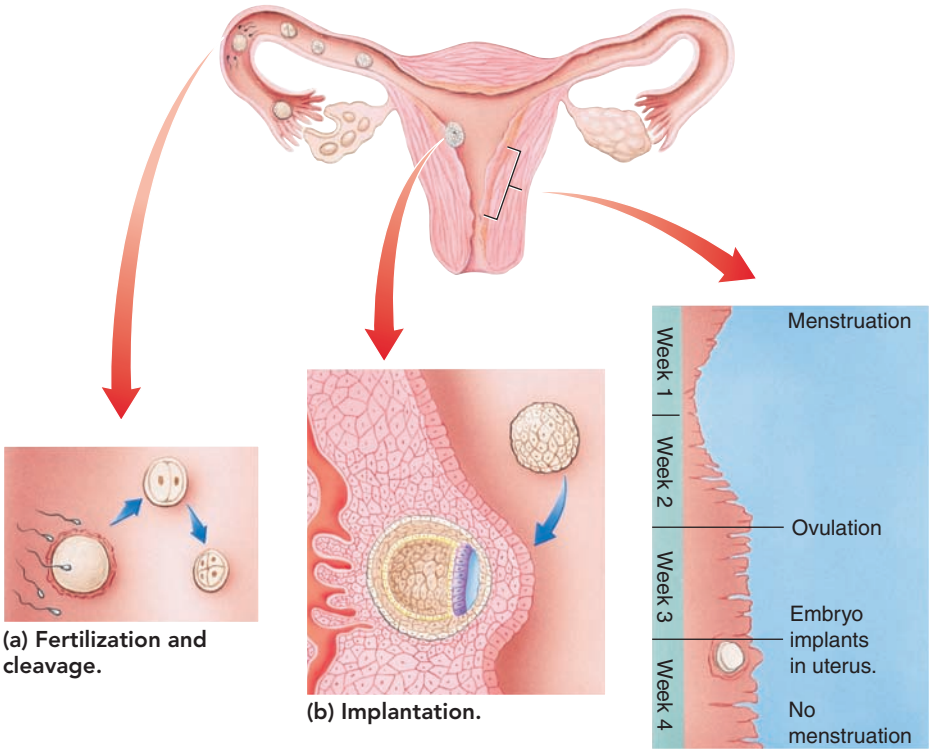
Membranes that develop around the embryo secrete **human chorionic gonadotropin (hCG)**, a peptide hormone that signals the mother's corpus luteum to continue to function. (The presence of hCG in urine or blood is used as an early pregnancy test.) Concentrations of estrogen and progesterone remain high throughout pregnancy. During the first two months, the corpus luteum secretes almost all the estrogen and progesterone necessary to maintain the pregnancy. During this time, membranes surrounding the embryo, together with uterine tissue, form the **placenta**, the organ of exchange between the mother and developing embryo. By the tenth week of pregnancy, hCG secretion decreases, and the corpus luteum begins to deteriorate. The placenta takes over and secretes large amounts of estrogen and progesterone.

The birth process depends on a positive feedback system

A normal human pregnancy is about 38 weeks long, counting from the day of fertilization, or about 40 weeks from the first day of the last menstrual cycle. The mechanisms that terminate pregnancy and initiate the birth process depend on several hormones. High levels of estrogen secreted by the placenta greatly increase the number of receptors for oxytocin in the uterine wall. As a result, the uterus becomes about one hundred times more responsive to oxytocin, the hormone that stimulates uterine contractions. (Other hormones are involved, but discussion of their roles is beyond the scope of this chapter.)

At the end of pregnancy, the stretching of the uterine muscle by the growing fetus combined with the effects of increased estrogen concentration and oxytocin produce strong uterine contractions. A long series of involuntary contractions of the uterus are experienced as *labor*. Real labor begins when uterine contractions occur in a frequent, regular pattern and cause the cervix to change in preparation for delivery.

Labor can be divided into three stages. During the first stage, which typically lasts 8 to 10 hours, the contractions of the uterus move the fetus toward the cervix, causing the cervix to *dilate* (open) to a maximum diameter of 10 cm (4 in.). The cervix also becomes *effaced*; that is, it thins out so that the fetal head can pass through. During the first stage of labor, the amnion (the membrane that forms a fluid-filled sac around the embryo/fetus) usually ruptures and releases about a liter of amniotic fluid, which flows out through the vagina.



A positive feedback cycle operates during the birth process. As the baby's head pushes against the cervix, a reflex action causes the uterus to contract. The contraction forces the head against the cervix again, resulting in another contraction, and the positive feedback cycle repeats again and again until the baby descends through the cervix.

During the second stage, which normally lasts from 20 minutes to an hour, the fetus passes through the cervix and vagina and is born, or "delivered" (FIG. 50-18). With each uterine contraction, the woman bears down so that the fetus is expelled by the combined forces of uterine contractions and contractions of abdominal wall muscles.

At birth, the baby is still connected to the placenta by the umbilical cord. Contractions of the uterus squeeze much of the fetal blood

(c) Changes in endometrium.

Figure 50-17 Events following fertilization

The ovarian and uterine cycles are interrupted when pregnancy occurs. The corpus luteum does not degenerate, and menstruation does not take place. Instead, the wall of the uterus continues to thicken, permitting the embryo to implant and develop within it. (Cleavage is the early series of mitotic divisions that converts the zygote to a multicellular embryo.)

from the placenta into the infant. The cord is tied and cut, separating the child from the mother. (The stump of the cord gradually shrivels until nothing remains but the scar, the *navel*.)

During the third stage of labor, which may last 5 to 30 minutes after the birth, the placenta and the fetal membranes are loosened from the lining of the uterus by another series of contractions and are expelled. At this stage they are collectively called the *afterbirth* because these tissues are expelled from the vagina after the baby has been delivered.

During labor, an obstetrician may administer synthetic oxytocin to increase the contractions of the uterus or may assist delivery with special forceps or a vacuum device. In some women, the opening between the pelvic bones is too small to permit the passage of the baby vaginally. In this situation, the obstetrician performs a *cesarean section* (C-section), a surgical procedure in which the baby is delivered through an incision made in the abdominal and uterine walls. A C-section may also be performed if the baby's position prevents normal delivery or if the baby shows signs of distress.

CHECKPOINT 50.4

50.5 Human Sexual Response

LEARNING OBJECTIVE

9 Describe the physiological changes that take place during human heterosexual intercourse.

Human sexual responses can be varied. Here we describe *heterosexual intercourse*, the type of human sexual activity that has been the focus of the most extensive scientific research. During heterosexual intercourse, the male deposits semen into the upper end of the vagina. The complex structures of the male and female reproductive systems, and the physiological, endocrine, and psychological processes associated with sexual activity, are adaptations that promote fertilization of the secondary oocyte and thus perpetuation of the species.

Sexual stimulation results in two basic physiological responses: (1) vasocongestion, the concentration of blood in reproductive structures as well as in certain other areas of the body; and (2) increased muscle tension. Sexual response includes four phases: sexual excitement, plateau, orgasm, and resolution. The *desire* to have sexual activity may be motivated by fantasies or thoughts about sex. This anticipation can lead to (physical) sexual excitement and a sense of sexual pleasure.

Physiologically, the *sexual excitement phase* involves *vasocongestion*, engorging a tissue with blood, and increased muscle tension. Penile erection is the first male response to sexual excitement. Vasocongestion makes the penis erect so that it can enter the vagina and function in sexual intercourse. In the female, vasocongestion occurs in the vagina,

(d) During the third stage of labor, the placenta is delivered.

Figure 50-18 The birth process

Uterine contractions during labor expel the fetus from the uterus. In about 95% of human births, the baby descends through the cervix and vagina in the head-down position.

clitoris, labia, and breasts. The vaginal epithelium secretes a sticky lubricant. Vaginal lubrication is the female's first response to effective sexual stimulation. During the excitement phase, the vagina lengthens and expands in preparation for receiving the penis.

If erotic stimulation continues, sexual excitement heightens to the *plateau phase*. Vasocongestion and muscle tension increase markedly. In both sexes, heart rate, blood pressure, and respiration rate increase. Sexual intercourse is usually initiated during the plateau phase. The penis creates friction as it is moved inward and outward in the vagina, in actions referred to as pelvic thrusts. Physical sensations resulting from this friction and the psychological experience of emotional intimacy lead to **orgasm**, the intense physical pleasure that is the climax of sexual excitement. In the female, stimulation of the clitoris heightens the sexual excitement that leads to orgasm.

Although it lasts only a few seconds, orgasm is the phase of maximum sexual tension and its release. Musculoskeletal contractions occur, especially in the reproductive structures. Heart rate and respiration more than double, and blood pressure increases markedly, just before and during orgasm. In both sexes, orgasm is marked by rhythmic contractions of the muscles of the pelvic floor and reproductive structures. These muscular contractions continue at about 0.8-second intervals for several seconds. After the first few contractions, their intensity decreases, and they become less regular and less frequent.

The male orgasm is marked by *ejaculation* of semen from the penis. Semen is typically ejaculated in about seven spurts that accompany the rhythmic contractions. No fluid ejaculation accompanies orgasm in the female. Orgasm is followed by the *resolution phase*, a state of well-being during which the body is restored to its unstimulated state.

- What physiological changes take place during the sexual response cycle?

50.6 Birth Control Methods and Abortion

LEARNING OBJECTIVE

10 Compare the modes of action, effectiveness, advantages, and disadvantages of the methods of birth control discussed, including sterilization and emergency contraception; distinguish between spontaneous and induced abortions.

Worldwide, there are about 135 million births per year. Population experts estimate that more than one-fourth of them are unplanned. An estimated 50 million induced abortions are performed annually. Although most couples worldwide might agree that it is best to have babies by choice rather than by chance, many do not have contraceptives available to them. (About one-fourth of women in developing countries have an unmet need for contraception.) Women who do not have access to modern contraceptives account for 84% of unintended pregnancies.

In the United States, nearly half of all pregnancies are unintended. Teen pregnancy is a particularly serious problem. Many teens lack the knowledge and means of protecting themselves from unwanted pregnancy. Not surprisingly, about 80% of teen pregnancies are unplanned. About 30% of teen pregnancies end in abortion. According to the Centers for Disease Control and Prevention, in 2015, 229,715 babies were born to teenagers aged 15 to 19 years. (This represents a birth rate of 22.3 per 1000 women in this age group.) These numbers represent a decline in teen birth rate, apparently due to fewer teens engaging in sexual activity and the greater availability of effective birth control methods.

Many birth control methods are available

When a fertile, heterosexually active woman uses no form of birth control, her chances of becoming pregnant during the course of a year are about 85%. Any method for deliberately separating sexual intercourse from reproduction is **contraception** (literally, "against conception").

Since ancient times, humans have searched for effective methods of preventing fertilization and pregnancy. Of course, fertilization can be avoided by abstaining from sexual intercourse, particularly around the time of ovulation. This cyclical temporary abstinence is called the *rhythm method* or *natural family planning*. Because the time of ovulation is difficult to determine, the rhythm method has a high failure rate (about 25%). Scientists continue to develop a variety of contraceptives with a high percentage of reliability. Some common methods of birth control are described in the following paragraphs and in TABLE 50-3. Oral contraceptives, intrauterine devices (IUDs), and female sterilization account for more than two-thirds of all contraception practiced worldwide.

Most hormonal contraceptives prevent ovulation

Hormonal contraceptives include oral contraceptives, contraceptive patches, rings, implants, and injectable contraceptives. More than 80 million women worldwide (more than 11 million in the United States alone) use oral contraceptives. When used as prescribed, oral contraceptives are about 99.7% effective in preventing pregnancy. They are also used to regulate menstrual cycles and help with symptoms associated with menstruation. The most common preparations are combinations of *progestins*, which are synthetic progesterones, and synthetic estrogen. (Natural hormones are destroyed by the liver almost immediately, but synthetic ones are chemically modified during production so that they can be absorbed effectively and metabolized slowly.) In a typical regimen, a woman takes one pill each day for about three weeks. Then, for one week she takes a sugar pill that allows menstruation to occur as a result of the withdrawal of the hormones. One type of oral contraceptive works on a 91-day regimen, reducing menstruation to four times per year. Other new oral contraceptives are being marketed as methods to manipulate menstrual cycles so that menstruation is shorter.

Oral contraceptives prevent ovulation. When postovulatory levels of ovarian hormones are maintained in the blood, the body is tricked into responding as though conception has occurred. The pituitary gland is inhibited and does not produce the surge of LH that stimulates ovulation.

Studies suggest that women older than age 35 who smoke or have other risk factors, such as untreated hypertension, should not take oral contraceptives. Women in this category who take oral contraceptives have an increased risk of death from stroke and myocardial infarction. Low-dose oral contraceptive pills appear safe for nonsmokers up to the time of menopause. Oral contraceptives are linked to deaths in about 3 per 100,000 users per year, which compares favorably with the death rate of about 9 per 100,000 pregnancies.

Trends in contraception are geared toward convenience and improved compliance. The birth control patch (Ortho Evra) delivers estrogen and progestin through the skin. Another approach is a thin, flexible plastic ring (NuvaRing) that women can flatten like a rubber band and insert into the vagina once a month. The ring releases progestin and estrogen in the amounts present in low-dose birth control pills. These types of contraception are convenient because they do not require a daily regimen, while maintaining a regular, predictable menstrual cycle.

Injectable progestin (Depo-Provera) is injected intramuscularly every three months. It prevents ovulation by suppressing anterior pituitary function; it also thickens the cervical mucus (which makes it more difficult for the sperm to reach the egg). Implanon and Nexplanon are implant systems. Each consists of a single plastic progestin rod (the size of a cardboard matchstick). The progestin is released over a three-year period. Many consider these implants the most effective birth control methods available.

Table 50-3 Selected Contraceptive Methods

Method	Percent Effective When Used Correctly	Mode of Action	Advantages	Disadvantages
Oral contraceptives (combined estrogen and progestin pill)	>99%	Inhibit ovulation	Highly effective; regulate menstrual cycle	Requires women to remember to take daily pill; should not be used by women over age 35 who smoke or have other risk factors
Contraceptive implants (progestin)	>99%	Prevent ovulation	Can be used for three years	May cause irregular vaginal bleeding
Injectable contraceptives (Depo-Provera)	97%–>99%	Inhibit ovulation	Effective; long-lasting	Irregular vaginal bleeding
Intrauterine devices (IUDs) (T-shaped plastic devices)	>99%		Provide continuous protection for several years; safe	Increase menstrual cramps and symptoms of endometriosis
One type releases progestins		Progestin thickens cervical mucus, preventing sperm from reaching ovum		
Second type has copper component		Copper stimulates inflammatory response in uterus		
Male condom	85% as commonly used; 98% with correct use	Mechanically prevents sperm from entering vagina	No side effects; some protection against STIs, including HIV	Slightly decreased sensation for male; could break
Rhythm method*	75% as commonly used	Abstinence or using condom during fertile period	No known side effects	Certain medications, such as antidepressants, anxiolytics, NSAIDS, and certain antibiotics may affect timing of ovulation
Withdrawal (coitus interruptus)	73% as commonly used	Male withdraws penis from vagina prior to ejaculation	No side effects	Not reliable; sperm in fluid secreted before ejaculation may be sufficient for conception
Sterilization				
Vasectomy	>99% after three months of semen evaluation		Most reliable male method	Requires surgery; considered permanent
Tubal ligation	>99%		Most reliable female method	Requires surgery; permanent
Chance of NOT becoming pregnant when NOT using contraception	About 15% (that is, about 85% become pregnant)			

SOURCES: World Health Organization, Centers for Disease Control and Prevention, and Guttmacher Institute.

* There are several variations of the rhythm method. For those who use the calendar method alone, the effective rate is about 65%. However, if body temperature is taken daily and careful records are kept (temperature rises after ovulation), the success rate can be increased. When women use some method to determine time of ovulation and have intercourse *only* more than 48 hours *after* ovulation, the effective rate can be even further increased.

Intrauterine devices are widely used

Contraceptive implants and IUDs are long-acting, reversible contraception (LARC). *The intrauterine device (IUD)* is the most widely used method of reversible contraception in the world, used by an estimated 90 million women. In the United States, however, only about 4 million women (about 10% of contraception users) use IUDs. The IUD is a small device that is inserted into the uterus by a health professional. The advantages of IUDs are that they are safe, about 99% effective, and completely reversible. IUDs can also improve the symptoms of a woman's menstrual periods. Disadvantages of the IUD include uterine cramping and bleeding in a small percentage of women.

IUDs are small, plastic T-shaped devices. Each releases a very small amount of a progestin hormone (levonorgestrel) onto the inner wall of the uterus. The progestin thickens the cervical mucus, which prevents sperm from reaching the secondary oocyte. Some brands of IUD (Mirena, Kyleena) can be left in place for up to five years. Another type of IUD (Skyla) contains less progestin; it can be left in place for about three years.

The Copper T IUD (ParaGard) contains no hormones. It is wrapped in copper, which stimulates an inflammatory response in the uterus. As a result, sperm are unable to reach the secondary oocyte. The Copper T IUD can be left in place for up to 10 years.

The IUD apparently prevents fertilization in a number of ways. Some IUDs cause the cervical mucus to thicken, which impedes passage of sperm into the uterus. The copper in an IUD apparently also reduces the ability of sperm to fertilize the egg. In addition, white blood cells mobilized in response to the foreign body (IUD) in the uterus may produce substances toxic to sperm.

Barrier methods of contraception include the diaphragm and condom

The *contraceptive diaphragm* mechanically blocks the passage of sperm from the vagina into the cervix. It is covered with spermicidal jelly or cream and inserted just prior to sexual intercourse. The contraceptive diaphragm has been largely replaced by more sophisticated birth control methods.

The *condom* is also a mechanical method of birth control. The only contraceptive device currently sold for men, the condom provides a barrier that contains the semen so that sperm cannot enter the female tract. The latex condom provides some protection against infection with HIV and other sexually transmitted infections (STIs).

The female condom is a strong, soft, polyurethane pouch, or sheath, inserted in the vagina before sexual intercourse. When used correctly, it provides protection against both pregnancy and sexually transmitted infections.

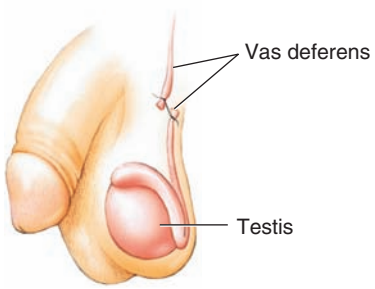
Emergency contraception is available

Emergency contraception is after-the-fact contraception for rape victims and others who have had unprotected sexual intercourse. Emergency contraception pills prevent fertilization or ovulation. They decrease the probability of pregnancy by about 89%. Although they are often called morning-after pills, emergency contraception pills can actually be taken up to four days after unprotected intercourse. The use of emergency contraception has significantly reduced the number of abortions. Emergency contraception is available to people of all ages without a prescription.

The most common types of emergency contraception are *progestin* pills, known as Plan B, and combination progestin-and-estrogen pills. Another pill, called "Ella," is also available for emergency contraception, but requires a prescription. Ella contains a nonhormonal medication (ulipristal) that works by preventing or postponing ovulation. This medication can be taken up to 120 hours (5 days) after unprotected intercourse. A less common type of emergency contraception is insertion of a copper IUD within five days of unprotected intercourse. This method is about 99% effective in preventing pregnancy.

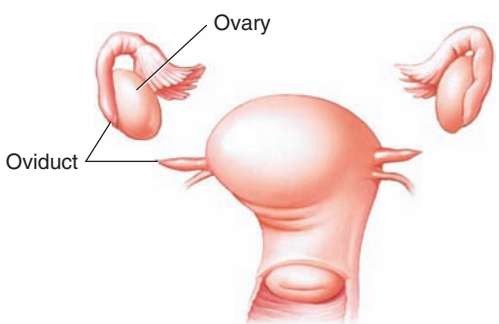
Sterilization renders an individual incapable of producing offspring

Sterilization is the only method of contraception not affected by failure to use a contraceptive method correctly. According to the World Health Organization, male sterilization is the most common contraceptive method in the world. It accounts for one-third of all contraceptive use. Interestingly, nine in ten sterilized persons are women.



Male sterilization is performed by vasectomy *Vasectomies* are performed using a local anesthetic. The physician makes a small incision on each side of the scrotum. Then each vas deferens is cut and its ends sealed so that they cannot grow back together (FIG. 50-19a). Because testosterone secretion is not affected, vasectomy does not affect masculinity. Sperm continue to be produced, although at a much slower rate, and are destroyed by macrophages in the testes. No change in amount of semen ejaculated is noticed because sperm account for very little of the semen volume.

By surgically reuniting the ends of the vasa deferentia, surgeons can successfully reverse sterilization in about 50% of males. However, some sterilized men eventually develop antibodies against their own sperm. These men remain sterile even after their vasectomies have been surgically reversed. Therefore, fertility rates are low (about 30%) for men who undergo vasectomy reversal after ten or more years.



An alternative to vasectomy reversal is the storage of frozen sperm in sperm banks. Such banks have been established throughout the United States. If the male should decide to father another child after he has been sterilized, he "withdraws" his sperm to artificially inseminate his mate. However, sperm do not always survive freezing, and even if they remain viable, there may be an increased risk of genetic defects.

Tubal sterilization blocks the oviducts In the United States, **tubal sterilization** is one of the most common means of birth control. As with the male, hormone balance and sexual performance of the female are not affected by sterilization. A surgeon performs this procedure either by laparoscopy or by open incision. Tubal sterilization is often performed at the time of a C-section. During female sterilization, the tubes are cauterized, clipped, or tied off (FIG. 50-19b).

More recently, tubal sterilization can be accomplished without an incision. Essure is a nonsurgical, permanent sterilization procedure in which small, flexible inserts are placed in the uterine tubes. Small coils are inserted through the vagina, so no incision is needed. The Essure apparatus causes tissue to grow around the insert. After about three months, this tissue growth blocks sperm from reaching an egg.

(a) Vasectomy. The vas deferens (sperm duct) on each side is cut and cauterized.

(b) Tubal sterilization. Each oviduct is cut and cauterized so that oocyte and sperm can no longer meet.

Future contraceptives may control regulatory peptides

Ideal contraceptives have not yet been developed. Among the issues that must be considered in developing contraceptives are safety, effectiveness, cost, convenience, and ease of use. Risks of cancer, birth defects in case the method fails and the woman becomes pregnant, permanent infertility, and side effects such as menstrual abnormalities must be minimized.

Investigators are currently exploring methods for interfering with sperm motility or with fertilization. For example, an injectable gel (Vasalgel) that blocks sperm passage through the vas deferens has been tested in primates. (Trials in humans will probably be taking place by the time you read these words.)

It is likely that current methods of contraception will be replaced by more sophisticated molecular methods within the next several years. Some researchers predict that future contraceptive methods will control regulatory peptides and the genes that code for them. For example, the genes that code for certain hormone signals could be interrupted. Another approach being studied is development of contraceptive vaccines that would stimulate the immune system to produce antibodies against hCG or some other protein essential to reproduction.

Abortions can be spontaneous or induced

Abortion is the termination of pregnancy that results in the death of the embryo or fetus. *Spontaneous abortions* (commonly referred to as miscarriages) occur without intervention. Embryos that are spontaneously aborted are frequently abnormal. *Induced abortions* are performed deliberately either for therapeutic reasons or as a means of birth control. *Therapeutic abortions* are performed when the mother's life is in danger or when there is reason to suspect that the embryo is grossly abnormal.

Abortions are sometimes used as a means of birth control. More than 40 million induced abortions are performed each year (more than 1 million in the United States). Many first-trimester abortions (those performed during the first three months of pregnancy) are performed by administering drugs that interrupt the pregnancy and induce expulsion of the embryo. The drug *RU-486* (mifepristone) binds competitively with progesterone receptors in the uterus but does not activate them. Because the normal actions of progesterone are blocked, the endometrium breaks down, and uterine contractions occur. These conditions prevent implantation of an embryo. Prostaglandins may then be administered to induce the uterine contractions that expel the embryo. Misoprostol (Cytotec) is a synthetic prostaglandin also used to terminate pregnancies. During a surgical abortion, the cervix is dilated, and a suction aspirator is inserted into the uterus. The embryo and other products of conception are evacuated.

After the first trimester, abortions are performed mainly because of fetal abnormalities or maternal illness. The method most commonly used is dilation and evacuation. The cervix is dilated, a forceps-type instrument is used to remove the fetus, and suction is used to aspirate the remaining contents of the uterus. Drugs such as prostaglandins are also used to induce labor in second-trimester abortions.

When abortions are performed by skilled medical personnel, they are relatively safe. The risk of death increases with the length of the pregnancy. In the United States, the mortality rate is less than 0.3 per 100,000 abortions performed at or before 8 weeks. Abortions performed at 18 weeks or later have a mortality rate of 6.7 per 100,000.[1] In countries where abortion is illegal (and unsafe), the death rate is as high as 450 per 100,000. These statistics can be contrasted with the death rate from pregnancy and childbirth of about 9 per 100,000. The World Health Organization estimates that about 13% of all maternal deaths result from poorly performed, illegal abortions.

CHECKPOINT 50.6

- How do hormone methods of contraception work?
- **PREDICT** The use of which types of contraception would have the greatest effect on the number of unwanted pregnancies?
- What is a spontaneous abortion? a therapeutic abortion?

50.7 Sexually Transmitted Infections

LEARNING OBJECTIVE

11 Identify common sexually transmitted infections and describe their symptoms, effects, and treatments.

Sexually transmitted infections (STIs), also called *sexually transmitted diseases (STDs)*, are the most prevalent communicable diseases in the world next to the common cold. The World Health Organization has estimated that more than 350 million new curable sexually transmitted infections occur each year. More than 62 million people are infected each year with *gonorrhea*, and more than 12 million are infected with *syphilis*. Globally, more than 37 million people are living with HIV, and more than 35 million have died of AIDS since 1981 (discussed in Chapter 45).

In the United States, more than 110 million people are currently living with an STI, and more than 20 million people (including 3 million teens) are diagnosed with new STI infections each year. One in three sexually active young people will acquire an STI by age 24. These young people account for 50% of all new STIs. Some common STIs are described in TABLE 50-4. (See Chapter 45 for a discussion of HIV.)

Human papillomavirus (HPV) is one of the two most common STIs in the United States. An estimated 14 million people in the United States are infected with HPV each year. In most infected individuals, the immune system destroys or suppresses the virus before it causes serious health problems. However,

[1] Data are from the Guttmacher Institute.

HPV can cause abnormal Pap smears and is the main cause of cervical cancer. Some strains of HPV cause genital warts.

Vaccines (Gardasil and Cervarix) prevent infection by several harmful HPV strains. Health professionals anticipate that use of these vaccines will lead to the decline of genital warts and cervical cancer. For the vaccine to be most effective, individuals should be vaccinated before they become sexually active. These vaccines are recommended for both females and males at ages 9 through 14.

Chlamydia is the most commonly reported STI in the United States. This STI is transmitted by having vaginal, anal, or oral sex with someone who has chlamydia. Most individuals infected with chlamydia do not know it because this disease causes no symptoms in about 50% of infected men and 75% of infected women. Infected men may notice a discharge from the penis, and infected women may have a vaginal discharge. In women, the infection can spread and cause *pelvic inflammatory disease (PID)*. This serious infection leads to infertility in about 20% of infected women.

About 16% of individuals age 14 to 49 years old are infected with **genital herpes**. This STI is caused by a herpes virus and can be transmitted by genital contact or by oral sex. Most infected individuals do not know they have the infection because it causes minimal symptoms, or no symptoms. When outbreaks occur, symptoms may include blisters around the genital area.

CHECKPOINT 50.7

- What are the two most common STIs in the United States?
- **CONNECT** What is PID? What causes it?

Table 50-4 Some Common Sexually Transmitted Infections

Disease and Causative Organism	Course of Disease	Treatment
Human papillomavirus (HPV; about 30 strains of HPV can infect reproductive organs)	Causes abnormal Pap smears and cervical cancer; some strains cause genital warts	Immune modifiers; interferon; vaccines available
Chlamydia (*Chlamydia trachomatis*, a bacterium)	Discharge and burning with urination, or asymptomatic; men ages 15–30 with multiple sex partners are most at risk; in women can cause pelvic inflammatory disease (PID), infection of reproductive organs and pelvic cavity that may lead to sterility (>15% of cases)	Antibiotics
Genital herpes (herpes simplex type 2 virus)	Symptoms may be absent or minimal; when they occur, symptoms include painful blisters in genital area that develop into ulcers; symptoms recur periodically; threat to fetus or newborn infant; can be contracted via oral sex	No effective cure; some drugs may shorten outbreaks or reduce severity; medication can be taken to prevent outbreak
Acquired immunodeficiency syndrome (AIDS)* (caused by human immunodeficiency virus, HIV)	First few weeks: no symptoms or influenza-like symptoms (fever, headache, rash, sore throat); later, other symptoms may include swollen lymph glands, fever, night sweats, weight loss; depressed immunity may lead to pneumonia, rare forms of cancer, and other diseases	No effective cure; a variety of drugs reduce symptoms and prolong life
Trichomoniasis (a protozoon)	Itching, discharge, soreness; can be contracted from dirty toilet seats and towels; may be asymptomatic in males	Metronidazole (an antibiotic)
"Yeast" infections (genital candidiasis; *Candida albicans*)	Irritation, soreness, discharge; especially common in females; rare in males; can be acquired nonsexually	Antifungal drugs
Gonorrhea (*Neisseria gonorrhoeae*, a gonococcus bacterium)	Bacterial toxin may produce redness and swelling at infection site; symptoms in males are painful urination and discharge of pus from penis; in about 60% of infected women, no symptoms initially; can spread to epididymis (in males) or oviducts and ovaries (in females), causing sterility; can cause widespread infection; damage to heart valves, meninges, and joints	Antibiotics, but strains of drug-resistant gonorrhea are an urgent public health issue
Syphilis (*Treponema pallidum*, a spirochete bacterium)	Incidence rising in the U.S.; bacteria enter body through defect in skin; primary chancre (small, painless ulcer) at site of initial infection; highly infectious at this stage; secondary stage, widespread rash and influenza-like symptoms; scaly lesions may occur that are highly infectious; latent stage that follows can last 20 years; eventually, lesions called gummae may form that damage liver, brain, bone, or spleen	Penicillin

* AIDS was discussed in Chapter 45.

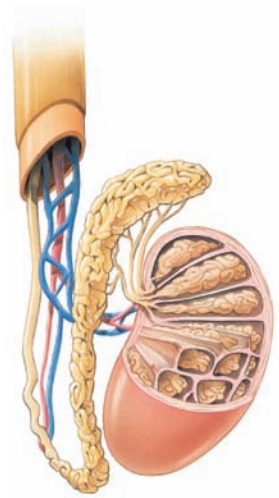
Summary: Focus on Learning Objectives

50.1 Asexual and Sexual Reproduction *(page 1075)*



1 Compare the benefits of asexual and sexual reproduction, and describe each mode of reproduction, giving specific examples.

- In **asexual reproduction**, a single parent produces offspring with a set of genes identical to its own. Asexual reproduction is energy efficient. It is most successful in stable environments.
- Three types of asexual reproduction are budding, fragmentation, and parthenogenesis. In **budding**, a part of the parent's body grows and separates from the rest of the body. In **fragmentation**, the parent's body may break into several pieces, and each piece can develop into a new animal. In **parthenogenesis**, an unfertilized egg develops into an adult.
- In **sexual reproduction**, offspring are produced by the fusion of two types of gametes: **ovum** and **sperm**. When a sperm and egg fuse, a fertilized egg, or **zygote**, is produced. Sexual reproduction promotes genetic variety and is especially adaptive in unstable, changing environments.
- In **external fertilization**, mating partners typically release eggs and sperm into the water simultaneously. In **internal fertilization**, the male delivers sperm into the female's body.
- In **hermaphroditism**, a single individual produces both eggs and sperm.

50.2 Human Reproduction: The Male *(page 1077)*

2 Relate the structure of each organ of the human male reproductive system to its function.

- The human male reproductive system includes the testes, which produce sperm and testosterone; a series of conducting ducts; accessory glands; and the penis.
- The **testes**, housed in the **scrotum**, contain the **seminiferous tubules**, where **spermatogenesis** (sperm production) takes place. The **interstitial cells** in the testes secrete testosterone.
- Sperm complete their maturation and are stored in the **epididymis** and **vas deferens**. During **ejaculation**, sperm pass from the vas deferens to the **ejaculatory duct** and then into the **urethra**, which passes through the penis.

- The **penis** consists of three columns of *erectile tissue*: two *cavernous bodies* and one *spongy body*, which surrounds the urethra. When its erectile tissue becomes engorged with blood, the penis becomes erect and functions as the copulatory organ.

3 Trace the passage of sperm cells through the human male reproductive system from their origin in the seminiferous tubules to their expulsion from the body in the semen; include a description of spermatogenesis.

- Spermatogenesis takes place in the seminiferous tubules of the testes. **Spermatogonia** divide by mitosis; some differentiate and become **primary spermatocytes**, which undergo **meiosis**. The first meiotic division produces two **secondary spermatocytes**. In the second meiotic division, each secondary spermatocyte produces two **spermatids**. Each spermatid differentiates to form a mature sperm.
- The head of a sperm consists of the nucleus and a cap, or *acrosome*, containing enzymes that help the sperm penetrate the egg.
- Sperm pass in sequence through the seminiferous tubules of the testis, epididymis, vas deferens, ejaculatory duct, and urethra.
- Each ejaculate of semen contains about 200 million sperm suspended in the secretions of the **seminal vesicles** and **prostate gland**. The *bulbourethral glands* release a mucous secretion.

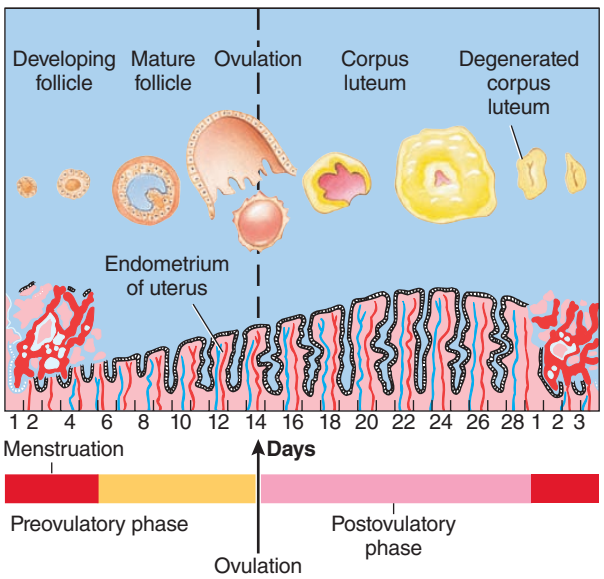
4 Describe endocrine regulation of reproduction in the human male.

- **Testosterone** establishes and maintains male *primary sex characteristics*, growth of reproductive organs, and spermatogenesis. Testosterone also stimulates development of **secondary sex characteristics** at puberty: growth of facial and body hair, muscle development, and deepened voice.
- Endocrine regulation of male reproduction involves the hypothalamus, pituitary gland, and testes. The hypothalamus secretes **gonadotropin-releasing hormone (GnRH)**, which stimulates the anterior pituitary gland to secrete the gonadotropic hormones: **follicle-stimulating hormone (FSH)** and **luteinizing hormone (LH)**.
- FSH, LH, and testosterone directly or indirectly stimulate sperm production. LH stimulates the interstitial cells of the testes to produce testosterone. FSH stimulates the Sertoli cells to produce (1) **androgen-binding protein (ABP)**, which binds to testosterone and concentrates it; and (2) **inhibin**, a hormone that inhibits FSH secretion.

50.3 Human Reproduction: The Female *(page 1082)*

5 Relate the structure of each organ of the human female reproductive system to its function.

- The **ovaries** produce gametes and the steroid hormones **estrogens** and **progesterone**. Fertilization takes place in the **oviducts** (uterine tubes).
- The **uterus** serves as an incubator for the developing embryo. The epithelial lining of the uterus, the **endometrium**, thickens each month in preparation for possible pregnancy. The lower part of the uterus, the **cervix**, extends into the vagina.



Copyright 2019 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

- The **vagina** receives the penis during heterosexual intercourse and is the lower part of the birth canal. The **vulva** includes the *labia majora, labia minora, vestibule* of the vagina, **clitoris**, and *mons pubis*.
- The breasts function in **lactation**, production of milk for the young. Each breast consists of 15 to 20 lobes of glandular tissue. The hormone **prolactin** stimulates milk production; **oxytocin** stimulates ejection of milk from the alveoli into the ducts, making it available to the nursing infant.

6 Trace the development of a human egg and trace its passage through the female reproductive system until it is fertilized.

- **Oogenesis** takes place in the ovaries. **Oogonia** differentiate into **primary oocytes**. A primary oocyte and the **granulosa cells** surrounding it make up a **follicle**.
- As the follicle grows, connective tissue cells surrounding the granulosa cells form a layer of **theca cells**. As the follicle matures, the primary oocyte undergoes the first meiotic division, giving rise to a **secondary oocyte** and a **polar body**.
- During **ovulation**, the secondary oocyte is ejected from the ovary and enters one of the paired oviducts, where it may be fertilized. The part of the follicle remaining in the ovary develops into a **corpus luteum**, a temporary endocrine gland.

7 Describe the endocrine regulation of reproduction in the human female and identify key events of the menstrual cycle, such as ovulation and menstruation.

- The hypothalamus, pituitary gland, and ovaries secrete hormones that regulate female reproduction. The first day of the **menstrual cycle** is marked by the beginning of menstrual bleeding. Ovulation occurs at about day 14 in a typical 28-day menstrual cycle.
- During the *preovulatory phase*, gonadotropin-releasing hormone (GnRH) from the hypothalamus stimulates the anterior lobe of the pituitary to secrete follicle-stimulating hormone (FSH) and luteinizing hormone (LH). FSH stimulates follicle development and stimulates the granulosa cells to produce estrogen. LH stimulates theca cells to multiply and produce androgens, which are converted to estrogen.
- Estrogen is responsible for primary and secondary female sex characteristics and stimulates development of the endometrium.
- After the first week, only one follicle continues to develop. Although at relatively low concentration, estrogen inhibits FSH secretion by negative feedback. Granulosa cells produce inhibin, which also inhibits FSH secretion.
- During the late *preovulatory phase*, estrogen concentration peaks. Through a positive feedback mechanism, estrogen signals the anterior pituitary to secrete LH. This hormone stimulates final maturation of the follicle and stimulates ovulation.
- During the *postovulatory phase*, LH promotes development of the corpus luteum. The corpus luteum secretes progesterone and estrogen, which stimulate final preparation of the uterus for pregnancy. During the postovulatory phase, progesterone, along with estrogen, inhibits secretion of GnRH, FSH, and LH.
- If fertilization does not occur, the corpus luteum degenerates, concentrations of estrogen and progesterone in the blood fall, and **menstruation** occurs.

50.4 Fertilization, Pregnancy, and Birth *(page 1091)*

8 Describe the process of human fertilization and summarize the actions of hormones that regulate pregnancy and birth.

- Human **fertilization** is the fusion of a secondary oocyte and a sperm to form a zygote. The processes of fertilization and establishing pregnancy together are called *conception*.
- If the secondary oocyte is fertilized, development begins and the embryo implants in the uterus. Membranes that develop around the embryo secrete **human chorionic gonadotropin (hCG)**, a hormone that maintains the corpus luteum. During the first two to three months of pregnancy, the corpus luteum secretes the large amounts of estrogen and progesterone needed to maintain pregnancy. After three months, the **placenta**, the organ of exchange between mother and embryo, assumes this function.
- Several hormones, including estrogen, oxytocin, and prostaglandins, regulate the birth process. Labor can be divided into three stages; the baby is delivered during the second stage.

50.5 Human Sexual Response *(page 1094)*

9 Describe the physiological changes that take place during human heterosexual intercourse.

- *Vasocongestion*, engorgement of a tissue with blood, and increased muscle tension, are physiological responses to sexual stimulation. The phases of the human sexual response include *sexual excitement, plateau*, **orgasm**, and *resolution*.

50.6 Birth Control Methods and Abortion *(page 1096)*

10 Compare the modes of action, effectiveness, advantages, and disadvantages of the methods of birth control discussed, including sterilization and emergency contraception; distinguish between spontaneous and induced abortions.

- Effective methods of **contraception** include *hormonal contraceptives*, such as oral contraceptives and injectable progestin; *intrauterine devices (IUDs)*; *condoms*; *contraceptive diaphragms*; and **sterilization** (*vasectomy* in the male and *tubal sterilization* in the female); see Table 50-3. Emergency contraception can be used to prevent unwanted pregnancy after rape or unprotected intercourse.

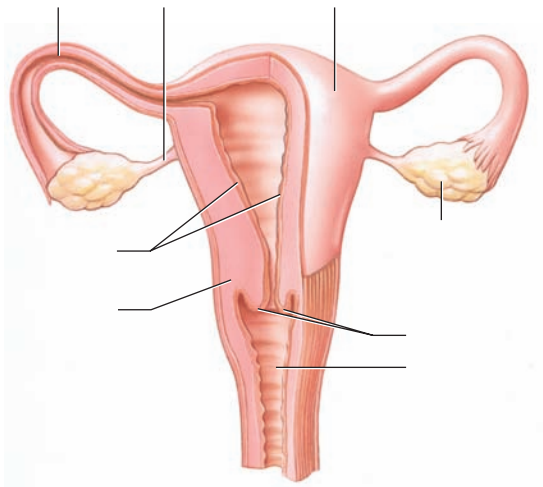
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

- *Spontaneous* **abortions** (miscarriages) occur without intervention. *Induced abortions* include *therapeutic abortions*, performed when the mother's health is in danger or when the embryo is thought to be grossly abnormal. Abortions are also induced as a means of birth control.

50.7 Sexually Transmitted Infections *(page 1099)*

11 Identify common sexually transmitted infections and describe their symptoms, effects, and treatments.

- Among the common types of *sexually transmitted infections (STIs)* are *chlamydia* (which causes *pelvic inflammatory disease*), *human papillomavirus (HPV), genital herpes, gonorrhea, syphilis*, and **human immunodeficiency virus (HIV)** (see Table 50-4).



Test Your Understanding

Know and Comprehend

1. Hermaphroditism (a) is a form of asexual reproduction (b) occurs when an unfertilized egg develops into an adult animal (c) is a form of sexual reproduction in which an animal produces both eggs and sperm (d) typically involves self-fertilization (e) typically requires only a male animal
2. In contrast to asexual reproduction, sexual reproduction (a) is a faster way to produce offspring (b) is more efficient (c) results in more offspring (d) is less efficient at removing harmful mutations from a population (e) increases genetic variety among members of a population
3. The seminiferous tubules (a) are the site of spermatogenesis (b) produce most of the seminal fluid (c) empty directly into the vas deferens (d) are located within the cavernous body (e) receive fluid from the bulbourethral glands
4. Which of the following cells is haploid? (a) primary oocyte (b) secondary oocyte (c) oogonium (d) cells of the corpus luteum (e) follicle cell
5. The corpus luteum (a) is surrounded by ova (b) degenerates if fertilization occurs (c) develops in the preovulatory phase (d) is maintained by prostaglandins (e) serves as a temporary endocrine gland
6. After ovulation, the secondary oocyte enters the (a) oviduct (b) corpus luteum (c) cervix (d) ovary (e) vagina
7. Hormonal contraceptives (a) prevent ovulation (b) decrease estrogen concentration in the blood (c) are not as effective as barrier methods of contraception (d) decrease risk of STIs (e) a and b only
8. Pelvic inflammatory disease is commonly caused by (a) syphilis (b) gonorrhea (c) genital herpes (d) HIV (e) chlamydia

Apply and Analyze

9. Arrange the following stages into the correct sequence: 1. spermatid 2. spermatogonium 3. sperm 4. secondary spermatocyte 5. primary spermatocyte (a) 2, 1, 3, 4, 5 (b) 5, 1, 3, 4, 2 (c) 1, 3, 4, 2, 5 (d) 2, 5, 4, 1, 3 (e) 1, 4, 3, 2, 5
10. Which sequence best describes the passage of sperm? 1. urethra 2. vas deferens 3. epididymis 4. ejaculatory duct 5. seminiferous tubules (a) 3, 1, 2, 4, 5 (b) 1, 3, 2, 4, 5 (c) 5, 3, 2, 4, 1 (d) 1, 3, 4, 2, 5 (e) 3, 1, 4, 2, 5
11. **VISUALIZE** Label the diagram.

12. **INTERPRET DATA** Examine Figure 50-14. Which hormones are present in largest concentration just before ovulation? During which part of the menstrual cycle is the endometrium most prepared to receive an embryo? Which hormones stimulate thickening of the endometrium?

Evaluate and Synthesize

13. **EVOLUTION LINK** Contrast the biological advantages of hermaphroditism that involves cross-fertilization with hermaphroditism that involves self-fertilization.
14. **EVOLUTION LINK** Asexual reproduction is more common in habitats with few parasites, and sexual reproduction is more common in habitats with larger numbers of parasites. Develop a hypothesis to explain why.
15. **SCIENCE, TECHNOLOGY, AND SOCIETY** Why do you think that a variety of effective methods of male contraception have not yet been developed? If you were a researcher, what are some approaches you might take to develop a method of male contraception?
16. **SCIENCE, TECHNOLOGY, AND SOCIETY** The incidence of abortion has declined more in countries where abortions are legal (and safe) than in countries in which they are illegal (and unsafe). Can you suggest an explanation?

51 Animal Development

KEY CONCEPTS

51.1 The development of form requires not only cell division and growth, but also cell determination and cell differentiation as well as pattern formation and morphogenesis.

51.2 Fertilization includes contact and recognition between egg and sperm, regulated sperm entry, activation of the fertilized egg, and fusion of egg and sperm pronuclei.

51.3 Cleavage, a series of rapid cell divisions without growth, provides cellular building blocks for development.

51.4 Gastrulation establishes ectoderm, mesoderm, and endoderm; each gives rise to specific types of tissues.

51.5 One of the earliest events in organogenesis (organ development) is neurulation, the origin of the central nervous system.

51.6 Extraembryonic membranes (amnion, chorion, allantois, and yolk sac) have evolved in terrestrial vertebrates as adaptations to reproduction on land.

51.7 Human development follows the pattern for placental mammals.

PHOTO: Human embryo at 7 to 8 weeks of development. The embryo, enclosed in its amniotic sac, is about 2.5 cm (1.0 in.) long. Note the umbilical cord attached to the placenta (*upper left*) and the balloon-like remnant of the yolk sac (*upper right*). The limbs and one of the eyes are visible. Dr. G. Moscoso/Science Source

Development includes all the changes that take place during the entire life of an individual. In this chapter, however, we focus mainly on the fertilization of the egg to form a zygote and the subsequent development of the young animal before birth or hatching.

Just how does a microscopic, unicellular zygote give rise to the bones, muscles, brain, and other structures of a complex animal? The zygote divides by mitosis, forming an **embryo** that subsequently undergoes an orderly sequence of cell divisions. In animals, growth (i.e., increase in mass) occurs primarily by an increase in the number of cells, but it also occurs by an increase in cell size, as in fat cells. Although the very early embryo usually does not grow, later cell divisions typically contribute to growth. However, by itself cell division, which is governed by a genetic program that interacts with environmental signals (see Chapter 10), would produce only a formless heap of similar cells. We therefore begin this chapter with a discussion of the fundamental processes introduced in Chapter 17 that contribute to the development of form: cell determination and cell differentiation; and pattern formation and morphogenesis.

The photograph shows a human embryo enclosed in its fluid-filled amniotic cavity and attached to its yolk sac. In this chapter you have an opportunity to compare and contrast the sequences of developmental events in several different animals in addition to humans. Researchers have chosen these model organisms because they have certain desirable characteristics. For example, the embryos of certain types of animals, such as echinoderms and amphibians, can be obtained in large quantities, which facilitates studies in which biochemical changes are correlated with developmental landmarks. The embryos of echinoderms are particularly easy to observe because they are transparent. The embryos of echinoderms, amphibians, and birds are easily grown in the laboratory. As you read, note the intimate

inter-relationships among the sequential developmental processes as well as the fundamental similarities among the early developmental events in the different animal groups featured. Many decades of painstaking investigations on these similarities became the foundations of the science of evolutionary developmental biology, popularly known as **Evo Devo**, introduced in Chapters 17 and 30.

51.1 Development of Form

LEARNING OBJECTIVES

1 Analyze the relationship between cell determination and cell differentiation and between pattern formation and morphogenesis.
2 Relate differential gene expression to nuclear equivalence.

The development of the form of an animal is a consequence of a balanced combination of several fundamental processes that go beyond cell division and growth: cell determination and cell differentiation, and pattern formation and morphogenesis.

As embryonic development proceeds, cell division gives rise to increasing numbers of cells, which serve as the building blocks of development. At various times, certain cells become biochemically and structurally specialized to carry out specific functions through a process known as **cell differentiation**. In our discussion of the genetic control of development in Chapter 17, you learned how cell differentiation occurs through **cell determination**, a series of molecular events in which the activities of certain genes are altered in ways that cause a cell to progressively commit to a particular differentiation pathway. This process proceeds even though there may not be any immediate changes in the cell's morphology. You also evaluated evidence supporting the principle of **nuclear equivalence**, which states that in most cases neither cell determination nor cell differentiation entails a loss of genetic information from the cell nucleus. That is, the nuclei of virtually all differentiated cells of an animal contain the same genetic information present in the zygote, but each cell type *expresses* a different subset of that information. In fact, nuclear equivalence is the principle that underlies the cloning of organisms.

Cell differentiation is therefore an expression of changes in the activity of specific genes, which in turn is influenced by a variety of factors inside and outside the cell. This **differential gene expression** is responsible for variations in chemistry, behavior, and structure among cells. Through this process, an embryo can develop into an organism of more than 200 types of cells, each specialized to perform specific functions. However, not all cells differentiate. Some, known as **stem cells**, remain in a relatively undifferentiated state and retain the ability to give rise to various cell types.

Cell differentiation by itself does not explain development. The differentiated cells must become progressively organized, shaping the intricate pattern of tissues and organs that characterizes a multicellular animal. This development of form, known as **morphogenesis**, proceeds through the process of pattern formation. **Pattern formation** is a series of steps requiring signaling between cells, changes in the shapes of certain cells, precise cell migrations, interactions with the extracellular matrix, and even **apoptosis** (programmed cell death; see Chapter 4) of some cells.

CHECKPOINT 51.1

- Which typically comes first, cell differentiation or cell determination?
- **CONNECT** What are some kinds of events that contribute to pattern formation? How does pattern formation lead to morphogenesis?

51.2 Fertilization

LEARNING OBJECTIVES

3 Describe the four processes involved in fertilization.
4 Describe fertilization in echinoderms and point out some ways in which mammalian fertilization differs.

In Chapter 50 you studied **spermatogenesis** and **oogenesis**, the processes by which meiosis leads to the formation of haploid cells, which differentiate as sperm and eggs, respectively. In **fertilization** a usually flagellated, motile sperm fuses with a much larger, immotile egg cell to produce a **zygote**, or fertilized egg.

Fertilization has two important genetic consequences: restoration of the diploid chromosome number and, in mammals and many other animals, determination of the sex of the offspring (see Chapter 11). Fertilization also has profound physiological effects because it activates the egg, thus initiating reactions that permit development.

Fertilization involves four events, some of which may occur simultaneously: (1) the sperm contacts the egg and recognition occurs; (2) the sperm or sperm nucleus enters the egg; (3) the egg becomes activated, and certain developmental changes begin; and (4) the sperm and egg nuclei fuse. These events do not necessarily follow the same temporal sequence in all animals. Unless otherwise stated, our discussion applies to sea urchins and other echinoderms such as sea stars, which have been studied intensively because they produce large numbers of gametes and because fertilization is external.

The first step in fertilization involves contact and recognition

Although eggs are immotile, they are active participants in fertilization. An egg is surrounded by a plasma membrane and by one or more external coverings that are important in fertilization. For example, a mammalian egg is enclosed by a thick, noncellular **zona pellucida**, which is surrounded by a layer of granulosa cells derived from the follicle in which the egg developed.

The egg coverings not only facilitate fertilization by sperm of the same species but also bar interspecific fertilization, a particularly important function in species that practice external fertilization. External to the plasma membrane of a sea urchin egg are two acellular layers that interact with sperm: a very thin **vitelline envelope** and, outside it, a thick glycoprotein layer called the **jelly coat**. Sea urchin sperm become motile when released into sea

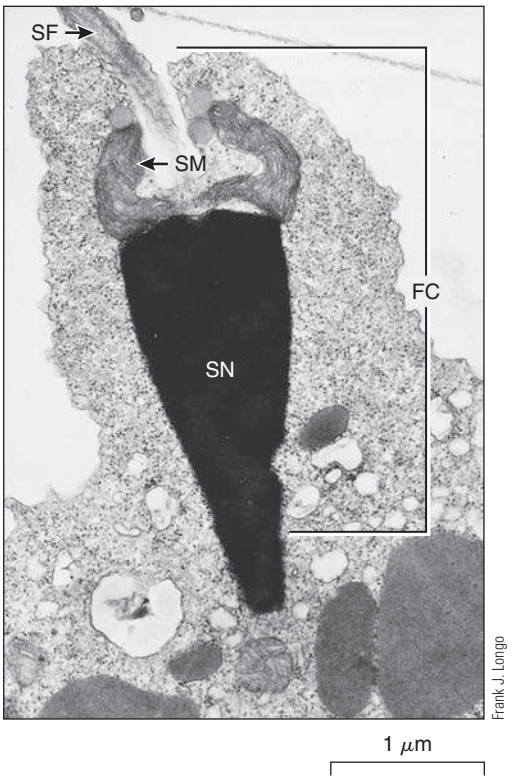
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

water, and their motility increases when they reach the vicinity of a sea urchin egg. Motility improves the probability that sperm will encounter the egg, but motility alone may not be sufficient to ensure actual contact with the egg. In sea urchins as well as certain fishes and some cnidarians, the egg or one of its coverings secretes a chemotactic substance that attracts sperm from the same species. However, for many species, researchers have not found a specific chemical that attracts the sperm to the egg.

When a sea urchin sperm contacts the jelly coat, the sperm undergoes an **acrosome reaction**, in which the membranes surrounding the acrosome (the cap at the head of the sperm; see Fig. 50-6) fuse and pores in the membrane enlarge. Calcium ions from the sea water move into the acrosome, which swells and begins to disorganize. The acrosome then releases proteolytic enzymes that digest a path through the jelly coat to the vitelline envelope of the egg. If the sperm and egg are of the same species, *bindin*, a species-specific binding protein located on the acrosome, adheres to species-specific bindin receptors located on the egg's vitelline envelope.

Before a mammalian sperm participates in fertilization, it first undergoes **capacitation**, a maturation process in the female reproductive tract. During capacitation, which in humans can take several hours, sperm become increasingly motile and capable of undergoing an acrosome reaction when they encounter an egg. Evidence indicates that mammalian fertilization requires interaction between sperm and species-specific glycoproteins in the egg's zona pellucida.



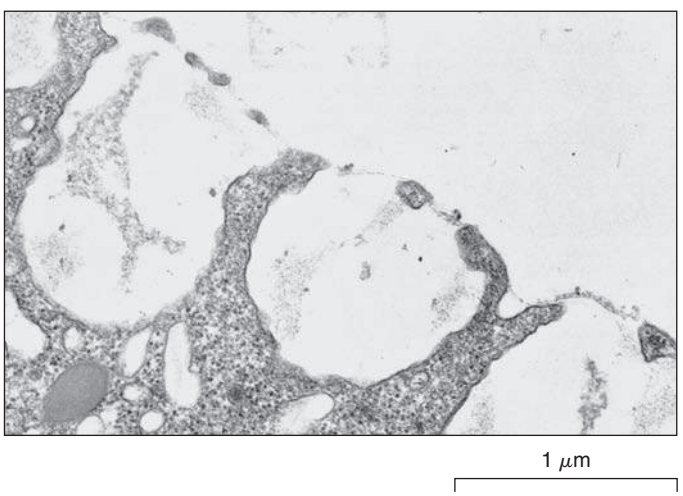


Figure 51-1 Fertilization
In this TEM, a fertilization cone (FC) forms as a sperm enters a sea urchin egg. (SN, sperm nucleus; SM, sperm mitochondrion; SF, sperm flagellum).

Sperm entry is regulated

In sea urchins, once contact occurs between acrosome and vitelline envelope, enzymes dissolve a bit of the vitelline envelope in the area of the sperm head. The plasma membrane of the egg is covered with microvilli, several of which elongate to surround the head of the sperm. As they do so, the plasma membranes of sperm and egg fuse, and a *fertilization cone* is formed that contracts to draw the sperm into the egg (FIG. 51-1).

Fertilization of the egg by more than one sperm, a condition known as **polyspermy**, results in an offspring with extra sets of chromosomes, which is usually lethal. Two reactions, known as the fast and slow blocks to polyspermy, prevent this occurrence. In the *fast block to polyspermy*, the egg plasma membrane depolarizes, which prevents its fusion with additional sperm. An unfertilized egg is polarized; that is, the cytoplasm is negatively charged relative to the outside. However, within a few seconds after sperm fusion, ion channels in the plasma membrane open, permitting positively charged calcium ions to diffuse across the membrane and depolarize the egg.

The *slow block to polyspermy*, the **cortical reaction**, requires up to several minutes to complete, but it is a complete block. Binding of the sperm to receptors on the vitelline envelope activates one or more *signal transduction* pathways (see Chapter 6) in the egg. These events cause calcium ions stored in the egg endoplasmic reticulum to be released into the cytosol. This rise in the level of intracellular calcium causes thousands of cortical granules, membrane-enclosed vesicles in the egg cortex (region close to the plasma membrane), to release enzymes, various proteins, and other substances by exocytosis into the space between the plasma membrane and the vitelline envelope (FIG. 51-2). Some of the enzymes dissolve the protein linking the two membranes; thus, the space enlarges as additional substances released by the cortical granules

Reprinted from E. Anderson, *The Journal of Cell Biology*, 1968, Vol. 37, pp. 514–539, by copyright permission of the Rockefeller University Press

Figure 51-2 The cortical reaction
Three cortical granules are undergoing exocytosis in this TEM of the plasma membrane of a sea urchin egg shortly after fertilization. This release of the contents of the cortical granules initiates the slow block to polyspermy.

raise the osmotic pressure, which causes an influx of water from the surroundings. The vitelline envelope then becomes elevated away from the plasma membrane and forms the fertilization envelope, a hardened covering that prevents entry of additional sperm.

In mammals, a fertilization envelope does not form. Instead, the enzymes released during exocytosis of the cortical granules alter the sperm receptors on the egg's zona pellucida so that no additional sperm bind to them.

Not all species have these types of blocks to polyspermy. In some species, such as salamanders, several sperm usually enter the egg, but only one sperm nucleus fuses with the egg nucleus; the rest degenerate.

Fertilization activates the egg

Release of calcium ions into the egg cytoplasm does more than stimulate the cortical reaction; it also triggers the *activation program*, a series of metabolic changes within the egg. Aerobic respiration increases; certain maternal enzymes and other proteins become active; and within a few minutes after sperm entry, a burst of protein synthesis occurs. In addition, the egg nucleus is stimulated to complete meiosis. (Recall from Chapter 50 that in most animal species, including mammals, at the time of fertilization an egg is actually a secondary oocyte, arrested early in the second meiotic division.)

In some species, an egg can be artificially activated without sperm penetration by swabbing it with blood and pricking the plasma membrane with a needle, by calcium injection, or by certain other treatments. These haploid eggs go through some developmental stages *parthenogenetically*—that is, without fertilization (see Chapter 50)—but they cannot complete development. Special mechanisms of egg activation have evolved in species that are naturally parthenogenetic.

Sperm and egg pronuclei fuse, restoring the diploid state

After the sperm nucleus enters the egg, researchers think that it is guided toward the egg nucleus by a system of microtubules that forms within the egg. The sperm nucleus swells and forms the *male pronucleus*. The nucleus formed during completion of meiosis in the egg becomes the *female pronucleus*. (Recall from Figure 50-11 that the other nucleus formed during meiosis II in the egg becomes the second polar body.) The haploid male and female pronuclei then fuse to form the diploid nucleus of the zygote, and DNA synthesis occurs in preparation for the first cell division.

CHECKPOINT 51.2

- How do the mechanisms of fertilization ensure control of both quality (fertilization by a sperm of the same species) and quantity (fertilization by only one sperm)?
- **CONNECT** What is the function of the cortical reaction in echinoderms? in mammals?

51.3 Cleavage

LEARNING OBJECTIVES

5 Trace the generalized pattern of early development of the embryo from zygote through early cleavage and formation of the morula and blastula.

6 Contrast early development, including cleavage, in the echinoderm (or in amphioxus), the amphibian, and the bird, paying particular attention to the importance of the amount and distribution of yolk.

Despite its simple appearance, the zygote is **totipotent**; that is, it gives rise to all the cell types of the new individual. Because the egg is very large compared with the sperm, the bulk of the zygote cytoplasm and organelles comes from the egg. However, the sperm and egg usually contribute equal numbers of chromosomes.

Shortly after fertilization, the zygote undergoes **cleavage**, a series of rapid mitotic divisions with no period of growth during each cell cycle. For this reason, although the cell number increases, the embryo does not increase in size. The zygote initially divides to form a 2-celled embryo. Then each of these cells undergoes mitosis and divides, bringing the number of cells to 4. Repeated divisions increase the number of cells, called **blastomeres**, that make up the embryo. At about the 32-cell stage, the embryo is a solid ball of blastomeres called a **morula**. Eventually, anywhere from 64 to several hundred blastomeres form the **blastula**, which is usually a hollow ball with a fluid-filled cavity, the **blastocoel**.

The pattern of cleavage is affected by yolk

Many animal eggs contain **yolk**, a mixture of proteins, phospholipids, and fats that serves as food for the developing embryo. The amount and distribution of yolk vary among different animal groups, depending on the needs of the embryo. Mammalian eggs have very little yolk because the embryo obtains maternal nutritional support throughout most of its development, whereas the eggs of birds and reptiles must contain sufficient yolk to sustain the embryo until hatching. Echinoderm eggs typically need only enough yolk to nourish the embryo until it becomes a tiny larva capable of obtaining its own food.

Most invertebrates and simple chordates have **isolecithal eggs** with relatively small amounts of yolk uniformly distributed through the cytoplasm. Isolecithal eggs divide completely in a process called **holoblastic cleavage**. Cleavage of these eggs is radial or spiral. Radial cleavage is characteristic of *deuterostomes*, such as chordates and echinoderms; spiral cleavage is common in the embryos of *protostomes*, such as annelids and mollusks (see Fig. 30-5).

In **radial cleavage**, the first division is vertical and splits the egg into two equal cells. The second cleavage division, also vertical, is at right angles to the first division and separates the two cells into four equal cells. The third division is horizontal, at right angles to the other two, and separates the four cells into eight cells: four above and four below the third line of cleavage.

Key Point

Cleavage in sea stars is radial and holoblastic.

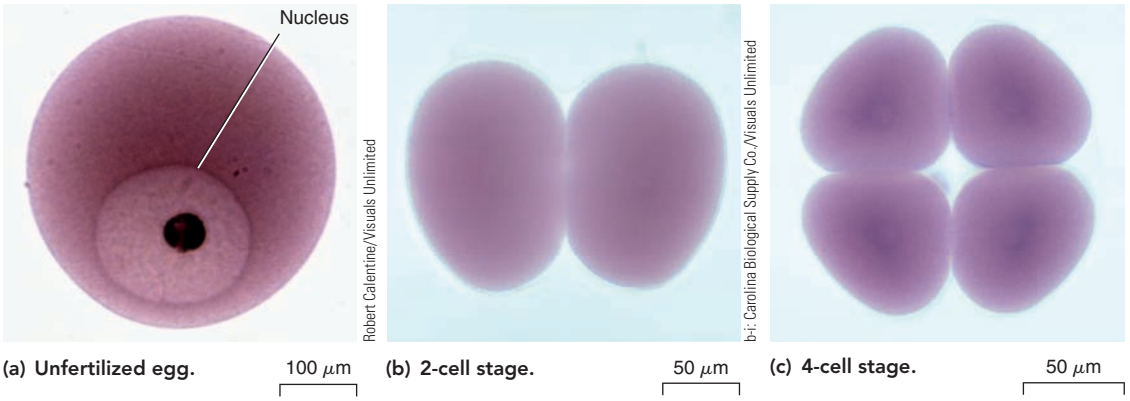

Figure 51-3
LMs showing sea star development

(a) The isolecithal egg has a small amount of uniformly distributed yolk. **(b–e)** The cleavage pattern is radial and holoblastic (the entire egg becomes partitioned into cells). **(f, g)** The three germ layers form during gastrulation. The blastopore is the opening into the developing gut cavity, the archenteron. The rudiments of organs are evident in the sea star larva **(h)** and the young sea star **(i)**. All views are side views with the animal pole at the top except **(c)** and **(i)**, which are top views. Note that the sea star larva is bilaterally symmetrical, but differential growth produces a radially symmetrical young sea star.

VISUALIZE Draw a simple sketch illustrating a horizontal section through the midplane of the middle gastrula in part **(g)**. Label the archenteron and blastocoel. Is the blastopore included in your drawing?

This pattern of radial cleavage occurs in echinoderms and in the cephalochordate amphioxus (FIGS. 51-3 and 51-4).

In **spiral cleavage**, the plane of cytokinesis after the first two divisions is diagonal to the polar axis (FIG. 51-5). The result is a spiral arrangement of cells, with each cell located above and between the two underlying cells. This pattern is typical of annelids and mollusks.

Many vertebrate eggs are **telolecithal**, meaning that they have large amounts of yolk concentrated at one end of the cell, known as the **vegetal pole**. The opposite, more metabolically

Key Point

Cleavage in amphioxus is radial and holoblastic.

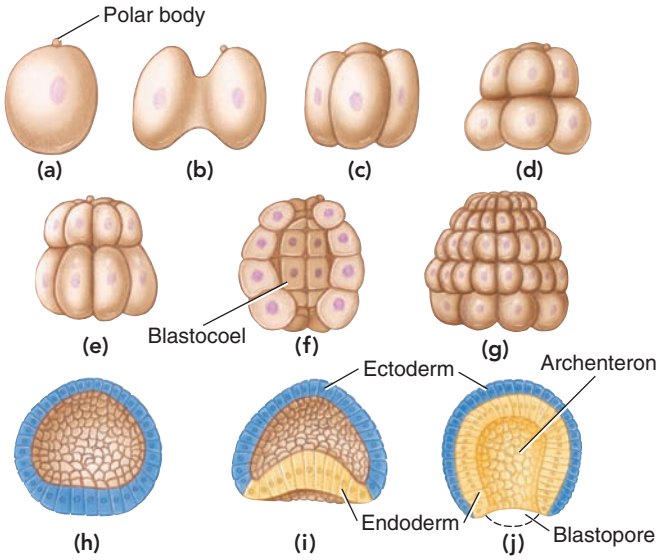

Figure 51-4 Cleavage and gastrulation in amphioxus
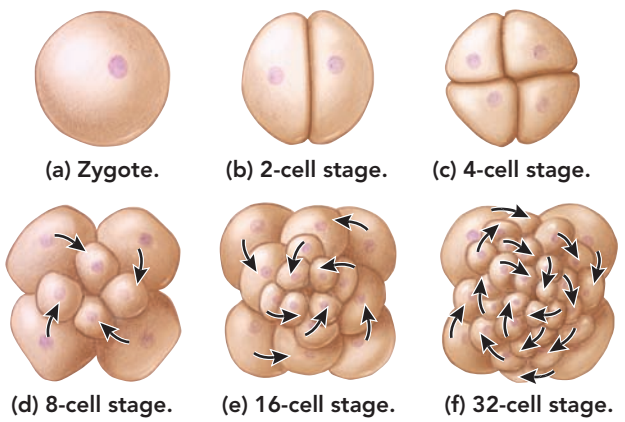
As in the sea star, cleavage is holoblastic and radial. The embryos are shown from the side. **(a)** Mature egg with polar body. **(b–e)** The 2-, 4-, 8-, and 16-cell stages. **(f)** Embryo cut open to show the blastocoel. **(g)** Blastula. **(h)** Blastula cut open. **(i)** Early gastrula showing beginning of invagination at vegetal pole. **(j)** Late gastrula. Invagination is completed, and the blastopore has formed.

VISUALIZE Draw a simple sketch illustrating a horizontal section through the midplane of part **(j)**. Label the archenteron, endoderm, and ectoderm. Is the blastopore included in your drawing?

active pole is the **animal pole**. The eggs of amphibians are moderately telolecithal (mesolecithal). Although cleavage is radial and holoblastic, the divisions in the vegetal hemisphere are slowed by the presence of the inert yolk. As a result, the blastula consists of many small cells in the animal hemisphere and fewer but larger cells in the vegetal hemisphere (FIG. 51-6). The blastocoel is displaced toward the animal pole.



The telolecithal eggs of non-avian reptiles and birds have very large amounts of yolk at the vegetal pole and only a small amount of cytoplasm concentrated at the animal pole. The yolk of such eggs never cleaves. Cell division is restricted to the **blastodisc**, the small disc of cytoplasm at the animal pole (FIG. 51-7); this type of cleavage is called **meroblastic cleavage**. In birds and some reptiles, the blastomeres form two layers separated by the blastocoel cavity: an upper *epiblast* and a lower, thin layer of flat cells, the *hypoblast*.

Cleavage may distribute developmental determinants

The pattern of cleavage in a particular species depends on both yolk and other factors. Recall from Chapter 17 that some animals have relatively rigid developmental patterns, known as **mosaic development**. This type of development is largely a consequence of the unequal distribution of important materials in the cytoplasm of the zygote. Because the zygote cytoplasm is not homogeneous, cytoplasmic developmental determinants portioned out to each new cell during cleavage may be different. Such differences help determine the course of development. At the other extreme are mammals, which have zygotes with very homogeneous cytoplasm. They exhibit highly **regulative development**, in which individual cells produced by the cleavage divisions are equivalent, thus allowing the embryo to develop as a self-regulating whole. Developmental patterns of most animals fall somewhere on a continuum between these two extremes.

Key Point

Cleavage in annelids is spiral and holoblastic.

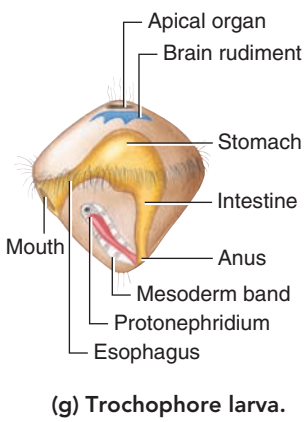


Figure 51-5 Spiral cleavage in an annelid embryo
(a–f) Top views of the animal pole. The successive cleavage divisions occur in a spiral pattern as illustrated. **(g)** A typical trochophore larva. The upper half of the trochophore develops into the extreme anterior end of the adult worm; all the rest of the adult body develops from the lower half.

VISUALIZE Draw a simple sketch illustrating how the embryo in part **(d)** (8-cell stage) would look if cleavage were radial rather than spiral.

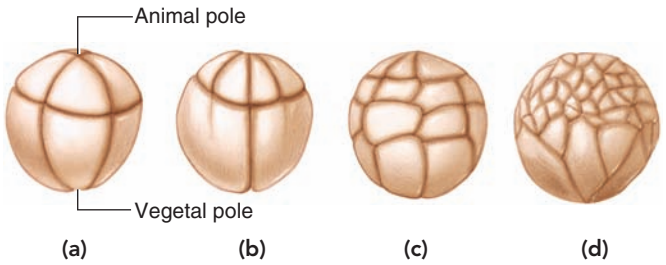
Key Point

Cleavage in the moderately telolecithal frog egg is radial and holoblastic but is retarded by yolk in the vegetal hemisphere.



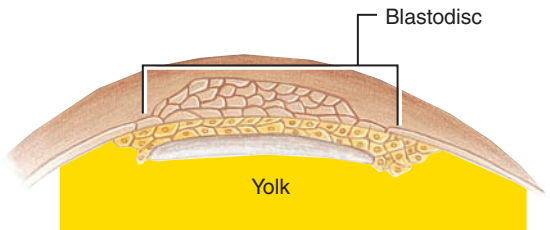


Figure 51-6 Cleavage pattern in a frog egg
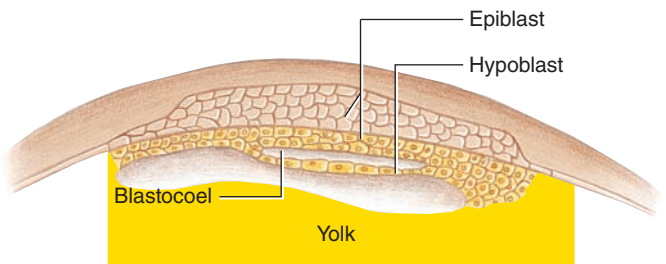
(a–d) Although cleavage is holoblastic, the large amount of yolk concentrated in the vegetal hemisphere slows cleavage. As a result, fewer cells develop at the vegetal hemisphere than at the animal hemisphere. These embryos are shown from the side.



VISUALIZE Draw a simple sketch illustrating how the embryo in part **(a)** would look if the frog egg were isolecithal.

In some species the distribution of developmental determinants in the unfertilized egg is maintained in the zygote. In other species sperm penetration initiates rearrangement of the cytoplasm. For example, fertilization in the amphibian egg causes a shift of some of the cortical cytoplasm. These cytoplasmic movements can be easily followed because the egg cortex contains dark pigment granules. As a result of this rearrangement, a crescent-shaped region of underlying lighter colored (gray) cytoplasm becomes evident directly opposite the point on the cell where the sperm penetrated the egg. This **gray crescent** region is thought to contain growth factors and other developmental determinants. The first cleavage bisects the gray crescent, distributing half to each of the first two blastomeres; in this way the position of the gray crescent establishes the future right and left halves of the embryo. As cleavage continues, the gray crescent material becomes partitioned into certain blastomeres. Those that contain parts of the gray crescent eventually develop into the dorsal region of the embryo.

Experiments have confirmed the importance of determinants in the gray crescent to development. If the first two frog blastomeres are separated experimentally, each develops into a complete tadpole (FIG. 51-8a). When the plane of the first division is altered so that the gray crescent is completely absent from one of the cells, that cell does not develop normally (FIG. 51-8b).

(a) Early blastodisc formation. The blastodisc is a small disc of cytoplasm on the upper surface of the egg yolk. This cutaway view shows cells on the blastodisc surface as well as in the interior.

(b) The blastodisc splits into two tissue layers, an upper epiblast and a lower hypoblast, separated by the blastocoel.

Figure 51-7 Cleavage in a bird embryo
Cleavage in bird embryos is restricted to the blastodisc (meroblastic cleavage).

Cleavage provides building blocks for development

Cleavage partitions the zygote into many small cells that serve as the basic building blocks for subsequent development. At the end of cleavage, the small cells that make up the blastula begin to move about with relative ease, arranging themselves into the patterns necessary for further development. Surface proteins are important in helping cells "recognize" one another and therefore in determining which ones adhere to form tissues.

CHECKPOINT 51.3

- **VISUALIZE** Draw simple sketches illustrating the difference between radial cleavage and spiral cleavage.
- What type of cleavage is characteristic of telolecithal eggs of reptiles and birds?
- **CONNECT** How do the amount and distribution of cytoplasm in the fertilized egg influence early development?

51.4 Gastrulation

LEARNING OBJECTIVE

7 Identify the significance of gastrulation in the developmental process and compare gastrulation in the echinoderm (or in amphioxus), the amphibian, and the bird.

The process by which the blastula becomes a three-layered embryo, or **gastrula**, is called **gastrulation**. Thus, early development proceeds through the following stages:

zygote → early cleavage stages → morula → blastula → gastrula

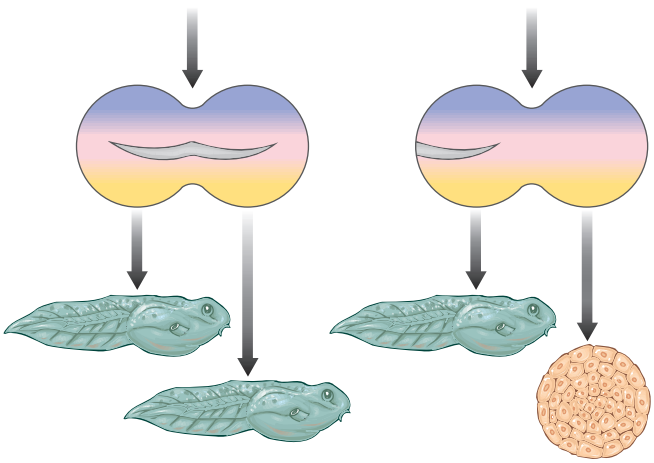
Key Experiment

Is the development of a frog egg influenced by cytoplasmic developmental determinants?



HYPOTHESIS: The gray crescent, which is normally bisected by the first cleavage division and thus establishes right and left halves of the embryo, is the location of crucial developmental determinants.

EXPERIMENT: The two blastomeres resulting from the first cleavage division are separated by the researcher and allowed to develop independently.

(a) The first cleavage is allowed to occur normally, and each separated blastomere includes half of the gray crescent.

(b) The plane of cleavage is altered by the experimenter such that only one blastomere contains the gray crescent.

Each of the separated blastomeres contained half of the gray crescent, and each developed into a normal tadpole.

The separated blastomere that received the entire gray crescent developed normally, but the blastomere lacking the gray crescent gave rise to a disorganized ball of cells.

RESULTS AND CONCLUSION: Because only blastomeres containing all or part of the gray crescent developed into tadpoles, the gray crescent marks the location of essential developmental determinants in the fertilized egg.

Figure 51-8 Cytoplasmic determinants in frog development

PREDICT Consider Gurdon's experiments demonstrating nuclear totipotency in frogs illustrated in Figure 17-3. What do you think would be the result if the same experiments were done, but substituting a blastomere lacking a gray crescent for an unfertilized egg?

During gastrulation, the embryo begins to approximate its body plan as cells arrange themselves into three distinct **germ layers**, or embryonic tissue layers: the outermost layer, the **ectoderm**; the innermost layer, the **endoderm**; and the **mesoderm**, which develops between them. Additional cell divisions take place during gastrulation, and the germ layers become established through a combination of processes. Many cells lose their old cell-to-cell contacts and establish new ones through cell recognition and adhesion processes involving interactions among the integrins and other plasma membrane proteins and the extracellular matrix (see Chapters 4 and 5). Many cells undergo cytoskeletal changes, particularly alterations in the distribution of actin microfilaments; these changes in the internal architecture of the cells allow them to change shape and/or undergo specific, directional, amoeboid movements. As a result of these movements, many cells ultimately take up new positions in the interior of the embryo.

Each of the germ layers develops into specific parts of the embryo. As you study the illustrations, keep in mind that a conventional color code accepted by developmental biologists is used to depict the germ layers: endoderm, yellow; mesoderm, red or pink; and ectoderm, blue.

The amount of yolk affects the pattern of gastrulation

The simple type of gastrulation that occurs in echinoderms and in amphioxus is illustrated in Figures 51-3f and g and 51-4i and j, respectively. Gastrulation begins when a group of cells at the vegetal pole undergoes a series of changes in shape that cause that part of the blastula wall to first flatten and then bend inward (invaginate). The invaginated wall eventually meets the opposite wall, obliterating the blastocoel.

You can roughly demonstrate this type of gastrulation by pushing inward on the wall of a partly deflated rubber ball until it rests against the opposite wall. In a similar way, the embryo is converted into a double-walled, cup-shaped structure. The new internal wall lines the **archenteron**, the newly formed cavity of the developing gut. The opening of the archenteron to the exterior, the **blastopore**, is the site of the future anus in deuterostomes.

This simple type of gastrulation cannot occur in the amphibian embryo because the large yolk-laden cells in the vegetal half of the blastula obstruct any inward movement at the vegetal pole. Instead, cells from the animal pole move down the embryo surface; when they reach the region derived from the gray crescent, they move into the interior. This inward movement is accomplished as the cells change shape, first becoming flask- or bottle-shaped (so that most of their mass is actually below the surface) and then sinking into the interior as they lose their remaining connections with other cells on the surface. This spot on the embryo's surface, referred to as the *dorsal lip of the blastopore*, is marked by a dimple, shaped like a C lying on its side (FIG. 51-9). As the process continues, the blastopore becomes ring-shaped as cells lateral, and then ventral, to its dorsal lip become involved in similar

Key Point

Gastrulation forms the three germ layers: endoderm, ectoderm, and mesoderm.

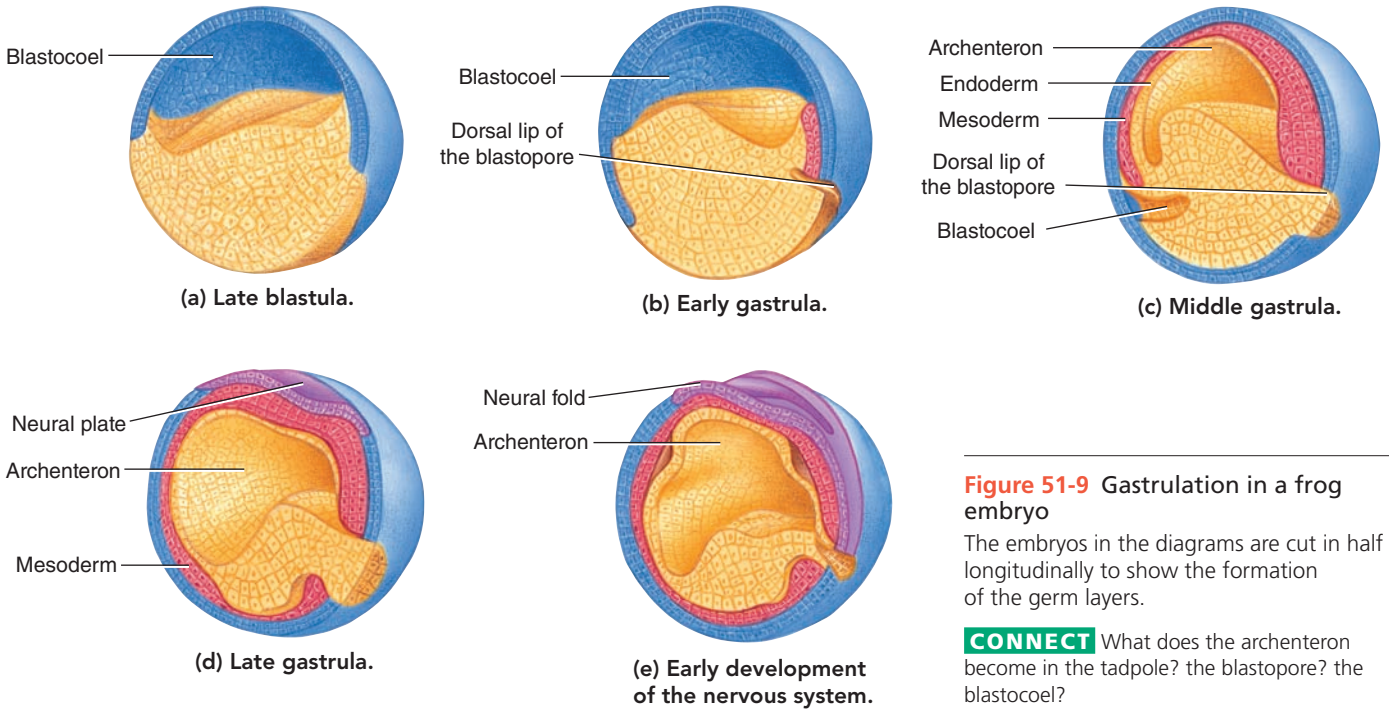

Figure 51-9 Gastrulation in a frog embryo

The embryos in the diagrams are cut in half longitudinally to show the formation of the germ layers.

CONNECT What does the archenteron become in the tadpole? the blastopore? the blastocoel?

movements. The yolk-filled cells fill the space enclosed by the lips of the blastopore, forming the yolk plug.

The archenteron forms and is lined on all sides by cells that have moved in from the surface. At first, the archenteron is a narrow slit, but it gradually expands at the anterior end of the embryo. As a result, the blastocoel progressively shrinks and eventually disappears.

Although the details differ somewhat, gastrulation in birds is basically similar to amphibian gastrulation. Cells that make up the upper layer (the epiblast) migrate toward the midline to form a thickened region known as the **primitive streak**, which elongates and narrows as it develops. At its center is a narrow furrow, the **primitive groove**. The primitive streak is a dynamic structure. Its cells constantly change as they migrate in from the epiblast, sink inward at the primitive groove, and then move out laterally and anteriorly in the interior (FIG. 51-10). The primitive groove is the functional equivalent of the blastopore of the echinoderm, amphioxus, and amphibian embryos. However, a bird embryo contains no cavity homologous to the archenteron.

At the anterior end of the primitive streak, cells destined to form the **notochord** (supporting rod of mesodermal cartilage-like cells that serves as the flexible skeletal axis in all chordate embryos) concentrate in a thickened knot known as **Hensen's node**. These cells sink into the interior and then move anteriorly just beneath the epiblast, forming a narrow extension from the node. Cells that will form other types of mesoderm move laterally and anteriorly from the primitive streak, between the epiblast (which becomes ectoderm) and the hypoblast. Other cells that form the endoderm displace the hypoblast cells and cause them to move laterally. These displaced cells will form part of the extraembryonic membranes, discussed in a later section.

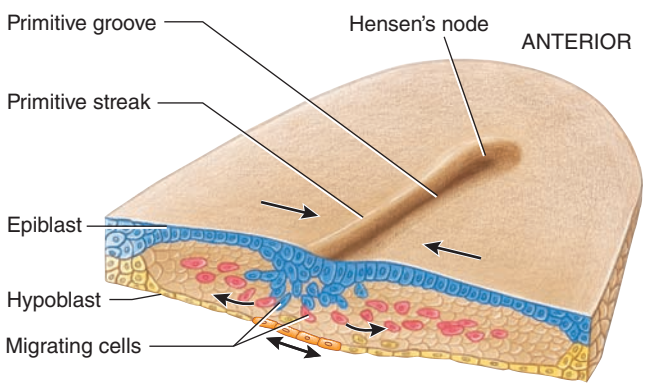

Figure 51-10 Gastrulation in birds

A three-layered embryo forms as cells move toward the primitive streak, move inward at the primitive groove, and migrate laterally and anteriorly in the interior. The *red cells* will develop as mesoderm. Cells shown just above the double-headed arrow have migrated into the hypoblast; they are moving laterally and will eventually become endoderm.

CHECKPOINT 51.4

- **CONNECT** What is the archenteron? Is an archenteron formed in sea stars? in amphibians? in birds?
- **CONNECT** How do the amount and distribution of yolk influence gastrulation?

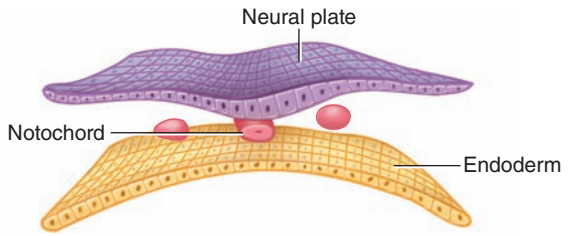
51.5 Organogenesis

LEARNING OBJECTIVES

8 Define *organogenesis* and summarize the fate of each of the germ layers.

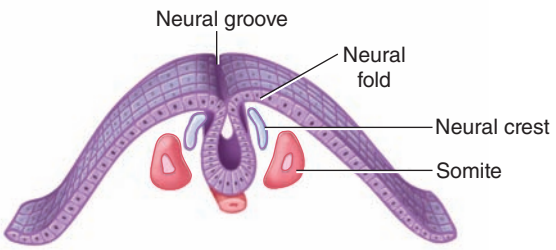
9 Trace the early development of the vertebrate nervous system.

Gastrulation leads to **organogenesis**, or organ formation, in which the cells of the three germ layers continue the processes of pattern formation that lead to the formation of specific structures. The ectoderm eventually forms the outer layer of the skin and gives rise to the nervous system and sense organs. Tissues that eventually line the digestive tract, and organs that develop as outgrowths of the digestive tract (including the liver, pancreas, and lungs), are all of endodermal origin. Skeletal tissue, muscle, and the circulatory, excretory, and reproductive systems all are derived from mesoderm (TABLE 51-1; see Fig. 17-1).



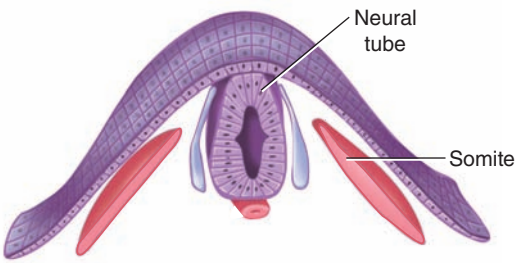
The notochord, brain, and spinal cord are among the first organs to develop in the early vertebrate embryo (FIG. 51-11; see also Figs. 51-9d and e). First, the notochord, which is mesodermal tissue, grows forward along the length of the embryo as a cylindrical rod of cells. The notochord is eventually replaced by the vertebral column, although notochord remnants will remain in the cartilage discs between the vertebrae.

Table 51-1 Fate of the Germ Layers Formed at Gastrulation



ECTODERM
Nervous system and sense organs
Outer layer of skin (epidermis) and its associated structures (nails, hair, etc.)
Pituitary gland
MESODERM
Notochord
Skeleton (bone and cartilage)
Muscles
Circulatory system
Excretory system
Reproductive system
Inner layer of skin (dermis)
Outer layers of digestive tube and of structures that develop from it, such as part of the respiratory system
ENDODERM
Lining of digestive tube and of structures that develop from it, such as lining of the respiratory system

The developing notochord has yet another crucial function. Numerous experiments in which researchers have transplanted portions of the notochord mesoderm to other locations in the embryo show that the notochord causes the overlying ectoderm to thicken and differentiate to form the precursor of the central nervous system, the **neural plate**. Such phenomena, in which certain cells stimulate or otherwise influence the differentiation of their neighbors, are examples of **induction** (see Chapter 17).



Repeated testing supports the hypothesis that induction of the neural plate cells does not require direct cell-to-cell contact with the developing notochord cells. Researchers therefore think that this induction involves the diffusion of some type of signal molecule, although they have not yet identified the chemical signal itself. The induction of the neural plate by the notochord is a good example of the importance of a cell's position in relation to other cells. That position is often

(a) Approximately 19 days. The neural plate has begun to indent and form a shallow groove that will be flanked by neural folds.

(b) Approximately 20 days. The neural folds approach one another. The neural crest cells, derived from ectoderm, will migrate in the embryo and give rise to sensory neurons; the somites are blocks of mesoderm that become the vertebrae and other segmented body parts. (The endoderm is not shown.)

(c) Approximately 26 days. The neural folds have joined to form the hollow neural tube, which gives rise to the brain at the anterior end of the embryo and the spinal cord posteriorly. (The endoderm is not shown.)

critical in determining the fate of a cell because it determines the cell's exposure to substances released from other cells.

The cells of the neural plate undergo changes in shape that cause the central cells of the neural plate to move downward and form a depression called the *neural groove*; the cells flanking the groove on each side form *neural folds*. Continued changes in cell shape bring the folds closer together until they meet and fuse to form the **neural tube**. In this process, the hollow neural tube comes to lie beneath the surface. The ectoderm overlying it will form the outer layer of skin. The anterior portion of the neural tube grows and differentiates into the brain; the rest of the tube develops into the spinal cord. The brain and the spinal cord remain hollow, even in the adult; the ventricles of the brain and central canal of the spinal cord are persistent reminders of their embryonic origins.

Various motor nerves grow out of the developing brain and spinal cord, but sensory nerves have a separate origin. When the neural folds fuse to form the neural tube, bits of nervous tissue known as the *neural crest* arise from ectoderm on each side of the tube. **Neural crest cells** migrate downward from their original position and form the dorsal root ganglia of the spinal nerves and the postganglionic sympathetic neurons. From sensory cells in the dorsal root ganglia, dendrites grow out to the sense organs, and axons grow into the spinal cord. Other neural crest cells migrate to various locations in the embryo. They give rise to parts of certain sense organs, nearly all pigment-forming cells in the body, and parts of the head. Some head derivatives of the neural crest are the cartilage and bone of the skull, face, and jaw; connective tissue in the eye and face dermis; sensory nerves and other parts of the peripheral nervous system; and ganglia of the autonomic nervous system.

As the nervous system develops, other organs also begin to take shape. Blocks of mesoderm known as somites form on either side of the neural tube and will give rise to the vertebrae, muscles, and other components of the body axis. In addition to the skeleton and muscles, mesodermal structures include the kidneys, reproductive structures, and the circulatory organs. In fact, the heart and blood vessels are among the first structures to form, and they must function while still developing.

The development of the four-chambered heart of birds and mammals is a good example of organogenesis (FIG. 51-12; see Chapter 44). The heart originates through the fusion of paired blood vessels. Venous blood enters the single atrium; passes into the single ventricle, which is located above the atrium; and is then pumped into the embryo. During subsequent development, the atrium undergoes a process of torsion that brings it to a position above the ventricle, and partitions form that divide the atrium and the ventricle into right and left chambers.

The digestive tract is first formed as a separate foregut and hindgut as the body wall grows and folds; this process cuts them off as two simple tubes. As the embryo grows, these tubes, which are lined with endoderm, grow and become greatly elongated. The liver, pancreas, and trachea originate as hollow, tubular outgrowths from the gut. As the trachea grows downward, it gives rise to the paired lung buds, which develop into lungs. The most anterior part of the foregut becomes the pharynx.

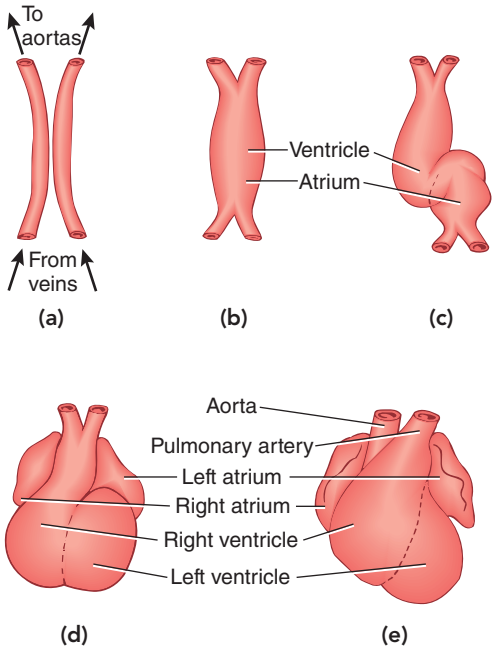

Figure 51-12 Formation of the heart in birds and mammals
These ventral views of successive stages show that the heart forms from the fusion of two blood vessels and that at first the end that receives blood from the veins is at the bottom. The developing heart twists to carry the atrium to a position above the ventricle, and the chambers then divide to form the four-chambered heart.

A series of small outpocketings of the pharynx, the *pharyngeal pouches*, bud out laterally. These pouches meet the *branchial grooves*, a corresponding set of inpocketings from the overlying ectoderm. The arches of tissue formed between the grooves are called *branchial arches*. They contain the rudimentary skeletal, neural, and vascular elements of the face, jaws, and neck.

In fishes and some amphibians, the pharyngeal pouches and branchial grooves meet and form a continuous passage from the pharynx to the outside; these gill slits function as respiratory organs. In terrestrial vertebrates, each branchial groove remains separated from the corresponding pharyngeal pouch by a thin membrane of tissue, and these structures give rise to organs more appropriate for life on land. For example, the middle-ear cavity and its connection to the pharynx, the eustachian tube, derive from a pharyngeal pouch.

CHECKPOINT 51.5

- **CONNECT** What adult structures develop from each germ layer?
- **CONNECT** How do cell division, growth, cell differentiation, and morphogenesis interact in the formation of the neural tube?
- What is the developmental significance of the neural crest cells?

51.6 Extraembryonic Membranes

LEARNING OBJECTIVE

10 Give the origins and functions of the chorion, amnion, allantois, and yolk sac.

In terrestrial vertebrates, the three germ layers also give rise to four **extraembryonic membranes**: the chorion, amnion, allantois, and yolk sac (FIG. 51-13). Although they develop from the germ layers, these membranes are not part of the embryo itself and are discarded at hatching or birth. The extraembryonic membranes are adaptations to the challenges of embryonic development on land. They protect the embryo, prevent it from drying out, and help in obtaining food and oxygen and eliminating wastes.

The outermost membrane, the **chorion**, encloses the entire embryo as well as the other membranes. Lying underneath the eggshell in birds and reptiles, it functions as the major organ of gas exchange. As you will see in the next section, its functions have been extended in humans and most other mammals.

Like the chorion, the **amnion** encloses the entire embryo. The amniotic cavity, the space between the embryo and the amnion, becomes filled with amniotic fluid secreted by the membrane. (Recall from Chapter 32 that terrestrial vertebrates are known as *amniotes* because their embryos develop within this pool of fluid.) The amniotic fluid prevents the embryo from drying out and permits it a certain freedom of motion. The fluid also serves as a protective cushion that absorbs shocks and prevents the amniotic membrane from sticking to the embryo. In current medical practice, a sample of amniotic fluid can be obtained through a procedure known as *amniocentesis* and analyzed for biochemical or chromosomal abnormalities that indicate a possible birth defect (see Fig. 16-12).

The **allantois** is an outgrowth of the developing digestive tract. In reptiles and birds, it stores nitrogenous wastes. In humans, the allantois is small and nonfunctional except that its blood vessels contribute to the formation of umbilical vessels joining the embryo to the placenta. In vertebrates with yolk-rich eggs, the **yolk sac** encloses the yolk, slowly digests it, and makes it available to the embryo. A yolk sac, connected to the embryo by a yolk stalk, develops even in mammalian embryos that have little or no yolk. Its walls serve as temporary centers for the formation of blood cells.

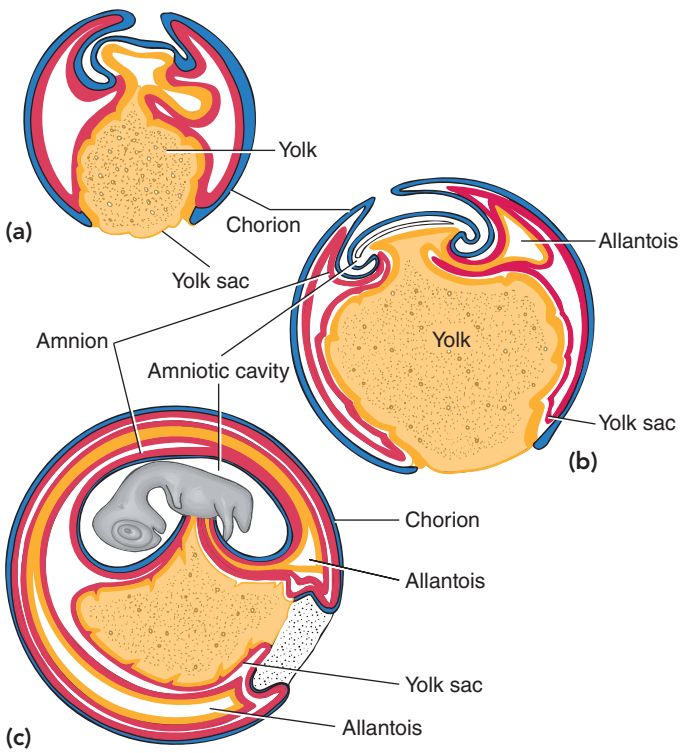

Figure 51-13 Extraembryonic membranes

The formation of the extraembryonic membranes of the chick is illustrated at **(a)** four days, **(b)** five days, and **(c)** nine days of development. Each of the membranes develops from a combination of two germ layers. The chorion and amnion form from lateral folds of the ectoderm and mesoderm that extend over the embryo and fuse. The allantois and the yolk sac develop from endoderm and mesoderm.

CHECKPOINT 51.6

- What are the roles of the chorion and amnion in terrestrial vertebrate embryos?
- **CONNECT** What are the functions of the allantois and yolk sac in birds? Do they have comparable roles in mammals? Explain your answer.

51.7 Human Development

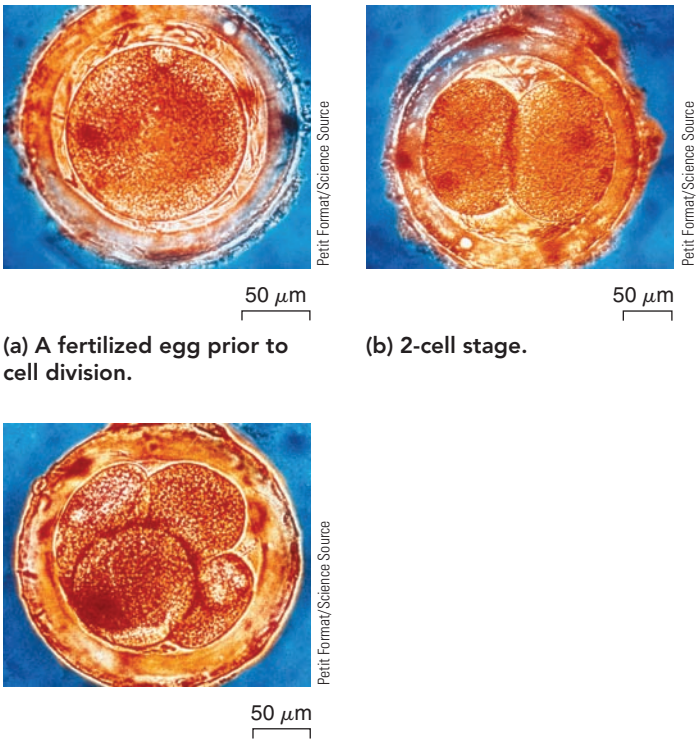
LEARNING OBJECTIVES

11 Describe the general course of early human development, including fertilization, the fates of the trophoblast and inner cell mass, implantation, and the role of the placenta.

12 Contrast postnatal and prenatal life, describing several changes that occur at or shortly after birth that allow the neonate to live independently.

The human *gestation period*, the duration of pregnancy, averages 266 days (38 weeks, or about 9 months) from the time of fertilization to the birth of the baby (TABLE 51-2). We will use this system of timing when discussing the events of early development. Because the time of fertilization is not easily marked, obstetricians usually time the pregnancy by counting from the date of onset of the woman's last menstrual period; by this calculation, an average pregnancy is 280 days (40 weeks).

Fertilization occurs in the oviduct, and within 24 hours the human zygote has divided to become a 2-celled embryo (FIG. 51-14). Cleavage continues as the embryo is propelled along the oviduct by ciliary action.



When the embryo enters the uterus on about the fifth day of development, the *zona pellucida* (its surrounding coat) is dissolved. During the next few days, the embryo floats free in the uterine cavity and is nourished by a nutritive fluid secreted

Table 51-2 Some Important Developmental Events in the Human Embryo

Time from Fertilization	Event
24 hours	Embryo reaches 2-cell stage
3 days	Morula reaches uterus
7 days	Blastocyst begins to implant
2.5 weeks	Notochord and neural plate are formed; tissue that will give rise to heart is differentiating; blood cells are forming in yolk sac and chorion
3.5 weeks	Neural tube forming; primordial eye and ear visible; pharyngeal pouches forming; liver bud differentiating; respiratory system and thyroid gland just beginning to develop; heart tubes fuse, bend, and begin to beat; blood vessels are laid down
4 weeks	Limb buds appear; three primary divisions of brain forming
2 months	Muscles differentiating; embryo capable of movement; gonad distinguishable as testis or ovary; bones begin to ossify; cerebral cortex differentiating; principal blood vessels assume final positions
3 months	Sex can be determined by external inspection; notochord degenerates; lymph glands develop
4 months	Face begins to look human; lobes of cerebrum differentiate; eyes, ears, and nose look more "normal"
Third trimester	Downy hair covers the fetus, then later is shed; neuron myelination begins; tremendous growth of body
266 days	Birth

(a) A fertilized egg prior to cell division.

(b) 2-cell stage.

(c) Cleavage divisions continue.

Figure 51-14 Cleavage in a human embryo

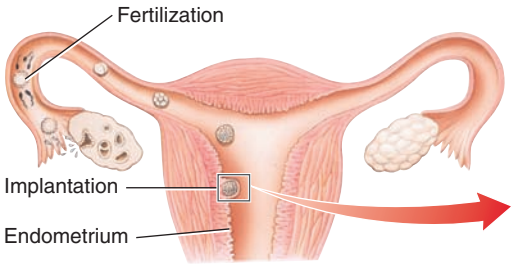
by the glands of the uterus. Its cells arrange themselves, forming a blastula, which in mammals is called a **blastocyst**. The outer layer of cells, the **trophoblast**, eventually forms the chorion and amnion that surround the embryo. A little cluster of cells, the **inner cell mass**, projects into the cavity of the blastocyst. The inner cell mass gives rise to the embryo proper.

On about the seventh day of development, the embryo begins the process of **implantation**, in which it embeds in the endometrium of the uterus (FIG. 51-15). The trophoblast cells in contact with the endometrium secrete enzymes that erode an area just large enough to accommodate the tiny embryo. As the embryo slowly works its way into the underlying connective and vascular tissues, the opening in the endometrium repairs itself. All further development of the embryo takes place *within* the endometrium.

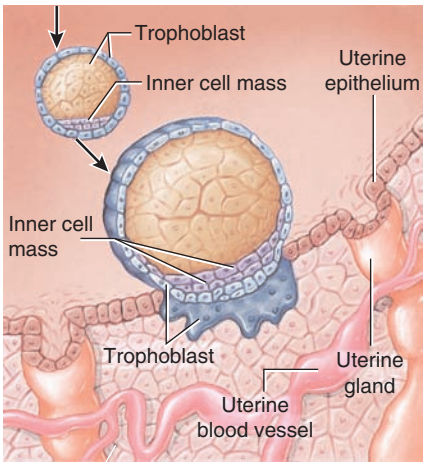
The placenta is an organ of exchange

In placental mammals, the **placenta** is the organ of exchange between mother and embryo (see Fig. 51-15). The placenta provides nutrients and oxygen for the fetus and removes wastes, which the mother then excretes. In addition, the placenta is an endocrine organ that secretes estrogens and progesterone to maintain pregnancy. The placenta develops from both the chorion of the embryo and the uterine tissue of the mother. In early development, the chorion grows rapidly, invading the endometrium and forming fingerlike projections known as *chorionic villi*. The chorionic villus sampling technique allows prenatal detection of certain genetic disorders (see Fig. 16-13). The villi become vascularized (infiltrated with blood vessels) as the embryonic circulation develops.

As the human embryo grows, the **umbilical cord** develops and connects the embryo to the placenta (see Fig. 51-15e). The umbilical cord contains the two umbilical arteries and the umbilical vein. The umbilical arteries connect the embryo to a vast network of capillaries developing within the chorionic villi. Blood from the villi returns to the embryo through the umbilical vein.



The placenta consists of the portion of the chorion that develops villi, together with the underlying uterine tissue that contains maternal capillaries and small pools of maternal blood. The fetal blood in the capillaries of the chorionic villi comes in close contact with the mother's blood in the tissues between the villi. The two circulations are always separated by a membrane through which substances may diffuse or be actively transported. Maternal and fetal blood do not normally mix in the placenta or any other place.



The placenta produces several hormones. From the time the embryo first begins to implant itself, its trophoblastic cells release **human chorionic gonadotropin (hCG)**, which signals the corpus luteum (see Chapter 50) that pregnancy has begun. In response, the corpus luteum increases in size and releases large amounts of progesterone and estrogens. These hormones stimulate continued development of the endometrium and placenta.

Without hCG, the corpus luteum would degenerate and the embryo would abort and be flushed out with the menstrual flow. The woman would probably not even know she had been pregnant. If the corpus luteum is removed before about the 11th week after fertilization, the embryo spontaneously aborts. After that time, the placenta itself produces enough progesterone and estrogens to maintain pregnancy.

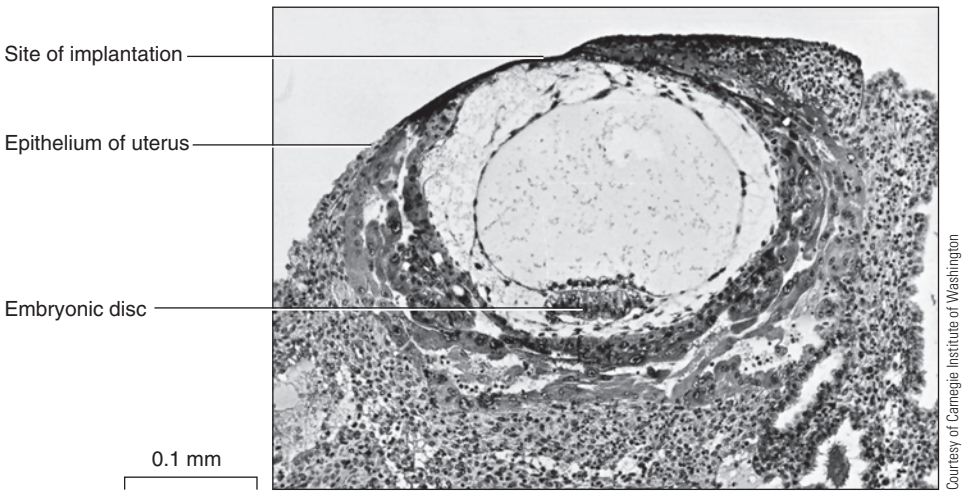
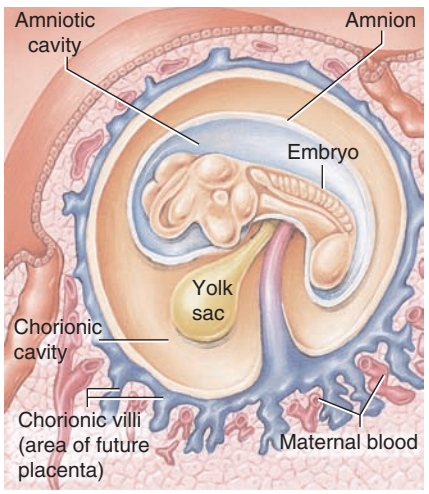
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.





(a) 7 days. About 7 days after fertilization, the blastocyst drifts to an appropriate site along the uterine wall and begins to implant. The cells of the trophoblast proliferate and invade the endometrium.

(b) 10 days. About 10 days after fertilization, the chorion has formed from the trophoblast.

(c) 12 days. This LM shows an implanted blastocyst at about 12 days after fertilization.

(d) 25 days. After 25 days, the maternal blood vessels provide the embryo with oxygen and nutrients. Note the specialized region of the chorion that will become the placenta.

(e) 45 days. At about 45 days, the embryo and its membranes together are about the size of a Ping-Pong ball, and the mother still may be unaware of her pregnancy. The amnion filled with amniotic fluid surrounds and cushions the embryo. The yolk sac has been incorporated into the umbilical cord. Blood circulation has been established through the umbilical cord to the placenta.

Organ development begins during the first trimester

Gastrulation occurs during the second and third weeks of development. Then the notochord begins to form and induces formation of the neural plate. The neural tube develops, and the forebrain, midbrain, and hindbrain are evident by the fifth week of development. A week or so later, the forebrain begins to grow outward, forming the rudiments of the cerebral hemispheres.

The heart begins to develop and after 3.5 weeks begins to beat spontaneously because the embryo is growing large enough to require a functional circulatory system. Pharyngeal pouches, branchial grooves, and branchial arches form in the region of the developing pharynx. In the floor of the pharynx, a tube of cells grows downward to form the primordial trachea, which gives rise to the lung buds. The digestive system also gives rise to outgrowths that develop into the liver, gallbladder, and pancreas. A thin tail becomes evident but does not grow as rapidly as the rest of the body and so becomes inconspicuous by the end of the second month. Near the end of the fourth week, the limb buds begin to differentiate; they eventually give rise to arms and legs.

The reproductive system begins development during the fourth week. Paired gonads form, but they are undifferentiated and not distinguishable as ovaries or testes. As shown in FIGURE 51-16, two pairs of potential systems of reproductive ducts form, the *Wolffian ducts* and the *Müllerian ducts*, as well as the *genital tubercle*, a small precursor of the penis or clitoris. If the embryo is XY, as discussed in Chapter 11, the *SRY (sex reversal on Y)* gene becomes activated, causing the gonads to develop as testes. The testes produce testosterone and other hormones that cause the Wolffian ducts to develop into the vasa deferentia and associated internal structures of the male and the genital tubercle to develop as a penis. The Müllerian ducts degenerate. If the embryo is XX, the gonads differentiate as ovaries, the Wolffian ducts degenerate, the Müllerian ducts develop into the oviducts and associated internal structures, and the genital tubercle develops as the clitoris.

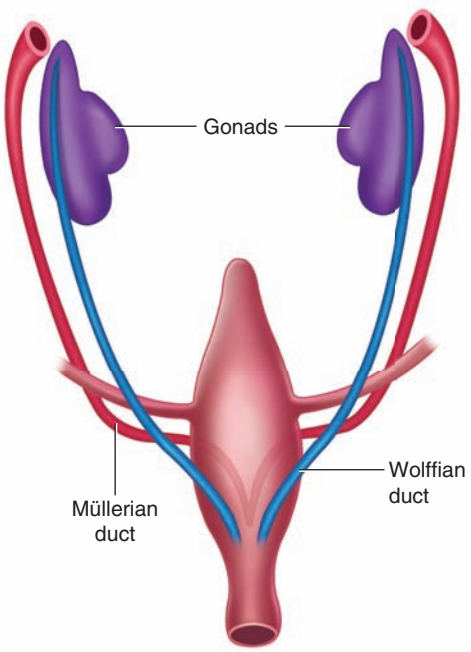

Figure 51-16 The human reproductive system in its early, undifferentiated state

If the embryo is XY, the gonads will develop as testes, the Wolffian ducts will become the vasa deferentia and associated structures, and the Müllerian ducts will degenerate. In an XX embryo, the gonads develop as ovaries, the Müllerian ducts become the oviducts and associated structures, and the Wolffian ducts degenerate.

All the organs continue to develop during the second month (see chapter-opening photograph). Muscles develop, and the embryo becomes capable of movement. The brain begins to send impulses that regulate the functions of some organs, and a few simple reflexes are evident. After the first two months of development, the embryo is referred to as a **fetus** (FIG. 51-17).

By the end of the *first trimester* (the first three months of development), the fetus is about 56 mm (2.2 in.) long and weighs about 14 g (0.5 oz). Although small, it looks human. The external genital structures have differentiated, indicating the sex of the fetus. Ears and eyes approach their final positions. Some of the skeleton becomes distinct, and the developing vertebral column has replaced the notochord. The fetus performs breathing movements, pumping amniotic fluid into and out of its lungs, and even makes sucking motions.

Development continues during the second and third trimesters

During the second trimester (months four through six), the fetal heart can be heard with a stethoscope. The fetus moves freely within the amniotic cavity, and during the fifth month the mother usually becomes aware of relatively weak fetal movements ("quickening"). The fetus grows rapidly during the final trimester (months seven through nine), and final

differentiation of tissues and organs occurs. If born at 24 weeks (out of 40 weeks), the fetus has only about a 50% chance of surviving, even with the best of medical care. Its brain is not yet sufficiently developed to sustain vital functions such as rhythmic breathing, and the kidneys and lungs are immature.

During the seventh month, the cerebrum grows rapidly and develops convolutions. The grasping and sucking reflexes are evident, and the fetus may suck its thumb. Any infant born before 37 weeks (out of 40) is considered premature. According to statistics made available by the March of Dimes, premature birth is an increasing problem in the United States, its incidence having risen to 9.6% in 2016. Each year, well over half a million premature babies are born in the United States and more than 15 million worldwide. Babies born at 28 or fewer weeks are at greatest risk of death and severe defects. Babies born closer to 37 weeks have a greater chance of survival with competent medical care but may still face multiple long-term health problems.

At birth the average full-term baby in the United States weighs about 3400 g (7.5 lb) and measures about 52 cm (20 in.) in total length. A baby that weighs less than 2500 g (5.5 lb) is considered low birth weight and is at risk even if not premature.

More than one mechanism can lead to a multiple birth

Occasionally, the cells of the 2-cell embryo separate, and each cell develops into a complete organism. Alternatively, sometimes the inner cell mass subdivides, forming two groups of cells, each of which develops independently. Because these cells have identical sets of genes, the individuals formed are exactly alike and are called **monozygotic**, or identical, twins. Very rarely, the two inner cell masses do not completely separate and so give rise to *conjoined twins*, who are physically attached and usually share one or more body parts.

Dizygotic twins, also called fraternal twins, develop when two eggs are ovulated and each is fertilized by a different sperm. Each zygote has its own distinctive genetic endowment, so the individuals produced are not identical. They may not even be of the same sex. Similarly, triplets (and other multiple births) may be either identical or fraternal.

Before fertility-inducing agents became available in the United States, about 2.5% of babies born were twins, and higher multiples were very rare. However, widespread use of drugs to improve fertility has been linked to an increase in multiple births. The March of Dimes reports that between 1980 and 2004 the rate of twin births increased by about 70% and the rate of triplet births increased fivefold. These rates may now be stabilizing; the rate of twin births does not appear to be increasing, and the rate of triplet births has declined slightly.

A family history of twinning increases the probability of having dizygotic twins. However, giving birth to monozygotic twins is probably not influenced by heredity, age of the mother, or other known factors. An estimated two-thirds of multiple pregnancies end in the birth of a single baby; the other embryo(s) may be absorbed within the first ten weeks of pregnancy, or spontaneously aborted. Ultrasound imaging techniques are used to produce a type of image known as a **sonogram**, which can provide valuable data regarding the presence of multiple embryos. This information is medically important because multiple births are associated with higher infant mortality, which is largely a consequence of an increased risk of prematurity and low birth weight.

Environmental factors affect the embryo

We all know that the growth and development of babies are influenced by the food they eat, the air they breathe, the disease organisms that infect them, and the chemicals or drugs to which they are exposed. **Prenatal** development is also affected by these environmental influences. Life before birth is even more sensitive to environmental changes than it is for the fully formed baby. Although there is no direct mixing of maternal and fetal blood, diffusion and various other mechanisms allow many substances—nutrients, drugs, pathogens, and gases—to travel across the placenta.

TABLE 51-3 describes some environmental influences on development. Some of them are **teratogens**, drugs or other substances that interfere with morphogenesis and so cause malformations. Many factors, such as smoking, alcohol use, and poor nutrition, contribute to low birth weight, a condition responsible for many infant deaths.

About one out of every 33 newborns in the United States has a defect of clinical significance. Such birth defects account for more than 20% of deaths among newborns. Birth defects may be caused by genetic and/or environmental factors. Genetic factors were discussed in Chapter 17. In this section we examine some environmental conditions that affect the well-being of the embryo.

Timing is important. Each developing structure has a critical period during which it is most susceptible to unfavorable conditions. Generally, this critical period occurs early in the structure's development, when interference with cell movements or divisions may prevent formation of normal shape or size, resulting in permanent malformation. Because most structures form during the first three months of embryonic life, the embryo is most susceptible to environmental factors during this early period. During part of this time, the woman may not even realize that she is pregnant and so may not take special precautions to minimize potential dangers.

Physicians diagnose some defects while the embryo is in the uterus. In some cases, treatment is possible before birth. Amniocentesis and chorionic villus sampling, discussed in Chapter 16, are techniques used to detect certain defects. Ultrasound imaging techniques mentioned previously help diagnose defects and determine the position of the fetus. Ultrasound has been used for many years, and unlike imaging techniques that use radiation, no risk of harm to the fetus has been traced to its use. New methods currently under development or refinement include special types of magnetic resonance imaging, or MRI, and high-resolution, three-dimensional ultrasound imaging (FIG. 51-18).

The neonate must adapt to its new environment

Important changes take place after birth. During prenatal life, the fetus received both food and oxygen from the mother through the placenta. Now the newborn's own digestive and

Table 51-3 Environmental Influences on the Embryo

Factor	Example and Effect	Comment
NUTRITION	Severe protein malnutrition doubles number of defects, fewer brain cells are produced, and learning ability may be permanently affected; deficiency of folic acid (a vitamin) linked to CNS defects such as spina bifida (open spine), low birth weight.	Growth rate mainly determined by rate of net protein synthesis by embryo's cells.
MEDICATIONS	Many medications, even aspirin, affect development of the fetus.	Herbal drugs and dietary supplements are unregulated.
Excessive vitamins	Vitamin D essential, but excessive amounts may result in a form of intellectual disability; an excess of vitamins A and K may also be harmful.	Vitamin supplements are normally prescribed for pregnant women, but only the recommended dosage should be taken.
Thalidomide	Thalidomide, marketed in Europe as a mild sedative, was responsible for serious malformations in about 10,000 babies born in the late 1950s in 20 countries; principal defect was phocomelia, a condition in which babies are born with extremely short limbs, often with no fingers or toes.	This teratogenic drug interferes with the development of blood vessels and nerves; most hazardous when taken during fourth to fifth weeks, when limbs are developing; thalidomide has been approved for the treatment of leprosy and certain cancers (e.g., myeloma), and clinical trials are being conducted to test its usefulness in the treatment of other cancers and some of the complications of AIDS.*
Accutane (isotretinoin)	Accutane, a synthetic derivative of vitamin A, is used for the treatment of cystic acne. A woman who takes Accutane during pregnancy has a one in five chance of having a child with serious malformations of the brain (causing intellectual disability), head and face, thymus gland (interfering with immune function), or heart.	Although Accutane is marketed with severe restrictions to prevent pregnant women from taking this teratogenic drug, several children are born each year with birth defects attributable to Accutane exposure.
PATHOGENS		
Zika	Zika virus is carried by mosquitos and is also transmitted sexually.	One study found that fetal infection with Zika virus caused a variety of birth defects in at least 10% of cases; these included microcephaly (smaller than usual head size), brain damage and other neurological abnormalities, and limb defects. As of 2017, there was no vaccine and no treatment.
Rubella	Rubella (German measles) virus crosses placenta and infects embryo; interferes with normal metabolism and cell movements; causes syndrome that involves blinding cataracts, deafness, heart malformations, and intellectual disability; risk is greatest (about 50%) when rubella is contracted during the first month of pregnancy; risk declines with each succeeding month.	Rubella epidemic in the United States in 1963–1965 resulted in about 20,000 fetal deaths and 30,000 infants born with serious defects; immunization is available but must be administered several months before conception.
HIV*	HIV can be transmitted from mother to baby before birth.	See discussion of AIDS in Chapter 45.
Syphilis	Syphilis is transmitted to fetus in about 40% of infected women; fetus may die or be born with defects and congenital syphilis.	Pregnant women are routinely tested for syphilis during prenatal examinations; most cases can be safely treated with antibiotics.
IONIZING RADIATION	When a pregnant woman is subjected to X-rays or other forms of radiation, infant has a higher risk of birth defects and leukemia.	Radiation was one of the earliest causes of birth defects to be recognized.
RECREATIONAL AND/OR ABUSED SUBSTANCES		
Alcohol	When a woman drinks heavily during pregnancy, the baby may be born with fetal alcohol syndrome (FAS), which includes certain physical deformities and intellectual disability; low birth weight and structural abnormalities have been associated with as little as two drinks a day; some cases of hyperactivity and learning disabilities have occurred.	FAS is the leading cause of preventable intellectual disability in the United States.
Cigarette smoking	Cigarette smoking reduces the amount of oxygen available to the fetus because some of the maternal hemoglobin is combined with carbon monoxide; may slow growth and can cause subtle forms of damage.	Mothers who smoke cigarettes deliver babies with lower-than-average birth weights and have a higher incidence of spontaneous abortions, stillbirths, and neonatal deaths, especially from SIDS;* studies also indicate a possible relationship between maternal smoking and slower intellectual development in offspring.
Cocaine	Constricts fetal arteries, resulting in retarded development and low birth weight; in severe cases there may be learning and behavioral problems, heart defects, and other medical problems.	Cocaine users frequently abuse alcohol as well, so it is difficult to separate the effects.
Heroin	High rates of mortality and prematurity; low birth weight.	Infants who survive are born addicted and must be treated for weeks or months; risk of SIDS is increased ten-fold.

* AIDS, acquired immunodeficiency syndrome; HIV, human immunodeficiency virus; SIDS, sudden infant death syndrome

GE Medical Systems/Science Source

Figure 51-18 Three-dimensional ultrasound image of a human fetus at about 16 weeks gestation
Note the enhanced soft tissue detail.

respiratory systems must function. Correlated with these changes are several major changes in the circulatory system.

Normally, the **neonate** (newborn infant) begins to breathe within a few seconds of birth and cries within half a minute. If anesthetics have been given to the mother, however, the fetus may also be anesthetized, and its breathing and other activities may be depressed. Some infants may not begin breathing immediately, which is one reason many women request childbirth methods that minimize the use of medication.

Researchers think that the neonate's first breath is initiated by the accumulation of carbon dioxide in the blood after the umbilical cord is cut. Carbon dioxide stimulates the respiratory centers in the medulla. The resulting expansion of the lungs enlarges its blood vessels (which in the uterus were partially collapsed). Blood from the right ventricle flows in increasing amounts through these larger pulmonary vessels. (During fetal life, blood bypasses the lungs in two ways: by flowing through an opening, the *foramen ovale*, which shunts blood from the right atrium to the left atrium; and by flowing through an arterial duct connecting the pulmonary artery and aorta. Both of these routes close off after birth.)

Aging is not a uniform process

We have examined briefly the development of the embryo and fetus, the birth process, and the adjustments required of the neonate. The human life cycle then proceeds through the stages of infant, child, adolescent, young adult, middle-aged adult, and elderly adult.

Development encompasses any biological change within an organism over time, including the changes commonly called **aging**. Changes during the aging process decrease function in the older individual. The declining capacities of the various systems in the human body, although most apparent in the elderly, may begin much earlier in life. Relatively little is known about the aging process itself; it is now an active field of investigation, and researchers are gaining considerable insight through genetic studies on model organisms such as the nematode worm, *Caenorhabditis elegans*; the fruit fly, *Drosophila melanogaster*; and the laboratory mouse, *Mus musculus* (see Chapter 17).

CHECKPOINT 51.7

- How does a human blastocyst form and implant?
- How does the placenta form, and what is its function?
- During which trimester does the cerebrum develop convolutions? When do the limb buds begin to differentiate?
- **CONNECT** What differences between fetal life and the life of a neonate require adaptations immediately after birth?

Summary: Focus on Learning Objectives

51.1 Development of Form *(page 1105)*

1 Analyze the relationship between cell determination and cell differentiation and between pattern formation and morphogenesis.

- **Cell determination** is a series of molecular events that lead to **cell differentiation**, in which a cell becomes specialized and carries out specific functions. Relatively undifferentiated cells are known as **stem cells**.
- **Morphogenesis**, the development of form, occurs through **pattern formation**, a series of events in which cells may communicate by signaling, migrate, undergo changes in shape, and even undergo **apoptosis** (programmed cell death).

2 Relate differential gene expression to nuclear equivalence.

- Usually no genetic changes occur in cell determination and cell differentiation (the principle of **nuclear equivalence**). Instead, various types of differentiated cells express different subsets of their genes (**differential gene expression**).

51.2 Fertilization *(page 1105)*

3 Describe the four processes involved in fertilization.

- Contact and recognition occur between noncellular egg coverings and sperm.
- Sperm entry is regulated to prevent interspecific fertilization and **polyspermy**, which is fertilization of the egg by more than one sperm.

Copyright 2019 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in

Copyright 2019 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

- Fertilization activates the egg, triggering the events of early development.
- Sperm and egg pronuclei fuse and initiate DNA synthesis.

4 Describe fertilization in echinoderms and point out some ways in which mammalian fertilization differs.

- The coverings of echinoderm eggs are the **vitelline envelope** and the **jelly coat**; a **zona pellucida** encloses the mammalian egg.
- On contact, a sperm undergoes an **acrosome reaction**, which facilitates penetration of the egg coverings; in mammals the acrosome reaction is preceded by **capacitation**, a maturation process that results in the ability of a sperm to fertilize an egg.
- Sea urchin fertilization is followed by a fast block to polyspermy (depolarization of the plasma membrane) and a slow block to polyspermy (the **cortical reaction**); changes in the zona pellucida prevent polyspermy in mammals.

51.3 Cleavage *(page 1107)*

5 Trace the generalized pattern of early development of the embryo from zygote through early cleavage and formation of the morula and blastula.

- The zygote undergoes **cleavage**, a series of rapid cell divisions without a growth phase. The main effect of cleavage is to partition the zygote into many small **blastomeres**.
- Cleavage forms a solid ball of cells called the **morula** and then usually a hollow ball of cells called the **blastula**.

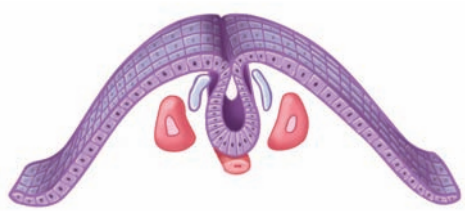
6 Contrast early development, including cleavage, in the echinoderm (or in amphioxus), the amphibian, and the bird, paying particular attention to the importance of the amount and distribution of yolk.

- The **isolecithal eggs** of most invertebrates and simple chordates have evenly distributed yolk. They undergo **holoblastic cleavage**, which involves division of the entire egg.
- In the moderately **telolecithal eggs** of amphibians, a concentration of yolk at the **vegetal pole** slows cleavage so that only a few large cells form there compared with a large number of smaller cells at the **animal pole**.
- The highly telolecithal eggs of reptiles and birds, with a large concentration of yolk at one end, undergo **meroblastic cleavage**, which is restricted to the **blastodisc**.
- Animals whose zygotes have relatively homogeneous cytoplasm exhibit **regulative development**, in which the embryo develops as a self-regulating whole. The relatively rigid developmental patterns of some animals (**mosaic development**) is a consequence of the unequal distribution of cytoplasmic components.
- The **gray crescent** of an amphibian zygote determines the body axis of the embryo.

51.4 Gastrulation *(page 1110)*

7 Identify the significance of gastrulation in the developmental process and compare gastrulation in the echinoderm (or in amphioxus), the amphibian, and the bird.

- In **gastrulation**, the basic body plan is laid down as three germ layers form: the outer **ectoderm**, the inner **endoderm**, and the **mesoderm** between them.
- The **archenteron**, the forerunner of the digestive tube, forms in some groups; its opening to the exterior is the **blastopore**.
- In gastrulation in the sea star and in amphioxus, cells from the blastula wall invaginate and eventually meet the opposite wall, forming the archenteron.



- In the amphibian, invagination at the vegetal pole is obstructed by large, yolk-laden cells; instead, cells from the animal pole move down over the yolk-rich cells and invaginate, forming the *dorsal lip of the blastopore*.
- In the bird, invagination occurs at the primitive streak, and no archenteron forms.

51.5 Organogenesis *(page 1113)*

8 Define *organogenesis* and summarize the fate of each of the germ layers.

- **Organogenesis** is the process of organ formation.
- Ectoderm becomes the nervous system, sense organs, and outer layer of skin (epidermis).
- Mesoderm becomes the notochord, skeleton, muscles, circulatory system, and inner layer of skin (dermis).
- Endoderm becomes the lining of the digestive tube.

9 Trace the early development of the vertebrate nervous system.

- The developing **notochord** is responsible for **induction**, which causes the overlying ectoderm to differentiate as the **neural plate**, the precursor of the central nervous system.
- The cells of the neural plate undergo changes in shape to form the hollow **neural tube**, from which the brain and spinal cord develop.

51.6 Extraembryonic Membranes *(page 1115)*

10 Give the origins and functions of the chorion, amnion, allantois, and yolk sac.

- The **chorion** and **amnion** derive from ectoderm and mesoderm; the **allantois** and **yolk sac** derive from endoderm and mesoderm.
- The chorion is used in gas exchange. The amnion is a fluid-filled sac that surrounds the embryo and keeps it moist; it also acts as a shock absorber. The allantois stores nitrogenous wastes. The yolk sac makes food available to the embryo.

51.7 Human Development *(page 1115)*

11 Describe the general course of early human development, including fertilization, the fates of the trophoblast and inner cell mass, implantation, and the role of the placenta.

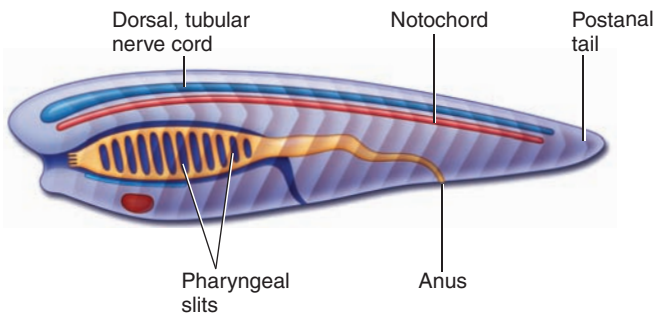
- Fertilization occurs in the oviduct.
- Cleavage takes place as the embryo is moved down the oviduct.
- In the uterus, the embryo develops into a **blastocyst** consisting of an outer **trophoblast**, which gives rise to the chorion and amnion, and an **inner cell mass**, which becomes the embryo proper. The blastocyst undergoes **implantation** in the endometrium.
- The **umbilical cord** connects the embryo to the **placenta**, the organ of exchange between the maternal and fetal circulation. The placenta derives from the embryonic chorion and maternal tissue.

12 Contrast postnatal and prenatal life, describing several changes that occur at or shortly after birth that allow the neonate to live independently.

- Human **prenatal** development requires 266 days from the time of fertilization; organogenesis begins during the *first trimester*. After the first two months of development, the embryo is referred to as a **fetus**. Growth and refinement of the organs continue in the second and third trimesters.
- The **neonate** (newborn) must undergo rapid adaptations, especially changes in the respiratory and digestive systems.

Test Your Understanding

Know and Comprehend



1. The mechanism that leads directly to morphogenesis is (a) differential gene expression (b) pattern formation (c) nuclear equivalence (d) cell differentiation (e) cell determination
2. The main function of the acrosome reaction is to (a) activate the egg (b) improve sperm motility (c) prevent interspecific fertilization (d) facilitate penetration of the egg coverings by the sperm (e) cause fusion of the sperm and egg pronuclei
3. The fast block to polyspermy in sea urchins (a) is a depolarization of the egg plasma membrane (b) requires exocytosis of the cortical granules (c) includes the elevation of the fertilization envelope (d) involves the hardening of the jelly coat (e) is a complete block
4. The cleavage divisions of a sea urchin embryo (a) occur in a spiral pattern (b) do not include DNA synthesis (c) do not include cytokinesis (d) are holoblastic (e) do not occur at the vegetal pole
5. Meroblastic cleavage is typical of embryos formed from _____ eggs. (a) moderately telolecithal (b) highly telolecithal (c) isolecithal (d) b and c (e) a, b, and c
6. The primitive groove of the bird embryo is the functional equivalent of the _____ in the amphibian embryo. (a) yolk plug (b) archenteron (c) blastocoel (d) gray crescent (e) blastopore
7. Which of the following are mismatched? (a) endoderm; lining of the digestive tube (b) ectoderm; circulatory system (c) mesoderm; notochord (d) mesoderm; reproductive system (e) ectoderm; sense organs
8. Which of the following has three germ layers? (a) morula (b) gastrula (c) blastula (d) blastocyst (e) trophoblast
9. An unidentified substance (or substances) released from the developing notochord causes the overlying ectoderm to form the neural plate. This phenomenon is known as (a) activation (b) determination (c) induction (d) implantation (e) mosaic development
10. Which of the following consists of both fetal and maternal tissues? (a) umbilical cord (b) placenta (c) amnion (d) allantois (e) yolk sac
11. The embryo proper of a mammal develops from the (a) trophoblast (b) umbilical cord (c) inner cell mass (d) entire blastocyst (e) yolk sac

Apply and Analyze

12. Place the following events of sea urchin fertilization in the proper sequence: 1. fusion of egg and sperm pronuclei 2. DNA synthesis 3. increased protein synthesis 4. release of calcium ions into the egg cytoplasm (a) 4, 3, 1, 2 (b) 3, 2, 4, 1 (c) 2, 3, 1, 4 (d) 1, 2, 3, 4 (e) 4, 1, 2, 3

Evaluate and Synthesize

13. For almost 200 years, scientists debated whether an egg or sperm cell contains a completely formed, miniature human (preformation) or whether structures develop gradually from a formless zygote (epigenesis). Relate these views to current concepts of development.
14. Not all teratogenic medications are banned by the U.S. Food and Drug Administration. Why?
15. **EVOLUTION LINK** Consider the chordate characteristics described in Chapter 32 (notochord, dorsal hollow nerve cord, postanal tail, and pharynx with slits, a deuterostome characteristic). How are they evident in a human embryo? Do they have the same functions in humans as they do in a less specialized chordate, such as amphioxus? Why have they persisted in humans?

16. **EVOLUTION LINK** What is the adaptive value of developing a placenta?
17. **SCIENCE, TECHNOLOGY, AND SOCIETY** As a public health official, what policies might you promote to reduce the incidence of prematurity and/or low birth weight? of malformations at birth?

52 Animal Behavior

Suppose that your professor gave you a hypodermic syringe full of poison and told you to find a particular type of insect, one that you had never seen before and that was armed with active defenses. You then had to inject the ganglia of your prey's nervous system (about which you had been taught nothing) with just enough poison to paralyze but not kill it. You would have difficulty accomplishing these tasks, but a solitary wasp no larger than the first joint of your thumb does it all with elegance and surgical precision, without instruction.

Philanthus, the sand wasp (also called beewolf), captures a bee, stings it, and places the paralyzed insect in a burrow excavated in the sand (see photograph). She then lays an egg on her prey. The larva that hatches from that egg devours the bee. *Philanthus* brings provisions to her hidden burrow until autumn, when the larva becomes a hibernating pupa. Her offspring will repeat this behavior, precisely executing each step without ever having seen it done.

An animal's **behavior** is *what it does and how it does it*, usually in response to stimuli in its environment. A dog may wag its tail, a bird may sing, a butterfly may release a volatile sex attractant. Behavior is just as diverse as biological structure and just as characteristic of a given species as its anatomy or physiology. Like its morphology and physiology, an animal's behavior is the product of natural selection on phenotypes and indirectly on the genotypes that code for those phenotypes. Thus, an animal's repertoire of behavior is a set of adaptations that equip it for survival in a particular environment.

Whether biologists study behavior in an animal's natural environment or in the laboratory, they must consider that what an animal does cannot be isolated from the way in which it lives. **Behavioral ecology** is the study of behavior in natural environments from an

KEY CONCEPTS

52.1 Proximate causes of behavior are the immediate causes that explain *how* an animal carries out a specific behavior. Ultimate causes of behavior are the evolutionary explanations for *why* a certain behavior occurs. A behavior is adaptive if its benefits are greater than its costs.

52.2 The capacity for behavior is inherited, but behavior is modified in response to environmental experience; the changed behavior is learned behavior.

52.3 Biological clocks regulate biological rhythms. Migration is an example of a behavior that involves interactions among biological rhythms, physiology, and the environment.

52.4 Optimal foraging is the most efficient way for most animals to obtain food.

52.5 Social behavior requires communication among animals in the group. Dominance hierarchies and defense of a territory benefit many social groups.

52.6 Sexual selection is a type of natural selection in which individuals with reproductive advantages are selected over others of the same sex and species.

52.7 Altruism is a type of cooperative behavior in which one animal behaves in a way that appears to benefit others rather than itself. Kin selection is a form of natural selection that increases inclusive fitness through the successful reproduction of close relatives.

52.8 Some bird and mammal species transmit culture, learned behavior common to a population, that one generation teaches to the next.

evolutionary perspective. For more than two decades, behavioral ecology has been the main approach of biologists who study animal behavior. Before this approach emerged, the study of animal behavior was called *ethology*, and this term is sometimes still used to refer to the overall study of animal behavior.

In this chapter we consider how an animal's behavior contributes to its reproductive success and to the survival of its species. We discuss types of learning and then focus on the *hows* and *whys* of some key types of behavior, including migration, foraging, and social behavior. We also explore sexual selection and helping behavior.

52.1 Behavior and Adaptation

LEARNING OBJECTIVES

1. Distinguish between proximate and ultimate causes of behavior and apply the concepts of ultimate cause and cost–benefit analysis to decide whether a particular behavior is adaptive.
2. Describe the interactions of heredity, environment, and maturation in animal behavior.

In considering the reproductive behavior of *Philanthus*, we might wonder *how* she accomplishes her task and *why* she behaves as she does. Early investigators of animal behavior focused on *how* questions. These questions address **proximate causes**, immediate causes such as the genetic, developmental, and physiological processes that permit the animal to carry out the particular behavior.

Today, biologists also ask *why* questions that address the **ultimate causes** of behavior. These questions, which have evolutionary explanations, ask *why* a particular behavior has evolved. Ultimate considerations address costs and benefits of behavior patterns. When studying ultimate causes, we may ask what the adaptive value of a particular behavior might be. An understanding of behavior requires consideration of both proximate and ultimate causes.

Behaviors have benefits and costs

Behavioral ecologists use **cost–benefit analysis** to understand specific behaviors. A behavior may help an animal obtain food or water, protect itself, reproduce, or acquire and maintain territory in which to live. The benefits typically contribute to **direct fitness**, which is an individual's reproductive success, measured by the number of viable offspring it produces. Reproduction is, of course, the key to evolutionary success.

Behaviors also involve costs. For example, while a parent is away hunting for food for its offspring, the youngsters may be killed by predators. Behaviors also have energy costs and costs of missed opportunities to carry out other behaviors. When an animal is foraging for food, it may be missing opportunities to mate. If the benefits are greater than the costs, a behavior is adaptive.

The ultimate cause of a behavior is to increase the probability that the genes of the individual animal will be passed to future generations. Certain responses may lead to the death of the individual while increasing the chance that copies of its genes will survive through the enhanced production or survival of its offspring or other relatives.

Genes interact with environment

Early biologists debated nature versus nurture, that is, the relative importance of genes compared with environmental experience. They defined **innate behavior** (inborn behavior, popularly referred to as *instinct*) as genetically programmed and **learned behavior** as behavior that has been modified in response to environmental experience. More recently, behavioral ecologists have recognized that no true dichotomy exists. All behavior has a genetic basis. Even the *capacity* for learned behavior is inherited. However, behavior is modified by the environment in which an animal lives; behavior is a product of the interaction between genetic capacity and environmental influences. Thus, behavior begins with an inherited framework that experience can modify.

We can think of a range of behaviors from the more rigidly genetically programmed types through those that, although they have a genetic component, are extensively developed through experience. The sand wasp *Philanthus*, discussed in the chapter introduction, efficiently carries out a sequence of behaviors that depends mainly on genetic programming. How to dig the burrow, how to cover it, how to kill the bees—these behaviors are genetically determined. Yet some of her behavior is learned. There is no way that her ability to locate the burrow could be genetically programmed. Because a burrow can be dug only in a suitable spot, its location must be learned *after* it is dug. When *Philanthus* covers her burrow with sand, she takes precise bearings of its location by circling the area a few times before flying off again to hunt.

Dutch ethologist Niko Tinbergen studied this behavior of *Philanthus*. He surrounded the wasp's burrow with a circle of pine cones as potential landmarks (FIG. 52-1). Before the wasp returned with another bee, Tinbergen rearranged or removed the pine cones. Without them, the wasp could not find her burrow. When Tinbergen moved the pine cones to an area where there was no burrow, the female wasp responded as though the burrow were there. When the investigator completely removed them, the female seemed very confused. Only when Tinbergen restored the cones to their original location could the wasp find her burrow.

When Tinbergen substituted a ring of stones for the cones, the wasp responded as though the burrow were in the center of the stones. Thus, *Philanthus* responded to the *arrangement* of the cones rather than to the cones themselves. Tinbergen's findings demonstrated that for *Philanthus*, learning the landmarks surrounding the burrow was critical for burrow locating.

Studies of fruit fly courtship and mating have provided interesting examples of interaction between genes and behavior. A ritual consisting of a complex sequence of steps, almost like a dance, must occur before mating takes place. This courtship ritual involves an exchange of visual, auditory, tactile, and chemical signals between the male and female. J.B. Hall of Brandeis

Key Experiment

How does *Philanthus* locate her burrow when she returns to provision it with food?

HYPOTHESIS: *Philanthus* uses visual cues to locate her burrow.

EXPERIMENT:

1. While *Philanthus* was in the burrow, Tinbergen placed a circle of pine cones around its entrance.
2. While the wasp was out foraging, Tinbergen moved the cones to a new position (away from the burrow entrance).
3. In a second experiment, Tinbergen left the pine cones around the burrow but rearranged them in a triangle shape in the wasp's absence. Nearby, he made a circle of stones.

RESULTS AND CONCLUSION:

1. When *Philanthus* emerged from her burrow, she responded to the circle of pine cones by circling the site, an orientation flight. When she returned with prey, she flew to the middle of the circle of pine cones to locate the small, concealed entrance to her burrow.
2. When Tinbergen relocated the circle of pine cones away from the burrow, *Philanthus* flew to the middle of the new circle because she had learned the position of the burrow in relation to the cones.
3. When Tinbergen rearranged the cones in the shape of a triangle and made a circle of stones nearby, *Philanthus* flew to the middle of the circle of stones.

Philanthus used visual cues (a circle of cones) to learn the location of her burrow. Later she looked for the circle of cones to locate her burrow. She responded to the *arrangement* of cones rather than to the cones themselves. Learning landmarks (visual cues) is critical for locating the burrow.

SOURCE: N. Tinbergen, *The Animal in Its World*, Vol. 1 (Harvard University Press, Cambridge, MA, 1972).

Figure 52-1 Niko Tinbergen's experiments determining how the wasp *Philanthus* locates her burrow

PREDICT Imagine that when *Philanthus* first emerged from her nest, the investigator scared her away before she could orient herself to any visual cues. Would she be able to find her burrow?

University and his colleagues identified more than a dozen genes controlling these actions, suggesting that courtship behavior is largely inherited and preprogrammed. Nevertheless, the fruit fly has the capacity to learn from experience, a capacity that, of course, is also inherited.

The interaction between genes and environment has been studied in many vertebrates. Several species of the lovebird (*Agapornis*) differ not only in appearance but in behavior. One species uses its bill to transport small pieces of bark for building a nest. Another species tucks nest-building materials under its rump feathers. Hybrid birds attempt to tuck material under their feathers and then try to carry it in their bills, repeating the pattern several times. Eventually, most of the birds carry the material in their bills, but it takes them up to three years to perfect this behavior, and most continue to make futile attempts to tuck material into their feathers. Thus, the method of transporting materials is inherited but somewhat flexible. (In nature, hybrids would likely experience dramatically reduced fitness because of the long delay in breeding onset.)

Behavior depends on physiological readiness

Although behavior involves all body systems, it is influenced mainly by the nervous and endocrine systems. The capacity for behavior depends on the genetic characteristics that govern the development and functions of these systems. Before an animal can exhibit any pattern of behavior, it must be physiologically ready to produce the behavior. For example, breeding behavior does not ordinarily occur among birds or most mammals unless sufficient concentrations of sex hormones are present in their blood. A human baby cannot walk until its neurons and muscles are sufficiently developed. These states of physiological readiness are themselves produced by a continuous interaction with the environment. The level of sex hormones in a bird's blood may

be determined by seasonal variations in day length. The baby's muscles develop with experience as well as age.

Several factors influence the development of song in male white-crowned sparrows (generally only male songbirds sing a complex song). These birds show considerable regional variation in their song. During early development, young sparrows normally hear adult males sing the distinctive song of their population. Days 10 to 52 after hatching are a critical period for learning the song. When he is several months old, a young male sparrow "practices" the song over several weeks until he eventually sings in the local "dialect."

In laboratory experiments, birds kept in isolation and deprived of the acoustic experience of hearing the song of mature males eventually sing a poorly developed but recognizable white-crowned sparrow song. When a young white-crowned sparrow is permitted to interact socially with a strawberry finch (which belongs to a different genus of birds), it learns the song of the finch rather than its own species-specific song. This learning occurs even if the white-crowned sparrow can hear the song of other sparrows but does not interact with them socially. From these experiments, investigators have concluded that the white-crowned sparrow is hatched equipped with a rough genetic pattern of its song, but social and acoustic stimuli are important in developing the ability to sing its specific song.

Many behavior patterns depend on motor programs

Many behaviors that we think of as automatic depend on coordinated sequences of muscle actions called **motor programs**. Some motor programs—for example, walking in newborn gazelles—seem mainly innate. Others, such as walking in human infants, have a greater learned component.

A classic example of a motor program in vertebrates is egg rolling in the European graylag goose (FIG. 52-2). Once activated by a simple sensory stimulus, egg-rolling behavior continues to completion regardless of sensory feedback. There is little flexibility. Behavioral ecologists call this behavior a **behavioral pattern**. Certain behavioral patterns can be elicited by a **sign stimulus**, or *releaser*, a simple signal that triggers a specific behavioral response. A wooden egg is a sign stimulus that elicits egg-rolling behavior in the graylag goose.

In a set of classic experiments performed in 1951, Tinbergen showed that the red stripe on the ventral surface (belly) of a male stickleback fish is a sign stimulus. The ventral surface of the male stickleback is normally silver but turns red at the beginning of the breeding season. The male stickleback selects a territory, builds a nest, and defends his territory against rival males. After a female lays her eggs, she leaves; the male then guards the eggs and, later, the newly hatched fish.

Tinbergen showed that the red stripe triggers aggressive behavior by a male when his territory is being invaded. Tinbergen found that crude models painted with a red belly were more likely to be attacked than more realistic models lacking the red belly (FIG. 52-3). Aggressive behavior is triggered by the red belly rather than by recognition based on a combination of features.

CHECKPOINT 52.1

- In what ways are the behaviors of *Philanthus*, the sand wasp, adaptive?
- **CONNECT** Give an example showing that behavior capacity is inherited and is modified by learning.
- **CONNECT** How does physiological readiness affect innate behavior? How does it affect learned behavior?

52.2 Learning: Changing Behavior as a Result of Experience

LEARNING OBJECTIVE

3 Discuss the adaptive significance of habituation, imprinting, classical conditioning, operant conditioning, and cognition.

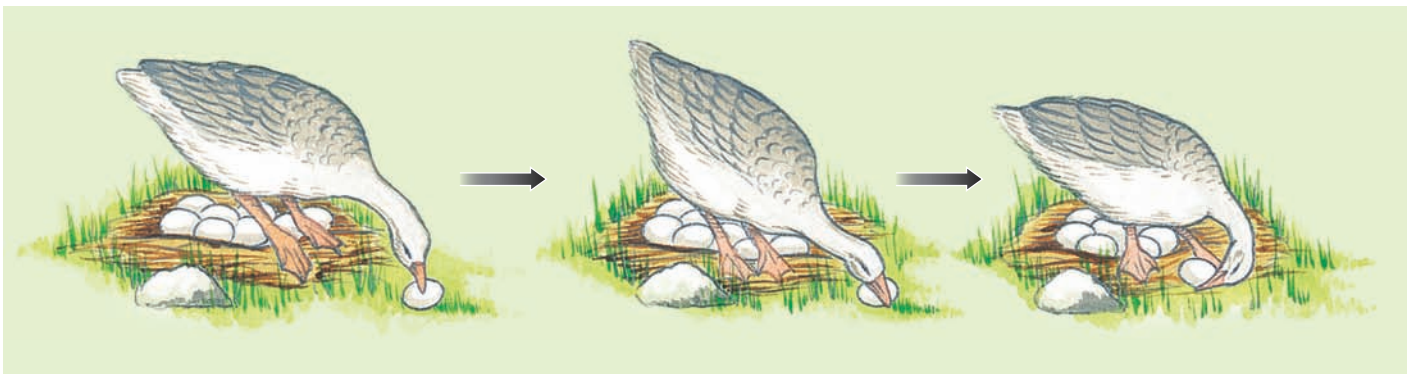

Figure 52-2 Egg-rolling behavior in the European graylag goose (*Anser anser*)
In this rigid behavioral pattern, the goose reaches out by extending her neck and uses her bill to pull the egg back into the nest. If the investigator quickly removes the egg while the goose is in the process of reaching for it or pulling it back, the goose continues the behavior to completion, as though pulling the now-absent egg back to the nest.

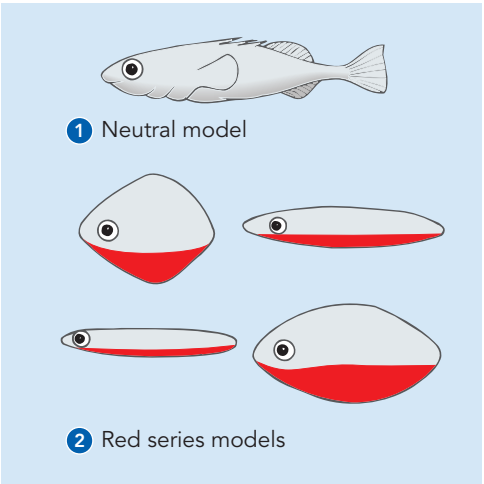
Key Experiment



What triggers aggressive behavior in the male stickleback?

HYPOTHESIS: The red ventral surface (belly) of a male stickleback is a sign stimulus that triggers aggressive behavior in other male sticklebacks.

EXPERIMENT: Niko Tinbergen presented male sticklebacks with two series of models.

1. The models in the neutral series were the neutral color of the male in the nonbreeding season.
2. The models in the red series were red on the ventral surface.

RESULTS AND CONCLUSION: The male fish did not attack realistic models of another male stickleback when they lacked a red belly. The male fish did attack other models that had red ventral surfaces, even when their shapes were unrealistic.

The red belly of another male stickleback is a sign stimulus (releaser) that activates stereotyped aggressive behavior in a male stickleback.

SOURCE: N. Tinbergen, *The Study of Instinct* (Oxford University Press, New York, 1951).

Figure 52-3 Niko Tinbergen's experiments on aggressive behavior in the male stickleback fish

PREDICT Imagine that a male stickleback has a mutation that prevents him from responding to the red belly of another male stickleback. How might that affect his direct fitness?

Based on our discussion thus far, it should be clear that much inherited behavior can be modified by experience. **Learning** involves persistent changes in behavior that result from experience. The capacity to learn new responses to new situations is adaptive, enabling animals to survive as their environment changes.

Learning abilities are biased; information most important to survival appears most easily learned. It may have taken a rat a dozen trials to learn the artificial task of pushing a lever to get a reward. However, the same rat learns from *one* experience to avoid a food that has made it ill. People who poison rats to get rid of them can readily appreciate the adaptive value of this learning ability. Such quick learning in response to an unpleasant experience forms the basis of **warning coloration**, or **aposematic coloration**, which is found in many poisonous insects and brilliantly colored, but distasteful, bird eggs. Once made ill by such a meal, predators quickly learn to avoid them. In the following sections, we consider several types of learning, including habituation, imprinting, classical conditioning, operant conditioning, and cognition.

An animal habituates to irrelevant stimuli

Habituation is a type of learning in which an animal learns to ignore a repeated, irrelevant stimulus, that is, one that neither rewards nor punishes. Pigeons gathered in a city park learn by repeated harmless encounters that humans are not dangerous to them and behave accordingly. This behavior benefits them. A pigeon intolerant of people might waste energy by flying away each time a human approached and might not get enough to eat. Many African animals habituate to humans on photo safari and to the vans that transport them (FIG. 52-4). Urban humans habituate to the noise of traffic. In fact, many urban dwellers report that they do not sleep well when they visit a quiet rural area.

McMurray Photography

Figure 52-4 Habituation

After repeated safe encounters with vans transporting humans on photo safari, many animals, including giraffes, zebras, antelope, and lions in the Serengeti, learn to ignore them. Elephants typically ignore the vans unless the driver provokes them by moving too close. In that event an elephant may challenge and even charge the van.

Imprinting occurs during an early critical period

Anyone who has watched a mother goose with her goslings must have wondered how she can "keep track" of such a horde of almost identical little creatures tumbling about in the grass, let alone distinguish them from those of another goose (FIG. 52-5). Although she can recognize her offspring to some extent, basically *they* have the responsibility of keeping track of *her*. The survival of a gosling requires that it quickly learn to discriminate its mother (care provider) from other geese.

Imprinting, a type of social learning based on early experience, has been studied in some mammals as well as birds. It occurs during a *critical period*, usually within a few hours or days after birth (or hatching). Konrad Lorenz, an Austrian physician and early ethologist, discovered that a newly hatched bird imprints on the first moving object it sees, even a human or an inanimate object such as a colored sphere or light. Although the process of imprinting is genetically determined, the bird *learns* to respond to a particular animal or object.

Among many types of birds, especially ducks and geese, older embryos can exchange calls with their nest mates and parents through the porous eggshell. When they hatch, at least one parent is normally on hand, emitting the characteristic sounds with which the hatchlings are already familiar. If the parent moves, the chicks follow. This movement and the sounds produce imprinting. During a brief critical period after hatching, the chicks learn the appearance of the parent.

Imprinting in some mammals depends on scent. Baby shrews, for example, become imprinted on the odor of their mother (or any female nursing them). In many species the mother also learns to distinguish her offspring during a critical period. In some species of hoofed mammals, such as sheep, the mother will accept her offspring for only a few hours after its birth; if the mother and her offspring are kept apart past that time, the young are rejected. Normally, the mother learns to distinguish her own offspring from those of others by olfactory cues.

Doug Cheeseman/Getty Images

Figure 52-5 Imprinting

Parent–offspring bonds generally form during an early critical period. The goslings have imprinted on their mother, an Egyptian goose (*Alopochen aegyptiacus*). Photographed in Ndutu, Tanzania, Africa.

In classical conditioning, a reflex becomes associated with a new stimulus

In **classical conditioning**, an association forms between some normal body function and a new stimulus. If you have observed dog or cat behavior, you know that the sound of a can opener at dinnertime can captivate a pet's attention! Early in the 20th century, Ivan Pavlov, a Russian physiologist, discovered that if he rang a bell just before he fed a dog, the dog learned to associate the sound of the bell with food. Eventually, the dog salivated even when the bell was rung in the absence of food (FIG. 52-6).

Pavlov called the physiologically meaningful stimulus (food, in this case) the *unconditioned stimulus*. The normally irrelevant stimulus (the bell) that became a substitute for it was the *conditioned stimulus*. Salivating to the food was an *unconditioned response*, whereas salivating to the bell was a *conditioned response*. Because a dog does not normally salivate at the sound of a bell, the association was clearly learned. It could also be forgotten. If the bell no longer signaled food, the dog eventually stopped responding to it. Pavlov called this latter process **extinction**. Classical conditioning can be adaptive. For example, if an animal is threatened by a predator in a particular area, it associates the place with danger and avoids that area in the future. In this case the animal learns to *avoid* a negative stimulus rather than to expect a reward.

In operant conditioning, spontaneous behavior is reinforced

In **operant conditioning**, the animal must do something to gain a reward (positive reinforcement) or avoid punishment. Operant conditioning has been studied in many animals, including flatworms, insects, spiders, birds, and mammals. In a typical laboratory experiment, a rat is placed in a cage containing a movable bar. When random actions of the rat result in pressing the bar, a pellet of food rolls down a chute to the rat. Thus, the rat is positively reinforced for pressing the bar. Eventually, the rat learns the association and presses the bar to obtain food.

In negative reinforcement, removal of a stimulus increases the probability that a behavior will occur. For example, a rat may be subjected to an unpleasant stimulus, such as a low-level electric shock. When the animal presses a bar, this negative reinforcer is removed.

Many variations of these techniques have been developed. A pigeon may be trained to peck at a lighted circle to obtain food, a chimpanzee may learn to perform some task to get tokens that can be exchanged for food, and children may learn to sit quietly in their seats at school to obtain the teacher's praise.

Key Experiment

Can an animal learn to respond in a certain way to a new (previously neutral) stimulus by associating it with a familiar stimulus?

HYPOTHESIS: A dog can be conditioned to salivate at the sound of a bell.

EXPERIMENT: Ivan Pavlov presented food (the unconditioned stimulus) to a dog and observed that the dog salivated (unconditioned response). He then rang a bell (conditioned stimulus) just before he gave food to the dog. Pavlov repeated this pairing several times. Then he sounded the bell in the absence of food.

1. Dog salivates when given food.
2. Bell is rung just before dog is given food. This step is repeated a number of times.
3. Eventually, dog salivates at sound of bell alone.

RESULTS AND CONCLUSION: The dog became conditioned to salivate at the sound of the bell alone. When a bell (conditioned stimulus) is paired with food (an unconditioned stimulus), an animal learns to associate them. The animal then salivates to the sound of the bell alone (conditioned response).

Figure 52-6 Classical conditioning: Pavlov's dog

PREDICT A young boy was bitten by a dog. He was startled, scared, and hurt, and he cried. A few weeks later, he sees another dog. How do you think he is likely to respond?

Operant conditioning plays a role in the development of some behaviors that appear genetically programmed. An example is the feeding behavior of gull chicks. Herring gull chicks peck the beaks of the parents, which stimulates the parents to regurgitate partially digested food for them. The chicks are attracted by two stimuli: the general appearance of the parent's beak with its elongated shape and distinctive red spot, and its downward movement as the parent lowers its head. Like the rat's chance pressing of the bar, the chicks' initial exploratory pecking behavior is sufficiently functional for them to get their first meal, but they waste a lot of energy in pecking. Some pecks are off target and are therefore not rewarded. However, pecking behavior becomes more efficient with practice. Thus, a behavior that might appear to be entirely genetic is improved by learning (FIG. 52-7).

Animal cognition is controversial

Cognition is the process of gaining and using knowledge; it includes thinking, processing information, learning, reasoning, and awareness of thoughts, perceptions, and self. Cognition allows us to carry out high-level mental functions. For example, we can make difficult decisions; solve problems, including mathematical problems; plan; and develop and comprehend languages. How closely animal cognition approximates human thought processes has been hotly debated and is the focus of a great deal of research.

Cognition allows some animals to *problem solve*. For example, a chimpanzee presented with a new problem is likely to have the insight to make new associations from tasks it has learned previously. The chimp can adapt prior knowledge and experience to solve the current problem (FIG. 52-8). Primates are especially skilled at cognition and problem solving, but some other mammals and a few birds, notably some crows (e.g., ravens), also appear to problem solve to some degree.

Play may be practice behavior

Perhaps you have watched a kitten pouncing on a dead leaf or practicing a carnivore neck bite or a hind-claw disemboweling stroke on a littermate without causing injury. Many animals, especially young birds and mammals, appear to practice adult patterns of behavior while they play (FIG. 52-9). They may improve their ability to escape, hunt, kill prey, or perform sexual behavior. Play may be an example of operant conditioning in action. Hypotheses for the ultimate causes of play behavior include exercising, learning to coordinate movements, and learning social skills. Of course, there could be other unknown explanations.

52.3 Behavioral Responses to Environmental Stimuli

LEARNING OBJECTIVES

4 Give examples of biological rhythms and describe some of the physiological mechanisms responsible for them.
5 Analyze costs and benefits of migrations and distinguish between directional orientation and navigation.

Think of the many variations that take place in our natural surroundings: cycles of day and night, changes in length of day with changing seasons, lunar cycles, high and low tides, changes in weather, and variations in amount and distribution of food. Biologically successful animals are physiologically and behaviorally adapted to the continuous changes that take place in their environment.

Biological rhythms regulate many behaviors

The biochemical, physiological, and behavioral responses that animals make to the periodic changes in the environment are referred to as **biological rhythms**. Biologists have identified many types of biological rhythms, including daily, monthly, and annual rhythms. Among many animals, physiological cycles such as body-temperature fluctuations and hormone secretion are rhythmic. Human body temperature, for example, follows a typical daily curve, with the lowest temperature early in the morning and the highest in the late afternoon. (Women also have a monthly temperature rhythm, with the highest body temperature during the last half of the menstrual cycle.) Biological rhythms regulate many behaviors, including activity, sleep, feeding, drinking, reproduction, and migration.

The behavior of many animals, like the activities of many plants, is organized around **circadian rhythms** (circadian means "approximately one day"), which are daily, 24-hour cycles of activity. **Diurnal animals**, such as honeybees and pigeons, are most active during the day. Most bats, moths, and cats are **nocturnal animals** and are most active during the hours of darkness. **Crepuscular animals**, like many mosquitoes and fiddler crabs, are busiest at dawn, dusk, or both. Generally, there are

ecological reasons for these patterns. If an animal's food is most plentiful in the early morning, for example, its cycle of activity must be regulated so that it becomes active shortly before dawn.

Some biological rhythms of animals reflect the *lunar cycle* (moon). The most striking rhythms are those in marine organisms that are attuned to changes in tides and phases of the moon. For instance, a combination of tidal, lunar, and annual rhythms governs the reproductive behavior of the grunion, a small fish that lives off the Pacific coast of North America. Grunions swarm from April through June on those three or four nights when the highest tides of the year occur. At precisely the high point of the tide, the fish squirm onto the beach and deposit eggs and sperm in the sand. They return to the sea in the next wave. By the time the next tide reaches that portion of the beach 15 days later, the young fish have hatched in the damp sand and are ready to enter the sea. This synchronization may help protect fish eggs from aquatic predators.

An animal's metabolic processes and behavior are typically synchronized with the cyclic changes in its external environment. Its behavior anticipates these regular changes. The little fiddler crabs of marine beaches often emerge from their burrows at low tide to engage in social activities such as territorial disputes. To avoid being washed away, they must return to their burrows before the tide returns. How do the crabs "know" that high tide is about to occur? One might guess that the crabs recognize clues present in the seashore. However, when the crabs are isolated in the laboratory away from any known stimulus that could relate to time and tide, their characteristic behavioral rhythms persist.

Many biological rhythms are regulated by *internal* timing mechanisms that serve as **biological clocks**. As illustrated by the fiddler crabs, these timing mechanisms do not simply respond to environmental cues but are capable of sustaining biological rhythms independently. Such internal clocks have been identified in almost every eukaryote as well as in some prokaryotes. Molecular biologists have demonstrated that genes control biological clocks. In *Drosophila* seven genes produce clock proteins that seem to interact in feedback loops in many cell types both inside and outside the nervous system. Researchers have identified similar genes and proteins in many animal groups, including mammals. The principal clock is located in specific areas of the central nervous system.

In mammals, the master clock is located in the **suprachiasmatic nucleus (SCN)** in the hypothalamus (see Chapter 42). This SCN clock generates approximately 24-hour cycles even without input from the environment. However, the SCN-generated cycles are normally adjusted every day based on visual input received from the retina. Signals from the retina reflecting changes in light intensity adjust internal circadian rhythms to light–dark cycles in the environment. The SCN sends rhythmic signals, in the form of neuropeptides, to the **pineal gland**, an endocrine gland located in the brain. In response, the pineal gland secretes *melatonin*, a hormone that promotes sleep in humans. Clock genes in the SCN are turned on and off by the very proteins they encode, setting up feedback loops that have a 24-hour cycle.

In addition to the master clock, most cells have timing mechanisms that use many of the same clock proteins. These peripheral clocks may function independently of the SCN.

Environmental signals trigger physiological responses that lead to migration

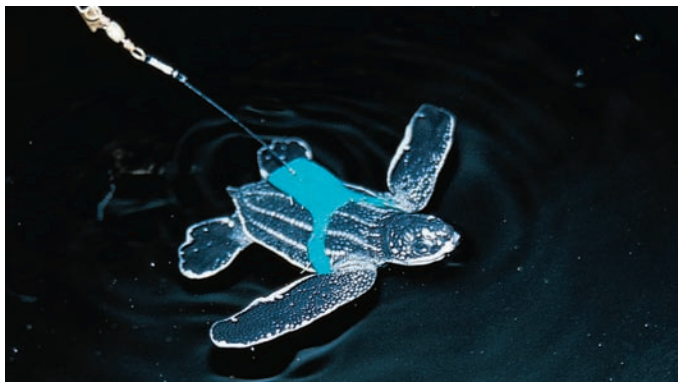
Ruby-throated hummingbirds cross the vast distance of the Gulf of Mexico twice each year. The sooty tern travels across the entire South Atlantic from Africa to reach its tiny island breeding grounds south of Florida. Birds, butterflies, fishes, sea turtles, wildebeest, zebras, and whales are among the many animals that travel long distances. Behavioral ecologists define **migration** as a periodic long-distance travel from one location to another. Many migrations involve astonishing feats of endurance and navigation.

Why do animals migrate? Ultimate causes of migration apparently involve the advantages of moving from an area that seasonally becomes less hospitable to a region more likely to support reproduction or survival. Seasonal changes include shifts in climate, availability of food resources, and safe nesting sites. For example, as winter approaches, many birds migrate to a warmer region.

Proximate causes of migration include signals from the environment that trigger physiological responses leading to migration. In migratory birds, for example, the pineal gland senses changes in day length and then releases hormones that cause restless behavior. The birds show an increased readiness to fly and to fly for longer periods.

Migration has costs and benefits An interesting example of migration is the annual journey of millions of monarch butterflies (*Danaus plexippus*) from Canada and the continental United States to Mexico, a journey of 2520 km (about 1520 mi) for some. Their dramatic annual migration appears related to the availability of milkweed plants on which females lay their eggs. On hatching, the larvae (caterpillars) feed on the leaves of the milkweed plant. In cold regions, these plants die in late autumn and grow again with the warmer weather of spring.

The wintering destinations of monarchs also may be determined by temperature and humidity. Possible benefits include the opportunity to winter in an area that offers an abundant food supply, nonfreezing temperatures, and moist air. Thus, the investment made by migrating monarch butterflies in their long journey increases their chances of surviving the winter.



The benefits of migration are not without costs in time, energy, and even survival. Many weeks may be spent each year on energy-demanding journeys. Some animals may become lost or die along the way from fatigue or predation. When in unfamiliar areas, migrating individuals are often at greater risk from predators.

In recent years, human activities have interfered with migrations of many kinds of animals. For example, after millions of years of biological success, survival of sea turtles is threatened by fishing and shrimping nets in which they become entangled. As a result, thousands of migrating turtles drown each year. Sea turtles also die as a result of contamination from oil spills, entanglement in discarded fishing line, and ingestion of floating plastic bags that they mistake for jellyfish.

Animals find their way using directional orientation and navigation How do migrating animals find their way?

Kenneth Lohmann

Figure 52-10 Navigation by light and magnetic field

To study turtle navigation, researcher Kenneth Lohmann harnessed leatherback turtles (*Dermochelys coriacea*), such as this hatchling, and wired them to a computer that recorded their swimming direction.

Directional orientation refers to travel in a specific direction. To travel in a straight line toward a destination requires a sense of direction, or **compass sense**. Many animals use the sun to orient themselves. Because the sun appears to move across the sky each day, an animal must have a sense of time. Biological clocks seem to sense time and regulate circadian rhythms.

Navigation is more complex than traveling in a specific direction. Navigation requires both compass sense and **map sense**, which is an "awareness" of location. Navigation involves the use of cues to change direction when necessary to reach a specific destination. When navigating, an animal must integrate information about distance and time, as well as direction.

DNA tests confirm that loggerhead sea turtles that hatch on Florida beaches along the Atlantic swim hundreds of miles across the ocean to the Mediterranean Sea, an area rich in food. Several years later, those that survive to become adults mate, and the females navigate back, often to the same beach, to lay their eggs. Their journey requires both compass sense and map sense.

Marine biologist Kenneth Lohmann of the University of North Carolina fitted hatchling turtles with harnesses connected to a swivel arm in the center of a large tank (FIG. 52-10). A computer connected to the swivel arm recorded the turtles' swimming movements. By manipulating light and magnetic fields, Lohmann demonstrated that both these environmental cues are important in turtle migration. The turtles swam toward the east until Lohmann reversed the magnetic field. The turtles then reversed their direction to swim toward the new "magnetic east," which was now actually west. Subsequent research suggests that young turtles use wave direction to help set magnetic direction preference.

Some biologists suspect that turtles also use their sense of smell to guide them, particularly to guide the females to the very same beach to lay their eggs. Similarly, adult salmon use the unique odors of different streams to help find their way back to the same stream from which they hatched.

Birds and some other animals that navigate by day rely on the position of the sun (our local star); those that travel at night use the stars to guide them. When birds see the star patterns of the night sky, they fly in the appropriate migration direction for their species, even when they have had no opportunity to learn this feat from other birds.

Studies by Stephen Emlen of Cornell University showed that young indigo buntings learn the constellations using the position of the North Star as their reference point. (Other stars in the Northern Hemisphere appear to rotate about the North Star.) When Emlen rearranged the constellations in a planetarium sky, birds in the planetarium learned the altered patterns of stars and later attempted to fly outside in a direction consistent with the artificial pattern. These and other studies suggested that birds have a genetic ability to learn constellation patterns and use them to orient during migration.

Investigators have long observed that some species of birds navigate even when the sky is overcast and they cannot see the stars. They hypothesized that these birds use Earth's magnetic field to navigate. Studies of garden warblers indicate that as these birds make their way from central Europe to Africa each winter, they navigate both by the stars and by Earth's magnetic field. The warblers use stars to determine the general direction of travel and then use magnetic information to refine and correct their course. In addition to birds and sea turtles, honeybees, some fishes, and some other animals are sensitive to Earth's magnetic field and use it as a guide.

CHECKPOINT 52.3

- **CONNECT** Why is it adaptive for some species to be diurnal but for others to be nocturnal or crepuscular?
- What is the difference between directional orientation and navigation?

52.4 Foraging Behavior

LEARNING OBJECTIVE

6 Define *optimal foraging behavior* and explain how it is adaptive.

Feeding behavior, or **foraging**, involves locating and selecting food as well as gathering and capturing food. Some behavioral ecologists study the costs and benefits of searching for and selecting certain types of food as well as the mechanisms used to locate prey. For example, many camouflage strategies have evolved that make potential prey difficult to detect. As predators experience repeated success in locating a particular prey species, they are thought to develop a *search image*, a constellation of cues that help them identify hidden prey.

Why do grizzly bears spend hours digging arctic ground squirrels out of burrows while ignoring larger prey such as caribou? It is more energy efficient to dig for squirrels because the bears' efforts most probably will be rewarded, whereas caribou are more likely to escape, leaving the bears hungry. This behavior is an example of **optimal foraging**,

the most efficient way for an animal to obtain food. According to *optimal foraging theory*, when animals forage, they maximize their energy intake per unit of foraging time. When animals maximize energy obtained per unit of foraging time, they may maximize their reproductive success. Many factors, such as avoiding predators while foraging, must be considered in determining efficient or optimal strategies.

In habitats where the most-preferred food items are abundant and an animal does not have to travel far to obtain them, animals can afford to be selective. In contrast, the optimal strategy in poor habitats, where it takes longer to find the best food items, is to select less-preferred items. Animals may learn to forage efficiently through operant conditioning, that is, by randomly trying various strategies and selecting the one associated with the most rewards (and the fewest hunger pangs at the end of the day).

Foraging is also affected by the forager's risk of predation. British biologist Guy Cowlishaw studied foraging behavior in a population of baboons in Namibia. He found that the baboons spent more time foraging in a habitat in which food was relatively scarce than in an area with more-abundant food that had a high risk of predation by lions and leopards.

Lions live, and often forage, in social units called *prides*. A pride typically consists of a group of related adult females, their cubs, and unrelated males. Biologist Craig Packer of the University of Minnesota and his research team studied lion behavior in Serengeti National Park, Tanzania. Packer radio-collared at least one female in each of 21 prides and tracked them for several years. During the season when prey was abundant, lions hunted wildebeest, gazelle, and zebra that migrated into the area. When these herds migrated out of the area during the dry season, these prey become scarce, and lions fed mainly on warthog and Cape buffalo.

Packer reported that when prey was abundant, the size of the foraging group had little effect on daily food intake. Whether a lion hunted individually or in small (two to four females) or large (five to seven) groups, food was captured by individuals or groups of any size. During the season when prey was scarce, however, lions were more successful if they hunted alone or in large groups (FIG. 52-11). Nevertheless, Packer's data from radio-collared lions indicated that females typically foraged in as large a group as they could, even if the group consisted of three or four females, an approach that decreased foraging efficiency. Thus, selection pressure seems to be stronger to protect cubs and defend territory against larger prides than to forage maximally (alone).

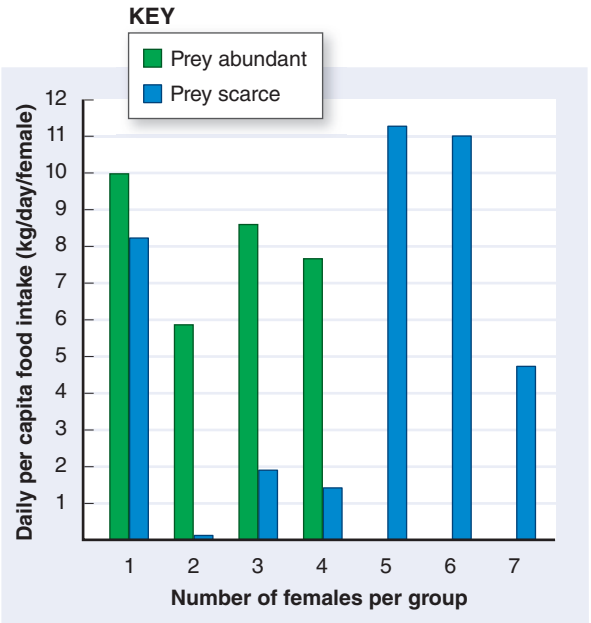

Figure 52-11 Optimal foraging and group size in lions
During times of prey scarcity, optimal foraging is related to group size: lions hunt most successfully alone or in large groups of five to seven. Observations of group size suggest that the benefits of optimal defense often outweigh the benefits of optimal foraging. Based on data from Packer, C., D. Scheel, and A.E. Pusey, "Why Lions Form Groups: Food Is Not Enough," *American Naturalist*, Vol. 136 (July 1990).

CHECKPOINT 52.4

- What is optimal foraging?
- **CONNECT** How is optimal foraging adaptive?

52.5 Costs and Benefits of Social Behavior

LEARNING OBJECTIVES

7 Analyze social behavior in terms of costs and benefits, and compare different types of social groups, including societies of social insects.

8 Describe common modes of animal communication, including signaling by pheromones.

9 Compare the costs and benefits of dominance hierarchies and of territoriality.

The mere presence of more than one individual does not mean that a behavior is social. Many factors of the physical environment bring animals together in *aggregations*, but whatever interaction they experience may be circumstantial. A light shining in the dark is a stimulus that draws large numbers of moths, and the high humidity under a log attracts wood lice. Although these aggregations may have adaptive value, they are not truly social because the animals are not communicating with one another.

We can define **social behavior** as the interaction of two or more animals, usually of the same species. In the same way that natural selection led to the evolution of behaviors in response to environmental factors, natural selection has resulted in the evolution of social behavior. In this chapter we examine several familiar types of social behavior, including

communication, living together, dominance behaviors, territoriality, mating rituals, parenting, and helping behavior.

An organized **society** is an actively cooperating group of individuals belonging to the same species and often closely related. Many insects, such as tent caterpillars, which spin communal nests, cooperate socially. A school of fish, a flock of birds, a pack of wolves, and a hive of bees are other examples of societies. Some societies are loosely organized, whereas others are elaborately structured.

Many animals benefit from living in groups. Schools of fishes tend to confuse predators, so individuals within the school may be less vulnerable to predators than a solitary fish would be (see Fig. 53-1b). Zebra stripes appear to be a visual antipredator adaptation. When viewed from a distance, the stripes tend to visually break up the form of the animal so that individuals cannot be distinguished. A herd of zebras confuses predators, whereas a solitary animal is easy prey for lions, cheetahs, or spotted hyenas (FIG. 52-12).

Social foraging is an adaptive strategy used routinely by many animal species. A pack of wolves has greater success in hunting than an individual wolf would have. Among some birds of prey, such as certain hawks, group hunting locates prey more quickly than hunting alone.

Social behavior has benefits in addition to defense against predators and in some cases more successful foraging. Living together provides opportunities for interfering with reproduction of competitors, such as destroying their eggs. Social living also provides the opportunity to receive help from others in the group. Thus, for many types of animals, social behavior increases direct fitness. However, social behavior also has certain costs. Living together means increased competition for food and habitats, increased risk of attracting predators, and increased risk of transmitting disease. In addition, time and energy must often be invested in gaining and maintaining social status.

McMurray Photography

Figure 52-12 Social behavior in zebras

The social unit consists of a fairly stable group of females with young and a dominant stallion. When viewed from a distance, the stripes of a group of zebras serve as camouflage, confusing predators.

Communication is necessary for social behavior

One animal can influence the behavior of another only if the two of them can exchange mutually recognizable signals (FIG. 52-13). *Communication* is most evident when one animal performs an act that changes the behavior of another. Animals may communicate to hold a group together, warn of danger, signal social status, indicate willingness to accept or provide care, identify members of the same species, or indicate sexual maturity or readiness to mate. Communication may also be important in finding food, as in the elaborate dances of honeybees. Animals use electrical, tactile, visual, auditory, and chemical signals to transmit information to one another.

Certain fishes (gymnotids) emit electric pulses that generate electric fields in the water. These electric pulses can be used for navigation and communication, including territorial threat, in a

fashion similar to bird vocalization. As Harvard sociobiologist Edward O. Wilson said, "The fish, in effect, sing electrical songs."

Examples of animal touch include grooming and sharing food. Social insects, such as ants, groom and stroke one another with their antennae and mouthparts. Many types of bird chicks stimulate their parents to feed them by pecking at their beaks.

Visual signals can be transmitted quickly Visual signals are fast, communicate a great deal of information, and indicate the location and position of the animal sending the signal. An animal's own body, such as its coloration, may serve as the visual message. Numerous species communicate with visual displays that serve as social signals. For example, many birds present visual displays along with their songs.

Auditory signals can be conveyed in the dark Most animals cannot communicate effectively with visual signals when it is dark. However, animals can hear at night as well as during the day. Auditory signals can also be transmitted over longer distances than visual signals. Sound can move in all directions at once, and an auditory signal can be rapidly terminated. Most animals that communicate with auditory signals use **calls**, short, simple sounds. Birds and mammals use more complex auditory signals. In many bird species, males announce their presence and willingness to interact socially by singing. Some birds respond to a particular sound by matching it.

Some mammals, in addition to humans, learn to produce new sounds. These mammals include bats, cetaceans (dolphins and whales), elephants, seals, baboons, and orangutans. Orcas (formerly known as killer whales) communicate by sounds and songs. Members of a given pod (social group) have an average of 12 different calls, which vary in pitch and duration and appear to reflect their "emotional" state.

Bottlenose dolphins match sounds in communicating. These dolphins respond to the whistles of members of their own species by imitating and emitting the same sound. Researchers suggest that vocal matching was important in the evolution of human language.

Some animals communicate by scent Dogs and wolves mark territory by frequent urination. Antelopes, deer, and cats rub facial gland secretions on conspicuous objects in their vicinity and urinate on the ground. **Pheromones** are chemical signals secreted into the environment that convey information between members of a species. These small, volatile molecules provide a simple, widespread means of communication. Animals use pheromones to communicate danger, ownership of territory, and availability for mating. For example, female moths release pheromones that attract males. Ants mark their trails with pheromones.

Most pheromones elicit a very specific, immediate, but transitory type of behavior. Others trigger hormonal activities that result in slow but longer-lasting responses. Still other pheromones may elicit both transitory and longer-lasting responses. An advantage to pheromone communication is that relatively little energy is needed to synthesize the simple, but distinctive, organic compounds involved. Members of the same species have receptors that fit the molecular configuration of the pheromone; other species usually ignore it or do not detect it at all.

Pheromones are effective in the dark, can pass around obstacles, and last for several hours or longer. A major disadvantage of pheromone communication is that pheromones are transmitted slowly. Also, their information content is limited. However, some animals secrete several pheromones with different meanings.

Pheromones are important in attracting the opposite sex and in sex recognition in many species. Many social insects use these chemical signals to regulate reproduction. Humans have taken advantage of some sex-attractant pheromones to help control pests such as gypsy moths. They lure the males to traps baited with synthetic versions of female gypsy moth pheromones.

In honeybees, certain fatty acids are mixed with hydrocarbons from wax glands, and this mixture is transferred onto worker bees when they touch the comb. This mixture serves as a pheromone that identifies all the bees that belong to a particular hive. Should a bee from another hive attempt to enter, guard bees sting and may even kill the foreigner.

In vertebrates, pheromones affect sexual cycles and reproductive behavior, including choice of a mate. Pheromones may also play a role in defending territory. Among some mammals, an ovulating female (one physiologically ready to mate) releases pheromones as part of her vaginal secretion. When males detect these chemical odors, their sexual interest increases. When the odor of a male mouse is introduced among a group of females, the reproductive cycles of the female mice synchronize. In some species of mice, the odor of a strange male, a sign of high population density, causes a newly impregnated female to abort.

The extent to which humans respond to pheromones is the focus of considerable research. One interesting finding suggests that an unconsciously perceived body odor can synchronize the menstrual cycles of women who associate closely (e.g., college roommates or prison cell mates). Human steroids used in commercial fragrances such as perfumes may act as subtle signals that modulate mood and behavior.

As discussed in Chapter 43, mammals detect pheromones with specialized chemoreceptor cells that make up the **vomeronasal organ** in the epithelium of the nose. The vomeronasal sensory neurons signal the amygdala and hypothalamus, brain structures that regulate emotional responses and certain endocrine processes. When neurons of the vomeronasal system are damaged in virgin mice, they do not mate. Biologists have identified about 100 genes that code for pheromone receptors in the mouse and rat. These receptors initiate **signal transduction** pathways that involve G proteins.

Dominance hierarchies establish social status

In the spring, female paper wasps awaken from hibernation and begin to build a nest together. During the early course of construction, a series of squabbles among the females takes place in which the combatants bite one another's bodies or legs. Finally, one of the wasps emerges as dominant. After that, she is rarely challenged. This queen wasp spends more and more time tending the nest and less and less time out

foraging for herself. She takes the food she needs from the others as they return.

The queen then begins to take an interest in raising a family, her family. Because she is almost always in the nest, she can prevent other wasps from laying eggs in the brood cells by rushing at them, jaws agape. Because of her supreme dominance, the queen can bite any other wasp without serious risk of retaliation.

The other wasps of the nest are further organized into a **dominance hierarchy**, a ranking of social status in which each wasp has more status than the wasps that are lower in rank. Wasps lower in the hierarchy are subordinate to those above them, as follows:

queen → wasp A → wasp B → . . . wasp M

Once a dominance hierarchy is established, little or no time is wasted in fighting. When challenged, subordinate wasps communicate with submissive poses that inhibit the queen's aggressive behavior. Consequently, few or no colony members are lost through wounds sustained in fighting one another. This social organization ensures greater reproductive success for the colony.

In many species, males and females have separate dominance systems. For example, both female and male chimpanzees establish dominance hierarchies. Some females apparently become dominant through aggressive behavior, whereas others achieve high rank by virtue of their mother's status. Dominant females are more successful reproductively than those with lower social status. In many monogamous animals, especially birds, the female acquires the dominance status of her mate by virtue of their relationship and the male's willingness to defend her.

Like many fishes and some invertebrates, certain coral reef fishes (labrids) are capable of sex reversal. The largest, most dominant individual of a group is always male, and the remaining fish within his territory are all female. If the male dies or is removed, the most dominant female becomes the new male. Should any harm come to him, the next-ranking female undergoes sex reversal, takes charge, and protects the group territory. Other fishes exhibit the reverse behavior, in which the most dominant fish is always female. In such species size is less important for aggressive defense than for maximal egg production.

In establishing dominance, males may expend energy in posturing, roaring, leaping about, or sometimes fighting fiercely. These behaviors appear to be a test of male quality. The male with the greatest endurance will likely gain dominance and will have the greatest opportunity to mate and perpetuate his genes. In many animals, social dominance is a function of aggressiveness (FIG. 52-14). Tremendous energy is often needed for the fights engaged in by some birds and many mammals, including baboons, rams, and elephant seals. Establishing dominance is often strenuous and dangerous.

Sex hormones, particularly the male reproductive hormone testosterone, increase aggressiveness. The female hormone estrogen sometimes reduces dominance. Among chickens, the rooster is the most dominant. If a hen receives testosterone injections, her place in the dominance hierarchy shifts upward. When male rhesus monkeys are dominant, their testosterone levels are much higher than when they have been defeated. Not only can testosterone increase dominance, but dominance may even increase testosterone production. It is not always easy to determine cause and effect. (Studies suggest that the effects of testosterone on human mood and behavior may be different from those in other vertebrates.)

Paul Brough/Science Source

Figure 52-14 Communicating dominance in social groups
This "sacred" baboon (*Papio hamadryas*) bares his teeth and screams in an unmistakable show of aggression. As in many social groups, such signals allow him to establish and maintain dominance.

Social status affects many organs and systems, including brain structure. For example, dominant male rats have more new neurons in the hippocampus than subordinate rats or controls.

Many animals defend a territory

Most animals have a **home range**, a geographic area they seldom leave (FIG. 52-15). Because the animal has the opportunity to become familiar with everything in that range, it has an advantage over its competitors, predators, and prey in negotiating the terrain and finding food. Some animals exhibit **territoriality**. They defend a *territory*, a portion of the home range, often against other individuals of their species and sometimes against individuals of other species. Many species are territorial for only part of the year, often during the breeding season, but others are territorial throughout the year. Territoriality has been positively correlated with the availability of needed resources that occur in small areas that can be defended.

Territoriality is easily studied in birds. Typically, the male chooses a territory at the beginning of the breeding season. This behavior results from high sex hormone concentrations in his blood. The males of adjacent territories fight until territorial boundaries become established. Generally, the dominance of a male is directly associated with how close he is to the center of his territory. When close to home, he acts like a lion, but when invading some other bird's territory, he may behave more like a lamb. Sometimes males respect a neutral line, an area between their territories in which neither is dominant.

McMurray Photography

Figure 52-15 Home range

Cape buffalo (*Syncerus caffer*) live in herds of several hundred animals. Each herd, such as this one photographed in the Serengeti, has a fairly constant home range. Buffalo protect herd members, especially calves, from potential predators.

Birds use songs to announce their territory and songs often substitute for fighting. Songs also announce to eligible females that a propertied male resides in the territory. Typically, male birds take up a conspicuous station, sing, and sometimes display striking patterns of coloration or aerial acrobatics to their neighbors, their rivals, and sometimes their mates.

The costs of territoriality include the time and energy expended in staking out and defending a territory and the risks involved in fighting for it. Benefits often include exclusive rights to food within the territory and greater reproductive success. The males of a lion pride father all the cubs born within that pride. Their ability to defend their territory from invasion by strange males ensures their reproductive success. Among many species, animals that fail to establish territories fail to reproduce. Territoriality also tends to reduce conflict among members of the same species and ensures efficient use of environmental resources by encouraging individuals to spread throughout a habitat.

Usually, territorial behavior is related to the specific lifestyle of the animal and to whatever aspect of its environment is most critical to its reproductive success. For instance, seabirds may range over hundreds of square kilometers of open water but exhibit territorial behavior only at crowded nesting sites on an island. The nesting sites are their scarcest resource and the one for which competition is keenest.

Some insect societies are highly organized

Social insects form elaborate societies. Characteristics of a highly organized society include cooperation and division of labor among animals of different sexes, age groups, or castes. An intricate system of communication reinforces the organization of the society. The members tend to remain together and to resist attempts by outsiders to enter the group.

By cooperation and division of labor, some insects construct elaborate nests and raise young by mass-production methods. Bees, ants, wasps, and termites form the most organized insect societies. (The first three of these all belong, not coincidentally, to the same order, Hymenoptera.) Insect societies are held together by a complex system of sign stimuli that are keyed to social interaction, and their behaviors tend to be quite rigid.

The social organization of honeybees has been studied more extensively than that of any other social insect. Instructions for the honeybee society are inherited and preprogrammed, and the size and structure of the bee's nervous system permit only a limited range of behavioral variation. These insects are not automatons, however. Within its inherited limits, the complex bee society can respond with some flexibility to food and other stimuli in the environment.

A honeybee society generally consists of a single adult queen, up to 80,000 worker bees (all female), and at certain times, a few males called drones that fertilize newly developed queens. The queen, the only female in the hive capable of reproduction, deposits about 1000 fertilized eggs per day in the wax cells of a comb.

The composition of a bee society is generally controlled by a pheromone secreted by the queen. It inhibits the workers from raising a new queen and prevents development of ovaries in the workers (FIG. 52-16). If the queen dies or if the colony becomes so large that the inhibiting effect of the pheromone dissipates, the workers begin to feed some larvae special food that promotes their development into new queens.

Treat Davidson/Science Source

Figure 52-16 Maintaining a complex social structure

Numerous worker honeybees surround their queen (*center*). Workers constantly lick secretions from the queen bee. These secretions, transmitted throughout the hive, suppress the activity of the workers' ovaries.

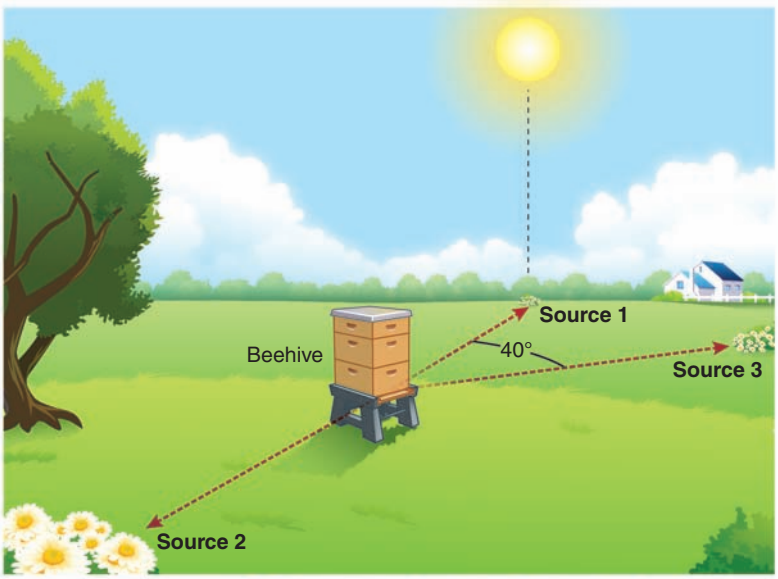
The queen bee stores sperm cells from previous matings in a seminal receptacle. If she releases sperm to fertilize an egg as it is laid, the resulting offspring is female; otherwise, it is male. Thus, males develop by parthenogenesis from unfertilized eggs and are haploid. Because a drone is haploid, each of his sperm cells has *all* his chromosomes; that is, meiosis does not occur during sperm production. The queen bee stores this sperm throughout her lifetime and uses it to produce worker bees.

The worker bees of a hive are more closely related to one another than would be sisters born of a diploid father. Indeed, they have up to three-fourths of their genes in common. (Assuming the queen bred with a single drone, they share half of the queen's chromosomes and all the drone's chromosomes.) As a consequence, they are more closely related to one another than they would be to their own offspring, if they could have any. (A worker bee's female offspring would have only half of its genes in common with its worker mother.) New queens are also their sisters. Worker bees are therefore more likely to pass on copies of their genes to the next generation by raising these individuals than they would if they were to produce their own offspring.

Division of labor among worker bees is mostly determined by age. The youngest worker bees serve as nurses that nourish larval bees. After about a week as nurse bees, workers begin to produce wax and build and maintain the wax cells. Older workers are foragers, bringing home nectar and pollen. Most worker bees die at the ripe old age of 42 days.



Bees have the most sophisticated mode of communication known among nonmammals. They perform a stereotyped series of body movements called a *dance*. The dance re-enacts, in miniature, the bee's flight to the food. When a honeybee scout locates a rich source of nectar, it apparently observes the angles among the food, hive, and the sun. The forager bee then communicates the direction and distance of the food source relative to the hive (FIG. 52-17). If the food supply is within about 52 m (about 55 yd), the scout performs a *round dance*, which generally excites the other bees and prompts them to fly short distances in all directions from the hive until they find the nectar. If the food is distant, however, the scout performs a *waggle dance*, which follows a figure-eight pattern.

In the 1940s, German zoologist Karl von Frisch pioneered studies in bee communication. He found that the waggle dance conveys information about both distance and direction. During the straight run part of the figure eight, the number and frequency of the waggles indicate the distance. The orientation of the movements indicates the direction of the food source in reference to the position of the sun. For example, if the bee dances straight up, the nectar is located directly toward the sun. If the bee dances 40 degrees to the left of the vertical surface of the comb, the nectar is located 40 degrees to the left of a line between the hive and the sun.

(a) Round dance. If the scout performs the round dance, it indicates the food source is close to the hive (within about 52 m).

(b) Waggle dance. If the scout performs the waggle dance, it indicates the food source is more distant from the hive. Distance is further indicated by how many abdominal waggles are performed in the straight part of the dance.

Source 1: Located toward the sun

Source 2: Located opposite the sun

Source 3: Located 40 degrees to the right of the sun

(c) Direction coded in waggle dance. If the scout waggles upward, it indicates the food source is toward the sun. If the scout waggles downward, it indicates the food source is in the opposite direction of the sun. If the scout waggles 40 degrees to the right, it indicates the food source is at a 40° angle to the right of the sun.

The forager bee typically performs the dance in the dark hive on the vertical surface of the comb. How, then, does its audience "see" the dance? Investigators have shown that the bee produces sounds as it dances. The auditory signals apparently communicate the position of the dancing bee.

52.6 Sexual Selection

LEARNING OBJECTIVE

10 Define *sexual selection* and describe different types of mating systems and approaches to parental care.

Sexual selection is a type of natural selection for successful mating. Animals vary in their ability to compete for mates. Individuals with some inherited advantage, such as males with large size, have a greater chance to mate and pass on their genes to the next generation. The beneficial trait becomes more common in the population over time. Thus, sexual selection results in the reproductive advantage that some individuals have over others of the same species and sex.

For a male, reproductive success depends on how many females he can impregnate. For a female, reproductive success depends on how many eggs she can produce during her reproductive lifetime, on the quality of the sperm that fertilize them, and on the survival of her offspring to reproductive age. Recall that an animal's reproductive success is a measure of its *direct fitness*. We can distinguish between *intrasexual selection* and *intersexual selection*.

Animals of the same sex compete for mates

In **intrasexual selection**, individuals of the same sex actively compete for mates. Typically, in such populations abundant males compete for a limited number of receptive females. Competition may take the form of physical combat. Among many species—for example, baboons and elephant seals—the largest male has the advantage.

Often, males establish dominance in more subtle ways than direct competition. Many males use elaborate ornamental displays to establish dominance. For example, the male deer with the largest antlers may discourage his competitors. The male bird with the most dramatic plumage and brightest colors may have a psychological advantage over competing males.

Several studies confirm that males ranking higher in a dominance hierarchy mate more frequently than males that rank lower. However, exceptions demonstrate the complexity of reproductive behavior among some species. For example, among baboons with a definite dominance hierarchy, males lower in the hierarchy copulated with females as frequently as did males of higher status. Investigators observed, though, that dominant males copulated more frequently with females that were in *estrus*, their fertile period.

Animals select quality mates

Females frequently have the opportunity to select a sexual partner from among several males. In **intersexual selection**, females select their mates on the basis of some physical trait or some resource offered by the winning suitors. The physical trait typically indicates genetic quality or good health. In many species, the success of a male in dominance encounters with other males indicates his quality to the female, and she allows the victorious male to court her. Some lower ranking males develop alternative strategies for attracting females. For instance, a male may win a female's interest by protecting her baby, even though it is not his own.

Females of some species select their mates based on ornamental displays. A female fish may select the most brightly colored male. Female birds often select males with the showiest plumage and brightest colors, and female deer prefer males that display elaborate antlers. Expression of ornamental traits may give the female important information about the male's physical condition and ability to fight. The size of the antlers of red deer, for example, may indicate combat effectiveness as well as proper nutrition and good health. Female lions are attracted to males with thick, dark manes, an indicator of good nutrition and plenty of testosterone (which regulates growth of hair and melanin production). Thus, in some species, ornaments signal good health and good genes.

Among crickets and many other insect species, a courting male offers a gift of food to a prospective mate. Studies show that the larger or higher quality the food offering is, the better the chances the male will be accepted.

Among some species of insects, birds, and bats, males gather in a small display area called a **lek**, where they compete for females. When a receptive female appears, males may excitedly display themselves and compete for her attention. Among some species, the female selects a male based on his location in the lek rather than on his appearance. The dominant male may occupy a central position and be chosen by most of the females. The female selects a male, mates with him, and then leaves the lek. The male remains to woo other females.

Courtship rituals ensure that the male is indeed a male and is a member of the same species. Rituals provide the female further opportunity to evaluate him. In some species, courtship may also be necessary as a signal to trigger nest building or ovulation. Courtship rituals can last seconds, hours, or days and often involve a series of behavioral patterns (FIG. 52-18). The first

Figure 52-18 Courtship rituals

Elaborate courtship rituals help animals determine that a potential mate is of the same species and gives each animal a chance to evaluate the other as a potential mate.

display by the male releases a counter behavior by the female. Her response, in turn, releases additional male behavior, and so on until the pair is physiologically ready for copulation. Specific cues enable courtship rituals to function as reproductive isolating mechanisms among species (see Fig. 20-3).

An extreme courtship ritual has been described for redback spiders, which are closely related to the black widow spider. During copulation, the small male spider positions himself above his larger mate's jaws. During 65% of mating acts, the finale is that the female eats her suitor. The apparent explanation for this behavior is that the risk-taking male is able to copulate for a longer period and thus fertilize more eggs than males that are not cannibalized. Also, the female is more likely to reject additional mates.

Sexual selection favors polygynous mating systems

In most species, males make little parental investment in their offspring apart from providing sperm. Males ensure reproductive success by impregnating many females, increasing the probability that their genes will be propagated in multiple offspring. Thus, sexual selection often favors **polygyny**, a mating system in which males fertilize the eggs of many females during a breeding season.

In the mating system known as **polyandry**, one female mates with several males. Benefits may include receiving gifts from several males or enlisting several males' help in caring for the young. Data collected at Jane Goodall's research center at Gombe National Park in Tanzania indicate that female chimpanzees practice polyandry. Females mate with males of their own group, but when they are most fertile, many females slip off to neighboring communities and copulate with less familiar males. Perhaps these sexual rendezvous protect against inbreeding.

Investigators also hypothesize that mating with many males provides insurance against infanticide. Males do not aggress against infants of mothers with which they have copulated. Studies indicate that females with multiple mates are more fertile and produce more offspring than those without multiple mates.

Polyandry and polygyny sometimes occur in the same species. After mating, a female giant water bug attaches a clutch of eggs to her mate's back (FIG. 52-19a). He cares for the eggs until they hatch. She then may mate with a different male and glue the new clutch of eggs to his back. However, if the male has more space for eggs, he may mate with another female.

Apparently, in most species it is not certain which male fathered the offspring. However, raising some other male's offspring is a genetic disadvantage, so males of some species may compromise mate-chasing behavior in favor of **mate guarding**. The male guards his partner after copulation to ensure that she does not copulate with another male.

Mate-guarding behavior is likely to occur when the female is receptive and has eggs that might be fertilized by another male. For example, dominant male African elephants guard a female only during the phase of estrus when she is most likely to be fertile. Before that time, or later in estrus after mating has already occurred, younger male elephants of lesser social status can copulate with the female. A high cost of mate guarding is the loss of opportunity for a dominant male to mate with other females.

Sexual selection favors males that inseminate many females and produce many offspring. Perhaps for this reason, **monogamy**, a mating system in which a male mates with only one female during a breeding season, is not common. Less than 10% of mammals are monogamous.

Researchers long thought that monogamy was common among birds because many species form **pair bonds**, which are stable relationships that ensure cooperative behavior in mating and the rearing of the young. However, genetic evidence shows

Figure 52-19 Caring for the young

Parental investment in offspring increases the probability that the young will survive.

that some offspring are fathered by males other than the one caring for them. For example, DNA tests show that among eastern bluebirds, 15% to 20% of the chicks are fathered by other males. The extra-pair male contributes new genes. The female then produces offspring with greater genetic variability, increasing the chance that at least some of her offspring will survive. Some researchers distinguish between *sexual monogamy* and *social monogamy*, in which animals form a pair bond.

Monogamy does occur in some species, typically when males are needed to protect and feed the young. For example, the California mouse is sexually as well as socially monogamous. The offspring need their parents' body heat to survive, and the parents take turns keeping them warm.

Some animals care for their young

Parental investment is the contribution that each parent makes in producing and rearing offspring. The benefit of parental investment is the greater probability that each offspring will survive. Despite this, most animals do not invest time and energy in caring for their offspring because the costs of parenting are high. For example, an animal busy feeding and protecting offspring might produce fewer additional offspring. There are also risks in protecting the young from predators.

Natural selection has favored parental care in species in which the female produces few young or reproduces only once during a breeding season. Parental care is an important part of successful reproduction in some invertebrates, including some cnidarians (jellyfish), rotifers, mollusks, and arthropods (crustaceans, insects, spiders, and scorpions), and is a common practice among vertebrates (FIG. 52-19b–d).

Females of many vertebrate species produce relatively few, large eggs. Because of the time and energy invested in producing eggs and carrying the developing embryo, the female has

more to lose than the male if the young do not develop. Thus, females are more likely than males to brood eggs and young, and usually females invest more in parental care. Parental care is especially skewed toward the female in mammals because females provide milk to nourish their young. Investing time and effort in care of the young is usually less advantageous to a male than to a female (assuming that the female can handle the job by herself) because time spent in parenting is time lost from inseminating other females.

In some situations a male benefits by helping rear his own young or even those of a genetic relative. Receptive females may be scarce, breeding territories may be difficult to establish or guard, and gathering sufficient food may require more effort than one parent can provide. In some habitats the young need protection against predators or cannibalistic males of the same species. Among wolves and many other carnivores, for example, males defend the young and the food supply.

Among many species of fish, the male cares for the young. Apparently, parenting costs to the males are less than they would be for the females. A male fish must have a territory to attract a female. While guarding his territory, the male guards the fertilized eggs as well. Having eggs also appears to make the male more attractive to potential mates. In contrast, when a female is caring for her eggs or young, she is not able to feed optimally. As a result, her body size is smaller, and her fertility is reduced.

Behavioral ecologist Bryan D. Neff of the University of Western Ontario showed that male bluegill sunfish (*Lepomis macrochirus*) adjust their level of caregiving according to their degree of certainty that the offspring are indeed their own. Adult males, called parentals, defend a nest, attract females, and care for the eggs and newly hatched offspring. Some males, called *sneaker males* (or cuckolders), sneak into nests and fertilize eggs during spawning. Other sneaker males have developed in a way that gives them characteristics of females. The parental male is tricked into regarding the sneaker male as another female, allowing it access to the eggs (FIG. 52-20).

Neff performed a series of experiments in which he placed sneaker males in transparent containers so that they could not fertilize eggs but the parentals could see them. In response, parentals reduced their level of protecting the eggs (FIG. 52-21). However, after the eggs hatched, the parentals increased their level of care. Apparently, olfactory cues indicated that these young fish were indeed the offspring of the parental caring for them. (They smelled right.)

In a second experiment, Neff exchanged about one-third of the eggs between two nests. Parentals continued to protect the eggs, but after the eggs hatched, parentals decreased their level of care. This investigator showed that parentals responded to olfactory cues. At least some of their offspring did not smell right. (The odor may be produced by the offspring's urine.) Neff suggested that an animal learns its own odor (or appearance) and forms a template of what its relatives should smell (or look) like. If they don't match up closely enough, they may be rejected.

Does a male bluegill sunfish adjust his level of caregiving if he perceives that he is not the genetic parent of the eggs or offspring that he is guarding?

HYPOTHESIS: Behavioral ecologist Bryan D. Neff hypothesized that male bluegill sunfish adjust the level of their parental care according to their level of perceived paternity.

EXPERIMENTS: Neff manipulated visual and olfactory cues.

In **Experiment 1**, Neff manipulated sneaker males. He placed two transparent containers with sneaker males near the nests of 34 parentals (adult males) and left them there during spawning. Empty containers were placed around 20 control nests. After the fish spawned, a potential egg predator (a pumpkinseed sunfish in a clear plastic container) was presented, and the parental's defensive behavior was observed and quantified for both experimental and control groups.

In **Experiment 2**, the investigator removed one-third of the eggs from the nests of 20 parentals and replaced them with eggs from other nests. Sham egg swaps were carried out on eggs of 15 control parentals. Parental defensive behavior was observed before and after the eggs hatched.

RESULTS:

Experiment 1: As indicated on the *y*-axis, which measures level of parental care, parentals reduced their level of guarding the eggs. Eight of the males in the experimental group abandoned their nests, and egg defense was significantly lower in this group compared with that in the control group. However, after eggs hatched, there was little difference in parental care of the young between the two groups.

Experiment 2: During the egg phase, there was little difference in level of parental care between experimental and control groups. However, after eggs hatched, the experimental parentals significantly decreased their level of guarding the nest.

CONCLUSION: Male bluegill sunfish adjust their level of parental care according to their level of perceived paternity.

In **Experiment 1**, parentals provided less care when they perceived that the eggs may have been fertilized by sneaker males. After the eggs hatched, olfactory cues indicated that the offspring were indeed their own, and their level of care increased.

In **Experiment 2**, parentals cared for the eggs even though some had been swapped. However, after they hatched, olfactory cues from the offspring indicated that they were not the parental's own offspring. The level of parental care decreased significantly.

Among wild turkeys and many other species, subordinate males help dominant males attract a mate, but the subordinate males do not reproduce. If an animal's principal evolutionary mandate is to perpetuate its genes, we must wonder why some animals spend time and energy in helping others.

Altruistic behavior can be explained by inclusive fitness

In a type of cooperative behavior known as **altruistic behavior**, one individual behaves in a way that seems to benefit others rather than itself, with no potential payoff. In fact, the helper experiences a fitness cost, whereas the recipient of the altruistic behavior benefits. How could true altruistic behavior be adaptive if the animal's response decreases its reproductive success relative to individuals that do not exhibit the altruistic behavior? In 1964, British evolutionary biologist William D. Hamilton offered a plausible explanation. He suggested that evolution does not distinguish between genes transmitted directly from parent to offspring and those transmitted indirectly through close relatives.

According to Hamilton, natural selection favors animals that help a relative because the relative's offspring carries some of the helper's alleles. **Inclusive fitness** is the sum of direct fitness (which can be measured by the number of alleles an animal perpetuates in its offspring) plus indirect fitness (the alleles it helps perpetuate in the offspring of its kin).

We can measure the potential genetic gain from helping relatives by the *coefficient of relatedness*, the probability that two individuals inherit the same uncommon allele from a recent common ancestor. The coefficient of relatedness for two animals that are not related is 0, whereas between a parent and its offspring this coefficient is 0.5, indicating that half of their genes are the same. The coefficient of relatedness for siblings is also 0.5; for first cousins, it is 0.125. The higher the coefficient of relatedness, the more likely an animal will help a relative.

Hamilton developed a mathematical model to show how an allele that promotes altruistic behavior can increase in frequency in a population. According to *Hamilton's rule*, an altruistic act is adaptive if (1) its indirect fitness benefits are high for the animals that profit, (2) the recipients are close relatives of the altruist, and (3) the direct fitness cost to the altruistic animal is low.

Behavioral ecologists have made DNA fingerprints of lions in the Serengeti National Park and in the Ngorongoro Crater (both in Tanzania). Their findings confirm that lion brothers that cooperate in prides have a greater probability of perpetuating their genes than those that go off on their own. This finding is true even if the lion perpetuates his genes only by proxy, through his brother. **Kin selection**, also called *indirect selection*, is a form of natural selection that increases inclusive fitness through the breeding success of close relatives.

The bee society provides an interesting example of kin selection. Recall that worker bees do not reproduce, but they do nourish larval bees. The worker bees have up to three-fourths of their genes in common with the larval bees. For this reason, worker bees are more likely to perpetuate their genes by raising larval bees than they would by producing their own offspring.

Some birds (such as Florida scrub jays) engage in a type of *cooperative breeding* in which non-reproducing individuals aid in rearing the young. Nests tended by these additional helpers as well as parents produce more young than do nests with the same number of eggs overseen only by parents. The non-reproducing helpers are close relatives that increase their own biological success by ensuring the successful, although indirect, perpetuation of their genes. Helpers may be prevented from producing their own offspring by limiting factors such as a shortage of mates or territories.

Helping behavior may have alternative explanations

Some behavioral ecologists are questioning the role of kin selection in helping behavior. One of the time-honored examples of kin selection has been sentinel behavior, keeping watch for predators and warning other members of the group when danger threatens. Until recently, biologists thought that sentinels were at greater risk for predation than other members of that group, yet selflessly engaged in risky behavior that benefited their relatives. This explanation appears valid for some species, including prairie dogs and ground squirrels. However, some studies suggest an opposing hypothesis for guarding behavior in other species.

U.S. biologist Peter A. Bednekoff developed a model to explain how guarding could result from selfish behavior. Bednekoff observed that for some species sentinels are not at higher risk than others in their group. In fact, the opposite may be true, and sentinels may actually have an advantage. By detecting predators first, the sentinels can escape more rapidly than others in the group.

Studies of sentinel behavior in the African mongoose, commonly known as the meerkat, support Bednekoff's model (FIG. 52-22). During 2000 hours of researcher observation, no sentinel was killed. In fact, investigators concluded that guarding is a selfish behavior in meerkat populations because sentinels were able to escape quickly into their nearby burrows. This research is an important reminder that it is risky for biologists to generalize the meanings of complex social behavior from one species to another. Many explanations are possible. Helpers often derive direct benefits in safety and eventual reproductive success. For example, among some species, younger animals that help are permitted to remain in the social group and derive the benefits of group protection. These helpers are also positioned to take over territories and mates when older members of the group die.

Some animals help nonrelatives

Occasionally, an animal helps a nonrelative in a fight, grooms it, or even shares food. Evolutionary biologist Robert L. Trivers of Rutgers University explained this behavior in 1971 with his hypothesis of **reciprocal altruism**. According to this hypothesis, one animal helps a nonrelative with no immediate benefit, but at some later time the animal that was helped repays the debt. In this way, the original helper experiences a net fitness benefit. A vampire bat that has just fed regurgitates blood for hungry bats that share the roost. If a bat does not share blood with a neighbor that has fed it in the past, the "cheater" will probably not be helped in the future.

Figure 52-22 Sentinel behavior in the meerkat (*Suricata suricatta*), also known as the African mongoose

Studies of sentinel behavior in meerkats suggest that meerkat sentinels are not being altruistic and their behavior is not about kin selection. In fact, guarding may actually be a selfish behavior, because when danger threatens, sentinels can quickly escape into the burrow.

CHECKPOINT 52.7

- **CONNECT** How does kin selection explain the evolution of altruistic behavior?
- **PREDICT** How might an animal benefit by helping a nonrelative?

52.8 Culture in Vertebrate Societies

LEARNING OBJECTIVE

12 Contrast a vertebrate society with a society of social insects, give examples of transmission of culture, and briefly describe sociobiology.

Vertebrate societies typically have nothing comparable to the physically and behaviorally specialized castes of honeybees or ants. An exception is the naked mole rat of southern Africa, a rodent that has a social structure closely resembling that of the social insects. Although most vertebrate societies seem simpler than insect societies, they are also more flexible. Vertebrate societies share a great range and plasticity of potential behaviors and can effectively modify behavior to meet environmental challenges.

Some vertebrates transmit culture

The behavioral plasticity of vertebrates makes possible the transmission of culture in some bird and mammal species. **Culture** is behavior common to a population, learned from other members of the group, and transmitted from one generation to another. Culture is not inherited. It is maintained by **social learning**, such as through observing others and imitating them or by teaching.

About 17 behaviors that may be considered cultural have been described among cetaceans (whales, dolphins, porpoises). For example, female orcas teach their offspring to hunt seals according to the custom of their particular group. Orcas also have local dialects that have been documented for at least six generations, suggesting that they are passed on from parent to offspring. Separate dialects are maintained even when various populations of orcas interact socially.

Biologists have reported that humpback whales learn new strategies for feeding by observing one another. Bottlenose dolphins are well known for their ability to learn by imitation. Behavioral ecologists have documented foraging practices that appear to be cultural, that is, transmitted by social learning.

Teaching is an efficient form of social learning. If adult animals can teach younger ones, critical information can be rapidly transferred from one generation to the next (FIG. 52-23). University of Cambridge researchers Alex Thornton and Katherine McAuliffe reported that helper meerkats teach pups skills for capturing prey. Meerkats feed on a variety of animals, many of which are difficult to subdue. Some, such as scorpions, are potentially dangerous. Young meerkat pups cannot find and capture their own prey. Instead, they emit begging calls that induce helpers to feed them. Helpers monitor and nudge the pups to handle the prey efficiently. As they grow older, the pups' begging calls change. In response, helpers modify their teaching, giving the pups the opportunity to practice a greater range of skills. The helpers gradually introduce the pups to live prey.

Studies of chimpanzee populations demonstrate that some groups develop local customs and teach them to their offspring. Using data provided by researchers at seven chimpanzee research sites, animal behaviorists identified 39 chimpanzee behaviors that they considered cultural variations. These behaviors included various ways of using tools, courtship rituals, and grooming techniques. Each of these local customs was learned from other chimpanzees in the population, and customs varied among different populations. For example, chimpanzees on the western side of the Sassandra-N'Zo River use stone hammers to crack coula nuts. Researchers have photographed mother chimpanzees

Figure 52-23 Mother orca and her calf breaching

As this mother orca and her calf breach, they leap out of the water, exposing two-thirds or more of their bodies, and then land on their sides. Orcas educate and discipline their calves.

teaching this behavior to their offspring. Just a few miles away on the eastern side of the river, chimpanzees do not crack nuts, even though they are available.

When a chimp migrates and joins a new population, it can transmit knowledge learned in its previous culture. In this way, cracking nuts and other customs spread from one population to another. An example of cultural transmission has been observed in a chimp community at Gombe. (Anthropologist Jane Goodall has studied the chimps there since 1960.) An adult female chimp that joined the Gombe chimp community in the early 1990s had apparently learned to use tools to fish out carpenter ants in her former community. Some of the young chimps of her new community observed this behavior and learned how to insert sticks into holes to fish out ants.

As researchers continue to study cultural variation among chimpanzee populations, learning ever more about our closest relatives, it is important to remember that the capacity to learn such behaviors is the product of natural selection. The behaviors that are maintained are adaptive for these animals in their environment. Studying culture in nonhuman primates may provide insights into the evolutionary origins of human culture. Human society is based to a great extent on the symbolic transmission of culture through spoken and written language.

Sociobiology explains human social behavior in terms of adaptation

Sociobiology focuses on the evolution of social behavior through natural selection. In his landmark book, *Sociobiology: The New Synthesis*, published in 1975, Edward O. Wilson combined principles of population genetics, evolution, and animal behavior to present a comprehensive view of the evolution of social behavior. Like Darwin and many other biologists of the past, Wilson suggested that human behavior can be studied in evolutionary terms. Many of the concepts discussed in this chapter, such as paternal investment in care of the young, are based on contributions made by Wilson and other sociobiologists. Wilson's work greatly influenced the development of behavioral ecology, evolutionary psychology, and evolutionary anthropology.

Sociobiology has been controversial, at least in part because of its application to human behavior and the possible ethical implications of such application. Some critics have complained that according to sociobiology human behavior may not be flexible enough to permit substantial improvements in the quality of our social lives. Sociobiologists, however, agree with their critics that human behavior *is* flexible. At least some of the debate focuses on the *degree* to which human behavior is genetically determined and the extent to which it can be modified.

As sociobiologists acknowledge, people can, through culture, change their way of life far more profoundly in a few years than could a hive of bees or a troop of baboons in hundreds of generations of genetic evolution. This capacity to make changes is indeed genetically determined, and it is a great gift. How we use it and what we accomplish with it are not a gift but, rather, a responsibility on which our own well-being and the survival of other species depend.

CHECKPOINT 52.8

- **CONNECT** How are vertebrate societies different from those of social insects?
- What are some examples of culture?
- According to sociobiologists, what determines social behavior?

Summary: Focus on Learning Objectives

52.1 Behavior and Adaptation *(page 1125)*

1 Distinguish between proximate and ultimate causes of behavior and apply the concepts of ultimate cause and cost–benefit analysis to decide whether a particular behavior is adaptive.

- **Behavior** is what an animal does and how it does it, usually in response to stimuli in its environment. **Proximate causes** of behavior are immediate causes, such as genetic, developmental, and physiological processes that permit the animal to carry out a specific behavior. Proximate causes answer *how* questions. **Ultimate causes** are the evolutionary explanations for *why* a certain behavior occurs.
- We can use **cost–benefit analysis** to determine whether a behavior is adaptive. Benefits contribute to **direct fitness**, the animal's reproductive success measured by the number of viable offspring it produces. If benefits outweigh costs, the behavior is adaptive.

2 Describe the interactions of heredity, environment, and maturation in animal behavior.

- Behavior results from the interaction of genes (**innate behavior**) and environmental factors. The capacity for behavior is inherited, but behavior is modified in response to environmental experience.
- An organism must be mature—physiologically ready to produce a given behavior—before it can perform that pattern of behavior. Walking and many other behaviors that we view as automatic are **motor programs**, coordinated sequences of muscle actions.
- A **behavioral pattern** is an automatic behavior that, once activated by a simple sensory stimulus, continues to completion regardless of sensory feedback. A behavioral pattern can be triggered by a specific unlearned **sign stimulus**, or *releaser*.

52.2 Learning: Changing Behavior as a Result of Experience *(page 1127)*

3 Discuss the adaptive significance of habituation, imprinting, classical conditioning, operant conditioning, and cognition.

- **Learning** is a change of behavior that results from experience. **Habituation** is a type of learning in which an animal learns to ignore a repeated, irrelevant stimulus so that it can focus on finding food and carrying out other life activities.
- **Imprinting** establishes a parent–offspring bond during a *critical period* early in development, ensuring that the offspring recognizes its mother.
- In **classical conditioning**, an association is formed between some normal body function and a new stimulus. This type of learning allows an animal to make an association between two stimuli.
- In **operant conditioning**, an animal learns a behavior so as to receive positive reinforcement or to avoid punishment. This type of learning is important in many natural situations; for example, young herring gulls perfect their pecking behavior so as to obtain food.
- **Cognition** is the process of gaining and using knowledge; it includes knowing, thinking, processing information, learning, reasoning, and awareness of thoughts, perceptions, and self. Cognition allows some animals to adapt past experiences to solve new problems that may involve different stimuli.

52.3 Behavioral Responses to Environmental Stimuli *(page 1131)*

4 Give examples of biological rhythms and describe some of the physiological mechanisms responsible for them.

- It is adaptive for an organism's metabolic processes and behavior to be synchronized with cyclical changes in the environment. In many species physiological processes and activities follow **circadian rhythms**, which are daily cycles of activity.
- **Diurnal animals** are most active during the day; **nocturnal animals**, at night; and **crepuscular animals**, at dawn or dusk. Some biological rhythms—for example, the changes in tides due to changes in the phase of the moon—reflect the *lunar cycle*.
- Many biological rhythms are regulated by internal timing mechanisms that serve as **biological clocks**. In mammals the master clock is located in the **suprachiasmatic nucleus (SCN)** in the hypothalamus.

5 Analyze costs and benefits of migrations and distinguish between directional orientation and navigation.

- **Migration** is periodic long-distance travel from one location to another. Proximate causes of migration include physiological responses that are triggered by environmental changes. Ultimate causes of migration include the benefit of moving away from an area that seasonally becomes too cold, dry, or depleted of food to a more hospitable area. Costs of migration include time, energy, and greater risk of predation.
- *Directional orientation* is travel in a specific direction and requires **compass sense**, a sense of direction. Many migrating animals use the sun to orient themselves.
- **Navigation** requires both compass sense and **map sense**, an awareness of location. Birds that navigate at night use the stars as guides. Birds and many other animals also use Earth's magnetic field to navigate.

52.4 Foraging Behavior *(page 1133)*

6 Define *optimal foraging behavior* and explain how it is adaptive.

- **Optimal foraging**, the most efficient strategy for an animal to get food, can enhance reproductive success.

52.5 Costs and Benefits of Social Behavior *(page 1134)*

7 Analyze social behavior in terms of costs and benefits, and compare different types of social groups, including societies of social insects.

- **Social behavior** is the interaction of two or more animals, usually of the same species. An organized **society** is an actively cooperating group of individuals belonging to the same species and often closely related. In some species social organization ensures greater reproductive success than do noncooperative arrangements.
- Many animal societies are characterized by a means of communication, cooperation, division of labor, and a tendency to stay together. Benefits include cooperative foraging

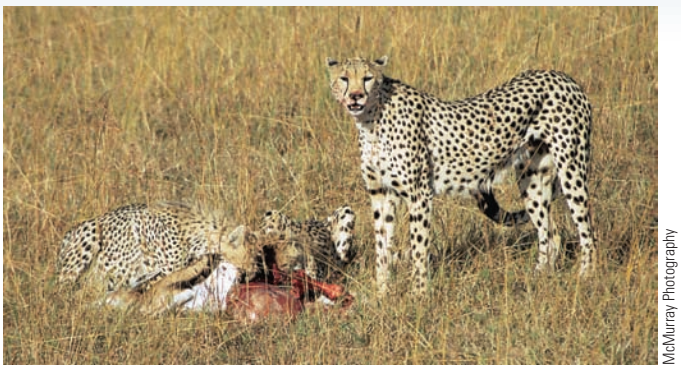
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

or hunting and defense from predators. Costs include increased competition for food and habitats and increased risks of attracting predators and transmitting disease.

8 Describe common modes of animal communication, including signaling by pheromones.

- Animal *communication* involves the exchange of mutually recognizable signals, which can be electrical, tactile, visual, auditory, or chemical. **Pheromones** are chemical signals that convey information between members of a species.



9 Compare the costs and benefits of dominance hierarchies and of territoriality.

- A **dominance hierarchy** is a ranking of status within a group in which more dominant members are accorded benefits (such as food or mates) by subordinates. Establishing dominance often, but not always, involves aggressive behavior. Social ranking reduces costly physical fights.
- Animals often inhabit a **home range**, a geographic area that they seldom leave but do not necessarily defend. A defended area within a home range is called a *territory*, and the defensive behavior is territoriality. Costs of **territoriality** include time and energy expended in staking out and defending a territory and risks in fighting for it. Benefits include rights to food in the territory and reduction in conflict among members of a population.

52.6 Sexual Selection *(page 1140)*

10 Define *sexual selection* and describe different types of mating systems and approaches to parental care.

- **Sexual selection**, a type of natural selection, occurs when individuals vary in their ability to compete for mates. Individuals with reproductive advantages are selected over others of the same sex and species. In **intrasexual selection**, animals of the same sex actively compete for mates.
- In **intersexual selection**, females may choose their mates based on dominance, gifts, ornaments, or courtship displays. Males of some species gather in a **lek**, a small display area where they compete for females. **Courtship rituals** ensure that the male is a member of the same species and permit the female to assess the quality of the male.
- Sexual selection often favors **polygyny**, a mating system in which a male mates with many females. In **polyandry** a female mates with several males. **Monogamy**, mating with a single partner during a breeding season, is less common. Among many species, males engage in **mate guarding**, especially when the female is most fertile, to prevent other males from fertilizing her eggs.
- A **pair bond** is a stable relationship between a male and a female that may involve cooperative behavior in mating and in rearing the young. **Parental investment** in care of eggs and offspring increases the probability that offspring will survive. A high investment in parenting is typically less advantageous to the male than to the female.

McMurray Photography

52.7 Helping Behavior *(page 1143)*

11 Relate the concepts of inclusive fitness and kin selection to altruism.

- **Altruism** is a type of cooperative behavior in which one individual appears to behave in a way that benefits others rather than itself. **Inclusive fitness** is the sum of an individual's direct fitness and indirect fitness (number of offspring of kin). This concept suggests that natural selection favors animals that help a relative because it is an indirect way to perpetuate some of the helper's own alleles.
- According to *Hamilton's rule*, an altruistic act is adaptive if its indirect fitness benefits are high for the animals that are helped, if the recipients are close relatives of the altruist, and if the direct fitness cost to the altruist is low.
- **Kin selection** is a type of natural selection that increases inclusive fitness through successful reproduction of close relatives. Some types of cooperative behavior may increase the direct fitness of the helper.
- In a type of cooperative behavior known as **reciprocal altruism**, the helper does not immediately benefit but is helped later by the animal it helped.

52.8 Culture in Vertebrate Societies *(page 1146)*

12 Contrast a vertebrate society with a society of social insects, give examples of transmission of culture, and briefly describe sociobiology.

- Compared with insect societies, vertebrate societies are more flexible and the role of the individual less narrowly defined. Some bird and mammal species develop **culture**, learned behavior common to a population that is transmitted from one generation to the next. Symbolic transmission of culture is important in human societies.
- **Sociobiology** focuses on the evolution of social behavior through natural selection.

Test Your Understanding

Know and Comprehend

1. The responses of an organism to signals from its environment are its (a) behavior (b) culture (c) ultimate behavior (d) releasers (e) motor programs
2. A behavioral pattern is elicited by (a) a motor program (b) a sign stimulus (c) an imprint (d) a, b, and c (e) b and c
3. A form of learning in which an animal forms a strong attachment to a moving object (usually its parent) within a few hours of birth is (a) classical conditioning (b) operant conditioning (c) imprinting (d) insight learning (e) parental investment

4. Both compass sense and map sense are necessary for (a) navigation (b) migration (c) directional orientation (d) both navigation and migration (e) the action of biological clocks
5. In optimal foraging (a) animals always hunt in social groups (b) an animal obtains food in the most efficient way (c) animals can rarely afford to be selective (d) groups of five to seven animals are most successful (e) animals are typically most successful when they hunt alone
6. Chemical signals that convey information among members of a species are (a) pheromones (b) hormones (c) neurotransmitters (d) leks (e) neuropeptides
7. The benefits of territoriality include (a) right to defend a home range (b) higher potential for monogamy (c) energy investment in staking out and defending the area (d) increased reproductive success (e) pair bonding
8. Sexual selection (a) occurs mainly among animals that practice polyandry (b) occurs when animals are very similar in their ability to compete for mates (c) results in animals that have lower direct fitness (d) occurs mainly among animals that practice polygyny (e) is a form of natural selection
9. In most species mate choice is least likely influenced by (a) ornamental displays such as antlers (b) fidelity of the male (c) gifts (d) courtship behavior (e) dominance
10. Behavior that appears to have no payoff—that is, an individual appears to act to benefit others rather than itself—is known as (a) mutualism (b) helping behavior (c) reciprocal altruism (d) inclusive fitness (e) altruism
11. Kin selection (a) increases inclusive fitness through the breeding success of close relatives (b) is a way of perpetuating genes of nonrelatives (c) accounts for some forms of migration (d) typically involves mate guarding (e) involves ornamental displays and use of a lek
12. Culture (a) is common among invertebrate groups (b) does not vary within the same species (c) is behavior learned from other members of the group and shared by members of a population (d) has a strong genetic component in primates (e) is a shared derived character of humans

Apply and Analyze

13. Behavioral ecologists have demonstrated that young tiger salamanders can become cannibals and devour other salamanders. Investigators observed that the cannibal salamanders preferred eating unrelated salamanders over their own cousins and preferred eating cousins over their siblings. Explain this behavior based on what you have learned in this chapter.

Evaluate and Synthesize

14. **INTERPRET DATA** Look at the two graphs in Figure 52-21. In which experiment did the parentals in the experimental group guard the eggs more closely? In which experiment did the experimental parentals guard the young more closely? Account for these differences.
15. **INTERPRET DATA** Look at the diagram (Fig. 52-11) and identify the groups most likely to be hungry at the end of the day's hunt during times of prey scarcity. Develop a hypothesis to explain why these groups hunt as they do.
16. How is the society of a social insect different from human society? What are some similarities between the transmission of information by heredity and by culture? What are some differences?
17. **EVOLUTION LINK** What might be the adaptive value of sea turtle migration?
18. **SCIENCE, TECHNOLOGY, AND SOCIETY** Consider how the adaptive value of sea turtle migration has changed if, as a result of human activities, migration now puts sea turtles at greater risk than if they restricted their habitat to a single location. Discuss the possible evolutionary mechanisms by which the behavior of these species may (or may not) adapt to these environmental pressures. What conservation efforts should we take to increase the probability of successful migration?

53 Introduction to Ecology: Population Ecology

The science of **ecology** is the study of how living organisms and the physical environment interact in an immense and complicated web of relationships. Biologists call the interactions among organisms **biotic factors** and those between organisms and their nonliving, physical environment **abiotic factors**. Abiotic factors include precipitation, temperature, pH, wind, and chemical nutrients. Ecologists formulate hypotheses to explain such phenomena as the distribution and abundance of life, the ecological roles of specific species, the interactions among species in communities, and the importance of ecosystems in maintaining the health of the biosphere. They then test these hypotheses.

The focus of ecology can be local or global, specific or generalized, depending on what questions the scientist is asking and trying to answer. Ecology is the broadest field in biology, with explicit links to evolution and every other biological discipline. It includes studies on transfer of information among organisms and analyses of the transfer of energy for life. Its universality encompasses subjects that are not traditionally part of biology. Earth science, geology, chemistry, oceanography, climatology, and meteorology are extremely important to ecology, especially when ecologists examine the abiotic environment of planet Earth. Because humans are part of Earth's web of life, all our activities, including economics and politics, have profound ecological implications. *Environmental science*, a scientific discipline with ties to ecology, focuses on how humans interact with the environment.

As you learned in Chapter 1, most ecologists are interested in the levels of biological organization including and above the level of the individual organism: population, community, ecosystem, landscape, and biosphere. Each level has its own characteristic composition, structure, and functioning.

An individual belongs to a **population**, a group consisting of members of the same species that live together in a prescribed area

KEY CONCEPTS

53.1 A population can be described in terms of its density, dispersion, birth and death rates, growth rate, survivorship, and age structure.

53.2 Changes in population size are caused by natality, mortality, immigration, and emigration.

53.3 Population size may be influenced by density-dependent factors and density-independent factors.

53.4 Life history traits of a population are adaptations that affect the ability of individuals to survive and reproduce.

53.5 A metapopulation consists of two or more local populations with dispersal occurring among them.

53.6 Human population structure differs among countries in ways that are primarily related to differences in level of development.

at the same time. The boundaries of the area are defined by the ecologist performing a particular study. A population ecologist might study a population of microorganisms, animals, or plants, like the poet's daffodils in the photograph, to see how individuals within it live and interact with one another, with other species in their community, and with their physical environment.

In this chapter we begin our study of ecological principles by focusing on the study of populations as functioning systems and end with a discussion of the human population. Subsequent chapters examine the interactions among different populations within communities (Chapter 54), the dynamic exchanges between communities and their physical environments (Chapter 55), the characteristics of Earth's major biological ecosystems (Chapter 56), and biological diversity and conservation biology (Chapter 57).

53.1 Features of Populations

LEARNING OBJECTIVE

1 Define *population density* and *dispersion*, and describe the main types of population dispersion.

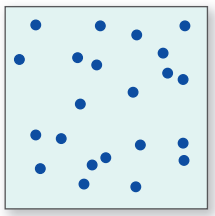
Populations exhibit characteristics distinctive from those of the individuals of which they are composed. Some features discussed in this chapter that characterize populations are population density, population dispersion, birth and death rates, growth rates, survivorship, and age structure.

Although communities consist of all the populations of all the different species that live together within an area, populations have properties that communities lack. Populations, for example, share a common gene pool (see Chapter 19). Consequently, natural selection can cause changes in allele frequencies in populations. As a result, allele frequency changes resulting from natural selection occur in populations. Natural selection therefore acts directly to produce adaptive changes in populations and only indirectly affects the community level.

Population ecology considers both the number of individuals of a particular species that are found in an area and the dynamics of the population. **Population dynamics** is the study of changes in populations: how and why those numbers increase or decrease over time. Population ecologists try to determine the processes common to all populations. They study how a population interacts with its environment, such as how individuals in a population compete for food or other resources and how predation, disease, and other environmental pressures affect the population. Population growth, whether of bacteria, maples, or giraffes, cannot increase indefinitely because of such environmental pressures.

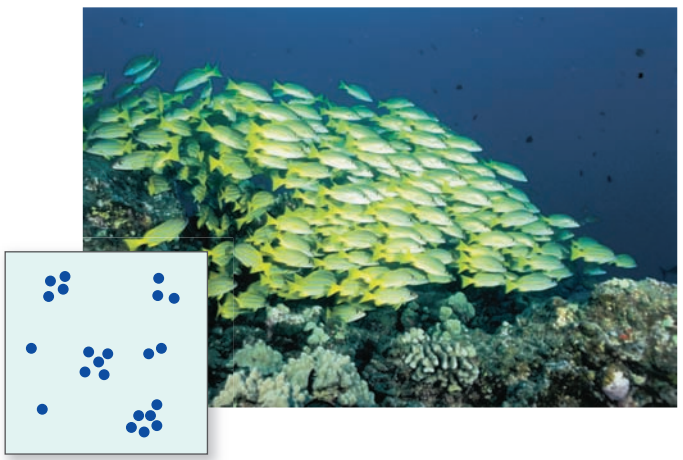
Additional aspects of populations that interest biologists are their reproductive success or failure (extinction), their evolution, their genetics, and the way they affect the normal functioning of communities and ecosystems. Biologists in applied disciplines, such as forestry, agronomy (crop science), and wildlife management, must understand population ecology to manage populations of economic importance, such as forests, field crops, game animals, or fishes. Understanding the population dynamics of endangered and threatened species plays a key role in efforts to prevent their slide to extinction. Knowledge of population ecology helps in efforts to prevent the increase of pest populations to levels that cause significant economic or health effects.

Density and dispersion are important features of populations



The concept of population size is meaningful only when the boundaries of that population are defined. Consider, for example, the difference between 1000 mice in 100 hectares (250 acres) and 1000 mice in 1 hectare (2.5 acres). Often a population is too large to study in its entirety. Researchers examine such a population by sampling a part of it and then expressing the population in terms of density. Examples include the number of dandelions per square meter of lawn, the number of water fleas per liter of pond water, and the number of cabbage aphids per square centimeter of cabbage leaf. **Population density**, then, is the number of individuals of a species per unit of area or volume at a given time.

Different environments vary in the population density of any species they can support. This density may also vary in a single habitat from season to season or year to year. For example, red grouse are ground-dwelling game birds whose populations are managed for hunting. Consider two red grouse populations in the treeless moors of northwestern Scotland, at locations only 2.5 km (1.5 mi) apart. At one location the population density remained stationary during a three-year period, but at the other site it almost doubled in the first two years and then declined to its initial density in the third year. The reason was likely a difference in habitat. Researchers had experimentally burned the area where the population density increased initially and then decreased. Young heather shoots (*Calluna vulgaris*) produced after the burn provided nutritious food for the red grouse. So, population density may be determined in large part by biotic or abiotic factors in the environment that are external to the individuals in the population.



The individuals in a population often exhibit characteristic patterns of **dispersion**, or spacing, relative to one another. Individuals may be spaced in a random, clumped, or uniform dispersion. **Random dispersion** occurs when individuals in a population are spaced throughout an area in a manner that is unrelated to the presence of others (FIG. 53-1a). Of the three major types of dispersion, random dispersion is least common and hardest to observe in nature, leading some ecologists to question its existence. Trees of the same species, for example, sometimes appear to be distributed randomly in a tropical rain forest. However, an international team of 13 ecologists studied six tropical forest plots that were 25 to 52 hectares (62 to 130 acres) in area and reported that most of the 1000 tree species observed were clumped and not randomly dispersed. (Ecologists determine both clumped and uniform dispersion by statistically testing for differences from an assumed random distribution.) Random dispersion may occur infrequently because important environmental factors affecting dispersion usually do not occur at random. Flour beetle larvae in a container of flour are randomly dispersed, but their environment (flour) is unusually homogeneous.

(a) Random dispersion, illustrated for comparison, rarely, if ever, occurs in nature.

Andrew G. Wood/Science Source

(b) Clumped dispersion is evident in the schooling behavior of certain fish species. Shown are bluestripe snappers (*Lutjanus kasmira*), photographed in Hawaii. This introduced fish, which grows to 30 cm (12 in.), may be displacing native fish species in Hawaiian waters.

Robert Hernandez/Science Source

(c) Uniform dispersion is characteristic of these nesting Cape gannets (*Morus capensis*) on the coast of South Africa. The birds space their nests more or less evenly.

Figure 53-1 Dispersion of individuals within a population

Perhaps the most common spacing is **clumped dispersion**, also called **aggregated distribution** or **patchiness**, which occurs when individuals are concentrated in specific parts of the habitat. Clumped dispersion often results from the patchy distribution of resources in the environment. It also occurs among animals because of the presence of family groups and pairs, and among plants because of limited seed dispersal or asexual reproduction. An entire grove of aspen trees, for example, may originate asexually from a single plant. Clumped dispersion may sometimes be advantageous because social animals derive many benefits from their association. Many fish species, for example, associate in dense schools for at least part of their life cycle, possibly because schooling may reduce the risk of predation for any particular individual (FIG. 53-1b). The many pairs of eyes of schooling fish tend to detect predators more effectively than a single pair of eyes of a single fish. When threatened, schooling fish clump together more closely, making it difficult for a predator to single out an individual.

Uniform dispersion occurs when individuals are more evenly spaced than would be expected from a random occupation of a given habitat. A nesting colony of seabirds, in which the birds are nesting in a relatively homogeneous environment and place their nests at a more or less equal distance from one another, is an example of uniform dispersion (FIG. 53-1c). What might this spacing pattern tell us? In this case, uniform dispersion may occur as a result of nesting territoriality. Aggressive interactions among the nesting birds as they peck at one another from their nests cause each pair to place its nest just beyond the reach of nearby nesting birds. Uniform dispersion also occurs when competition among individuals is severe, when plant roots or leaves that have been shed produce toxic substances that inhibit the growth of nearby plants, or when animals establish feeding or mating territories.

Some populations have different spacing patterns at different ages. Competition for sunlight among same-aged sand pine in a Florida scrub community resulted in a change over time from either random or clumped dispersion when the plants were young to uniform dispersion when the plants were old. Sand pine is a fire-adapted plant with cones that do not release their seeds until they have been exposed to high temperatures (45°C to 50°C or higher). As a result of seed dispersal and soil conditions following a fire, the seedlings grow back in dense stands that exhibit random or slightly clumped dispersion. Over time, however, many of the more crowded trees tend to die from shading or competition, resulting in uniform dispersion of the surviving trees (TABLE 53-1).

CHECKPOINT 53.1

- What is the difference between population density and dispersion?
- **CONNECT** What are some biological advantages of a clumped dispersion? What are some disadvantages?

Table 53-1 Dispersion in a Sand Pine Population in Florida

Tree Trunks Examined	Density (per m^2)	Dispersion
All (alive and dead)	0.16	Random
Alive only	0.08	Uniform

53.2 Changes in Population Size

LEARNING OBJECTIVES

2 Explain the four factors (natality, mortality, immigration, and emigration) that produce changes in population size and solve simple problems involving these changes.

3 Define *intrinsic rate of increase* and *carrying capacity*, and explain the differences between J-shaped and S-shaped growth curves.

One goal of science is to discover common patterns among separate observations. As mentioned previously, population ecologists wish to understand general processes that are shared by many different populations, so they develop mathematical models based on equations that describe the dynamics of a single population. Population models are not perfect representations of a population, but models help illuminate complex processes. Moreover, mathematical modeling enhances the scientific process by providing a framework with which experimental population studies can be compared. We can test a model and see how it fits or does not fit with existing data. Data that are inconsistent with the model are particularly useful because they demand that we ask how the natural system differs from the mathematical model that we developed to explain it. As more knowledge accumulates from observations and experiments, the model is refined and made more precise.

Population size, whether of sunflowers, elephants, or humans, changes over time. On a global scale, this change is ultimately caused by two factors, expressed on a per capita (i.e., per individual) basis: **natality**, the average per capita birth rate; and **mortality**, the average per capita death rate. In humans the birth rate is usually expressed as the number of births per 1000 people per year and the death rate as the number of deaths per 1000 people per year.

To determine the rate of change in population size, we must also take into account the time interval involved, that is, the change in time. To express change in equations, we employ the Greek letter delta (Δ). In equation (1), ΔN is the change in the number of individuals in the population, Δt the change in time, N the number of individuals in the existing population, b the natality, and d the mortality.

$$(1)\ \Delta N/\Delta t = N(b - d)$$

The **growth rate (*r*)**, or rate of change (increase or decrease) of a population on a per capita basis, is the birth rate minus the death rate:

$$(2)\ r = b - d$$

As an example, consider a hypothetical human population of 10,000 in which there are 200 births per year (i.e., by convention, 20 births per 1000 people) and 100 deaths per year (10 deaths per 1000 people):

$$r = 20/1000 - 10/1000 = 0.02 - 0.01 = 0.01, \text{ or } 1\% \text{ per year}$$

A modification of equation (1) tells us the rate at which the population is growing at a particular instant in time, that is, its instantaneous growth rate (dN/dt). (The symbols dN and dt are the mathematical differentials of N and t, respectively; they are not products, nor should the d in dN or dt be confused with the death rate, d.) Using differential calculus, this growth rate can be expressed as follows:

$$(3)\ dN/dt = rN$$

where N is the number of individuals in the existing population, t the time, and r the per capita growth rate.

Because $r = b - d$, if individuals in the population are born faster than they die, r is a positive value and population size increases. If individuals in the population die faster than they are born, r is a negative value and population size decreases. If r is equal to zero, births and deaths match, and population size is stationary despite continued reproduction and death.

Dispersal affects the growth rate in some populations

In addition to birth and death rates, **dispersal**, which is movement of individuals among populations, must be considered when examining changes in populations on a *local* scale. There are two types of dispersal: immigration and emigration. **Immigration** occurs when individuals enter a population and thus increase its size. **Emigration** occurs when individuals leave a population and thus decrease its size. The growth rate of a local population must take into account birth rate (b), death rate (d), immigration rate (i), and emigration rate (e) on a per capita basis. The per capita growth rate equals the birth rate minus the death rate, plus the immigration rate minus the emigration rate:

$$(4)\ r = (b - d) + (i - e)$$

For example, the growth rate of a human population of 10,000 that has 200 births (by convention, 20 per 1000), 100 deaths (10 per 1000), 10 immigrants (1 per 1000), and 100 emigrants (10 per 1000) in a given year would be calculated as follows:

$$r = (20/1000 - 10/1000) + (1/1000 - 10/1000)$$
$$= 0.001, \text{ or } 0.1\% \text{ per year}$$

Each population has a characteristic intrinsic rate of increase

The maximum rate at which a population of a given species could increase under ideal conditions, when resources are abundant and its population density is low, is known as its **intrinsic rate of increase (r_{max})**. Different species have different intrinsic rates of increase. A particular species' intrinsic rate of increase is influenced by several factors. They include the age at which reproduction begins, the fraction of the **lifespan** (duration of the individual's life) during which the individual

is capable of reproducing, the number of reproductive periods per lifetime, and the number of offspring the individual is capable of producing during each period of reproduction. These factors, which we discuss in greater detail later in the chapter, determine whether a particular species has a large or small intrinsic rate of increase.

Generally, large species such as blue whales and elephants have the smallest intrinsic rates of increase, whereas microorganisms have the greatest intrinsic rates of increase. Under ideal conditions (an environment with unlimited resources), certain bacteria can reproduce by binary fission every 20 minutes. At this rate of growth, a single bacterium would increase to a population of more than one billion in just ten hours!

If we plot the population size versus time under optimal conditions, the graph has a J shape that is characteristic of **exponential population growth**, which is the accelerating population growth rate that occurs when optimal conditions allow a constant per capita growth rate (FIG. 53-2). When a population grows exponentially, it grows faster as it gets larger.

Regardless of which species we are considering, whenever a population is growing at its intrinsic rate of increase, population size plotted versus time gives a curve of the same shape. The only variable is time. It may take longer for an elephant population than for a bacterial population to reach a certain size (because elephants do not reproduce as rapidly as bacteria), but both populations will always increase exponentially as long as their per capita growth rates remain constant.

No population can increase exponentially indefinitely

Certain populations may grow exponentially for brief periods. Exponential growth has been experimentally demonstrated in certain insects and in cultures of bacteria or protists (by continually supplying nutrients and removing waste products). However, organisms cannot reproduce indefinitely at their intrinsic rate of increase because the environment sets limits.

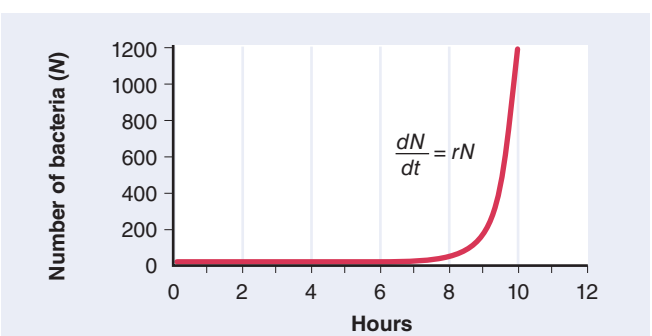

Figure 53-2 Exponential population growth

When bacteria divide every 20 minutes, their numbers (expressed in millions) increase exponentially. The curve of exponential population growth has a characteristic J shape. The ideal conditions under which bacteria or other organisms reproduce exponentially rarely occur in nature, and when they do, they are of short duration.

These limits include such unfavorable environmental conditions as the limited availability of food, water, shelter, and other essential resources (resulting in increased competition) as well as limits imposed by disease and predation.

In the earlier example, bacteria in nature would never be able to reproduce unchecked for an indefinite period because they would run out of food and living space, and poisonous wastes would accumulate in their vicinity. With crowding, bacteria would also become more susceptible to parasites (high population densities facilitate the spread of infectious organisms such as viruses among individuals) and predators (high population densities increase the likelihood of a predator catching an individual). As the environment deteriorated, their birth rate (b) would decline and their death rate (d) would increase. Conditions might worsen to a point where d would exceed b, and the population would decrease. The number of individuals in a population, then, is controlled by the ability of the environment to support it. As the number of individuals in a population (N) increases, environmental limits act to control population growth.

Over longer periods, the rate of population growth may decrease to nearly zero. This leveling out occurs at or near the limits of the environment to support the population. The **carrying capacity (K)** represents the largest population that can be maintained for an indefinite period by a particular environment, assuming that there are no changes in that environment. In nature the carrying capacity is dynamic and changes in response to environmental changes. An extended drought, for example, could decrease the amount of vegetation growing in an area; this change, in turn, would lower the carrying capacity for deer and other herbivores in that environment.

When a population regulated by environmental limits is plotted over longer periods, the curve has a characteristic S shape (FIG. 53-3). The curve shows the population's initial exponential increase (note the curve's J shape at the start, when environmental limits are few), followed by a leveling out as the carrying capacity of the environment is approached. The S-shaped growth curve, also called **logistic population growth**, can be modeled by a modified growth equation called a *logistic equation*. The logistic model of population growth was developed to explain population growth in continually breeding populations. Similar models exist for populations that have specific breeding seasons.

The logistic model describes a population increasing from a small number of individuals to a larger number of individuals that are ultimately limited by the environment. The logistic equation takes into account the carrying capacity of the environment:

$$(5)\ dN/dt = rN[(K - N)/K]$$

Note that part of the equation is the same as equation (3). The added element, $[(K - N)/K]$, reflects a decline in growth as a population size approaches its carrying capacity. When the number of organisms (N) is small, the rate of population growth is unchecked by the environment because the expression $[(K - N)/K]$ has a value of almost 1. As the population

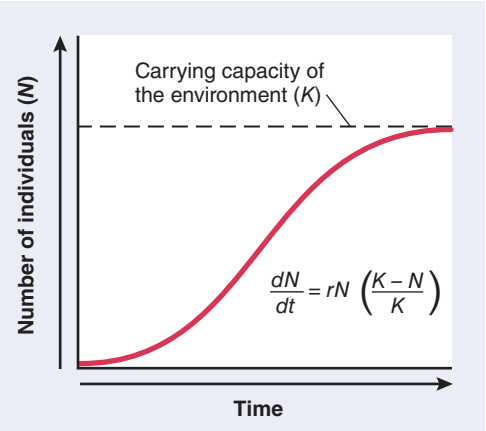

Figure 53-3 Carrying capacity and logistic population growth

In many laboratory studies, exponential population growth slows as the carrying capacity (K) of the environment is approached. The logistic model of population growth, when plotted, has a characteristic S-shaped curve.

(N) begins to approach the carrying capacity (K), however, the growth rate declines because the value of $[(K - N)/K]$ approaches zero.

Although the S curve is an oversimplification of how most populations change over time, it does appear to fit some populations that have been studied in the laboratory as well as a few that have been studied in nature. For example, Georgyi F. Gause, a Russian ecologist who conducted experiments during the 1930s, grew a population of a single species, *Paramecium caudatum*, in a test tube. He supplied a limited amount of food (bacteria) daily and replenished the growth medium occasionally to eliminate the accumulation of metabolic wastes. Under these conditions, the population of *P. caudatum* increased exponentially at first; then its growth rate declined to zero, and the population size leveled off (see Fig. 54-5, middle graph).

A population rarely stabilizes at K (carrying capacity), but it may temporarily rise higher than K. It will then drop back to, or below, the carrying capacity. Sometimes a population that overshoots K will experience a *population crash*, an abrupt decline from high to low population density. Such an abrupt change is commonly observed in bacterial cultures, zooplankton, and other populations whose resources have been exhausted.

The carrying capacity for reindeer, which live in cold northern habitats, is determined largely by the availability of winter forage. In 1910, humans introduced a small herd of 26 reindeer onto one of the Pribilof Islands of Alaska. The herd's population increased exponentially for about 25 years until there were approximately 2000 reindeer, many more than the island could support, particularly in winter. The reindeer overgrazed the vegetation until the plant life was almost wiped out. Then, in slightly longer than a decade, as reindeer died from starvation, the number of reindeer plunged to 8, one-third the size of the original introduced population. Recovery of subarctic and arctic vegetation after overgrazing by reindeer can take 15 to 20 years, during which time the carrying capacity for reindeer is greatly reduced.

CHECKPOINT 53.2

- What effect does each of the following have on population size: natality, mortality, immigration, and emigration?
- **CONNECT** How does a J-shaped population growth curve differ from an S-shaped curve in terms of intrinsic rate of increase and carrying capacity?
- **VISUALIZE** Sketch simple graphs representing the long-term growth of two populations of bacteria cultured in test tubes, one in which the nutrient medium is replenished and the other in which it is not replenished.

53.3 Factors Influencing Population Size

LEARNING OBJECTIVE

4 Contrast the influences of density-dependent and density-independent factors on population size and give examples of each.

Certain natural mechanisms influence population size. Factors that affect population size fall into two categories: density-dependent factors and density-independent factors. These two sets of factors vary in importance from one species to another and, in most cases, probably interact simultaneously to determine the size of a population.

Density-dependent factors regulate population size

Sometimes the influence of an environmental factor on the individuals in a population varies with the density or crowding of that population. If a change in population density alters how an environmental factor affects that population, the environmental factor is said to be a **density-dependent factor**.

As population density increases, density-dependent factors tend to slow population growth by causing an increase in death rate and/or a decrease in birth rate. The effect of these density-dependent factors on population growth increases as the population density increases; that is, density-dependent factors affect a larger proportion, not just a larger number, of the population. Density-dependent factors can also affect population growth when population density declines by decreasing the death rate and/or increasing the birth rate. Thus, density-dependent factors tend to regulate a population at a relatively constant size that is near the carrying capacity of the environment. (Keep in mind, however, that the carrying capacity of the environment frequently changes.) Density-dependent factors are an excellent example of a **negative feedback system** (FIG. 53-4).

Predation, disease, and competition are examples of density-dependent factors. As the density of a population increases, predators are more likely to find an individual of a given prey species than before. When population density

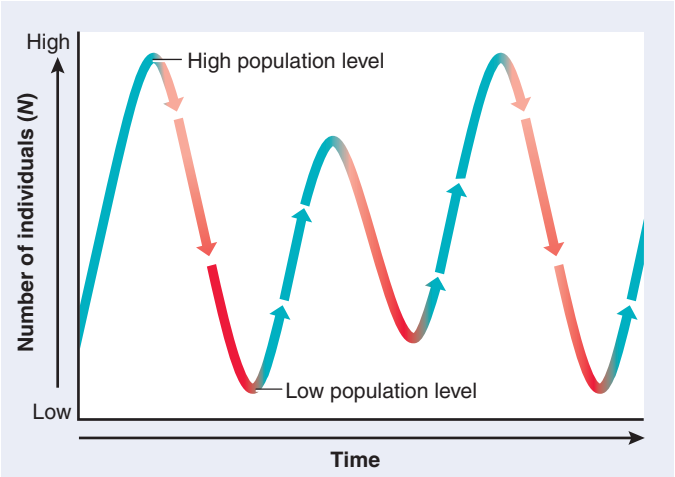

Figure 53-4 Density-dependent factors and negative feedback

When the number of individuals in a population increases, density-dependent factors cause a decline in the population. When the number of individuals in a population decreases, a relaxation of density-dependent factors allows the population to increase.

is high, the members of a population encounter one another more frequently than previously, and the chance of their transmitting parasites and infectious disease organisms increases. As population density increases, so does competition for resources such as living space, food, cover, water, minerals, and sunlight; eventually, the point may be reached at which many members of a population fail to obtain the minimum amount of whatever resource is in shortest supply. At higher population densities, density-dependent factors raise the death rate and/or lower the birth rate, inhibiting further population growth. The opposite effect occurs when the density of a population decreases. Predators are less likely to encounter individual prey, parasites and infectious diseases are less likely to be transmitted from one host to another, and competition among members of the population for resources such as living space and food declines.

Density-dependent factors may explain what makes certain populations fluctuate cyclically over time

Lemmings are small, stumpy-tailed rodents that are found in colder regions of the Northern Hemisphere (FIG. 53-5). They are herbivores that feed on sedges and grasses in the Arctic tundra. It has long been known that lemming populations have a three- to four-year cyclical oscillation that is often described as "boom or bust." That is, the population increases dramatically and then crashes; the population peaks may be 100 times as high as the low points in the population cycle. Many other populations, such as snowshoe hares and red grouse, also exhibit cyclic fluctuations.

What is the driving force behind these fluctuations? Several hypotheses have been proposed to explain the cyclical periodicity of lemming and other boom-or-bust populations, and many involve density-dependent factors. One possibility is that as a prey population becomes more dense, it overwhelms its food supply; as a result, the population declines. In the lemming example, researchers have studied the shape of several lemming population curves during their oscillations; the data suggest that lemming populations crash because they overgraze the plants, not because predators eat them.

Another explanation is that the population density of predators, such as long-tailed jaegers (birds related to gulls that eat lemmings), increases in response to the increasing density of prey. Few jaegers breed when the lemming population is low. However, when the lemming population is high, most jaegers breed, and the number of eggs per clutch is greater than usual. As more predators consume the abundant prey, the prey population declines. Later, with fewer prey in an area, the population of predators declines (some disperse out of the area, and fewer offspring are produced).

In a long-term study of collared lemmings in Greenland, researchers at the University of Helsinki, Finland, observed four-year cycles of lemming population density that were not affected by availability of food or living space. They developed a model in which the fluctuations in the lemming population are most accurately predicted by those of another species, the stoat. The population of the stoat, a member of the weasel family that preys almost exclusively on lemmings, peaks a year after a peak in the lemming population. On the other hand, populations of three other lemming predators—snowy owls, arctic foxes, and long-tailed skuas (birds related to gulls)—respond more immediately to changes in the lemming population and thus tend to stabilize the population cycle established by the stoats.

Tom McHugh/Science Source

Figure 53-5 Lemming

The brown lemming (*Lemmus trimucronatus*) lives in the Arctic tundra. Although lemming populations have been studied for decades, much about the cyclic nature of lemming population oscillations and their effects on the rest of the tundra ecosystem is still not well understood. This species ranges from Alaska eastward to the Hudson Bay.

Climate change may also be affecting lemming population dynamics. Researchers from the University of Oslo, Norway, and a group of international collaborators have observed a correlation between climate and lemming cycles. They found that lemming populations increase in the years in which they can survive by eating moss in the space between the ground and the snow pack. Populations are reduced in warmer years, when slight melting and refreezing of the snow eliminates this space.

Parasites may also interact with their hosts to cause regular cyclic fluctuations. Detailed studies of red grouse have shown that even managed populations in wildlife preserves may have significant cyclic oscillations. Reproduction in red grouse is related to the density of parasitic nematodes (roundworms) living in adult intestines. Fewer birds breed successfully when adults are infected with worms; thus, a high density of worms leads to a population crash. Hypothesizing that red grouse populations fluctuate in response to the parasites, ecologists at the University of Stirling in Scotland successfully reduced or eliminated population fluctuations in several red grouse populations. They did so by catching and orally treating the birds with a chemical that causes worms to be ejected from their bodies.

Competition is an important density-dependent factor **Competition** is an interaction among two or more individuals that attempt to use the same essential resource, such as food, water, sunlight, or living space, that is in limited supply. The use of the resource by one of the individuals reduces the availability of that resource for other individuals. Competition occurs both within a given population (**intraspecific competition**) and among populations of different species (**interspecific competition**). We consider the effects of intraspecific competition here; interspecific competition is discussed in Chapter 54.

Individuals of the same species compete for a resource in limited supply by interference competition or by exploitation competition. In **interference competition**, also called **contest competition**, certain dominant individuals obtain an adequate supply of the limited resource at the expense of other individuals in the population; that is, the dominant individuals actively interfere with other individuals' access to resources. In **exploitation competition**, also called **scramble competition**, all the individuals in a population "share" the limited resource more or less equally so that at high population densities none of them obtains an adequate amount. The populations of species in which exploitation competition operates often oscillate over time, and there is always a risk that the population size will drop to zero. In contrast, those species in which interference competition operates experience a relatively small drop in population size, caused by the death of individuals that are unable to compete successfully.

Intraspecific competition among red grouse involves interference competition. When red grouse populations are small, the birds are less aggressive, and most young birds establish a feeding territory (an area defended against other members of the same species). However, when the population is large, establishing a territory is difficult because there are more birds than there are territories and the birds are therefore much more aggressive. Those birds without territories often die from predation or starvation. Thus, birds with territories use a larger share of the limited resource (the territory with its associated food and cover), whereas birds without territories cannot compete successfully.

The moose population on Isle Royale, Michigan, the largest island in Lake Superior, provides a vivid example of exploitation competition that is similar to that of the reindeer population on the Pribilof Islands (discussed earlier). Isle Royale differs from most islands in that large mammals can walk to it when the lake freezes over in winter. The minimum distance to be walked is 24 km (15 mi), however, so this movement has happened infrequently. Around 1900, a small herd of moose wandered across the ice of frozen Lake Superior and reached the island for the first time. By 1934, the moose population on the island had increased to about 3000 and had consumed almost all the edible vegetation. In the absence of this food resource, there was massive starvation in 1934. More than 60 years later, in 1996, a similar die-off claimed more than 60% of the moose after they had again increased to a high density. Thus, exploitation competition for scarce resources can result in dramatic population oscillations.

The effects of density-dependent factors are difficult to assess in nature Most studies of density dependence have been conducted in laboratory settings where all density-dependent (and density-independent) factors except one are controlled experimentally. Populations in natural settings, however, are exposed to a complex set of variables that continually change. As a result, in natural communities it is difficult to evaluate the relative effects of different density-dependent factors.

Ecologists from the University of California, Davis, noted that few spiders occur on tropical islands inhabited by lizards, whereas more spiders and more species of spiders are found on lizard-free islands. Deciding to study these observations experimentally, David Spiller and Thomas Schoener staked out plots of vegetation (mainly seagrape shrubs) and enclosed some of them with lizard-proof screens (FIG. 53-6). Some of the plots were emptied of all lizards; each control enclosure had approximately nine lizards. Nine web-building spider species were observed in the enclosures. Spiders were counted approximately 30 times from 1989 to 1994. During the 4.5 years of observations reported here, spider population densities were higher in the lizard-free enclosures than in enclosures with lizards. Moreover, the enclosures without lizards had more species of spiders. Therefore, we might conclude that lizards control spider populations.

Even this relatively simple experiment, though, may be explained by a combination of two density-dependent factors: predation (lizards eat spiders) and interspecific competition (lizards compete with spiders for insect prey; i.e., both spiders and lizards eat insects). In this experiment the effects of the two density-dependent factors in determining spider population size cannot be evaluated separately. Additional lines of evidence support the actions of both competition and predation at these sites.

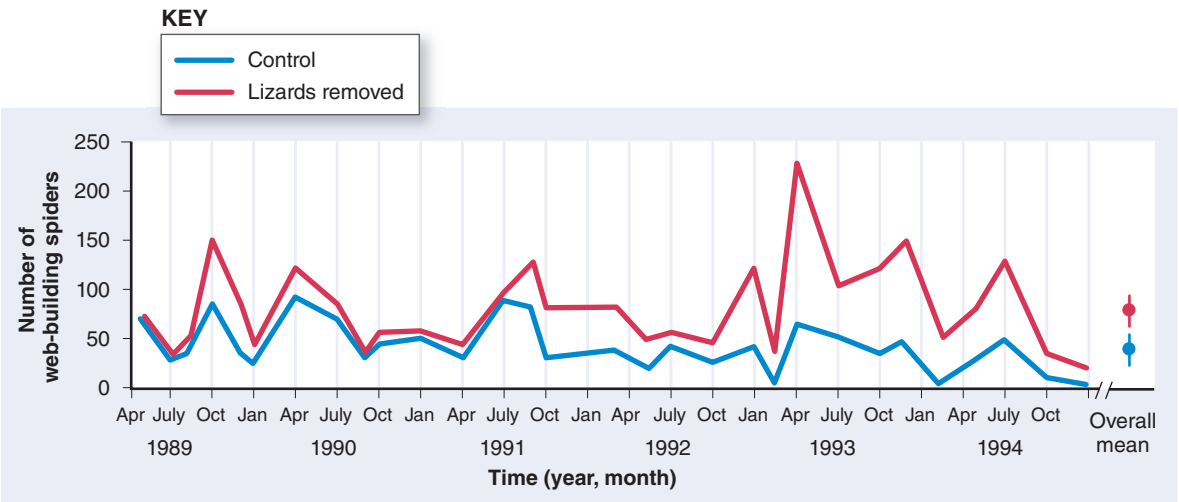
Key Experiment



What is the influence of density-dependent factors on population size in a natural habitat?

NNehring/istockphoto.com

HYPOTHESIS: Lizards reduce the size of spider populations.

EXPERIMENT: Researchers conducted a field experiment in which they constructed enclosed plots; spiders and insects could pass freely into and out of the enclosures, but the lizards could not. There were several lizard species in the study, but over 90% of the individuals were brown anoles, *Anolis sagrei* (see photograph). Some plots included lizards; the other plots were lizard-free. The spiders were periodically counted over a period of 4.5 years. An earlier experiment indicated that the enclosures themselves have no effect on the number of web-building spiders.

RESULTS AND CONCLUSION: The graph of the mean number of web-building spiders at each count per enclosure with lizards (*control*, *blue*) and per enclosure with lizards removed (*red*) demonstrates that the number of web-building spiders was consistently higher in the absence of lizards. Lizards may control spider populations by preying on them, by competing with them for insect prey, or by a combination of these factors.

SOURCE: Graph from Spiller, D.A., and T.W. Schoener, "Lizards Reduce Spider Species Richness by Excluding Rare Species," *Ecology*, Vol. 79, No. 2 (1998). Copyright © 1998 Ecological Society of America. Reprinted with permission.

Figure 53-6 Interaction of density-dependent factors

PREDICT Note that the spider populations fluctuated during the experiment, although the lizard-free populations were consistently larger. Formulate a hypothesis relating to whether such fluctuations are due to biotic factors, abiotic factors, or a combination, and devise a way to test it.

Density-independent factors are generally abiotic

Any environmental factor that affects the size of a population but is not influenced by changes in population density is called a **density-independent factor**. Such factors are typically abiotic. Random weather events that reduce population size serve as density-independent factors. They often affect population density in unpredictable ways. A killing frost, severe blizzard, or hurricane, for example, may cause extreme and irregular reductions in a vulnerable population, regardless of its size, and thus may be considered largely density-independent.

Consider a density-independent factor that influences mosquito populations in arctic environments. These insects produce several generations per summer and achieve high population densities by the end of the season. A shortage of food does not seem to be a limiting factor for mosquitoes, nor is there any shortage of ponds in which to breed. What puts a stop to the skyrocketing mosquito population is winter. Not a single adult mosquito survives winter, and the entire population must grow afresh the next summer from the few eggs and hibernating larvae that survive. Thus, severe winter weather is a density-independent factor that affects arctic mosquito populations.

Density-independent and density-dependent factors are often inter-related. Social animals, for example, often resist dangerous weather conditions by collective behavior, as in the case of sheep huddling together in a snowstorm. In this case it appears that the greater the population density of the sheep, the better their ability to resist the environmental stress of a density-independent event (such as a snowstorm).

CHECKPOINT 53.3

- What are three examples of density-dependent factors that affect population growth?
- What are three density-independent factors?

53.4 Life History Traits

LEARNING OBJECTIVES

5 Contrast semelparous and iteroparous reproduction.
6 Distinguish among species exhibiting an *r* strategy, those with a *K* strategy, and those that do not easily fit either category.
7 Describe Type I, Type II, and Type III survivorship curves and explain how life tables and survivorship curves indicate mortality and survival.

Each species is uniquely suited to its lifestyle. Many years pass before a young magnolia tree flowers and produces seeds, whereas an annual plant grows from seed, flowers, and dies within a single season. A mating pair of black-browed albatrosses produces a single chick every year, but a mating pair of gray-headed albatrosses produces a single chick biennially (every other year).

Species that expend their energy in a single, immense reproductive effort are said to be **semelparous**. Most insects and invertebrates, many plants, and some species of fish exhibit semelparity. Pacific salmon, for example, hatch in fresh water and swim to the ocean, where they live until they mature. Adult salmon swim from the ocean back into the same rivers or streams in which they hatched to spawn (reproduce). After they spawn, the salmon die.

Agaves are semelparous plants that are common in arid tropical and semitropical areas. The thick, fleshy leaves of the agave plant are crowded into a rosette at the base of the stem. Commonly called the century plant because it was mistakenly thought to flower only once in a century, agaves can flower after they are ten years old or so, after which the entire plant dies (FIG. 53-7).

Many species are **iteroparous** and exhibit repeated reproductive cycles—that is, reproduction during several breeding seasons—throughout their lifetimes. Iteroparity is common in most vertebrates as well as in perennial herbaceous plants, shrubs, and trees. The timing of reproduction, earlier or later in life, is a crucial aspect of iteroparity and involves trade-offs. On the one hand, reproducing earlier in life may mean a reduced likelihood of survival (because an individual is expending energy toward reproduction instead of its own growth), which reduces the potential for later reproduction. On the other hand, reproducing later in life means that the individual has less time for additional reproductive events.

R. Gustafson/Visuals Unlimited

Figure 53-7 Semelparity
Agaves flower once and then die. The agave is a succulent with sword-shaped leaves arranged as a rosette around a short stem. Shown is *Agave shawii*, whose leaves grow to 61 cm (2 ft). Note the floral stalk, which can grow more than 3 m (10 ft) tall.

Ecologists try to understand the adaptive consequences of various **life history traits**, such as semelparity and iteroparity. Adaptations such as reproductive rate, age at maturity, and **fecundity** (potential capacity to produce offspring), all of which are a part of a species' life history traits, influence an organism's survival and reproduction. The ability of an individual to reproduce successfully, thereby making a genetic contribution to future generations of a population, is called its **fitness** (recall the discussion of fitness in Chapter 19).

Although many different life histories exist, some ecologists recognize two extremes: *r*-selected species and *K*-selected species. As you read the following descriptions of *r* selection and *K* selection, keep in mind that these concepts, although useful, oversimplify most life histories. Species tend to possess a combination of *r*-selected and *K*-selected traits as well as traits that cannot be classified as either *r*-selected or *K*-selected. In addition, some populations within a species may exhibit the characteristics of *r* selection, whereas other populations in different environments may assume *K*-selected traits.

Populations described by the concept of ***r* selection** have traits that contribute to a high population growth rate. Recall that *r* designates the per capita growth rate. Because such organisms have a high *r*, biologists call them ***r* strategists** or ***r*-selected species**. Small body size, early maturity, short lifespan, large broods, and little or no parental care are typical of many *r* strategists, which are usually opportunists found in variable, temporary, or unpredictable environments where the probability of long-term survival is low. Some of the best representatives of *r* strategists are insects and many annual plants. For example, following a rainy period, desert annuals rapidly grow from seed, flower and set seed, and then die.

In populations described by the concept of ***K* selection**, traits maximize the chance of surviving in an environment where the number of individuals is near the carrying capacity (*K*) of the environment. These organisms, called ***K* strategists** or ***K*-selected species**, do not produce large numbers of offspring. They characteristically have long lifespans with slow development, late reproduction, large body size, and a low reproductive rate. *K* strategists tend to be found in relatively constant or stable environments, where they have a high competitive ability. Redwood trees as well as most tropical rainforest trees are classified as *K* strategists. Animals that are *K* strategists typically invest in parental care of their young. Tawny owls (*Strix aluco*), for example, are *K* strategists that pair-bond for life, with both members of a pair living and hunting in adjacent, well-defined territories. Their reproduction is regulated in accordance with the resources, especially the food supply, present in their territories. In an average year, 30% of the birds do not breed at all. If food supplies are more limited than initially indicated, many of those that do breed fail to incubate their eggs. Rarely do the owls lay the maximum number of eggs that they are physiologically capable of laying, and breeding is often delayed until late in the season, when the rodent populations on which they depend have become large. Thus, the behavior of tawny owls ensures better reproductive success of the individual and leads to a stable population at or near the carrying capacity of the environment. Starvation, an indication that the tawny owl population has exceeded the carrying capacity, rarely occurs.

Life tables and survivorship curves indicate mortality and survival

A **life table** can be constructed to show the mortality and survival data of a population or **cohort**, a group of individuals of the same age, at different times during their lifespan. Insurance companies were the first to use life tables, using them to calculate the relationship between a client's age and the likelihood of the client surviving to pay enough insurance premiums to cover the cost of the policy. Ecologists construct such tables for animals and plants based on data that rely on a variety of population sampling methods and age determination techniques.

TABLE 53-2 shows a life table for a cohort of 530 gray squirrels. The first two columns show the units of age (years) and the number of individuals in the cohort that were alive at the beginning of each age interval (the actual data collected in the field by the ecologist). The values for the third column (the proportion alive at the beginning of each age interval) are calculated by dividing each number in column 2 by 530, the number of squirrels in the original cohort. The values in the fourth column (the proportion dying during each age interval) are calculated using the values in the third column and subtracting the number of survivors at the beginning of the next interval from those alive at the beginning of the current interval. For example, the proportion dying during interval 0–1 years is $1.000 - 0.253 = 0.747$. The far right column, the death rate for each age interval, is calculated by dividing the proportion dying during the age interval (column 4) by the proportion alive at the beginning of the age interval (column 3). For example, the death rate for the age interval 1–2 years is $0.147 \div 0.253 = 0.581$.

Survivorship is the probability that a given individual in a population or cohort will survive to a particular age. Plotting the logarithm (base 10) of the number of surviving individuals against age, from birth to the maximum age reached by any individual, produces a **survivorship curve**. FIGURE 53-8 shows the three main survivorship curves that ecologists recognize.

In *Type I survivorship*, as exemplified by bison and humans, the young and those at reproductive age have a high probability of surviving. The probability of survival decreases more rapidly with increasing age; mortality is concentrated later in

Table 53-2 Life Table for a Cohort of 530 Gray Squirrels (*Sciurus carolinensis*)

Age Interval (years)	Number Alive at Beginning of Age Interval	Proportion Alive at Beginning of Age Interval	Proportion Dying during Age Interval	Death Rate for Age Interval
0–1	530	1.000	0.747	0.747
1–2	134	0.253	0.147	0.581
2–3	56	0.106	0.032	0.302
3–4	39	0.074	0.031	0.418
4–5	23	0.043	0.021	0.488
5–6	12	0.022	0.013	0.591
6–7	5	0.009	0.006	0.666
7–8	2	0.003	0.003	1.000
8–9	0	0.000	0.000	—

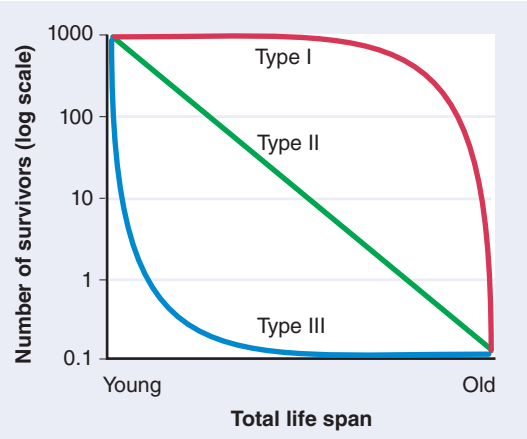

Figure 53-8 Survivorship curves

These curves represent the ideal survivorships of species in which mortality is greatest in old age (Type I), spread evenly across all age groups (Type II), and greatest among the young (Type III). The survivorship of most organisms can be compared to these curves.

life. FIGURE 53-9 shows a survivorship curve for a natural population of Drummond phlox, an annual native to East Texas that became widely distributed in the southeastern United States after it escaped from cultivation. Because most Drummond phlox seedlings survive to reproduce, after germination the plant exhibits a Type I survivorship that is typical of annuals.

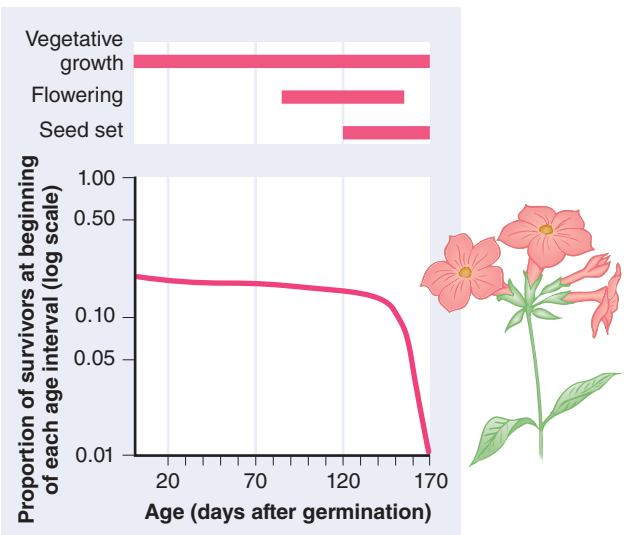

Figure 53-9 Survivorship curve for a Drummond phlox population

Drummond phlox has a Type I survivorship after germination of the seeds. *Bars above the graph* indicate the various stages in the Drummond phlox life history. Data were collected from Nixon, Texas, in 1974 and 1975. Survivorship on the *y*-axis begins at 0.296 instead of 1.00 because the study took into account death during the seed dormancy period prior to germination (*not shown*). Adapted from Leverich, W.J., and D.A. Levin, "Age-Specific Survivorship and Reproduction in *Phlox drummondii*," *American Naturalist*, Vol. 113, No. 6 (1979): 1148. Copyright © 1979 University of Chicago Press. Reprinted with permission.

In *Type III survivorship*, the probability of mortality is greatest early in life, and those individuals that avoid early death subsequently have a high probability of survival, that is, the probability of survival increases with increasing age. Type III survivorship is characteristic of oysters; young oysters have three free-swimming larval stages before settling down and secreting a shell. These larvae are vulnerable to predation, and few survive to adulthood.

In *Type II survivorship*, which is intermediate between Types I and III, the probability of survival does not change with age. The probability of death is equally likely across all age groups, resulting in a linear decline in survivorship. This constancy probably results from essentially random events that cause death with little age bias. Although this relationship between age and survivorship is rare, some lizards have Type II survivorship.

The three survivorship curves are generalizations, and few populations exactly fit one of the three. Some species have one type of survivorship curve early in life and another type as adults. Herring gulls, for example, start out with a Type III survivorship curve but develop a Type II curve as adults (FIG. 53-10). The survivorship curve shown in this figure is characteristic of birds in general. Note that most death occurs almost immediately after hatching, despite the protection and care given to the chicks by the parent bird. Herring gull chicks die from predation or attack by other herring gulls, inclement weather, infectious diseases, or starvation following death of the parent. Once the chicks become independent, their survivorship increases dramatically, and death occurs at about the same rate throughout their remaining lives. Few or no herring gulls die from the degenerative diseases of "old age" that cause death in most humans.

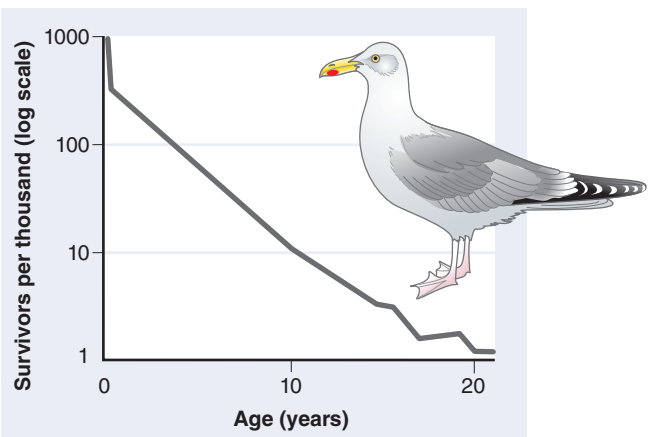

Figure 53-10 Survivorship curve for a herring gull population

Herring gulls (*Larus argentatus*) have Type III survivorship as chicks and Type II survivorship as adults. Data were collected from Kent Island, Maine, during a five-year period in the 1930s; baby gulls were banded to establish identity. The very slight increase just prior to 20 years of age is due to sampling error. Adapted from Paynter, R.A., Jr., "A New Attempt to Construct Lifetables for Kent Island Herring Gulls," *Bulletin of the Museum of Comparative Zoology*, Vol. 133, No. 11 (1966): 489–528.

CHECKPOINT 53.4

- What are the advantages of semelparity? of iteroparity? Are there disadvantages?
- **CONNECT** Why is parental care of young a common characteristic of *K* strategists?
- Do all survivorship curves neatly fit the Type I, II, or III models? Explain.

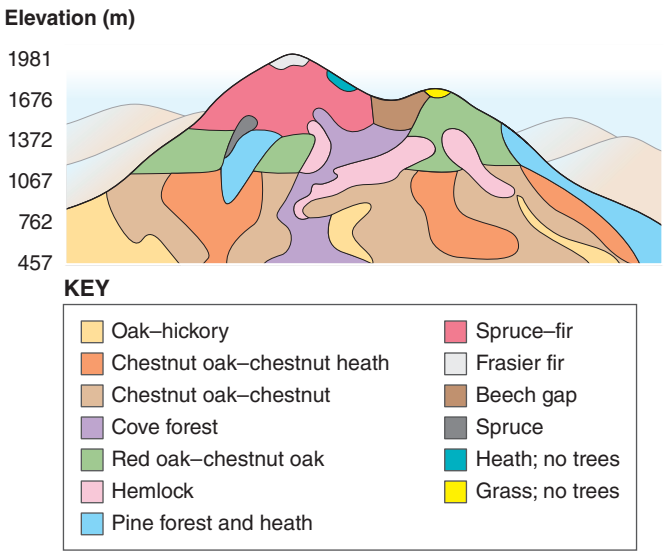
53.5 Metapopulations

LEARNING OBJECTIVE

8 Define *metapopulation* and distinguish between source habitats and sink habitats.

The natural environment is a heterogeneous **landscape** consisting of interacting ecosystems that provide a variety of habitat patches. Landscapes, which are typically several to many square kilometers in area, cover larger land areas than individual ecosystems. Consider a forest, for example. The forest landscape is a mosaic of different elevations, temperatures, levels of precipitation, soil moisture, soil types, and other properties. Because each species has its own habitat requirements, this heterogeneity in physical properties is reflected in the different organisms that occupy the various patches in the landscape (FIG. 53-11). Some species occur in very narrow habitat ranges, whereas others have wider habitat distributions.

Population ecologists have discovered that many species are not distributed as one large population across the landscape. Instead, many species exist as a series of local populations distributed in distinct habitat patches. Each local population has its own characteristic demographic features, such as birth, death, emigration, and immigration rates. A population that is divided into several local populations among which individuals occasionally disperse (emigrate and immigrate) is known as a **metapopulation**. For example, note the various local populations of red oak on the mountain slope in Figure 53-11b.



The spatial distribution of a species occurs because different habitats vary in suitability, from unacceptable to preferred. The preferred sites are more productive habitats that increase the likelihood of survival and reproductive success for the individuals living there. Good habitats, called **source habitats**, are areas where local reproductive success is greater than local mortality. *Source populations* generally have greater population densities than populations at less suitable sites, and surplus individuals in the source habitat disperse and find another habitat in which to settle and reproduce.

Individuals living in lower quality habitats may suffer death or, if they survive, poor reproductive success. Lower quality habitats, called **sink habitats**, are areas where local reproductive success is less than local mortality. Without immigration from other areas, a *sink population* declines until

Jerry Whaley/Getty Images

(a) This early spring view from Newfound Gap Rd., Great Smoky Mountains National Park, gives some idea of the heterogeneity of the landscape. During the summer, when all the vegetation is a deep green, the landscape appears homogeneous.

(b) An evaluation of the distribution of vegetation on a typical west-facing slope in the Great Smoky Mountains National Park reveals that the landscape consists of patches. Chestnut oak is a species of oak (*Quercus prinus*); chestnut heath is an area within chestnut oak forest where the trees are widely scattered and the slopes underneath are covered by a thick growth of laurel (*Kalmia*) shrubs; cove forest is a mixed stand of deciduous trees.

Figure 53-11 The mosaic nature of landscapes

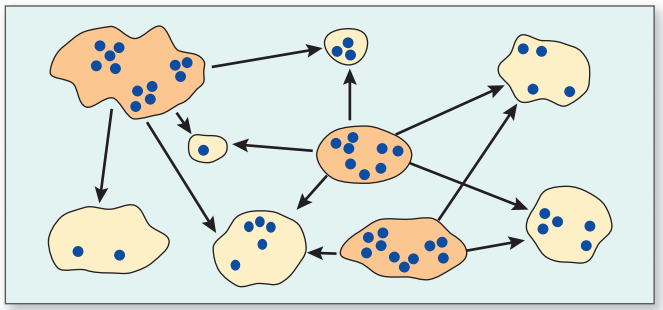

Figure 53-12 Source and sink populations in a hypothetical metapopulation

The local populations in the habitat patches shown here collectively make up the metapopulation. Source habitats provide individuals that emigrate and colonize sink habitats. Studied over time, the metapopulation is shown to exist as a shifting pattern of occupied and vacant habitat patches.

extinction occurs. If a local population becomes extinct, individuals from a source habitat may recolonize the vacant habitat at a later time. Source and sink habitats, then, are linked to one another by dispersal (FIG. 53-12).

Metapopulations are becoming more common as humans alter the landscape by fragmenting existing habitats to accommodate homes and factories, agricultural fields, and logging. As a result, the concept of metapopulations, particularly as it relates to endangered and threatened species, has become an important area of study in conservation biology.

CHECKPOINT 53.5

- **CONNECT** What roles do source habitats and sink habitats play in the dynamic nature of a metapopulation?

53.6 Human Populations

LEARNING OBJECTIVES

9 Summarize the history of human population growth.

10 Explain how highly developed and developing countries differ in population characteristics such as infant mortality rate, total fertility rate, replacement-level fertility, and age structure.

11 Distinguish between people overpopulation and consumption overpopulation.

Now that we have examined some of the basic concepts of population ecology, we can apply those concepts to the human population. Examine FIGURE 53-13, which shows the world increase in the human population since the development of agriculture approximately 10,000 years ago. Now look back at Figure 53-2 and compare the two curves. The characteristic J curve of exponential population growth shown in Figure 53-13 reflects the decreasing amount of time it has taken to add each additional billion people to our numbers. It took thousands of years for the human population to reach 1 billion, a milestone that took place around 1800. It took 130 years to reach 2 billion (in 1930), 30 years to reach 3 billion (in 1960), 15 years to reach 4 billion (in 1975), 12 years to reach 5 billion (in 1987), and 12 years to reach 6 billion (in 1999). The world population reached 7.5 billion in 2017, and the United Nations projects that it will rise to more than 8.5 billion by 2030.

Thomas Malthus (1766–1834), a British clergyman and economist, was one of the first to recognize that the human population cannot continue to increase indefinitely (see Chapter 18). He pointed out that human population growth is not always desirable (a view contrary to the beliefs of his day and to those of many people even today) and that the human population is capable of increasing faster than the food supply. He maintained that the inevitable consequences of population growth are famine, disease, and war.

The world population is currently increasing by about 100 million people per year. This rise is not caused by an increase in the birth rate (*b*). In fact, the world birth rate has actually declined during the past 200 years. The increase in population is due instead to a dramatic decrease in the death rate (*d*). This decrease in mortality has occurred primarily because greater food production, better medical care, and improved sanitation practices have increased the life expectancies of a great majority of the global population. For example, from 1920 to 2000, the death rate in Mexico fell from approximately 40 per 1000 individuals to 4 per 1000, whereas the birth rate dropped from approximately 40 per 1000 individuals to 24 per 1000 (FIG. 53-14). As of 2017

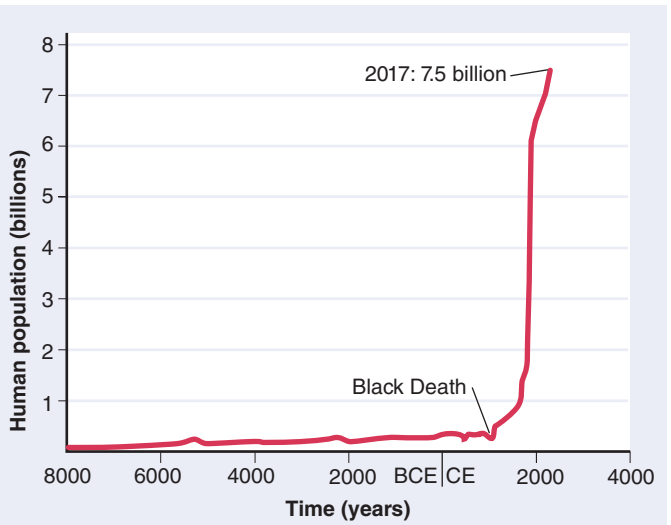

Figure 53-13 Human population growth

During the last 1000 years, the human population has been increasing nearly exponentially. Population experts predict that the population will level out during the 21st century, forming the S curve observed in other species. (Black Death refers to a devastating disease, probably bubonic plague, that decimated Europe and Asia in the 14th century.)

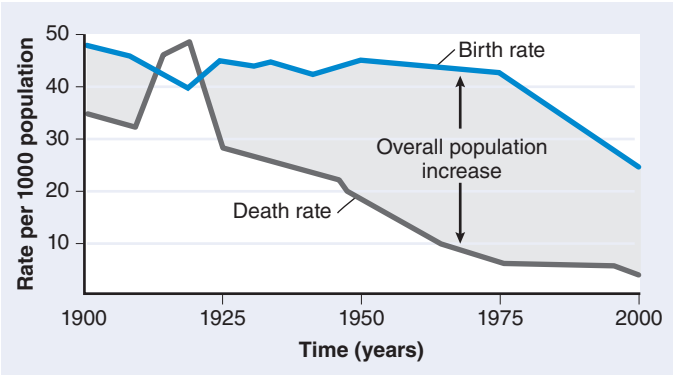

Figure 53-14 Birth and death rates in Mexico, 1900 to 2000
Both birth and death rates declined during the 20th century, but because the death rate declined much more than the birth rate, Mexico has experienced a high growth rate. (The high death rate prior to 1920 was caused by the Mexican Revolution; Population Reference Bureau.)

Mexico's birth rate had continued to fall, to about 20 per 1000; its death rate increased slightly to 5 per 1000. (As a population's birth rate falls, its death rate tends to increase somewhat because of an increase in the average age of the population.)

The human population has reached a turning point. Although our numbers continue to increase, the world per capita growth rate (r) has declined over the past several years, from a peak of 2.2% per year in the mid-1960s to 1.2% per year in 2017. Population experts at the United Nations and the World Bank have projected that the growth rate may continue to slowly decrease until zero population growth is attained. Thus, exponential growth of the human population may end, and if it does, the S curve will replace the J curve. Demographers project that **zero population growth**, the point at which the birth rate equals the death rate ($r = 0$), will occur toward the end of the 21st century.

The latest (2017) projections available through the Population Reference Bureau, based on data from the United Nations, forecast that the human population will exceed 9.8 billion in the year 2050. This forecast is a "medium" projection; such population projections are "what-if" exercises. Given certain assumptions about future tendencies in natality, mortality, and dispersal, population experts can calculate an area's population for a given number of years into the future. Population projections indicate the changes that may occur, but they must be interpreted with care because they vary depending on what assumptions have been made. Small differences in fertility as well as death rates produce large differences in population forecasts.

The main unknown factor in any population growth scenario is Earth's carrying capacity. According to Joel Cohen of the Earth Institute at Columbia University, most published estimates of how many people Earth can support range from 4 billion to 16 billion. These estimates vary so widely because of the assumptions that are made about standard of living, resource consumption, technological innovations, and waste generation. If we want all people to have a high level of material well-being equivalent to the lifestyles common in highly developed countries, Earth will clearly be able to support far fewer humans than if everyone lives just above the subsistence level. Thus, Earth's carrying capacity for the human population is not decided simply by natural environmental constraints. Human choices and values have to be factored into the assessment.

It is also not clear what will happen to the human population if or when the carrying capacity is approached. Optimists suggest that the human population will stabilize because of a decrease in the birth rate. Some experts take a more pessimistic view and predict that the widespread degradation of our environment caused by our ever-expanding numbers will make Earth uninhabitable for humans and other species. These experts contend that a massive wave of human suffering and death will occur. Some experts think that the human population has already exceeded the carrying capacity of the environment, a potentially dangerous situation that threatens our long-term survival as a species.

Not all countries have the same growth rate

Although world population figures illustrate overall trends, they do not describe other important aspects of the human population story, such as population differences from country to country. Human **demographics**, the science that deals with human population statistics such as size, density, and distribution, provides information on the populations of various countries. As you probably know, not all parts of the world have the same rates of population increase. Countries can be classified into two groups, highly developed and developing, based on their rates of population growth, degrees of industrialization, and relative prosperity (TABLE 53-3).

Highly developed countries, such as the United States, Canada, France, Germany, Sweden, Australia, and Japan, have low rates of

Table 53-3 Comparison of 2017 Population Data in Selected Developed and Developing Countries

	Developed	Developing	
	(Highly Developed) United States	(Moderately Developed) Brazil	(Less Developed) Ethiopia
Fertility rate	1.8	1.6	4.6
Doubling time	175 years	100 years	27 years
Infant mortality rate	5.8 per 1000	14 per 1000	48 per 1000
Life expectancy at birth	79 years	76 years	65 years
GNI PPP per capita (U.S. $)	$58,030	$14,810	$1,730
Married women 15–49 using modern contraception	70%	77%	35%

Data from Population Reference Bureau.

population growth and are highly industrialized relative to the rest of the world. Highly developed countries have the lowest birth rates in the world. Indeed, some highly developed countries such as Germany have birth rates just below that needed to sustain the population and are thus declining slightly in numbers. Highly developed countries also have low **infant mortality rates** (the number of infant deaths per 1000 live births). The infant mortality rate of the United States in 2017 was 5.8, compared with a world infant mortality rate of 32.

Highly developed countries also have longer life expectancies (79 years at birth in the United States versus 72 years worldwide) and higher average GNI PPP per capita ($58,030 in the United States versus $16,101 worldwide) than other countries. GNI PPP per capita is gross national income (GNI) in purchasing power parity (PPP) divided by midyear population. It indicates the amount of goods and services an average citizen of that particular region or country could buy in the United States.

Developing countries fall into two subcategories: moderately developed and less developed. Mexico, Turkey, Thailand, and most countries of South America are examples of *moderately developed countries*. Their birth rates and infant mortality rates are generally higher than those of highly developed countries, but the rates are declining. Moderately developed countries have a medium level of industrialization, and their average GNI PPP per capita is lower than those of highly developed countries.

Bangladesh, Niger, Ethiopia, Laos, and Cambodia are examples of *less developed countries*. These countries have the highest birth rates, the highest infant mortality rates, the lowest life expectancies, and the lowest average GNI PPP per capita in the world.

One way to represent the population growth of a country is to determine the **doubling time**, the amount of time it would take for its population to double in size assuming that its current growth rate did not change. A simplified formula for doubling time (t_d) is $t_d = 70 \div r$. (The actual formula involves calculus and is beyond the scope of this text. This simplified formula actually has many practical applications; e.g., you can use it to estimate how long it will take to double your money in a savings account at a specific rate of compound interest.)

A look at a country's doubling time identifies it as a highly, moderately, or less developed country: the shorter the doubling time, the less developed the country. At rates of growth in 2017, the approximate doubling time is 27 years for Ethiopia, 41 years for Laos, 58 years for Turkey, 175 years for the United States, and 233 years for France.

It is also instructive to examine **replacement-level fertility**, the number of children a couple must produce to "replace" themselves. Replacement-level fertility is usually given as 2.1 children in highly developed countries and 2.7 children in developing countries. The number is always greater than 2.0 because some children die before they reach reproductive age. Higher infant mortality rates are the main reason that replacement levels in developing countries are greater than in highly developed countries. The **total fertility rate**—the average number of children born to a woman during her lifetime—is 2.5 worldwide, which is well above replacement levels. However, it has fallen below replacement levels, to 1.7, in the highly developed countries. The total fertility rate in the United States is 1.8, which is higher than in other industrialized countries.

The population in many developing countries is beginning to approach stabilization. The fertility rate must decline for the population to stabilize (TABLE 53-4; note the general decline in total fertility rate from the 1960s to 2017 in selected developing countries). The total fertility rate in developing countries has decreased from an average of 6.1 children per woman in 1970 to 2.9 in 2017 (excluding China), or 2.6 if China is included. Fertility is highly variable among developing countries, and although the fertility rates in most of these countries have declined, it should be remembered that most still exceed replacement-level fertility. Consequently, the populations in these countries are still increasing. Also, even when fertility rates equal replacement-level fertility, population growth will still continue for some time. To understand why, we now examine the age structure of various countries.

The age structure of a country helps predict future population growth

To predict the future growth of a population, it is important to know its **age structure**, which is the number and proportion of people at each age in a population. The number of males and number of females at each age, from birth to death, are represented in an **age structure diagram**.

The overall shape of an age structure diagram indicates whether the population is increasing, stationary, or shrinking (FIG. 53-15). The age structure diagram for less developed countries is shaped like a pyramid. Because the largest percentage of the population is in the pre-reproductive age group (i.e., 0 to 14 years of age), the probability of future population growth is great. A strong **population growth momentum** exists because when all these children mature they will become the parents of the next generation, and this group of parents will be larger than the previous group. Thus, even if the fertility rates in these countries decline to replacement level (i.e., couples have smaller families than their parents did), the

Table 53-4 Fertility Changes in Selected Developing Countries

	Total Fertility Rate	
Country	1960–1965	2017
Bangladesh	6.7	2.3
Brazil	6.2	1.6
China	5.9	1.8
Egypt	7.1	3.3
Guatemala	6.9	2.9
India	5.8	2.3
Kenya	8.1	3.9
Mexico	6.8	2.2
Nepal	5.9	2.3
Nigeria	6.9	5.5
Thailand	6.4	1.5

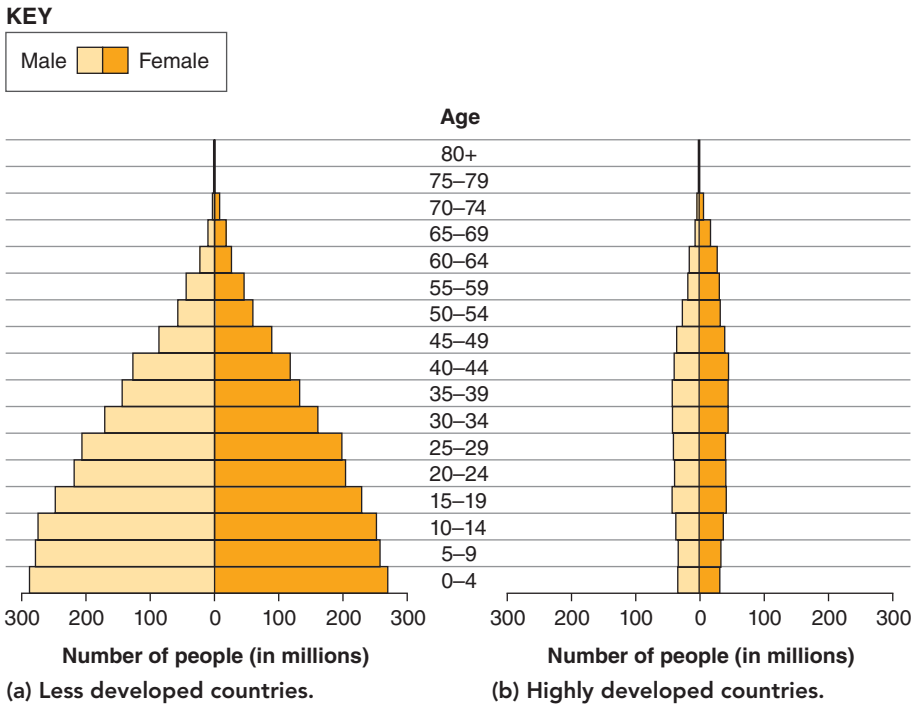

Figure 53-15 Age structure diagrams

These age structure diagrams for **(a)** less-developed countries and **(b)** highly developed countries indicate that less developed regions have a greater percentage of young people than do highly developed countries. As a result, less-developed countries are projected to have greater population growth than are highly developed countries. Adapted from Population Reference Bureau using data from United Nations, World Population Prospects: The 2002 Revision (2003).

population will continue to grow for some time. Population growth momentum can have either a positive value (i.e., the population will grow) or a negative value (i.e., the population will decline). However, it is usually discussed in a positive context, to explain how the future growth of a population is affected by its present age distribution.

In contrast, the more tapered bases of the age structure diagrams of highly developed countries with slowly growing, stable, or declining populations indicate that a smaller proportion of the population will become the parents of the next generation. The age structure diagram of a stable population, one that is neither growing nor shrinking, demonstrates that the number of people at pre-reproductive and reproductive ages are approximately the same. Also, a larger percentage of the population is older—that is, post-reproductive—than in a rapidly increasing population. Many countries in Europe have stable populations. In a population that is shrinking in size, the pre-reproductive age group is smaller than either the reproductive or post-reproductive group. Germany, Russia, and Bulgaria are examples of countries with slowly shrinking populations.

Worldwide, 26% of the human population is younger than age 15. When these people enter their reproductive years, they have the potential to cause a large increase in the growth rate. Even if the birth rate does not increase, the growth rate will increase simply because more people are reproducing.

Most of the world population increase since 1950 has taken place in developing countries as a result of the younger age structure and the higher-than-replacement-level fertility rates of their populations. In 1950, 66.8% of the world's population was in the developing countries in Africa, Asia (minus Japan), and Latin America. Between 1950 and 2017, the world's population more than doubled in size, but most of that growth occurred in developing countries. As a reflection of this growth, in 2017 the people in developing countries had increased to more than 84% of the world's population. Most of the population increase that will occur during the 21st century will also take place in developing countries, largely the result of their young age structures. These countries, most of which are poor, are least able to support such growth.

Environmental degradation is related to population growth and resource consumption

The relationships among population growth, use of natural resources, and environmental degradation are complex, but we can make two useful generalizations.

First, although the amount of resources essential to an individual's survival may be small, a rapidly increasing population tends to overwhelm and deplete a country's soils, forests, and other natural resources. Thus, **people overpopulation** occurs when the environment is worsening from too many people, even if those people consume few resources per person. People overpopulation is the current problem in many developing nations.

Second, in affluent highly developed nations, individual resource demands are large, far above requirements for survival. **Consumption overpopulation** occurs when people in more affluent nations exhaust resources and degrade the global environment through excessive consumption and "throwaway" lifestyles.

The effects of human populations on the environment are explored in more detail in Chapter 57.

CHECKPOINT 53.6

- What is the reason for the dramatic increase in the world population over the last 200 years?
- **CONNECT** Why is replacement-level fertility greater in developing countries than in highly developed countries? Explain your answer.
- How can a single child born in the United States have a greater effect on the environment and natural resources than a dozen children born in Kenya?

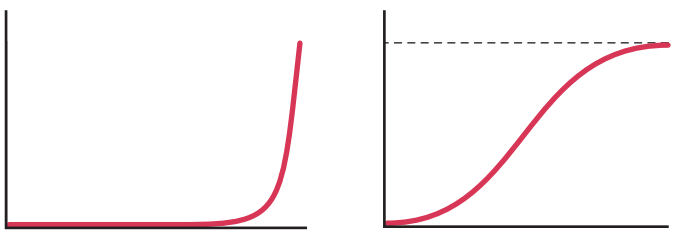
Summary: Focus on Learning Objectives

53.1 Features of Populations *(page 1152)*

1 Define *population density* and *dispersion*, and describe the main types of population dispersion.

- **Population density** is the number of individuals of a species per unit of area or volume at a given time.

Random dispersion | Clumped dispersion | Uniform dispersion



- Population **dispersion** (spacing) may be **random dispersion** (unpredictably spaced), **clumped dispersion** (clustered in specific parts of the habitat), or **uniform dispersion** (evenly spaced).

53.2 Changes in Population Size *(page 1154)*

2 Explain the four factors (natality, mortality, immigration, and emigration) that produce changes in population size and solve simple problems involving these changes.

- Population size is affected by the average per capita birth rate (b), average per capita death rate (d), and two measures of **dispersal**: average per capita **immigration** rate (i) and average per capita **emigration** rate (e).
- The **growth rate (r)** is the rate of change (increase or decrease) of a population on a per capita basis. On a global scale (when dispersal is not a factor), $r = b - d$. Populations increase in size as long as the average per capita birth rate (**natality**) is greater than the average per capita death rate (**mortality**).
- For a local population (where dispersal is a factor), $r = (b - d) + (i - e)$.

3 Define *intrinsic rate of increase* and *carrying capacity*, and explain the differences between J-shaped and S-shaped growth curves.

Exponential population growth | Logistic population growth

- **Intrinsic rate of increase (r_{max})** is the maximum rate at which a species or population could increase in number under ideal conditions.
- Although certain populations exhibit an accelerated pattern of growth known as **exponential population growth** for limited periods of time (the J-shaped curve), eventually the growth rate decreases to around zero or becomes negative.
- Population size is modified by limits set by the environment. The **carrying capacity (*K*)** of the environment is the largest population that can be maintained for an indefinite time by a particular environment. **Logistic population growth**, when plotted, shows a characteristic S-shaped curve. Seldom do natural populations follow the logistic growth curve very closely.

53.3 Factors Influencing Population Size *(page 1156)*

4 Contrast the influences of density-dependent and density-independent factors on population size and give examples of each.

- **Density-dependent factors** regulate population growth by affecting a larger proportion of the population as population density rises. Predation, disease, and competition are examples.
- **Density-independent factors** limit population growth but are not influenced by changes in population density. Hurricanes and blizzards are examples.

53.4 Life History Traits *(page 1160)*

5 Contrast semelparous and iteroparous reproduction.

- **Semelparous** species expend their energy in a single, immense reproductive effort. **Iteroparous** species exhibit repeated reproductive cycles throughout their lifetimes.

6 Distinguish among species exhibiting an *r* strategy, those with a *K* strategy, and those that do not easily fit either category.

- Although many different combinations of life history traits exist, some ecologists recognize two extremes: *r* strategy and *K* strategy.
- An *r* strategy emphasizes a high growth rate. Organisms characterized as ***r* strategists** often have small body sizes, high reproductive rates, and short **lifespans**, and they typically inhabit variable environments.
- A *K* strategy maintains a population near the carrying capacity of the environment. Organisms characterized as ***K* strategists** often have large body sizes, low reproductive rates, and long lifespans, and they typically inhabit stable environments.
- The two strategies oversimplify most life histories. Many species combine *r*-selected and *K*-selected traits as well as traits that cannot be classified as either *r*-selected or *K*-selected.

7 Describe Type I, Type II, and Type III survivorship curves and explain how life tables and survivorship curves indicate mortality and survival.

- A **life table** shows the mortality and survival data of a population or **cohort**—a group of individuals of the same age—at different times during the population's lifespan.
- **Survivorship** is the probability that a given individual in a population or cohort will survive to a particular age. There are three general **survivorship curves**: *Type I survivorship*, in which mortality is greatest in old age; *Type II survivorship*, in which mortality is spread evenly across all age groups; and *Type III survivorship*, in which mortality is greatest among the young.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

53.5 Metapopulations *(page 1163)*

8 Define *metapopulation* and distinguish between source habitats and sink habitats.

- Many species exist as a **metapopulation**, a set of local populations among which individuals are distributed in distinct habitat patches across a **landscape**, which is a large area of terrain (several to many square kilometers) composed of interacting ecosystems.
- Within a metapopulation, individuals occasionally disperse from one local habitat to another by emigration and immigration. **Source habitats** are preferred sites where local reproductive success is greater than local mortality. Surplus individuals disperse from source habitats. **Sink habitats** are lower quality habitats where individuals may suffer death or, if they survive, poor reproductive success. If extinction of a local *sink population* occurs, individuals from a *source population* may recolonize the vacant habitat at a later time.

53.6 Human Populations *(page 1164)*

9 Summarize the history of human population growth.

- The world population increases by about 100 million people per year and reached 7.5 billion in 2017.
- Although our numbers continue to increase, the per capita growth rate (r) has declined over the past several years, from a peak in 1965 of about 2% per year to a 2017 growth rate of 1.2% per year.
- Scientists who study human **demographics** (human population statistics) project that the world population will become stationary ($r = 0$, or **zero population growth**) by the end of the 21st century.

10 Explain how highly developed and developing countries differ in population characteristics such as infant mortality rate, total fertility rate, replacement-level fertility, and age structure.

- *Highly developed countries* have the lowest birth rates, lowest infant mortality rates, lowest total fertility rates, longest life expectancies, and highest GNI PPP per capita (a measure of the amount of goods and services the average citizen could purchase in the United States) of all countries. *Developing countries* have the highest birth rates, highest infant mortality rates, highest total fertility rates, shortest life expectancies, and lowest GNI PPP per capita.
- The **age structure** of a population greatly influences population dynamics. It is possible for a country to have **replacement-level fertility** and still experience population growth if the largest percentage of the population is in the pre-reproductive years. A young age structure causes a positive **population growth momentum** as the very large pre-reproductive age group matures and becomes parents.

11 Distinguish between people overpopulation and consumption overpopulation.

- Developing countries tend to have **people overpopulation**, in which population increase degrades the environment even though each individual uses few resources.
- Highly developed countries tend to have **consumption overpopulation**, in which each individual in a slow-growing or stationary population consumes a large share of resources, which results in environmental degradation.

Test Your Understanding

Know and Comprehend

1. Population _____ is the number of individuals of a species per unit of habitat area or volume at a given time. (a) dispersion (b) density (c) survivorship (d) age structure (e) demographics
2. The per capita growth rate of a population where dispersal is not a factor is expressed as (a) $i + e$ (b) $b - d$ (c) dN/dt (d) $rN(K - N)$ (e) $(K - N) \div K$
3. The maximum rate at which a population could increase under ideal conditions is known as its (a) total fertility rate (b) survivorship (c) intrinsic rate of increase (d) doubling time (e) age structure
4. When r is a positive number, the population size is (a) stable (b) increasing (c) decreasing (d) either increasing or decreasing, depending on interference competition (e) either increasing or stable, depending on whether the species is semelparous
5. In a graph of population size versus time, a J-shaped curve is characteristic of (a) exponential population growth (b) logistic population growth (c) zero population growth (d) replacement-level fertility (e) population growth momentum
6. The largest population that can be maintained by a particular environment for an indefinite period is known as a (a) semelparous population (b) population undergoing exponential growth (c) metapopulation (d) population's carrying capacity (e) source population
7. Giant bamboos live many years without reproducing, then send up a huge flowering stalk and die shortly thereafter. Giant bamboo is therefore an example of (a) iteroparity (b) a source population (c) a metapopulation (d) an r strategist (e) semelparity
8. Predation, disease, and competition are examples of _____ factors. (a) density-dependent (b) density-independent (c) survivorship (d) dispersal (e) semelparous
9. _____ competition occurs within a population, and _____ competition occurs among populations of different species. (a) Interspecific; intraspecific (b) Intraspecific; interspecific (c) Type I survivorship; Type II survivorship (d) Interference; exploitation (e) Exploitation; interference
10. A highly developed country has a (a) long doubling time (b) low infant mortality rate (c) high GNI PPP per capita (d) a and b (e) a, b, and c
11. The continued growth of a population with a young age structure, even after its fertility rate has declined, is known as (a) population doubling (b) iteroparity (c) population growth momentum (d) r selection (e) density dependence

Apply and Analyze

12. Which of the following patterns of cars parked along a street is an example of uniform dispersion? (a) five cars

parked next to one another in the middle, leaving two empty spaces at one end and three empty spaces at the other end (b) five cars parked in this pattern: car, empty space, car, empty space, and so on (c) five cars parked in no discernible pattern, sometimes having empty spaces on each side and sometimes parked next to another car

13. A female elephant bears a single offspring every two to four years. Based on this information, which survivorship curve do you think is representative of elephants? Explain your answer.

Evaluate and Synthesize

14. Explain why the population size of a species that competes by interference competition is often near the carrying capacity, whereas the population size of a species that competes by exploitation competition is often greater than or below the carrying capacity.
15. **EVOLUTION LINK** In developing his scientific theory of evolution by natural selection, Charles Darwin considered four main observations: heritable variation among individuals in a population, overproduction of offspring, limits on population growth, and differential reproductive success. Compare how these observations may apply to populations that tend to fit the concepts of *r* selection and *K* selection.
16. **INTERPRET DATA** In Bolivia, 35% of the population is younger than age 15, and 5% is older than 65. In Austria, 14% of the population is younger than 15, and 18% is older than 65. Which country will have the highest growth rate over the next two decades? Explain your answer.
17. **INTERPRET DATA** The 2017 population of the Netherlands was 17.1 million, and its land area is 15,768 square miles. The 2017 population of the United States was 325.4 million, and its land area is 3,717,796 square miles. Which country has the greater population density?
18. **INTERPRET DATA** The population of India in 2017 was 1,352.6 million, and its growth rate was 1.4% per year. Calculate the 2018 population of India.
19. **INTERPRET DATA** The world population in 2017 was 7.5 billion, and its annual growth rate was 1.2%. If the birth rate was 20 per 1000 people in the year 2017, what was the death rate, expressed as number per 1000 people?
20. **INTERPRET DATA** Consider the age structure diagrams for counties **(a)** and **(b)**. Which diagram is consistent with negative growth momentum? Why?

21. **SCIENCE, TECHNOLOGY, AND SOCIETY** In what ways has technology contributed to consumption overpopulation? Can you propose some applications of technology that might help alleviate its effects?

54 Community Ecology

In Chapter 53 we examined the dynamics of populations. In the natural world, most populations are part of a **community**, which consists of an association of populations of different species. These populations and species live and interact, directly and indirectly with each other, in the same place at the same time. The definition for *community* is deliberately broad because it refers to ecological categories that vary greatly in size, lack precise boundaries, and are rarely completely isolated.

Smaller communities nest within larger communities. A mangrove forest is a community, but so are the interlacing roots that support each tree (see photograph). Mangrove roots, anchored in sediment made up of sand and peat, are breeding grounds and nurseries for crabs, shrimp, and many commercially important fish. Blue crabs, lizards, and turtles feed on insects, algae, and dead animal material. Small mammals scurry among the roots, and manatees and alligators find shelter from the tropical sun. Mangrove root surfaces are home to invertebrates, algae, bacteria, archaea, and fungi, which provide nutrients for other organisms. Mangroves also filter excess nutrients and some toxic pollutants from the water.

Organisms exist in an abiotic (nonliving) environment that is as essential to their lives as their interactions with one another. Minerals, air, water, and sunlight are just as much a part of a bat's environment, for example, as the flowers it pollinates and depends on for nectar and insects. A biological community and its abiotic environment together compose an **ecosystem**. Like communities, ecosystems are broad entities that refer to ecological units of various sizes.

In this chapter, we focus on living communities. We explore some of the challenges in understanding common patterns and processes that govern communities. The abiotic components of ecosystems, including energy flow and trophic structure (feeding relationships), nutrient cycling, and climate, are considered in Chapter 55.

KEY CONCEPTS

54.1 A community consists of populations that live in the same place at the same time. Community ecologists focus on questions concerning the number of species, the relative abundance of each species, interactions among species, and resistance of the community to environmental disturbances (natural and human-made).

54.2 Both dominant species and keystone species have community-wide effects on energy flow and community structure: dominant species because of their large biomass or abundance, and keystone species despite their relatively small biomass or abundance.

54.3 Factors that influence community diversity include the number, variety, and abundance of species. Field experiments with plants beginning in the 1990s suggest that more diverse communities have a greater stability, or resistance to change.

54.4 Most ecologists think that communities are loose associations of organisms that have similar environmental requirements and therefore live together in the same environment. Following a disturbance, communities undergo succession from pioneer communities to mature communities.

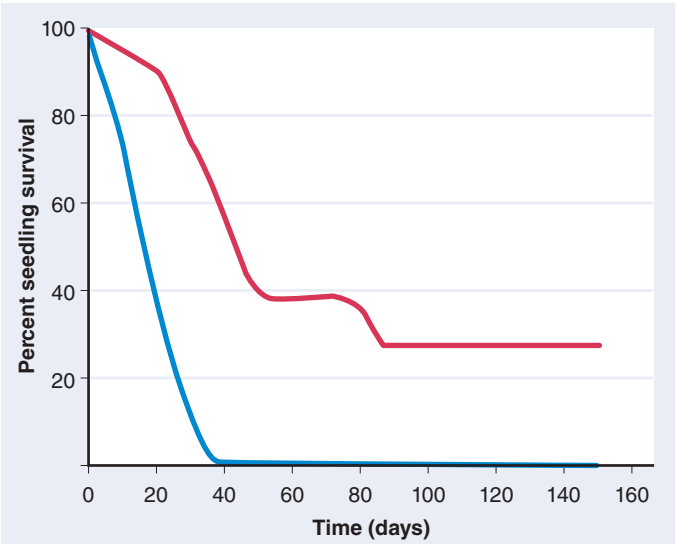
54.1 Community Structure and Functioning

LEARNING OBJECTIVES

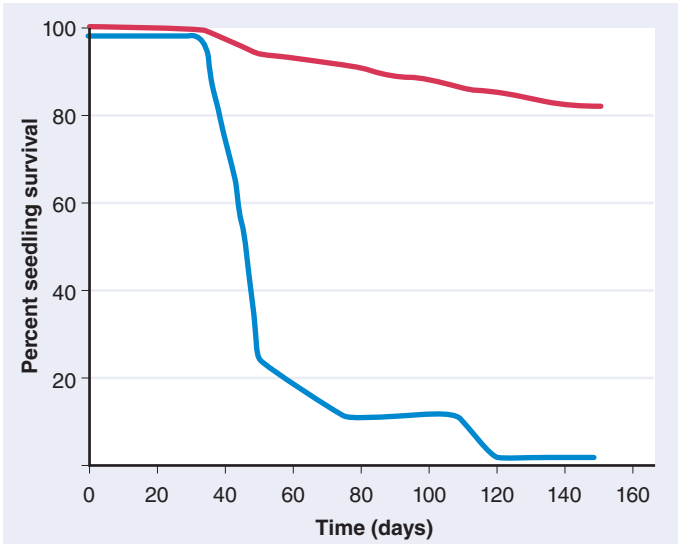
1. Define *ecological niche* and distinguish between an organism's fundamental niche and its realized niche.
2. Define *competition* and distinguish between interspecific and intraspecific competition.
3. Summarize the concepts of the competitive exclusion principle, resource partitioning, and character displacement.
4. Define *predation* and describe the effects of natural selection on predator–prey relationships.
5. Distinguish among mutualism, commensalism, and parasitism, and give examples of each.

Communities exhibit characteristic properties that populations lack. These properties, known collectively as *community structure* and *community functioning*, include the number and types of species present, the relative abundance of each species, the interactions among different species, community resilience to disturbances, energy and nutrient flow throughout the community, and productivity. **Community ecology** is the description and analysis of patterns and processes within the community. Finding common patterns and processes in a wide variety of communities—for example, a pond community, a pine forest community, and a human gut community—helps ecologists understand community structure and functioning.



Communities are exceedingly difficult to study because a large number of individuals of many different species interact with one another and are interdependent in a variety of ways. Species compete with one another for food, water, living space, and other resources. (Used in this context, a *resource* is anything from the environment that meets needs of a particular species.) Some organisms kill and eat other organisms, cause disease, or alter their immediate surroundings to inhibit competing life.

Some species form intimate, complex associations with one another, whereas other species seem only remotely connected. Certain species interact in positive ways in a process known as **facilitation**, which modifies and enhances the local environment for other species. For example, alpine plants in harsh mountain environments grow faster and larger and reproduce more successfully when certain other plants are growing nearby (FIG. 54-1).



Jardin Lauraret/Station Alpine Joseph Fourier

(a) *Laretia acaulis* plants increase the survival rate of certain nearby plants at 2800 m (9100 ft) in the Andes Mountains of Chile. The effect is less pronounced at higher elevations.

(b) Field mouse-ear chickweed (*Cerastium arvense*) plants were planted and grown within (*red*) and outside (*blue*) clumps of *Laretia acaulis*.

(c) Alpine barley (*Hordeum comosum*) plants were planted and grown within (*red*) and outside (*blue*) clumps of *Laretia acaulis*.

Also, each organism plays one of three main roles in community life: producer, consumer, or decomposer. Unraveling the many positive and negative, direct and indirect interactions of organisms living together as a community is one of the goals of community ecologists.

Community interactions are complex and often not readily apparent

During the late 1990s, an intricate relationship emerged among acorn production, white-footed mice, deer, gypsy moth population growth, and the potential occurrence of Lyme disease in humans (FIG. 54-2). Large-scale experiments conducted in oak forests of the northeastern United States linked bumper acorn crops, which occur every three to four years, to booming mouse populations (the mice eat the acorns). Because the mice also eat gypsy moth pupae, high acorn conditions also lead to low populations of gypsy moths. This outcome helps the oaks because gypsy moths cause serious defoliation. However, abundant acorns also attract tick-bearing deer to oak forests. The ticks' hungry offspring feed on the mice, which often carry the Lyme disease–causing bacterium. The bacterium infects the maturing ticks and, in turn, spreads to humans who are bitten by affected ticks. In 2006, scientists concluded that it is possible to predict which years pose the greatest potential threat of Lyme disease to humans based on when oaks are most productive. They determined that the risk of Lyme disease is greater two years following a bumper acorn crop than in other years.

Within a community, no species exists independently of other species. As the preceding example shows, the populations of a community interact with and affect one another through complex networks that are not always obvious. Three main types of interactions occur among species in a community: competition, predation, and symbiosis. Before we address these interactions, however, we need to examine the way of life of a given species in its community.

The niche is a species' ecological role in the community

Every species is thought to have its own ecological role within the structure and function of a community; we call this role its **ecological niche**. Although the concept of ecological niche has been in use in ecology since early in the 20th century, Yale ecologist G. E. Hutchinson first described in 1957 the multidimensional nature of the niche that is accepted today. An ecological niche takes into account all biotic and abiotic aspects (and combinations) of the species' existence, that is, all the physical, chemical, and biological factors that the species needs to survive, remain healthy, and reproduce. A niche includes the local environment in which a species lives, its **habitat**. A niche also encompasses what a species eats, what eats it, and the organisms with which the species has a relationship (positive, negative, or neutral). Ecologists also consider how each species interacts with and is influenced by the abiotic components of its environment, such as light, temperature, and moisture. The

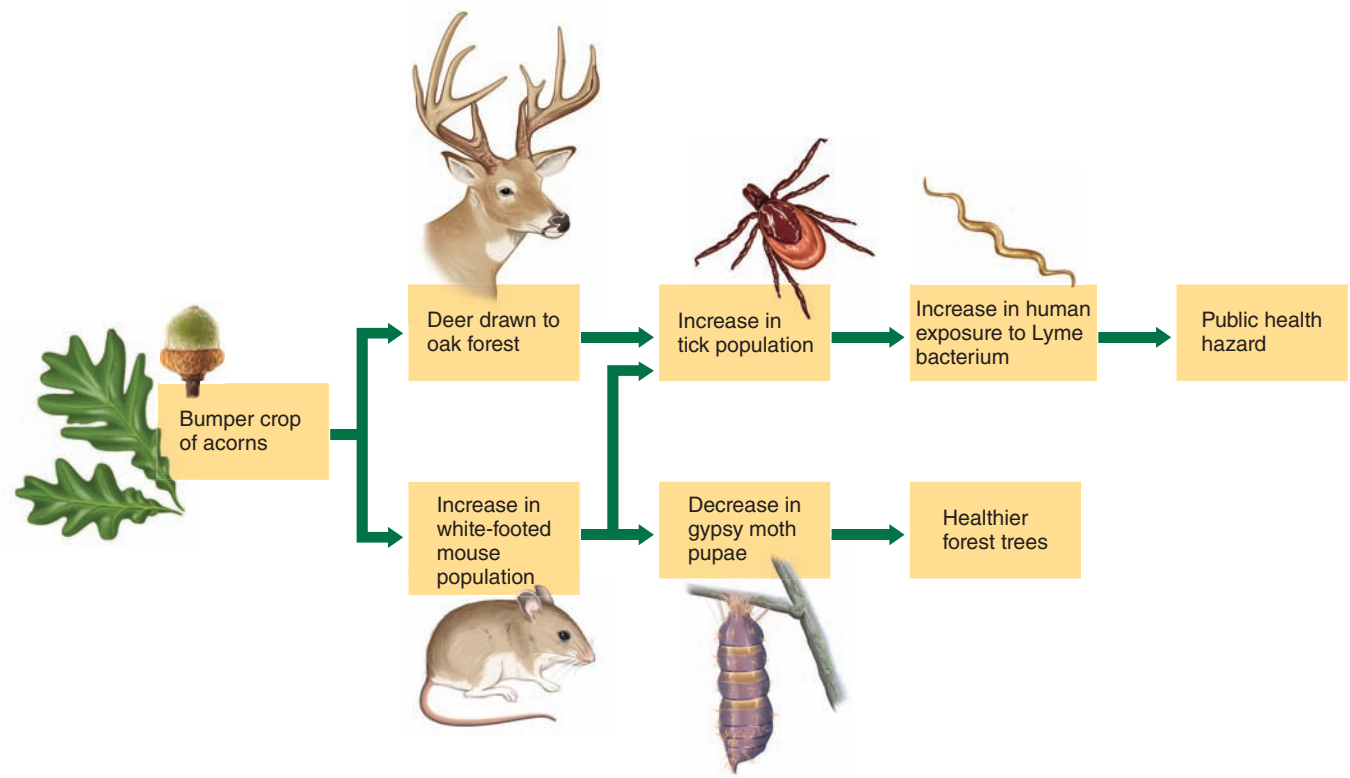

Figure 54-2 Connections to the size of an acorn crop

When there is a bumper crop of acorns, more mice survive and breed in winter, and more deer are attracted to oak forests. Both mice and deer are hosts of ticks that may carry the Lyme disease bacterium to humans. Abundant mice also reduce gypsy moth populations, thereby improving the health of forest trees.

niche thus represents the totality of adaptations by a species to its environment, its use of resources, and the lifestyle to which it is suited. Clearly, a complete description of an organism's ecological niche involves many dimensions and is difficult to define precisely. For these reasons, ecologists usually confine their studies to one or a few niche variables, such as feeding behaviors or ability to tolerate temperature extremes.

The ecological niche of a species is far broader hypothetically than in actuality. A species is usually capable of using much more of its environment's resources or of living in a wider assortment of habitats than it actually does. The potential ecological niche of a species, or the conditions it can theoretically live in without competitors, is its **fundamental niche**. Various factors, such as competition with other species, may exclude it from part of this fundamental niche. Thus, the lifestyle that a species actually pursues and the resources it actually uses make up its **realized niche**.

An example may help make this distinction clear. The green anole, a lizard native to Florida and other southeastern states, perches on trees, shrubs, walls, or fences during the day, waiting for insect and spider prey (FIG. 54-3a). In the past, these little lizards were widespread in Florida. Several decades ago, however, a related species, the brown anole introduced from Cuba into southern Florida, spread northward up the Florida peninsula and quickly became common (FIG. 54-3b). Suddenly, the green anoles became rare, apparently driven out of their habitat by competition from the slightly larger brown anoles. Careful investigation, however, disclosed that green anoles were still around. They were now confined largely to the vegetation in wetlands and to the foliated crowns of trees, where they were less easily seen.

The habitat portion of the green anole's fundamental niche includes the trunks and crowns of trees, exterior house walls, and many other locations. Once the brown anoles became established in the green anole habitat, they drove the green anoles from all but wetlands and tree crowns; competition between the two species shrank the green anole's realized niche (FIGS. 54-3c and d). Because communities consist of numerous species, many of which compete to some extent, the interactions among them produce the realized niche of each species.

Limiting resources restrict the ecological niche of a species A species' structural, physiological, and behavioral adaptations determine its tolerance for environmental extremes. If any feature of an environment lies outside the bounds of its tolerance, the species cannot live there. Just as you would not expect to find a cactus living in a pond, you would not expect water lilies in a desert.

The environmental factors that actually determine a species' ecological niche are difficult to identify. For this reason, the concept of ecological niche is largely abstract, although some of its dimensions can be experimentally determined. Any environmental resource that, because it is scarce or unfavorable, tends to restrict the ecological niche of a species is called a **limiting resource**.

Most of the limiting resources that have been studied are simple variables, such as the soil's mineral content, temperature extremes, and precipitation amounts. Such investigations have disclosed that any factor, either exceeding the tolerance of a species or present in quantities smaller than the required minimum, limits the presence of that species in a community. By their interaction, such factors help define the ecological niche for a species.

Limiting resources may affect only part of an organism's life cycle. For example, although adult blue crabs live in fresh or slightly brackish water, they do not become permanently established in such areas because

their larvae (immature forms) require salt water. Similarly, the ring-necked pheasant, a popular game bird native to Eurasia, has been widely introduced in North America but has not become established in the southern United States. The adult birds do well there, but the eggs do not develop properly in the warmer southern temperatures.

Biotic and abiotic factors influence a species' ecological niche In the 1960s, U.S. ecologist Joseph H. Connell investigated biotic and abiotic factors that affect the distribution of two barnacle species in the rocky *intertidal zone* along the coast of Scotland. The intertidal zone is a challenging environment, and organisms in the intertidal zone must tolerate exposure to the drying air during low tides. Barnacles are sessile crustaceans whose bodies are covered by a shell of calcium carbonate (see Fig. 31-29a). When the shell is open, feathery appendages extend to filter food from the water.

Along the coast of Scotland, more adults of one barnacle species, *Semibalanus balanoides* (formerly called *Balanus balanoides*), are attached on lower rocks in the intertidal zone than are adults of the other species, *Chthamalus stellatus* (FIG. 54-4). The distributions of the two species do not overlap, although immature larvae of both species live together in the intertidal zone. Connell manipulated the two populations to determine what factors were affecting their distribution. When he removed *Chthamalus* from the upper rocks, *Semibalanus* barnacles did not expand into the vacant area. Connell's experiments showed that *Chthamalus* is more resistant than *Semibalanus* to desiccation when the tide retreats. However, when Connell removed *Semibalanus* from the lower rocks, *Chthamalus* expanded into the lower parts of the intertidal zone. The two species compete for space, and *Semibalanus*, which is larger and grows faster, outcompetes the smaller *Chthamalus* barnacles.

Competition among barnacle species for the limiting resource of living space was one of the processes that Connell's research demonstrated. We now examine other aspects of competition that various ecologists have demonstrated in both laboratory and field studies.

Competition is intraspecific or interspecific

Competition occurs when two or more individuals attempt to use the same essential resource, such as food, water, shelter, living space, or sunlight. Because resources are often in limited supply in the environment, their use by one individual decreases the amount available to others (TABLE 54-1). If a tree in a dense forest grows taller than surrounding trees, for example, it absorbs more of the incoming sunlight. Less sunlight is therefore available for nearby trees that are shaded by the taller tree. Competition occurs among individuals within a population (**intraspecific competition**) or between different species (**interspecific competition**). (Intraspecific competition was discussed in Chapter 53.)

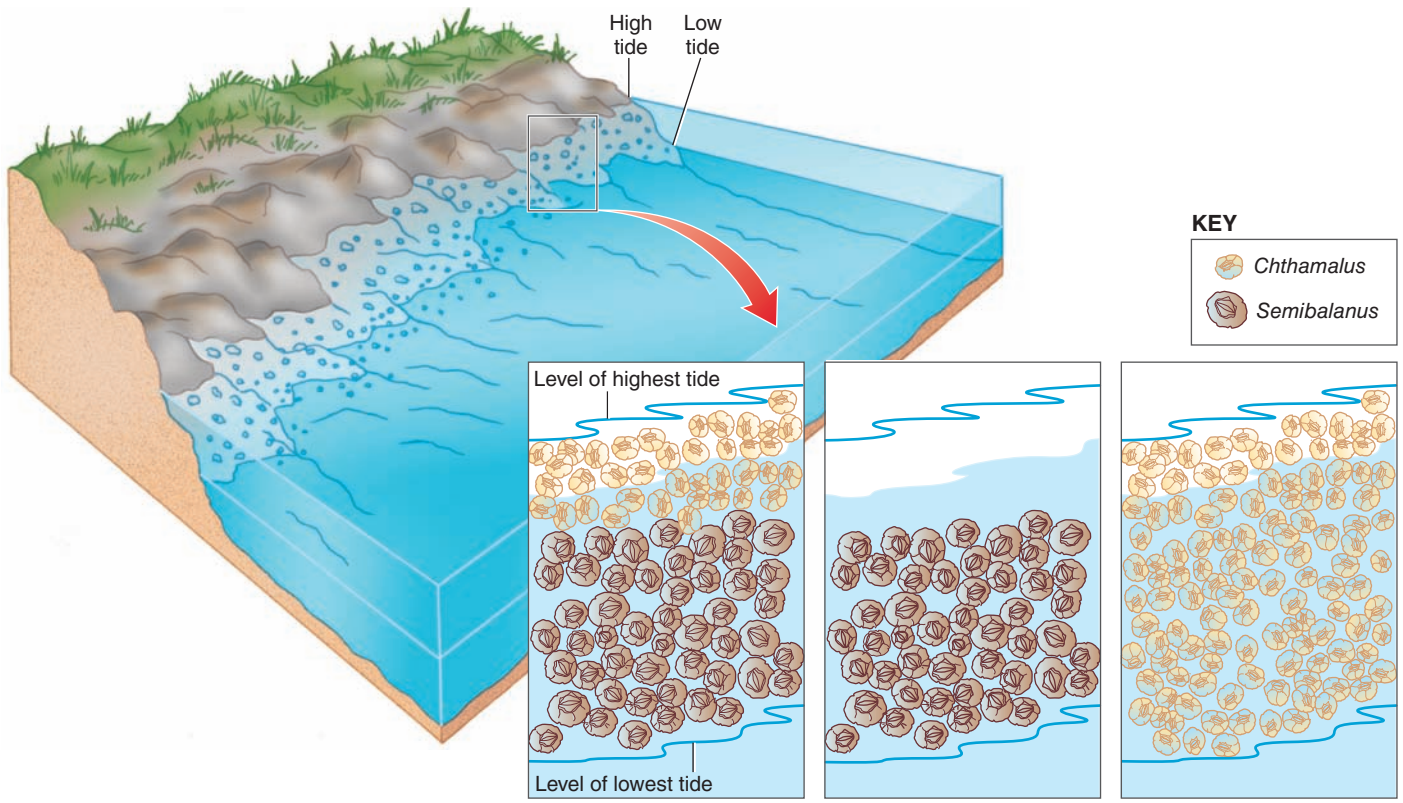

Figure 54-4 Abiotic and biotic factors that affect barnacle distribution

After J.H. Connell, "The Influence of Interspecific Competition and Other Factors on the Distribution of the Barnacle *Chthamalus stellatus*," *Ecology*, Vol. 42 (1961).

(a) Species of barnacles belonging to two genera, *Chthamalus* and *Semibalanus*, grow in the intertidal zone of a rocky shore in Scotland.

(b) When *Chthamalus* individuals were experimentally removed, *Semibalanus* individuals did not expand into their section of the rock.

(c) When *Semibalanus* individuals were experimentally removed, *Chthamalus* individuals spread into the empty area.

Table 54-1 Ecological Interactions among Species

Interaction	Effect on Species 1	Effect on Species 2
Competition between species 1 and species 2	Harmful	Harmful
Predation of species 2 (prey) by species 1 (predator)	Beneficial	Harmful
Symbiosis		
Mutualism of species 1 and species 2	Beneficial	Beneficial
Commensalism of species 1 with species 2	Beneficial	No effect
Parasitism by species 1 (parasite) on species 2 (host)	Beneficial	Harmful

Ecologists traditionally assumed that competition is the most important determinant of both the number of species found in a community and the size of each population. Today ecologists recognize that competition is only one of many interacting biotic and abiotic factors that affect community structure. Furthermore, competition is not always a straightforward, direct interaction. Several kinds of flowering plants, for example, live in a young pine forest and presumably compete with the conifers for such resources as soil moisture and soil minerals. Their relationship, however, is more complex than simple competition. The flowers produce nectar that is consumed by some insect species that also prey on needle-eating insects, thereby reducing the number of insects feeding on pines. It is therefore difficult to assess the overall effect of flowering plants on pines. If the flowering plants were removed from the community, would the pines grow faster because they were no longer competing for necessary resources? Or would the increased presence of needle-eating insects (caused by fewer predatory insects) inhibit pine growth?

Short-term experiments in which one competing plant species is removed from a forest community have often demonstrated an improved growth for the remaining species. However, very few studies have tested the long-term effects on forest species of removing a single competing species. These long-term effects may be subtle, indirect, and difficult to ascertain; they may lessen or negate the short-term effects of competition for resources.

Competition between species with overlapping niches may lead to competitive exclusion When two species are similar, as are the green and brown anoles or the two species of barnacles, their fundamental niches may overlap. However, based on experimental and modeling work, many ecologists think that no two species indefinitely occupy the same niche in the same community. According to the **competitive exclusion principle**, it is hypothesized that one species excludes another from its niche as a result of interspecific competition. Although it is possible for species to compete for some necessary resource without being total competitors, two species with absolutely identical ecological niches cannot coexist. Coexistence occurs, however, if the overlap between the two niches is reduced. In the lizard example, direct competition between the two species was reduced as the brown anole excluded the green anole from most of its former habitat.

The initial evidence that interspecific competition contributes to a species' realized niche came from a series of laboratory experiments by Russian biologist Georgyi F. Gause in the 1930s. In one study Gause grew populations of two species of protozoa, *Paramecium aurelia* and the larger *P. caudatum*, in controlled conditions (FIG. 54-5). When grown in separate test tubes—that is, in the absence of the second species—the population of each species quickly increased to a level imposed by the resources and remained there for some time thereafter. When grown together, however, only *P. aurelia* thrived, whereas *P. caudatum* dwindled and eventually died out. Under different sets of culture conditions, *P. caudatum* prevailed over *P. aurelia*. Gause interpreted these results to mean that although one set of conditions favored one species, a different set favored the other. Nonetheless, because both species were so similar, in time one or the other would eventually triumph. Similar experiments with competing species of fruit flies, mice, beetles, and annual plants have supported Gause's results: one species thrives, and the other eventually dies out.

Thus, competition has adverse effects on species that use a limited resource and may result in competitive exclusion of one or more species. It therefore follows that over time natural selection should favor individuals of each species that avoid or reduce competition for environmental resources. Reduced competition among coexisting species as a result of each species' niche differing from the others in one or more ways is called **resource partitioning**. Resource partitioning is well-documented in animals; studies in tropical forests of Central America and South America demonstrate little overlap in the diets of fruit-eating birds, primates, and bats that coexist in the same habitat. Although fruits are the primary food for several hundred bird, primate, and bat species, the wide variety of fruits available has allowed fruit eaters to specialize, which reduces competition.

Resource partitioning may also include timing of feeding, location of feeding, nest sites, and other aspects of a species' ecological niche. Princeton ecologist Robert MacArthur's study of five North American warbler species is a classic example of resource partitioning (FIG. 54-6). Although initially the warblers' niches seemed nearly identical, MacArthur found that individuals of each species spend most of their feeding time in different portions of the spruces and other conifer trees they frequent. They also move in different directions through the canopy, consume different combinations of insects, and nest at slightly different times.

Difference in root depth is an example of resource partitioning in plants. For example, three common annuals found in certain abandoned fields are smartweed, Indian mallow, and bristly foxtail. Smartweed roots extend deep into the soil, Indian mallow roots grow to a medium depth, and bristly foxtail roots are shallow. This difference reduces competition for the same soil resources—water and minerals—by allowing the plants to exploit different portions of the resource.

Character displacement is an adaptive consequence of interspecific competition Sometimes populations of two similar species occur together in some locations and separately in others. Where their geographic distributions overlap, the two species tend to differ more in their structural, ecological, and behavioral characteristics than they do where

Key Experiment

Can competitive exclusion be demonstrated in the laboratory under controlled conditions?

HYPOTHESIS: When two species of paramecia (ciliated protozoa) are grown together in a mixed culture, one species outcompetes the other.

EXPERIMENT: Gause grew two species of paramecia, both separately and together.

RESULTS AND CONCLUSION: The *top* and *middle graphs* show how each species of *Paramecium* flourishes when grown alone. The *bottom graph* shows how they grow together, in competition with each other. In a mixed culture, *P. aurelia* outcompetes *P. caudatum*, resulting in competitive exclusion.

SOURCE: Adapted from G.F. Gause, *The Struggle for Existence* (Williams and Wilkins, Baltimore, 1934).

Figure 54-5 G.F. Gause's classic experiment on interspecific competition

PREDICT What would happen to the two competing cultures shown in the bottom graph if a medium containing a nutrient that could be metabolized only by *P. caudatum* replaced the existing growth medium at day 6?

each occurs in separate geographic areas. Such divergence in traits in two similar species living in the same geographic area is known as **character displacement**. Biologists think that character displacement reduces competition between two species because their differences give them somewhat different ecological niches in the same environment.

There are several well-documented examples of character displacement between two closely related species. The flowers of two *Solanum* species in Mexico are quite similar in

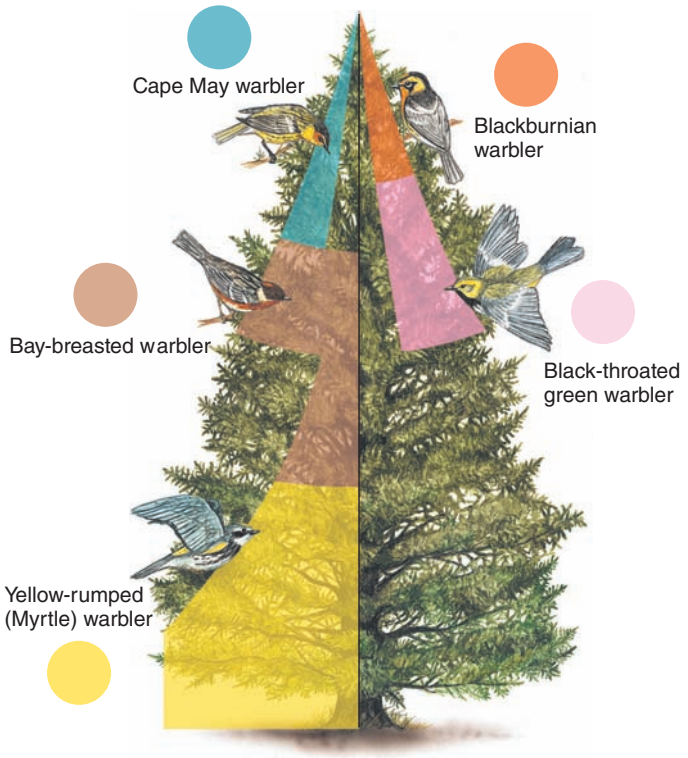

Figure 54-6 Resource partitioning

Each warbler species spends at least half its foraging time in its designated area of a spruce tree, thereby reducing the competition among warbler species. After R.H. MacArthur, "Population Ecology of Some Warblers of Northeastern Coniferous Forests," *Ecology*, Vol. 39 (1958).

areas where either one or the other occurs. However, where their distributions overlap, the two species differ significantly in flower size and are pollinated by different kinds of bees. In other words, character displacement reduces interspecific competition, in this case for the same animal pollinator.

The bill sizes of Darwin's finches provide another example of character displacement (FIG. 54-7). On large islands in the Galápagos where the medium ground finch (*Geospiza fortis*) and the small ground finch (*G. fuliginosa*) occur together, their bill depths are distinctive. *Geospiza fuliginosa* has a smaller bill depth that enables it to crack small seeds, whereas *G. fortis* has a larger bill depth that enables it to crack medium-sized seeds. However, *G. fortis* and *G. fuliginosa* also live on separate islands. Where the two species live separately, bill depths are about the same intermediate size, perhaps because there is no competition from the other species.

Although these examples of the coexistence of similar species are explained in terms of character displacement, the character displacement hypothesis has been demonstrated in nature in only a few instances. In 2006, Peter and Rosemary Grant, who had studied Darwin's finches in the Galápagos Islands since the 1970s, reported in the journal *Science* another example of character displacement in Darwin's finches. The medium ground finch (*G. fortis*) originally lived on one of the small Galápagos islands by itself. Different *G. fortis* individuals had varying beak sizes that allowed them to eat small, medium, or

Key Experiment

Can character displacement be demonstrated in the wild?

HYPOTHESIS: Two species of finches are more different where they occur together than where they occur separately.

EXPERIMENT: Two species of Darwin's finches in the Galápagos were observed on islands where they occur separately and on an island where they exist together. Bill depth **(a)**, which varies considerably in the two species, was measured in the different environments.

RESULTS AND CONCLUSION: **(b)** Where the two species are found on the same island (Santa Cruz), *G. fuliginosa* (*red*) has a smaller average bill depth than *G. fortis* (*blue*). Where they occur on separate islands (**c**, on Daphne Major, and **d**, on Los Hermanos), the average bill depths of each are similar. Thus, they illustrate character displacement.

SOURCE: After D. Lack, *Darwin's Finches* (Cambridge University Press, Cambridge, 1947).

Figure 54-7 Character displacement

PREDICT If *G. fuliginosa* were removed from the shared island, would you expect the beaks of the *G. fortis* population to change over time? In what way?

large seeds. However, in recent years the large ground finch (*G. magnirostris*) colonized the island and began to compete with the medium ground finch for the larger seeds. A severe drought reduced the seed supply, putting additional pressure on the medium finch population. In response, the medium ground finch's beak quickly diverged, becoming significantly smaller in length, depth, and width on average than it had been. The altered population of medium ground finches now consumes small seeds almost exclusively; their small beaks cannot crack the larger seeds preferred by the large ground finch.

Natural selection shapes the bodies and behaviors of both predator and prey

Predation is the consumption of one species, the *prey*, by another, the *predator* (see Table 54-1). Predation includes animals eating other animals as well as animals eating plants (*herbivory*). Predation has resulted in an evolutionary "arms race," with the evolution of predator strategies (more efficient ways to catch prey) and prey strategies (better ways to escape the predator). A predator that is more efficient at catching prey exerts a strong selective force on its prey. Over time, adaptations that reduce the probability of being captured may evolve in the prey species. In turn, these adaptations exert a strong selective force on the predator. This type of interdependent evolution of two interacting species is known as **coevolution** (see discussion of coevolution in Chapter 37).

We now consider several adaptations related to predator–prey interactions, including predator strategies (pursuit and ambush) and prey strategies (plant defenses and animal defenses). Keep in mind as you read these descriptions that such strategies are not "chosen" by the respective predators or prey. New traits arise randomly in a population as a result of genetic changes. Some new traits are beneficial, some are harmful, and others have no effect. Beneficial strategies, or traits, persist in a population because such characteristics make the individuals that have them well suited to thrive and reproduce. In contrast, characteristics that make the individuals that have them poorly suited to their environment tend to disappear in a population.

Pursuit and ambush are two predator strategies

A brown pelican sights its prey—a fish—while in flight. Less than 2 seconds after diving into the water at a speed as great as 72 km/h (45 mph), it has its catch. Orcas, formerly known as killer whales, hunt in packs and often herd salmon or tuna into a cove so that they are easier to catch. Any trait that increases hunting efficiency, such as the speed of brown pelicans or the intelligence and cooperative behavior of orcas, favors predators that pursue their prey. Because these carnivores must process information quickly during the pursuit of prey, their brains are generally larger, relative to body size, than those of the prey they pursue.

Ambush is another effective way to catch prey. The yellow crab spider, for example, is the same color as the white or yellow flowers on which it hides (FIG. 54-8). This camouflage keeps unwary insects that visit the flower for nectar from noticing the spider until it is too late. It also fools birds that prey on the crab spider.

Predators that *attract* prey are particularly effective at ambushing. For example, a diverse group of deep-sea fishes

called anglerfish possess rodlike bioluminescent lures close to their mouths to attract prey.

Chemical protection is an effective plant defense against herbivores Plants cannot escape predators by fleeing, but they have several physical and chemical adaptations that protect them from being eaten. The presence of spines, thorns, tough leathery leaves, or even thick wax on leaves discourages foraging herbivores from grazing. Other plants produce an array of protective chemicals that are unpalatable or even toxic to herbivores. The active ingredients in such plants as marijuana and tobacco affect hormone activity and nerve, muscle, liver, and kidney functions and may discourage foraging by herbivores. Interestingly, many of the chemical defenses in plants are useful to humans. India's neem tree, for example, contains chemicals effective against more than 100 species of herbivorous insects, mites, and nematodes. Nicotine from tobacco, pyrethrum from chrysanthemum, and rotenone from the derris plant are other examples of chemicals extracted and used as insecticides.

Milkweeds are an excellent example of the biochemical coevolution between plants and herbivores (FIG. 54-9). Milkweeds produce alkaloids and cardiac glycosides, chemicals that are poisonous to all animals except a small group of insects. The ability to either tolerate or metabolize the milkweed toxins has evolved in these insects. They eat milkweeds and avoid competition from other herbivorous insects because few others tolerate milkweed toxins. Predators also learn to avoid these insects, which accumulate the toxins in their tissues and therefore become toxic themselves. The black, white, and yellow coloration of the monarch caterpillar, a milkweed feeder, clearly announces its toxicity to predators that have learned to associate bright colors with illness. Conspicuous colors or patterns, which advertise a species' unpalatability to potential predators, are known as **aposematic coloration** (pronounced "ap′-uh-suh-mat′-ik"; from the Greek *apo*, "away," and *semat*, "a mark or sign"), or **warning coloration**.

Animal prey possess various defensive adaptations to avoid predators Many animals, such as prairie voles and woodchucks, flee from predators by running to their underground burrows. Others have mechanical defenses, such as the barbed quills of a porcupine and the shell of a pond turtle. To discourage predators, the porcupine fish inflates itself to three times its normal size by pumping water into its stomach (see Fig. 32-14a). Some animals live in groups, such as a herd of antelope, colony of honeybees, school of anchovies, or flock of pigeons. Because a group has so many eyes, ears, and noses watching, listening, and smelling for predators, this social behavior decreases the likelihood of a predator catching any one of them unaware.

Chemical defenses are also common among animal prey. The South American poison arrow frog (*Dendrobates*) stores poison in its skin. (These frogs obtain the toxins from ants and other insects in their diet.) The frog's bright aposematic coloration prompts avoidance by experienced predators (see Fig. 32-18a). Snakes and other animals that have tried once to eat a poisonous frog do not repeat their mistake! Other examples of aposematic coloration occur in the striped skunk, which sprays acrid chemicals from its anal glands, and the bombardier beetle, which spews harsh chemicals at potential predators (see Fig. 7-8).

Some animals have **cryptic coloration**, colors or markings that help them hide from predators by blending into their physical surroundings. Certain caterpillars resemble twigs so closely that you would never guess that they were animals unless they moved. Pipefish are slender green fish that are almost perfectly camouflaged in green eelgrass. Leaf-tailed geckos in southern Madagascar resemble dead leaves or mossy bark, depending on the species (FIG. 54-10). Such cryptic coloration has been preserved and accentuated by means of natural selection. Predators are less likely to capture animals with cryptic coloration than other animals. Such animals are therefore more likely to live to maturity and produce offspring that also carry the genes for cryptic coloration.

Figure 54-10 Cryptic coloration

The mossy leaf-tailed gecko (*Uroplatus sikorae*) hunts for insects by night and sleeps pressed against a tree branch by day. It is virtually invisible when it sleeps (look closely to see its head and front foot). Photographed in a rain forest in southern Madagascar.

Sometimes a defenseless species (a *mimic*) is protected from predation by its resemblance to a species that is dangerous in some way (a *model*). Such a strategy is known as **Batesian mimicry**. Many examples of this phenomenon exist. For example, a harmless scarlet king snake looks so much like a venomous coral snake that predators may avoid it (FIG. 54-11). Interestingly, the range of the scarlet king snake extends far beyond that of the coral snake. In an area where coral snakes do not occur, having the coloration of the model confers no special advantage to the king snake and may be harmful, triggering natural selection. This seems to be the case: scientists have reported that scarlet king snake populations located far from coral snakes have undergone natural selection and look less like their model.

In **Müllerian mimicry**, two or more different species (*co-models*), all of which are poisonous, harmful, or distasteful, come to resemble one another during the course of evolution. Although their harmfulness protects them as individual species, their similarity in appearance works as an adaptive advantage because potential predators more easily learn a single common aposematic coloration. Scientists hypothesize that viceroy and monarch butterflies are an example of Müllerian mimicry. Researchers have found that fewer butterflies of either species are eaten and more individuals survive to reproduce.

Symbiosis involves a close association between species

Symbiosis is any intimate relationship or association between members of two or more species. Usually, symbiosis involves one species living on or in another species. The partners of a symbiotic relationship, called **symbionts**, may benefit from, be unaffected by, or be harmed by the relationship (see Table 54-1). Examples of symbiosis occur across all the domains and kingdoms of life. Most of the millions of symbiotic associations are products of coevolution. Symbiosis takes three forms: mutualism, commensalism, and parasitism.

Benefits are shared in mutualism **Mutualism** is a symbiotic relationship in which both partners benefit. Mutualism is either obligate (essential for the survival of both species) or facultative (either partner can live alone under certain conditions).

Inquiring About

The Human Microbiota: Our Many Symbionts

We humans are much more complex than you might imagine, particularly when we identify and count our microbiota. Tens (or even hundreds) of trillions of bacteria, fungi, archaea, protists, and viruses colonize the human body. Biologists have yet to agree on a total count for our symbionts. Currently, researchers estimate that our bacteria count alone surpasses the number of our human cells (about 30 trillion for an adult male) and likely outnumbers them by a ratio of more than 3:1. These figures do not take into account the various species of worms and the many arthropod parasites we may carry.

The majority of microbiota colonize our gastrointestinal tract, but distinct, diverse populations also reside on our skin and on or within our mouth, genitourinary tract, lungs, and body fluids. Biologists now understand that our microbiota play an extremely significant role both in maintaining our health and in preventing disease. Our microbiota support digestion, improve nutrition, help regulate metabolism and the immune system, and repel pathogen invasions. The symbiotic relationships between our microbiota and our human cells are not always mutual or commensal, however.

When the normal habitats, or balance, of the symbiont ecosystem is disturbed, or altered, some of our microbiotic relationships can contribute to or cause disease. Crohn's disease, irritable bowel syndrome, chronic periodontitis, obesity, cancer, and bacterial vaginosis are examples. Antibiotic-associated diarrhea is a disturbance in which abrupt changes occur in the gut community composition. Many members of the community are killed by antibiotics, providing niches for opportunistic pathogens and/or overgrowth of remaining species of bacteria. *Clostridium difficile*, for example, is responsible for serious and often long-term diarrhea after a course of antibiotics. In extreme cases, the colon can become inflamed, resulting in serious infection and even death.

Recent advances in gene sequencing, genomics, and associated technologies, along with the growing research in microbial ecology, continue to rapidly expand our understanding of how we humans and our symbionts have coevolved. Biologists are now able to quickly survey our microbiota to answer many species diversity questions. Research is complicated not only by the incredible diversity of the microbiota, but also by many variations between individual humans and composition changes of communities at different stages of our lives. Biologists are now constructing a multifaceted view of how the microbial community works synergistically among species, including humans. Exploration and development of new methods that target, or deliberately manipulate, our microbiota will benefit our future health and survival.

Eye of Science / Science Source

Colorized SEM of bacteria on the end of an endoscope after a colonoscopy. This is a very small sample of the many types of bacteria that inhabit the colon.

The association between *nitrogen-fixing bacteria* of the genus *Rhizobium* and legumes (plants such as peas, beans, and clover) is an example of mutualism (see Fig. 55-9). Nitrogen-fixing bacteria, which live inside nodules on the roots of legumes, supply the plants with most of the nitrogen they require to manufacture such nitrogen-containing compounds as chlorophylls, proteins, and nucleic acids. The legumes supply sugars and other energy-rich organic molecules to their bacterial symbionts.

Another example of mutualism is the association between reef-building animals and dinoflagellates called **zooxanthellae**. These symbiotic protists live inside cells of the coral polyp (the coral forms a vacuole around the algal cell), where they photosynthesize and provide the animal with carbon and nitrogen compounds as well as oxygen (FIG. 54-12). Calcium carbonate skeletons form around the coral bodies much faster when zooxanthellae are present; their faster growth helps the corals dominate their location on a reef. The corals, in turn, supply the zooxanthellae with waste products such as ammonia, which the algae use to make nitrogen compounds for both partners. (Also see the discussion in Chapter 31 and Fig. 31-6.)

Mycorrhizae are mutualistic associations between fungi and the roots of plants. The association is common; biologists think that nearly 90% of all plant species have mycorrhizae. The fungus, which grows around and into the root as well as into the surrounding soil, absorbs essential minerals, especially phosphorus, from the soil and provides them to the plant. In return, the plant provides the fungus with organic molecules produced by photosynthesis. Plants grow more vigorously in the presence of mycorrhizal fungi (see Figs. 29-19 and 36-11), and they better tolerate

Oxford Scientific/Getty Images

Figure 54-12 Mutualism

The *greenish brown specks* in these polyps of stony coral (*Pocillopora*) are zooxanthellae, dinoflagellates that live symbiotically within the coral's translucent cells and supply the coral with carbon and nitrogen compounds. In return, the coral provides the zooxanthellae with nitrogen in the form of ammonia.

environmental stressors such as drought and high soil temperatures. Indeed, some plants cannot maintain themselves under natural conditions if the fungi with which they normally form mycorrhizae are not present.

Humans and bacteria also share mutualistic relationships. Recall that the term **microbiome** refers to a community of microorganisms, including their genomes and interactions (see Chapter 25). The term human **microbiota** refers to the community of microorganisms that inhabit the human body. The human intestinal microbiota includes bacteria that receive shelter and nutrients in exchange for breaking down complex carbohydrates and producing vitamins. In addition, human intestinal microbiota ferment unused materials, prevent colonization by pathogenic bacteria, and strengthen the immune system. Recent research suggests that intestinal microbiota are involved in endocrine and neurological functions and may play a major role in diseases such as diabetes and obesity (see *Inquiring About: The Human Microbiota: Our Many Symbionts*).

Commensalism is taking without harming

Commensalism is a type of symbiosis in which one species benefits and the other one is neither harmed nor helped. One example of commensalism is the relationship between social insects and scavengers, such as mites, beetles, or millipedes, which live in the social insects' nests. Certain types of silverfish, for example, move along in permanent association with marching columns of army ants and share the abundant food caught in the ant raids. The army ants derive no apparent benefit or harm from the silverfish.

Another example of commensalism is the relationship between a host tree and its epiphytes, which are smaller plants, such as orchids, ferns, or Spanish moss, attached to the host's branches (FIG. 54-13). The epiphyte anchors itself to the tree but does not obtain nutrients or water directly from it. Living on the tree enables it to obtain adequate light, water (as rainfall dripping down the branches), and required minerals (washed out of the tree's leaves by rainfall). Thus, the epiphyte benefits from the association, whereas the tree is apparently unaffected. (Epiphytes harm their host, however, if they are present in a large enough number to block sunlight from the host's leaves; in this instance, the relationship is no longer commensalism.)

Pete Oxford/Getty Images

Figure 54-13 Commensalism

Spanish moss (*Tillandsia usneoides*) is a gray-colored epiphyte that hangs suspended from larger plants in the southeastern United States. Spanish moss is not a moss but a flowering plant in the bromeliad, or pineapple, family. It often grows 6 m (20 ft) or longer, but it is not a parasite and rarely harms the host tree. Spanish moss provides shelter to small animals such as bats, spiders, and snakes.

Parasitism is taking at another's expense

Parasitism is a symbiotic relationship in which one member, the **parasite**, benefits, whereas the other, the **host**, is adversely affected. The parasite obtains nourishment from its host. A parasite rarely kills its host directly but may weaken it, rendering it more vulnerable to predators, competitors, or abiotic stressors. When a parasite causes disease and sometimes the death of a host, it is called a **pathogen**.

Ticks and other parasites that live outside the host's body are called **ectoparasites**. Figure 32-9 shows a lamprey, an ectoparasite on fish. Parasites such as tapeworms that live within the host are called **endoparasites**. Parasitism is a successful lifestyle. By one estimate, more than two-thirds of all species are parasites, and nearly 1000 species of parasites (including fungi, bacteria, viruses, and other animals) live in or on the human species! Examples of human parasites include *Entamoeba histolytica*, an amoeba that causes amoebic dysentery; *Plasmodium*, an apicomplexan that causes malaria; a variety of parasitic worms, such as blood flukes, tapeworms, pinworms, and hookworms (see Figs. 31-9 and 31-11); and *Pseudomonas aeruginosa*, an opportunistic bacterium responsible for many urinary tract and respiratory system infections.

Since the 1980s, wild and domestic honeybees in the United States have been dying off. According to the U.S. Department of Agriculture, many beekeepers have lost one-third to one-half of their bees each winter from a condition called colony collapse disorder. Habitat loss, severe weather, pesticide use, and higher pathogen load, as well as the mite *Varroa destructor* and smaller tracheal mites, have contributed to the problem. Although research continues, many scientists think that a combination of stressors may be the major reason for the continued honeybee decline (FIG. 54-14).

U.S. Department of Agriculture/Agricultural Research Service

Figure 54-14 Parasitism

Microscopic tracheal mites (*Acarapis woodi*) are endoparasites that live in the tracheal tubes of honeybees, clogging their airways so that they cannot breathe efficiently. Tracheal mites also suck the bees' circulatory fluid, weakening and eventually killing them. Entomologists think that the larger varroa mites (*not shown*), which are ectoparasites that also feed on the circulatory fluid, are more devastating to honeybee populations than are tracheal mites. Mites may also transmit viruses to their honeybee hosts.

CHECKPOINT 54.1

- **CONNECT** How are acorns, gypsy moths, and Lyme disease related?
- Why is an organism's realized niche usually narrower, or more restricted, than its fundamental niche?
- **CONNECT** Which principle of community ecology is illustrated by the following example: Two closely related species of small fish occupy the upper two feet of water when they occur in separate ponds, but if they are in the same pond, species *a* is more often found in the uppermost foot, and species *b* in the foot below.
- Name the three kinds of symbiosis and give an example of each.

54.2 Strength and Direction of Community Interactions

LEARNING OBJECTIVES

6 Distinguish between keystone species and dominant species.
7 Distinguish between bottom-up and top-down processes in ecosystem regulation.

There is a great deal of variation in the strength and direction of interactions among species within ecological communities. Some species, known as *keystone species*, are present in a community in low abundance and/or biomass but have strong effects on their communities. Other species, known as *dominant species*, exert strong effects on their communities because they are present in great abundance and/or biomass.

Two types of control affect ecological communities, bottom-up processes and top-down processes. In *bottom-up processes* nutrient availability or food organisms whose population is directly affected by nutrient availability affect the abundance of other community organisms. In *top-down processes* predators impact the abundance of other populations in the community. We now examine these aspects of interactions among species within ecological communities.

Other species of a community depend on or are greatly affected by keystone species

Certain species, called **keystone species**, are crucial in determining the nature of the entire community—its species composition and ecosystem functioning. Keystone species are usually not the most abundant species in the community. Although present in relatively small numbers, the individuals of a keystone species profoundly influence the entire community because they often impact the amount of available food, water, or some other resource. Thus, the impact of keystone species is greatly disproportionate to their abundance. Identifying and protecting keystone species are crucial goals of conservation biology (see Chapter 57). If a keystone species disappears from a community, many other species in that community may become more common or rarer, or may even disappear.

The term *keystone* species was coined by ecologist Robert T. Paine in 1969, based on his experimental studies along the Pacific coast in the state of Washington (FIG. 54-15). Paine removed a predatory sea star, *Pisaster ochraceus*, from a rocky intertidal community that included barnacles, mussels, limpets, and chitons, all of which the sea star preyed on. He observed the changes in community structure that resulted and compared these changes to a nearby control area in which the sea stars were left intact. After the sea stars were removed, about half of the 15 species disappeared from the test area. They were crowded out by certain mussel and barnacle populations, which increased rapidly when freed from predation by the sea stars. Paine noted that when a keystone predator such as the sea star is removed from a community, the species diversity, abundance, and distribution of that community changes dramatically.

One problem with the concept of keystone species is that it is often difficult to measure all the direct and indirect effects of a keystone species on an ecosystem. Consequently, most evidence for the existence of keystone species is based on indirect observations rather than on experimental manipulations. For example, consider the fig tree. Because fig trees produce a continuous crop of fruits, they may be keystone species in tropical rain forests of Central America and South America. Fruit-eating monkeys, birds, bats, and other fruit-eating vertebrates of the forest do not normally consume large quantities of figs in their diets.

During that time of the year when other fruits are less plentiful, however, fig trees become important in sustaining fruit-eating vertebrates. It is therefore assumed that should the fig trees disappear, most of the fruit-eating vertebrates would

Pisaster sea stars and chitons cling to the rock during low tide. *Pisaster* sea stars range in color from purple to brown to orange. Photographed in the summer in the Pacific Northwest.

as ravens, bald eagles, and grizzly bears have benefited from dining on scraps from wolf-kills.

Biologists think prey populations of elk in Yellowstone may now be in balance with the wolf population. Researchers have also recorded increases in the numbers of bear and cougar, which also feed on elk, resulting in a more balanced, healthier ecosystem. Interestingly, researchers have reported increases in the beaver population, resulting from the reintroduction of the wolves, part of the continued cascade effect. Apparently, wolves keep elk herds on the move, which reduces browsing on willow stems. The recovery of willow stands supports more beavers and an expanded habitat for songbirds. The beavers continue the cascade effect in the ecosystem by building more dams. The ponds and streams become deeper, supporting an expanded fish population.

also disappear. In turn, should the fruit eaters disappear, the spatial distribution of other fruit-bearing plants would become more limited because the fruit eaters help disperse their seeds. Thus, protecting fig trees in such tropical rainforest ecosystems probably increases the likelihood that monkeys, birds, bats, and many other tree species will survive. The question is whether this anecdotal evidence of fig trees as keystone species is strong enough for policy makers to grant special protection to fig trees.

Like the *Pisaster* sea stars, many keystone species are top predators; for example, consider the gray wolf. Where wolves were hunted to extinction, populations of elk, deer, and other larger herbivores increased exponentially. As these herbivores overgrazed the vegetation, many plant species that could not tolerate such grazing pressure disappeared. Smaller animals such as rodents, rabbits, and insects declined in number because the plants they depended on for food were now less abundant. The number of foxes, hawks, owls, and badgers that prey on these small animals decreased, as did the number of ravens, eagles, and other scavengers that eat wolf-kill. Thus, the disappearance of the wolf resulted in communities with considerably less biological diversity.

The reintroduction of wolves to Yellowstone National Park in 1995 has given ecologists a unique opportunity to study the impact of a keystone species. The wolf's return has already caused substantial changes for other residents in the park. The top predator's effects have ranged from altering relationships among predator and prey species to transforming vegetation profiles. Coyotes are potential prey for wolves, and wolf packs have decimated some coyote populations. A reduction in coyotes has allowed populations of the coyotes' prey, such as ground squirrels and chipmunks, to increase. Scavengers such

Dominant species influence a community as a result of their greater size or abundance

In contrast to keystone species, which have a large impact out of proportion to their abundance, **dominant species** greatly affect the community because they are very common. Trees, the dominant species of forests, change the local environment. Trees provide shade, which changes both the light and moisture availability on the forest floor. Trees provide numerous habitats and *microhabitats* (such as a hole in a tree trunk or a rotting log) for other species. Forest trees also provide food for many organisms and therefore play a large role in energy flow through the forest ecosystem. Similarly, cordgrass (*Spartina*) is the dominant species in salt marshes, prairie grass in grasslands, and kelp in kelp beds. Animals are also dominant species. Corals, for example, are dominant species in coral reefs, and cattle are dominant species in overgrazed rangelands. Typically, a community has one or a few dominant species, and most other species are relatively rare.

Ecosystem regulation occurs from the bottom up and top down

One question that ecologists have recently considered is which regulatory process—bottom-up or top-down—is more significant in the regulation of various ecosystems. Both energy flow (see Fig. 1-8) and cycles of matter are involved in bottom-up and top-down processes. **Bottom-up processes** are based on **food webs**, the interconnected series of organisms through

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

which energy flows in an ecosystem. Food webs always have plants or other producers at the first (lowest) trophic level (FIG. 54-16a). (A *trophic level* is an organism's position in a food web; e.g., producers are the first trophic level, and plant-eating herbivores are the second level.) In a sense, the biogeochemical cycles that regenerate necessary nutrients such as nitrates and phosphates for producers to assimilate are located "under" the first trophic level. Thus, bottom-up processes regulate ecosystem function by nutrient cycling and by availability of other resources. If bottom-up processes dominate an ecosystem, the availability of resources such as water or soil minerals controls the number of producers, which controls the number of herbivores, which controls the number of carnivores. (Recall the discussion earlier in this chapter explaining that *limiting resources* tend to restrict the ecological niches of organisms, which affects population size.)

Bottom-up processes apparently predominate in certain aquatic ecosystems in which nitrogen or phosphorus is limiting. An experiment in which phosphorus was added to a phosphorus-deficient river (the Kaparuk River in Alaska) resulted in an increase in algae, followed over time by increased populations of aquatic insects, other invertebrates, and fishes.

In contrast, **top-down processes** regulate ecosystem function by trophic interactions, particularly from the highest trophic level (FIG. 54-16b). Ecosystem regulation by top-down processes occurs because carnivores eat herbivores, which eat producers, which impacts levels of nutrients. If top-down processes dominate an ecosystem, the effects of an increase in the population of top predators cascades down the food web through the herbivores and producers. In fact, top-down processes are also known as a *trophic cascade*.

A change in the feeding preferences of orcas, off the coast of Alaska, provides an excellent example of a trophic cascade. A few decades ago, when orcas began preying on sea otters, the sea otter population sharply declined. As sea otters have declined, the number of sea urchins, which sea otters eat, has increased. Sea urchins eat kelp, the producers at the base of the food web, and the increase in the number of sea urchins has caused a decline in kelp populations. Kelp forests help reduce levels of carbon dioxide, a greenhouse gas that contributes to climate warming (discussed in Chapter 57).

(a) Bottom-up processes. (b) Top-down processes.

Figure 54-16 Bottom-up and top-down processes

Top-down regulation appears to predominate in ecosystems with few trophic levels and low species richness. Such ecosystems may have only one or a few species of dominant herbivores, but those species have a strong impact on the producer populations. An excellent example of top-down regulation—reindeer introduced to the Pribilof Islands of Alaska overgrazed the vegetation until the plants were almost wiped out—was discussed in Chapter 53.

It may be that top-down and bottom-up regulatory processes are not mutually exclusive. In a 13-year study of a thorn-scrub community in north-central Chile, ecologists demonstrated that top-down regulation predominates in certain small desert mammals and plant species. However, during periodic El Niño events (discussed later in the chapter), the increase in precipitation resulted in bottom-up increases in producers and consumers. In this ecosystem, it appears that both top-down and bottom-up regulatory processes are important in trophic dynamics over an extended period.

CHECKPOINT 54.2

- Both dominant and keystone species exert strong effects on the character of a community, but in different ways. How do dominant species and keystone species differ?
- **PREDICT** Biologists think that the reintroduction of wolves to Yellowstone National Park will ultimately result in a more varied and lush plant composition. How could that occur? Is it an example of a bottom-up or top-down process? Why?

54.3 Community Biodiversity

LEARNING OBJECTIVES

8 Summarize the main determinants of species richness in a community and relate species richness to community stability.
9 State the results of the analysis of the distance effect in South Pacific bird species.

Species diversity, species richness, and species evenness vary greatly from one community to another and are influenced by many biotic and abiotic factors. **Species diversity** is a measure of both the number of species within a community (*species richness*) and the relative importance of each species, based on its abundance, productivity, or size.

Species richness, the number of species in a community, is determined by counting the species of interest. Tropical rain forests and coral reefs are examples of communities with extremely high species richness. In contrast, geographically isolated islands and mountaintops exhibit low species

richness. **Species evenness** tells us about the relative abundance of one species compared to other species (FIG. 54-17).

Ecologists have developed various mathematical expressions, such as the *Shannon index*, to represent species diversity quantitatively. These *diversity indices* enable ecologists to compare species diversity in different communities. Conservation biologists use diversity indices as part of a comprehensive approach to saving biodiversity.

Ecologists seek to explain why some communities have more species than others

What determines the number of species in a community? No single conclusive answer exists, but several explanations appear plausible. They include the structural complexity of habitats, geographic isolation, habitat stress, closeness to the margins of adjacent communities, dominance of one species over others, and geologic history. Although these and other environmental factors have positive or negative effects on species richness, there are exceptions and variations in every explanation. Some explanations vary at different spatial scales: an explanation that seems to work at a large geographic scale (such as a continent) may not work at a smaller local scale (such as a meadow).

In many habitats, species richness is related to the structural complexity of habitats. In terrestrial environments, the types of plants growing in an area typically determine structural complexity. A structurally complex community, such as a forest, offers a greater variety of potential ecological niches than does a simple community, such as an arid desert or semiarid grassland (FIG. 54-18). An already complex habitat, such as a coral reef, may become even more complex if species potentially capable of filling vacant ecological niches evolve or migrate into the community because these species create "opportunities" for additional species. Thus, it appears that species richness is self-perpetuating to some degree.

Species richness is inversely related to the geographic isolation of a community. Isolated island communities are generally much less diverse than are communities in similar environments

(a) Low species evenness. In this community the abundance of broomsedge is high relative to the abundance of other wildflowers (burdock, yarrow, and oxeye daisy). Therefore, the community has low species evenness.

(b) High species evenness. In this community each species has the same abundance, and the community has high species evenness.

Figure 54-17 Species evenness

Shown are two hypothetical communities with different species evenness but the same species richness (i.e., each has four species of wildflowers).

Key Point

A community in which the vegetation is structurally complex generally provides animals with more kinds of food and hiding places than a community with a lower structural complexity.

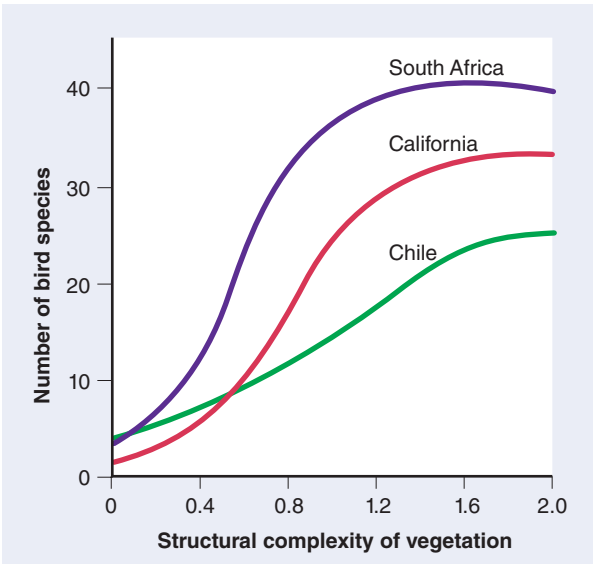

Figure 54-18 Effect of community complexity on species richness

Data were compiled in comparable chaparral habitats (shrubby and woody areas) in Chile, South Africa, and California. The structural complexity of vegetation (*x*-axis) is a numerically assigned gradient of habitats, based on height and density of vegetation, from low complexity (very dry scrub) to high complexity (woodland). After Cody, M.L., and J.M. Diamond, eds., *Ecology and Evolution of Communities* (Harvard University Press, Cambridge, MA, 1975).

Key Experiment

Does the geographic isolation of a community affect its species richness?

HYPOTHESIS: Islands close to the mainland (or to a large island) have a higher species richness than the islands that are farther from the mainland.

EXPERIMENT: The number of bird species was cataloged on South Pacific islands that are various distances from New Guinea, a source of colonizing species for these smaller islands. Each point on the graph represents a different island.

RESULTS AND CONCLUSION: The percentage of South Pacific bird species found on each island in the South Pacific is related to its distance from New Guinea. (New Guinea has 100% of the bird species living in that region.) Thus, species richness declines as the distance from New Guinea increases.

SOURCE: After J.M. Diamond, "Biogeographic Kinetics: Estimation of Relaxation Times for Avifaunas of Southwest Pacific Islands," *Proceedings of the National Academy of Sciences*, Vol. 69 (1972).

Figure 54-19 The distance effect

PREDICT Approximately what percentage of species have colonized islands 2000 km from New Guinea? 6000 km from New Guinea? Based on your answers, explain the relationship between species richness and geographic isolation.

found on continents. This difference is due partly to the *distance effect*, the difficulty encountered by many species in reaching and successfully colonizing the island (FIG. 54-19). Also, sometimes species become locally extinct as a result of random events. In isolated habitats such as islands or mountaintops, locally extinct species are not readily replaced. Isolated areas are usually small and have fewer potential ecological niches.

Generally, species richness is inversely related to the environmental stress of a habitat. Only those species capable of tolerating extreme conditions live in an environmentally stressed community. Thus, the species richness of a highly polluted stream is low compared with that of a nearby pristine stream. Similarly, the species richness of high-latitude (farther from the equator) communities exposed to harsh climates is lower than that of lower latitude (closer to the equator) communities with milder climates (FIG. 54-20). This observation, known as the *species richness–energy hypothesis*, suggests that different latitudes affect species richness because of variations in solar energy. Greater energy may permit more species to coexist in a given region. Although the equatorial countries of Colombia, Ecuador, and Peru occupy only 2% of Earth's land, they contain a remarkable 46,000 native plant species. The continental United States and Canada, with a significantly larger land area, host a total of 19,000 native plant species. Ecuador alone contains more than 1600 native species of birds, twice as many as the United States and Canada combined.

Species richness is usually greater at the margins of distinct communities than in their centers. The reason is that an **ecotone**, a transitional zone where two or more communities meet, contains all or most of the ecological niches of the adjacent communities as well as some that are unique to the ecotone (see Fig. 56-24). This change in species composition produced at ecotones is known as the **edge effect**.

Species richness is reduced when any one species enjoys a position of dominance within a community; a dominant species may appropriate a disproportionate share of available resources, thus crowding out, or outcompeting, other species. Ecologist James H. Brown of the University of New Mexico has addressed species composition and richness in experiments conducted since 1977 in the Chihuahuan Desert of southeastern Arizona. In one experiment the removal of three dominant species, all kangaroo rats, from several plots resulted in an increased diversity of other rodent species. This increase was ascribed both to lowered competition for food and to an altered habitat because the abundance of grass species increased dramatically after the removal of the kangaroo rats.

Species richness is greatly affected by geologic history. Many scientists think that tropical rain forests are old, stable communities that have undergone relatively few widespread disturbances through Earth's history. (In the ecology field, a **disturbance** is any event in time that disrupts community or population structure.) During this time, myriad species evolved in tropical rain forests. In contrast, glaciers have repeatedly altered temperate and arctic regions during Earth's history. An area recently vacated by glaciers will have low species richness because few species have had a chance to enter it and become established. The idea that older, more stable habitats have greater species richness than habitats subjected to frequent, widespread disturbances is known as the *time hypothesis*.

Species richness may promote community stability

Traditionally, most ecologists assumed that community stability—the ability of a community to withstand disturbances—is a consequence of community complexity. That is, ecologists hypothesized that a community with considerable species

Key Point

Species richness increases along a polar → equatorial gradient. This correlation has been observed for many organisms, from plants to primates, in both terrestrial and marine environments.

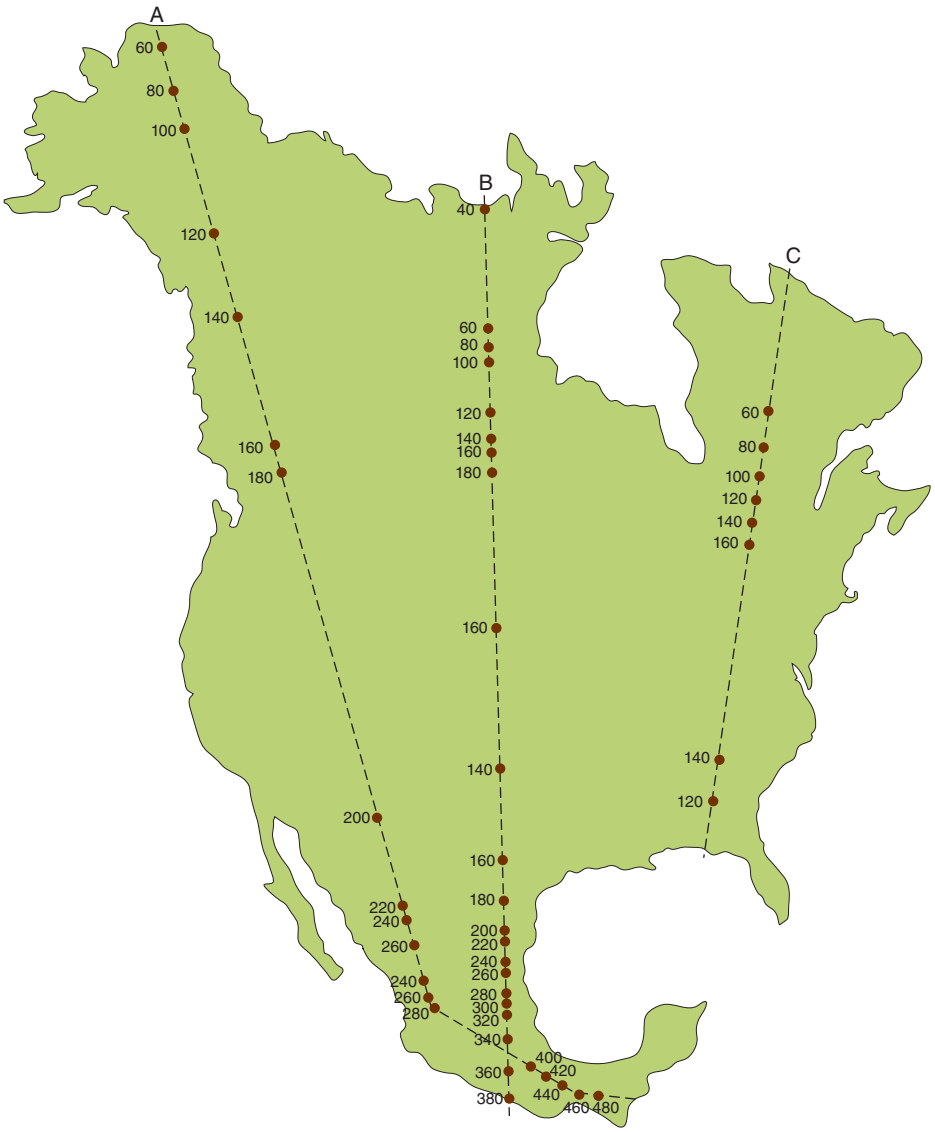

Figure 54-20 Effect of latitude on species richness of breeding birds in North America

The species richness for three north–south transects (A, B, and C) are shown. Note that the overall number of breeding bird species is greater at lower latitudes toward the equator than at higher latitudes. However, this pattern is strongly modified by other factors, such as precipitation and surface features (e.g., mountains). After R.E. Cook, "Variation in Species Density of North American Birds," *Systematic Zoology*, Vol. 18 (1969).

PREDICT How might an increase in temperature over time (climate change) affect species richness in Alaska?

richness is more stable than a community with less species richness. According to this view, the greater the species richness, the less critically important any single species should be. With many possible interactions within the community, it appears unlikely that any single disturbance could affect enough components of the system to make a significant difference in its functioning.

Supporting evidence for this hypothesis is found in destructive outbreaks of pests being more common in cultivated fields, which have a low species richness, than in natural communities with a greater species richness. As another example, the almost complete loss of the American chestnut tree to the chestnut blight fungus had little ecological effect on the moderately diverse Appalachian woodlands of which it was formerly a part.

Ongoing studies by David Tilman of the University of Minnesota and John Downing of the University of Iowa have strengthened the link between species richness and community stability. In their initial study, they established and monitored 207 plots of various grassland species in Minnesota for seven years. During the study period, Minnesota's worst drought in 50 years occurred (1987–1988). The ecologists found that those plots with the greatest number of plant species lost less ground cover, as measured by dry weight, and recovered faster than species-poor plots. Later studies by Tilman and his colleagues supported these conclusions and showed a similar effect of species richness on community stability during non-drought years. Similar work by almost three dozen ecologists at eight grassland sites in Europe also supports the link between species richness and community stability.

Some scientists do not agree with the conclusions of Tilman and other research groups that the presence of more species confers greater community stability. These critics argue that it is difficult to separate species number from other factors that could affect productivity. They suggest that it would be better to start with established ecosystems and study what happens to their productivity when plants are removed.

Another observation that adds a layer of complexity to the species richness–community stability debate is that populations of individual species within a species-rich community often vary significantly from year to year. It may seem paradoxical that variation within populations of individual species relates to the stability of the entire community. When you consider all the interactions among the organisms in a community, however, it is obvious that some species benefit at the expense of others. If one species declines during a particular year, other species that compete with it may flourish. Thus, if an ecosystem contains more species, it is likely that at least some will be resistant to any given disturbance.

CHECKPOINT 54.3

- **CONNECT** How is the species richness of a community related to geographic isolation?
- **CONNECT** How is the structural complexity of habitats relevant to species richness?
- **CONNECT** How is the species richness of a community related to the environmental stress of a habitat?

54.4 Community Development

LEARNING OBJECTIVES

10 Define *succession* and distinguish between primary and secondary succession.

11 Describe the intermediate disturbance hypothesis.

12 Discuss the two traditional views of the nature of communities: Clements's organismic model and Gleason's individualistic model.

A community does not spring into existence full-blown; rather, it develops gradually through a series of stages, each dominated by different organisms. The process of community development over time, which involves species in one stage being replaced by different species, is called **succession**. An area is initially colonized by certain early successional species that give way over time to others, and then, in turn, give way much later to late-successional species.

Succession is usually described in terms of the changes in the species composition of an area's vegetation, although each successional stage also has its own characteristic kinds of animals and other species. The time involved in succession is on the order of tens, hundreds, or thousands of years, not the millions of years involved in the evolutionary time scale.

Ecologists distinguish between two types of succession: primary and secondary. **Primary succession** is the change in species composition over time in a habitat that was not previously inhabited by organisms. No soil exists when primary succession begins. Bare rock surfaces, such as recently formed volcanic lava and rock scraped clean by glaciers, are examples of sites where primary succession might take place (FIG. 54-21).

Sierralara/RooM/Getty Images

(a) After the glacier's retreat, lichens initially colonize the gravel moraine. Mosses and shallow rooted herbs such as mountain avens (*Dryas*) follow.

Don Paulson/Alamy Stock Photo

(b) Dense mats of low-growing *Dryas* plants dominate the landscape, stabilizing the thin layer of developing soil.

Jupiter Images

(c) Alders replace the *Dryas* community. Both alders (*Alnus*) and *Dryas* have nitrogen-fixing bacteria in root nodules that improve the nitrogen content of the soil.

Don Paulson/Alamy Stock Photo

(d) As the condition of the soil improves, Sitka spruce (*Picea sichensis*) replaces the alder community. After several hundred years, the forest consists of Sitka spruce and western hemlock (*Tsuga heterophylla*).

Figure 54-21
Primary succession following retreating glaciers
Ecologists have documented primary succession as glaciers have retreated at Glacier Bay National Park, Alaska.

The Indonesian island of Krakatoa has provided scientists with a perfect long-term study of primary succession in a tropical rain forest. In 1883, a volcanic eruption destroyed virtually all life on the island. Ecologists have surveyed the ecosystem during the years since the devastation to document the return of life-forms. In the 1990s, ecologists found that the progress of primary succession was extremely slow, in part because of Krakatoa's isolation (recall the distance effect discussed earlier in the chapter). Many species are limited in their ability to disperse over water. Krakatoa's forest, for example, may have only one-tenth the tree species richness of undisturbed tropical rain forest of nearby islands. The lack of plant diversity has, in turn, limited the number of colonizing animal species. In a forested area of Krakatoa where zoologists would expect more than 100 butterfly species, for example, there are only 2.

Secondary succession is the change in species composition that takes place after some disturbance removes the existing vegetation; soil is already present at these sites. Abandoned agricultural fields or open areas produced by forest fires are common examples of sites where secondary succession occurs. During the summer of 1988, wildfires burned approximately one-third of Yellowstone National Park. This natural disaster provided a valuable chance for ecologists to study secondary succession in areas that had been forests. After the conflagration, gray ash covered the forest floor, and most of the trees, although standing, were charred and dead. Secondary succession in Yellowstone has occurred rapidly since 1988. Less than a year later, in the spring of 1989, trout lily and other herbs sprouted and covered much of the ground. By 1998, a young forest of knee-high to shoulder-high lodgepole pines dominated the area. Douglas fir seedlings also began appearing in 1998. Ecologists continue to monitor the changes in Yellowstone as secondary succession unfolds.

Disturbance influences succession and species richness

Early studies suggested that succession inevitably progressed to a stable and persistent community, known as a *climax community*, which was determined solely by climate. Periodic disturbances, such as fires or floods, were not thought to exert much influence on climax communities. If the climax community were disturbed in any way, it would return to a self-sustaining, stable equilibrium in time.

This traditional view of stability has fallen out of favor. The apparent end-point stability of species composition in a "climax" forest is probably the result of how long trees live relative to the human lifespan. It is now recognized that forest communities never reach a state of permanent equilibrium but instead exist in a state of continual disturbance. The species composition and relative abundance of each species vary in a mature community over a range of environmental gradients, although the community retains a relatively uniform appearance overall.

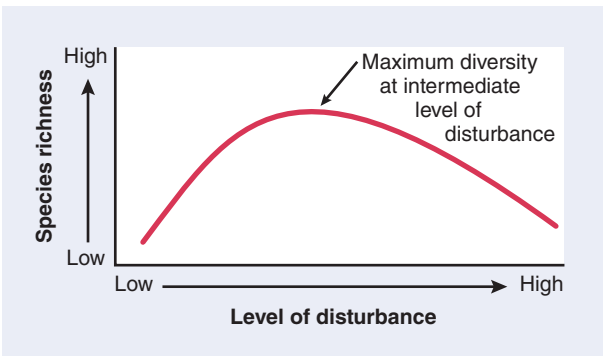
Because all communities are exposed to periodic disturbances, both natural and human-induced, ecologists have long tried to understand the effects of disturbance on species richness. A significant advance was the development of the **intermediate disturbance hypothesis** by Joseph H. Connell. When he examined species richness in tropical rain forests and coral reefs, he proposed that species richness is greatest at moderate levels of disturbance (FIG. 54-22). At a moderate level of disturbance, the community is a mosaic of habitat patches at different stages of succession; a range of sites exists, from those that were recently disturbed to those that have not been disturbed for many years. When disturbances are frequent or intense, only those species best adapted to earlier stages of succession persist, whereas low levels of disturbance allow late-successional species to dominate to such a degree that other species disappear. For example, when periodic wildfires are suppressed in forests, reducing disturbance to a low level, some of the "typical" forest herbs decline in number or even disappear.

One of the difficulties with the intermediate disturbance hypothesis is defining precisely what constitutes an "intermediate" level of disturbance. Despite this problem, the intermediate disturbance hypothesis has important ramifications for conservation biology because it tells us that we cannot maintain a particular community simply by creating a reserve around it. Both natural and human-induced disturbances will cause changes in species composition, and humans may have to intentionally intervene to maintain the species richness of the original community. What kind of and how much human intervention is necessary to maintain species richness is controversial (we discuss this issue in Chapter 57).

Ecologists continue to study community structure

One of the major issues in community ecology, from the early 1900s to the present, is the nature of communities. Are communities highly organized systems of predictable species, or are they abstractions produced by the minds of ecologists?

U.S. botanist Frederick E. Clements (1874–1945) was struck by the worldwide uniformity of large tracts of vegetation, such as tropical rain forests in South America, Africa, and Southeast Asia. He also noted that even though the species composition of a community in a particular habitat may be



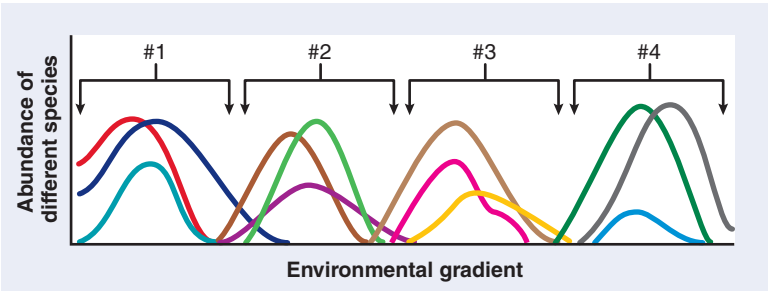


Figure 54-22 Intermediate disturbance hypothesis
Species richness is greatest at an intermediate level of disturbance.
After J.H. Connell, "Diversity in Tropical Rain Forests and Coral Reefs," *Science*, Vol. 199 (1978).

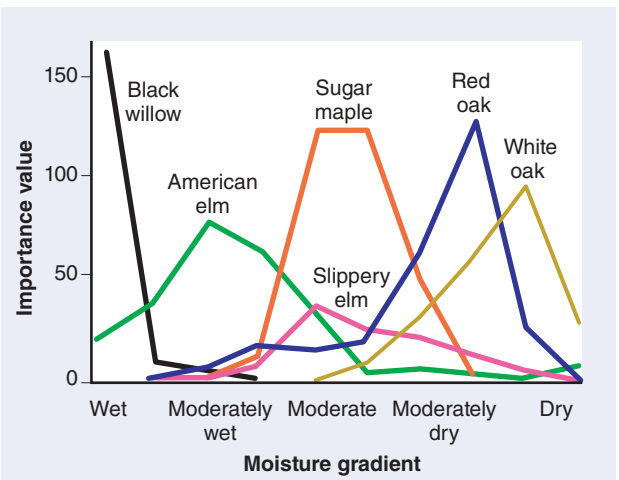
Key Point



Most communities are individualistic associations of species rather than distinct units that act like "superorganisms."

(a) Organismic model. According to this hypothesis, communities are organized as distinct units. Each of the four communities shown (*numbered brackets*) consists of an assemblage of distinct species (*each colored curve represents a single species*). The *arrows* indicate ecotones, regions of transition along community boundaries.

(b) Individualistic model. This model predicts a more random assemblage of species along a gradient of environmental conditions.

(c) Tree species in Wisconsin forests, which are distributed along a moisture gradient, more closely resemble the individualistic model. The "importance value" (*y-axis*) of each species in a given location combines three aspects (population density, frequency, and size).

Figure 54-23 Nature of communities

(c) Adapted from J.T. Curtis, *The Vegetation of Wisconsin* (University of Wisconsin Press, Madison, 1959).

VISUALIZE Create a graph with the same *x*-axis and *y*-axis titles as Figure 54-23c and show what the curves for a palm tree and a cactus might look like.

different from that of a community in a habitat with a similar climate elsewhere in the world, overall the components of the two communities are usually similar. He viewed communities as something like "superorganisms" whose member species cooperated with one another in a manner that resembled the cooperation of the parts of an individual organism's body. Clements's view was that a community went through certain stages of development, like the embryonic stages of an organism, and eventually reached an adult state; the developmental process was succession, and the adult state was the climax community. This cooperative view of the community, called the **organismic model**, stresses the interaction of the members, which tend to cluster in tightly knit groups within discrete community boundaries (FIG. 54-23a).

Opponents of the organismic model, particularly U.S. ecologist Henry A. Gleason (1882–1975), held that biological interactions are less important in the production of communities than are environmental gradients (such as climate and soil) or even chance. Indeed, the concept of a community is questionable. It may be a classification category with no reality, reflecting little more than the tendency of organisms with similar environmental requirements to live in similar places. This school of thought, called the **individualistic model**, emphasizes species individuality, with each species having its own particular abiotic living requirements. It holds that communities are therefore not interdependent associations of organisms. Rather, each species is independently distributed across a continuum of areas that meets its own individual requirements (FIG. 54-23b).

Debates such as this one over the nature of communities are an integral part of the scientific process because they fuel discussion and research that lead to a better understanding of broad scientific principles. Studies testing the organismic and individualistic hypotheses of communities do not support Clements's interactive concept of communities as discrete units. Instead, most studies favor the individualistic model. As shown in FIGURE 54-23c, tree species in Wisconsin forests are distributed in a gradient from wet to dry environments. Also, studies of plant and animal movements during the past 14,000 years support the individualistic model because it appears that individual species, not entire communities, became redistributed in response to changes in climate.

CHECKPOINT 54.4

- How does primary succession differ from secondary succession?
- What is Connell's intermediate disturbance hypothesis?
- How do the organismic and individualistic models of the nature of communities differ?

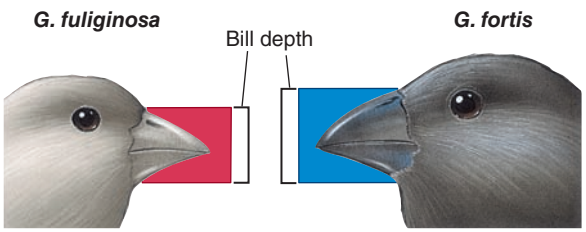
Summary: Focus on Learning Objectives

54.1 Community Structure and Functioning *(page 1172)*

1 Define *ecological niche* and distinguish between an organism's fundamental niche and its realized niche.



- The distinctive lifestyle and role of an organism in a community is its **ecological niche**. An organism's ecological niche takes into account all abiotic and biotic aspects of the organism's existence. An organism's **habitat** (where it lives) is one of the parameters used to describe the niche.
- Organisms potentially exploit more resources and play a broader role in the life of their community than they actually do. The potential ecological niche for an organism is its **fundamental niche**, whereas the niche it actually occupies is its **realized niche**.

2 Define *competition* and distinguish between interspecific and intraspecific competition.

- **Competition** occurs when two or more individuals attempt to use the same essential resource, such as food, water, shelter, living space, or sunlight.
- Competition occurs among individuals within a population (**intraspecific competition**) or between different species (**interspecific competition**).

3 Summarize the concepts of the competitive exclusion principle, resource partitioning, and character displacement.

- According to the **competitive exclusion principle**, two species cannot occupy the same niche in the same community for an indefinite period; one species is excluded by another as a result of competition for a limiting resource.
- The evolution of differences in resource use, known as **resource partitioning**, reduces competition between similar species.
- Competition among some species is reduced by **character displacement**, in which their structural, ecological, and behavioral characteristics diverge where their ranges overlap.

4 Define *predation* and describe the effects of natural selection on predator–prey relationships.

- **Predation** is the consumption of one species (the *prey*) by another (the *predator*). During **coevolution** between predator and prey, more efficient ways to catch prey evolve in the predator species, and better ways to escape the predator evolve in the prey species.

5 Distinguish among mutualism, commensalism, and parasitism, and give examples of each.

- **Symbiosis** is any intimate or long-term association between two or more species. The three types of symbiosis are mutualism, commensalism, and parasitism.
- In **mutualism**, both partners benefit. Three examples of mutualism are *nitrogen-fixing bacteria* and legumes, **zooxanthellae** and corals, and **mycorrhizae** (fungi and plant roots).
- In **commensalism**, one organism benefits and the other is unaffected. Two examples of commensalism are silverfish and army ants, and epiphytes and larger plants.
- In **parasitism**, one organism (the **parasite**) benefits and the other (the **host**) is harmed. One example of parasitism is mites that grow in or on honeybees. Some parasites are **pathogens** that cause disease.

54.2 Strength and Direction of Community Interactions *(page 1183)*

6 Distinguish between keystone species and dominant species.

- **Keystone species** are present in relatively small numbers but are crucial in determining the species composition and ecosystem functioning of the entire community.
- In contrast to keystone species, which have an effect that is out of proportion to their abundance, **dominant species** greatly affect the community of which they are a part because they are very common.

7 Distinguish between bottom-up and top-down processes in ecosystem regulation.

- If **bottom-up processes** dominate an ecosystem, the availability of resources such as minerals controls the number of producers (i.e., the lowest trophic level), which controls the number of herbivores, which controls the number of carnivores.
- **Top-down processes** regulate ecosystems from the highest trophic level, by consumers eating producers. If top-down processes dominate an ecosystem, an increase in the number of top predators cascades down the food web through the herbivores and producers.

54.3 Community Biodiversity *(page 1185)*

8 Summarize the main determinants of species richness in a community and relate species richness to community stability.

- Community complexity is expressed in terms of **species richness**, the number of species within a community, and **species diversity**, a measure of the relative importance of each species within a community based on abundance, productivity, or size.
- Species richness is often great in a habitat that has structural complexity; in a community that is not isolated (the distance effect) or severely stressed; in a community where more energy is available (the species richness–energy hypothesis); in **ecotones** (transition zones between communities); and in communities with long histories without major **disturbances**, events that disrupt community or population structure.
- Several studies suggest that species richness may promote community stability.

9 State the results of the analysis of the distance effect in South Pacific bird species.

- The number of bird species found on each island in the South Pacific is inversely related to its geographic isolation, that is, to its distance from New Guinea. Species richness declines as the distance from New Guinea increases.

54.4 Community Development *(page 1189)*

10 Define *succession* and distinguish between primary and secondary succession.

- **Succession** is the orderly replacement of one community by another. **Primary succession** occurs in an area that has not previously been inhabited (such as bare rock). **Secondary succession** begins in an area where there was a pre-existing community and well-formed soil (such as abandoned farmland).

11 Describe the intermediate disturbance hypothesis.

- Disturbance affects succession and species richness. According to the **intermediate disturbance hypothesis**, species richness is greatest at moderate levels of disturbance, which create a mosaic of habitat patches at different stages of succession.

12 Discuss the two traditional views of the nature of communities: Clements's organismic model and Gleason's individualistic model.

- The **organismic model** views a community as a "superorganism" that goes through certain stages of development (succession) toward adulthood (climax). According to this view, biological interactions are primarily responsible for species composition, and organisms are highly interdependent.
- Most ecologists support the **individualistic model**, which challenges the concept of a highly interdependent community. According to this model, abiotic environmental factors are the primary determinants of species composition in a community, and organisms are somewhat independent of one another.

Test Your Understanding

Know and Comprehend

1. A symbiotic association in which organisms are beneficial to one another is known as (a) predation (b) interspecific competition (c) intraspecific competition (d) commensalism (e) mutualism
2. A species' _____ is the totality of its adaptations, its use of resources, and its lifestyle. (a) habitat (b) ecotone (c) ecological niche (d) competitive exclusion (e) coevolution
3. Primary succession occurs on (a) bare rock (b) newly cooled lava (c) abandoned farmland (d) a and b (e) a, b, and c
4. The tendency for two similar species to differ from each other more markedly in areas where they occur together is known as (a) Müllerian mimicry (b) Batesian mimicry (c) resource partitioning (d) competitive exclusion (e) character displacement
5. Competition with other species helps determine an organism's (a) ecotone (b) fundamental niche (c) realized niche (d) limiting resource (e) ecosystem
6. "Complete competitors cannot coexist" is a statement of the principle of (a) primary succession (b) limiting resources (c) Müllerian mimicry (d) competitive exclusion (e) character displacement
7. Most of the diverse populations of the human microbiota inhabit the (a) skin (b) intestine (c) mouth (d) body fluid (e) lungs
8. The _____ signifies that species richness is greater where two communities meet than at the center of either community. (a) edge effect (b) fundamental niche (c) character displacement (d) realized niche (e) limiting resource
9. An unpalatable species demonstrates its threat to potential predators by displaying (a) character displacement (b) limiting resources (c) cryptic coloration (d) aposematic coloration (e) competitive exclusion
10. A limiting resource does all the following *except* that it (a) tends to restrict the ecological niche of a species (b) is in short supply relative to a species' need for it (c) limits the presence of a species in a given community (d) results in an intermediate disturbance (e) may be limiting for only part of an organism's life cycle

Apply and Analyze

11. An ecologist studying several forest-dwelling, insect-eating bird species does not find any evidence of interspecific competition. The most likely explanation is (a) lack of a keystone species (b) low species richness (c) pronounced intraspecific competition (d) coevolution of predator–prey strategies (e) resource partitioning
12. Support for the individualistic model of community structure includes (a) the decline of honeybees because of two species of parasitic mites (b) the identification of fig trees as a keystone species in tropical forests (c) the competitive exclusion of one *Paramecium* species by another (d) the distribution of trees along a moisture gradient in Wisconsin forests (e) the effects of the removal of a dominant rodent species from an Arizona desert

Evaluate and Synthesize

13. In your opinion, are humans a dominant species or a keystone species? Explain your answer.
14. Many plants that produce nodules for nitrogen-fixing bacteria are common on disturbed sites. Explain how these plants might simultaneously compete with and facilitate other plant species.
15. **EVOLUTION LINK** The rough-skinned newt, which lives in western North America, stores a poison in its skin and is avoided by predators. However, several populations of garter snakes have undergone one or a few mutations that enable them to tolerate the toxin, and these snakes eat the newts with no ill effects. How has natural selection affected this predator–prey relationship? Based on what you have learned about evolutionary arms races, predict what may happen to the newts and the poison-resistant garter snakes over time.
16. **EVOLUTION LINK** Competition is an important part of Darwin's scientific theory of evolution by natural selection, and the evolution of features that reduce competition increases a population's overall fitness. Relate this idea to character displacement and resource partitioning in Darwin's finches.
17. **INTERPRET DATA** Examine the top and middle graphs in Figure 54-5. Are these examples of exponential or logistic population growth? Where is *K* in each graph? (You may need to refer to Chapter 53 to answer these questions.)
18. **SCIENCE, TECHNOLOGY, AND SOCIETY** Describe the ecological niche of humans. How have science and technology changed our realized niche during the past 1000 years?

55 Ecosystems and the Biosphere

KEY CONCEPTS

55.1 Studying the energy content of the different trophic levels provides insight into how energy flows through the biotic and abiotic components of ecosystems.

55.2 Carbon, nitrogen, water, and other materials cycle through both biotic and abiotic parts of ecosystems.

55.3 The abiotic environment—including solar radiation, the atmosphere, the ocean, climate, and fire—helps shape the biotic portion of ecosystems.

55.4 Ecosystem ecologists focus on chemical, physical, and biological processes of ecosystems to learn how ecosystems function.

CE Photography/Shutterstock.com

Planet Earth has often been compared to a vast spaceship, inhabited by diverse communities of organisms. As Earth orbits around the sun, these organisms use the sun's energy to produce oxygen, transfer energy, and recycle water and minerals (inorganic nutrients) with great efficiency. Yet none of these ecological processes would be possible without the abiotic (nonliving) environment of spaceship Earth. As the sun warms the planet, it powers the hydrologic cycle (causes precipitation), drives ocean currents and atmospheric circulation patterns, and produces much of the climate to which organisms have adapted. The sun also supplies the energy that almost all organisms use to carry on life processes.

Individual communities and their abiotic environments are **ecosystems**, which are the basic units of ecology. An ecosystem encompasses all the interactions among organisms living together in a particular place and among those organisms and their abiotic environment. **Ecosystem ecology** is a subfield of ecology that studies energy flow and the cycling of chemicals among the interacting biotic and abiotic parts of an ecosystem.

Ecosystem interactions are complex because each organism responds not only to other organisms but to conditions in the atmosphere, soil, and water. In turn, organisms exert an effect on the abiotic environment, as when a beaver dam creates a pond in a formerly forested area (see photograph). The pond is formed as the beaver builds an island lodge that will be safe from predators. However, the beaver dam also regulates the flow of water in the stream or river: it holds back water during rainy periods and releases a controlled amount of water throughout the year, even during periods of drought.

Like communities, ecosystems vary in size, lack precise boundaries, and are nested within larger ecosystems. Earth's largest

ecosystem is the biosphere, which consists of all Earth's communities and their interactions and connections with the planet's abiotic environment: its water, soil, rock, and atmosphere.

55.1 Energy Flow through Ecosystems

LEARNING OBJECTIVES

1. Summarize the concept of energy flow through a food web.
2. Explain typical pyramids of numbers, biomass, and energy.
3. Distinguish between gross primary productivity and net primary productivity.

The passage of energy in a one-way direction through an ecosystem is known as **energy flow**. Energy enters an ecosystem as radiant energy (sunlight), a tiny portion (less than 1%) of which *producers* trap and use during photosynthesis. The energy, now in chemical form, is stored in the bonds of organic (carbon-containing) molecules such as glucose. When cellular respiration breaks these molecules apart, energy becomes available (in the form of ATP) to do work, such as repairing tissues, producing body heat, moving about, or reproducing. As the work is accomplished, energy escapes the organisms and dissipates into the environment as heat. Ultimately, this heat energy radiates into space. Thus, once an organism has used energy, the energy is unavailable for reuse (FIG. 55-1). (See also the discussion of the second law of thermodynamics in Chapter 7.)

In an ecosystem, energy flow occurs in **food chains**, in which energy from food passes from one organism to the next in a sequence. **Primary producers**, also called *autotrophs*, form the beginning of the food chain by capturing the sun's energy through photosynthesis. Producers, by incorporating the chemicals they manufacture into their own *biomass* (living material), become potential food resources for other organisms. Plants are the most significant producers on land, whereas algae and cyanobacteria are important producers in aquatic environments. (Alternative producers are photoheterotrophs and chemoautotrophs discussed in Chapters 9 and 25.) All other organisms in a community are **consumers**, also called *heterotrophs*, which extract energy from organic molecules produced by other organisms.

Food chains are divided into **trophic levels** (from the Greek *tropho*, which means "nourishment"). Producers occupy the first trophic level. **Herbivores**, which occupy the second trophic level, are *primary consumers* that eat plants. They obtain the chemical energy of the producers' molecules and the building materials used to construct their own tissues. Herbivores are, in turn, consumed by **carnivores**, *secondary consumers* that reap the energy stored in the herbivores' molecules. *Tertiary consumers* are carnivores that eat secondary consumers. **Omnivores** are consumers that eat a variety of organisms, both plant and animal. Omnivores and consumers occupy third or higher trophic levels depending on what they eat.

Some consumers, called **detritus feeders**, or **detritivores**, eat **detritus**, which is dead organic matter that includes animal carcasses, leaf litter, wood, and feces. Detritivores and microbial decomposers break down dead organisms and waste products.

Decomposers, also called **saprotrophs**, are a subset of detritus feeders. Decomposers include microbial heterotrophs

Key Point

Ecologists gain insights into how ecosystems function by examining energy flow and the energy content of each trophic level.

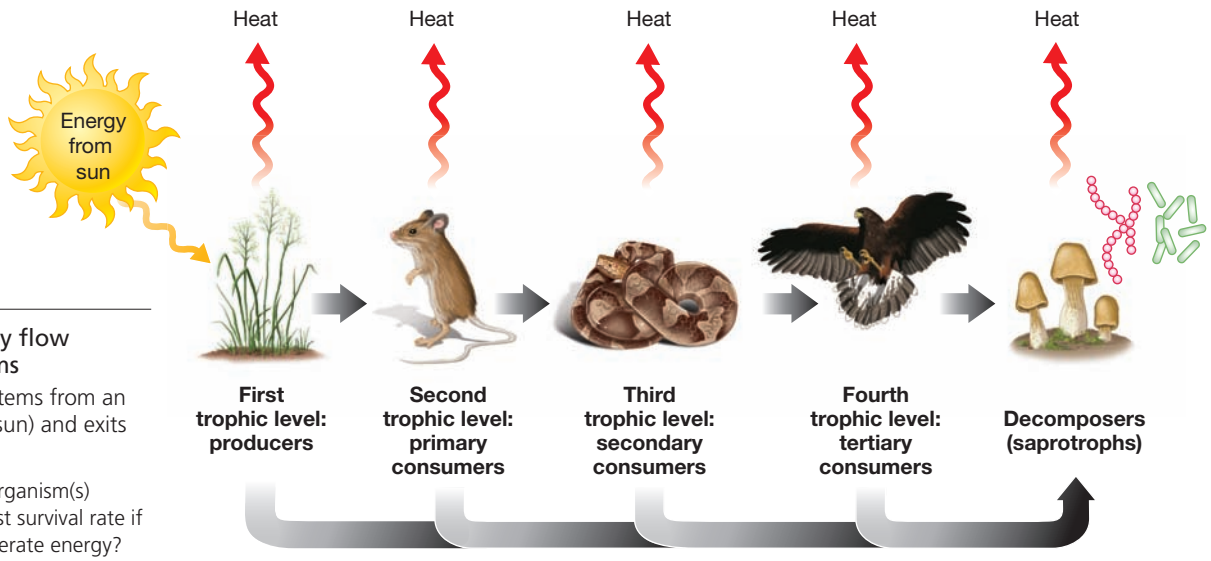

Figure 55-1 Energy flow through ecosystems

Energy enters ecosystems from an external source (the sun) and exits as heat loss.

PREDICT Which organism(s) would have the longest survival rate if the sun ceased to generate energy?

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Key Point

Food webs in all but the simplest ecosystems are too complex to depict all their species and links in a simple diagram. Some links are stronger than others. As food webs change over time, new links are added, and some links are deleted.

Figure 55-2 A food web at the edge of an Eastern deciduous forest

This diagram illustrates only a few of the thousands of species and links that might be part of a food web at the edge of a deciduous forest.

PREDICT What could happen to this food web if drought conditions occurred?

members of the food chain. (See Chapters 25 and 29.)

Simple food chains such as the one described rarely occur in nature because few organisms eat just one kind, or are eaten by just one other kind, of organism. More typically, the flow of energy and materials through ecosystems takes place in accordance with a range of food choices for each organism. In an ecosystem of average complexity, hundreds of alternative pathways are possible. Thus, a **food web**, which is a complex of interconnected food chains, is a more realistic model of the flow of energy and materials through ecosystems (FIG. 55-2).

Because food chains and food webs are descriptions of "who eats whom," they indicate the negative effects predators have on their prey. For example, consider a simple food chain: grass → field mouse → owl. The owl, which kills and eats mice, obviously exerts a negative effect on the mouse population; in like manner, field mice, which eat grass seeds, reduce the grass population.

A trophic level in a food web also influences other trophic levels to which it is not directly linked. Producers and top carnivores do not usually exert direct effects on one another, yet each indirectly affects the other. In our example, the owls help the grasses by keeping the population of seed-eating mice under control. Likewise, the grasses benefit owls by supporting a population of mice on which the owl population feeds. These indirect interactions are the focus of current research and may be as important in food-web dynamics as direct predator–prey interactions.

The most important thing to remember about energy flow in ecosystems is that it is linear, or a one-way system. That is, energy moves along a food web from one trophic level to the next trophic level. Once an organism has used energy, however, it is lost as heat and is unavailable to any other organism in the ecosystem.

and fungi. These organisms supply themselves with energy by externally breaking down organic molecules in remains (carcasses and body wastes) and ingesting the inorganic products. They typically release simple inorganic molecules, such as carbon dioxide and mineral salts, which may be reused by producers. Most bacteria and fungi are important decomposers of all

Ecological pyramids illustrate how ecosystems work

Ecologists sometimes compare trophic levels by determining the number of organisms, the biomass, or the relative energy found at each level. This information is presented graphically

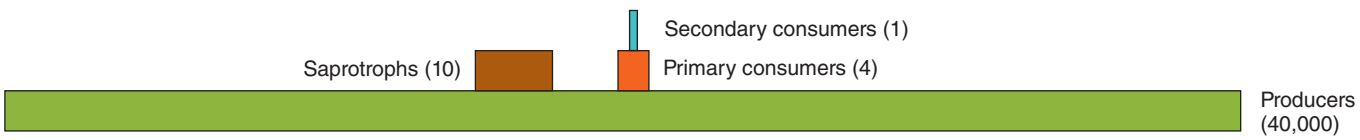
Copyright 2019 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in

Copyright 2019 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

as **ecological pyramids**. The base of each ecological pyramid represents the producers, the next level is the primary consumers (herbivores), the level above that is the secondary consumers (carnivores), and then tertiary consumers (carnivores), and so on. The relative area of each bar of the pyramid is proportional to what is being demonstrated.

A **pyramid of numbers** shows the number of organisms at each trophic level in a given ecosystem, with a larger area illustrating greater numbers for that section of the pyramid. In most pyramids of numbers, fewer organisms occupy each successive trophic level. Thus, in African grasslands the number of herbivores, such as zebras and wildebeests, is greater than the number of carnivores, such as lions. Inverted pyramids of numbers, in which higher trophic levels have more organisms than lower trophic levels, are often observed among decomposers, parasites, and herbivorous insects. One tree provides food for thousands of leaf-eating insects, for example. Pyramids of numbers are of limited usefulness because they do not indicate the biomass of the organisms at each level, nor do they indicate the amount of energy transferred from one level to another.

A **pyramid of biomass** illustrates the total biomass at each successive trophic level. **Biomass** is a quantitative estimate of the total mass, or amount, of living material; it indicates the amount of fixed energy at a particular time. Biomass units of measure vary: biomass may be represented as total volume, dry weight, or live weight. Typically, these pyramids illustrate a progressive reduction of biomass in succeeding trophic levels (FIG. 55-3a). Assuming an average biomass reduction of about 90% for each trophic level, 10,000 kg of grass should support 1000 kg of grasshoppers, which in turn support 100 kg of frogs. (The 90% reduction in biomass is an approximation; actual biomass reduction from one trophic level to the next varies widely.) If we use this logic, the biomass of frog eaters (such as snakes) could weigh, at most, only about 10 kg. From this brief exercise, you see that although carnivores do not eat producers, a large producer biomass is required to support carnivores in a food web.



Occasionally, we find an inverted pyramid of biomass in which the primary consumers outweigh the producers (FIG. 55-3b). In these instances, herbivores such as fishes and zooplankton (protozoa, tiny crustaceans, and immature stages of many aquatic animals) consume large numbers of producers, which are usually unicellular algae that are short-lived and reproduce quickly. Thus, although at any point in time relatively few algae are present, the rate of biomass production of the primary consumers is much less than that of the producers.

A **pyramid of energy** indicates the energy content, often expressed as kilocalories (or kilojoules), per square meter per year of the biomass of each trophic level. A common method ecologists use to measure energy content is to burn a sample of tissue in a calorimeter; the heat released during combustion is measured to determine the energy content of the organic material in the sample. Energy pyramids always have large bases and get progressively smaller through succeeding trophic levels. This illustrates the fact that most energy dissipates into the environment, and only about 10% of the usable energy is passed on when there is a transition from one trophic level to the next. Less energy reaches each successive trophic level from the level beneath it because those organisms at the lower level use some of the energy to perform work, and some of it is lost as heat (FIG. 55-4). (Remember that no biological process is 100% efficient.) The second law of thermodynamics explains why there are few trophic levels: energy pyramids are short because of the dramatic reduction in energy content that occurs at each successive trophic level.

Ecosystems vary in productivity

The **gross primary productivity (GPP)** of an ecosystem is the rate at which energy is captured during photosynthesis.[1] Thus, GPP is the total amount of photosynthetic energy captured in a given period. Of course, plants and other producers must respire to provide energy for their life processes, and cellular respiration acts as a drain on photosynthetic output. Energy that remains in plant tissues after cellular respiration has occurred is called **net primary productivity (NPP)**. That is, NPP is the amount of biomass (the energy stored in plant tissues) found in excess of that broken down by a plant's cellular respiration for normal daily activities. NPP represents the rate

[1] Gross and net primary productivities are referred to as primary because plants and other producers occupy the first position in food webs.

(a) A pyramid of biomass for a tropical forest in Panama.

(b) An inverted biomass pyramid, such as that for plankton in the English Channel, occurs when a highly productive lower trophic level experiences high rates of turnover. Plankton are free-floating, mainly microscopic algae and animals.

Figure 55-3 Pyramids of biomass

These pyramids are based on the biomass at each trophic level and generally have a pyramid shape with a large base and progressively smaller areas for each succeeding trophic level. Biomass values are in grams of dry weight per square meter.

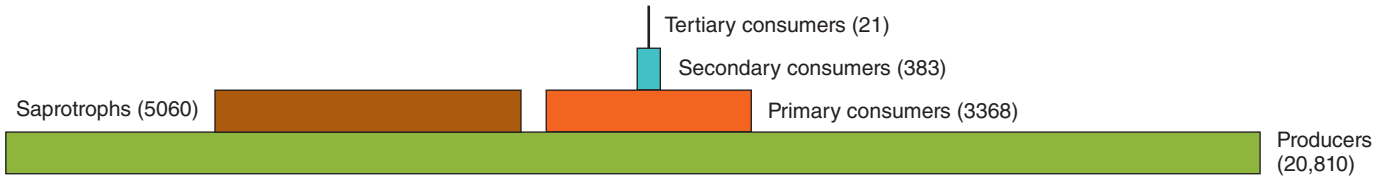

Figure 55-4 Pyramid of energy

A pyramid of energy for Silver Springs, Florida, represents energy flow, the functional basis of ecosystem structure. Energy values are in kilocalories per square meter per year. Note the substantial loss of usable energy from one trophic level to the next. The Silver Springs ecosystem is complex, but tape grass (producers), spiral-shelled snails (primary consumers), young river turtles (secondary consumers), gar (fish; tertiary consumers), and bacteria and fungi (saprotrophs) are representative organisms. When they are young, river turtles are carnivores and consume snails, aquatic insects, and worms; as adults, river turtles are herbivores. Based on H.T. Odum, "Trophic Structure and Productivity of Silver Springs, Florida," *Ecological Monographs*, Vol. 27 (1957).

at which this organic matter is actually incorporated into plant tissues to produce growth.

net primary productivity	=	gross primary productivity	−	plant respiration
(plant growth per unit area per unit time)		(total photosynthesis per unit area per unit time)		(per unit area per unit time)

Only the energy represented by net primary productivity is available for consumers, and of this energy only a portion is actually used by them. Both GPP and NPP are expressed as energy per unit area per unit time (e.g., kilojoules of energy fixed by photosynthesis per square meter per year) or as dry weight (e.g., grams of carbon incorporated into tissue per square meter per year).

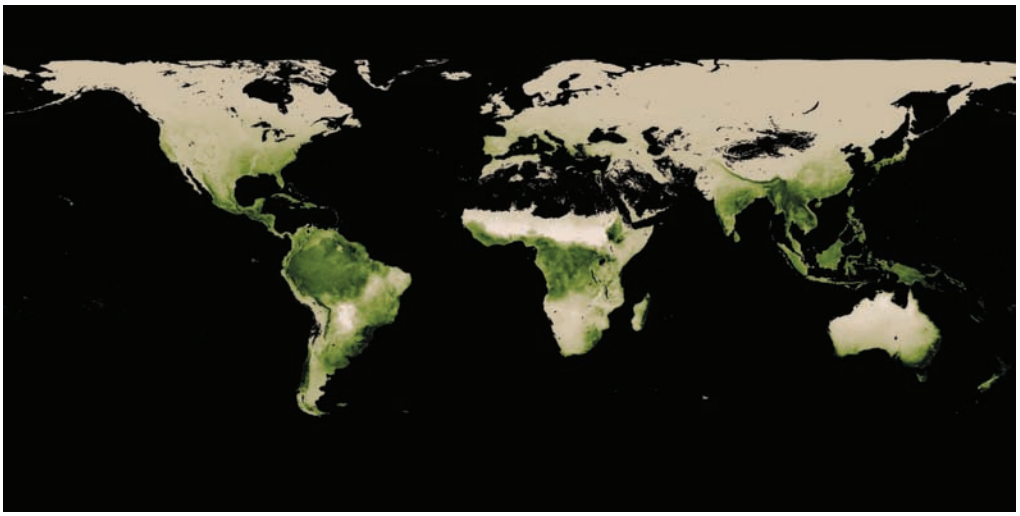
Ecologists use different methods to measure net primary productivity, such as through calorimetry (previously described) and change in dry biomass per unit time. Scientists also determine NPP by measuring carbon dioxide uptake and oxygen uptake over time. Another method to assess NPP in plants is through recording the change in chlorophyll *a* concentration, which measures daily carbon dioxide fixation.

Herbivores and other consumers eventually consume all of a plant's net primary production. What happens to this energy? Consider the transfer of net primary production from a plant to a deer that eats the plant. Much of the energy stored in the plant material that the deer consumes—about 25%—is not digested and is lost in its feces. (This energy is not lost from the ecosystem because detritivores and decomposers will make use of it; it is lost from the deer's point of view, however.) Perhaps 55% of the energy that the deer takes in as food is released during cellular respiration and used to do work such as muscle contraction and to maintain and repair the deer's body. The remaining energy—less than 20%—is available to produce new biomass, that is, new tissues. This net energy available for biomass production by consumer organisms is called **secondary productivity**. An ecosystem's secondary productivity is based on its primary productivity.

Many factors may interact to determine primary productivity. Some plants are more efficient than others in fixing carbon. Environmental factors are also important. They include the availability of solar energy, minerals, and water; other climate factors; the degree of maturity of the community; and the severity of human modification of the environment.

These factors are difficult to assess, particularly on a large scale. The summer of 2003, which was extremely hot and dry in Europe, provided ecologists with a chance to measure primary productivity changes in response to these unusual conditions. Based on their measurements, they estimate that GPP throughout Europe was reduced by 30% as a result of the heat and drought.

Ecosystems differ strikingly in their primary productivities (FIG. 55-5 and TABLE 55-1). On land, tropical rain forests have the highest productivity, probably as a result of the abundant rainfall, warm temperatures, and intense sunlight. As you might expect, tundra, because of its short, cool growing season, and deserts, because of their lack of precipitation, are the least productive terrestrial ecosystems. In ecosystems with comparable annual temperatures (e.g., temperate deciduous forest, temperate grassland, and temperate desert), water availability affects NPP. Availability of essential minerals such as nitrogen and phosphorus also affects NPP.



Wetlands (swamps and marshes) connect terrestrial and aquatic environments and are extremely productive. The most productive aquatic ecosystems are algal beds, coral reefs, and estuaries. The lack of available minerals in the sunlit region of the open ocean makes this area extremely unproductive, equivalent to an aquatic desert. Earth's major aquatic and terrestrial ecosystems are discussed in Chapter 56.

As primary productivity increases, species richness declines Ecologists have observed that an ecosystem's species richness declines with increasing productivity. For example, the resource-poor depths of the Atlantic Ocean's abyssal plain have more species richness than productive shallow waters near the coasts. Ecologists are designing experiments to help explain the pattern, which has been documented with rodents in Israel, birds in South America, and large mammals in Africa. Mathematical ecosystem models suggest that a less productive environment has a *patchy distribution of resources* that reduces competition and allows a greater variety of organisms to coexist.

The bad news for global biodiversity is that humans are constantly enriching the environment, such as with nitrogen

NASA/Reto Stockli, NASA's Earth Observatory Team, using data provided by the MODIS Land Science Team

Figure 55-5 View of Earth's net primary productivity

The colors on this NASA satellite image indicate how quickly plants took carbon in for every square meter of land during November, 2016. Values range from –1.0 gram of carbon per square meter per day (*tan*) to 6.5 grams per square meter per day (*dark green*). A negative value indicates that decomposition or respiration was greater than carbon production; more carbon was released to the atmosphere than plants captured. The least productive areas are deserts. The most productive regions are tropical rain forests. Images like this allow scientists to assess changes in productivity over time.

and phosphorus inputs from fossil fuels, fertilizers, and livestock. This continual enrichment is making Earth's ecosystems increasingly productive, but is costing the world a substantial reduction in species richness. Researchers in England conducted a long-term experiment in community composition by returning grasslands that had been heavily fertilized by conventional agricultural practices to organic farming methods. Over a period of 15 years, species diversity increased by 300%, as native plants became reestablished, while the productivity decreased by about 50%. Although the tradeoff for greater species richness was reduced productivity, the researchers showed that a healthy balance between the two is possible to attain and maintain. (Other factors that affect species richness were discussed in Chapter 54.)

Table 55-1 Net Primary Productivity (NPP) for Selected Ecosystems

Ecosystem	Average NPP (g dry matter/m²/year)
Algal beds and reefs	2500
Tropical rain forest	2200
Swamp and marsh	2000
Estuaries	1500
Temperate evergreen forest	1300
Temperate deciduous forest	1200
Savanna	900
Boreal (northern) forest	800
Woodland and shrubland	700
Agricultural land	650
Temperate grassland	600
Upwelling zones in ocean	500
Lake and stream	250
Arctic and alpine tundra	140
Open ocean	125
Desert and semidesert scrub	90
Extreme desert (rock, sand, ice)	3

Humans consume an increasingly greater percentage of global primary productivity

Humans consume far more of Earth's resources than do any of the other millions of animal species. Peter Vitousek and co-workers at Stanford University calculated in 1986 how much of the global NPP is appropriated for the human economy. When both direct and indirect human effects are accounted for, Vitousek estimated that humans use 32% to 40% of land-based annual NPP. Since 1986, scientists have done additional research on global ecology, resulting in improved data sets. In 2001, Stuart Rojstaczer and co-workers at Duke University used satellite-based data to determine a conservative estimate of land-based annual NPP appropriation by humans at 32%.

The take-home message from Vitousek's and Rojstaczer's research is simple. Essentially, human use of global productivity is competing with other species' needs for energy. Our use of so much of the world's productivity is contributing to the loss, through extinction or genetic impoverishment, of many species that have unique roles in maintaining functional ecosystems. Clearly, at these levels of consumption and exploitation of Earth's resources, human population growth threatens the planet's ability to support all its occupants.

Some toxins persist in the environment

You have seen how energy flows through food chains in ecosystems. Before leaving the discussion of food chains, let us consider how certain toxins, including some pesticides, radioactive isotopes, heavy metals such as mercury, and industrial chemicals such as polychlorinated biphenyls (PCBs), enter and pass through food chains. The effects of the pesticide DDT on some bird species first drew attention to the problem. Falcons, pelicans, bald eagles, and ospreys are generally secondary consumers that accumulate substances in their bodies from lower levels of the food chain. The birds are sensitive to traces of DDT, and DDT metabolites, in their tissues. A substantial body of scientific

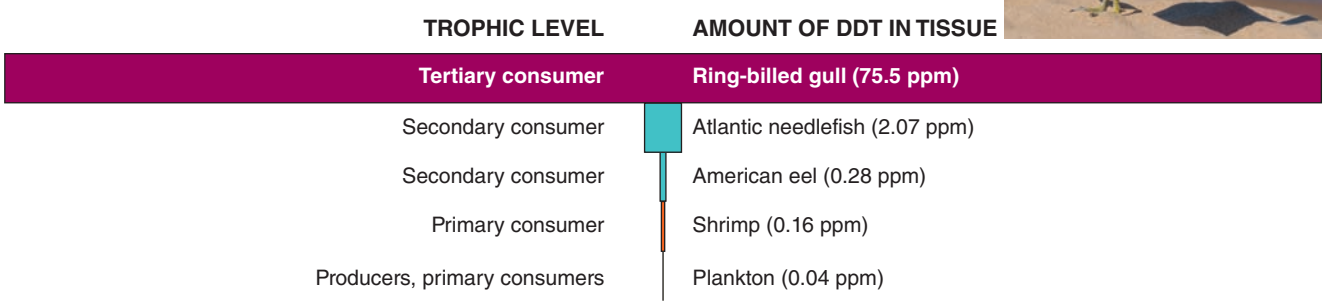
Key Experiment



Does DDT exhibit biological magnification as it moves through a food chain?

istock.com/Kenneth_Keifer

HYPOTHESIS: DDT, a persistent insecticide, increases in concentration at each level of a food chain.

EXPERIMENT: Biologists sampled the concentration of DDT in various organisms of a Long Island salt marsh.

RESULTS AND CONCLUSION: The level of DDT increased in the tissues of various organisms as DDT moved through the food chain from producers to consumers. Ring-billed gulls at the top of the food chain had approximately 1 million times as much DDT in their tissues as the concentration of DDT in the water (0.00005 ppm). (Plankton consisted of a mixture of phytoplankton and zooplankton.)

SOURCE: Based on data from G.M. Woodwell, C.F. Worster, Jr., and P.A. Isaacson, "DDT Residues in an East Coast Estuary: A Case of Biological Concentration of a Persistent Insecticide," *Science*, Vol. 156 (May 12, 1967).

Figure 55-6 Biological magnification of DDT (expressed as parts per million) in a Long Island salt marsh

PREDICT How might DDT be passed on by the ring-billed gull, and what might be the consequences?

evidence indicates that DDT accumulation causes birds to produce eggs that have extremely thin, fragile shells that usually break during incubation, causing the chicks' deaths. DDT also acts as an endocrine disruptor, reducing fertility due to the effects of males being feminized by the chemical. In 1962, U.S. biologist Rachel Carson published *Silent Spring*, which heightened public awareness about the dangers of DDT and other pesticides. After 1972, the year DDT was banned in the United States, the reproductive success of many birds gradually improved.

The effect of DDT on birds is the result of three characteristics of DDT (and other toxins that cause problems in food webs): its persistence, bioaccumulation, and biological magnification. Some toxins are extremely stable and may take many years to break down into less toxic forms. The **persistence** of synthetic pesticides and industrial chemicals is a result of their novel chemical structures. These toxins accumulate in the environment because ways to degrade them have not evolved in natural decomposers such as bacteria.

When an organism does not metabolize (break down) or excrete a persistent toxin, the toxin simply gets stored, usually in fatty tissues. Over time, the organism may accumulate high concentrations of the toxin. The buildup of such a toxin in an organism's body is known as **bioaccumulation**.

Organisms at higher trophic levels in food webs, such as tertiary consumers, tend to have greater concentrations of bio-accumulated toxins in their bodies than do those at lower levels. The increase in concentration, which occurs as the toxin passes through successive levels of the food web, is known as **biological magnification**.

As an example of the concentrating characteristic of persistent toxins, consider a food chain studied in a Long Island salt marsh that was sprayed with DDT over a period of years for mosquito control (FIG. 55-6). Although this example involved a bird at the top of the food chain, it is important to recognize that *all* top carnivores, from fishes to humans, are at risk from biological magnification of persistent toxins. Because of this risk, currently approved pesticides have been tested to ensure that they do not persist and accumulate in the environment. Unfortunately, many countries in Africa, South America, and Asia still rely on DDT and other persistent toxins to control the spread of malaria and reduce crop loss. Continued DDT use is a global concern because the pesticide travels long distances in the upper atmosphere and has been deposited worldwide. DDT is present in Arctic and Antarctic animal populations and may be re-entering food chains in areas where glaciers are melting due to climate change.

The danger from DDT and other pesticides, however, does not end with the death of the terminal consumer. DDT and its metabolites remain in the environment and have a soil half-life of up to 30 years. Recall that many organisms reside in soil and sediment. In aquatic environments, the DDT half-life is 150 years.

CHECKPOINT 55.1

- **VISUALIZE** Draw a diagram tracing energy flow through a food web such as one found in a deciduous forest.
- **CONNECT** What are trophic levels, and how are they related to ecological pyramids?
- How do gross primary productivity (GPP) and net primary productivity (NPP) differ?

55.2 Cycles of Matter in Ecosystems

LEARNING OBJECTIVE

4 Describe the main steps in each of these biogeochemical cycles: the carbon, nitrogen, phosphorus, and hydrologic cycles.

Matter moves in numerous cycles from one part of an ecosystem to another; that is, it moves from one organism to another (in food chains) and from living organisms to the abiotic environment and back again. We call these cycles of matter **biogeochemical cycles** because they involve biological, geologic, and chemical interactions. For all practical purposes, matter cannot escape from Earth's boundaries. The materials organisms use cannot be "lost," although this matter can end up in locations outside the reach of organisms for a long period. Usually, materials are reused and often recycled both within and among ecosystems.

We discuss four different biogeochemical cycles of matter—carbon, nitrogen, phosphorus, and water—as representative of all biogeochemical cycles. These four cycles are particularly important to organisms because they involve materials used to make the chemical components of cells.

Carbon dioxide is the pivotal molecule in the carbon cycle

Proteins, nucleic acids, lipids, carbohydrates, and other molecules essential to life contain carbon. Carbon is present in the atmosphere as the gas carbon dioxide (CO_2), which makes up 0.04% of the atmosphere. It is also present in the ocean and fresh water as dissolved carbon dioxide, that is, carbonate (CO_3^{2-}) and bicarbonate (HCO_3^-); other forms of dissolved inorganic carbon; and dissolved organic carbon from decay processes. Carbon is also present in rocks such as limestone ($CaCO_3$). The global movement of carbon between the abiotic environment, including the atmosphere and ocean, and organisms is known as the **carbon cycle** (FIG. 55-7).

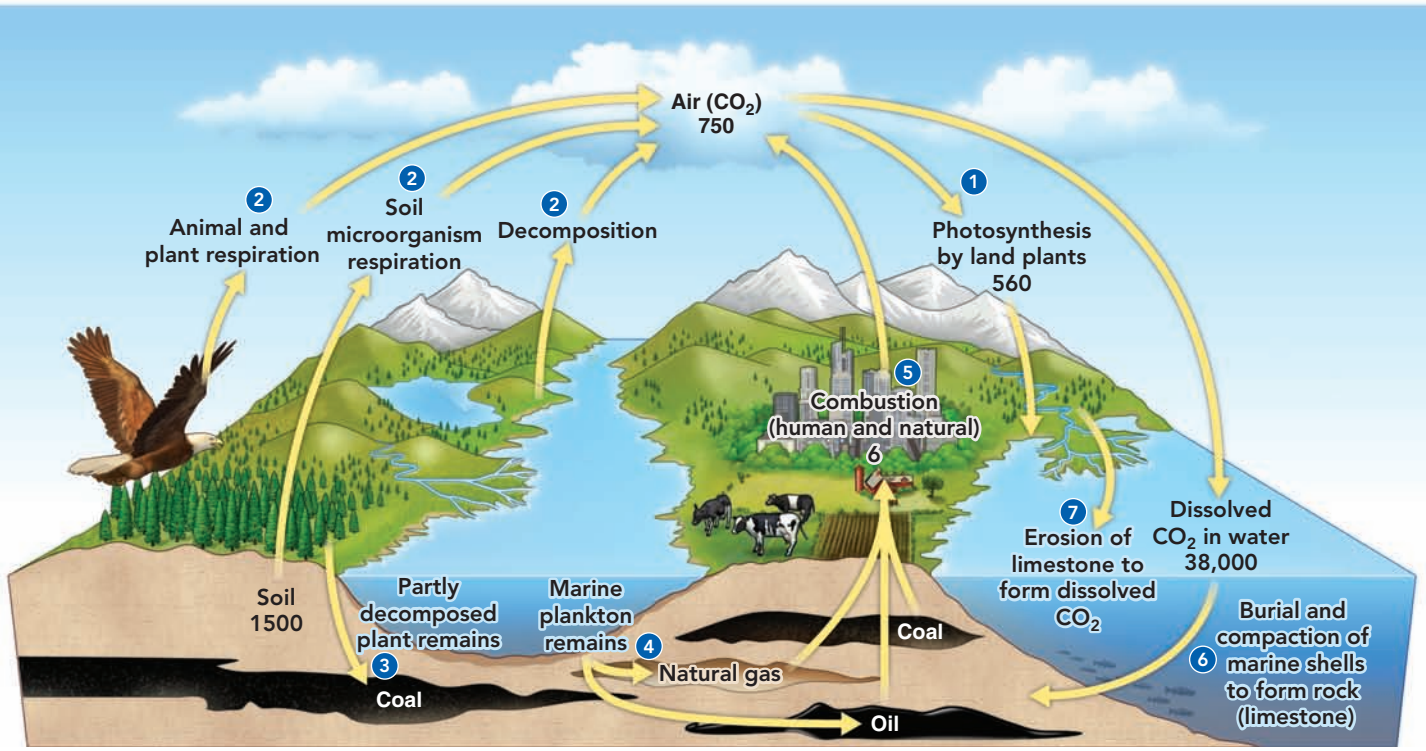

Figure 55-7 A simplified diagram of the carbon cycle

All but a tiny fraction of Earth's estimated 10^{23} g of carbon is buried in sedimentary rocks and fossil fuel deposits. The values shown for some of the active pools in the global carbon budget are expressed as 10^{15} g of carbon. For example, the soil contains an estimated 1500×10^{15} g of carbon. Values from W.H. Schlesinger, *Biogeochemistry: An Analysis of Global Change*, 2nd ed. (Academic Press, San Diego, 1997), and several other sources.

During photosynthesis, plants, algae, and cyanobacteria remove carbon dioxide from the air and *fix*, or incorporate, it into organic compounds such as glucose. Plants use much of the glucose to make cellulose, starch, amino acids, nucleic acids, and other compounds.

Many of these compounds are used as fuel for cellular respiration by the producer that made them, by a consumer that eats the producer, or by a decomposer that breaks down the remains of the producer or consumer. The process of cellular respiration returns carbon dioxide to the atmosphere. A similar carbon cycle occurs in aquatic ecosystems between aquatic organisms and dissolved carbon dioxide in the water (not shown in Figure 55-7).

Some archaea fix carbon using atmospheric CO_2. Other archaea, the methanogens, are decomposers and are the major source of methane in the atmosphere. The methanogens significantly contribute to global climate change (see discussion of methanogens in Chapter 25).

Sometimes the carbon in biological molecules is not recycled back to the abiotic environment for a long time and remains in reservoirs, or sinks, indefinitely. Carbon stored in the wood of trees may stay for several hundred years or even longer. Also, millions of years ago vast coal beds formed from the bodies of ancient trees that were buried and subjected to anaerobic conditions before they had fully decayed. Similarly, the oils of unicellular marine organisms probably gave rise to the underground deposits of oil and natural gas that accumulated in the geologic past. Coal, oil, and natural gas, called **fossil fuels** because they formed from the remains of ancient organisms, are vast deposits of carbon compounds, the end products of photosynthesis that occurred millions of years ago.

The process of burning, or combustion, may return the carbon in coal, oil, natural gas, and wood to the atmosphere. In combustion, organic molecules are rapidly oxidized (combined with oxygen) and converted to carbon dioxide and water with an accompanying release of light and heat.

An even greater amount of carbon that is stored for millions of years is incorporated into the shells of marine organisms. When these organisms die, their shells sink to the ocean floor, and sediments cover them, forming seabed deposits thousands of meters thick. The deposits are eventually cemented together to form limestone, a sedimentary rock. Earth's crust is dynamically active, and over millions of years, sedimentary rock on the bottom of the seafloor may lift to form land surfaces. When the process of geologic uplift exposes limestone, chemical and physical weathering processes slowly erode it away. This returns carbon to the water and atmosphere, where it is available to participate in the carbon cycle once again.

Human activities have disturbed the global carbon budget Before the Industrial Revolution, around 1750, the global carbon cycle was in a steady state. Enormous amounts of carbon moved to and from the atmosphere, ocean, and terrestrial ecosystems, but these movements within the global carbon cycle just about canceled out one another.

Since 1750, our industrial society has required a lot of energy, and we have burned increasing amounts of fossil fuels—coal, oil, and natural gas—to obtain this energy. This trend, along with a greater combustion of wood as a fuel and the burning of large sections of tropical forest, has released CO_2 into the atmosphere at a rate greater than the natural carbon cycle can handle.

Earth's ocean absorbs much of this excess CO_2 from the atmosphere. In the ocean, some dissolved CO_2 is converted to carbonic acid (H_2CO_3), which is acidifying surface ocean waters. The pH of modern surface waters is about 0.1 pH unit lower than it was in preindustrial times, and models predict 1.4 pH units, or more, of further acidification during the next 300 years. *Ocean acidification* harms marine organisms, particularly those that produce skeletons and shells of calcium carbonate ($CaCO_3$), which dissolve in the presence of acid.

The level of atmospheric CO_2 has increased dramatically beginning in the last half of the 20th century (see Fig. 57-16). This rise in CO_2 was caused by human activities and is responsible for major changes in climate. Global climate change is causing a rise in sea level, changes in precipitation patterns, death of forests, extinction of organisms, and problems for agriculture. It will drive the displacement of thousands or even millions of people, particularly from coastal areas. (Chapter 57 contains a more thorough discussion of increasing atmospheric CO_2 and the potential effects of global climate change.)

Bacteria and archaea are essential to the nitrogen cycle

Nitrogen is crucial for all organisms because it is an essential part of proteins, nucleic acids, and chlorophyll. Because Earth's atmosphere is about 78% nitrogen gas (N_2), it would appear that there could be no possible shortage of nitrogen for organisms. However, molecular nitrogen is so stable that it does not readily combine with other elements. Therefore, the N_2 molecule must be broken apart before the nitrogen atoms combine with other elements to form proteins, nucleic acids, and chlorophyll. Chemical reactions that break up N_2 and combine nitrogen with other elements require a great deal of energy.

The **nitrogen cycle**, in which nitrogen cycles between the abiotic environment and organisms, has five steps: nitrogen fixation, nitrification, assimilation, ammonification, and denitrification (FIG. 55-8). Certain bacteria and archaea are exclusively involved in all these steps except assimilation.

The first step in the nitrogen cycle, biological **nitrogen fixation**, involves conversion of gaseous nitrogen (N_2) to ammonia (NH_3). This process fixes nitrogen into a form that organisms can use. Combustion, volcanic action, lightning discharges, and industrial processes also fix nitrogen as nitrate (NO_3^-). Certain archaea and nitrogen-fixing bacteria, including cyanobacteria and certain other free-living and symbiotic bacteria, carry on biological nitrogen fixation in soil and aquatic environments. These nitrogen-fixing prokaryotes employ an enzyme called **nitrogenase** to break up molecular nitrogen and combine the resulting nitrogen atoms with hydrogen.

Because nitrogenase functions only in the absence of oxygen, the prokaryotes that fix nitrogen insulate the enzyme from oxygen in some way. Some nitrogen-fixing prokaryotes live beneath layers of oxygen-excluding slime

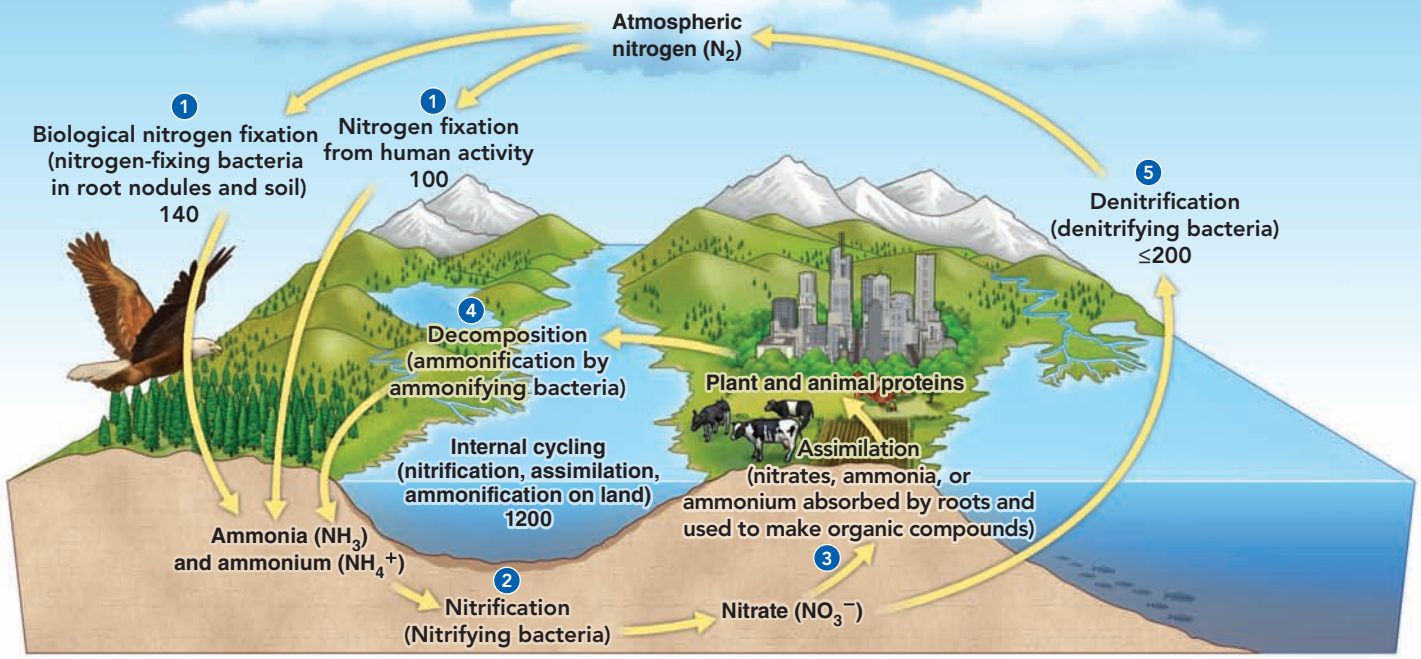

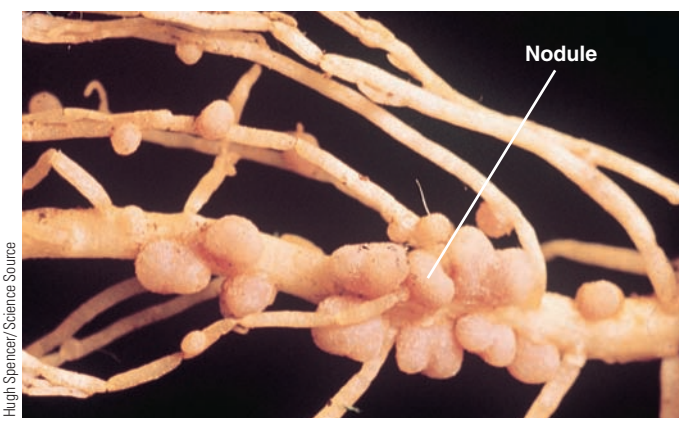

Figure 55-8 A simplified diagram of the nitrogen cycle

The largest pool of nitrogen, estimated at 3.9×10^{21} g, is in the atmosphere. The values shown for selected nitrogen fluxes in the global nitrogen budget are expressed as 10^{12} g of nitrogen per year and represent terrestrial values. For example, each year humans fix an estimated 100×10^{12} g of nitrogen. Values from W.H. Schlesinger, *Biogeochemistry: An Analysis of Global Change*, 2nd ed. (Academic Press, San Diego, 1997), and several other sources.

on the roots of several plant species. Other important nitrogen-fixing bacteria, in the genus *Rhizobium*, live in oxygen-excluding swellings, or **nodules**, on the roots of legumes such as beans and peas and some woody plants (FIG. 55-9; also see Table 25-3).

In aquatic environments, bacteria and archaea perform most nitrogen fixation. Filamentous cyanobacteria have special oxygen-excluding cells called **heterocysts** that function to fix nitrogen (see Table 25-3). Some water ferns have cavities in which cyanobacteria live, in a manner comparable to the way *Rhizobium* lives in root nodules of legumes. Other cyanobacteria fix nitrogen in symbiotic association with cycads and other terrestrial plants or as the photosynthetic partner of certain lichens.

Hugh Spencer/Science Source

Figure 55-9 Root nodules and nitrogen fixation

Root nodules on the roots of a pea plant provide an oxygen-free environment for nitrogen-fixing *Rhizobium* bacteria that live in them.

The second step of the nitrogen cycle is **nitrification** (see Fig. 55-8), the conversion of ammonia (NH_3) or ammonium (NH_4^+), formed when water reacts with ammonia, to nitrate (NO_3^-). Soil bacteria are responsible for the two-phase process of nitrification, which furnishes these bacteria, called *nitrifying bacteria*, with energy.

In the third step, **assimilation**, roots absorb ammonia (NH_3), ammonium (NH_4^+), or nitrate (NO_3^-) formed by nitrogen fixation and nitrification, and incorporate the nitrogen into proteins, nucleic acids, and chlorophyll. When animals consume plant tissues, they assimilate nitrogen by taking in plant nitrogen compounds and converting them to animal nitrogen compounds.

The fourth step, **ammonification**, is the conversion of organic nitrogen compounds into ammonia (NH_3) and ammonium ions (NH_4^+). Ammonification begins when organisms produce nitrogen-containing wastes such as urea in urine and uric acid in the wastes of birds (see Fig. 48-1). As these substances, along with the nitrogen compounds in dead organisms, decompose, nitrogen is released into the abiotic environment as ammonia (NH_3). The bacteria that perform ammonification in both the soil and aquatic environments are called *ammonifying bacteria*.

Most available nitrogen in the soil derives from the recycling of organic nitrogen by ammonification.

The fifth step of the nitrogen cycle is **denitrification**, the reduction of nitrate (NO_3^-) to gaseous nitrogen (N_2). Denitrifying prokaryotes reverse the action of nitrogen-fixing and nitrifying prokaryotes by returning nitrogen to the atmosphere as nitrogen gas. Denitrifying prokaryotes are anaerobic and therefore live and grow best where there is little or no free oxygen. For example, they are found deep in the soil near the water table, an environment that is nearly oxygen-free.

Human activities have changed the global nitrogen budget Human activities have disturbed the balance of the global nitrogen cycle. During the 20th century, humans more than doubled the amount of fixed nitrogen (nitrogen that has been chemically combined with hydrogen, oxygen, or carbon) entering the global nitrogen cycle. The excess nitrogen is seriously altering many terrestrial and aquatic ecosystems.

Large quantities of nitrogen fertilizer, for commercial farming operations and for residential use, are produced from nitrogen gas for agriculture. The increasing use of fertilizer has resulted in higher crop yields, but there are negative environmental effects from human-produced nitrogen. Nitrogen fertilizer is extremely mobile and is easily transferred from the land to rivers to estuaries to the ocean. Thus, the overuse of commercial fertilizer on the land causes water-quality problems that may help explain long-term declines in many coastal fisheries. The amount of nitrate or ammonium in most aquatic ecosystems is in limited supply and limits the growth of algae. Rain washes fertilizer into rivers and lakes, where it stimulates the growth of algae, some of which are toxic. As these algae die, their decomposition by bacteria robs the water of dissolved oxygen, which in turn causes other aquatic organisms, including many fishes, to suffocate.

Nitrates from fertilizer also leach (dissolve and wash down) through the soil and contaminate groundwater. Many people who live in rural areas drink groundwater. Groundwater contaminated by nitrates is dangerous, particularly for infants and small children.

Another human activity that affects the nitrogen cycle is the combustion of fossil fuels. When fossil fuels are burned, the nitrogen locked in organic compounds in the fuel is chemically altered and transferred to the atmosphere. In addition, the high temperature of combustion converts some atmospheric nitrogen to **nitrogen oxides**. Automobile exhaust is one of the main sources of nitrogen oxides. Nitrogen oxides are a necessary ingredient in the production of **photochemical smog**, a mixture of several air pollutants that injure plant tissues, irritate eyes, and cause respiratory problems in humans.

Nitrogen oxides also react with water in the atmosphere to form nitric acid (HNO_3) and nitrous acid (HNO_2). When these and other acids leave the atmosphere as precipitation (rain, sleet, snow, or hail), they decrease the pH of surface waters (lakes and streams) and soils. **Acid precipitation** includes rain, snow, fog, or dust that is unusually acidic (pH below 5.6). Acid precipitation has been linked to declining animal populations in aquatic ecosystems. On land, acid precipitation alters soil chemistry: certain essential minerals, such as calcium and potassium, wash out of the soil and are therefore unavailable for plants. Nitrous oxide (N_2O), one of the nitrogen oxides, retains heat in the atmosphere (like CO_2) and so promotes global climate change.

Nitrous oxide also contributes to the depletion of ozone in the stratosphere. (See Chapter 2 for a discussion of acids and pH, and Chapter 57 for a discussion of global climate change and stratospheric ozone depletion.)

The phosphorus cycle lacks a gaseous component

Phosphorus does not exist in a gaseous state and therefore does not enter the atmosphere. In the **phosphorus cycle**, phosphorus cycles from the land to sediments in the ocean and back to the land (FIG. 55-10).

As water runs over rocks containing phosphorus, it gradually erodes the surface and carries off inorganic phosphate (PO_4^{3-}). The erosion of phosphorus rocks releases phosphate into the soil, where it is taken up by roots in the form of inorganic phosphates. Once in cells, phosphates are incorporated into a variety of biological molecules, including nucleic acids, ATP, and the phospholipids that make up cell membranes. Animals obtain most of their required phosphorus from the food they eat, although in some places drinking water may contain a substantial amount of inorganic phosphate. Phosphate released by decomposers becomes part of the pool of inorganic phosphate in the soil that plants reuse. Thus, like carbon and nitrogen, phosphorus moves through the food web as one organism consumes another.

Phosphorus cycles through aquatic ecosystems in much the same way as through terrestrial ecosystems. Dissolved phosphate enters aquatic ecosystems through absorption by algae and aquatic plants, which zooplankton and larger organisms consume. In turn, a variety of fishes and mollusks eat the zooplankton. Ultimately, decomposers break down wastes and dead organisms to release inorganic phosphate into the water, making it available for use again by aquatic producers.

Phosphate can be lost for varying time periods from biological cycles. Streams and rivers carry some phosphate to the ocean, where it is deposited on the seafloor and remains for millions of years. The geologic process of uplift may someday expose these reservoirs of seafloor sediments as new land surfaces, from which phosphate will be once again eroded. Phosphate deposits are also mined for agricultural use in phosphate fertilizers.

Humans affect the natural cycling of phosphorus In natural terrestrial communities, very little phosphorus is lost from the cycle, but few communities today are in a natural state, that is, unaltered in some way by humans. Land-denuding practices, such as the clear-cutting of timber, and erosion of agricultural and residential lands accelerate phosphorus loss from the soil into waterways. Excess phosphorus enriches the water, causing algal blooms that rob the water of dissolved oxygen. For practical purposes, phosphorus that washes from the land into the ocean is permanently lost from the terrestrial phosphorus cycle (and from further human use) because it remains in the ocean for millions of years.

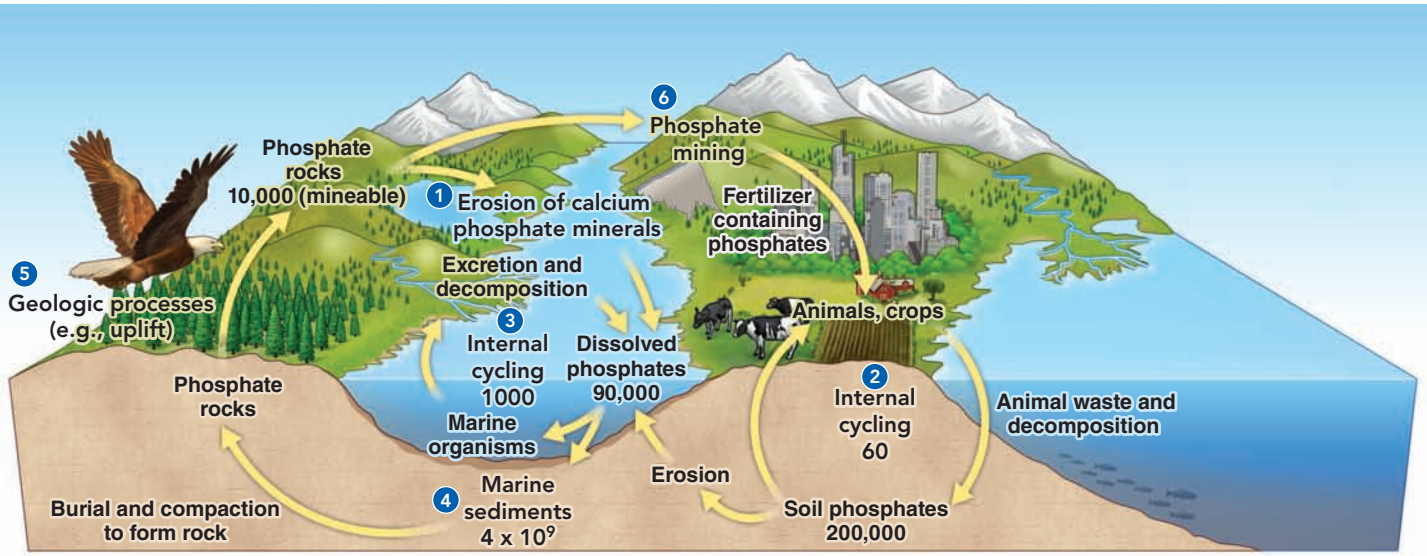

Figure 55-10 A simplified diagram of the phosphorus cycle

Some values of the global phosphorus budget are given, in units of 10^{12} g phosphorus per year. For example, each year an estimated 60×10^{12} g of phosphorus cycles from the soil to terrestrial organisms and back to the soil. Values from W.H. Schlesinger, *Biogeochemistry: An Analysis of Global Change*, 2nd ed. (Academic Press, San Diego, 1997), and several other sources.

Ecologists are also concerned that we are mining phosphorus faster than is sustainable. At its current rate of use, U.S. deposits of phosphorus will probably be depleted during the 21st century. There are currently no substitutes for phosphorus or synthetic methods to produce it.

Water moves among the ocean, land, and atmosphere in the hydrologic cycle

Life would be impossible without water, which makes up a substantial part of the mass of most organisms. All species, prokaryotes and eukaryotes, use water as a medium for chemical reactions as well as for the transport of materials within and among cells. (Recall from Chapter 2 that water has many unique properties that help shape the continents, moderate climate, and allow organisms to survive.)

In the **hydrologic cycle**, water continuously circulates from the ocean to the atmosphere to the land and back to the ocean (FIG. 55-11). Water moves from the atmosphere to the land and ocean in the form of precipitation. Water that evaporates from the ocean surface and from soil, streams, rivers, and lakes eventually condenses and forms clouds in the atmosphere. In addition, **transpiration**, the loss of water vapor from land plants, adds a considerable amount of water vapor to the atmosphere. Roughly 97% of the water a plant absorbs from the soil is transported to the leaves, where it is lost by transpiration.

Water may evaporate from land and re-enter the atmosphere directly. Alternatively, it may flow in rivers and streams to coastal **estuaries**, where fresh water meets and mixes with the ocean. The movement of surface water from land to ocean is called *runoff*, and the area of land drained by runoff is called a *watershed*. Water also percolates (seeps) downward in the soil to become *groundwater*, where it is trapped and held for a time. The underground caverns and porous layers of rock in which groundwater is stored are called *aquifers*. Groundwater may reside in the ground for hundreds to many thousands of years, but eventually it supplies water to the soil, streams and rivers, plants, and the ocean. The human removal of more groundwater than precipitation or melting snow recharges, called *aquifer depletion*, eliminates groundwater as a water resource and is an increasingly serious global conservation concern.

Regardless of its physical form (solid, liquid, or vapor) or location, every molecule of water eventually moves through the hydrologic cycle. Tremendous amounts of water cycle annually between Earth and its atmosphere. The volume of water entering the atmosphere from the ocean each year is estimated at about 425,000 km^3. Approximately 90% of this water re-enters the ocean directly as precipitation over water; the remainder falls on land. As is true of the other cycles, water (in the form of glaciers, polar ice caps, and certain groundwater) can be lost from the cycle for thousands of years. Scientists report that global warming continues to accelerate the melting of glaciers and polar ice, releasing fresh water back into the water cycle and raising sea levels worldwide.

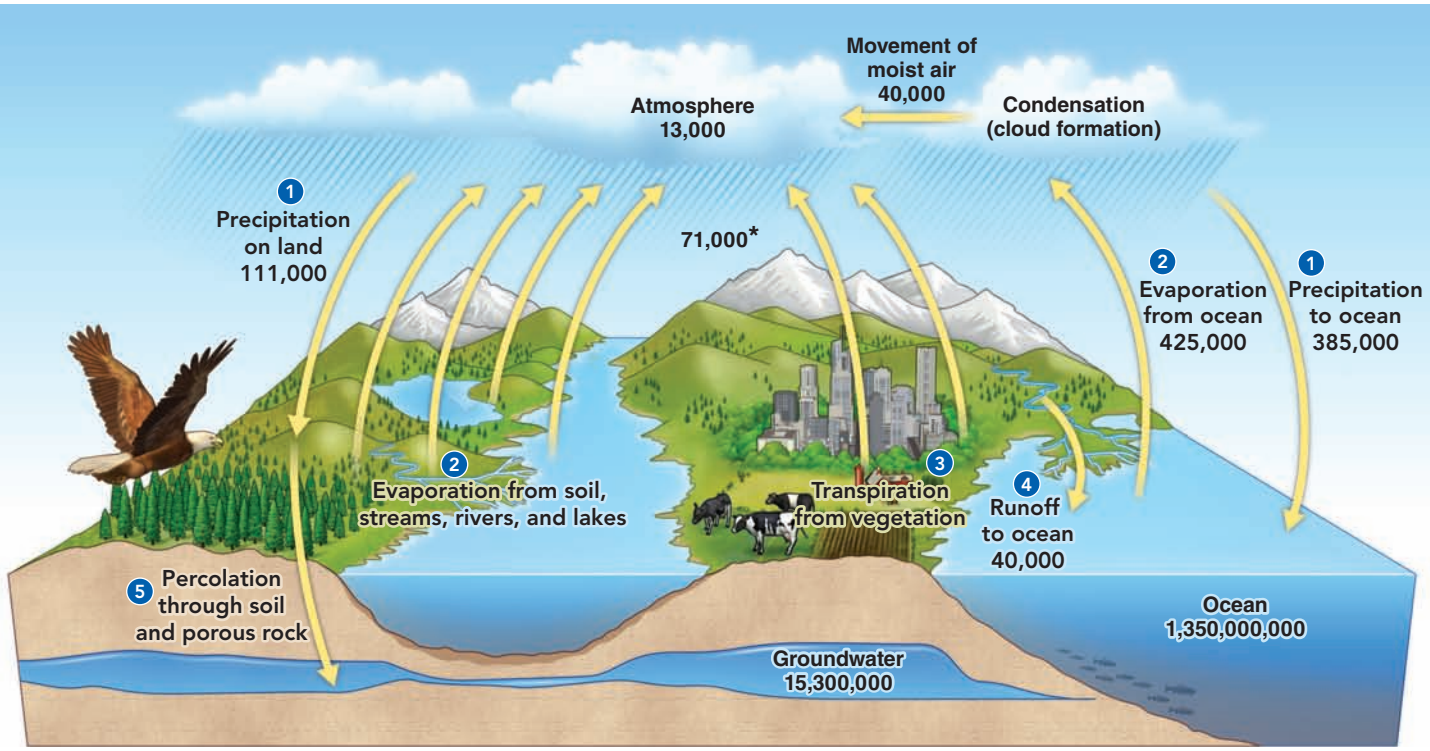

Figure 55-11 A simplified diagram of the hydrologic cycle

The global water budget values shown for pools are expressed as cubic kilometers; values for fluxes (movements associated with arrows) are in cubic kilometers per year. The *starred value* (71,000 km^3/yr) is the sum of both transpiration and evaporation from soil, streams, rivers, and lakes. Values from W.H. Schlesinger, *Biogeochemistry: An Analysis of Global Change*, 2nd ed. (Academic Press, San Diego, 1997), and several other sources.

55.3 Abiotic Factors in Ecosystems

LEARNING OBJECTIVES

5 Summarize the effects of solar energy on Earth's temperatures.
6 Discuss the roles of solar energy and the Coriolis effect in the generation of global air and water flow patterns.
7 Give two causes of regional precipitation differences.
8 Discuss the effects of fire on certain ecosystems.

You have seen how ecosystems depend on the abiotic environment to supply energy and essential materials (in biogeochemical cycles). Other abiotic factors such as solar radiation, the atmosphere, the ocean, climate, and fire also affect ecosystems. For a given abiotic factor, each organism living in an ecosystem has an optimal range in which it survives and reproduces. Water and temperature are probably the two abiotic factors that most affect organisms in ecosystems.

The sun warms Earth

The sun makes life on Earth possible. Without the sun's energy, the temperature on planet Earth would approach absolute zero (0 K or −273°C), and all water would be frozen, even in the ocean. The sun powers the hydrologic cycle, carbon cycle, and other biogeochemical cycles and is the primary determinant of climate. Photosynthetic organisms capture the sun's energy and use it to make organic compounds that almost all forms of life require. Most of our fuels, such as wood, oil, coal, and natural gas, represent solar energy captured by photosynthetic organisms. Without the sun, almost all life on Earth would cease (see *Inquiring About: Life without the Sun* for an interesting exception).

The sun's energy, which is the product of a massive nuclear fusion reaction, is emitted into space in the form of electromagnetic radiation, especially ultraviolet, visible, and infrared radiation. About one-billionth of the total energy that the sun releases strikes the atmosphere, and of this tiny trickle of energy, a minute part operates the biosphere. On average, clouds and surfaces—especially snow, ice, and the ocean—immediately reflect away 30% of the solar radiation that falls on Earth (FIG. 55-12). Earth's surface and atmosphere absorb the remaining 70%, which runs the water cycle, drives winds and ocean currents, powers photosynthesis, and warms the planet. Ultimately, the continual radiation of long-wave infrared (heat) energy returns all this energy to space. When heat gains do not exactly balance losses, Earth heats up or cools down.

Temperature changes with latitude The most significant local variations in Earth's temperature are produced because the sun's energy does not uniformly reach all places. Our planet's roughly spherical shape and the tilted angle of its axis produce significant variation in the exposure of the surface to sunlight. The

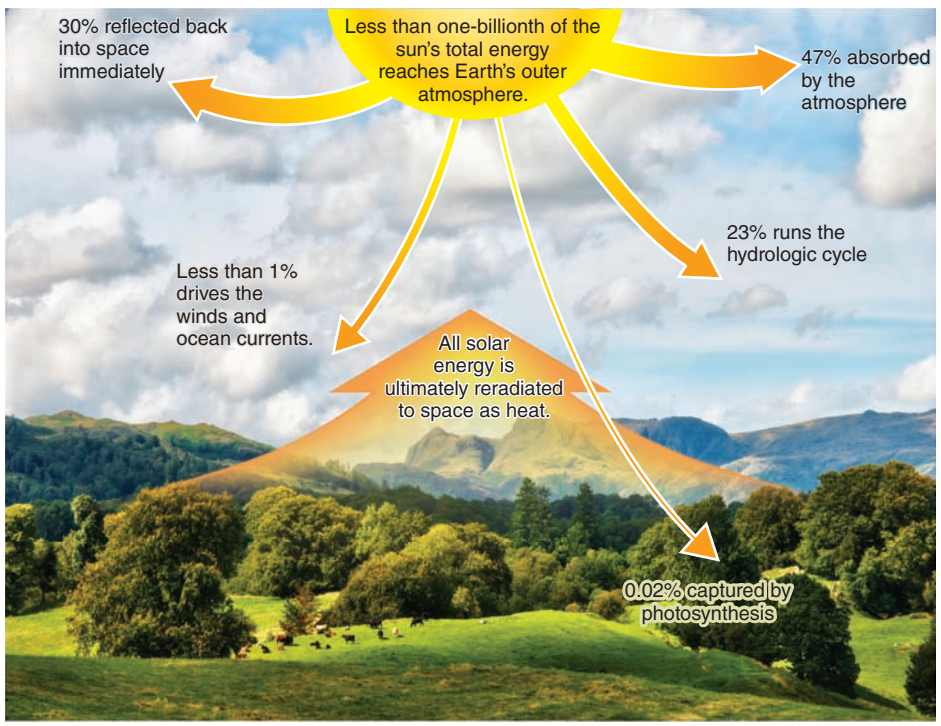
Inquiring About

Life without the Sun

Is the sun the energy source for all ecosystems? A notable exception was discovered in the late 1970s in a series of hydrothermal vents in the eastern Pacific where seawater apparently had penetrated and been heated by the radioactive rocks below. During its time within Earth, the water had become charged with inorganic mineral compounds, including hydrogen sulfide (H_2S).

No light is available for photosynthesis, but hydrothermal vents support a rich ecosystem that contrasts with the surrounding "desert" of the deep-ocean floor. Giant, blood-red tube worms almost 3 m (10 ft) in length cluster in great numbers around the vents (see figure). Other animals around the hydrothermal vents include unique species of clams, crabs, barnacles, and mussels.

Scientists initially wondered what energy source sustains the organisms in this dark environment. Most deep-sea communities depend on the organic matter that drifts down from the surface waters; in other words, they rely on energy ultimately derived from photosynthesis. Hydrothermal vent communities, however, are too densely clustered and too productive to be dependent on chance encounters with organic material from surface waters.



Instead, chemoautotrophic prokaryotes occupy the base of the food web in these aquatic oases. These prokaryotes have enzymes that catalyze the oxidation of hydrogen sulfide, yielding water plus sulfur or sulfate. Such chemical reactions are exergonic and provide the energy required to fix CO_2 dissolved in the water into organic compounds. Many of the animals consume the prokaryotes directly by filter-feeding, but others, such as the giant tube worms, get their energy from prokaryotes that live in their tissues.

D. Foster, Science VU-SHO/Visuals Unlimited

Hydrothermal vent ecosystem. Chemoautotrophic prokaryotes living in the tissues of these tube worms (*Riftia pachyptila*) extract energy from hydrogen sulfide to manufacture organic compounds. These worms lack digestive systems. They depend on the organic compounds the prokaryotes provide, along with materials filtered from the surrounding water. Also visible in the photograph are some filter-feeding clams (*yellow*) and a crab (*white*).

Scientists continue to discover hydrothermal vent communities as they explore and map the ocean bottom. Researchers generate numerous questions about hydrothermal vent communities. How do the organisms find and colonize vents, which are ephemeral and widely scattered on the ocean floor? How have the inhabitants of these communities adapted to survive the harsh living conditions, including high pressure, high temperatures, and toxic chemicals? As vent community research continues, scientists hope to discover answers to these questions and to identify organisms that potentially have medicinal or industrial value, untapped resources to aid humanity.

Kevin Eaves/Shutterstock.com

Figure 55-12 The fate of solar radiation that reaches Earth

Most of the energy released by the sun never reaches Earth. The solar energy that does reach Earth warms the planet's surface, drives the hydrologic and other biogeochemical cycles, produces the climate, and powers almost all life through the process of photosynthesis.

sun's rays strike almost vertically near the equator, concentrating the energy and producing warmer temperatures. Near the poles, the sun's rays strike more obliquely and, as a result, are spread over a larger surface area. Also, rays of light entering the atmosphere obliquely near the poles must pass through a deeper envelope of air than those entering near the equator. This angle causes more of the sun's energy to be scattered and reflected back into space, which further lowers temperatures near the poles. Thus, the solar energy that reaches polar regions is less concentrated and produces lower temperatures than elsewhere.

Temperature changes with each season Earth's inclination on its axis (23.5 degrees from a line drawn perpendicular to the orbital plane) primarily determines the seasons. During half of the year (March 21 to September 22), the Northern Hemisphere tilts toward the sun, concentrating the sunlight and making the days longer (FIG. 55-13). During the other half of the year (September 22 to March 21), the Northern Hemisphere

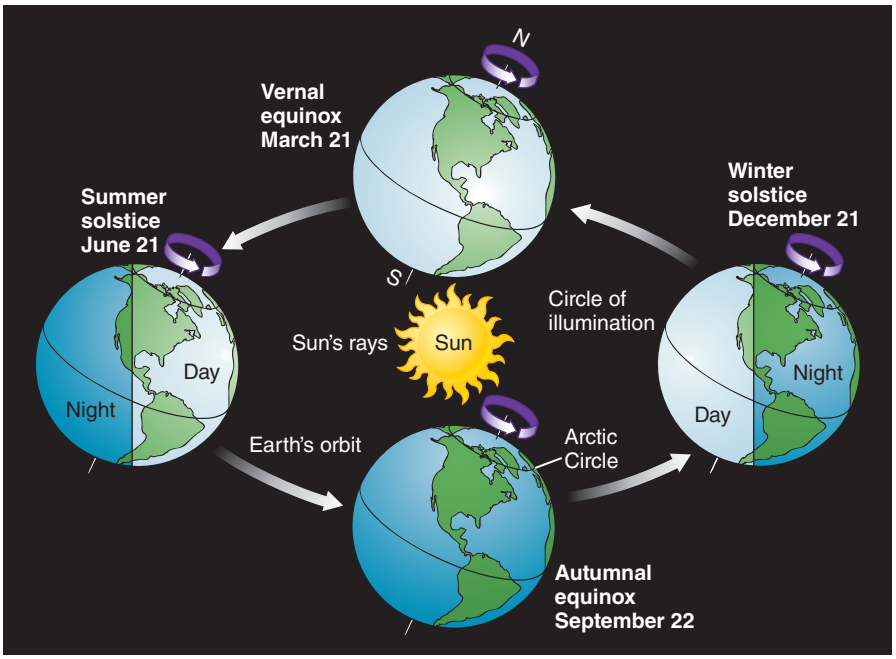

Figure 55-13 Seasonal changes in temperature

Earth's inclination on its axis remains the same as Earth travels around the sun. Thus, the sun's rays hit the Northern Hemisphere obliquely during winter months and more directly during summer months. In the Southern Hemisphere, the sun's rays are oblique during the winter, which corresponds to the Northern Hemisphere's summer. At the equator, the sun's rays are approximately vertical on March 21 and September 22.

tilts away from the sun, giving it a lower concentration of sunlight and shorter days. The orientation of the Southern Hemisphere is just the opposite at these times. Summer in the Northern Hemisphere corresponds to winter in the Southern Hemisphere.

The atmosphere contains several gases essential to organisms

The atmosphere is an invisible layer of gases that envelops Earth. Oxygen (21%) and nitrogen (78%) are the predominant gases in the atmosphere, accounting for about 99% of dry air; other gases, including argon, carbon dioxide, neon, and helium, make up the remaining 1%. In addition, water vapor and trace amounts of various air pollutants, such as methane, ozone, dust particles, pollen, microorganisms, and chlorofluorocarbons (CFCs), are present. Atmospheric oxygen is essential to plants, animals, and other organisms that respire aerobically; and plants and other photosynthetic organisms also require carbon dioxide.

The atmosphere performs several essential ecological functions. It protects Earth's surface from most of the sun's ultraviolet radiation and X-rays as well as from lethal amounts of cosmic rays from space. Without this atmospheric shielding, life as we know it would cease. Although the atmosphere protects Earth from high-energy radiation, visible light and some infrared radiation can penetrate it, and they warm the surface and the lower atmosphere. This interaction between the atmosphere and solar energy is responsible for weather and climate.

Organisms depend on the atmosphere. However, they also help maintain and, in certain instances, modify its composition. For example, atmospheric oxygen increased to its present level as a result of billions of years of photosynthesis. Today, an approximate balance between oxygen-producing photosynthesis and oxygen-using aerobic respiration helps maintain the level of atmospheric oxygen.

The sun drives the global atmospheric circulation In large measure, differences in temperature that are due to variations in the amount of solar energy at different locations on Earth drive the circulation of the atmosphere. The warm surface near the equator heats the air with which it comes into contact, causing this air to expand and rise. As the warm air rises, it flows away from the equator, cools, and sinks again (FIG. 55-14). Much of it recirculates to the same areas it left, but the remainder splits and flows in two directions, toward the poles. The air chills enough to sink to the surface at about 30 degrees north and south latitudes. Similar upward movements of warm air and its subsequent flow toward the poles occur at higher latitudes, farther from the equator. At the poles, the cold polar air sinks and flows toward the lower

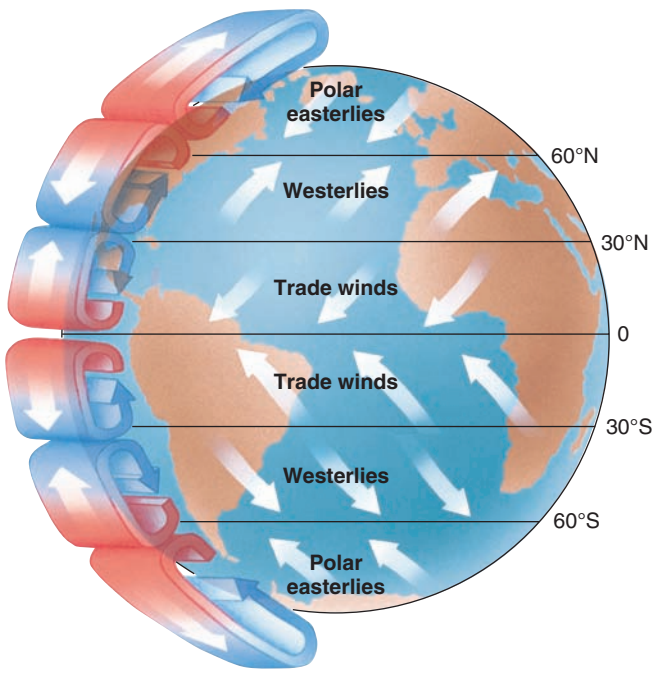

Figure 55-14 Atmospheric circulation

The greatest solar energy input occurs at the equator and heats air most strongly in that area. The air rises and travels poleward (*left*) but is cooled in the process, so much of it descends again around 30 degrees latitude in both hemispheres. At higher latitudes, the patterns of air movement are more complex.

Key Point

The driving force of wind produces Earth's major surface ocean currents.

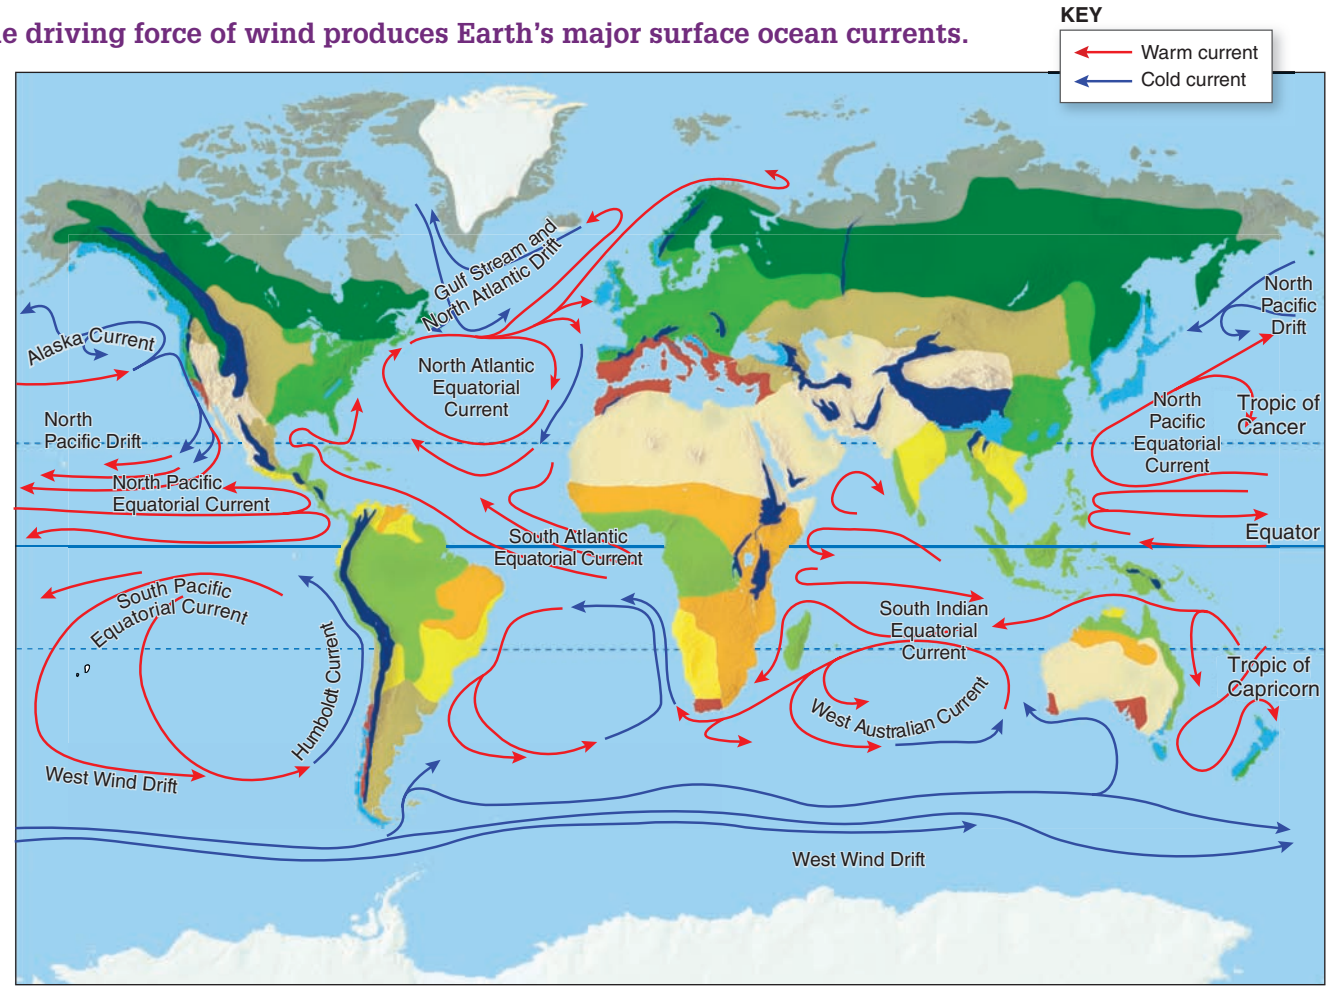

Figure 55-15 Major surface ocean currents
Each current has characteristic temperature and flow patterns.

PREDICT How could currents be affected by global climate change?

latitudes, generally beneath the warm air that simultaneously flows toward the poles. The constant motion of air transfers heat from the equator toward the poles, and as the air returns, it cools the land over which it passes. This continuous turnover moderates temperatures over Earth's surface.

The atmosphere exhibits complex horizontal movements In addition to global circulation patterns, the atmosphere exhibits complex horizontal movements called **winds**. The nature of wind, with its turbulent gusts, eddies, and lulls, is difficult to understand or predict. It results in part from differences in atmospheric temperature and pressure changes, Earth's rotation, and uneven heating of the oceans and continents.

The gases that constitute the atmosphere have weight and exert a pressure that is, at sea level, about 1013 millibars (14.7 lb/in.^{2}). Air pressure is variable, however, and changes with altitude, temperature, and humidity. Winds tend to blow from areas of high atmospheric pressure to areas of low pressure; the greater the difference and proximity between the high and low pressure areas, the stronger the wind.

Earth's rotation influences the direction that wind blows. Because Earth rotates from west to east, wind swerves to the right in the Northern Hemisphere and to the left in the Southern Hemisphere. This tendency of moving air to be deflected from its path by Earth's rotation is known as the **Coriolis effect**.

The global ocean covers most of Earth's surface

The global ocean is a huge body of salt water that surrounds the continents and covers almost three-fourths of Earth's surface. It is a single, continuous body of water, but geographers divide it into four sections separated by the continents: the Pacific, Atlantic, Indian, and Arctic Oceans. The Pacific Ocean, which covers one-third of Earth's surface and contains more than half of Earth's water, is the largest by far.

Winds drive surface ocean currents The persistent prevailing winds blowing over the ocean produce mass movements of surface ocean water known as **ocean currents** (FIG. 55-15). The

prevailing winds generate circular ocean currents called *gyres*. For example, in the North Atlantic, the tropical trade winds tend to blow toward the west, whereas the westerlies in the midlatitudes blow toward the east (see Fig. 55-14). This movement helps establish a clockwise gyre in the North Atlantic. Thus, surface ocean currents and winds tend to move in the same direction, although there are many variations on this general rule.

The Coriolis effect is partly responsible for the paths that surface ocean currents travel. Earth's rotation from west to east causes surface ocean currents to swerve to the right in the Northern Hemisphere, producing a clockwise gyre of water currents. In the Southern Hemisphere, ocean currents swerve to the left, producing a counterclockwise gyre.

The ocean interacts with the atmosphere The ocean and the atmosphere are strongly linked. Wind from the atmosphere affects the ocean currents, and heat from the ocean affects atmospheric circulation. One of the best examples of the interaction between the ocean and atmosphere is the **El Niño–Southern Oscillation (ENSO)** event. ENSO is a periodic warming of surface waters of the tropical eastern Pacific that alters both oceanic and atmospheric circulation patterns and results in unusual weather in areas far from the tropical Pacific. Normally, westward-blowing trade winds restrict the warmest waters to the western Pacific (near Australia). Every three to seven years, however, the trade winds weaken, and the warm water mass expands eastward to South America, raising surface temperatures in the eastern Pacific. Ocean currents, which normally flow westward in this area, slow down, stop altogether, or even reverse and go eastward. The phenomenon is called El Niño, which is Spanish for "the (Christ) child," because the warming usually reaches the fishing grounds off Peru just before Christmas. Most ENSOs last from one to two years. La Niña (Spanish for "the girl"), the opposite phase, is the cold phase, of the ENSO cycle and occurs when cold ocean waters return.

An ENSO event changes biological productivity in parts of the ocean. The warmer sea-surface temperatures and accompanying changes in ocean circulation patterns off the west coast of South America prevent colder, nutrient-laden deeper waters from **upwelling** (coming to the surface) (FIG. 55-16). The lack of nutrients in the water results in a severe decrease in the populations of anchovies and many other marine fishes. Other species, such as shrimp and scallops, thrive during an ENSO event. Along the Pacific coast of North America, ENSO shifts the distribution of tropical fishes northward and even affects the salmon run in Alaska.

Climate profoundly affects organisms

Climate is the average weather conditions, plus extremes (records), that occur in a given place over a period of years. The two most important factors that determine an area's climate are temperature (both average temperature and temperature extremes) and precipitation (both average precipitation and seasonal distribution). Other climate factors include wind, humidity, fog, cloud cover, and lightning-caused wildfires. Unlike weather, which changes rapidly, climate generally changes slowly, over hundreds or thousands of years.

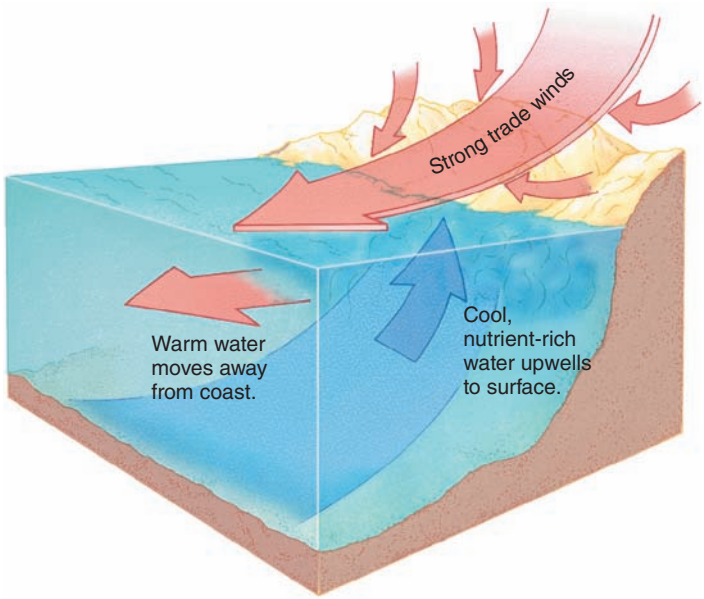

Figure 55-16 Upwelling
Coastal upwelling, where deeper waters come to the surface, occurs in the Pacific Ocean along the South American coast. Upwelling provides nutrients for microscopic algae, which in turn support a complex food web. Coastal upwelling weakens considerably during years with ENSO events, temporarily reducing fish populations.

Day-to-day variations, day-to-night variations, and seasonal variations are also important dimensions of climate that affect organisms. Latitude, elevation, topography, vegetation, distance from the ocean or other large bodies of water, and location on a continent or other landmass all influence temperature, precipitation, and other aspects of climate.

Earth has many different climates, and because they have been relatively constant for many years, organisms have adapted to them. The wide variety of organisms on Earth evolved in part because of the many different climates, ranging from cold, snow-covered, polar climates to hot, tropical climates where it rains almost every day.

Air and water movements and surface features affect precipitation patterns Precipitation varies from one location to another and has a profound effect on the distribution and kinds of organisms present. One of the driest places on Earth is in the Atacama Desert in Chile, where the average annual rainfall is 0.05 cm (0.02 in.). In contrast, Mawsynram in India, Earth's wettest spot, receives an average annual precipitation of 1187 cm (467 in.).

Differences in precipitation depend on several factors. The heavy-rainfall areas of the tropics result mainly from the uplifting of moisture-laden air. High surface-water temperatures (recall the enormous amount of solar energy striking the equator) cause the evaporation of vast quantities of water from tropical parts of the ocean. Prevailing winds blow the resulting moist, warm air over landmasses. Land surfaces warmed by the sun heat the air and cause moist air to rise. As it rises, the air cools, and its moisture-holding ability decreases. (Cool air holds

less water vapor than warm air.) When air reaches its saturation point, it cannot hold any additional water vapor; clouds form, and water is released as precipitation. The air eventually returns to the surface on both sides of the equator near the Tropics of Cancer and Capricorn (latitudes 23.5 degrees north and south, respectively). By then, most of the moisture has precipitated so that dry air returns to the equator. This dry air makes little biological difference over the ocean, but its lack of moisture produces some of the great subtropical deserts, such as the Sahara.

Air is also dried during long journeys over landmasses. Near the windward (side from which the prevailing wind blows) coasts of continents, rainfall may be heavy. However, in the temperate zones—the areas between the tropical and polar zones—continental interiors are usually dry because they are far from the ocean that replenishes water vapor in the air passing over it.

Mountains force air to rise, removing moisture from humid air. As it gains altitude, the air cools, clouds form, and precipitation typically occurs, primarily on the windward slopes of the mountains. As the air mass moves down on the other side of the mountain, it is warmed, and clouds then evaporate, thereby lessening the chance of precipitation of any remaining moisture. This situation exists on the west coast of North America, where precipitation falls on the western slopes of mountains that are close to the coast. The dry lands on the sides of the mountains away from the prevailing wind (in this case, east of the mountain range) are called **rain shadows** (FIG. 55-17).

Microclimates are local variations in climate Differences in elevation, in the steepness and direction of slopes, and therefore in exposure to sunlight and prevailing winds may produce local variations in climate known as **microclimates**, which are sometimes quite different from their overall surroundings. Patches of sun and shade on a forest floor, for example, produce a variety of microclimates for plants, animals, and microorganisms living there. The microclimate of an organism's habitat is of primary importance because it is the climate that an organism actually experiences and must cope with. (Keep in mind, however, that microclimates are largely affected by the regional climates in which they are located.)

Sometimes organisms modify their own microclimate. For example, trees modify the local climate within a forest so that in summer the temperature is usually lower, and the relative humidity greater, than outside the forest. The temperature and humidity beneath the litter of the forest floor differ still more; in the summer the microclimate of this area is considerably cooler and moister than the surrounding forest. As another example, many desert-dwelling animals burrow to avoid surface climate conditions that would kill them in minutes. The cooler daytime microclimate in their burrows permits them to survive until night, when the surface cools off and they come out to forage or hunt.

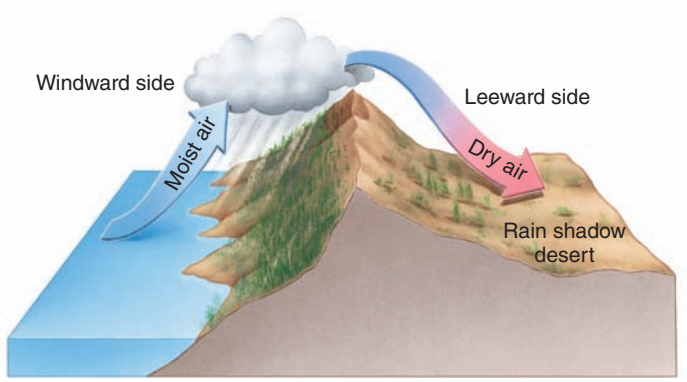

Figure 55-17 Rain shadow

A rain shadow is the arid or semiarid land that occurs on the leeward side of a mountain. Such a rain shadow occurs east of the Cascade Range in Washington State. The western side of the range receives more than 500 cm of precipitation annually, whereas the eastern side receives 40 to 50 cm.

Fires are a common disturbance in some ecosystems

Wildfires, which are fires started by lightning, are an important ecological force in many geographic areas. Those areas most prone to wildfires have wet seasons followed by dry seasons. Vegetation that grows and accumulates during the wet season dries out enough during the dry season to burn easily. When lightning hits vegetation or ground litter, it ignites the dry organic material, and a fire spreads through the area.

Fires have several effects on organisms. First, combustion frees the minerals that were locked in dry organic matter. The ashes remaining after a fire are rich in potassium, phosphorus, calcium, and other minerals essential for plant growth. With the arrival of precipitation, vegetation flourishes following a fire. Second, fire removes plant cover and exposes the soil. This change stimulates the germination and establishment of seeds requiring bare soil as well as encourages the growth of shade-intolerant plants. Third, fire causes increased soil erosion because it removes plant cover, leaving the soil more vulnerable to wind and water.

African savanna, California chaparral, North American grasslands, and ponderosa pine forests of the western United States are some fire-adapted ecosystems (see Chapter 56). Fire helps maintain grasses as the dominant vegetation in grasslands by removing fire-sensitive hardwood trees.

Humans try to prevent fires, and sometimes this effort has disastrous consequences. When fire is excluded from a fire-adapted ecosystem, deadwood and other plant litter accumulate. As a result, when a fire does occur, it can be very destructive. The sometimes deadly wildfires in Colorado and other western states and provinces are blamed in part on decades of suppressing fires in the region. Prevention of fire also converts grassland to woody vegetation and facilitates the invasion of fire-sensitive trees into fire-adapted forests.

Controlled burning is a tool of ecological management in which the undergrowth and plant litter are deliberately burned under controlled conditions before they have accumulated to dangerous levels (FIG. 55-18). Controlled burns are also used to suppress fire-sensitive trees, thereby maintaining the natural fire-adapted ecosystem. In a 2010 study of fire reintroduction in Sierra Nevada forests reported in *Ecosphere*, Karen Webster and Charles Halpern explored two decades of changes

in plant diversity and abundance following reintroduction and repeated use of fire in previously unmanaged forests. Results from their research suggest that repeated controlled burning can gradually enhance the diversity and abundance of understory species and may enhance the dispersal of those species impacted by fire exclusion. More research needs to be conducted on when controlled burning is appropriate or how often it should be carried out. Moreover, there are major practical, political, and educational issues that must be addressed in implementing controlled burns.

CHECKPOINT 55.3

- What basic forces produce the main ocean currents?
- **CONNECT** What are some of the factors that produce regional differences in precipitation?

55.4 Studying Ecosystem Processes

LEARNING OBJECTIVE

9 Briefly describe some of the long-term ecological research conducted at Hubbard Brook Experimental Forest.

Ecologists conduct detailed ecosystem studies in laboratory simulations and in the field to measure such processes as energy flow, the cycling of nutrients, and the effects of natural and human-induced disturbances (e.g., air pollution, tree harvesting, and land-use changes). Some ecosystem studies, such as those performed at the Hubbard Brook Experimental Forest (HBEF), a 3100-hectare (7750-acre) reserve in the White Mountain National Forest in New Hampshire, are long term (FIG. 55-19). Beginning in the late 1950s and continuing to the present, HBEF has been the site of numerous studies that address the hydrology (e.g., precipitation, surface runoff, and groundwater flow), biology, geology, and chemistry of forests and associated aquatic ecosystems. The National Science Foundation (NSF) has designated HBEF as one of its 24 long-term ecological research sites.

Many of the experiments at HBEF are based on field observations. For example, salamander populations were originally surveyed in forest communities in 1970 and have been resurveyed in recent years. Other studies involve manipulative experiments. In 1978, scientists added dilute sulfuric acid to a small stream in HBEF to study the chemical and biological effects of acidification. This experiment was of practical value because acid precipitation, a form of air pollution, has acidified numerous lakes and streams in industrialized countries.

Several researchers have studied the effects on HBEF stream ecosystems of **deforestation**, the clearance of large expanses of forest for agriculture or other uses. When a forest is removed, the total amount of water and minerals that flow into streams increases drastically. A concrete dam called a *catchment* can be constructed across a stream so that ecologists can measure the flow of water and chemical components out of the ecosystem. Catchments help scientists to measure the

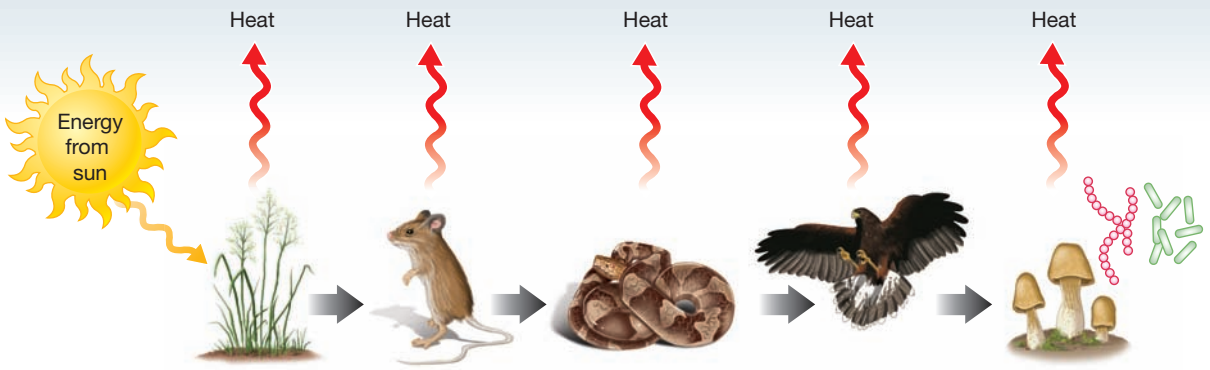
quantity, timing, and quality of water flowing from a forested watershed. Typically, outflow is measured in two separate ecosystems: one serves as a control, and one is experimentally manipulated. These studies demonstrate that deforestation causes soil erosion and leaching of essential minerals that result in decreased soil fertility. The summer temperatures in streams running through deforested areas are higher than in shady streams running through uncut forests. Many stream organisms do not fare well in deforested areas, in part because they are adapted to cooler temperatures.

Detailed studies such as those at HBEF provide ecologists with insights into how ecological processes function in individual ecosystems. Ecologists compare these data with similar information from other ecosystem studies to develop generalized insights into how ecosystems are structured and how they function. Long-term ecosystem experiments enable ecologists to evaluate and predict the effects of environmental change, including human-induced change.



Ecosystem experiments also contribute to our practical knowledge about how to maintain water quality, wildlife habitat, and productive forests. **Ecosystem management**, a conservation approach that emphasizes restoring and maintaining the quality of an entire ecosystem rather than the conservation of individual species, makes use of such knowledge.

Ecologists are also studying the causes of food-web flips and ecosystem collapse to recognize tipping points. A *food-web flip* occurs when there is a major persistent change in the sequences of organisms eating and being eaten by one another. As reported in *Science*, a team from the University of Wisconsin–Madison led by Stephen Carpenter examined 30 years of research on Peter Lake, Wisconsin, and developed mathematical models to recognize early signs of tipping points. The researchers identified signs of change in an endangered food web 15 months before it flipped. Continued research in this area may enhance our ability to recognize warning signs to protect ecosystems from natural and human effects before irreversible or costly damage occurs.

CHECKPOINT 55.4

- What are some of the environmental effects observed in the deforestation study at Hubbard Brook Experimental Forest?

Summary: Focus on Learning Objectives

55.1 Energy Flow through Ecosystems *(page 1195)*

1 Summarize the concept of energy flow through a food web.

- **Energy flow** through an ecosystem is linear, from the sun to producer to consumer to decomposer. Much of this energy is converted to heat as it moves from one organism to another, so organisms occupying the next **trophic level** cannot use it.
- Trophic relationships may be expressed as **food webs**, which show the many alternative pathways that energy may take among the producers, consumers, and decomposers of an ecosystem.

2 Explain typical pyramids of numbers, biomass, and energy.

- **Ecological pyramids** typically express the progressive reduction in numbers of organisms, biomass, and energy found in successive trophic levels. A **pyramid of numbers** shows the number of organisms at each trophic level in a given ecosystem. A **pyramid of biomass** shows the total biomass at each successive trophic level. A **pyramid of energy** indicates the energy content of the biomass of each trophic level. Toxins can pass through food webs, cause serious health concerns, and remain an environmental threat for decades.

3 Distinguish between gross primary productivity and net primary productivity.

- **Gross primary productivity (GPP)** of an ecosystem is the rate at which photosynthesis captures energy. **Net primary productivity (NPP)** is the energy that remains (as biomass) after plants and other producers carry out cellular respiration.

55.2 Cycles of Matter in Ecosystems *(page 1201)*

4 Describe the main steps in each of these biogeochemical cycles: the carbon, nitrogen, phosphorus, and hydrologic cycles.

- Carbon dioxide is the important gas of the **carbon cycle**. Carbon enters plants, algae, and cyanobacteria as CO_2, which photosynthesis incorporates into organic molecules. Cellular respiration, combustion, and erosion of limestone return CO_2 to the water and atmosphere, where it is again available to producers.
- The **nitrogen cycle** has five steps. **Nitrogen fixation** is the conversion of nitrogen gas to ammonia. **Nitrification** is the conversion of ammonia or ammonium to nitrate. **Assimilation** is the conversion of nitrates, ammonia, or ammonium to proteins and other nitrogen-containing compounds by plants; conversion of plant proteins into animal proteins is also assimilation. **Ammonification** is the conversion of organic nitrogen to ammonia and ammonium ions. **Denitrification** is the conversion of nitrate to nitrogen gas.
- The **phosphorus cycle** has no biologically important gaseous compounds. Phosphorus erodes from rock as inorganic phosphate, which the roots of plants absorb from the soil. Animals obtain the phosphorus they need from their diets. Decomposers release inorganic phosphate into the environment. When phosphorus washes into the ocean and is subsequently deposited in seabeds, it is lost from biological cycles for millions of years.
- The **hydrologic cycle** involves an exchange of water between the land, ocean, atmosphere, and organisms. Water enters the atmosphere by evaporation and **transpiration** and leaves the atmosphere as precipitation. On land, water filters through the ground or runs off to lakes, rivers, and the ocean. Aquifers are underground caverns and porous layers of rock in which groundwater is stored.

55.3 Abiotic Factors in Ecosystems *(page 1206)*

5 Summarize the effects of solar energy on Earth's temperatures.

- Of the solar energy that reaches Earth, 30% is immediately reflected away; the atmosphere and surface absorb the remaining 70%. Ultimately, all absorbed solar energy is reradiated into space as infrared (heat) radiation.
- A combination of Earth's roughly spherical shape and the tilted angle of its axis concentrates solar energy at the equator and dilutes it at the poles; the tropics are hotter and less variable in climate than are temperate and polar areas.

6 Discuss the roles of solar energy and the Coriolis effect in the generation of global air and water flow patterns.

- Visible light and some infrared radiation warm the surface and the lower part of the atmosphere. Atmospheric heat transferred from the equator to the poles produces movement of warm air toward the poles and of cool air toward the equator.
- **Winds** result in part from differences in atmospheric pressure and from the **Coriolis effect**, the tendency of moving air or water, because of Earth's rotation, to be deflected to the right in the Northern Hemisphere and to the left in the Southern Hemisphere.
- Surface **ocean currents** result in part from prevailing winds and the Coriolis effect.

7 Give two causes of regional precipitation differences.

- Latitude, elevation, topography, vegetation, distance from the ocean or other large bodies of water, and location on a continent or other landmass influence precipitation.
- Precipitation is greatest where warm air passes over the ocean, absorbs moisture, and then cools, such as in areas where mountains force humid air upward. Deserts develop in the **rain shadows** of mountain ranges or in continental interiors.

8 Discuss the effects of fire on certain ecosystems.

- Fire frees the minerals locked in dry organic matter, removes plant cover and exposes the soil, and increases soil erosion. Many ecosystems, such as savanna, chaparral, grasslands, and certain forests, contain fire-adapted organisms.

55.4 Studying Ecosystem Processes *(page 1212)*

9 Briefly describe some of the long-term ecological research conducted at Hubbard Brook Experimental Forest.

- Hubbard Brook Experimental Forest (HBEF) in New Hampshire is the site of numerous long-term studies that address the hydrology (precipitation, surface runoff, and groundwater flow), biology (effects of deforestation and changes in salamander populations), geology, and chemistry (acid precipitation) of forests and associated aquatic ecosystems.

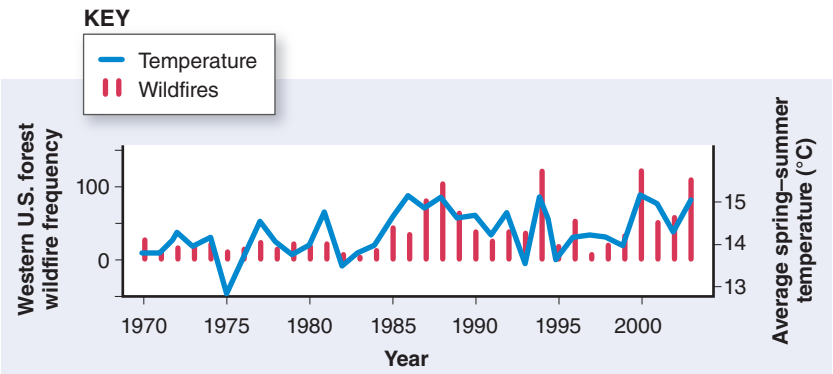
Test Your Understanding

Know and Comprehend

1. The movement of matter is _____ in ecosystems, and the movement of energy is _____. (a) linear; linear (b) linear; cyclic (c) cyclic; cyclic (d) cyclic; linear (e) cyclic; linear or cyclic
2. A complex of interconnected food chains in an ecosystem is called (a) an ecosystem (b) a pyramid of numbers (c) a pyramid of biomass (d) a biosphere (e) a food web
3. The quantitative estimate of the total amount of living material is called (a) biomass (b) energy flow (c) gross primary productivity (d) plant respiration (e) net primary productivity
4. Which of the following equations shows the relationship between gross primary productivity (GPP) and net primary productivity (NPP)?
   (a) GPP = NPP − photosynthesis
   (b) NPP = GPP − photosynthesis
   (c) GPP = NPP − plant respiration
   (d) NPP = GPP − plant respiration
   (e) NPP = GPP − animal respiration
5. Which of the following processes increase(s) the amount of atmospheric carbon in the carbon cycle? (a) photosynthesis (b) cellular respiration (c) combustion (d) a and c (e) b and c
6. In the nitrogen cycle, gaseous nitrogen is converted to ammonia during (a) nitrogen fixation (b) nitrification (c) assimilation (d) ammonification (e) denitrification
7. The conversion of ammonia to nitrate, known as _____, is a two-step process performed by soil bacteria. (a) nitrogen fixation (b) nitrification (c) assimilation (d) ammonification (e) denitrification
8. Which biogeochemical cycle does not have a gaseous component but cycles from the land to sediments in the ocean and back to the land? (a) carbon cycle (b) nitrogen cycle (c) phosphorus cycle (d) hydrologic cycle (e) neither a nor c has a gaseous component
9. Which of the following processes is not directly involved in the hydrologic cycle? (a) transpiration (b) evaporation (c) precipitation (d) nitrification (e) condensation
10. The periodic warming of surface waters of the tropical eastern Pacific that alters both oceanic and atmospheric circulation patterns is known as (a) upwelling (b) prevailing wind (c) ocean current (d) El Niño–Southern Oscillation (e) Coriolis effect
11. A mountain range may produce a downwind arid (a) upwelling (b) rain shadow (c) ocean current (d) microclimate (e) ecological pyramid

Apply and Analyze



12. **VISUALIZE** Draw the simplest stable ecosystem you can imagine.
13. **PREDICT** How might a food web change if all decomposers were eliminated from it?
14. Why is the cycling of matter essential to the long-term continuance of life?
15. What would happen to the nitrogen cycle if all bacteria were absent? Explain your answer.

Evaluate and Synthesize

16. Would the microclimate of an ant be the same as that of an elephant living in the same area? Why or why not?
17. **INTERPRET DATA** Examine Figure 55-3b (*shown here*). Explain why this pyramid of biomass is inverted. In other words, how can 4 g of producers support 21 g of primary consumers?

18. **INTERPRET DATA** Scientists have compiled databases of large forest wildfires in the western United States and compared them to climate and land-surface data. Examine the graph showing wildfire frequency compared to average spring–summer temperature. Do you see a correlation? If so, describe it. Based on these data, do you think that climate warming is causing more wildfires? Explain your answer.

Adapted from Westerling, A.L., H.G. Hidalgo, D.R. Cayan, and T.W. Swetnam, "Warming and Earlier Spring Increase Western U.S. Forest Wildfire Activity," *Science*, Vol. 313 (Aug. 18, 2006).

19. **SCIENCE, TECHNOLOGY, AND SOCIETY** How do humans alter the nitrogen cycle, and what can scientists, engineers, and the public do to mitigate the damage?

56 Ecology and the Geography of Life

KEY CONCEPTS

56.1 Climate, particularly temperature and precipitation, affects the distribution of Earth's major biomes, such as tropical rain forests and tundra.

56.2 Abiotic factors—such as water salinity, amount of dissolved oxygen, availability of essential minerals, light, and water depth—influence the distribution of organisms in aquatic ecosystems.

56.3 Ecotones—areas of transition where two communities meet and intergrade—provide diverse conditions that encourage species richness.

56.4 Earth has several biogeographic realms, each consisting of a major landmass separated by deep water, mountains, or a desert.

PHOTO: Black-tailed prairie dogs. Prairie dogs (*Cynomys ludovicianus*) never wander far from their burrows, which they use to escape from predators. scooperdigital/shutterstock.com

Earth has many different environments. *Natural selection* affects an organism's ability to survive and reproduce in a given environment. In natural selection both **abiotic** (nonliving) and **biotic** (living) factors eliminate the least-fit individuals in a population. Over time, succeeding generations of organisms that live in each biome or major aquatic ecosystem become better adapted to local environmental conditions.

Black-tailed prairie dogs are superbly adapted to the biotic and abiotic factors of their environment. Their teeth and digestive tracts are modified to eat and easily digest the seeds and leaves of grasses that grow in great profusion on the Great Plains of western North America.

Prairie dogs live in large colonies of about 500 individuals. The eyes of every individual in the colony watch for potential danger, and when they see it, prairie dogs call out to warn the rest of the colony (see photograph). When danger approaches, each prairie dog dives into its underground home. Each burrow has at least two openings and consists of an elaborate network of long tunnels with several chambers: a nursery for the young, a sleeping chamber, a toilet chamber, and a listening chamber (close to an entrance). Piles of excavated soil surround the burrow entrances and help prevent flooding during rainstorms.

To survive winter, black-tailed prairie dogs sleep in their burrows. Their metabolism slows, and they subsist on the stored fat in their bodies. They do not truly hibernate, however, and may leave their burrows to look for food when the weather warms.

Like prairie dogs, each species has structural, behavioral, and physiological adaptations for its own particular environment. As you examine Earth's major terrestrial and aquatic ecosystems, including the species characteristic of each, think about the variety of adaptations that natural selection has produced in organisms in response to their particular environments.

56.1 Biomes

LEARNING OBJECTIVES

1. Define *biome* and briefly describe the nine major terrestrial biomes, giving attention to the climate, soil, and characteristic plants and animals of each.
2. Describe at least one human effect on each of the biomes discussed.

A **biome** is a large, relatively distinct terrestrial region that has similar climate, soil, plants, and animals regardless of where it occurs. Because it covers such a large geographic area, a biome encompasses many interacting landscapes. Recall from Chapter 53 that a **landscape** is a large land area (several to many square kilometers) composed of interacting ecosystems.

Biomes largely correspond to major climate zones, with temperature and precipitation being most important (FIG. 56-1). Near the poles, temperature is generally the overriding climate factor. In tropical and temperate regions, precipitation becomes more significant than temperature. Other abiotic factors to which biomes are sensitive include temperature extremes, rapid temperature changes, floods, droughts, strong winds, and fires (see section on fires in Chapter 55).

We discuss nine major biomes in this chapter: tundra, boreal forest, temperate rain forest, temperate deciduous forest, temperate grassland, chaparral, desert, savanna, and tropical rain forest. Although we discuss each biome as a distinct entity, biomes intergrade into one another at their boundaries.

Key Point

The distribution of the world's biomes is largely the result of climate patterns, which determine an area's water (measured as precipitation) and energy (measured as temperature).

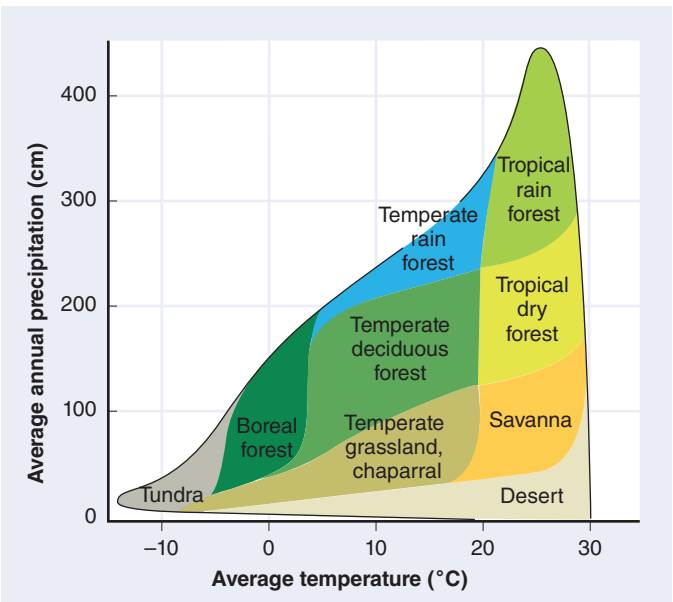

Figure 56-1 Using precipitation and temperature to identify biomes

Factors such as soil type, fire, and seasonality of climate affect whether temperate grassland or chaparral develops. Adapted from R.H. Whittaker, *Communities and Ecosystems*, 2nd ed. (Macmillan, New York, 1975).

PREDICT As global climate continues to change, how might Earth's biomes be affected?

Tundra is the cold, boggy plains of the far north

Tundra (also called **arctic tundra**) occurs in extreme northern latitudes wherever snow melts seasonally (FIG. 56-2). In the Southern Hemisphere, the **Antarctic tundra**, located on the Antarctic Peninsula and nearby islands, is home to animals such as penguins and elephant seals. Plant life in this warmer, slightly moister region of Antarctica consists of many mosses and lichens and some liverworts and fungi, but only two species of vascular plants. A third similar ecosystem, located in the higher elevations of mountains, above the tree line, is called **alpine tundra** (see *Inquiring About: The Distribution of Vegetation on Mountains*).

Arctic tundra has long, harsh winters and extremely short summers. Although the growing season, with its warmer temperatures, is as short as 50 days, the days are long. Above the Arctic Circle, the sun does not set at all for many days in midsummer. However, the amount of light at midnight is only one-tenth that at noon. There is little precipitation (10 to 25 cm, or 4 to 10 in., per year) over much of the tundra, and most of it falls during summer months.

Rolf Nussbaumer Photography/Alamy Stock Photo

Figure 56-2 Arctic tundra

Because of the short growing season and permafrost in arctic tundra, only small, hardy plants grow in this northernmost biome that encircles the Arctic Ocean. Photographed during autumn in Alaska.

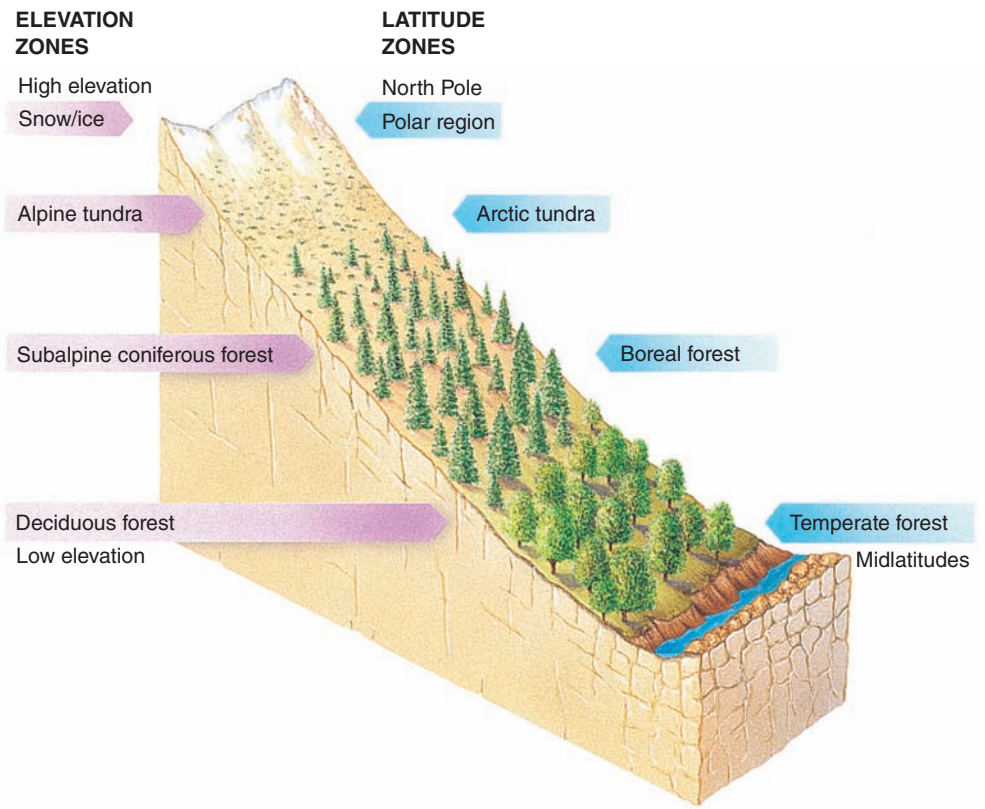
Inquiring About

The Distribution of Vegetation on Mountains



Does the type of vegetation change at different elevations on a mountain? Hiking up a mountain is similar to traveling toward the North Pole with respect to the major life zones encountered (see figure). This elevation—latitude similarity occurs because the temperature drops as one climbs a mountain, just as it does when one travels north; the temperature drops about 6°C (11°F) with each 1000-m increase in elevation. The types of species growing on the mountain change as the temperature changes.

Deciduous trees, which shed their leaves every autumn, may cover the base of a mountain in Colorado, for example. At higher elevations, where the climate is colder and more severe, a coniferous *subalpine forest* resembling boreal forest grows. Spruces and firs are the dominant trees here.

Higher still, the forest thins, and the trees become smaller, gnarled, and shrublike. These twisted, shrublike trees, called *krummholz* (a German word meaning "crooked wood"), are found at their elevational limit (the *tree line*). The exact elevation at which the tree line occurs depends on the latitude and distance from the ocean. In the Rocky Mountains, between 35° and 50° north latitude, the tree line drops 100 m with each 1° latitude northward.

Above the tree line, where the climate is quite cold, a kind of tundra occurs, with vegetation composed of grasses, sedges, and small tufted plants, most of which are hardy perennials. Some alpine plants (e.g., buttercups) are lowland species that have adapted to the alpine environment, whereas other plants (e.g., mountain douglasia) live exclusively in the mountains. This tundra is called *alpine tundra* to distinguish it from arctic tundra. At the top of the mountain, a permanent ice cap or snowcap might be found, similar to the nearly lifeless polar land areas.

Important environmental differences exist between high elevations and high latitudes that affect the types of organisms found in each place. Alpine tundra typically lacks permafrost and receives more precipitation than does arctic tundra. High elevations of temperate mountains do not have the great extremes of day length that are associated with the changing seasons in high-latitude biomes. The intensity of solar radiation is greater at high elevations than at high latitudes. At high elevations, the sun's rays pass through less atmosphere, which results in greater exposure to ultraviolet radiation (less is filtered out by the atmosphere) than occurs at high latitudes.

Comparison of elevation and latitude zones. The cooler temperatures at higher elevations of a mountain produce a series of ecosystems similar to those encountered when going toward the North Pole.

Tundra soils tend to be geologically young (with the exception of Antarctic tundra) because most were formed only after the last Ice Age.[1] These soils are usually nutrient poor and have little organic litter (dead leaves and stems, animal droppings, and remains of organisms) in the uppermost layer of soil. Although the soil surface melts during the summer, tundra has a layer of permanently frozen ground called **permafrost** that varies in depth and thickness. Because permafrost interferes with drainage, the thawed upper zone of soil is usually waterlogged during the summer. Limited precipitation, combined with low temperatures, flat topography (surface features), and permafrost, produces a landscape of broad, shallow lakes, sluggish streams, and bogs. Many scientists are concerned that global warming is accelerating the melting of permafrost, resulting in a rapidly increasing release of carbon dioxide and methane (another potent greenhouse gas) into the atmosphere.

Low species richness and low primary productivity characterize tundra. Mosses, lichens (such as reindeer moss), grasses, and grasslike sedges dominate tundra vegetation. Most of these short plants are herbaceous perennials that live 20 to 100 years. No readily recognizable trees or shrubs grow except in sheltered locations. However, dwarf willows, dwarf birches, and other dwarf trees are common.

Year-round animal life of the tundra includes voles, weasels, arctic foxes, gray wolves, snowshoe hares, ptarmigan, snowy owls, musk oxen, and lemmings (see Figure 53-5 and

[1] Glacier ice, which occupied about 30% of Earth's land during the last Ice Age, began retreating about 17,000 years ago. Today, glacier ice occupies about 10% of the land surface.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

the discussion of lemming population cycles in Chapter 53). In the summer, caribou migrate north to the tundra to graze on sedges, grasses, and dwarf willow. Dozens of bird species also migrate north in summer to nest and feed on abundant insects. Mosquitoes, blackflies, and deerflies survive the winter as eggs or pupae and occur in great numbers during summer weeks.

Tundra regenerates quite slowly after it has been disturbed. Even casual recreational use causes damage and pollution. Long-lasting injury, likely to persist for hundreds of years, has been done to large portions of the arctic tundra as a result of oil and gas exploration, road and pipe construction, and military use.

Boreal forest is the evergreen forest of the north

Just south of the tundra lies the **boreal forest**, also known as *coniferous forest* or **taiga**. (Conifers are cone-bearing evergreens.) The boreal forest, which stretches across both North America and Eurasia, is the world's largest terrestrial biome, covering about 10% of Earth's land (FIG. 56-3). A biome comparable to the boreal forest is not found in the Southern Hemisphere because it has no land at the corresponding latitudes. Winters are extremely cold and severe, although not as harsh as in the tundra. Boreal forest receives little precipitation, perhaps 50 cm (20 in.) per year. Its soil is typically acidic, low in minerals (inorganic nutrients), and has a deep layer of partly decomposed conifer needles at the surface. Boreal forest contains numerous ponds and lakes in water-filled depressions dug by grinding ice sheets during the last Ice Age.

White and black spruces, balsam fir, eastern larch, and other conifers dominate the boreal forest. However, **deciduous** trees such as aspen or birch, which shed their leaves in autumn, form striking stands. Conifers have many drought-resistant adaptations, such as needlelike leaves with a minimal surface area to reduce water loss (see Fig. 34-9). Such an adaptation enables conifers to withstand the "drought" of the northern winter months, when roots do not absorb water because the ground is frozen. Natural selection also favors conifers in the boreal forest because, being evergreen, they resume photosynthesis as soon as warmer temperatures return.

iStock.com/TT

Figure 56-3 Boreal forest
Boreal forest is coniferous forest that occurs in cold regions of the Northern Hemisphere adjacent to the tundra. Photographed in Banff National Park, Canada.

Animal life of the boreal forest includes some larger species, such as caribou (which migrate from the tundra to the boreal forest for winter), wolves, bears, and moose. However, most animal life is medium-sized to small and includes rodents, rabbits, and fur-bearing predators such as lynx, sable, and mink. Most species of birds are seasonally abundant but migrate to warmer climates for winter. Insects are numerous, but there are few amphibians and reptiles except in the southern boreal forest.

Most of the boreal forest is not suitable for agriculture because of its short growing season and mineral-poor soil. The boreal forest, which is harvested primarily by clear-cutting, is currently the primary source of the world's industrial wood and wood fiber.

Temperate rain forest has cool weather, dense fog, and high precipitation

Coniferous **temperate rain forest** grows on the northwestern coast of North America. Similar vegetation exists in southeastern Australia and in southwestern South America. Annual precipitation in this biome is high, from 200 to 380 cm (80 to 150 in.). Condensation of water from dense coastal fog augments the annual precipitation. The proximity of temperate rain forest to the coastline moderates the temperature so that seasonal fluctuation is narrow; winters are mild, and summers are cool. Temperate rain forest has a relatively nutrient-poor soil, although its organic content may be high. Cool temperatures slow the activity of bacterial and fungal decomposers. Thus, needles and large fallen branches and trunks accumulate on the ground as litter. It takes many years for the litter to decay and release inorganic minerals to the soil.

The dominant vegetation type found in the North American temperate rain forest is large evergreen trees, such as western hemlock, Douglas fir, Sitka spruce, and western red cedar. Temperate rain forest is rich in epiphytic vegetation, which consists of smaller plants that grow nonparasitically on the trunks and branches of large trees (FIG. 56-4). Epiphytes in this biome are mainly mosses, lichens, and ferns, all of which also carpet the ground. Squirrels, wood rats, mule deer, elk, numerous bird species (such as jays, nuthatches, and chickadees), several species of reptiles (such as painted turtles and western terrestrial garter snakes), and amphibians (such as Pacific giant salamanders and Pacific treefrogs) are common temperate rainforest animals.

Temperate rain forest, one of the richest wood producers in the world, supplies us with lumber and pulpwood. It is also one of the most complex ecosystems in terms of species richness. Care must be taken to avoid overharvesting original old-growth forest because such an ecosystem takes hundreds of years to develop. When the logging industry harvests old-growth forest, it typically replants the area with a monoculture (a single species) of trees that it harvests in 40- to 100-year cycles. Thus, the old-growth forest ecosystem, once harvested, never has a chance to redevelop. Less than 10% of the original,

Terry Donnelly Dembinsky/Photo Associates

Figure 56-4 Temperate rain forest

Large amounts of precipitation characterize temperate rain forest. Note the epiphytes hanging from the branches of coniferous trees. Photographed in Olympic National Park in Washington State.

old-growth temperate rain forest in Washington, Oregon, and northern California remains untouched. These stable forest ecosystems provide biological habitat for many organisms, including more than 50 endangered and threatened species.

Temperate deciduous forest has a canopy of broad-leaf trees

Seasonality (hot summers and cold winters) is characteristic of **temperate deciduous forest**, which occurs in temperate areas where precipitation ranges from about 75 to 126 cm (30 to 50 in.) annually. Typically, the soil of a temperate deciduous forest consists of both a topsoil rich in organic material and a deep, clay-rich lower layer. As organic materials decay, mineral ions are released. If roots of living trees do not absorb these ions, they leach into the clay, where they may be retained.

Broad-leaf hardwood trees, such as oak, hickory, maple, and beech, which lose their foliage annually, dominate temperate deciduous forests of the northeastern and Mid-Atlantic United States and much of Central Europe (FIG. 56-5). The trees of the temperate deciduous forest form a dense canopy that overlies saplings and shrubs.

Temperate deciduous forests in North America originally contained a variety of large mammals such as mountain lions, wolves, bison, and other species now regionally extinct, plus

DEA/C. SAPPA/Getty Images

Figure 56-5 Temperate deciduous forest

The broad-leaf trees that dominate the temperate deciduous forest shed their leaves before winter. Photographed during autumn at the Durance River in France.

deer, bears, and many small mammals and birds (such as wild turkeys, blue jays, and scarlet tanagers). Both reptiles (such as box turtles and rat snakes) and amphibians (such as spotted salamanders and wood frogs) abounded, together with a denser and more varied insect life than exists today.

In Europe and North America, logging and land clearing for farms, tree plantations, and cities have removed much of the original temperate deciduous forest. Where it has regenerated, temperate deciduous forest is often in a seminatural state, highly modified by humans for recreation, livestock foraging, timber harvest, and other uses. Although these returning forests do not have the biological diversity of virgin stands, many forest organisms have successfully become re-established. For example, in the eastern United States, white-tailed deer populations were decimated by hunting by 1900. As large parts of forests were modified for agricultural use and large predators (wolves and panthers) were eliminated, the white-tailed deer population rebounded. In fact, many regions now consider the animals an agricultural or suburban nuisance and have increasingly invested in research to monitor and manage the deer population.

Worldwide, temperate deciduous forest was among the first biomes to be converted to agricultural use. In Europe and Asia, many soils that originally supported temperate deciduous forest have been cultivated by traditional agricultural methods for thousands of years without a substantial loss in fertility. During the 20th century, however, intensive agricultural practices were adopted. Along with overgrazing and deforestation, these methods have contributed to the degradation of some agricultural lands.

Temperate grasslands occur in areas of moderate precipitation

Summers are hot, winters are cold, fires help shape the landscape, and rainfall is often uncertain in **temperate grasslands**. Annual precipitation averages 25 to 75 cm (10 to 30 in.). In grasslands with less precipitation, minerals tend to accumulate in a marked layer just below the topsoil. These minerals tend to leach out of the soil in areas with more precipitation. Grassland soil contains considerable organic material because surface

Harvey Payne

Figure 56-6 Temperate grassland

The Nature Conservancy owns this tallgrass prairie preserve in Oklahoma. Like other moist temperate grasslands, it is mostly treeless but contains a profusion of grasses and other herbaceous flowering plants. As bison graze on the plants, they affect community structure and diversity.

parts of many grasses die off each winter and contribute to the organic content of the soil (the roots and rhizomes survive underground). Many grasses are sod formers: their roots and rhizomes form a thick, continuous underground mat.

Moist temperate grasslands, also known as *tallgrass prairies*, occur in the United States in Iowa, western Minnesota, eastern Nebraska, and parts of other midwestern states and across Canada's prairie provinces. Although few trees grow except near rivers and streams, grasses, some as tall as 2 m (6.5 ft), grow in great profusion in the deep, rich soil (FIG. 56-6). Before most of this area was converted to arable land, it was covered with herds of grazing animals, particularly bison. The principal predators were wolves, although in sparser, drier areas, coyotes took their place. Smaller fauna included prairie dogs and their predators (foxes, black-footed ferrets, and birds of prey such as prairie falcons), western meadowlarks, bobolinks, reptiles (such as gopher snakes and short-horned lizards), and great numbers of insects.

Shortgrass prairies, in which the dominant grasses are less than 0.5 m (1.6 ft) tall, are temperate grasslands that receive less precipitation than the moister grasslands just described but more precipitation than deserts. In the United States, shortgrass prairies occur in the eastern half of Montana, the western half of South Dakota, and parts of other midwestern states; they also appear in western Alberta in Canada. The plants grow in less abundance than in the moister grasslands, and occasionally some bare soil is exposed.

The North American grassland, particularly the tallgrass prairie, was so well suited to agriculture that little of it remains. More than 90% has vanished under the plow, and the remainder is so fragmented that almost nowhere can we see even an approximation of what European settlers saw when they settled in the Midwest. Today, the tallgrass prairie is considered North America's rarest biome.

In recent decades, woody shrubs and small trees such as juniper have invaded many of the world's grasslands in North and South America, Africa, and Australia. These plants displace native grasses, reducing the amount of food available for grazing animals. Fires in such altered ecosystems are more catastrophic, and the deep roots of these invasive plants tap into water, altering the area's water resources. Scientists are studying the roles that climate change, increased droughts, overgrazing, and fire suppression all play to better protect and manage the grasslands.

Chaparral is a thicket of evergreen shrubs and small trees

Some hilly temperate environments have mild winters with abundant rainfall combined with extremely dry summers. Such Mediterranean climates, as they are called, occur not only in the area around the Mediterranean Sea, but also in California, Western Australia, portions of Chile, and South Africa. In southern California, this environment is called **chaparral**. This vegetation type is also known as maquis in the Mediterranean region, mallee scrub in Australia, matorral in Chile, and Cape scrub in Africa. Chaparral soil is thin and infertile. Frequent fires occur naturally in this environment, particularly in late summer and autumn.

Chaparral vegetation looks strikingly similar in different areas of the world, even though the individual species are quite different. A dense growth of evergreen shrubs, often of drought-resistant pine or scrub oak trees, dominates chaparral (FIG. 56-7). During the rainy winter season, the landscape may be lush and green, but during the hot, dry summer, the plants lie dormant. Trees and shrubs often have hard, small, leathery leaves that resist water loss. Many plants are also fire-adapted and grow best in the months following a fire. Such growth is possible because fire releases minerals that were tied up in the plants that burned. With the new availability of essential minerals, plants sprout vigorously during winter rains. Mule deer, wood rats, brush rabbits, skinks and other

Chaparral, which consists primarily of drought-resistant evergreen shrubs and small trees, develops where hot, dry summers alternate with mild, rainy winters. Photographed in the western Sierra Nevada foothills.

lizards, and many species of birds (such as Anna's hummingbird, scrub jay, and bushtit) are common animals of the chaparral.

Fires, which occur at irregular intervals in California chaparral vegetation, often consume expensive homes built on the hilly chaparral landscape. Unfortunately, efforts to control naturally occurring fires sometimes backfire. Denser, thicker vegetation tends to accumulate when periodic fires are prevented; then, when a fire does occur, it is much more severe. Also, more frequent fires, due to human activity, are driving ecosystem changes in which sensitive native species are being displaced by non-native weeds. The highly flammable weeds contribute to more severe fires, reducing biodiversity and converting chaparral to weedy wastelands. Removing the chaparral vegetation, whose roots hold the soil in place, also causes problems such as mud slides that sometimes occur during winter rains in these areas.

Deserts are arid ecosystems

Deserts are dry areas found in temperate (*cold deserts*) and subtropical or tropical regions (*warm deserts*). North America has four distinct deserts. The Great Basin Desert in Nevada, Utah, and neighboring states is a cold desert dominated by sagebrush. The Mojave Desert in Nevada and California is a warm desert known for its Joshua trees (a type of yucca with an erect, woody stem). The Chihuahuan Desert, home of century plants (agaves; see Fig. 53-7), is a warm desert found in Texas, New Mexico, and Mexico. The warm Sonoran Desert, with its many species of cacti, is found in Arizona, California, and Mexico (FIG. 56-8).

The low water-vapor content of the desert atmosphere leads to daily temperature extremes of heat and cold, so a major change in temperature occurs in each 24-hour period. Deserts vary greatly depending on the amount of precipitation they receive, which is generally less than 25 cm (10 in.) per year. A few deserts are so dry that virtually no plant life occurs in them. As a result of sparse vegetation, desert soil is low in organic material but often high in mineral content, particularly the salts NaCl, $CaCO_3$, and $CaSO_4$.

Desert vegetation includes both perennials (cacti, yuccas, Joshua trees, and sagebrushes) and, after a rain, flowering annuals. Desert plants tend to have reduced leaves or no leaves, an adaptation that conserves water. In cacti such as the giant saguaro, for example, the stem carries out photosynthesis and also expands accordion-style to store water; the leaves are modified into spines, which discourage herbivores. Other desert plants shed their leaves for most of the year, growing only during the brief moist season.

blickwinkel/Alamy Stock Photo

Figure 56-8 Desert

Summer rainfall characterizes the warmer deserts of North America, such as the Sonoran Desert shown here. The Sonoran Desert contains many species of cacti, including the large, treelike saguaro (*Carnegiea gigantea*), which grows 15 to 18 m (50 to 60 ft) tall. Photographed in Arizona.

Desert animals tend to be small. During the heat of the day, they remain under cover or return to shelter periodically, whereas at night they come out to forage or hunt. In addition to desert-adapted insects, there are many specialized desert reptiles (such as desert iguanas, desert tortoises, and rattlesnakes) and a few desert-adapted amphibians (such as western spadefoot toads). Mammals include rodents such as the American kangaroo rat, which does not need to drink water but subsists solely on the water content of its food (primarily seeds and insects). American deserts are also home to jackrabbits, and kangaroos live in Australian deserts. Carnivores such as the African fennec fox and some birds of prey, especially owls, live on rodents and rabbits. During the driest months of the year, many desert insects, amphibians, reptiles, and mammals tunnel underground, where they remain inactive; this period of dormancy is known as *estivation*.

Humans have altered North American deserts in several ways. Off-road vehicles damage desert vegetation, which sometimes takes years to recover. When the top layer of desert soil is disturbed, erosion occurs more readily than when the soil is undamaged, and less vegetation grows to support native animals. Another problem is that certain cacti and desert tortoises have become rare as a result of poaching. Houses, factories, and farms built in desert areas require vast quantities of water, which must be imported from distant areas. Irrigation of desert soils often causes them to become salty and unfit for crops or native vegetation. Increased groundwater consumption by many desert cities has caused groundwater levels to drop. Aquifer depletion in U.S. deserts is particularly critical in central and southern Arizona and southwestern New Mexico and is an increasing concern in southern California, Nevada, and Utah.

Wide expanses of grasses interrupted by occasional trees characterize savanna. Trees such as *Acacia* bristle with thorns that provide protection against herbivores. Both trees and grasses have fire-adapted features, such as extensive underground root systems, that enable them to survive seasonal droughts as well as periodic fires that sweep through the savanna.

The world's greatest assemblage of hoofed mammals occurs in the African savanna. Here live great herds of herbivores, including wildebeests, antelopes, giraffes, zebras, and elephants. Large predators, such as lions and hyenas, kill and scavenge the herds. In areas of seasonally varying rainfall, the herds and their predators may migrate annually.

Savanna is rapidly being fragmented and converted to rangeland for cattle and other domesticated animals, which are replacing the big herds of wild animals. The problem is particularly acute in Africa, which has the most rapidly growing human population of any continent. In some places severe overgrazing by domestic animals has contributed to the conversion of marginal savanna into desert, a process known as **desertification**. In desertification the reduced grass cover caused by overgrazing allows wind and water to erode the soil; erosion removes the topsoil and decreases the soil's ability to support crops or livestock. Desertification has also become a serious problem in South America, Mexico, and the Caribbean due to overgrazing, farming, and drought. Satellite monitoring, in concert with local-level management, has shown promising results to reclaim fringe areas. (Desertification is not restricted to savanna. Temperate grasslands and tropical dry forests can also be degraded to desert.)

Savanna is a tropical grassland with scattered trees

The **savanna** biome is a tropical grassland with widely scattered clumps of low trees (FIG. 56-9). Savanna is found in areas of relatively low or seasonal rainfall with prolonged dry periods. Temperatures in savannas vary little throughout the year, and precipitation, not temperature (as in temperate grasslands), regulates seasons. Annual precipitation is 85 to 150 cm (34 to 60 in.). Savanna soil is low in essential minerals, in part because it is strongly leached. Savanna soil is often rich in aluminum, which resists leaching, and in places the aluminum reaches levels that are toxic to many plants. Although the African savanna is best known, savanna also occurs in South America and northern Australia.

Carlyn Iverson

Figure 56-9 Savanna

In this photograph of African savanna in Tanzania, the smaller animals in the foreground are Thomson's gazelles (*Gazella thomsonii*), and the larger ones near the trees are wildebeests (*Connochaetes taurinus*).

There are two basic types of tropical forests

There are many kinds of tropical forests, but ecologists generally classify them as one of two types: tropical dry forests or tropical rain forests. **Tropical dry forests** occur in regions with a wet season and a dry season (usually two to three months each year). Annual precipitation is 150 to 200 cm (60 to 80 in.). During the dry season, many tropical trees shed their leaves and remain dormant, much as temperate trees do during the winter. India, Brazil, Thailand, and Mexico are some of the countries that have tropical dry forests. Tropical dry forests intergrade with savanna on their dry edges and with tropical rain forests on their wet edges. Logging and overgrazing by domestic animals have fragmented and degraded many tropical dry forests.

The annual precipitation of **tropical rain forests** is 200 to 450 cm (80 to 180 in.). Much of this precipitation, which occurs almost daily, comes from locally recycled water that enters the atmosphere by transpiration from the forest's own trees. Tropical rain forests are often located in areas with ancient, highly weathered, mineral-poor soil. Little organic matter accumulates in such soils. Because temperatures are high and soil moisture is abundant year-round, decay organisms and detritus-feeding ants and termites decompose organic litter quite rapidly. Vast networks of roots and mycorrhizae quickly absorb minerals from decomposing materials. Thus, minerals of tropical rain forests are tied up in the vegetation rather than in the soil.

Tropical rain forests are found in Central and South America, Africa, and Southeast Asia. A tropical rain forest is very productive despite the scarcity of minerals in the soil. Its plants, stimulated by abundant solar energy and precipitation, capture considerable energy by photosynthesis. Of all the biomes, the tropical rain forest is unrivaled in species richness.

Most trees of tropical rain forests are evergreen flowering plants. A fully developed rain forest has several distinct stories of vegetation (FIG. 56-10). The topmost story, called the *emergent layer*, consists of the crowns of the oldest, tallest trees, some 40 m (130 ft) or more in height; these trees

Figure 56-10 Tropical rain forest

Tropical rainforest vegetation is stratified. Except at river banks, tropical rain forest has a closed canopy that admits little light to the forest floor. The animals highlighted in this figure occupy a variety of ecological niches in the rain forest. Adapted from Miller, G.T., and S.E. Spoolman, *Living in the Environment*, 17th ed. (Cengage/Brooks Cole, Belmont, CA, 2012): 162, Figure 7-15.

are exposed to direct sunlight and are subject to the warmest temperatures, lowest humidities, and strongest winds. The next story, the *canopy*, reaches a height of 30 to 35 m (100 to 115 ft). The canopy allows little sunlight for the support of the sparse *understory*, shrub layer, and ground layer. These layers all consist of smaller plants specialized for life in the shade, as well as seedlings of taller trees. Vegetation of tropical rain forests is generally not dense at ground level except near stream banks or where a fallen tree has opened the canopy.

Tropical rainforest trees support extensive epiphytic communities of smaller plants such as orchids and bromeliads. Although epiphytes grow in crotches of branches, on bark, or even on the leaves of their hosts, most use their host trees only for physical support, not for nourishment.

Because little light penetrates to the understory, many plants living there are adapted to climb already-established host trees. Lianas (woody tropical vines), some as thick as a human thigh, twist up through the branches of tropical rainforest trees. Once in the canopy, lianas grow from the upper branches of one tree to another, connecting the tops of the trees and providing a walkway for many of the canopy's residents.

Not counting bacteria and other soil-dwelling organisms, about 90% of tropical rainforest organisms live in the middle and upper canopies. Rainforest animals include the most abundant and varied insect, reptile, and amphibian fauna on Earth. Birds, too, are diverse, with some specialized to consume fruits (such as parrots), some to consume nectar (such as hummingbirds and sunbirds), and others to consume insects. Most rainforest mammals, such as sloths and monkeys, live only in the trees and never climb down to the ground. Some large ground-dwelling mammals, including elephants, are also found in tropical rain forests.

Unless strong conservation measures are initiated soon, human population growth and agricultural and industrial expansion in tropical countries may spell the end of tropical rain forests by the early 22nd century. Many rainforest species may become extinct before they are even identified and scientifically described. (Tropical rainforest destruction is discussed in detail in Chapter 57.)

To review, examine **FIGURE 56-11**, which shows the geographic distribution of the world's biomes.

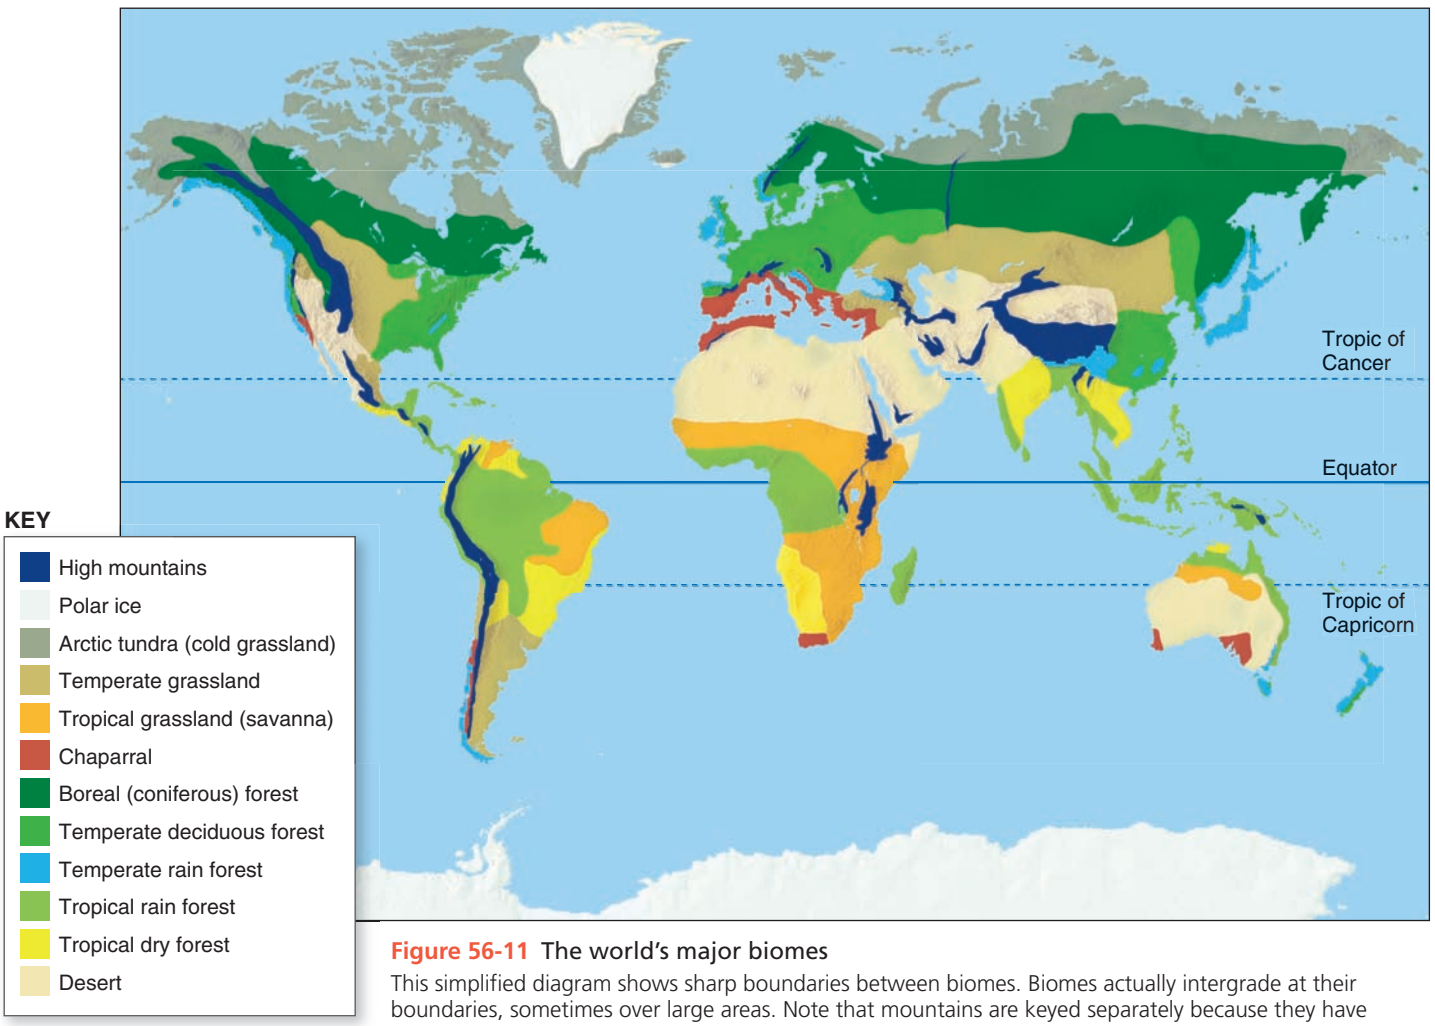

Figure 56-11 The world's major biomes
This simplified diagram shows sharp boundaries between biomes. Biomes actually intergrade at their boundaries, sometimes over large areas. Note that mountains are keyed separately because they have variable vegetation. Adapted from Miller, G.T., and S.E. Spoolman, *Living in the Environment*, 17th ed. (Cengage/Brooks Cole, Belmont, CA, 2012): 153, Figure 7-7.

CHECKPOINT 56.1

- **CONNECT** What climate and soil factors produce the major biomes?
- **CONNECT** What representative organisms are found in each of these forest biomes: boreal forest, temperate deciduous forest, temperate rain forest, and tropical rain forest?
- **CONNECT** In which biome do you live? Does it match the description given in this text? If not, explain the discrepancy.
- **CONNECT** How does tundra compare to desert? How does temperate grassland compare to savanna?

56.2 Aquatic Ecosystems

LEARNING OBJECTIVES

3 Explain the important environmental factors that affect aquatic ecosystems.
4 Distinguish among plankton, nekton, and benthos.
5 Briefly describe the various freshwater, estuarine, and marine ecosystems, giving attention to the environmental characteristics and representative organisms of each.
6 Describe at least one human effect on each of the aquatic ecosystems discussed.

The term *biome*, generally used to describe terrestrial environments based on dominant forms of vegetation, animals, and climate, does not adequately describe aquatic environments. Aquatic ecologists do not distinguish aquatic ecosystems based on the dominant form of vegetation. Instead, they use primarily abiotic factors, such as salinity, to determine an aquatic life zone's boundaries. **Salinity**, the concentration of dissolved salts in a body of water, affects the kinds of organisms present in aquatic ecosystems, as does the amount of dissolved oxygen. Because water greatly interferes with the penetration of light, floating aquatic organisms that photosynthesize remain near the water's surface, and vegetation attached to the bottom grows only in shallow water. In addition, low levels of essential minerals often limit the number and distribution of organisms in certain aquatic environments. Other abiotic determinants of species composition in aquatic ecosystems include water depth, temperature, pH, and presence or absence of waves and currents.

Aquatic ecosystems, both fresh water and marine, contain three main ecological categories of organisms: free-floating plankton, strongly swimming nekton, and bottom-dwelling benthos. **Plankton** are usually small or microscopic organisms that are relatively feeble swimmers. For the most part, they are carried about at the mercy of currents and waves. They are unable to swim far horizontally, but some species are capable of large vertical migrations and are found at different depths of water at different times of the day or at different seasons. Plankton are generally subdivided into two major categories: phytoplankton and zooplankton. **Phytoplankton** (photosynthetic cyanobacteria and free-floating algae) are producers that form the base of most aquatic food webs. **Zooplankton** are nonphotosynthetic organisms that include protozoa, tiny crustaceans, and the larval stages of many animals. **Nekton** are larger, actively swimming organisms such as fishes, turtles, and whales. **Benthos** are bottom-dwelling organisms that fix themselves to one spot (sponges, oysters, and barnacles), burrow into the sand (many worms and echinoderms), or walk or swim about on the bottom (crayfish, aquatic insect larvae, and brittle stars).

Freshwater ecosystems are linked to land and marine ecosystems

Freshwater ecosystems include streams and rivers (flowing-water ecosystems), ponds and lakes (standing-water ecosystems), and marshes and swamps (freshwater wetlands). Each type of freshwater ecosystem has its own specific abiotic conditions and characteristic organisms. Although freshwater ecosystems occupy a relatively small portion—about 2%—of Earth's surface, they are important in the hydrologic cycle because they assist in recycling precipitation that flows as surface runoff to the ocean (see discussion of the hydrologic cycle in Chapter 55). Freshwater habitats also provide homes for many species.

Streams and rivers are flowing-water ecosystems

Many different conditions exist along the length of a stream or river (FIG. 56-12). The nature of a **flowing-water ecosystem** changes greatly from its source (where it begins) to its mouth (where it empties into another body of water). Headwater streams (small streams that are the sources of a river) are usually shallow, clear, cold, swiftly flowing, and highly oxygenated. In contrast, rivers downstream from the headwaters are wider and deeper, turbid (i.e., they contain suspended particulates), not as cold, slower flowing, and less oxygenated than headwater streams. Surrounding forest may shade certain parts of the stream or river, whereas other parts may be exposed to direct sunlight. Along parts of a stream or river, groundwater wells up through sediments on the bottom. This local input of water moderates the water temperature so that summer temperatures are cooler and winter temperatures are warmer than in adjacent parts of the flowing-water ecosystem.

The kinds of organisms in flowing-water ecosystems vary greatly from one stream to another, depending primarily on the strength of the current. In streams with fast currents, inhabitants have adaptations such as suckers to attach themselves to rocks so that they are not swept away. The larvae of blackflies, for example, attach themselves with suction discs located on the ends of their abdomens. Some stream inhabitants, such as immature water-penny beetles, have flattened bodies that enable them to slip under or between rocks. The water-penny beetle larva gets its common name from its flattened, nearly circular shape. Alternatively, inhabitants such as the brown trout are streamlined and muscular enough to swim in the current.

Streams and rivers depend on land for much of their energy. In headwater streams, up to 99% of the energy input comes from detritus (dead organic material such as leaves) carried from the land into streams and rivers by wind or surface runoff.

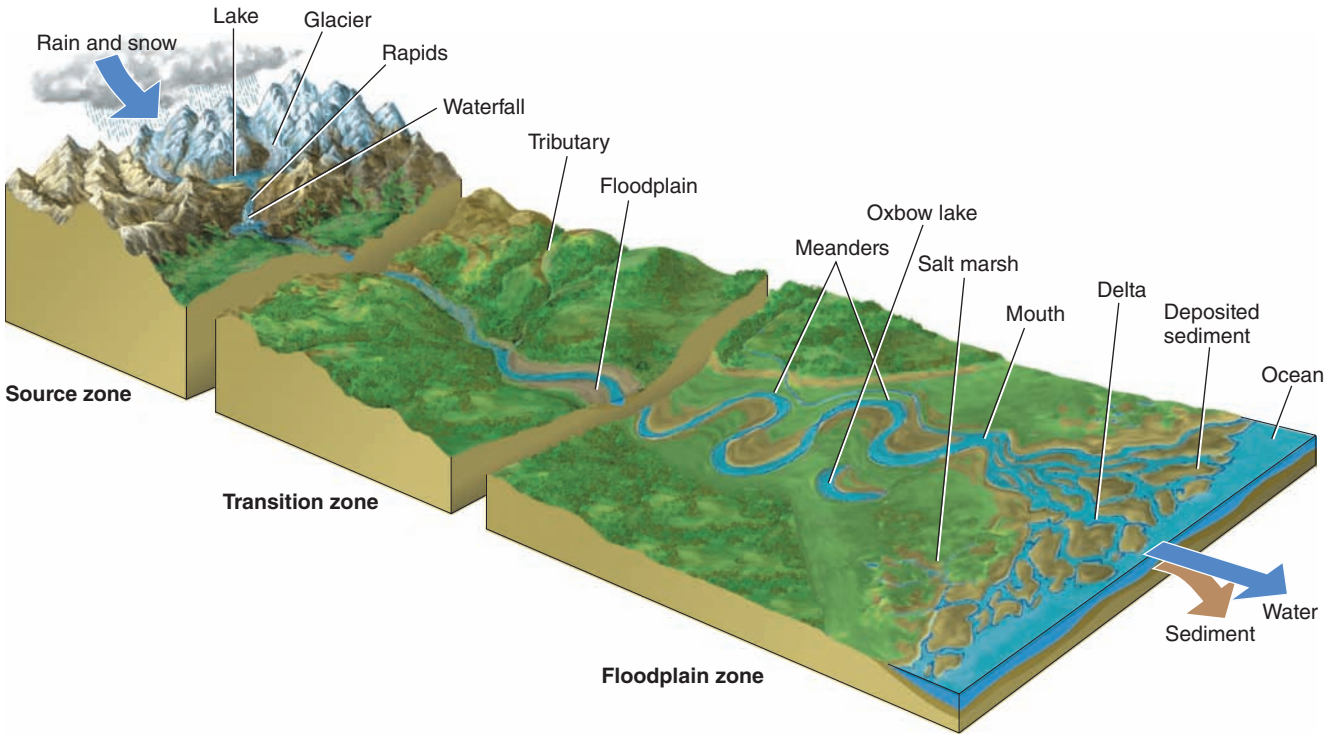

Figure 56-12 Features of a typical river

The river begins at a source, often high in mountains and fed by melting snows or glaciers. Headwater streams flow downstream rapidly, often over rocks (as rapids) or bluffs (as waterfalls). Along the way, tributaries feed into the river. As the river's course levels, the river flows more slowly and winds from side to side. Some of these winding streams may become cut off from the main river and become U-shaped oxbow lakes. The floodplain is the area on either side of the river that is subject to flooding. Near the ocean, the river may form a salt marsh where fresh water from the river and salt water from the ocean mix. Sediments deposited by the river as it empties into the ocean form the delta, a fertile, low-lying plain at the river's mouth. Rivers eventually empty into larger rivers or into the ocean. Adapted from Miller, G.T., and S.E. Spoolman, *Living in the Environment*, 17th ed. (Cengage/Brooks Cole, Belmont, CA, 2012): 183, Figure 8-18.

Downstream, rivers contain more producers and therefore depend slightly less on detritus as a source of energy than do the headwaters.

Human activities have several adverse effects on rivers and streams, including water pollution and the impacts of dams built to contain the water of rivers or streams. Pollution, such as sewage and fertilizer runoff, alters the physical environment of a flowing-water ecosystem and changes the biotic component downstream from the pollution source. Dams change the nature of flowing-water ecosystems, both upstream and downstream from the dam location. A dam causes water to back up, resulting in flooding of large areas of land and formation of a reservoir, which destroys terrestrial habitat. Below the dam, the once-powerful river is reduced to a relative trickle, so the flowing-water ecosystem is altered.

Ponds and lakes are standing-water ecosystems In contrast to moving water systems such as rivers, ponds, and lakes, **standing-water ecosystems** are characterized by zonation. A large lake has four basic zones: the littoral, limnetic, profundal, and benthic zones (FIG. 56-13). Smaller lakes and ponds typically lack a profundal zone.

The **littoral zone** is a shallow-water area along the shore of a lake or pond. It includes rooted, emergent vegetation, such as cattails and bur-reeds (flowering wetland plants), plus several deeper-dwelling aquatic plants and algae. The littoral zone is the most productive zone of the lake. Photosynthesis is greatest in the littoral zone, in part because light is abundant and because the littoral zone receives nutrient inputs from surrounding land that stimulate the growth of plants and algae. In addition, ponds and lakes—like streams and rivers—depend on detritus carried from the land for much of their energy. Animals of the littoral zone include frogs and their tadpoles, turtles, worms, crayfish and other crustaceans, insect larvae, and many fishes such as perch, carp, and bass. Surface dwellers, such as water striders and whirligig beetles, are found in the quieter areas.

The **limnetic zone** is the open water beyond the littoral zone, that is, away from the shore; it extends down as far as sunlight penetrates to permit photosynthesis. The main organisms of the limnetic zone are microscopic phytoplankton and zooplankton. Larger fishes also spend some of their time in the limnetic zone, although they may visit the littoral zone to feed and reproduce. Because of the depth of this zone, less vegetation grows in the limnetic zone than in the littoral zone.

Beneath the limnetic zone of a large lake is the **profundal zone**. Because light does not penetrate effectively to this depth, plants and algae do not live in this zone. Food drifts into the profundal zone from the littoral and limnetic zones. Bacteria and archaea decompose dead plants and animals that reach the profundal zone, thus liberating minerals. These minerals are not effectively recycled because no photosynthetic organisms are present to absorb them and incorporate them into the

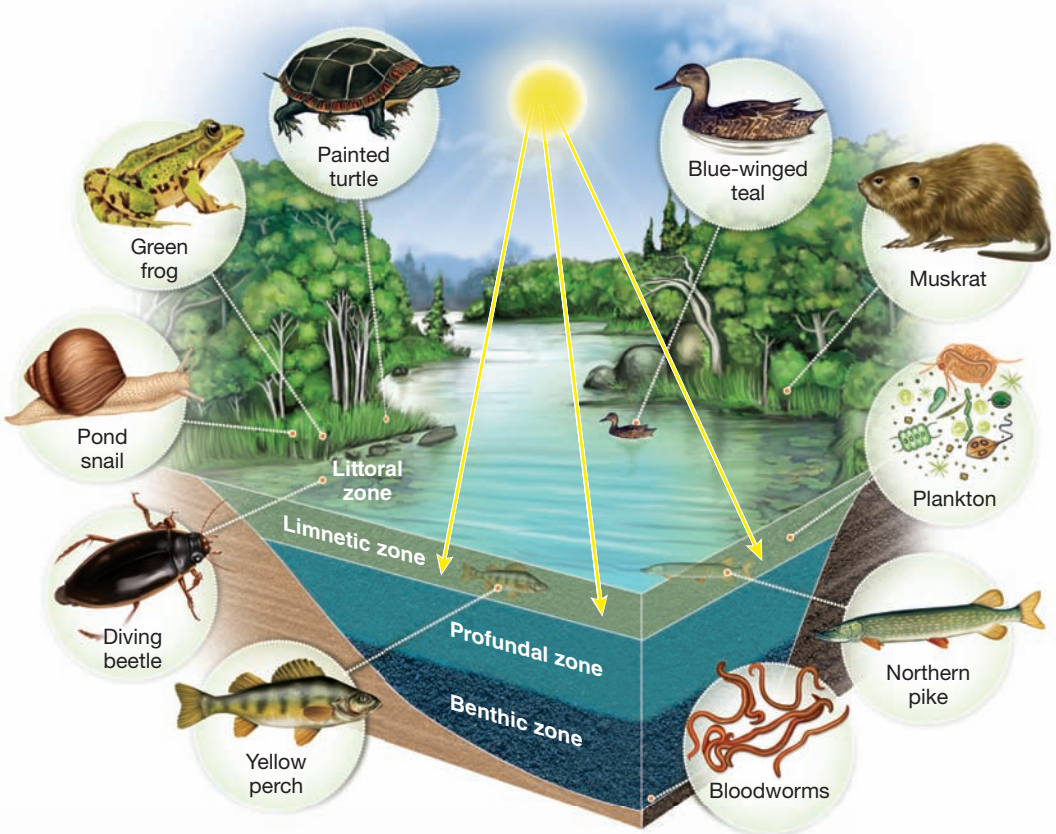

Figure 56-13 Zonation in a large, deep, temperate lake

A lake is a standing-water ecosystem surrounded by land. A large lake has littoral, limnetic, profundal, and benthic zones.

Adapted from Miller, G.T., and S.E. Spoolman, *Living in the Environment*, 17th ed. (Cengage/Brooks Cole, Belmont, CA, 2012): 182, Figure 8-16.

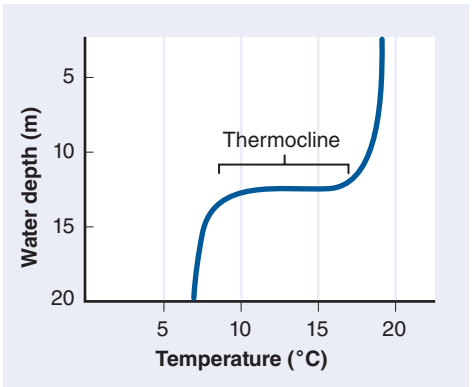
food web. As a result, the profundal zone tends to be both mineral rich and anaerobic (oxygen deficient), with few organisms other than anaerobic bacteria and archaea occupying it.

The **benthic zone** is the bottom layer of the lake. Decomposers, detritus feeders, and some fish live here. These organisms depend mainly on organic matter that drifts down from the upper zones.

Thermal stratification in temperate lakes The marked layering of large temperate lakes caused by light penetration is accentuated by **thermal stratification**, in which the temperature changes sharply with depth (FIG. 56-14a). Thermal stratification occurs because the summer sunlight penetrates and warms surface water, making it less dense. (Recall from Chapter 2 that the density of water is greatest at 4°C; both above and below this temperature, water is less dense.) In summer, cool (and therefore *more* dense) water remains at the lake bottom and is separated from warm (and therefore *less* dense) water above by an abrupt temperature transition called the **thermocline**. Seasonal distribution of temperature and oxygen (more oxygen dissolves in water at cooler temperatures) affects the distribution of fish in the lake.

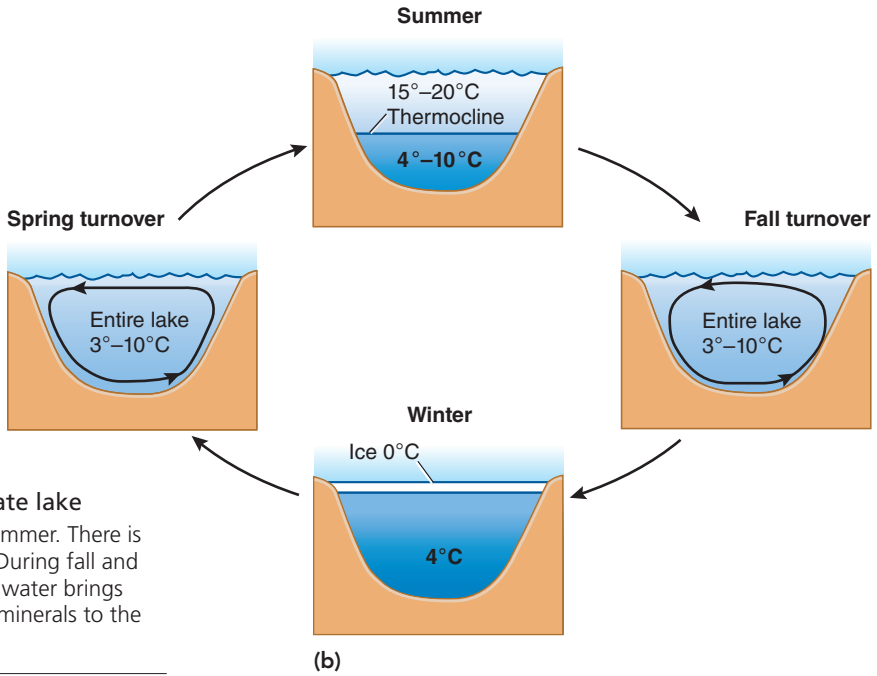
In temperate lakes, falling temperatures in autumn cause a mixing of the lake waters called the **fall turnover** (FIG. 56-14b). As surface water cools, its density increases, and it sinks and displaces the less dense, warmer, mineral-rich water beneath. Warmer water then rises to the surface where it, in turn, cools and sinks. This process of cooling and sinking continues until the lake reaches a uniform temperature throughout.

In winter, surface water cools to below 4°C, its temperature of greatest density. Ice, which forms at 0°C, is less dense than cold water. Thus, ice forms on the surface, and the water on the lake bottom is warmer than the ice on the surface. In spring, a **spring turnover** occurs as ice melts and surface water reaches 4°C. Surface water again sinks to the bottom, and bottom water returns to the surface. As summer arrives, thermal stratification occurs once again.



The mixing of deeper, nutrient-rich water with surface, nutrient-poor water during the fall and spring turnovers brings essential minerals to the surface and oxygenated water to the bottom. The sudden presence of large amounts of essential minerals in surface waters encourages the development of large algal and cyanobacterial populations, which may form temporary **blooms** in the fall and spring.

Increased nutrients and algal growth The presence of high levels of plant and algal nutrients such as nitrogen and phosphorus causes *enrichment*, the fertilization of a body of water. Excess amounts of these nutrients enter waterways from sewage and from fertilizer runoff from lawns and fields. The water in an enriched pond or lake is cloudy because of the vast numbers of algae and cyanobacteria that the nutrients support.



The species composition is different in enriched and unenriched lakes. For example, an unenriched lake in the northeastern United States may contain pike, sturgeon, and whitefish in the deeper, colder part of the lake where there is a higher concentration of dissolved oxygen. In contrast, the deeper, colder levels of water in enriched lakes are depleted of dissolved oxygen because of the greater amount of decomposition on the lake floor. Fishes such as pike, sturgeon, and whitefish die out,

(a)

(b)

Figure 56-14 Thermal stratification in a temperate lake

(a) Temperature varies at different depths during the summer. There is an abrupt temperature transition, the thermocline. **(b)** During fall and spring turnovers, a mixing of upper and lower layers of water brings oxygen to the oxygen-depleted depths of the lake and minerals to the mineral-deficient surface waters.

and fishes such as catfish and carp, which tolerate lower concentrations of dissolved oxygen, replace them.

Enrichment is reversible and has declined in North America since the 1970s because legislation limits the phosphate content of detergents and because better sewage treatment plants have been constructed. Agriculture is the leading source of water-quality impairment of U.S. surface waters today. Major causes of enrichment problems in waterways include fertilizer runoff, animal wastes, and sewage plant residues. States and communities continue to improve storm water management practices, and many have passed laws to ban phosphate fertilizers.

Freshwater wetlands are transitional between aquatic and terrestrial ecosystems

Freshwater wetlands, which are usually covered by shallow water for at least part of the year, have characteristic soils and water-tolerant vegetation. They include marshes, dominated by grasslike plants, and swamps, in which woody trees or shrubs dominate (FIG. 56-15). Freshwater wetlands also include hardwood bottomland forests (lowlands along streams and rivers that are periodically flooded), prairie potholes (small, shallow ponds that formed when glacial ice melted at the end of the last Ice Age), and peat moss bogs (peat-accumulating wetlands where sphagnum moss dominates).

Wetlands are valued as a wildlife habitat for migratory waterfowl and many other bird species, beavers, otters, muskrats, and game fishes. A huge variety of microorganisms, fungi, plants, and invertebrates are also members of these ecosystems. Wetlands are holding areas for excess water when rivers flood their banks, and also for nutrient-rich runoff from surrounding land. The floodwater stored in wetlands then drains slowly back into the rivers, providing a steady flow of water throughout the year. Wetlands also serve as groundwater recharging areas. One of their most important roles is to trap and hold pollutants in the flooded soil, thereby cleansing and purifying the water. Such important environmental functions as these are known as **ecosystem services**.

Wetlands were once considered wastelands, areas to be filled in or drained so that farms, housing developments, and industrial plants could be built on them. Wetlands are also breeding places for mosquitoes and therefore were viewed as a menace to public health. The crucial ecosystem services that wetlands provide are widely recognized today, and wetlands have some legal protection. Despite this recognition of their value, agriculture, pollution, engineering (dams), and urban and suburban development continue to threaten wetlands.

Cordgrass (*Spartina alterniflora*) is the dominant vegetation in this salt marsh in Georgia.

Estuaries occur where fresh water and salt water meet

Where the ocean meets the land, there may be one of several kinds of ecosystems: a rocky shore, a sandy beach, an intertidal mudflat, or a tidal estuary. An **estuary** is a coastal body of water, partly surrounded by land, with access to the open ocean and a large supply of fresh water from rivers. Water levels in an estuary rise and fall with the tides, and salinity fluctuates with tidal cycles, the time of year, and precipitation. Salinity also changes gradually within the estuary, from fresh water at the river entrance to salty ocean water at the mouth of the estuary. Because estuaries undergo marked daily, seasonal, and annual variations in temperature, salinity, and other physical properties, estuarine organisms have a wide tolerance to such changes.

Estuaries are among the most fertile ecosystems in the world, often having much greater productivities than the adjacent ocean or freshwater river (see Table 55-1). This high productivity is the result of four factors: (1) the action of tides promotes a rapid circulation of nutrients, helps remove waste products, and increases oxygenation; (2) minerals, transported from land into streams and rivers emptying into the estuary, provide nutrients; (3) the high level of light that penetrates the shallow water supports photosynthesis; and (4) the presence of many plants provides an extensive photosynthetic carpet and also mechanically traps detritus, forming the basis of detritus food webs. Most commercially important fishes and shellfish spend their larval stages in estuaries among the protective tangle of decaying stems.

Temperate estuaries are usually bordered by **salt marshes**, shallow wetlands in which salt-tolerant grasses dominate (FIG. 56-16). Uninformed people have often considered salt marshes as worthless, empty stretches of land. As a result, people have used them as dumps, severely polluting them, or filled them with dredged bottom material to form artificial land for residential and industrial development. A large part of the estuarine environment is lost in this way, along with many of its ecosystem services, such as biological habitats, sediment and pollution trapping, groundwater supply, and storm buffering (salt marshes absorb much of the energy of a storm surge and therefore prevent flood damage elsewhere).

Mangrove forests, the tropical equivalent of salt marshes, cover perhaps 70% of tropical and subtropical coastal mudflats where tides and waves fluctuate (FIG. 56-17; Chapter 54 introduction). Like salt marshes, mangrove forests provide valuable ecosystem services. Mangrove roots stabilize the sediments, preventing coastal erosion and providing a barrier against the ocean during storms. Their interlacing roots are breeding grounds and nurseries for commercially important fish and shellfish species, such as blue crabs, shrimp, mullet, and spotted sea trout. Mangrove branches are nesting sites for many species of birds, such as pelicans, herons, egrets, and roseate spoonbills. Mangroves are under assault from coastal development, including aquaculture

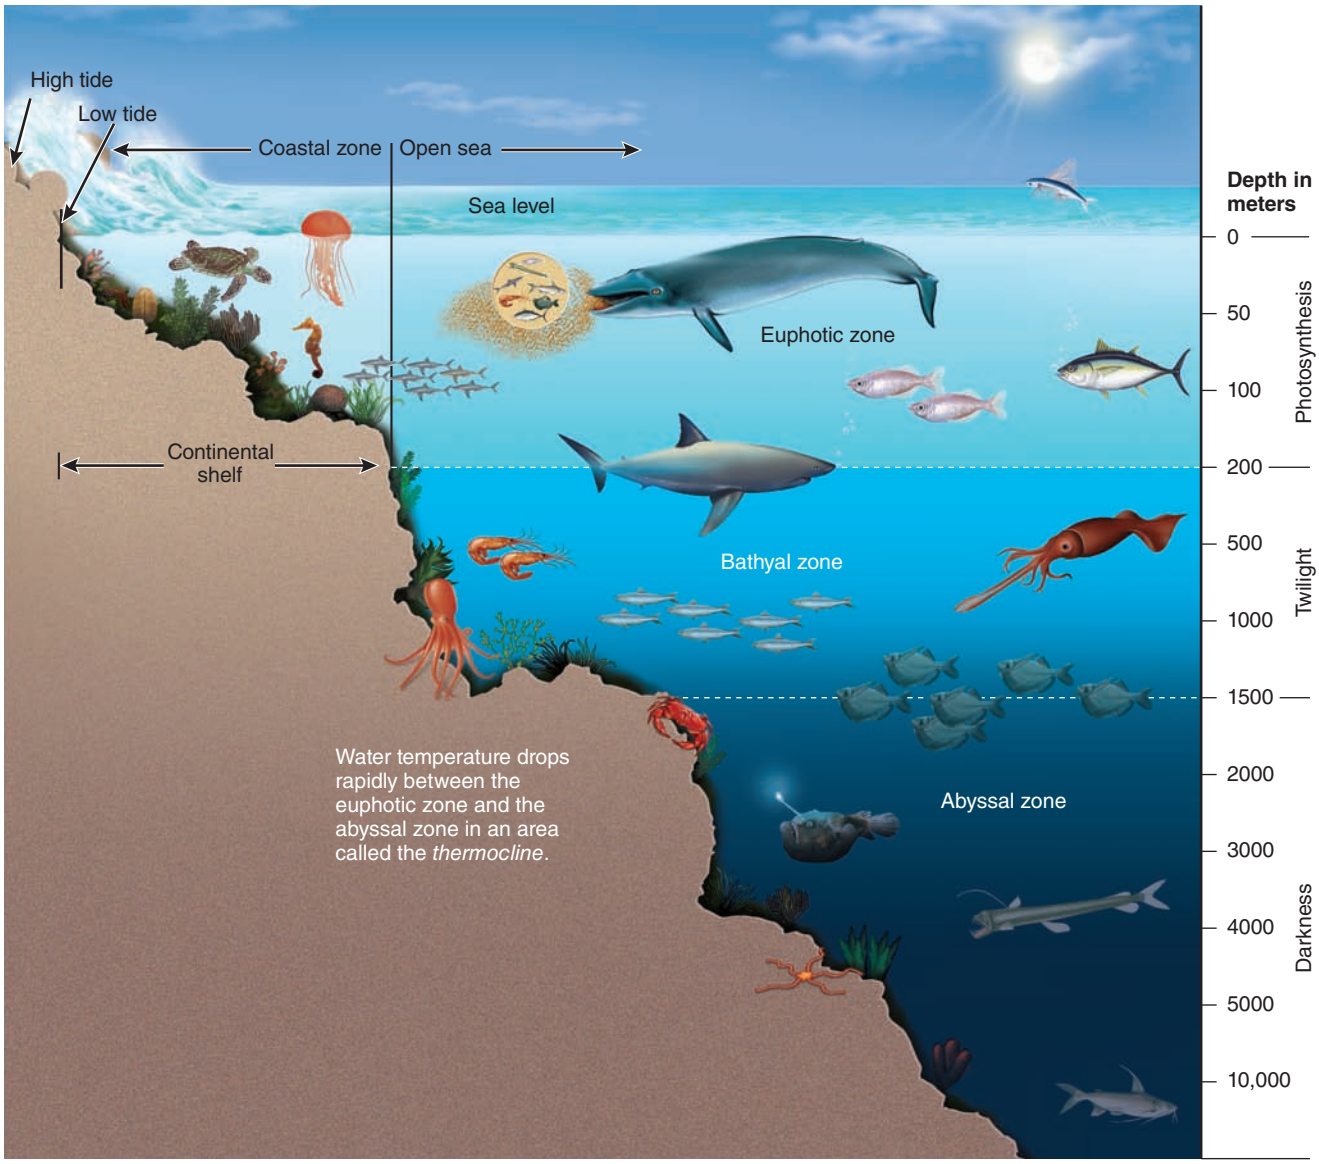

Figure 56-18 Vertical zones in an ocean

The euphotic zone, the brightly lit upper region of an ocean, is inhabited by plankton and plankton-eating nekton. The bathyal zone, which receives little sunlight, does not support phytoplankton. Zooplankton and some invertebrates and fish live in the bathyal zone. The dark, cold abyssal zone is inhabited by some sponges, clams, oysters, squid, worms, and fish. Many organisms that inhabit the abyssal zone are filter feeders that depend on organic material that drifts down from the upper layers. Note that the slopes of the ocean floor are not as steep as shown; they are exaggerated to save space. Adapted from Miller, G.T., and S.E. Spoolman, *Living in the Environment*, 17th ed. (Cengage/Brooks Cole, Belmont, CA, 2012): 173, Figure 8-6.

facilities, and unsustainable logging. Some countries, such as the Philippines, Bangladesh, and Guinea-Bissau, have cut down more than two-thirds of their mangrove forests. In the United States, commercial developers, home builders, and some residents continue to sidestep conservation laws by destroying mangroves to provide waterfront properties with unobstructed views.

Marine ecosystems dominate Earth's surface

Although lakes and the ocean are comparable in many ways, they have many differences. Depths of even the deepest lakes do not approach those of the ocean, which has areas that extend more than 6 km (3.6 mi) below the sunlit surface. Tides and currents profoundly influence the ocean. Gravitational pulls of both the sun and the moon produce two tides a day throughout most areas of the ocean, but the height of those tides varies with season, local topography, and phases of the moon (full moons and new moons cause the highest tides).

The immense, complex marine environment is subdivided into several zones based on characteristics affected by water depth and distance from shore: the narrow intertidal zone, the broad benthic (ocean floor) environment, and the vast pelagic (ocean water) environment (FIG. 56-18). The pelagic environment is, in turn, divided into two provinces: the neritic province above the continental shelves and the deep water oceanic province.

The intertidal zone is transitional between land and ocean The **intertidal zone** is the shoreline area between low tide and high tide. Although high levels of light and nutrients, together with an abundance of oxygen, make the intertidal zone a biologically productive environment, it is also a stressful one. Predators abound in the surrounding water and in the air above. Competition is fierce for space where organisms attach to rocks and pier pilings. In the lowest, most biodiverse region of the intertidal zone, an area only exposed during the lowest lunar cycle tide, beds of algae, echinoderms, other invertebrates, and fishes dwell. If an intertidal beach is sandy, inhabitants must contend with a constantly shifting environment that threatens to engulf them and gives them scant protection against wave action. Consequently, most sand-dwelling organisms, such as mole crabs, are continual and active burrowers. Because they follow the tides up and down the beach, most do not have any notable adaptations to survive drying or exposure.

A rocky shore provides a fine anchorage for seaweeds and invertebrate animals. However, it is exposed to constant wave action when immersed during high tides and to drying and temperature changes when exposed to the air during low tides. A typical rocky-shore inhabitant has some way of sealing in moisture, perhaps by closing its shell, if it has one, plus a powerful means of anchoring itself to rocks. Mussels, for example, have horny, threadlike anchors, and barnacles have special cement glands. Rocky-shore intertidal algae (seaweeds) usually have thick, gummy polysaccharide coats, which dry out slowly when exposed, and flexible bodies not easily broken by wave action (FIG. 56-19). Some rocky-shore community inhabitants hide in burrows or crevices at low tide.

Seagrass beds, kelp forests, and coral reefs are part of the benthic environment The **benthic environment** is the ocean floor. It begins at the intertidal zone and is divided into zones based on distance from land, light availability, and depth. This benthic region continues along the gradually sloping *continental shelf*, which at a depth of 200 meters becomes the *continental slope* that extends out from the land as the ocean bottom.

The ocean bottom, or **abyssal zone** (abyssal plain), extends from a depth of 4000 to 6000 m (2.5 to 3.7 mi). (In Chapter 55, *Inquiring About: Life without the Sun* describes some of the unusual organisms in hydrothermal vents in the abyssal zone.) It contains deep trenches, called the **hadal zone**, which is that part of the benthic environment deeper than 6000 m with tall submarine ridges.

The benthic environment consists of sediments (mostly sand and mud) in which many marine animals, such as worms and clams, burrow. Archaea and bacteria are common in marine sediments, and living archaea and bacteria have been found in deeply buried ocean sediments at least 800 m (2600 ft) below the ocean floor at several different sites in the Pacific Ocean.

Here we describe benthic communities in shallow ocean waters: seagrass beds, kelp forests, and coral reefs. **Sea grasses** are some 60 species of flowering plants that have adapted to complete submersion in ocean water (FIG. 56-20). They are not true grasses. Sea grasses live in shallow water, to depths of 10 m (33 ft), where they receive enough light to photosynthesize efficiently. Extensive beds of sea grasses occur in calm, temperate, subtropical, and tropical waters; no sea grasses live in polar waters.

Sea grasses have a high primary productivity and are therefore ecologically important in shallow marine areas. Their roots and rhizomes stabilize the sediments, reducing surface erosion.

Sea grasses provide food and habitat for many marine organisms. In temperate waters, ducks and geese eat sea grasses; in tropical waters, manatees, green turtles, parrot fish, surgeon fish, and sea urchins eat them. These herbivores consume only about 5% of the sea grasses. The remaining 95% eventually enter the detritus food web when the sea grasses die and bacteria decompose them. In turn, a variety of animals such as mud shrimp, lug worms, and mullet consume the bacteria. Seagrass beds have been severely

damaged and depleted by water pollution and by boat propellers. Fortunately, many coastal communities and environmental organizations are replanting seagrass beds and educating boaters about the importance of healthy seagrass ecosystems.
