Many plant varieties were also produced by artificial selection. For example, cabbage, broccoli, brussels sprouts, cauliflower, collard greens, kale, and kohlrabi are distinct vegetable crops that are all members of the same species, *Brassica oleracea* (FIG. 18-3). Selective breeding of the colewort, or wild cabbage, a leafy plant native to Europe and Asia, produced all seven vegetables. Beginning more than 4000 years ago, some farmers artificially selected wild cabbage plants that formed overlapping leaves. Over time, these leaves became so prominent that the plants, which resembled modern cabbages, became recognized as separate and distinct from their wild cabbage ancestor. Other farmers selected different features of the wild cabbage, giving rise to the other modifications. For example, kohlrabi was produced by selection for an enlarged storage stem and brussels sprouts by selection for enlarged axillary buds. Thus, humans are responsible for the evolution of *B. oleracea* into seven distinct vegetable crops. Darwin was impressed by the changes induced by artificial selection and hypothesized that a similar selective process occurred in nature. He therefore used artificial selection as a model when he developed the concept of natural selection.

John Amaldi

An enlarged terminal bud (the "head") was selected in cabbage (*lower left*), flower clusters in broccoli (*upper left*) and cauliflower (*middle right*), axillary buds in brussels sprouts (*bottom middle*), leaves in collards (*upper right*) and kale (*lower right*), and stems in kohlrabi (*middle*).

The ideas of Thomas Malthus (1766–1834), a British clergyman and economist, were another important influence on Darwin. In *An Essay on the Principle of Population as It Affects the Future Improvement of Society*, published in 1798, Malthus noted that population growth is not always desirable, a view contrary to the beliefs of his day. He observed that populations have the capacity to increase geometrically ($1 \rightarrow 2 \rightarrow 4 \rightarrow 8 \rightarrow 16$) and thus outstrip the food supply, which only has the capacity to increase arithmetically ($1 \rightarrow 2 \rightarrow 3 \rightarrow 4 \rightarrow 5$). In the case of humans, Malthus suggested that the conflict between population growth and food supply generates famine, disease, and war, which serve as inevitable brakes on population growth.

Malthus's idea that there is a strong and constant check on human population growth strongly influenced Darwin's explanation of evolution. Darwin's years of observing the habits of animals and plants had introduced him to the struggle for existence described by Malthus. It occurred to Darwin that in this struggle inherited variations favorable to survival would tend to be preserved, whereas unfavorable ones would be eliminated.

The result would be **adaptation**, an evolutionary modification that improves the chances of survival and reproductive success in a given environment. Eventually, the accumulation of modifications might result in a new species. Time was the only thing required for new species to originate, and the geologists of the era, including Lyell, had supplied evidence that Earth was indeed old enough to provide adequate time.

Darwin had at last developed a workable scientific explanation of evolution, that of **natural selection**, in which better adapted organisms are more likely to survive and become the parents of the next generation. As a result of natural selection, the population changes over time; the frequency of favorable traits

increases in successive generations, whereas less-favorable traits become scarce or disappear. Darwin spent the next 20 years formulating his arguments for natural selection, accumulating an immense body of evidence to support this explanatory mechanism, and corresponding with other scientists.

As Darwin was pondering his ideas, Alfred Russel Wallace (1823–1913), a British naturalist who had studied the plants and animals of the Malay Archipelago for eight years, was similarly struck by the diversity of species and the peculiarities of their distribution. He wrote a brief essay on this subject and sent it to Darwin, by then a world-renowned biologist, asking his opinion. Darwin recognized his own ideas and realized that Wallace had independently arrived at the same conclusion: that evolution occurs by natural selection. Darwin's colleagues persuaded him to present Wallace's manuscript along with an abstract of his own work, which he had prepared and circulated to a few friends several years earlier. Both papers were presented in July 1858 at a London meeting of the Linnaean Society. Darwin's monumental book, *On the Origin of Species by Natural Selection; or, The Preservation of Favored Races in the Struggle for Life*, was published in 1859. In 1870, Wallace's book, *Contributions to the Theory of Natural Selection*, was published, eight years after he had returned from the Malay Archipelago.

Figure 18-4 Genetic variation in garden tree boas
These juvenile snakes, all the same species (*Corallus enydris*), were caught in a small section of forest in French Guiana. Many snake species exhibit considerable variation in their coloration and patterns.

Darwin proposed that evolution occurs by natural selection

Darwin's mechanism of evolution by natural selection consists of observations on four aspects of the natural world: variation; overproduction; limits on population growth, or a struggle for existence; and differential reproductive success.

1. **Variation.** The individuals in a population exhibit variation (FIG. 18-4). Each individual has a unique combination of traits, such as size, color, ability to tolerate harsh environmental conditions, and resistance to certain parasites or infections. Some traits improve an individual's chances of survival and reproductive success, whereas others do not. Remember that the variation necessary for evolution by natural selection must be inherited. Although Darwin recognized the importance to evolution of inherited variation, he did not know the mechanism of inheritance.
2. **Overproduction.** The reproductive ability of each species has the potential to cause its population to geometrically increase over time. A female frog lays about 10,000 eggs, and a female cod produces perhaps 40 million eggs! In each case, however, only about two offspring survive to reproduce. Thus, in every generation each species has the capacity to produce more offspring than can survive.
3. **Limits on population growth, or a struggle for existence.** There is only so much food, water, light, growing space, and other resources available to a population, so organisms compete with one another for these limited resources. Because there are more individuals than the environment can support, not all survive to reproduce. Other limits on population growth include predators, disease organisms, and unfavorable weather conditions.
4. **Differential reproductive success.** Those individuals that have the most favorable combination of characteristics (those that make individuals better adapted to their environment) are more likely to survive and reproduce. Offspring tend to resemble their parents because the next generation inherits the parents' genetically based traits. Successful reproduction is the key to natural selection: the best-adapted individuals produce the most offspring, whereas individuals that are less well adapted die prematurely or produce fewer or inferior offspring.

Over time, enough changes may accumulate in geographically separated populations (often with slightly different environments) to produce new species. Darwin noted that the Galápagos finches appeared to have evolved in this way. The 14 species are closely related. All descended from a common ancestor, a single species that found its way from the South American mainland two million to three million years ago. (The closest genetic relatives of the Galápagos finches are small seed-eating birds known as grassquits that live in western South America.)

During this two-million- to three-million-year period, the number of islands increased, the climate changed, and the plant life and food supply changed. The different islands of the Galápagos kept the finches isolated from one another, thereby allowing them to diverge into separate species in response to varying conditions (FIG. 18-5).

Peter Grant, Rosemary Grant, and their colleagues have documented natural selection in the Galápagos finches in their natural environment since the early 1970s. As an example of the evolutionary process in action, consider the sharp-beaked ground finch (*Geospiza difficilis*). This species lives on several different islands, and different beak shapes and sizes

(d) The woodpecker finch (*Camarhynchus pallidus*) digs insects out of bark and crevices by using spines, twigs, or even dead leaves.

Figure 18-5 Galápagos finches

Darwin inferred that these birds are derived from a common ancestral population of seed-eating birds from South America. Variation in their beaks is the result of adaptation to the availability of different kinds of food.

have evolved in each population depending on the diet available on the island where it lives.

We revisit the Galápagos finches in later chapters. Some long-term research by Peter Grant, Rosemary Grant, and their colleagues on the microevolution of Galápagos finches when droughts affect the food supply is described in Chapter 19; these studies have demonstrated that environmental change can drive natural selection. *Character displacement*, an aspect of evolutionary ecology, is described in Galápagos finches in Chapter 54.

The modern synthesis combines Darwin's scientific theory of evolution with genetics

One premise on which Darwin based his scientific theory of evolution by natural selection is that individuals transmit traits to the next generation. However, Darwin was unable to explain *how* this occurs or *why* individuals vary within a population. As discussed in Chapter 11, Gregor Mendel elucidated the basic patterns of inheritance. Darwin, who was a contemporary of Mendel, was apparently not acquainted with Mendel's work. Indeed, the scientific community did not recognize Mendel's work until the early part of the 20th century.

Beginning in the 1930s and 1940s, biologists experienced a conceptual breakthrough when they combined the principles of Mendelian inheritance with Darwin's principle of natural selection. The result was a unified explanation of evolution known as the **modern synthesis**. In this context, *synthesis* refers to combining parts of several scientific theories to form a unified whole. Some of the founders of the modern synthesis were U.S. geneticist Theodosius Dobzhansky, British geneticist and statistician Ronald Fisher, British geneticist J.B.S. Haldane, British biologist Julian Huxley, U.S. biologist Ernst Mayr, U.S. paleontologist George Gaylord Simpson, U.S. botanist G. Ledyard Stebbins, and U.S. geneticist Sewell Wright.

Today, the modern synthesis incorporates our expanding knowledge in genetics (which on its own makes an irrefutable case for evolution), systematics, paleontology, developmental biology, behavior, and ecology. The modern synthesis explains Darwin's observation of variation among offspring in terms of **mutation**, or changes in DNA, such as nucleotide substitutions. Mutations provide the genetic variability on which natural selection acts during evolution. The modern synthesis, which emphasizes the genetics of populations as the central focus of evolution, has held up well since it was developed. It has dominated the thinking and research of biologists working in many areas and has resulted in an enormous accumulation of new discoveries that validate evolution by natural selection.

Most biologists not only accept the basic principles of the modern synthesis but also try to better understand the causal processes of evolution. For example, what is the role of chance in evolution? How rapidly do new species evolve? These and other questions have arisen in part from a re-evaluation of the fossil record and in part from new discoveries in molecular aspects of inheritance. Such critical analyses are an integral part of the scientific process because they stimulate additional observation and experimentation along with re-examination of previous evidence. Science is an ongoing process, and information obtained in the future may require modifications to certain parts of the modern synthesis.

We now consider one of the many evolutionary questions currently being addressed by biologists: What are the relative effects of chance and natural selection on evolution?

Biologists study the effect of chance on evolution

Biologists have wondered whether we would get the same results if we were able to repeat evolution by starting with similar organisms exposed to similar environmental conditions. That is, would the same kinds of changes evolve as a

result of natural selection, or would the organisms be quite different as a result of random events? Studies of evolution in action suggest that chance may not be as important as natural selection, at least at the population level.

A fruit fly species (*Drosophila subobscura*) native to Europe inhabits areas from Denmark to Spain. Biologists noted that the northern flies have larger wings than southern flies (FIG. 18-6). The same fly species was accidentally introduced to North America in the late 1970s. Ten years after its introduction, biologists determined that no statistically significant changes in wing size had occurred in the different regions of North America. However, 20 years after its introduction, the fruit flies in North America exhibited the same type of north–south wing changes as in Europe. (It is not known why larger wings evolve in northern areas and smaller wings in southern climates.)

A study of the evolution of fishes known as *sticklebacks* in three coastal lakes of western Canada yielded intriguingly similar results to the fruit fly study. Molecular evidence indicates that when the lakes first formed several thousand years ago, they were populated with the same ancestral species. (Analysis of the mitochondrial DNA of sticklebacks in the three lakes supports the hypothesis of a common ancestor.) In each lake the same two species have evolved from the common ancestral fish. One species is large and consumes invertebrates along the bottom of the lake, whereas the other species is smaller and consumes plankton at the lake's surface. Members of the two species within a single lake do not interbreed with each other, but individuals of the larger species from one lake interbreed in captivity with individuals of the larger species from the other lakes. Similarly, smaller individuals from one lake interbreed in captivity with smaller individuals from the other lakes.

In these examples, natural selection appears to be a more important agent of evolutionary change than chance. If chance were the most important factor influencing the direction of evolution, fruit fly evolution would not have proceeded the same way on two different continents and stickleback evolution would not have proceeded the same way in three different lakes. However, just because we have many examples of the importance of natural selection in evolution, it does not necessarily follow that random events should be discounted as a factor in evolutionary change. Proponents of the role of chance think that it is more important in the evolution of major taxonomic groups (macroevolution) than in the evolution of populations (microevolution). It also may be that random events take place but that their effects on evolution are harder to demonstrate than natural selection.

George Gilchrist, College of William & Mary

Figure 18-6 Wing size in female fruit flies
In Europe female fruit flies (*Drosophila subobscura*) in southern countries have smaller wings than flies in northern countries. Shown are two flies: one from Spain (*left*) and the other from Denmark (*right*). The same evolutionary pattern emerged in North America after the accidental introduction of *D. subobscura* to the Americas.

CHECKPOINT 18.3

- **CONNECT** What is the relationship between artificial selection and natural selection?
- Why are only inherited variations important in the evolutionary process? Explain your answer.
- **CONNECT** What was missing in Darwin's explanation of evolution by natural selection? How does the modern synthesis fill this gap?

18.4 Evidence for Evolution

LEARNING OBJECTIVES

5 Summarize the evidence for evolution obtained from the fossil record.
6 Define *biogeography* and describe how the distribution of organisms supports evolution.
7 Describe the evidence for evolution derived from comparative anatomy.
8 Briefly explain how molecular biology and developmental biology provide insights into the evolutionary process.
9 Give an example of how evolutionary hypotheses are tested experimentally.

A vast body of scientific evidence supports evolution, including observations from the fossil record, biogeography, comparative anatomy, molecular biology, and developmental biology. In addition, evolutionary hypotheses are increasingly being tested experimentally. Taken together, this evidence confirms the scientific theory that life unfolded on Earth by the process of evolution.

The fossil record provides strong evidence for evolution

Perhaps the most direct evidence for evolution comes from the discovery, identification, and interpretation of **fossils**, which are the remains or traces typically left in sedimentary rock by previously existing organisms. (The term *fossil* comes from the Latin word *fossilis*, meaning "something dug up.") Sedimentary rock forms by the accumulation and solidification of particles (pebbles, sand, silt, or clay) produced by the

weathering of older rocks, such as volcanic rocks. The sediment particles, which are usually deposited on a riverbed, lake bottom, or the ocean floor, accumulate over time and exhibit distinct layers (FIG. 18-7). In an undisturbed rock sequence, the oldest layer is at the bottom, and upper layers are successively younger. The study of sedimentary rock layers, including their composition, arrangement, and similarity from one location to another, enables geologists to place events recorded in rocks in their correct sequence.

The fossil record shows a progression from the earliest unicellular organisms to the many unicellular and multicellular organisms living today (see Table 21-1). The fossil record therefore demonstrates that life has evolved through time. To date, paleontologists (scientists who study extinct species) have described and named about 300,000 fossil species, and others are still being discovered.

Although most fossils are preserved in sedimentary rock, some more recent remains have been exceptionally well preserved in bogs, tar, amber (ancient tree resin), or ice (FIG. 18-8). For example, the remains of a woolly mammoth deep-frozen in Siberian ice for more than 25,000 years were so well preserved that part of its DNA could be analyzed.

Few organisms that die become fossils. The formation and preservation of a fossil require that an organism be buried under conditions that slow or prevent the decay process. These conditions are most likely to occur if an organism's remains are covered quickly by a sediment of fine soil particles suspended in water. In this way, the remains of aquatic organisms may be trapped in bogs, mudflats, sandbars, or deltas. Remains of terrestrial organisms that lived on a floodplain may also be covered by waterborne sediments or, if the organism lived in an arid region, by windblown sand. Over time, the sediments harden to form sedimentary rock, and minerals usually replace the organism's remains so that many details of its structure, even cellular details, are preserved.

Alan Sirulnikoff/Science Source

Figure 18-7 Exposed layers of sedimentary rock at the Burgess shale fossil bed

This site, located in the Canadian Rockies, was formed about 500 million years ago when an avalanche of mud buried and preserved diverse and unusual marine animals.

The fossil record is not a random sample of past life but instead is biased toward aquatic organisms and those living in the few terrestrial habitats conducive to fossil formation. Relatively few fossils of tropical rainforest organisms have been found, for example, because their remains decay extremely rapidly on the forest floor, before fossils can develop. Another reason for bias in the fossil record is that organisms with hard body parts such as bones and shells are more likely to form fossils than are those with soft body parts. Also, rocks of different ages are unequally exposed at Earth's surface; some rocks of certain ages are more accessible to paleontologists for fossil study than are rocks of other ages.

Because of the nature of the scientific process, each fossil discovery represents a separate "test" of scientific evolutionary theory. If any of the tests fail, the theory would have to be modified to fit the existing evidence. The verifiable discovery, for example, of fossil remains of modern humans (*Homo sapiens*) in Precambrian rocks, which are more than 570 million years old, would falsify evolutionary theory as currently proposed. However, Precambrian rocks examined to date contain only fossils of simple organisms, such as algae and small, soft-bodied animals, that evolved early in the history of life. The earliest fossils of *H. sapiens* with anatomically modern features do not appear in the fossil record until approximately 300,000 years ago (see Chapter 22).

Fossils provide a record of ancient organisms and some understanding of where and when they lived. Using fossils of organisms from different geologic ages, scientists can sometimes infer the lines of descent (evolutionary relationships) that gave rise to modern-day organisms. In many instances, fossils provide direct evidence of the origin of new species from pre-existing species, including many transitional forms.

Transitional fossils document whale evolution Over the past century, biologists have found evidence suggesting that whales and other cetaceans (an order of marine mammals) evolved from land-dwelling mammals. During the 1980s and 1990s, paleontologists discovered several fossil intermediates in whale evolution that help document the whales' transition from land to water.

Fossils of *Ambulocetus natans*, a 50-million-year-old transitional form discovered in Pakistan, have many features of modern whales but also possess hind limbs and feet (FIG. 18-9a). (Modern whales do not have hind limbs, although *vestigial* pelvic and hind-limb bones persist. Vestigial structures are

(a) *Ambulocetus natans*, a transitional form between modern whale descendants and their terrestrial ancestors, possessed several recognizable whale features. It retained the hind limbs of its four-legged ancestors, however.

(b) The more recent *Rodhocetus* had flexible vertebrae that permitted a powerful dorsoventral movement during swimming.

(c) *Basilosaurus* was more streamlined and possessed tiny, nonfunctional hind limbs.

(d) *Balaenoptera*, the modern blue whale, contains vestiges of pelvis and leg bones embedded in its body.

Figure 18-9 Fossil intermediates in whale evolution

Biologists hypothesize that the ancestors of whales had four legs, as shown in these reconstructions of whale intermediates based on fossil evidence. Fossils indicate that ankle bones in whale intermediates match those found in present-day hippos, cows, pigs, and camels. Figures are not drawn to scale.

discussed later in the chapter.) The vertebrae of *Ambulocetus*'s lower back were very flexible, allowing the back to move dorsoventrally (up and down) during swimming and diving, as with modern whales. This ancient whale could swim but also moved about on land, perhaps as sea lions do today.

Rodhocetus is a fossil whale found in more recent rocks in Pakistan (FIG. 18-9b). The vertebrae of *Rodhocetus* were even more flexible than those found in *Ambulocetus*. The flexible vertebrae allowed *Rodhocetus* a more powerful dorsoventral movement during swimming. *Rodhocetus* may have been totally aquatic.

By 40 million years ago (mya), the whale transition from land to ocean was almost complete. Egyptian fossils of *Basilosaurus* show a whale with a streamlined body and front flippers for steering, like those of modern-day whales (FIG. 18-9c). *Basilosaurus* retained vestiges of its land-dwelling ancestors—a pair of reduced hind limbs that were disjointed from the backbone and probably not used in locomotion—and this reduction in the hind limbs continued to the present. The modern blue whale has vestigial pelvis and femur bones embedded in its body (FIG. 18-9d).

Various methods determine the age of fossils

Because layers of sedimentary rock occur naturally in the sequence of their deposition, with the more recent layers on top of the older, earlier ones, most fossils are dated by their relative position in sedimentary rock. However, geologic events occurring after the rocks were initially formed have occasionally changed the relationships of some rock layers. Geologists identify specific sedimentary rocks not only by their positions in layers but also by features such as mineral content and by the fossilized remains of certain organisms, known as **index fossils**, that characterize a specific layer over large geographic areas. Index fossils are fossils of organisms that existed for a relatively short geologic time but were preserved as fossils in large numbers. With this information, geologists can arrange rock layers and the fossils they contain in chronological order and identify comparable layers in widely separated locations.

Radioactive isotopes, also called **radioisotopes**, present in a rock provide a means to accurately measure its age (see Chapter 2). Radioisotopes emit invisible radiations. As radiation is emitted, the nucleus of a radioisotope changes into the nucleus of a different element through a process known as **radioactive decay**. The radioactive nucleus of uranium-235, for example, decays into lead-207.

Each radioisotope has its own characteristic rate of decay. The time required for one-half of the atoms of a radioisotope to change into a different atom is known as its **half-life** (FIG. 18-10).

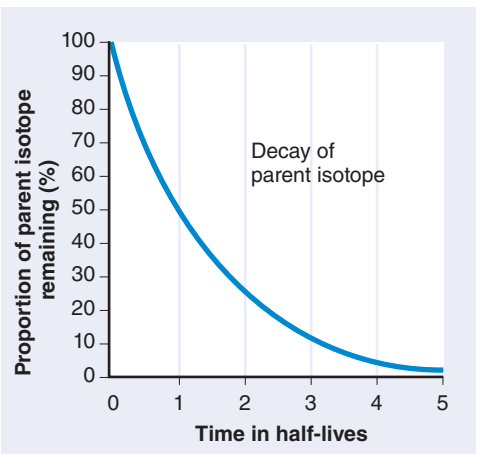

Figure 18-10 Radioisotope decay

At time zero, the sample is composed entirely of the radioisotope, and the radioactive clock begins ticking. After one half-life, only 50% of the original radioisotope remains. During each succeeding half-life, half of the remaining radioisotope is converted to decay product(s).

Copyright 2019 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Radioisotopes differ significantly in their half-lives. For example, the half-life of iodine-132 is only 2.4 hours, whereas the half-life of uranium-235 is 704 million years. The half-life of a particular radioisotope is constant and does not vary with temperature, pressure, or any other environmental factor.

The age of a fossil in sedimentary rock is usually estimated by measuring the relative proportions of the original radioisotope and its decay product in volcanic rock intrusions that penetrate the sediments. For example, the half-life of potassium-40 is 1.3 billion years, meaning that in 1.3 billion years half of the radioactive potassium will have decayed into its decay product, argon-40. The radioactive clock begins ticking when the magma solidifies into volcanic rock. The rock initially contains some potassium but no argon. Because argon is a gas, it escapes from hot rock as soon as it forms, but when potassium decays in rock that has cooled and solidified, the argon accumulates in the crystalline structure of the rock. If the ratio of potassium-40 to argon-40 in the rock being tested is 1:1, the rock is 1.3 billion years old.

Several radioisotopes are commonly used to date fossils, including potassium-40 (half-life 1.3 billion years), uranium-235 (half-life 704 million years), and carbon-14 (half-life 5730 years). Radioisotopes other than carbon-14 are used to date the *rock* in which fossils are found, whereas carbon-14 is used to date the *carbon remains* of anything that was once living, such as wood, bones, and shells. Whenever possible, the age of a fossil is independently verified using two or more different radioisotopes.

Carbon-14, which is continuously produced in the atmosphere from nitrogen-14 (by cosmic radiation), subsequently decays to nitrogen-14. Because the formation and the decay of carbon-14 occur at constant rates, the ratio of carbon-14 to carbon-12 (a more abundant, stable isotope of carbon) is constant in the atmosphere. Organisms absorb carbon from the atmosphere either directly (by photosynthesis) or indirectly (by consuming photosynthetic organisms). Because each organism absorbs carbon from the atmosphere, its ratio of carbon-14 to carbon-12 is the same as that in the atmosphere. When an organism dies, however, it no longer absorbs carbon, and the proportion of carbon-14 in its remains declines as carbon-14 decays to nitrogen-14. Because of its relatively short half-life, carbon-14 is useful for dating fossils that are 50,000 years old or less. It is particularly useful for dating archaeological sites.

The distribution of plants and animals supports evolution

The study of the past and present geographic distribution of organisms is called **biogeography**. The geographic distribution of organisms affects their evolution. Darwin was interested in biogeography, and he considered why the species found on ocean islands tend to resemble species of the nearest mainland, even if the environment is different. He also observed that species on ocean islands do not tend to resemble species on islands with similar environments in other parts of the world.

Darwin studied the plants and animals of two sets of arid islands: the Cape Verde Islands, nearly 640 km (400 mi) off western Africa; and the Galápagos Islands, about 965 km (600 mi) west of Ecuador, South America. On each group of islands, the plants and terrestrial animals were indigenous (native), but those of the Cape Verde Islands resembled African species and those of the Galápagos resembled South American species. The similarities of Galápagos species to South American species were particularly striking considering that the Galápagos Islands are dry and rocky and that the nearest part of South America is humid and has a lush, tropical rain forest. Darwin concluded that species from the neighboring continent migrated or were carried to the islands, where they subsequently adapted to the new environment and, in the process, evolved into new species.

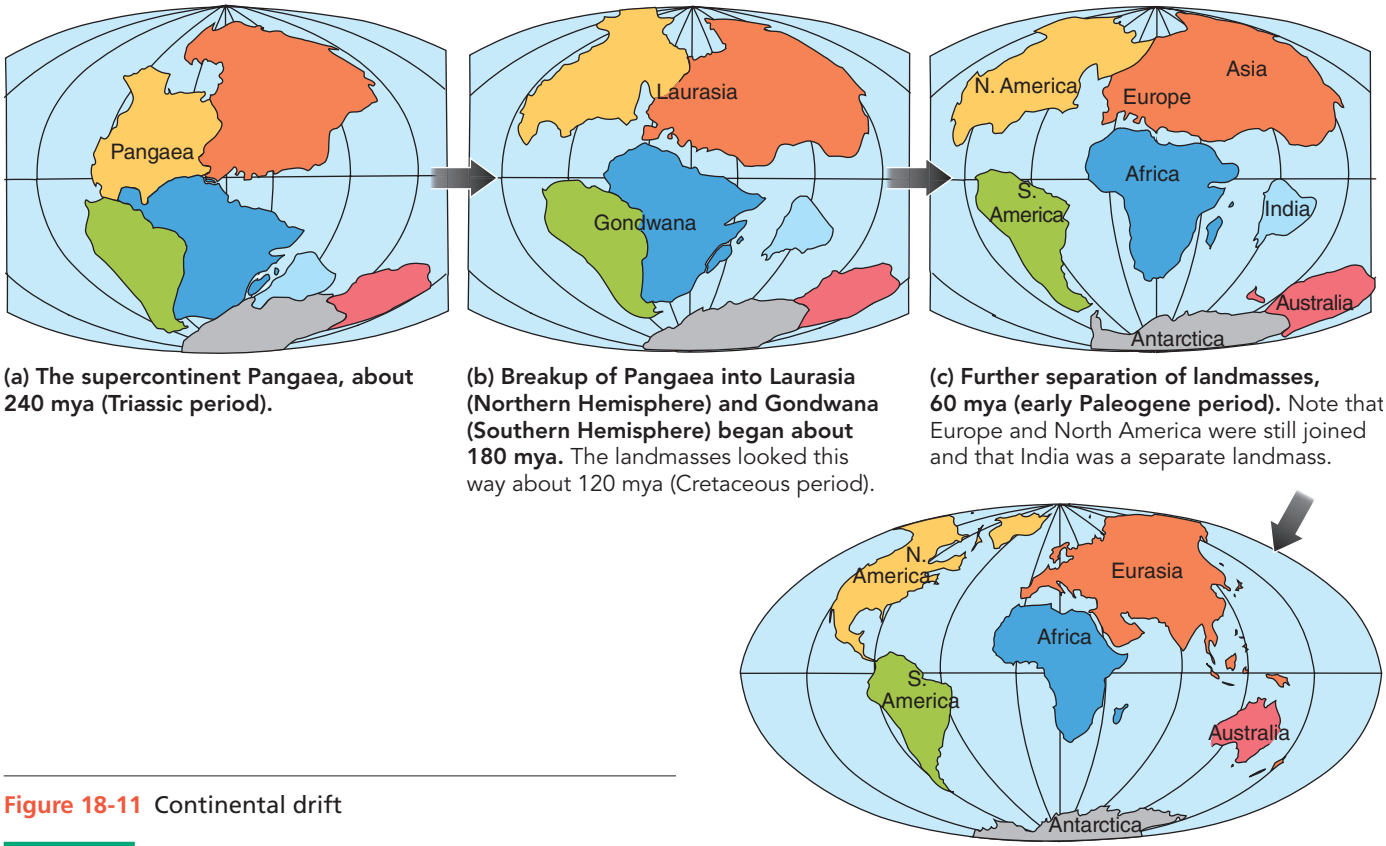
If evolution were not a factor in the distribution of species, we would expect to find a given species everywhere it could survive. However, the actual geographic distribution of organisms makes sense in the context of evolution. For example, Australia, which has been a separate landmass for millions of years, has distinctive organisms. Australia has populations of egg-laying mammals (monotremes) and pouched mammals (marsupials) not found anywhere else. Two hundred million years ago, Australia and the other continents were joined in a major landmass. Over the course of millions of years, the Australian continent gradually separated from the others. The monotremes and marsupials in Australia continued to thrive and diversify. The isolation of Australia also prevented placental mammals, which arose elsewhere at a later time, from competing with its monotremes and marsupials. In other areas of the world where placental mammals evolved, most monotremes and marsupials became extinct.

We now consider how Earth's dynamic geology has affected biogeography and evolution.

Biogeography and evolution are related to Earth's geologic history In 1915, German scientist Alfred Wegener, who had noted a correspondence between the geographic shapes of South America and Africa, proposed that all the landmasses had at one time been joined into one huge supercontinent, which he called Pangaea (FIG. 18-11a). He further suggested that Pangaea had subsequently broken apart and that the various landmasses had separated in a process known as **continental drift**. Wegener did not know of any mechanism that could have caused continental drift, so his idea, although debated initially, was largely ignored.

In the 1960s, scientific evidence provided the explanation for continental drift. Earth's crust is composed of seven large plates (plus a few smaller ones) that float on the mantle, which is the mostly solid layer of Earth lying beneath the crust and above the core. (Because of its hotter temperature, the solid rock of the mantle is more plastic than the solid rock of the crust above it.)

The landmasses are situated on some of these plates. As the plates move, the continents change their relative positions (FIGS. 18-11b, c, and d). The movement of the crustal plates is called *plate tectonics*.



Any area where two plates meet is a site of intense geologic activity. Earthquakes and volcanoes are common in such a region. Both San Francisco, noted for its earthquakes, and the Mount St. Helens volcano are situated where two plates meet. If

Key Point

Geologists hypothesize that the breakup of Pangaea is only the latest in a series of continental breakups and collisions that have taken place since early in Earth's history.

(a) The supercontinent Pangaea, about 240 mya (Triassic period).

(b) Breakup of Pangaea into Laurasia (Northern Hemisphere) and Gondwana (Southern Hemisphere) began about 180 mya. The landmasses looked this way about 120 mya (Cretaceous period).

(c) Further separation of landmasses, 60 mya (early Paleogene period). Note that Europe and North America were still joined and that India was a separate landmass.

(d) The continents today.

Figure 18-11 Continental drift

CONNECT If you were to find 60-million-year-old fossils of a species of land plants on the east coast of the northern part of North America, on what part of which continent would you begin a quest for similar fossils?

landmasses lie on the edges of two adjacent plates, mountains may form. The Himalayas formed when the plate carrying India rammed into the plate carrying Asia. When two plates grind together, one of them is sometimes buried under the other in a process known as *subduction*. When two plates move apart, a ridge of lava forms between them. The Atlantic Ocean is increasing in size because of the expanding zone of lava along the Mid-Atlantic Ridge, where two plates are separating.

Knowledge that the continents were at one time connected and have since drifted apart is useful in explaining certain aspects of biogeography (FIG. 18-12). Likewise, continental drift has played a major role in the evolution of different organisms. When Pangaea originally formed during the late Permian period, it brought together terrestrial species that had evolved separately from one another, leading to competition and some extinction. Marine life was adversely affected, in part because, with the continents joined as one large mass, less coastal area existed. (Shallow coastal areas contain a greater diversity of marine species than deep-water environments.)

Pangaea separated into several landmasses approximately 180 mya. As the continents began to drift apart, populations became geographically isolated, were exposed to different environmental conditions, and began to diverge along separate evolutionary pathways. As a result, the plants, animals, and other organisms of previously connected continents—South America and Africa, for example—differ. Continental drift also caused gradual changes in ocean and atmospheric currents that have profoundly influenced the biogeography and evolution of organisms. (Biogeography is discussed further in Chapter 56.)

Comparative anatomy of related species demonstrates similarities in their structures

Comparing the structural details of features found in different but related organisms reveals a basic similarity. Such features that are derived from the same structure in a common ancestor are called **homologous features**; the condition is

Key Point

Knowledge that the continents were united at one time explains the unique distribution of certain fossil plants and animals.

(a) *Cynognathus* was a carnivorous reptile found in Triassic rocks in South America and Africa.

(b) *Lystrosaurus* was a herbivorous reptile found in Triassic rocks in Africa, India, and Antarctica.

(c) *Mesosaurus* was a freshwater reptile found in Permian rocks in South America and Africa.

(d) *Glossopteris* was a seed-bearing tree found in Permian rocks in South America, Africa, India, Antarctica, and Australia.

Figure 18-12 Distribution of fossils on continents that were joined during the Permian and Triassic periods (286 mya to 213 mya) Adapted from E.H. Colbert, *Wandering Lands and Animals* (London, UK: Hutchinson, 1973).

CONNECT Examine Figure 18-11. With which continent is Antarctica most likely to share 60-million-year-old fossils of a particular species of land animals?

known as **homology**. For example, consider the limb bones of mammals. A human arm, a cat forelimb, a whale front flipper, and a bat wing, although quite different in appearance, have strikingly similar arrangements of bones, muscles, and nerves. **FIGURE 18-13** shows a comparison of their skeletal structures. Each has a single bone (the humerus) in the part of the limb nearest the trunk of the body, followed by the two bones (radius and ulna) of the forearm, a group of bones (carpals) in the wrist, and a variable number of digits (metacarpals and phalanges). This similarity is particularly striking because arms, forelimbs, flippers, and wings are used for different types of locomotion, and there is no overriding mechanical reason for them to be so similar structurally. Similar arrangements of parts of the forelimb are evident in ancestral birds, reptiles, and amphibians and even in the first fishes that came out of water onto land hundreds of millions of years ago (see Fig. 32-17).

Leaves provide an example of homology in plants. In many plant species, leaves have been modified for functions other than photosynthesis. A cactus spine and a pea tendril, although quite different in appearance, are homologous because both are modified leaves (**FIG. 18-14**). The spine protects the succulent stem tissue of the cactus, whereas the tendril, which winds around a small object once it makes contact, helps support the climbing stem of the pea plant. Such modifications in organs used in different ways are the expected outcome of a common evolutionary origin. The basic structure present in a common ancestor was modified in different ways for different functions as various descendants subsequently evolved.

Not all species with "similar" features have descended from a recent common ancestor, however. Sometimes similar environmental conditions result in the evolution of similar adaptations. Such independent evolution of similar structures in distantly related organisms is known as **convergent evolution**. Aardvarks, anteaters, and pangolins are an excellent example of convergent evolution (**FIG. 18-15**). They resemble one another in lifestyle and certain structural features. All have strong, sharp claws to dig open ant and termite mounds and elongated snouts with long, sticky tongues to catch these insects. Yet aardvarks, anteaters, and pangolins evolved from three distantly related groups of mammals. (See Figure 32-28, which shows several examples of convergent evolution in eutherian and marsupial mammals.)

Structurally similar features that are not homologous but have similar functions that evolved independently in distantly related organisms are said to be **homoplastic features**. Such similarities in different species that are independently acquired by convergent evolution and not by common descent are called **homoplasy**.[2]

For example, the wings of various distantly related flying animals, such as insects and birds, resemble one another superficially; they are homoplastic features that evolved over time to meet the common function of flight, although they differ in more fundamental aspects. Bird wings are modified forelimbs supported by bones, whereas insect wings may have evolved from gill-like appendages present in the aquatic ancestors of insects.

[2] An older, less precise term that some biologists still use for nonhomologous features with similar functions is *analogy*.

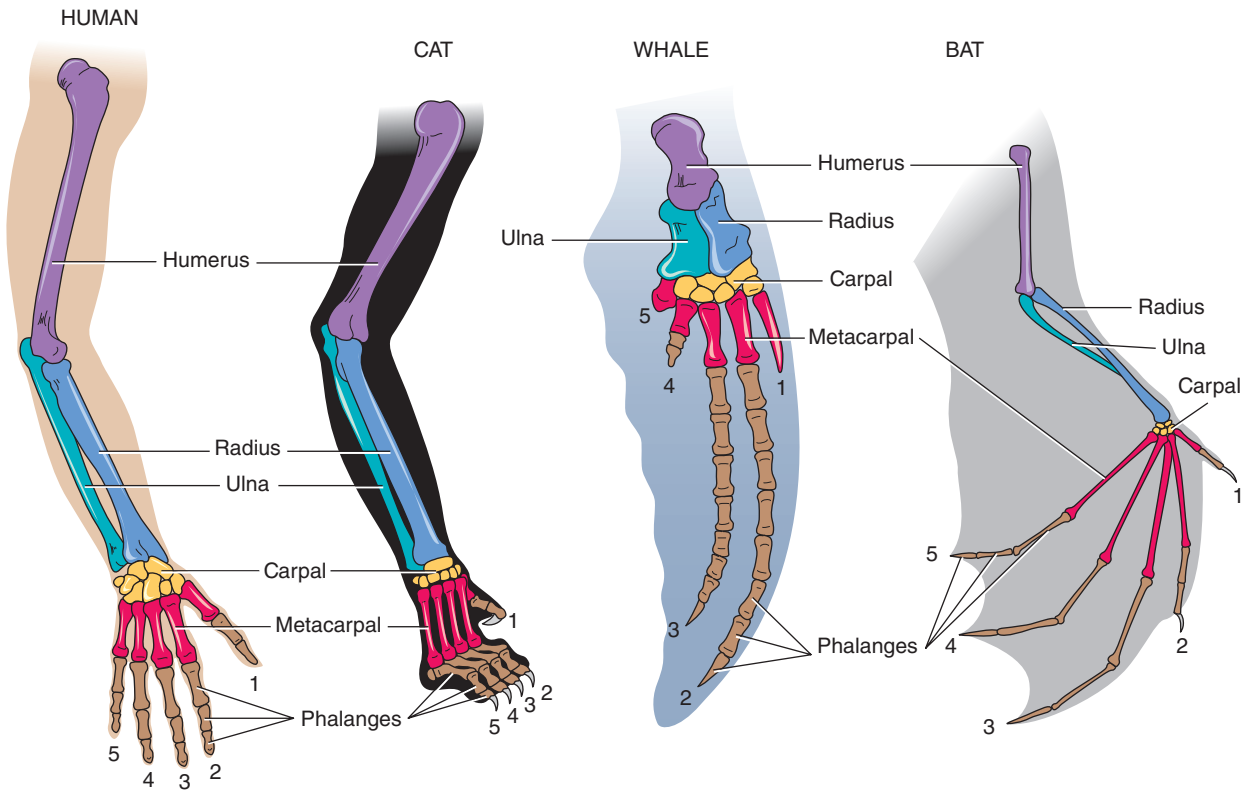

Figure 18-13 Structural homology in vertebrates

The human arm, cat forelimb, whale flipper, and bat wing have a basic underlying similarity of structure because they are derived from a common ancestor. The five digits are numbered in each drawing.

Spines, which are modified leaves, and thorns, which are modified stems, are an example of homoplasy in plants. Spines and thorns resemble each other superficially but are homoplastic features that evolved independently to solve the common need for protection from herbivores (FIG. 18-16).

Like homology, homoplasy offers crucial evidence of evolution. Homoplastic features are of evolutionary interest because they demonstrate that organisms with separate ancestries may adapt in similar ways to similar environmental demands.

Comparative anatomy also reveals the existence of **vestigial** structures. Many organisms contain organs or parts of organs that are seemingly nonfunctional and degenerate, often undersized or lacking some essential part. Vestigial structures are remnants of more developed structures that were present and functional in ancestral organisms. In the human body, more than one hundred structures are considered vestigial, including the coccyx (fused tailbones), third molars (wisdom teeth), and the muscles that move our ears. Whales and pythons (FIG. 18-17) have vestigial hind-limb bones; pigs have vestigial toes that do not touch the ground; wingless birds such as the kiwi have vestigial wing bones; and many blind, burrowing, or cave-dwelling animals have nonfunctioning, vestigial eyes.

The occasional presence of a vestigial structure is to be expected as a species adapts to a changing mode of life. Some structures become much less important for survival and may end up as vestiges. When a structure no longer confers a selective advantage, it may become smaller and lose all or much of its function with the passage of time. Because the presence of the vestigial structure is usually not harmful to the organism, however, selective pressure for completely eliminating it is weak, and the vestigial structure is found in many subsequent generations.

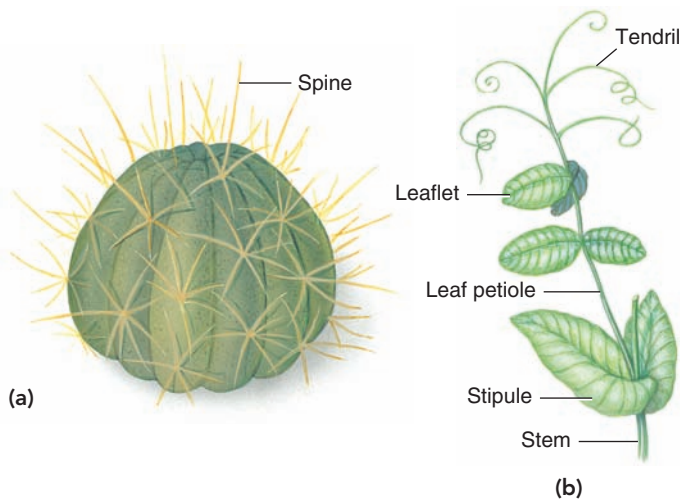

Figure 18-14 Homology in plants

(a) The spines of the fishhook cactus (*Ferocactus wislizenii*) are modified leaves, as are **(b)** the tendrils of the garden pea (*Pisum sativum*). Leaves of the garden pea are compound; that is, they are divided into smaller components called leaflets. The terminal leaflets are modified into tendrils that are frequently branched.

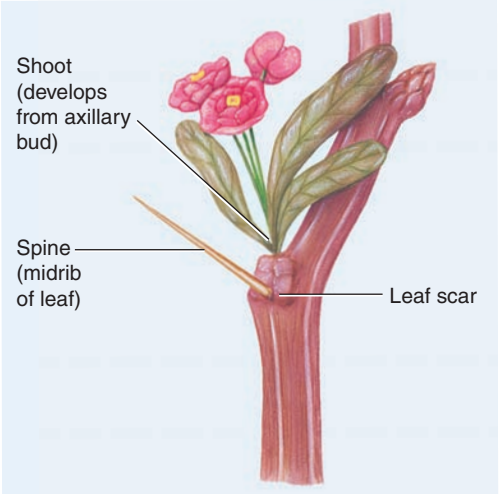
Molecular comparisons among organisms provide evidence for evolution

Fossils, biogeography, and comparative anatomy provided Darwin with important clues about the evolutionary history of life. Today, similarities and differences in the biochemistry and molecular biology of various organisms provide additional compelling evidence for evolutionary relationships. Molecular evidence for evolution includes the universal genetic code and the conserved sequences of amino acids in proteins and of nucleotides in DNA.

The genetic code is virtually universal Organisms owe their characteristics to the types of proteins they possess, which in turn are determined by the sequence of nucleotides in their messenger ribonucleic acid (mRNA) as specified by the order of nucleotides in their DNA. Evidence that all life is related comes from all organisms using a genetic code that is virtually identical. (There is some minor variation in the genetic code. For example, some mitochondria have several deviations from the standard code.)

Recall from Chapter 13 that the genetic code specifies a triplet (a sequence of three nucleotides in DNA) that codes for a particular codon (a sequence of three nucleotides in mRNA). The codon then codes for a particular amino acid in a polypeptide chain. For example, AAA in DNA codes for UUU in mRNA, which codes for the amino acid phenylalanine in organisms as diverse as shrimp, humans, bacteria, and tulips. In fact, AAA codes for phenylalanine in all organisms examined to date.



The universality of the genetic code—no other code has been found in any organism—is convincing evidence that all organisms arose from a common ancestor. The genetic code has been maintained and transmitted through all branches of the evolutionary tree since its origin in some extremely early (and successful) organism.

Proteins and DNA contain a record of evolutionary change Researchers have carried out thousands of comparisons of protein and DNA sequences from various species since the late 1970s. Moreover, the recent explosion in DNA sequencing information (thousands of species have now had their genomes sequenced) is beginning to provide a wealth of evolutionary data as these genomes are compared. Sequence-based relationships generally agree with earlier studies, which based evolutionary relationships on similarities in structure among living organisms and on fossil data of extinct organisms.

Investigations of the sequence of amino acids in proteins that play the same roles in many species have revealed both great similarities and certain specific differences. Even organisms that are only remotely related share some proteins, such as cytochrome *c*, which is part of the electron transport chain in aerobic respiration. To survive, all aerobic organisms need a respiratory protein with the same basic structure and function as the cytochrome *c* of their common ancestor. Consequently, not all amino acids that confer the structural and functional features of cytochrome *c* are free to change. Any mutations that changed the amino acid sequence at structurally important sites of the cytochrome *c* molecule would have been harmful, and natural selection would have prevented such mutations from being passed to future generations. However, in the course of the long, independent

Figure 18-16 Homoplasy in plants

evolution of different organisms, mutations have resulted in the substitution of many amino acids at less important locations in the cytochrome *c* molecule. The greater the differences in the amino acid sequences of their cytochrome *c* molecules, the longer it has been since two species diverged.

Because a protein's amino acid sequences are coded in DNA, the differences in amino acid sequences indirectly reflect the nature and number of underlying DNA base-pair changes that must have occurred during evolution. Of course, not all DNA codes for proteins (witness the regulatory RNAs summarized in Table 13-1, as well as ribosomal RNA and transfer RNA genes). **DNA sequencing**, that is, determining the order of nucleotide bases in both protein-coding DNA and non-protein-coding DNA, is proving invaluable in determining evolutionary relationships.

Generally, the more closely species are considered related on the basis of other scientific evidence, the greater the percentage of nucleotide sequences that their DNA molecules have in common. By using the DNA sequence data in FIGURE 18-18, for example, you can conclude that the closest living relative of humans is the chimpanzee (because its DNA has the lowest percentage of differences in the sequence examined). (Primate evolution is discussed in Chapter 22.)

In some cases, molecular evidence challenges traditional evolutionary ideas that were based on structural comparisons among living species and/or on studies of fossil skeletons. Consider even-toed hoofed mammals such as pigs, camels, deer, antelope, cattle, and hippos. Whales lack toes and were traditionally not classified as close relatives of hoofed mammals.

FIGURE 18-19 depicts a **cladogram**, or **phylogenetic tree**, based on molecular data for whales and selected hoofed mammals. Such cladograms—diagrams showing lines of descent—can be derived from differences in a given DNA nucleotide sequence. This diagram indicates that whales are more closely related to hippos than to any other hoofed mammal. The branches representing whales and hippos probably diverged relatively recently because of the close similarity of DNA sequences in these species. In contrast, camels, which have DNA sequences that are less similar to those of whales, diverged much earlier. The molecular evidence indicates that whales and hippos share a recent common ancestor.

The molecular evidence linking whales and even-toed hoofed mammals has led to a re-examination of early fossil whales. Like today's hoofed mammals, early fossil whales had an even number of toes on their appendages. Fossil whales also had the same type of specialized ankle bone (called a double pulley) as hippos and other hoofed mammals.

Developmental biology helps unravel evolutionary patterns

As early as 1975, biologists were suggesting that regulatory changes in gene expression, particularly of genes involved in development, were responsible for many differences between closely related species. Today much evidence supports the idea that regulatory changes—how genes are switched on and off during development—help explain the diversity of form in

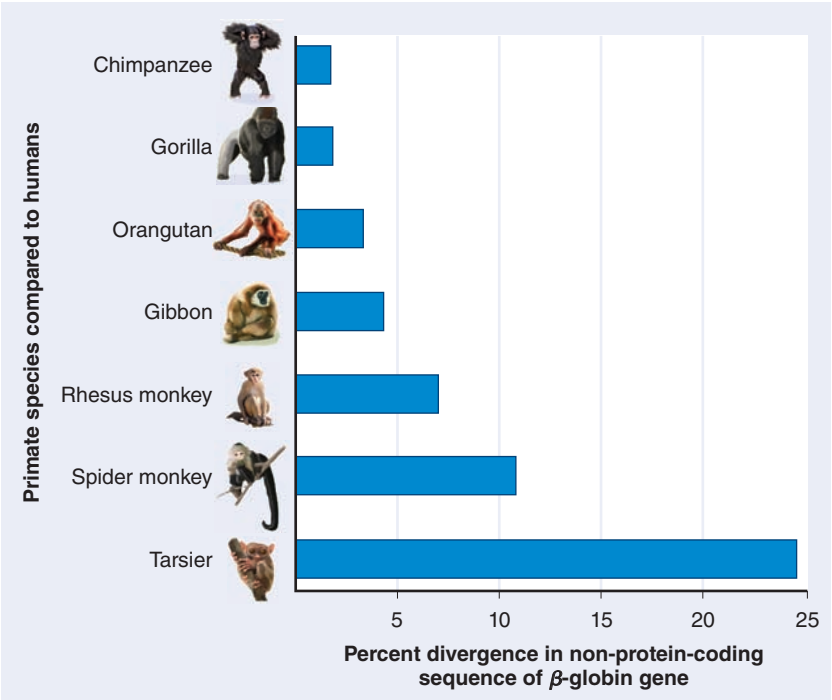

Figure 18-18 Differences in DNA nucleotide sequences as evidence of evolutionary relationships

Comparing the same gene in different organisms provides a window into evolution. Here the differences in the non-protein-coding region of the β-globin gene are compared between humans and other primates. Evolutionary biologists are rapidly expanding such studies from comparing one or several genes to comparing entire genomes.

species with similar genes. Mutations in genes that regulate development often result in dramatically different structures (see Fig. 17-12).

Increasingly, developmental biology, particularly at the molecular level, is providing answers to such questions as how snakes became elongated and lost their limbs. In many cases, evolutionary changes such as the loss of limbs in snakes occur as a result of changes in genes that regulate the orderly sequence of events that occurs during development. In pythons, for example, the loss of forelimbs and elongation of the body are linked to mutations in several *Hox* genes that affect the expression of body patterns and limb formation in a wide variety of animals. (See the discussion of *Hox* gene clusters in Chapter 17.) The hind limbs may not develop because python embryonic tissue does not respond to internal signals that trigger leg elongation.

Developmental geneticists at Harvard Medical School and Princeton University are studying the developmental basis for the different beak shapes of the Galápagos finches. They have determined that a gene that codes for an important signaling molecule, bone morphogenic protein 4 (Bmp4), affects the development of the birds' craniofacial skeletons. The gene for Bmp4 is turned on earlier in development and has a higher level of expression in finch species with longer, wider beaks than in finches with smaller beaks. Other signaling molecules have been shown to affect beak dimensions (length, depth, and/or width) in the various species of Galápagos finches.

Scientific evidence overwhelmingly demonstrates that development in different animals is controlled by the same kinds of genes; these genetic similarities in a wide variety of organisms reflect a shared evolutionary history. For example, vertebrates have similar patterns of embryological development that indicate that they share a common ancestor. All vertebrate embryos have segmented muscles, pharyngeal (throat) pouches, a tubular heart without left and right sides, a system of arteries known as *aortic arches* in the pharyngeal region, and many other shared features. All these structures are necessary and functional in the developing fish. The small, segmented muscles of the fish embryo give rise to the segmented muscles used by the adult fish in swimming. The pharyngeal pouches break through to the surface as gill slits. The adult fish heart remains undivided and pumps blood forward to the gills that develop in association with the aortic arches.

Because none of these embryonic features persists in the adults of reptiles, birds, or mammals, why are these fishlike structures present in their embryos? Evolution is a conservative process, and natural selection builds on what has come before rather than starting from scratch. The evolution of new features often does not require the evolution of new developmental genes but instead depends on a modification in developmental genes that already exist (see discussion of preadaptations in Chapter 20). Terrestrial vertebrates are thought to have evolved from fishlike ancestors; therefore, they share some of the early stages of development still found in fishes today. The accumulation of genetic changes over time in these vertebrates has modified the basic body plan laid out in fish development (FIG. 18-20).

Evolutionary hypotheses are tested experimentally

Increasingly, biologists are designing imaginative experiments, often in natural settings, to test evolutionary hypotheses. David Reznick from the University of California, Santa Barbara and John Endler from James Cook University in Australia have studied evolution in guppy populations in Venezuela and in Trinidad, a small island in the southern Caribbean.

Reznick and Endler observed that different streams have different kinds and numbers of fishes that prey on guppies. Predatory fishes that prey on larger guppies are present in all streams at lower elevations; these areas of intense predation pressure are known as *high-predation habitats*. Predators are often excluded from tributaries or upstream areas by rapids and waterfalls. The areas above such barriers are known as *low-predation habitats* because they contain only one species of small predatory fish that occasionally eats smaller guppies.

Key Point

This branching diagram, called a *cladogram*, shows proposed evolutionary relationships based on available data. The organisms depicted here share a common ancestor.

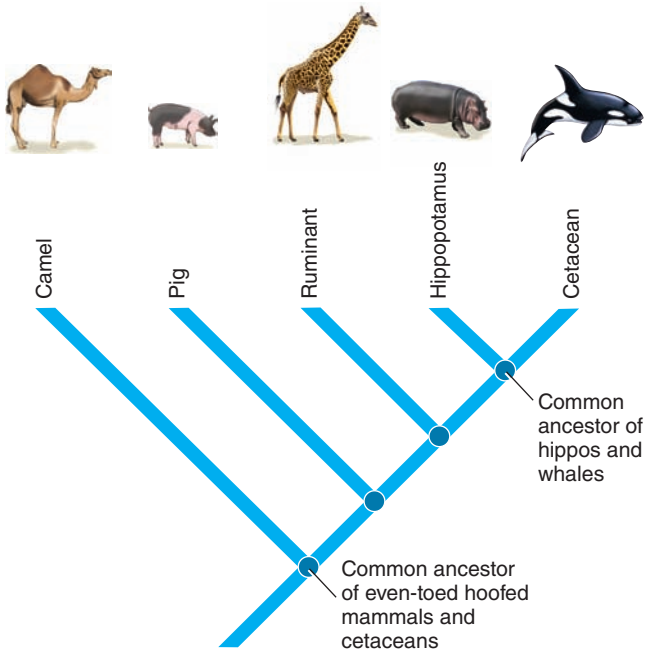

Figure 18-19 Cladogram of whales and their closest living relatives

DNA sequence differences among selected mammals suggest that hoofed mammals such as hippos and giraffes are the closest living relatives of whales. The hippopotamus is probably the closest living relative of whales and other cetaceans. The nodes (*circles*) represent branch points where a species splits into two or more lineages. (Ruminants are mammals such as cows, sheep, and giraffes that have a multichambered stomach and chew regurgitated plant material to make it more digestible.) Adapted from Nikaido, M., et al., "Phylogenetic Relationships among Cetartiodactyls Based on Insertions of Short and Long Interspersed Elements: Hippopotamuses Are the Closest Extant Relatives of Whales," *Proceedings of the National Academy of Sciences*, Vol. 96 (Aug. 31, 1999): 10261–10266.

CONNECT According to the cladogram, which animals other than the cetaceans are the closest relatives of ruminants?

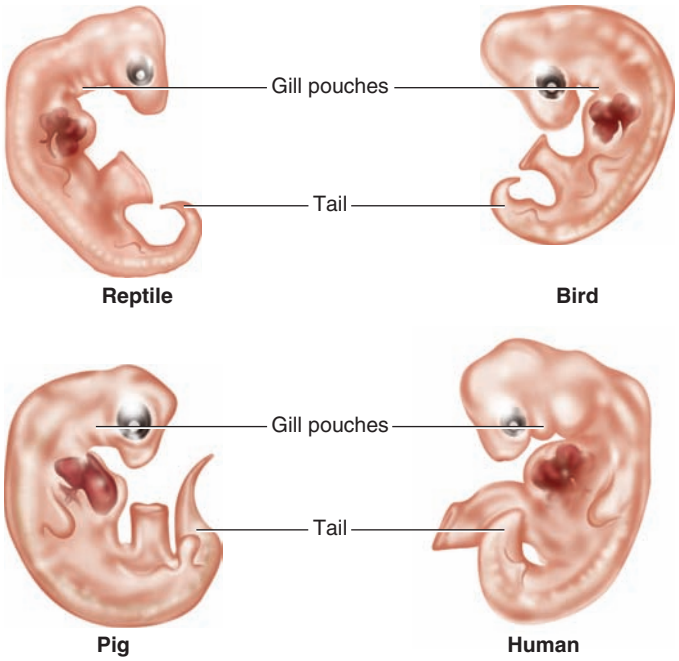

Figure 18-20 Similarities in vertebrate embryological development

The early stages of embryonic development are almost identical in different vertebrate species. Numerous structural similarities are shared by the early stages, including the presence of gill pouches and a tail. Figures are not drawn to scale.

Differences in predation are correlated with many differences in the guppies, such as male coloration, behavior, and attributes known as *life history traits* (discussed in more detail in Chapter 53). These traits include age and size at sexual maturity, the number of offspring per reproductive event, the size of the offspring, and the frequency of reproduction. For example, guppy adults are larger in streams found at higher elevations and smaller in streams found at lower elevations.

Do predators actually cause these differences to evolve? Reznick and his colleagues tested this evolutionary hypothesis by conducting field experiments in Trinidad. Taking advantage of waterfalls that prevent the upstream movement of guppies, guppy predators, or both, they moved either guppies or guppy predators over such barriers. For example, guppies from a high-predation habitat were introduced into a low-predation habitat by moving them over a barrier waterfall into a section of stream that was free of guppies and large predators. The only fish species that lived in this section of stream before the introduction was the small predatory fish.

Eleven years later, the researchers captured adult females from the introduction site (low-predation habitat) and the control site below the barrier waterfall (high-predation habitat). They bred these females in their laboratory and compared the life history traits of succeeding generations. The descendants of guppies introduced into the low-predation habitat matured at a larger size than did the descendants of guppies from the control site below the waterfall (FIG. 18-21). They also produced fewer, but larger, offspring. The introduced fish populations had evolved to have life histories similar to those of fishes typically found in such low-predation habitats. Similar studies have demonstrated that predators have played an active role in the evolution of other traits, such as the average number of offspring produced during the lifetime of an individual female (fecundity), male coloration, and behavior.

Rapid evolution on a scale of years has also been observed in organisms as diverse as marine snails, mussels, soapberry bugs, mayflies, anole lizards, ‘i’iwis (scarlet honeycreepers),

Key Experiment

Can natural selection be observed in a natural population?

HYPOTHESIS: A natural population will respond adaptively to environmental change.

EXPERIMENT: Male and female guppies from a stream in which the predators preferred large adult guppies as prey (*brown bars*) were transferred to a stream in which the predators preferred juveniles and small adults.

RESULTS AND CONCLUSION: After 11 years, the descendants of the transferred guppies (*purple bars*) were measurably larger than their ancestors, indicating that larger guppies had a selective advantage in the new environment.

SOURCE: Data from Reznick, D.N., et al., "Evaluation of the Rate of Evolution in Natural Populations of Guppies (*Poecilia reticulata*)," *Science,* 275 (Mar. 28, 1997): 1934–1937.

Figure 18-21 D.N. Reznick's experiment in guppy evolution

CONNECT What do you think would happen next if larger predators were introduced into this low-predation habitat?

and wild rabbits. These and other experiments and observations demonstrate not only that evolution is real but also that it is occurring now, driven by selective environmental forces, such as predation, that can be experimentally manipulated. Darwin incorrectly assumed evolution to be so gradual that humans cannot observe it. As Jonathan Weiner, author of *The Beak of the Finch: A Story of Evolution in Our Time*, notes, "Darwin did not know the strength of his own theory. He vastly underestimated the power of natural selection. Its action is neither rare nor slow. It leads to evolution daily and hourly, all around us, and we can watch."[3]

Summary: Focus on Learning Objectives

18.1 What Is Evolution? *(page 386)*

1 Define the scientific theory of *evolution*.

- **Evolution** is the accumulation of inherited changes within a **population** over time. Evolution is the unifying concept of biology because it links all fields of the life sciences into a coherent body of knowledge.

18.2 Pre-Darwinian Ideas about Evolution *(page 386)*

2 Discuss the historical development of evolutionary thought.

- Jean Baptiste de Lamarck was the first scientist to propose that organisms undergo change over time as a result of some natural phenomenon rather than divine intervention. Lamarck thought that organisms were endowed with a vital force that drove them to change toward greater complexity over time. He thought that organisms could pass traits acquired during their lifetimes to their offspring.
- Charles Darwin's observations while voyaging on the HMS *Beagle* were the basis for his evolutionary theory. Darwin tried to explain the similarities between animals and plants of the arid Galápagos Islands and the humid South American mainland.
- Darwin was influenced by **artificial selection**, in which breeders develop many varieties of domesticated plants and animals in just a few generations. Darwin applied Thomas Malthus's ideas on the natural increase in human populations to natural populations. Darwin was influenced by the idea that Earth was extremely old, an idea promoted by Charles Lyell and other geologists.

18.3 Darwin and Evolution *(page 387)*

3 Explain the four premises of evolution by natural selection as proposed by Charles Darwin.

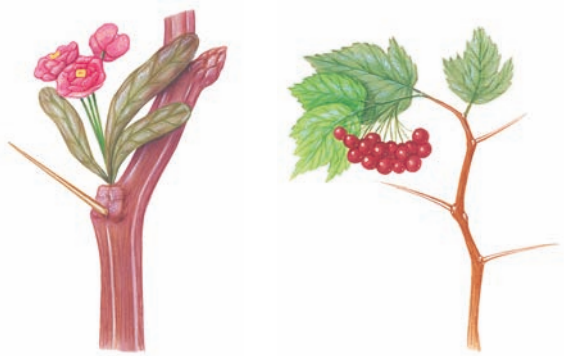
- Charles Darwin and Alfred Russel Wallace independently proposed evolution by **natural selection**, which is based on four observations. First, genetic variation exists among the individuals in a population. Second, the reproductive ability of each species causes its populations to have the potential to geometrically increase in number over time. Third, organisms compete with one another for the resources needed for life, such as food, living space, water, and light. Fourth, offspring with the most favorable combination of inherited characteristics are most likely to survive and reproduce, passing those genetic characteristics to the next generation.
- Natural selection results in **adaptations**, evolutionary modifications that improve the chances of survival and reproductive success in a particular environment. Over time, enough changes may accumulate in geographically separated populations to produce new species.

4 Compare the modern synthesis with Darwin's original view of evolution.

- The **modern synthesis** combines Darwin's evolutionary theory by natural selection with modern genetics to explain why individuals in a population vary and how species adapt to their environment.
- **Mutation** provides the genetic variability that natural selection acts on during evolution.

18.4 Evidence for Evolution *(page 391)*

5 Summarize the evidence for evolution obtained from the fossil record.



- Direct evidence of evolution comes from **fossils**, the remains or traces of ancient organisms. Layers of sedimentary rock normally occur in their sequence of deposition, with the more recent layers on top of the older, earlier ones. **Index fossils** characterize a specific layer over large geographic areas. **Radioisotopes** present in a rock provide a way to accurately measure the rock's age.

6 Define *biogeography* and describe how the distribution of organisms supports evolution.

- **Biogeography**, the geographic distribution of organisms, affects their evolution. Areas that have been separated from the rest of the world for a long time contain organisms that have evolved in isolation and are therefore unique to those areas.
- At one time the continents were joined to form a supercontinent. **Continental drift**, which caused the various landmasses to break apart and separate, has played a major role in evolution.

7 Describe the evidence for evolution derived from comparative anatomy.

- **Homologous features** have basic structural similarities even though the structures may be used in different ways because homologous features derive from the same structure in a common ancestor. Evolutionary affinities exist among the organisms that have homologous features.
- **Homoplastic features** evolved independently to have similar functions in distantly related organisms. Homoplastic features demonstrate **convergent evolution**, in which organisms with separate ancestries adapt in similar ways to comparable environmental demands.

- **Vestigial** structures are nonfunctional or degenerate remnants of structures that were present and functional in ancestral organisms. Structures occasionally become vestigial as species adapt to different modes of life.

8 Briefly explain how molecular biology and developmental biology provide insights into the evolutionary process.

- Molecular evidence for evolution includes the universal genetic code and the conserved sequences of amino acids in proteins and of nucleotides in DNA.
- Evolutionary changes are often the result of mutations in genes that affect the orderly sequence of events during development. Development in different animals is controlled by the same kinds of genes, which indicates that these animals have a shared evolutionary history.

- The accumulation of genetic changes since organisms diverged, or took separate evolutionary pathways, has modified the pattern of development in more complex vertebrate embryos.

9 Give an example of how evolutionary hypotheses are tested experimentally.

- David Reznick and John Endler have studied the effects of predation intensity on the evolution of guppy populations in the laboratory and in nature. Such experiments are a powerful way for investigators to test the underlying processes of natural selection.

Test Your Understanding

Know and Comprehend

1. Evolution is based on which of the following concepts? (a) organisms share a common origin (b) over time, organisms have diverged from a common ancestor (c) an animal's body parts can change over its lifetime, and these acquired changes are passed to the next generation (d) a and b (e) a, b, and c
2. Evolution is the accumulation of genetic changes within _____ over time. (a) individuals (b) populations (c) communities (d) a and b (e) a and c
3. Charles Darwin proposed that evolution could be explained by the differential reproductive success of organisms that resulted from their naturally occurring variation. Darwin called this process (a) coevolution (b) convergent evolution (c) natural selection (d) artificial selection (e) homoplasy
4. Which of the following is *not* part of Darwin's mechanism of evolution? (a) differential reproductive success (b) variation in a population (c) inheritance of acquired (nongenetic) traits (d) overproduction of offspring (e) struggle for existence
5. The evolution of beak size in the various species of Galápagos finches is associated with their (a) songs (b) diets (c) body sizes (d) predators (e) none of the preceding
6. The fossil record (a) usually occurs in sedimentary rock (b) sometimes appears fragmentary (c) is relatively complete for tropical rainforest organisms but incomplete for aquatic organisms (d) a and b (e) a, b, and c
7. In _____ the selecting agent is the environment, whereas in _____ the selecting agent is humans. (a) natural selection; convergent evolution (b) mutation; artificial selection (c) homoplasy; homology (d) artificial selection; natural selection (e) natural selection; artificial selection
8. Aardvarks, anteaters, and pangolins are only distantly related but are similar in structure and form as a result of (a) homology (b) convergent evolution (c) biogeography (d) vestigial structures (e) artificial selection
9. The species of the Galápagos Islands (a) are similar to those on other islands at the same latitude (b) are similar to those on the South American mainland (c) are identical to those on other islands at the same latitude (d) are identical to those on the South American mainland (e) are similar to those on both the African and South American mainlands

Apply and Analyze

10. **CONNECT** In what way does the modern synthesis strengthen scientific understanding of evolution? (a) is based on the sequence of fossils in rock layers (b) uses genetics to explain the source of hereditary variation that is essential to natural selection (c) was first proposed by ancient Greek scholars (d) considers the influence of the geographic distribution of organisms on their evolution (e) is reinforced by homologies that are explained by common descent
11. **CONNECT** What types of gene changes are most associated with the evolution of new anatomical features in a population?

Evaluate and Synthesize

12. **EVOLUTION LINK** The use of model organisms such as the mouse for research and biomedical testing of human diseases is based on the assumption that all organisms share a common ancestor. On what evidence is this assumption based?
13. **EVOLUTION LINK** Charles Darwin once said, "It is not the strongest of the species that survive, nor the most intelligent, but the one most responsive to change." Explain what he meant.
14. **EVOLUTION LINK** Write short paragraphs explaining each of the following statements:
    (a) Natural selection chooses from among the individuals in a population those most suited to *current* environmental conditions. It does not guarantee survival under future conditions.
    (b) Individuals do not evolve, but populations do.
    (c) The organisms that exist today do so because their ancestors had traits that allowed them and their offspring to thrive.
    (d) At the molecular level, evolution can take place by the replacement of one nucleotide by another.
    (e) Evolution is said to have occurred within a population when measurable genetic changes are detected.
15. **EVOLUTION LINK** Although most salamanders have four legs, a few species that live in shallow water lack hind limbs and have extremely tiny forelimbs (see photograph). Develop a hypothesis to explain how limbless salamanders came about according to Darwin's mechanism of evolution by natural selection. How could you test your hypothesis?

Suzanne L. & Joseph T. Collins/Science Source

The narrow-striped dwarf siren (*Pseudobranchus striatus axanthus*) is an aquatic salamander that resembles an eel. It is native to Florida.

16. **INTERPRET DATA** Which of the primates in Figure 18-18 is the most distantly related to humans? Explain your answer.
17. **SCIENCE, TECHNOLOGY, AND SOCIETY** Farmers often face a predicament, known as the pesticide treadmill, in which the cost of applying pesticides increases because the pesticides have to be applied more frequently or in larger doses, while their effectiveness decreases. Based on what you have learned in this chapter, offer an explanation for why the pesticides lose their effectiveness.

19 Evolutionary Change in Populations

KEY CONCEPTS

19.1 The genotype, phenotype, and allele frequencies of a population's gene pool (all alleles of all loci) can be calculated.

19.2 The Hardy–Weinberg principle predicts allele and genotype frequencies for a population that is not evolving.

19.3 Natural selection, as well as nonrandom mating, mutation, genetic drift, and gene flow, are forces that drive changes in a population's gene pool over successive generations (microevolution). Modes of natural selection include stabilizing selection, directional selection, and disruptive selection.

19.4 Populations typically exhibit genetic variation, which may include genetic polymorphism, balanced polymorphism, or geographic variation.

PHOTO: Genetic variation in snail shells. Shown are the shell patterns and colors in a single snail species (*Cepaea nemoralis*), native to Scotland. Variation in shell color may have adaptive value in these snails because some colors predominate in cooler environments, whereas other colors are more common in warmer habitats.
John Prior Images/Alamy Stock Photo

As you learned in Chapter 18, evolution occurs in populations, not individuals. Although natural selection acts on individuals, causing differential survival and reproduction, individuals themselves do not evolve during their lifetimes. Evolutionary change, which includes modifications in structure, physiology, ecology, and behavior, is inherited from one generation to the next. Although Darwin recognized that evolution occurs in populations, he did not understand how the attributes of organisms are passed to successive generations. One of the most significant advances in biology since Darwin's time has been the demonstration of the genetic basis of evolution.

Recall from Chapter 18 that a **population** consists of all individuals of the same species that live in a particular place at the same time. Individuals within a population vary in many recognizable characters. A population of snails, for example, may vary in shell size, weight, or color (see photograph). Some of this variation is due to heredity, and some is due to environment (nonheritable variation), such as the individual differences observed in the pink color of flamingos, which is partly attributable to differences in diet.

Biologists study variation in a particular character (characteristic) by taking measurements of that character in a population. By comparing the character in parents and offspring, it is possible to estimate the amount of observed variation that is genetic, as represented by the number, frequency, and kinds of alleles in a population. (Recall from Chapter 11 that an **allele** is one of two or more alternate forms of a gene. Alleles occupy corresponding positions, or **loci**, on homologous chromosomes.)

This chapter will help you develop an understanding of the importance of genetic variation as the raw material for evolution

and of the basic concepts of **population genetics**, the study of genetic variability within a population and of the evolutionary forces that act on it. Population genetics represents an extension of Gregor Mendel's principles of inheritance (see Chapter 11). You will learn how to distinguish genetic equilibrium from evolutionary change and how to assess the roles of the five factors responsible for evolutionary change: nonrandom mating, mutation, genetic drift, gene flow, and natural selection.

19.1 Genotype, Phenotype, and Allele Frequencies

LEARNING OBJECTIVES

1 Define what is meant by a population's gene pool.
2 Distinguish among genotype, phenotype, and allele frequencies.

Each population possesses a **gene pool**, which includes all the alleles for all the loci present in the population. Because diploid organisms have a maximum of two different alleles at each genetic locus, a single individual typically has only a small fraction of the alleles present in a population's gene pool. The genetic variation that is evident among individuals in a given population indicates that each individual has a different subset of the alleles in the gene pool.

The evolution of populations is best understood in terms of genotype, phenotype, and allele frequencies. Suppose, for example, that all 1000 individuals of a hypothetical population have their genotypes tested with respect to a single locus, with the following results:

Genotype	Number	Genotype Frequency
AA	490	0.49
Aa	420	0.42
aa	90	0.09
Total	1000	1.00

Each **genotype frequency** is the proportion of a particular genotype in the population. Genotype frequency is usually expressed as a decimal fraction, and the sum of all genotype frequencies is 1.0 (somewhat like probabilities, which were discussed in Chapter 11). For example, the genotype frequency for the *Aa* genotype is $420 \div 1000 = 0.42$.

A **phenotype frequency** is the proportion of a particular phenotype in the population. If each genotype corresponds to a specific phenotype, the phenotype and genotype frequencies are the same. If allele *A* is dominant over allele *a*, however, the phenotype frequencies in our hypothetical population would be the following:

Phenotype	Number	Phenotype Frequency
Dominant	910	0.91
Recessive	90	0.09
Total	1000	1.00

In this example, the dominant phenotype is the sum of two genotypes, *AA* and *Aa*, so the number 910 is obtained by adding 490 and 420.

An **allele frequency** is the proportion of a specific allele (i.e., of *A* or *a*) in a particular population. As mentioned earlier, each individual, being diploid, has two alleles at each genetic locus. Because we started with a population of 1000 individuals, we must account for a total of 2000 alleles. The 490 *AA* individuals have 980 *A* alleles, and the 420 *Aa* individuals have 420 *A* alleles, for a total of 1400 *A* alleles in the population. The total number of *a* alleles in the population is $420 + 90 + 90 = 600$. Now it is easy to calculate allele frequencies:

Allele	Number	Allele Frequency
A	1400	0.7
a	600	0.3
Total	2000	1.0

CHECKPOINT 19.1

- Does the term *gene pool* apply to individuals, populations, or both?
- **CONNECT** Can the frequencies of all genotypes in a population be determined directly with respect to a locus that has only two alleles: one dominant and the other recessive?
- **INTERPRET DATA** In a human population of 1000, 840 are tongue rollers (360 *TT* and 480 *Tt*), and 160 are not tongue rollers (*tt*). What is the frequency of the dominant allele (*T*) in the population?

19.2 The Hardy–Weinberg Principle

LEARNING OBJECTIVES

3 Discuss the significance of the Hardy–Weinberg principle as it relates to evolution and list the five conditions required for genetic equilibrium.
4 Use the Hardy–Weinberg principle to solve problems involving populations.

In the example just discussed, we observe that only 90 of the 1000 individuals in the population exhibit the recessive phenotype characteristic of the genotype *aa*. The remaining 910 individuals exhibit the dominant phenotype and are either *AA* or *Aa*. You might assume that after many generations, genetic recombination during sexual reproduction would cause the dominant allele to become more common in the population. You might also assume that the recessive allele would eventually disappear altogether. These assumptions were common among many biologists early in the 20th century. However, they are incorrect because the frequencies of alleles and genotypes do not change from generation to generation unless influenced by outside factors (discussed later in this chapter).

A population whose allele and genotype frequencies do not change from generation to generation is said to be at **genetic equilibrium**. Such a population, with no net change in allele or genotype frequencies over time, is not undergoing evolutionary change. A population that is at genetic equilibrium is not evolving with respect to the locus being studied. However, if allele frequencies change over successive generations, evolution is occurring.

The explanation for the stability of successive generations in populations at genetic equilibrium was provided independently by Godfrey Hardy, an English mathematician, and Wilhelm Weinberg, a German physician, in 1908. They pointed out that the expected frequencies of various genotypes in a population can be described mathematically. The resulting **Hardy–Weinberg principle** shows that if the population is large, the process of inheritance does not by itself cause changes in allele frequencies. It also explains why dominant alleles are not necessarily more common than recessive ones. The Hardy–Weinberg principle represents an ideal situation that seldom occurs in the natural world. However, it is useful because it provides a model to help us understand the real world. Knowledge of the Hardy–Weinberg principle is essential to understanding the mechanisms of evolutionary change in sexually reproducing populations.

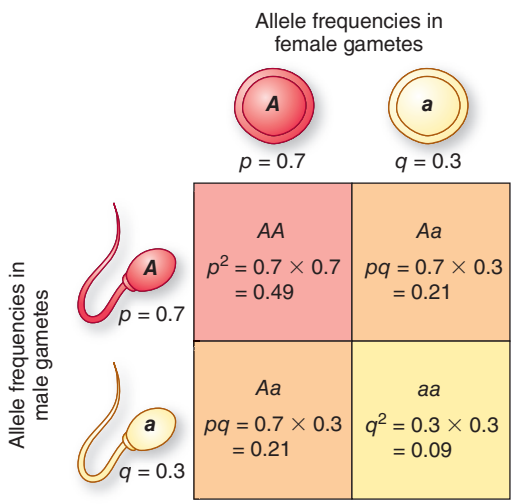
We now expand our original example to illustrate the Hardy–Weinberg principle. Keep in mind as we go through these calculations that in most cases we know only the phenotype frequencies. When alleles are dominant and recessive, it is usually impossible to visually distinguish heterozygous individuals from homozygous dominant individuals. The Hardy–Weinberg principle lets us use phenotype frequencies to calculate the expected genotype frequencies and allele frequencies, assuming that we have a clear understanding of the genetic basis for the character under study.

As mentioned earlier, the frequency of either allele, *A* or *a*, is represented by a number that ranges from 0 to 1. An allele that is totally absent from the population has a frequency of zero. If all the alleles of a given locus are the same in the population, the frequency of that allele is 1.

Because only two alleles, *A* and *a*, exist at the locus in our example, the sum of their frequencies must equal 1. If we let p represent the frequency of the dominant (*A*) allele in the population and q the frequency of the recessive (*a*) allele, we can summarize their relationship with a simple binomial equation, $p + q = 1$. When we know the value of either p or q, we can calculate the value of the other: $p = 1 - q$, and $q = 1 - p$.

Squaring both sides of $p + q = 1$ results in $(p + q)^2 = 1$. This equation can be expanded to describe the relationship of the allele frequencies to the genotypes in the population. When it is expanded, we obtain the frequency of the offspring genotypes:

$$\underset{\text{Frequency of } AA}{p^2} + \underset{\text{Frequency of } Aa}{2pq} + \underset{\text{Frequency of } aa}{q^2} = \underset{\text{All individuals in the population}}{1}$$



We always begin Hardy–Weinberg calculations by determining the frequency of the homozygous recessive genotype. We had 90 homozygous recessive individuals in our population of 1000, so we can infer that the frequency of the *aa* genotype, q^2, is 90/1000, or 0.09. Because q^2 equals 0.09, q (the frequency of the recessive *a* allele) is equal to the square root of 0.09, or 0.3. From the relationship between p and q, we conclude that the frequency of the dominant *A* allele, p, is $1 - q = 1 - 0.3 = 0.7$.

Given this information, we can calculate the frequency of homozygous dominant (*AA*) individuals: $p^2 = 0.7 \times 0.7 = 0.49$ (FIG. 19-1). The expected frequency of heterozygous individuals (*Aa*) would be $2pq = 2 \times 0.7 \times 0.3 = 0.42$. Thus, approximately 490 individuals are expected to be homozygous dominant, and approximately 420 are expected to be heterozygous. Note that the sum of homozygous dominant and heterozygous individuals equals 910, the number of individuals showing the dominant phenotype with which we started.

Any population in which the distribution of genotypes conforms to the relation $p^2 + 2pq + q^2 = 1$, whatever the absolute values for p and q may be, is at genetic equilibrium. The Hardy–Weinberg principle allows biologists to calculate allele frequencies in a given population if we know the genotype frequencies and vice versa. These values provide a basis of comparison with a population's allele or genotype frequencies in succeeding generations. During that time, if the allele or genotype frequencies deviate from the values predicted by the Hardy–Weinberg principle, the population is evolving.

Genotypes	*AA*	*Aa*	*aa*
Frequency of genotypes in population	0.49	0.42 (0.21 + 0.21)	0.09
Frequency of alleles in gametes	*A* = 0.49 + 0.21 = 0.7		*a* = 0.21 + 0.09 = 0.3

(a) Genotype and allele frequencies. The figure illustrates how to calculate frequencies of the alleles *A* and *a* in the gametes produced by each genotype.

(b) Segregation of alleles and random fertilization. When eggs and sperm containing *A* or *a* alleles unite randomly, the frequency of each of the possible genotypes (*AA*, *Aa*, *aa*) among the offspring is calculated by multiplying the frequencies of the alleles *A* and *a* in eggs and sperm.

Genetic equilibrium occurs if certain conditions are met

The Hardy–Weinberg principle of genetic equilibrium tells us what to expect when a sexually reproducing population is not evolving. The relative proportions of alleles and genotypes in successive generations will always be the same provided that the following five conditions are met:

1. **Random mating.** In unrestricted random mating, each individual in a population has an equal chance of mating with any individual of the opposite sex. In our example, the individuals represented by the genotypes *AA*, *Aa*, and *aa* must mate with one another at random and must not select their mates on the basis of genotype or any other factors that result in nonrandom mating.
2. **No net mutations.** There must be no mutations that convert *A* into *a* or vice versa. That is, the frequencies of *A* and *a* in the population must not change because of mutations.
3. **Large population size.** Allele frequencies in a small population are more likely to change by random fluctuations (i.e., by genetic drift, which is discussed later) than are allele frequencies in a large population.
4. **No migration.** There can be no exchange of alleles with other populations that might have different allele frequencies. In other words, there can be no migration of individuals into or out of a population.[1]
5. **No natural selection.** If natural selection is occurring, certain phenotypes (and their corresponding genotypes) are favored over others. These more successful genotypes are said to have greater **fitness**, which is the relative ability to make a genetic contribution to subsequent generations. Consequently, the allele frequencies will change, and the population will evolve.

Human MN blood groups are a valuable illustration of the Hardy–Weinberg principle

Humans have dozens of antigens on the surfaces of their blood cells. (An *antigen* is a molecule, usually a protein or carbohydrate, that is recognized as foreign by cells of another organism's immune system.) One group of antigens, designated the MN blood group, stimulates the production of antibodies when injected into rabbits or guinea pigs. However, humans do not produce antibodies for M and N, so the MN blood group is not medically important, for example, when giving blood transfusions. (Recall the discussion of the medically important ABO alleles in Chapter 11.) The MN blood group is of interest to population geneticists because the alleles for the MN blood group, usually designated *M* and *N*, are codominant (genotype *MM* produces antigen M only, genotype *NN* produces antigen N only, and the heterozygous genotype *MN* produces both antigens). This property allows population geneticists to directly observe all three possible genotype frequencies and compare them with calculated frequencies. The following data are typical of the MN blood group in people in the United States:

Genotype	Observed
MM	320
MN	480
NN	200
Total	1000

Because 1000 diploid individuals are in the sample, there are a total of 2000 alleles. The frequency of *M* alleles in the population is $p = (2 \times 320 + 480) \div 2000 = 0.56$. The frequency of *N* alleles in the population is $q = (2 \times 200 + 480) \div 2000 = 0.44$. As a quick check, the sum of the frequencies should equal 1. Does it?

If this population is in genetic equilibrium, the expected *MM* genotype frequency is $p^2 = (0.56)^2 = 0.31$. The expected *MN* genotype frequency is $2pq = 2 \times 0.56 \times 0.44 = 0.49$. The expected *NN* genotype frequency is $q^2 = (0.44)^2 = 0.19$. As a quick check, the sum of the three genotype frequencies should equal 1. Does it? You can use the calculated genotype frequencies to determine how many individuals in a population of 1000 should have the expected genotype frequencies. By comparing the expected numbers with the actual results observed, you see how closely the population is to genetic equilibrium. Simply multiply each genotype frequency by 1000:

Genotype	Observed	Expected
MM	320	313.6
MN	480	492.8
NN	200	193.6
Total	1000	1000.0

The expected numbers closely match the observed numbers, indicating that the MN blood groups in the human population are almost at genetic equilibrium. This finding is not surprising because the lack of medical significance suggests that the *MN* characteristic is not subject to natural selection and that it does not produce a visible phenotype that might affect random mating.

CHECKPOINT 19.2

- **INTERPRET DATA** In a population at genetic equilibrium, the frequency of the homozygous recessive genotype (*tt*) is 0.16. What are the allele frequencies of *T* and *t*, and what are the expected frequencies of the *TT* and *Tt* genotypes?
- **INTERPRET DATA** In a population at genetic equilibrium, the frequency of the dominant phenotype is 0.96. What are the frequencies of the dominant (*A*) and recessive (*a*) alleles, and what are the expected frequencies of the *AA*, *Aa*, and *aa* genotypes?
- **INTERPRET DATA** The genotype frequencies of a population are determined to be 0.6 *BB*, 0.0 *Bb*, and 0.4 *bb*. Is it likely that this population meets all the conditions required for genetic equilibrium?

[1] Note that evolutionary biologists use the term *migration*, not in its ordinary sense of periodic or seasonal movement of individuals from one location to another but in reference to a movement of individuals that results in a transfer of alleles from one population to another.

19.3 Microevolution

LEARNING OBJECTIVES

5 Define *microevolution*.
6 Discuss how each of the following microevolutionary forces alters allele frequencies in populations: nonrandom mating, mutation, genetic drift, gene flow, and natural selection.
7 Distinguish among stabilizing selection, directional selection, and disruptive selection.

Evolution represents a departure from the Hardy–Weinberg principle of genetic equilibrium. The degree of departure between the observed allele or genotype frequencies and those expected by the Hardy–Weinberg principle indicates the amount of evolutionary change. This type of evolution—generation-to-generation changes in allele or genotype frequencies *within* a population—is sometimes referred to as **microevolution** because it often involves relatively small or minor changes, usually over a few generations.

Changes in the allele frequencies of a population result from five microevolutionary processes: nonrandom mating, mutation, genetic drift, gene flow, and natural selection. These microevolutionary processes are the opposite of the conditions that must be met if a population is in genetic equilibrium. When one or more of these processes acts on a population, allele or genotype frequencies change from one generation to the next.

Nonrandom mating changes genotype frequencies

When individuals select mates on the basis of phenotype (thereby selecting the corresponding genotype), they bring about evolutionary change in the population. Two examples of nonrandom mating are inbreeding and assortative mating.

In many populations, individuals mate more often with close neighbors than with more distant members of the population. As a result, neighbors tend to be more closely related—that is, genetically similar—to one another. The mating of genetically similar individuals who are more closely related than if they had been chosen at random from the entire population is known as **inbreeding**. Although inbreeding does not change the overall allele frequency, the frequency of homozygous genotypes increases with each successive generation of inbreeding. The most extreme example of inbreeding is self-fertilization, which is particularly common in certain plants.

Inbreeding does not appear to be detrimental in some populations, but in others it causes **inbreeding depression**, in which inbred individuals have lower fitness than those not inbred. Fitness is usually measured as the average number of surviving offspring of one genotype compared with the average number of surviving offspring of competing genotypes. Inbreeding depression, as evidenced by fertility declines and high juvenile mortality, is thought to be caused by the expression of harmful recessive alleles because homozygosity increases with inbreeding.

Several studies have provided direct evidence of the deleterious consequences of inbreeding in nature. For example, white-footed mice (*Peromyscus leucopus*) were taken from a field and used to develop both inbred and non-inbred populations in the laboratory. When these laboratory-bred populations were returned to nature, their survivorship was estimated from release–recapture data. The non-inbred mice had a statistically significant higher rate of survival than the inbred mice (FIG. 19-2). It is not known why the inbred mice had a lower survival rate. Some possibilities include higher disease susceptibility, poorer ability to evade predators, less ability to find food, and less ability to win fights with other white-footed mice.

Assortative mating, in which individuals select mates by their phenotypes, is another example of nonrandom mating. For example, biologists selected two phenotypes—high bristle number and low bristle number—in a fruit fly (*Drosophila melanogaster*) population. Although the researchers made no effort to control mating, they observed that the flies preferentially mated with those of similar phenotypes. Females with high bristle number tended to mate with males with high bristle number, and females with low bristle number tended to mate with males with low bristle number. Such selection of mates with the same phenotype is known as *positive assortative mating* (as opposed to the less common phenomenon, *negative assortative mating*, in which mates with opposite phenotypes are selected).

Positive assortative mating is practiced in many human societies, in which men and women tend to marry individuals like themselves in such characteristics as height or intelligence. Like inbreeding, assortative mating usually increases homozygosity at the expense of heterozygosity in the population and does not change the overall allele frequencies in the population. However, assortative mating changes genotype frequencies only at the loci involved in mate choice, whereas inbreeding affects genotype frequencies in the entire genome.

Mutation increases variation within a population

Variation is introduced into a population through **mutation**, which is an unpredictable change in deoxyribonucleic acid (DNA). As discussed in Chapter 13, mutations, which are the source of all new alleles, result from (1) a change in the nucleotide base pairs of a gene, (2) a rearrangement of genes within chromosomes so that their interactions produce different effects, or (3) a change in chromosome structure. Mutations occur unpredictably and spontaneously. A particular locus may have a DNA sequence that causes certain types of mutations to occur more frequently than others. The rate of mutation appears relatively constant for a particular locus but may vary by several orders of magnitude among genes within a single species and among different species.

Not all mutations pass from one generation to the next. Those occurring in somatic (body) cells are not inherited. When an individual with such a mutation dies, the mutation is lost. Some mutations, however, occur in reproductive cells. These mutations may or may not overtly affect the offspring because at least some of the DNA in a cell appears to be nonfunctional.

Key Experiment

Does inbreeding affect survival?

HYPOTHESIS: Non-inbred white-footed mice (*Peromyscus leucopus*) will have a survival advantage over inbred mice in a natural environment.

EXPERIMENT: Field-captured mice were used to establish inbred and non-inbred laboratory populations. The mice were marked and then released back into the field population. The population was then sampled by capturing mice, noting the number of inbred and non-inbred mice, and re-releasing the mice. The *x*-axis represents the 10-week period during which the samples were collected (note that no samples were collected in weeks 4 through 7). Values on the *y*-axis are the estimated proportion of mice that survived since the last time the population was sampled. For example, the value of 0.2 in week 3 for the inbred mice means that 20% of the inbred mice that were alive at the beginning of the week survived through that week.

RESULTS AND CONCLUSION: Non-inbred mice (*red*) had a consistently higher survival rate than inbred mice (*blue*). Thus, inbreeding had a negative effect on survival in this species in nature.

Figure 19-2 Survival of inbred and non-inbred mice

CONNECT If the researchers estimated there were 200 inbred mice in the population at the beginning of week 3, how many would be estimated to be alive at the beginning of week 4?

Even if a mutation occurs in the DNA that codes for a polypeptide, it may still have little effect on the structure or function of that polypeptide (we discuss such *neutral variation* later in this chapter). However, when a polypeptide is sufficiently altered to change its function, the mutation is usually harmful. By acting against seriously abnormal phenotypes, natural selection eliminates or reduces to low frequencies the most harmful mutations. Mutations with small phenotypic effects, even if slightly harmful, have a better chance of being incorporated into the population, where at some later time, under different environmental conditions, they may produce phenotypes that are useful or adaptive.

The "needs" of a population do not determine what mutations will occur. Consider a population living in an increasingly dry environment. A mutation producing a new allele that helps an individual adapt to dry conditions is no more likely to occur than one for adapting to wet conditions or one with no relationship to the changing environment. The production of new mutations simply increases the genetic variability that is acted on by natural selection and therefore increases the potential for new adaptations.

Mutation by itself causes small deviations in allele frequencies from those predicted by the Hardy–Weinberg principle. Although allele frequencies may be changed by mutation, these changes are typically several orders of magnitude smaller than changes caused by other evolutionary forces, such as genetic drift. Mutation is usually negligible as an evolutionary force, but it is essential to the evolutionary process because it is the ultimate source of genetic variation.

In genetic drift, random events change allele frequencies

The size of a population has important effects on allele frequencies because random events, or chance, tend to cause changes of relatively greater magnitude in a small population. If a population consists of only a few individuals, an allele present at a low frequency in the population could be completely lost by chance. Such an event would be unlikely in a large population. For example, consider two populations, one with 10,000 individuals and one with 10 individuals. If an uncommon allele occurs at a frequency of 10%, or 0.1, in both populations, then 1900 individuals in the large population have the allele.[2] That same frequency, 0.1, in the smaller population means that only about 2 individuals have the allele.[3] From this exercise, it is easy to see that there is a greater likelihood of losing the rare allele from the smaller population than from the larger one. Predators, for example, might happen to kill one or two individuals possessing the uncommon allele in the smaller population purely by chance, so these individuals would leave no offspring.

The production of random evolutionary changes in small breeding populations is known as **genetic drift**. Genetic drift results in changes in allele frequencies in a population from one generation to another. One allele may be eliminated from the population purely by chance, regardless of whether that allele is beneficial, harmful, or of no particular advantage or disadvantage. Thus, genetic drift decreases genetic variation *within* a population, although it tends to increase genetic differences *among* different populations.

When bottlenecks occur, genetic drift becomes a major evolutionary force Because of fluctuations in the environment, such as depletion in food supply or an outbreak of disease, a population may rapidly and markedly decrease from time to time. The population is said to go through a bottleneck during which genetic drift can occur in the small population of survivors. As the population again increases in size, many allele frequencies may be quite different from those in the population preceding the decline.

[2] $2pq + q^2 = 2(0.9)(0.1) + (0.1)^2 = 0.18 + 0.01 = 0.19; 0.19 \times 10{,}000 = 1900$

[3] $0.19 \times 10 = 1.9$

Scientists hypothesize that genetic variation in the cheetah was considerably reduced by a bottleneck at the end of the last Ice Age, some 10,000 years ago. Cheetahs nearly became extinct, perhaps from overhunting by humans. The few surviving cheetahs had greatly reduced genetic variability, and as a result, the cheetah population today is so genetically uniform that unrelated cheetahs can accept skin grafts from one another. (Normally, only identical twins accept skin grafts so readily.)

The founder effect occurs when a few "founders" establish a new colony When one or a few individuals from a large population establish, or found, a colony (as when a few birds separate from the rest of the flock and fly to a new area), they bring with them only a small fraction of the genetic variation present in the original population. As a result, the only alleles among their descendants will be those of the colonizers. Typically, the allele frequencies in the newly founded population are quite different from those of the parent population. The genetic drift that results when a small number of individuals from a large population found a new colony is called the **founder effect**.

The Finnish people may illustrate the founder effect (FIG. 19-3). Geneticists who sampled DNA from Finns and from the European population at large found that Finns exhibit considerably less genetic variation than other Europeans. This evidence supports the hypothesis that Finns are descended from a small group of people who settled about 4000 years ago in the area that is now Finland and, because of the geography, remained separate from other European societies for centuries. The subpopulation in eastern Finland is especially homogeneous because it existed in relative isolation after being established by only several hundred founders in the 1500s.

The founder effect and population bottlenecks have also apparently affected the genetic composition of the population of Iceland. Most of Iceland's 332,000 citizens are descended from a small group of Norse and Celtic people who settled that island in the ninth century. Isolation and population bottlenecks due to disease and natural disasters have contributed to the relative genetic homogeneity of the Icelandic people.

Eugene Sergeev/Alamy Stock Photo

Figure 19-3 Finns and the founder effect
The Finnish people are thought to have descended from a small founding population that remained separate from the rest of Europe for centuries.

The founder effect can be of medical importance. For example, by chance one of the approximately two hundred founders of the Amish population of Pennsylvania carried a recessive allele that, when homozygous, is responsible for a form of dwarfism, Ellis–van Creveld syndrome. Although this allele is rare in the general population (frequency about 0.001), today it is relatively common in the Amish population (frequency about 0.07).

The Finnish and Icelandic populations, as well as certain Amish populations, are being studied by researchers who employ sophisticated technologies such as genome-wide association studies (GWAS; see Chapters 15 and 16) in the quest to identify genetic contributions to a large number of diseases. The task is simplified in these studies because confounding factors such as variability in the rest of the genome and differences in such environmental factors as nutrition, access to medical care, and exposure to pollutants are relatively controlled.

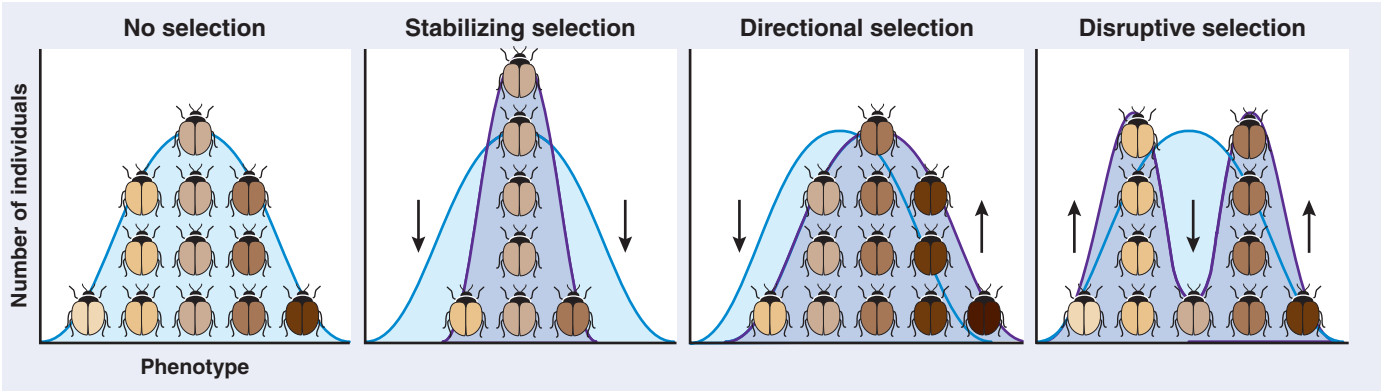
Gene flow generally increases variation within a population

Individuals of a species tend to be distributed in local populations that are genetically isolated to some degree from other populations. For example, the bullfrogs of one pond form a population separated from those in an adjacent pond. Some exchanges occur by migration between ponds, but the frogs in one pond are much more likely to mate with those in the same pond. Because each population is isolated to some extent from other populations, each has distinct genetic traits and gene pools.

The migration of breeding individuals between populations causes a corresponding movement of alleles, or **gene flow**, that has significant evolutionary consequences. As alleles flow from one population to another, they usually increase the amount of genetic variability within the recipient population. If sufficient gene flow occurs between two populations, they become more similar genetically. Because gene flow reduces the amount of variation between two populations, it tends to counteract the effects of natural selection and genetic drift, both of which often cause populations to become increasingly distinct.

If migration by members of a population is considerable and if populations differ in their allele frequencies, significant genetic changes occur in local populations. For example, by ten thousand years ago, modern humans occupied almost all Earth's major land areas except a few islands and Antarctica. Because the population density was low in most locations, the small, isolated human populations underwent random genetic drift and natural selection. More recently (during the past three hundred years or so), major migrations have increased gene flow, significantly altering allele frequencies within previously isolated human populations.

Natural selection changes allele frequencies in a way that increases adaptation



Natural selection is the mechanism of evolution first proposed by Darwin in which members of a population that are more successfully adapted to the environment have greater

Key Point

Stabilizing, directional, and disruptive selection can change the distribution of phenotypes in a population.

(a) A character that is under polygenic control (in this example, wing colors in a hypothetical population of beetles) exhibits a normal distribution of phenotypes in the absence of selection.

(b) As a result of stabilizing selection, which trims off extreme phenotypes, variation about the mean is reduced.

(c) Directional selection shifts the curve in one direction, changing the average value of the character.

(d) Disruptive selection, which trims off intermediate phenotypes, results in two or more peaks.

Figure 19-4 Modes of selection

The *blue screen* represents the distribution of individuals by phenotype (in this example, color variation) in the original population. The *purple screen* represents the distribution by phenotype in the evolved population. The *arrows* represent the pressure of natural selection on the phenotypes.

PREDICT If a population is experiencing directional selection with respect to wing color, what type of selection would you expect it to experience with respect to antenna length?

fitness; that is, they are more likely to survive and reproduce (see Chapter 18). Over successive generations, the proportion of favorable alleles increases in the population. In contrast with other microevolutionary processes (nonrandom mating, mutation, genetic drift, and gene flow), natural selection leads to adaptive evolutionary change. Natural selection not only explains why organisms are well adapted to the environments in which they live, but it also helps account for the remarkable diversity of life. Natural selection enables populations to change, thereby adapting to different environments and different ways of life.

Natural selection results in the differential reproduction of individuals with different traits, or phenotypes (and therefore different genotypes), in response to the environment. Natural selection preserves individuals with favorable phenotypes and eliminates those with unfavorable phenotypes. Individuals that survive and produce fertile offspring have a selective advantage.

The mechanism of natural selection does not develop a "perfect" organism. Rather, it weeds out those individuals whose phenotypes are less adapted to environmental challenges, while allowing better-adapted individuals to survive and pass their alleles to their offspring. By reducing the frequency of alleles that result in the expression of less favorable traits, the probability is increased that favorable alleles responsible for an adaptation will come together in the offspring.

Natural selection operates on an organism's phenotype Natural selection does not act directly on an organism's genotype. Instead, it acts on the phenotype, which is, at least in part, an expression of the genotype. The phenotype represents an interaction between the environment and all the alleles in the organism's genotype. It is rare that alleles of a single locus determine the phenotype, as Mendel originally observed in garden peas. Much more common is the interaction of alleles of several loci for the expression of a single phenotype. Many plant and animal characteristics are under this type of *polygenic* control (see Chapter 11).

When characters are under polygenic control (as is human height), a range of phenotypes occurs, with most of the population located in the median range and fewer at either extreme. This arrangement is a normal distribution or standard bell curve (FIG. 19-4a; see also Fig. 11-20). Three kinds of selection—stabilizing, directional, and disruptive—cause changes in the normal distribution of phenotypes in a population. Although we consider each process separately, in nature their influences generally overlap.

Stabilizing selection The process of natural selection associated with a population well adapted to its environment is known as **stabilizing selection**. Most populations are probably influenced by stabilizing forces most of the time. Stabilizing selection selects against phenotypic extremes. In other words, individuals with average, or intermediate, phenotypes are favored.

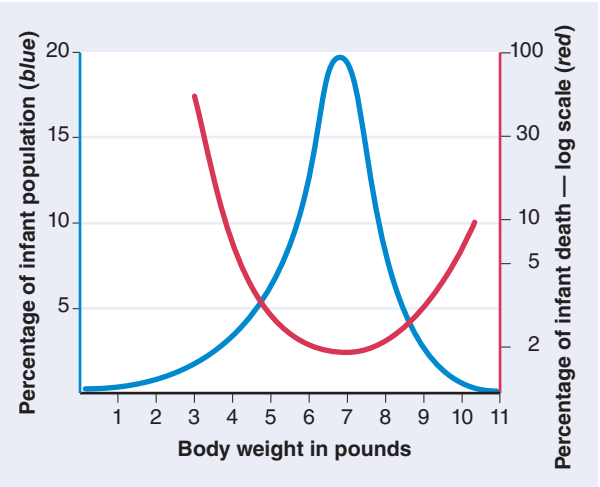

Figure 19-5 Stabilizing selection

The *blue curve* shows the distribution of birth weights in a sample of 13,730 infants. The *red curve* shows mortality (death) at each birth weight. Infants with very low or very high birth weights have higher death rates than infants of average weight. The optimum birth weight—that is, the one with the lowest mortality—is close to the average birth weight (about 7 lb). Adapted from Cavalli-Sforza, L.L., and W.F. Bodmer, *The Genetics of Human Populations* (San Francisco, CA: W.H. Freeman and Company, 1971).

Because stabilizing selection tends to decrease variation by favoring individuals near the mean of the normal distribution at the expense of those at either extreme, the bell curve narrows (FIG. 19-4b). Although stabilizing selection decreases the amount of variation in a population, variation is rarely eliminated by this process because other microevolutionary processes act against a decrease in variation. For example, mutation is slowly but continually adding to the genetic variation within a population.

One of the most widely studied cases of stabilizing selection involves human birth weight, which is under polygenic control and is also influenced by environmental factors. Extensive data from hospitals have shown that infants born with intermediate weights are the ones most likely to survive (FIG. 19-5). Infants at either extreme (too small or too large) have higher rates of mortality. When newborn infants are too small, their body systems are immature, and when they are too large, they have difficult deliveries because they cannot pass as easily through the cervix and vagina. Stabilizing selection operates to reduce variability in birth weight so that it is close to the weight with the minimum mortality rate.

Directional selection If an environment changes over time, **directional selection** may favor phenotypes at one of the extremes of the normal distribution (FIG. 19-4c). Over successive generations, one phenotype gradually replaces another. So, for example, if greater size is advantageous in a new environment, larger individuals will become increasingly common in the population. However, directional selection occurs only if alleles favored under the new circumstances are already present in the population.

Darwin's Galápagos finches provide an excellent example of directional selection. Since 1973, Peter Grant and Rosemary Grant of Princeton University have studied the Galápagos finches. The Grants did a meticulous analysis of finch eating habits and beak sizes on Isla Daphne Major during three extended droughts (1976–1977, 1980, and 1982), one of which was followed by an extremely wet El Niño event (1983). During the droughts, the number of insects and small seeds declined, and large, heavy seeds became the finches' primary food source.

Many finches died during this time, and most of the survivors were larger birds whose beaks were larger and deeper. In a few generations, these larger birds became more common in the population (TABLE 19-1). After the El Niño event, however, smaller seeds became the primary food source, and smaller finches with average-sized beaks were favored. In this example, natural selection is directional: during the drought, natural selection operated in favor of the larger phenotype; whereas after the wet period, selection occurred in the opposite direction, favoring the smaller phenotype. The guppy populations studied in Venezuela and Trinidad (see Chapter 18) are another example of directional selection.

Table 19-1 Population Changes in *Geospiza fortis* before and after the 1976–1977 Drought

Character	Average before Drought (634)*	Average after Drought (135)*	Difference
Weight (g)	16.06	17.13	+1.07
Wing length (mm)	67.88	68.87	+0.99
Tarsus (leg, just above the foot) length (mm)	19.08	19.29	+0.21
Bill length (mm)	10.63	10.95	+0.32
Bill depth (mm)	9.21	9.70	+0.49
Bill width (mm)	8.58	8.83	+0.25

Directional selection by hunters has been observed in bighorn sheep (*Ovis canadensis*) in Canada. Sport hunters target large rams with rapidly growing horns for their trophy value (FIG. 19-6). Because these rams are typically killed prior to reaching their full reproductive potential, they contribute less to the gene pool; the result was a 25% decline in average ram weight and horn length over a period of 30 years. Paradoxically, the rams that would normally have the greatest fitness because of their size and ability to use their horns in competition with other males for mates become less fit when these attributes cause them to be singled out by hunters.

Disruptive selection Sometimes extreme changes in the environment may favor two or more different phenotypes at the expense of the mean. That is, more than one phenotype may be favored in the new environment. **Disruptive selection** is a special type of directional selection in which there is a trend in several directions rather than just one (FIG. 19-4d). It results in a divergence, or splitting apart, of distinct groups of individuals within a population. Disruptive selection, which is relatively rare, selects against the average, or intermediate, phenotype.

Limited food supply during a severe drought caused a population of finches on another island in the Galápagos to experience disruptive selection. The finch population initially exhibited a variety of beak sizes and shapes. Because the only foods available on this island during the drought were woodboring insects and seeds from cactus fruits, natural selection favored birds with beaks suitable for obtaining these types of food. Finches with longer beaks survived because they could open cactus fruits, and those with wider beaks survived because they could strip off tree bark to expose insects. However, finches with intermediate beaks could not use either food source efficiently and had a lower survival rate.

Natural selection induces change in the types and frequencies of alleles in populations only if there is pre-existing inherited variation. Genetic variation is the raw material for evolutionary change because it provides the diversity on which natural selection acts. Without genetic variation, evolution cannot occur. In the next section, we explore the genetic basis for variation that is acted on by natural selection.

CHECKPOINT 19.3

- Which microevolutionary force leads to adaptive changes in allele frequencies?
- **CONNECT** Why is mutation important to evolution if it is the microevolutionary force that generally has the smallest effect on allele frequencies?
- Which microevolutionary forces are most associated with an increase in variation within a population? among populations?
- Which microevolutionary force typically changes genotype frequencies without changing allele frequencies? Explain.

19.4 Genetic Variation in Populations

LEARNING OBJECTIVE

8 Describe the nature and extent of genetic variation, including genetic polymorphism, balanced polymorphism, neutral variation, and geographic variation.

Populations contain abundant genetic variation that was originally introduced by mutation. Sexual reproduction—with its associated crossing-over, independent assortment of chromosomes during meiosis, and random union of gametes—also contributes to genetic variation. The sexual process allows the variability introduced by mutation to be combined in new ways, which may be expressed as new phenotypes.

Genetic polymorphism can be studied in several ways

Genetic polymorphism, which is genetic variation among individuals in a population, is extensive in populations, although many of the genetic variants are present at low frequencies. Much of genetic polymorphism is not evident because it does not produce distinct phenotypes.

One way biologists estimate the total amount of genetic polymorphism in populations is by comparing the different forms of a particular protein. Each form consists of a slightly different amino acid sequence that is coded for by a different allele. For example, tissue extracts containing a particular enzyme may be analyzed for different individuals by gel electrophoresis. In *gel electrophoresis*, the enzymes are placed in slots on an agarose gel and an electric current is applied, causing each enzyme to migrate across the gel (see Fig. 15-9). Slight variations in amino acid sequences in the different forms of a particular enzyme cause each to migrate at a different rate, which can be detected using special stains or radioactive labels. Depending on the species studied, the percentage of enzymes that are polymorphic can range from about 15% to as much as 70%. In general, polymorphism of enzyme-coding loci tends to be greater in plants than in animals.

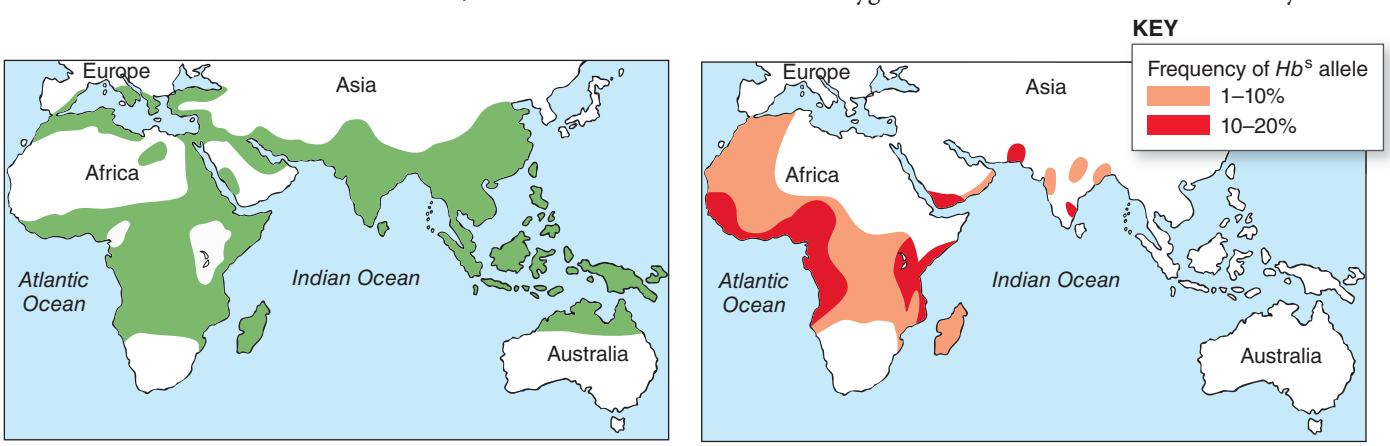
Determining the sequence of nucleotides in DNA from individuals in a population provides a *direct* estimate of genetic polymorphism that is sensitive enough to detect alleles that differ by only one nucleotide (**single nucleotide polymorphisms**, or **SNPs**). (DNA sequencing is discussed in Chapter 15.) DNA sequencing of specific alleles in an increasing number of organisms, including humans, indicates that SNPs are common in most populations.

Recent studies have revealed that genetic changes in which segments of DNA have been gained or lost (compared to a reference genome) are common in model organisms such as mice and *Drosophila*, as well as humans. These **copy number variations**, or **CNVs**, can involve DNA segments that range from as few as five hundred to one thousand base pairs up to about two million base pairs. It is currently estimated that the average human may have a dozen or more CNVs in their genome. In most cases, there does not appear to be an associated phenotype, or the phenotype is benign, such as an effect on eye color. However, as more sophisticated technologies have been developed to support ongoing research, evidence is accumulating that links specific CNVs to increased risk for certain medically important conditions, such as autism, Alzheimer's disease, and susceptibility to HIV infection.

Balanced polymorphism exists for long periods



Balanced polymorphism is a special type of genetic polymorphism in which two or more alleles persist in a population over many generations as a result of natural selection. Heterozygote advantage and frequency-dependent selection are mechanisms that preserve balanced polymorphism.

Genetic variation may be maintained by heterozygote advantage We have seen that natural selection often eliminates unfavorable alleles from a population, whereas favorable alleles are retained. However, natural selection sometimes helps maintain genetic diversity. In some cases, natural selection may even maintain a population's alleles that are unfavorable in the homozygous state. That happens, for example, when the heterozygote *Aa* has a higher degree of fitness than either homozygote *AA* or *aa*. This phenomenon, known as **heterozygote advantage**, is demonstrated in humans by the selective advantage of heterozygous carriers of the sickle cell allele.

The mutant allele (Hb^S) for sickle cell anemia produces an altered hemoglobin that deforms or sickles the red blood cells, making them more likely to form dangerous blockages in capillaries and to be destroyed in the liver, spleen, or bone marrow (discussed in Chapter 16). People who are homozygous for the sickle cell allele ($Hb^S Hb^S$) usually die at an early age if medical treatment is not available.

Heterozygous individuals carry alleles for both normal (Hb^A) and sickle cell hemoglobin. The heterozygous condition ($Hb^A Hb^S$) makes a person more resistant to a type of severe malaria (caused by the parasite *Plasmodium falciparum*) than people who are homozygous for the normal hemoglobin allele ($Hb^A Hb^A$). In a heterozygous individual, each allele produces its own specific kind of hemoglobin, and the red blood cells contain the two kinds in roughly equivalent amounts. Such cells sickle much less readily than cells containing only the Hb^S allele. They are more resistant to infection by the malaria-causing parasite, which lives in red blood cells, than are the red blood cells containing only normal hemoglobin.

Where malaria is a problem, each of the two types of homozygous individuals is at a disadvantage. Those homozygous for the sickle cell allele are likely to die of sickle cell anemia, whereas those homozygous for the normal allele may die of malaria. The heterozygote is therefore more fit than either homozygote. In parts of Africa, the Middle East, and southern Asia where falciparum malaria is prevalent, heterozygous individuals survive in greater numbers than either homozygote (FIG. 19-7). The Hb^S allele is maintained at a high frequency in the population, even though the homozygous recessive condition is almost always lethal.

(a) The geographic distribution of falciparum malaria (*green*). **(b) The distribution of the sickle cell anemia allele (*red* and *orange*).**

Figure 19-7 Heterozygote advantage

Over large geographic areas, the distribution of individuals heterozygous for the sickle cell (Hb^S) allele is similar to the distribution of falciparum malaria. This evidence for greater fitness of heterozygous individuals in malarial regions supports the hypothesis of heterozygote advantage. Adapted from Allison, A.C., "Protection Afforded by Sickle-Cell Trait against Subtertian Malareal Infection," *British Medical Journal*, Vol. 1 (1954): 290–294.

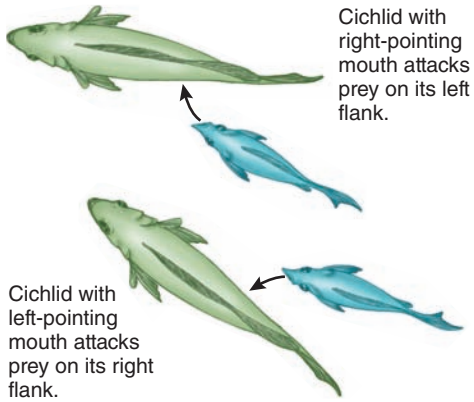
What happens to the frequency of Hb^S alleles in Africans and others who possess it when they migrate to the United States and other countries with few cases of malaria? As might be expected, the frequency of the Hb^S allele gradually declines in such populations, possibly because it confers a selective disadvantage by causing sickle cell anemia in homozygous individuals but no longer confers a selective advantage by preventing malaria in heterozygous individuals. The Hb^S allele never disappears from the population, however, because it is "hidden" from strong selection in heterozygous individuals and because it is reintroduced into the population by gene flow from the African population.

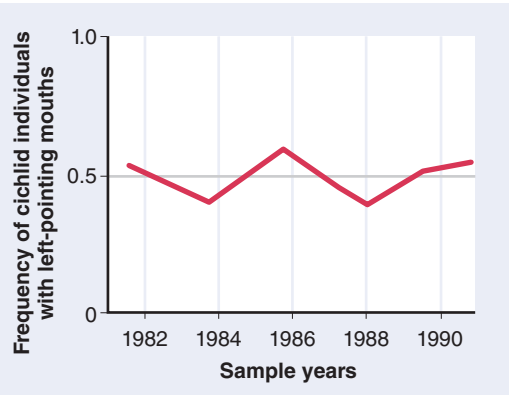
Genetic variation may be maintained by frequency-dependent selection Thus far in our discussion of natural selection, we have assumed that the fitness of particular phenotypes (and their corresponding genotypes) is independent of their frequency in the population. However, in cases of **frequency-dependent selection**, the fitness of a particular phenotype depends on how frequently it appears in the population. Often a phenotype has a greater selective value when rare than when common in the population. Such phenotypes lose their selective advantage as they become more common.

Frequency-dependent selection often acts to maintain genetic variation in populations of prey species. In this case, the predator catches and consumes the more common phenotype but may ignore the rarer phenotypes. Consequently, the less common phenotype produces more offspring and therefore makes a greater relative contribution to the next generation.



Frequency-dependent selection is demonstrated in scale-eating fish (cichlids of the species *Perissodus microlepsis*) from Lake Tanganyika in Africa (FIG. 19-8). The scale-eating fish, which obtain food by biting scales off other fish, have either left-pointing or right-pointing mouths. A single locus with two alleles determines this characteristic; the allele for right-pointing mouth is dominant over the allele for left-pointing mouth. These fish attack their prey from behind and from a single direction, depending on mouth morphology. Those with left-pointing mouths always attack the right flanks of their prey, whereas those with right-pointing mouths always attack the left flanks.

The prey species are more successful at evading attacks from the more common form of scale-eating fish. For example, if the cichlids with right-pointing mouths are more common than those with left-pointing mouths, the prey are attacked more often on their left flanks. They therefore become more wary against such attacks, conferring a selective advantage to the less common cichlids with left-pointing mouths. The cichlids with left-pointing mouths would be more successful at obtaining food and would therefore have more offspring. Over time, the frequency of fish with left-pointing mouths would increase in the population until their abundance causes frequency-dependent selection to work against them and confer an advantage on the now less common fish with right-pointing mouths. Thus, frequency-dependent selection maintains both populations of fish at approximately equal numbers.



Key Experiment

Can evidence for frequency-dependent selection be found in natural populations?

HYPOTHESIS: Equal proportions of scale-eating cichlids with right-pointing mouths versus left-pointing mouths in a population are maintained by frequency-dependent selection.

EXPERIMENT: The relative frequencies of scale-eating cichlids with left-pointing mouths and right-pointing mouths in Lake Tanganyika in Africa were monitored over a 10-year period.

RESULTS AND CONCLUSION: Relative frequencies of left-pointing cichlids and right-pointing cichlids varied slightly from year to year, but remained close to 0.5. This approximate 1:1 ratio is consistent with frequency-dependent selection because prey fish become especially wary to attacks by the cichlid type that is currently most common; therefore, either type is at a selective disadvantage if its frequency rises above 0.5.

SOURCE: Adapted from Hori, M., "Frequency-Dependent Natural Selection in the Handedness of Scale-Eating Cichlid Fish," *Science*, Vol. 260 (April 9, 1993): 216–219.

Figure 19-8 Frequency-dependent selection in scale-eating cichlids

INTERPRET DATA Recall that the allele for right-pointing mouth (*A*) is dominant over that for left-pointing mouth (*a*). Use the Hardy–Weinberg principle to calculate the allele frequencies that would correspond to approximately equal frequencies of the two phenotypes. Does your answer surprise you?

Neutral variation may give no selective advantage or disadvantage

Some of the genetic variation observed in a population may confer no apparent selective advantage or disadvantage in a particular environment. For example, random changes in DNA that do not alter protein structure usually do not affect the phenotype. Variation that does not alter the ability of an individual to survive and reproduce—and is therefore not adaptive—is called **neutral variation**.

The extent of neutral variation in organisms is difficult to determine. It is relatively easy to demonstrate that an allele is beneficial or harmful if its effect is observable, but the variation in alleles that involves only slight differences in the proteins they code for may or may not be neutral. These alleles may be influencing the organism in subtle ways that are difficult to measure or assess. Also, an allele that is neutral in one environment may be beneficial or harmful in another.

Populations in different geographic areas often exhibit genetic adaptations to local environments

In addition to the genetic variation among individuals within a population, genetic differences often exist among different populations within the same species, a phenomenon known as **geographic variation**. One type of geographic variation is a **cline**, which is a gradual change in a species' phenotype and genotype frequencies through a series of geographically separate populations as a result of an environmental gradient. A cline exhibits variation in the expression of such an attribute as color, size, shape, physiology, or behavior. Clines are common among species with continuous ranges over large geographic areas. For example, the body sizes of many widely distributed birds and mammals increase gradually as the latitude increases, presumably because larger animals are better able to withstand the colder temperatures of winter.

The common yarrow (*Achillea millefolium*), a wildflower that grows in a variety of North American habitats from lowlands to mountain highlands, exhibits clinal variation in height in response to different climates at different elevations. Although substantial variation exists among individuals within each population, individuals in populations at higher elevations are, on average, shorter than those at lower elevations. The genetic basis of these clinal differences was experimentally demonstrated in a set of classical experiments in which series of populations from different geographic areas were grown in the same environment (FIG. 19-9). Despite being exposed to identical environmental conditions, each experimental population exhibited the traits characteristic of the elevation from which it was collected.

CHECKPOINT 19.4

- How does the sickle cell allele illustrate heterozygote advantage?
- How does frequency-dependent selection affect genetic variation within a population over time?
- **CONNECT** How can researchers test the hypothesis that clinal variation among populations of a particular species has a genetic basis?

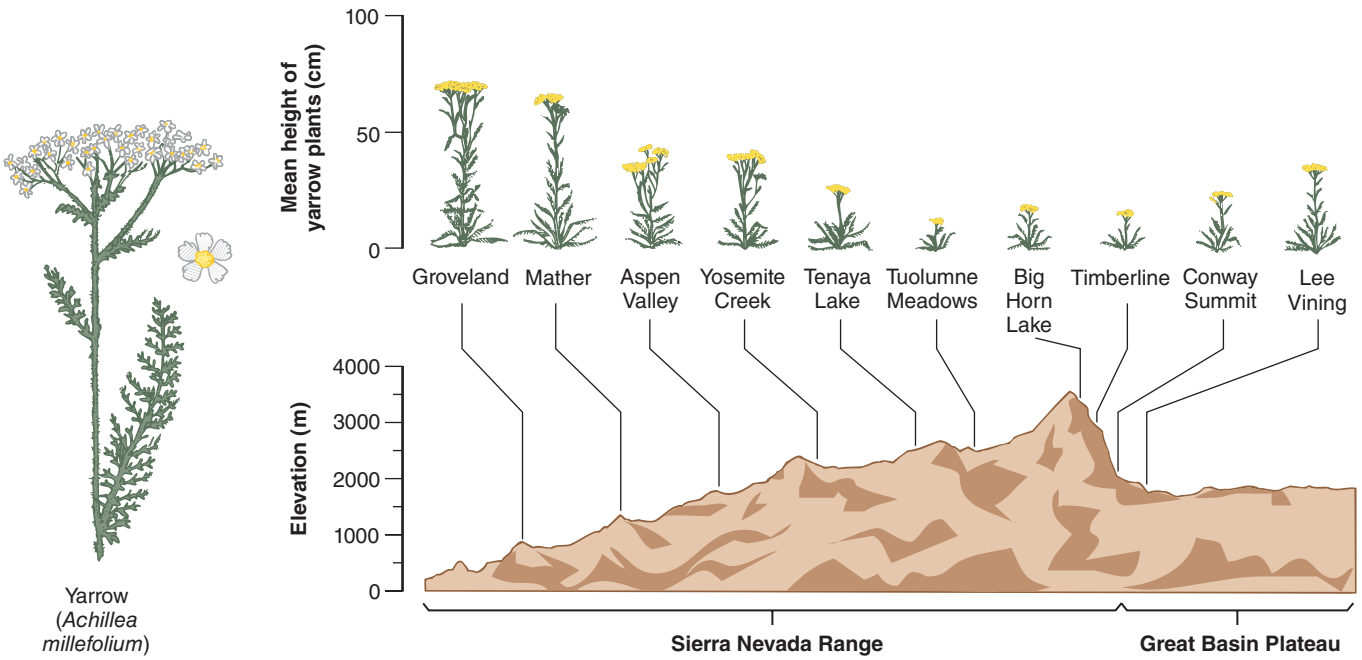

Figure 19-9 Clinal variation in yarrow (*Achillea millefolium*)

Summary: Focus on Learning Objectives

19.1 Genotype, Phenotype, and Allele Frequencies *(page 407)*

1 Define what is meant by a population's gene pool.

- All the individuals that live in a particular place at the same time make up a **population**. Each population has a **gene pool**, which includes all the **alleles** for all the **loci** present in the population.
- **Population genetics** is the study of genetic variability within a population and of the forces that act on it.

2 Distinguish among genotype, phenotype, and allele frequencies.

- A **genotype frequency** is the proportion of a particular genotype in the population. A **phenotype frequency** is the proportion of a particular phenotype in the population. An **allele frequency** is the proportion of a specific allele of a given genetic locus in the population.

19.2 The Hardy–Weinberg Principle *(page 407)*

3 Discuss the significance of the Hardy–Weinberg principle as it relates to evolution and list the five conditions required for genetic equilibrium.

- The **Hardy–Weinberg principle** states that allele and genotype frequencies do not change from generation to generation (no evolution is occurring) in a population at **genetic equilibrium**.
- The Hardy–Weinberg principle applies only if mating is random in the population, there are no net mutations that change the allele frequencies, the population is large, individuals do not migrate between populations, and natural selection does not occur.

4 Use the Hardy–Weinberg principle to solve problems involving populations.

- In the Hardy–Weinberg equation, p = the frequency of the dominant allele, q = the frequency of the recessive allele, and $p + q = 1$.
- The genotype frequencies of a population are described by the relationship $p^2 + 2pq + q^2 = 1$, where p^2 is the frequency of the homozygous dominant genotype, $2pq$ is the frequency of the heterozygous genotype, and q^2 is the frequency of the homozygous recessive genotype.

19.3 Microevolution *(page 410)*

5 Define *microevolution*.

- **Microevolution** is a change in allele or genotype frequencies within a population over successive generations.

6 Discuss how each of the following microevolutionary forces alters allele frequencies in populations: nonrandom mating, mutation, genetic drift, gene flow, and natural selection.

- In nonrandom mating individuals select mates on the basis of phenotype, indirectly selecting the corresponding genotype(s). **Inbreeding** is the mating of genetically similar individuals that are more closely related than if they had been chosen at random from the entire population. Inbreeding in some populations causes **inbreeding depression**, in which inbred individuals have lower **fitness** (relative ability to make a genetic contribution to the next generation) than non-inbred individuals. In **assortative mating**, individuals select mates by their phenotypes. Both inbreeding and assortative mating increase the frequency of homozygous genotypes.
- **Mutations**, unpredictable changes in DNA, are the source of new alleles. Mutations increase the genetic variability acted on by natural selection.
- **Genetic drift** is a random change in the allele frequencies of a small population. Genetic drift decreases genetic variation within a population, and the changes caused by genetic drift are usually not adaptive. A sudden decrease in population size caused by adverse environmental factors is known as a bottleneck. The **founder effect** is genetic drift that occurs when a small population colonizes a new area.
- **Gene flow**, a movement of alleles caused by the migration of individuals between populations, causes changes in allele frequencies.
- **Natural selection** causes changes in allele frequencies that lead to adaptation. Natural selection operates on an organism's phenotype, but it changes the genetic composition of a population in a favorable direction for a particular environment.

7 Distinguish among stabilizing selection, directional selection, and disruptive selection.

- **Stabilizing selection** favors the mean at the expense of phenotypic extremes. **Directional selection** favors one phenotypic extreme over another, causing a shift in the phenotypic mean. **Disruptive selection** favors two or more phenotypic extremes.

Harry Engels/Science Source

19.4 Genetic Variation in Populations *(page 415)*

8 Describe the nature and extent of genetic variation, including genetic polymorphism, balanced polymorphism, neutral variation, and geographic variation.

- **Genetic polymorphism** is the presence of genetic variation within a population.
- **Balanced polymorphism** is a special type of genetic polymorphism in which two or more alleles persist in a population over many generations as a result of natural selection.
- **Heterozygote advantage** occurs when the heterozygote exhibits greater fitness than either homozygote. In **frequency-dependent selection**, a genotype's selective value varies with its frequency of occurrence.
- **Neutral variation** is genetic variation that confers no detectable selective advantage.
- **Geographic variation** is genetic variation that exists among different populations within the same species. A **cline** is a gradual change in a species' phenotype and genotype frequencies through a series of geographically separate populations.

Test Your Understanding

Know and Comprehend

1. The genetic description of an individual is its genotype, whereas the genetic description of a population is its (a) phenotype (b) gene pool (c) genetic drift (d) founder effect (e) changes in allele frequencies
2. In a diploid species, each individual possesses (a) one allele for each locus (b) two alleles for each locus (c) three or more alleles for each locus (d) all the alleles found in the gene pool (e) half of the alleles found in the gene pool
3. The MN blood group is of interest to population geneticists because (a) people with genotype *MN* cannot receive blood transfusions from either *MM* or *NN* people (b) the *MM*, *MN*, and *NN* genotype frequencies can be observed directly and compared with calculated expected frequencies (c) the *M* allele is dominant to the *N* allele (d) people with the *MN* genotype exhibit frequency-dependent selection (e) people with the *MN* genotype exhibit heterozygote advantage
4. If a population's allele and genotype frequencies remain constant from generation to generation, (a) the population is undergoing evolutionary change (b) the population is said to be at genetic equilibrium (c) microevolution has taken place (d) directional selection is occurring, but only for a few generations (e) genetic drift is a significant evolutionary force
5. Analysis of DNA sequences for a particular locus among individuals within a population provides biologists with one way to estimate (a) genetic drift (b) genetic polymorphism (c) gene flow (d) heterozygote advantage (e) frequency-dependent selection
6. The continued presence of the allele that causes sickle cell anemia in areas where falciparum malaria is prevalent demonstrates which of the following phenomena? (a) inbreeding depression (b) frequency-dependent selection (c) heterozygote advantage (d) genetic drift (e) a genetic bottleneck
7. According to the Hardy–Weinberg principle, (a) allele frequencies are not dependent on dominance or recessiveness but remain essentially unchanged from generation to generation (b) the sum of allele frequencies for a given locus is always greater than 1 (c) if a locus has only one allele, the frequency of that allele is zero (d) allele frequencies change from generation to generation (e) the process of inheritance, by itself, causes changes in allele frequencies
8. The Hardy–Weinberg principle may be applicable if (a) the population size is small (b) migration occurs only at the beginning of the breeding season (c) mutations occur at a constant rate (d) matings occur exclusively between individuals of the same genotype (e) natural selection does not occur
9. Mutation (a) leads to adaptive evolutionary change (b) adds to the genetic variation of a population (c) is the result of genetic drift (d) almost always benefits the organism (e) a and b
10. Which of the following is *not* true of natural selection? (a) natural selection acts to preserve favorable traits and eliminate unfavorable traits (b) the offspring of individuals that are better adapted to the environment will make up a larger proportion of the next generation (c) natural selection directs the course of evolution by preserving the traits acquired during an individual's lifetime (d) natural selection acts on a population's genetic variability, which arises through mutation (e) natural selection may result in changes in allele frequencies in a population

Apply and Analyze

11. If all copies of a given locus have the same allele throughout the population, the allele frequency is (a) 0 (b) 0.1 (c) 0.5 (d) 1.0 (e) 10.0
12. **VISUALIZE** Draw four simple graphs, each with a range of phenotypes (e.g., height) on the *x*-axis and numbers of individuals on the *y*-axis. Each graph should illustrate one of the following: (a) no selection (b) stabilizing selection (c) directional selection (d) disruptive selection.

Evaluate and Synthesize

13. **EVOLUTION LINK** Given that mutations are almost always neutral or harmful, why are mutations nevertheless essential to evolution? Explain your answer.
14. **EVOLUTION LINK** Explain this apparent paradox: Scientists discuss evolution in terms of *genotype* fitness (the selective advantage that a particular genotype confers on an individual), yet natural selection acts on an organism's *phenotype*.
15. **EVOLUTION LINK** Why is it easier for researchers to study the genetic contribution to disease in the population of Finland or Iceland as opposed to that of the United States?
16. **EVOLUTION LINK** Evolution is sometimes characterized as "survival of the fittest." Is this wording consistent with an evolutionary biologist's definitions of *fitness* and *natural selection*? Is it a good way to think about evolution or a poor one?
17. **INTERPRET DATA** The recessive allele that causes Ellis–van Creveld syndrome when homozygous has a frequency of about 0.07 in the Amish population of Pennsylvania, although its frequency is only about 0.001 in the general population. How many persons out of one thousand in the Amish population would be expected to have the disease? How many out of one million in the general population?
18. **PREDICT** You study males in populations of a certain species of minnows in a series of lakes at different latitudes. You find that they exhibit clinal variation in average weight at maturity and hypothesize that the weight differences are due to genetic factors. What might you predict about the average weights at maturity of representatives of each population reared in aquaria if your hypothesis is correct?
19. **SCIENCE, TECHNOLOGY, AND SOCIETY** Automated techniques are providing new information on the extent of genetic polymorphism among humans, particularly with respect to single nucleotide polymorphisms (SNPs) and copy number variations (CNVs). In what ways might this information prove useful? In what ways might it present challenges?

20 Speciation and Macroevolution

A Brazilian rain forest contains thousands of species of insects, amphibians, reptiles, birds, and mammals. The Great Barrier Reef off the coast of Australia has thousands of species of sponges, corals, mollusks, crustaceans, sea stars, and fishes. The various environments on Earth abound in rich assemblages of species. Scientists have currently named about 1.8 million species.

We do not know exactly how many species exist today, but many biologists estimate the number to be on the order of 4 million to 100 million! Often this diversity has been portrayed as many twig tips on a "tree of life." As one follows the twigs from the tips toward the main body of the tree, they form connections that represent common ancestors that are now extinct. Indeed, more than 99.9% of all species that ever existed are now extinct. Tracing the branches of the tree of life to larger and larger connections eventually leads to a single trunk that represents the few simple unicellular organisms that evolved early in Earth's history and became the ancestors of all species living today.

Thus, life today is the product of three billion to four billion years of evolution. How did all these species diversify throughout Earth's history? Darwin's studies led him to conclude that the Galápagos Islands were the birthplace of many new species (see photograph). Our understanding of how species evolve has advanced significantly since Darwin published *On the Origin of Species by Means of Natural Selection*.

In this chapter we consider the reproductive barriers that isolate species from one another and the possible evolutionary mechanisms that explain how the millions of species that live

KEY CONCEPTS

20.1 According to the biological species concept, a species consists of individuals that can successfully interbreed with one another but not with individuals from other species.

20.2 The evolution of different species begins with reproductive isolation, in which two populations are no longer able to interbreed successfully.

20.3 In allopatric speciation populations diverge into different species due to geographic isolation, or physical separation. In sympatric speciation populations become reproductively isolated from one another despite living in the same geographic area.

20.4 Speciation may require millions of years but sometimes occurs much more quickly.

20.5 The evolution of species and higher taxa is known as macroevolution.

PHOTO: **Blue-footed boobies.** Blue-footed boobies are large sea birds that nest on the Galápagos Islands and several other arid islands in the eastern Pacific Ocean. Male and female pairs are monogamous and typically nest on black lava. The largest blue-footed booby breeding population is found in the Galápagos Islands. Charles Martin

today or lived in the past originated from ancestral species. We then examine the rate of evolutionary change and the evolution of higher taxonomic categories (species, genus, family, order, class, and phylum), which is the focus of macroevolution.

20.1 What Is a Species?

LEARNING OBJECTIVE

1 Describe the biological species concept and list two potential problems with the concept.

The concept of distinct kinds of organisms, known as **species** (from Latin, meaning "kind"), is not new. However, there are several different definitions of species, and each definition has some sort of limitation. Linnaeus was the 18th-century biologist who founded modern taxonomy: the science of naming, describing, and classifying organisms. He classified plants and other organisms into separate species based on their visible structural differences, such as feathers or number of flower parts. This method, known as the *morphological species concept*, is still used to help characterize species, but structural differences alone are not adequate to explain what constitutes a species.

The biological species concept is based on reproductive isolation

Population genetics did much to clarify the concept of species. According to the **biological species concept**, first expressed by evolutionary biologist Ernst Mayr in 1942, a species consists of one or more populations whose members interbreed in nature to produce fertile offspring and do not interbreed with—that is, are reproductively isolated from—members of different species. Individuals belonging to the same species tend to share common features because their genes are derived from a common *gene pool* (see Chapter 19). Gene flow occurs between individuals of a given species when they mate, but reproductive barriers restrict individuals of one species from interbreeding, or exchanging genes, with members of other species. As a result, reproductive barriers keep a given species genetically distinct from other species. An extension of the biological species concept holds that new species evolve when formerly interbreeding populations become reproductively isolated from one another.

The biological species concept is currently the most widely accepted definition of species, but it has several shortcomings. One problem is that it applies only to sexually reproducing organisms. Bacteria reproduce asexually, although they may have considerable exchange of genetic material by means of *horizontal gene transfer* among bacterial individuals that are classified as different species. Thus, reproductive isolation is not a good criterion for defining species of bacteria.

Small marine organisms known as bdelloid rotifers are an example of animals that reproduce asexually (FIG. 20-1). All bdelloid rotifers are females, and they produce offspring without needing males. Interestingly, these animals engage in massive horizontal gene transfer, and their genomes include DNA sequences that appear to have originated in bacteria, fungi, and even plants! These organisms and also extinct organisms must be classified based on their structural and biochemical characteristics; the biological species concept does not apply to them. (Horizontal gene transfer is discussed in more detail in Chapter 23.)

Another potential problem with the biological species concept is that although individuals assigned to different species do not normally interbreed, they may *sometimes* successfully interbreed. For example, where their ranges overlap, some coyotes have been known to mate with wolves. As a result, some wolves carry coyote genes and vice versa. Most biologists agree that wolves and coyotes are separate species, however.

The phylogenetic species concept defines species based on such evidence as molecular sequencing

Some biologists prefer the **phylogenetic species concept**, also called the *evolutionary species concept*, in which a population is declared a separate species if it has undergone evolution long enough for statistically significant differences in diagnostic traits to emerge. If a population has a unique diagnostic trait—a set of spines running down the back, for example—that can be demonstrated to be inherited, this population is considered a separate species. This approach has the advantage of being testable by comparing gene sequences between two groups. However, many biologists do not want to abandon the biological species concept, in part because the phylogenetic species concept cannot be applied if the evolutionary

Visual Unlimited/Wim van. Egmond/Getty Images

Figure 20-1 Bdelloid rotifer (*Philodina roseola*)
Bdelloid rotifers are all females. Because they do not reproduce sexually, it is difficult to classify these small marine animals as species under the biological species concept.

history (as determined by DNA sequencing) of a taxonomic group has not been carefully studied, and most groups have not been rigorously analyzed. Also, if the phylogenetic species concept were universally embraced, the number of named species would probably double. This increase would occur because many closely related populations that are classified as *subspecies* (a taxonomic subdivision of a species) under the biological species concept would fit the requirements of separate species under the phylogenetic species concept.

Thus, the exact definition of a species remains fuzzy. Unless we clearly state otherwise, when we mention *species* in this text, we are referring to the biological species concept.

CHECKPOINT 20.1

- What is a species, according to the biological species concept?
- Is the biological species definition likely to work well for classifying insects in amber? Plants that reproduce asexually? Fish in an aquarium?
- **CONNECT** If a population meets all the criteria of the biological species concept, is it likely to meet the definition of a morphological species? Explain your answer.

20.2 Reproductive Isolation

LEARNING OBJECTIVE

2 Explain the significance of reproductive isolating mechanisms and distinguish among the various prezygotic and postzygotic barriers.

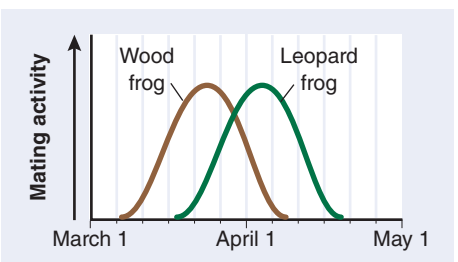
Various **reproductive isolating mechanisms** prevent interbreeding between two different species whose *ranges* (areas where each lives) overlap. These mechanisms preserve the genetic integrity of each species because gene flow between the two species is prevented.

Most species have two or more mechanisms that block a chance occurrence of individuals from two closely related species overcoming a single reproductive isolating mechanism. Although most mechanisms operate before mating or fertilization occurs (*prezygotic*), others work after fertilization has taken place (*postzygotic*).

Prezygotic barriers interfere with fertilization

Prezygotic barriers are reproductive isolating mechanisms that prevent fertilization from taking place. Because male and female gametes never come into contact, an *interspecific zygote*—that is, a fertilized egg formed by the union of an egg from one species and a sperm from another species—is never produced. Prezygotic barriers include temporal isolation, habitat isolation, behavioral isolation, mechanical isolation, and gametic isolation.

Sometimes genetic exchange between two groups is prevented because they reproduce at different times of the day, season, or year. Such examples demonstrate **temporal isolation**. For example, two very similar species of fruit flies, *Drosophila pseudoobscura* and *D. persimilis*, have ranges that overlap to a great extent, but they do not interbreed. *Drosophila pseudoobscura* is sexually active only in the afternoon; and *D. persimilis*, only in the morning. Similarly, two frog species have overlapping ranges in eastern Canada and the United States. The wood frog (*Rana sylvatica*) usually mates in late March or early April, when the water temperature is about 7.2°C (45°F), whereas the northern leopard frog (*R. pipiens*) usually mates in mid-April, when the water temperature is 12.8°C (55°F) (FIG. 20-2).



Although two closely related species may be found in the same geographic area, they usually live and breed in different habitats in that area, providing **habitat isolation** between the two species. For example, the five species of small birds known as flycatchers are nearly identical in appearance and have overlapping ranges in the eastern part of North America. They exhibit habitat isolation because during the breeding season, each species stays in a particular habitat within its range, so potential mates from different species do not meet. The least flycatcher (*Empidonax minimus*) frequents open woods, farms, and orchards; whereas the acadian flycatcher (*E. virescens*) is found in deciduous forests, particularly in beech trees,

(a) The wood frog (*Rana sylvatica*) mates in early spring, often before the ice has completely melted in the ponds.

(b) The leopard frog (*Rana pipiens*) typically mates a few weeks later.

(c) Graph of peak mating activity in wood and leopard frogs. In nature, wood and leopard frogs do not interbreed.

Figure 20-2 Temporal isolation in wood and leopard frogs

Tim Laman/National Geographic Creative

Figure 20-3 Behavioral isolation in bowerbirds

Each bowerbird species has highly specialized courtship patterns that prevent its mating with another species. The male satin bowerbird (*Ptilonorhynchus violacens*) constructs an enclosed place, or bower, of twigs to attract a female. (The bower is the dark "tunnel" on the left.) Note the parrot feather in his beak and blue decorations, including human-made objects such as bottle caps, that he has arranged at the entrance to his bower.

and swampy woods. The alder flycatcher (*E. alnorum*) prefers wet thickets of alders, the yellow-bellied flycatcher (*E. flaviventris*) nests in conifer woods, and the willow flycatcher (*E. traillii*) frequents brushy pastures and willow thickets.

Many animal species exchange a distinctive series of signals before mating. Such courtship behaviors illustrate **behavioral isolation** (also known as **sexual isolation**). Bowerbirds, for example, exhibit species-specific courtship patterns. The male satin bowerbird of Australia constructs an elaborate bower of twigs, adding decorative blue parrot feathers and white flowers at the entrance (FIG. 20-3). When a female approaches the bower, the male dances around her, holding a particularly eye-catching decoration in his beak. While dancing, he puffs his feathers, extends his wings, and sings a courtship song that consists of a variety of sounds, including loud buzzes and hoots. These specific courtship behaviors keep closely related bird species reproductively isolated from the satin bowerbird. If a male and a female of two different bowerbird species begin courtship, it stops when one member does not recognize or respond to the signals of the other.

Another example of behavioral isolation involves the wood frogs and northern leopard frogs just discussed as an example of temporal isolation. Males of these two species have very specific vocalizations to attract females of their species for breeding. These vocalizations reinforce each species' reproductive isolation.

Sometimes members of different species court and even attempt copulation, but the incompatible structures of their genital organs prevent successful mating. Structural differences that inhibit mating between species produce **mechanical isolation**. For example, many flowering plant species have physical differences in their flower parts that help them maintain their reproductive isolation from one another. In such plants the flower parts are adapted for specific insect pollinators. Two species of sage, for example, have overlapping ranges in southern California. Black sage (*Salvia mellifera*), which is pollinated by small bees, has a floral structure different from that of white sage (*S. apiana*), which is pollinated by large carpenter bees (FIG. 20-4). Interestingly, black sage and white sage are also prevented from mating by a temporal barrier: black sage flowers in early spring, and white sage flowers in late spring and early summer. Presumably, mechanical isolation prevents insects from cross-pollinating the two species should they happen to flower at the same time.

If mating takes place between two species, their gametes may still not combine. Molecular and chemical differences between species cause **gametic isolation**, in which the egg and sperm of different species are incompatible. In aquatic animals that release their eggs and sperm into the surrounding water simultaneously, interspecific fertilization is extremely rare. The surface of the egg contains specific proteins that bind only to complementary molecules on the surface of sperm cells of the same species (see Chapter 51). A similar type of molecular recognition often occurs between

(a) The petal of the black sage functions as a landing platform for small bees. Large bees cannot fit on this platform.

(b) The larger landing platform and longer stamens of white sage allow pollination by larger California carpenter bees (a different species). If smaller bees land on white sage, their bodies do not brush against the stamens. (In the figure, the upper part of the white sage flower has been removed.)

Figure 20-4 Mechanical isolation in black sage and white sage

The differences in their floral structures allow black sage and white sage to be pollinated by different insects. Because the two species exploit different pollinators, they cannot interbreed.

pollen grains and the stigma (receptive surface of the female part of the flower) so that pollen does not germinate on the stigma of a different plant species.

Postzygotic barriers prevent gene flow when fertilization occurs

Fertilization sometimes occurs between gametes of two closely related species despite the existence of prezygotic barriers. When such fertilization happens, **postzygotic barriers** that increase the likelihood of reproductive failure come into play. Generally, the embryo of an interspecific hybrid spontaneously aborts. **Development**, the orderly sequence of events that occurs as an organism grows and matures, is a complex process requiring the precise interaction and coordination of many genes. Apparently, the genes from parents belonging to different species do not interact properly in regulating the mechanisms for normal development. In this case, reproductive isolation occurs by **hybrid inviability**. For example, in crosses between different species of irises, the embryos die before reaching maturity. Similarly, nearly all the hybrids die in the embryonic stage when the eggs of a bullfrog are fertilized artificially with sperm from a leopard frog.

If an interspecific hybrid does live, it may not reproduce for any of several reasons. Hybrid animals may exhibit courtship behaviors incompatible with those of either parental species, and as a result they will not mate. More often, **hybrid sterility** occurs when problems during meiosis cause the gametes of an interspecific hybrid to be abnormal. Hybrid sterility is particularly common if the two parental species have different chromosome numbers. For example, a mule is the offspring of a female horse ($2n = 64$) and a male donkey ($2n = 62$) (FIG. 20-5). This type of union almost always results in sterile offspring ($2n = 63$) because synapsis (the pairing of homologous chromosomes during meiosis) and segregation of chromosomes cannot occur properly.

Occasionally, a mating between two F_1 hybrids produces a second hybrid generation (F_2). The F_2 hybrid may exhibit **hybrid breakdown**, the inability of a hybrid to reproduce because of some defect. For example, hybrid breakdown in the F_2 generation of a cross between two sunflower species was 80%. In other words, 80% of the F_2 generation were defective in some way and could not reproduce successfully. Hybrid breakdown also occurs in the F_3 and later generations.

TABLE 20-1 summarizes the various prezygotic and postzygotic barriers that prevent interbreeding between two species.

John Eastcott/Yva Momatiuk/Earth Scenes/Animals Animals

Figure 20-5 Hybrid sterility in mules
Mules are interspecific hybrids formed by mating a female horse (*left*) with a male donkey (*right*). Although the mule (*center*) exhibits valuable characteristics of each of its parents, it is sterile.

Biologists are discovering genes responsible for reproductive isolating mechanisms

Progress has been made in identifying some of the genes involved in reproductive isolation. For example, scientists have determined the genetic basis for prezygotic isolation in species of abalone, large mollusks found along the Pacific coast of North America. In abalone the fertilization of eggs by sperm requires *lysin*, a sperm protein that attaches to a lysin receptor protein located on the egg envelope. After attachment, the lysin produces a hole in the egg envelope that permits the sperm to penetrate the egg. Scientists cloned the lysin receptor gene and demonstrated that this gene varies among abalone species. Differences in the lysin receptor protein in various abalone species determine sperm compatibility with the egg. Sperm of one abalone species do not attach to a lysin receptor protein of an egg of a different abalone species.

Other genes related to reproductive isolating mechanisms—loosely referred to as "speciation genes"—have been identified in a diverse group of organisms, such as Florida beach mice, cactus finches, fruit fly (*Drosophila*) species, and flycatcher birds in the South Pacific.

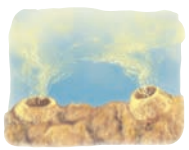
CHECKPOINT 20.2

- What barriers prevent wood frogs and leopard frogs from interbreeding in nature?
- How is temporal isolation different from behavioral isolation?
- How is mechanical isolation different from gametic isolation?
- Of which postzygotic barrier is the mule an example?

20.3 Speciation

LEARNING OBJECTIVES

3 Explain the mechanism of allopatric speciation and give an example.



4 Explain the mechanisms of sympatric speciation and give both plant and animal examples.

We are now ready to consider how entirely new species may arise from previously existing ones. The evolution of a new species is called **speciation**. The formation of two species from a single species occurs when a population becomes reproductively isolated

Table 20-1 Reproductive Isolating Mechanisms

Mechanism	How It Works		Example
PREZYGOTIC BARRIERS PREVENT FERTILIZATION			
Temporal isolation	Similar species reproduce at different times.		Two species of fruit flies of the genus *Drosophila* live in the same geographic area, but one is sexually active only in the afternoon and the other only in the morning.
Habitat isolation	Similar species reproduce in different habitats.		Several flycatcher species of the genus *Empidonax* live in the same geographic area but in different habitats; for example, the least flycatcher lives in open woods, farms, and orchards, and the acadian flycatcher lives in deciduous forests and swampy woods.
Behavioral isolation	Similar species have distinctive courtship behaviors.		The male satin bowerbird of Australia constructs an elaborate bower, dances around the female, and sings a specific courtship song that keeps closely related bowerbird species reproductively isolated from the satin bowerbird.
Mechanical isolation	Similar species have structural differences in their reproductive organs.		Black sage (genus *Salvia*) is pollinated by small bees, whereas white sage is pollinated by large carpenter bees. Because of differences in the flower structures, neither type of bee can successfully pollinate the other sage species.
Gametic isolation	Gametes of similar species are chemically incompatible.		In aquatic animals such as sponges that release their eggs and sperm into the water simultaneously, interspecific fertilization rarely occurs because the egg surface is compatible only with the sperm surface of the same species.
POSTZYGOTIC BARRIERS REDUCE VIABILITY OR FERTILITY OF HYBRID			
Hybrid inviability	Interspecific hybrid dies at early stage of embryonic development.		In crosses between different species of irises (genus *Iris*), fertilization occurs, but the embryos in the seeds die before reaching maturity.
Hybrid sterility	Interspecific hybrid survives to adulthood but is unable to reproduce successfully.		A mule, the offspring of a female horse and a male donkey, has sterile offspring because synapsis and segregation of chromosomes do not occur properly during gamete formation.
Hybrid breakdown	Offspring of interspecific hybrid are unable to reproduce successfully.		F_2 generation are defective in some way and cannot reproduce successfully. Hybrid breakdown also occurs in later generations.

from other populations of the species and the **gene pools** of the two separated populations begin to diverge in genetic composition. When a population is sufficiently different from its ancestral species that there is no genetic exchange between them, we consider speciation to have occurred. Speciation happens in two ways: allopatric speciation and sympatric speciation.

Long physical isolation and different selective pressures result in allopatric speciation

Speciation that occurs when one population becomes geographically separated from the rest of the species and subsequently evolves by natural selection and/or genetic drift is known as **allopatric speciation** (from the Greek *allo*, "different," and *patri*, "native land"). Recall from Chapter 18 that **natural selection** occurs as individuals that possess favorable adaptations to the environment survive and become parents of the next generation. **Genetic drift** is a random change in allele frequency resulting from the effects of chance on the survival and reproductive success of individuals in a small breeding population (see Chapter 19). Both natural selection and genetic drift result in changes in allele frequencies in a population, but only in natural selection is the change in allele frequency adaptive.

Allopatric speciation is the most common method of speciation and accounts for almost all evolution of new animal species. The geographic isolation required for allopatric speciation may occur in several ways. Earth's surface is in a constant state of change. Such change includes rivers shifting their courses; glaciers migrating; mountain ranges forming; land bridges forming that separate previously united aquatic populations; and large lakes diminishing into several smaller, geographically separated pools.

What may be an imposing geographic barrier to one species may be of no consequence to another. Birds and cattails, for example, do not become isolated when a lake subsides into smaller pools; birds easily fly from one pool to another, and cattails disperse their pollen and fruits by air currents. Fishes, in contrast, usually cannot cross the land barriers between the pools and so become reproductively isolated.

In the Death Valley region of California and Nevada, large interconnected lakes formed during wetter climates of the last Ice Age. These lakes were populated by one or several species of pupfishes. Over time, the climate became drier, and the large lakes dried up, leaving isolated pools. Presumably, each pool contained a small population of pupfish that gradually diverged from the common ancestral species by genetic drift and natural selection in response to habitat differences such as the high temperatures, high salt concentrations, and low oxygen levels characteristic of desert springs. Today, there are 20 or so distinct species, subspecies, and populations of pupfish in the area of Death Valley, California, and Ash Meadows, Nevada (FIG. 20-6). Many, such as the Devil's Hole pupfish and the Owens pupfish, are restricted to one or two isolated springs.

Allopatric speciation also occurs when a small population migrates or is dispersed (such as by a chance storm) and colonizes a new area away from the range of the original species. This colony is geographically isolated from its parental species, and the small *microevolutionary* changes that accumulate in the isolated gene pool over many generations may eventually be sufficient to form a new species. Because islands provide the geographic isolation required for allopatric speciation, they offer excellent opportunities to study this evolutionary mechanism. A few individuals of a few species probably colonized the Galápagos Islands and the Hawaiian Islands, for example. The hundreds of unique species presently found on each island presumably descended from these original colonizers (FIG. 20-7).

Figure 20-7 Allopatric speciation of the Hawaiian goose (the nene)

Nene (pronounced "nay-nay"; *Branta sandvicensis*) are geese originally found only on volcanic mountains on the geographically isolated islands of Hawaii and Maui, which are some 4200 km (2600 mi) from the nearest continent. Compared with those of other geese, the feet of Hawaiian geese are not completely webbed, their toenails are longer and stronger, and their foot pads are thicker; these adaptations enable Hawaiian geese to walk easily on lava flows. Mitochondrial DNA analysis has demonstrated that nenes evolved from a small population of Canada geese (*Branta canadensis*) that originated in North America.

Speciation is more likely to occur if the original isolated population is small. Recall from Chapter 19 that genetic drift, including the founder effect, is more consequential in small populations than larger ones. Genetic drift tends to result in rapid changes in allele frequencies in a small, isolated population. The different selective pressures of the new environment to which the population is exposed further accentuate the divergence caused by genetic drift.

The Kaibab squirrel is an example of allopatric speciation in progress

About 10,000 years ago, when the American Southwest was less arid than it is today, the ponderosa pine forests in the area supported a tree squirrel with conspicuous tufts of hair sprouting from its ears. A small tree squirrel population living on the Kaibab Plateau of the Grand Canyon became geographically isolated when the climate changed, thus causing areas to the north, west, and east to become desert. Just a few miles to the south lived the rest of the squirrels, which we know as Abert squirrels, but the two groups were separated by the Grand Canyon. With changes over time in both its appearance and its ecology, the Kaibab squirrel is on its way to becoming a new species.

During its many years of geographic isolation, the small population of Kaibab squirrels has diverged from the widely distributed Abert squirrels in several ways. Perhaps most evident are changes in fur color. The Kaibab squirrel now has a white tail and a gray belly in contrast to the gray tail and white belly of the Abert squirrel (FIG. 20-8). Biologists think that these striking changes arose in Kaibab squirrels as a result of genetic drift.

Scientists have not reached a consensus about whether the two squirrel populations are separate species, and most biologists today consider the Kaibab squirrel (*Sciurus aberti ssp. kaibabensis*) and the Abert squirrel (*S. aberti*) to be distinct subspecies. Because the Kaibab and Abert squirrels remain reproductively isolated from each other, it is assumed that they will continue to evolve into separate species.

Porto Santo rabbits diverged rapidly from European rabbits

Allopatric speciation has the potential to occur quite rapidly. Early in the 15th century, a small population of rabbits was released on Porto Santo, a small island off the coast of Portugal. Because there were no other rabbits or competitors and no predators on the island, the rabbits thrived. By the 19th century, these rabbits were markedly different from their European ancestors. They were only half as large (weighing slightly more than 500 g, or 1.1 lb), with a different color pattern and a more nocturnal lifestyle. More significant, attempts to mate Porto Santo rabbits with mainland European rabbits failed. Many biologists concluded that within four hundred years, an extremely brief period in evolutionary history, a new species of rabbit had evolved.

Not all biologists agree that the Porto Santo rabbit is a new species. The objection stems from a more recent breeding experiment and is based on biologists' lack of a consensus about the definition of a species. In the experiment, foster mothers of the wild Mediterranean rabbit raised newborn Porto Santo

Key Point

Changes in chromosome number have often led to speciation in plants.

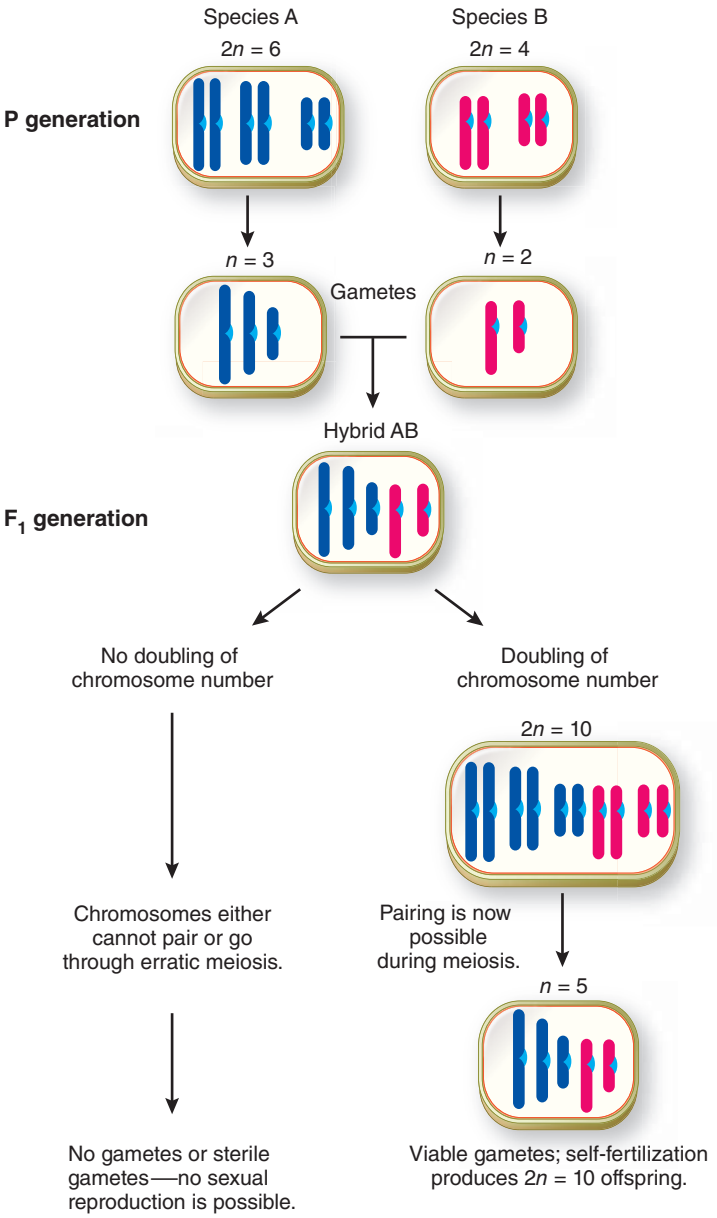

Figure 20-9 Sympatric speciation by allopolyploidy in plants

When two species (designated the P generation) successfully interbreed, the interspecific hybrid offspring (the F_1 generation) are almost always sterile (*bottom left*). If the chromosomes double, proper synapsis and segregation of the chromosomes can occur, and viable gametes may be produced (*bottom right*). (Unduplicated chromosomes are shown for clarity.)

PREDICT Do you think that the $2n = 10$ hybrids could produce fertile offspring when crossed with species A? with species B?

rabbits. When they reached adulthood, these Porto Santo rabbits mated successfully with Mediterranean rabbits to produce healthy, fertile offspring. To some biologists, this experiment clearly demonstrated that Porto Santo rabbits are not a separate species but a subspecies. These biologists cite the Porto Santo rabbits as an example of speciation in progress, much like the Kaibab squirrels just discussed.

Many other biologists think that the Porto Santo rabbit is a separate species because it does not interbreed with the other rabbits under natural conditions. They point out that the breeding experiment was successful only after the baby Porto Santo rabbits were raised under artificial conditions that probably modified their natural behavior.

Two populations diverge in the same physical location by sympatric speciation Although geographic isolation is an important factor in many cases of evolution, it is not an absolute requirement. In **sympatric speciation** (from the Greek *sym*, "together," and *patri*, "native land"), a new species evolves within the same geographic region as the parental species. The divergence of two populations in the same geographic range occurs when reproductive isolating mechanisms evolve at the *start* of the speciation process. Sympatric speciation is especially common in plants. The role of sympatric speciation in animal evolution is probably much less important than allopatric speciation; until recently, sympatric speciation in animals has been difficult to demonstrate in nature.

Sympatric speciation occurs in at least two ways: a change in **ploidy** (the number of chromosome sets making up an organism's genome) and a change in ecology. We now examine each of these mechanisms.

Allopolyploidy is an important mechanism of sympatric speciation in plants As a result of reproductive isolating mechanisms discussed earlier, the union of two gametes from different species rarely forms viable offspring; if offspring are produced, they are usually sterile. Synapsis cannot usually occur in interspecific hybrid offspring because not all the chromosomes are homologous. However, if the chromosome number doubles *before* meiosis, homologous chromosomes can undergo synapsis. Although not common, this spontaneous doubling of chromosomes has been documented in a variety of plants and a few animals. It produces nuclei with multiple sets of chromosomes.

Polyploids, which possess more than two sets of chromosomes, have played a major role in plant evolution. Reproductive isolation occurs in a single generation when a polyploid species with multiple sets of chromosomes arises from diploid parents. There are two kinds of polyploidy: autopolyploidy and allopolyploidy. An **autopolyploid** contains multiple sets of chromosomes from a single species, and an **allopolyploid** contains multiple sets of chromosomes from two or more species. We discuss only allopolyploidy because it is much more common in nature than autopolyploidy.

Allopolyploidy occurs in conjunction with **hybridization**, which is sexual reproduction between individuals from closely related species. Allopolyploidy produces a fertile interspecific hybrid because the polyploid condition provides the homologous chromosome pairs necessary for synapsis during meiosis. As a result, gametes may be viable (FIG. 20-9). An allopolyploid—that is, an interspecific hybrid produced by

allopolyploidy—reproduces with itself (self-fertilization) or with a similar individual. However, allopolyploids are reproductively isolated from both parents because their gametes have a different number of chromosomes from those of either parent.

If a population of allopolyploids (i.e., a new species) becomes established, selective pressures cause one of three outcomes. First, the new species may not compete successfully against species that are already established, so it becomes extinct. Second, the allopolyploid individuals may assume a new role in the environment and so coexist with both parental species. Third, the new species may successfully compete with either or both of its parental species. If it has a combination of traits that confers greater fitness than one or both parental species for all or part of the original range of the parent(s), the hybrid species may replace the parent(s).

Although allopolyploidy is extremely rare in animals, it is significant in the evolution of flowering plant species. As many as 80% of all flowering plant species are polyploids, and most of those are allopolyploids. Moreover, allopolyploidy provides a mechanism for extremely rapid speciation. A single generation is all that is needed to form a new, reproductively isolated species. Allopolyploidy may explain the rapid appearance of many flowering plant species in the fossil record and their remarkable diversity today (at least 300,000 species).

The kew primrose (*Primula kewensis*) is an example of sympatric speciation that was documented at the Royal Botanic Gardens at Kew, England, in 1898 (FIG. 20-10). Plant breeders developed *P. kewensis* as an interspecific hybrid of two primrose species, *P. floribunda* ($2n = 18$) and *P. verticillata* ($2n = 18$). *Primula kewensis* had a chromosome number of 18 but was sterile. Then, at three different times, it was reported to have spontaneously formed a fertile branch, which was an allopolyploid ($2n = 36$) that produced viable seeds of *P. kewensis*.

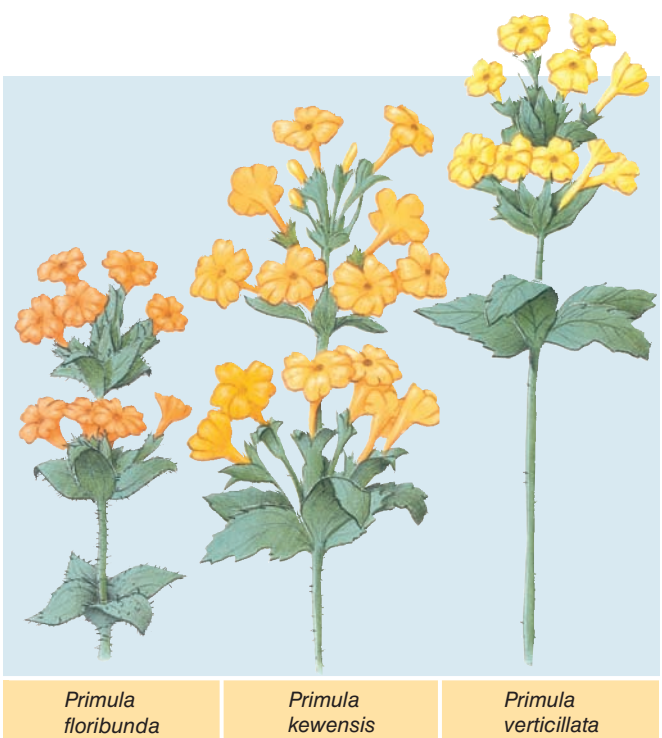

Figure 20-10 Sympatric speciation of a primrose
A new species of primrose, *Primula kewensis*, arose in 1898 as an allopolyploid derived from the interspecific hybridization of *P. floribunda* and *P. verticillata*. Today, *P. kewensis* is a popular houseplant.

The mechanism of sympatric speciation has been experimentally verified for many plant species. One example is a group of species, collectively called *hemp nettles*, that occur in temperate parts of Europe and Asia. One hemp nettle, *Galeopsis tetrahit* ($2n = 32$), is a naturally occurring allopolyploid hypothesized to have formed by the hybridization of two species, *G. pubescens* ($2n = 16$) and *G. speciosa* ($2n = 16$). This process occurred in nature but was experimentally reproduced. *Galeopsis pubescens* and *G. speciosa* were crossed to produce F_1 hybrids, most of which were sterile. Nevertheless, both F_2 and F_3 generations were produced. The F_3 generation included a polyploid plant with $2n = 32$ that self-fertilized to yield fertile F_4 offspring that could not mate with either of the parental species. These allopolyploid plants had the same appearance and chromosome number as the naturally occurring *G. tetrahit*. When the experimentally produced plants were crossed with the naturally occurring *G. tetrahit*, a fertile F_1 generation was formed. Thus, the experiment duplicated the speciation process that occurred in nature.

Changing ecology causes sympatric speciation in animals Biologists have observed the occurrence of sympatric speciation in animals, but its significance—how often it happens and under what conditions—is still debated. Many examples of sympatric speciation in animals involve parasitic insects and rely on genetic mechanisms other than polyploidy. For example, in the 1860s in the Hudson River valley of New York, a population of fruit maggot flies (*Rhagoletis pomonella*) parasitic on the small red fruits of native hawthorn trees was documented to have switched to a new host, domestic apples, which had been introduced from Europe. Although the sister populations (hawthorn maggot flies and apple maggot flies) continue to occupy the same geographic area, no gene flow occurs between them because they eat, mate, and lay their eggs on different hosts (FIG. 20-11). In other words, because the hawthorn and apple maggot flies have diverged and are reproductively isolated from each other, they have effectively become separate species. Most entomologists, however, still recognize hawthorn and apple maggot flies as a single species because their appearance is virtually identical.

In situations such as that of the fruit maggot flies, a mutation arises in an individual and spreads through a small group of insects by sexual reproduction. The particular mutation leads to *disruptive selection* (see Chapter 19), in which both the old and new phenotypes are favored. Selection is disruptive because the original population is still favored when it parasitizes the original host, and the mutants are favored by a new ecological opportunity, which in this case is to parasitize a different host species. Additional mutations may occur that cause the sister populations to diverge even further.

Cichlids in East Africa intrigue evolutionary biologists Biologists have studied the speciation of colorful fishes known as *cichlids* (pronounced "sik-lids") in

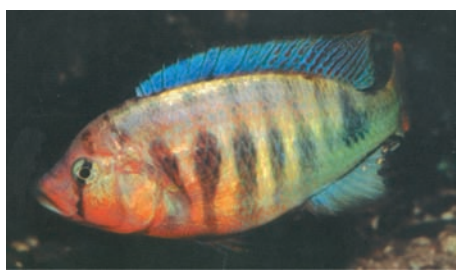
Apple and hawthorn maggot flies are sympatric throughout the northern half of the hawthorn maggot fly's range. Adapted from G.L. Bush, "Sympatric Host Race Formation and Speciation in Frugivorous Flies of the Genus *Rhagoletis* (Diptera, Tephritidae)," *Evolution*, Vol. 23, No. 2 (June 1969).

several East African lakes. The different species of cichlids in a given lake have remarkably different eating habits, which are reflected in the shapes of their jaws and teeth. Some graze on algae; some consume dead organic material at the bottom of the lake; and others are predatory and eat plankton (microscopic aquatic organisms), insect larvae, the scales of fish, or even other cichlid species. In some cichlids food preferences are related to size (smaller cichlids consume plankton), which in turn is related to mating preference (small, plankton-eating cichlids mate only with other small, plankton-eating cichlids).

In other cichlids, related species do not differ in size but only in color and mating habits. Each species has a distinct male coloration, which matches the preferences of females of that species in choosing mates (FIG. 20-12).

Charles Darwin called choosing a mate based on its color or some other characteristic **sexual selection**. He recognized that female preference for showy colors or elaborate ornaments on males, if it was based on *inherited* variation, could result in these male sexual traits becoming more common and more pronounced over time. Female preference for a particular male trait confers a selective advantage to the males exhibiting that trait because they have an improved chance to mate and pass on their genes. Darwin suggested that sexual selection, like natural selection, could eventually result in the evolution of new species. (Sexual selection is discussed in greater detail in Chapter 52.)

DNA sequence data indicate that the cichlid species within a single lake are more closely related to one another than to fishes in nearby lakes or rivers. These molecular data suggest that cichlid species evolved sympatrically, or at least within the confines of a lake, rather than by repeated colonizations by fish populations in nearby rivers. How rapidly did sympatric speciation occur in cichlids? Seismic and drill core data provide evidence that Lake Victoria dried up completely during the Late Pleistocene, when much of northern and equatorial Africa was arid. The diverse cichlid species may have arisen after the climate became wetter and Lake Victoria refilled. Further, the more than five hundred **endemic species** (species found nowhere else) of cichlids in Lake Victoria may have evolved from one or a few common ancestors in a remarkably short period, as little as 12,000 years. Other biologists have offered competing hypotheses about the timing and geographic origin of Lake Victoria's cichlids. Regardless of the uncertainties of certain details, Lake Victoria's cichlids are widely recognized as exemplifying the fastest rate of evolution known for such a large group of vertebrate species.



Loss of cichlid diversity in Lake Victoria In recent years, many of the cichlid species living in Lake Victoria have become extinct. The Nile perch, a voracious predator that was deliberately introduced into the lake in 1960 to stimulate the local fishing economy and whose population exploded in

(a) *Pundamilia pundamilia* males have bluish-silver bodies.

(b) *Pundamilia nyererei* males have red backs.

a–c: Ole Seehausen, University of Bern

Figure 20-12 Color variation in Lake Victoria cichlids

Some evidence suggests that changes in male coloration may be the first step in speciation of Lake Victoria cichlids. Later, other traits, including ecological characteristics, diverge. Female cichlids generally have cryptic coloration; their drab colors help them blend into their surroundings.

Key Experiment

Why is cichlid diversity declining in Lake Victoria?

HYPOTHESIS: Changes in their habitat are causing closely related cichlid species to interbreed in Lake Victoria.

EXPERIMENT: Seehausen and his colleagues took field measurements in 22 different locations in Lake Victoria and later verified those field observations with laboratory experiments in which two cichlid species were placed in aquaria that were either well-lit or not.

RESULTS AND CONCLUSION: When aquaria were well-lit (*left*), females of two closely related cichlid species (one in which the males are red, the other in which the males are blue) consistently chose mates of their own species (*circled area*) over those of other species. When light was blocked to simulate turbid conditions found in parts of Lake Victoria (*right*), females often chose males of other species.

Thus, increasing turbidity of Lake Victoria's water is preventing females of cichlid species from using color to select mates of their own species. As a result, females are interbreeding with males of other species, and the number of cichlid species is declining as the distinctive gene pools of different species are merging.

SOURCE: Seehausen, O., et al., "Speciation through Sensory Drive in Cichlid Fish," *Nature*, Vol. 455 (October 2, 2008): 620–626.

Figure 20-13 Explaining the rapid loss of cichlid diversity in Lake Victoria

PREDICT You conduct an experiment in which you test mate preferences of F_1 hybrid females for red males versus blue males in well-lit aquaria. Predict the results that would support the hypothesis that hybrid females do not use color cues to select mates.

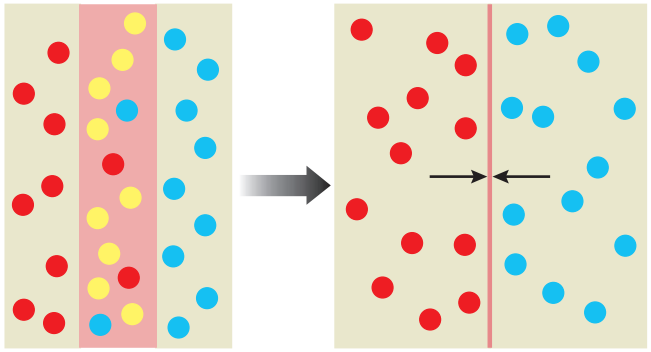
the 1980s, competes for fish prey and has been blamed for the extinction of most of the cichlid species that have disappeared.

Biologists from the University of Leiden in the Netherlands observed, however, that species were also disappearing in habitats in the lake where the Nile perch is known to have little or no effect. Ole Seehausen and his colleagues measured environmental features at 22 localities with such habitats and found strong correlations between bright and diverse male colors and clear, well-lit water. Each species has its own distinct male coloration, which is used by females of that species to choose mates. In clear water, members of each species do not interbreed with members of other species.

As nearby forests have been cut, soil erosion has made the water of Lake Victoria more turbid (cloudy). Agricultural practices in the area have also contributed fertilizer and sediment pollution. Seehausen demonstrated that as the water became more turbid from pollution, light could not penetrate it effectively. He hypothesized that as a result, females could not distinguish males of their own species from males of closely related species.

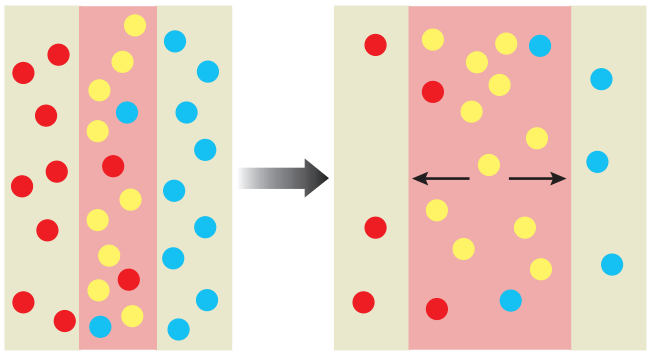
As already discussed, cichlids have evolved during the past 12,000 years. Their relative youth as species means that reproductive isolating mechanisms other than mate preference based on color may not have evolved. It also means that closely related species can be expected to interbreed without loss of fertility. With increasing turbidity, males lose their bright colors because they are no longer favored by sexual selection, and females have mated with males of other species (FIG. 20-13). Thus, many species are being replaced with a few hybrids.

The evolutionary importance of hybridization is being re-evaluated



When two populations have significantly diverged as a result of geographic separation, there is no easy way to determine if the speciation process is complete (recall the disagreement about whether Porto Santo rabbits are a separate species or a subspecies). If such populations, subspecies, or species come into secondary contact before strong prezygotic isolating mechanisms have evolved, they may hybridize, producing fertile offspring, where they meet.

A **hybrid zone** is an area of overlap between two recently diverged populations in which interbreeding takes place and hybrid offspring are common. Hybrid zones are typically narrow, presumably because the hybrids are not well adapted for either parental environment. The hybrid population is typically very small compared with the parental populations.



DNA analysis is allowing detection of hybridization between species at levels that would have seemed surprising in the past. Hybridization in nature between certain plant species

(a) Reinforcement. Hybrids are not as fit as the parents. Over time, the differences between the two parental populations increase, and hybrids are no longer produced. As the hybrid zone shrinks, the resulting outcome is two species.

(b) Fusion. Hybrids are as fit as the two parental populations. Over time, differences between the two parental populations weaken, and the hybrid zone enlarges. The essential result is a single species.

(c) Stability. Hybrids are more fit than either parental population. The fitness of the hybrids results in a stable hybrid zone. Eventually, a third species may form in the hybrid zone.

Figure 20-14 How hybrid zones between two closely related species or diverging populations can change over time

has long been accepted, but it has been thought that species barriers are stronger among animals. We now know that hybridization occurs among almost 10% of bird species, and evidence of hybridization has been detected in certain insects, mammals, and amphibians. Hybridization may have also played a role in human evolution. As discussed in Chapter 22, there is molecular evidence that some members of our species (*Homo sapiens*) interbred with Neandertals (*Homo neanderthalensis*).

On the Great Plains of North America, red-shafted and yellow-shafted flickers (types of woodpeckers) meet and interbreed. The red-shafted flicker, named for the bird's red underwings and tail, is found in the western part of North America, from the Great Plains to the Pacific Ocean. Yellow-shafted flickers, which have yellow underwings and tails, range east of the Rockies. Hybrid flickers, which form a stable hybrid zone from Texas to southern Alaska, are varied in appearance, although many have orange underwings and tails.

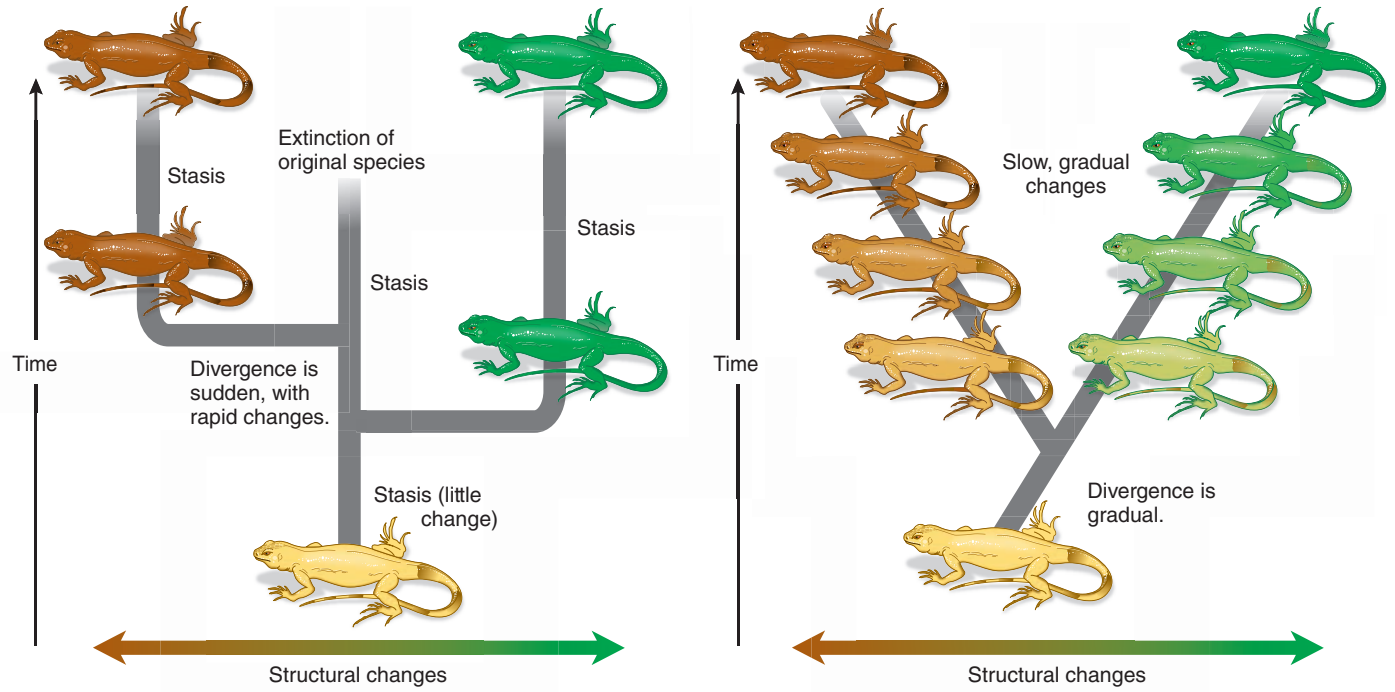
According to the biological species concept, if red-shafted flickers and yellow-shafted flickers are two species, they should maintain their reproductive isolation. Because a hybrid zone has formed, most biologists think that the red-shafted flickers and yellow-shafted flickers are geographic subspecies instead of separate species; red-shafted, yellow-shafted, and hybrid flickers are collectively called northern flickers.

Three evolutionary processes may occur in hybrid zones

When two diverging populations or closely related species come into contact and form a hybrid zone, one of three possibilities can occur: reinforcement, which helps maintain two separate species; fusion of the two species into one; or stability of the hybrid zone (FIG. 20-14). **Reinforcement** occurs when the hybrids in the hybrid zone are less fit than the two parental populations. Reinforcement is the increase in reproductive isolation that often occurs over time in a hybrid zone; that is, natural selection strengthens and increases the number of prezygotic barriers between the two species. As a result, fewer and fewer hybrids are formed, and the hybrid zone gradually disappears.

In *fusion* the hybrids in a hybrid zone are as fit as either of the parental populations. Over time, differences in the reproductive barriers between the two parental populations weaken, and the hybrid zone enlarges. The eventual result is a fusing of two species (or subspecies) into one. Hybridization of the Lake Victoria cichlids (discussed earlier in the chapter) is an example of species loss due to fusion.

Stability is an evolutionary process in which the hybrids are more fit than either parental population. Hybrids continue to be formed, resulting in a stable hybrid zone. Stable hybrid zones often occur in **ecotones**, areas of transition between two different environments. In this case, the two incipient species are adapted to two different communities, and the hybrids' combination of characters from both parental populations allows them to flourish in the ecotone. Eventually, a third species may form in such a hybrid zone. (Ecotones are discussed further in Chapter 56.) In some cases, hybrids may backcross with the parental species, allowing for gene flow between them. The acquisition of genes in this manner is known as *introgression*.



In the example of the flicker hybrid zone, reinforcement does not appear to be occurring. At the same time, the two kinds of flickers are not fusing together into one distinct group. The flicker hybrid zone has not expanded; the two types of flickers have maintained their distinctiveness and have not rejoined into a single, freely interbreeding population. Thus, at this time, flicker hybrids have formed a stable hybrid zone.

Key Point

Punctuated equilibrium and phyletic gradualism represent opposite ends of a spectrum of speciation patterns. Speciation often proceeds in an intermediate or mixed pattern.

(a) In **punctuated equilibrium**, long periods of stasis are interrupted by short periods of rapid speciation.

(b) In **phyletic gradualism**, a slow, steady change in species occurs over time.

Figure 20-15 Punctuated equilibrium and gradualism
In this figure, structural changes in the lizards are represented by changes in skin color.

CONNECT Many scientists think that tropical rain forests have been regions of long-term environmental stability, at least until modern times. If you had the means to follow the evolution of a particular clade of tropical rain forest organisms over the past one million years, would you expect to observe a pattern that would be closer to punctuated equilibrium or to phyletic gradualism?

CHECKPOINT 20.3

- What are five geographic barriers that might lead to allopatric speciation?
- How do hybridization and polyploidy cause a new plant species to form in as little as one generation?
- What is the likely mechanism of speciation for pupfishes? for cichlids?

20.4 The Rate of Evolutionary Change

LEARNING OBJECTIVE

5 Discuss the pace of evolution by describing punctuated equilibrium and phyletic gradualism.

We have seen that speciation is hard for us to directly observe as it occurs. Does the fossil record provide clues about how rapidly new species arise? Biologists have long recognized that the fossil record lacks many transitional forms; the starting points (ancestral species) and the end points (new species) are present, but the intermediate stages in the evolution from one species to another are often lacking. This observation has traditionally been explained by the incompleteness of the fossil record, although scientists have sometimes made new fossil discoveries that fill in the missing parts.

Two different models—punctuated equilibrium and phyletic gradualism—explain evolution as observed in the fossil record (FIG. 20-15). The **punctuated equilibrium** model was proposed by paleontologists who questioned whether the fossil record is actually as incomplete as it initially appeared. In the history of a species, long periods of **stasis** (little or no evolutionary change) appeared to be punctuated, or interrupted, by short periods of

rapid speciation that were perhaps triggered by changes in the environment—that is, periods of great evolutionary stress—and speciation therefore proceeded in "spurts." These relatively short periods of active evolution (perhaps 100,000 years) were followed by long periods (perhaps two million years) of stability.

Punctuated equilibrium accounts for the abrupt appearance of a new species in the fossil record, with little or no evidence of intermediate forms. Proponents hypothesize that few transitional forms appear in the fossil record because few transitional forms occurred during speciation.

In contrast, the traditional Darwinian view of evolution espouses the **phyletic gradualism** model, in which evolution proceeded continuously over long periods. Gradualism is rarely observed in the fossil record because the record is incomplete. (Recall from Chapter 18 that precise conditions are required for fossil formation. Most organisms leave no trace of their existence because they decompose when they die.) Occasionally, a complete fossil record of transitional forms has been discovered and cited as a strong case for gradualism. The gradualism model maintains that populations slowly diverge from one another by the gradual accumulation of adaptive characteristics within each population. These adaptive characteristics accumulate as a result of different selective pressures encountered in different environments.

Scientists supporting phyletic gradualism maintain that any periods of stasis evident in the fossil record are the result of *stabilizing selection* (see Chapter 19). They also emphasize that stasis in fossils is deceptive because fossils do not reveal all aspects of evolution. Although fossils display changes in external structure and skeletal structure, other genetic changes—in physiology, internal structure, resistance to infection, and behavior—all of which also represent evolution, are not evident. Gradualists recognize rapid evolution only when strong *directional selection* occurs.

Many biologists today embrace both models to explain the fossil record. They contend that the pace of evolution may be abrupt in certain instances and gradual in others and that neither punctuated equilibrium nor gradualism exclusively characterizes the changes associated with evolution. Many biologists do not view the distinction between punctuated equilibrium and phyletic gradualism as real. They suggest that genetic changes occur gradually and at a roughly constant pace and that the majority of these mutations do not cause speciation. When the mutations that do cause speciation occur, they are dramatic and produce a pattern consistent with the punctuated equilibrium model.

CHECKPOINT 20.4

- Are the phyletic gradualism and punctuated equilibrium models mutually exclusive? Explain your answer.

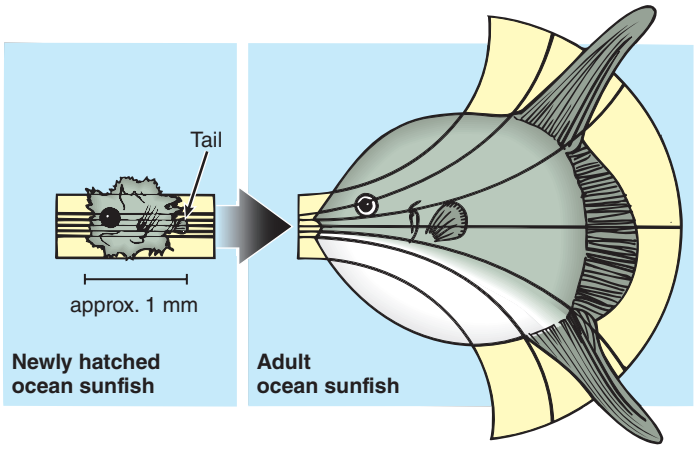
20.5 Macroevolution

LEARNING OBJECTIVES

6 Define *macroevolution*.
7 Discuss macroevolution in the context of novel features, including preadaptations, allometric growth, and paedomorphosis.
8 Discuss the macroevolutionary significance of adaptive radiation and extinction.

Macroevolution concerns large-scale phenotypic changes in populations that generally warrant their placement in taxonomic groups at the species level and higher, that is, new species, genera, families, orders, classes, and even phyla, kingdoms, and domains. One concern of macroevolution is to explain evolutionary novelties, which are large phenotypic changes such as the appearance of jointed limbs during the evolution of arthropods (crustaceans, insects, and spiders). These phenotypic changes are so great that the new species possessing them are assigned to different genera or higher taxonomic categories. Studies of macroevolution also seek to discover and explain major changes in species diversity through time such as occur during *adaptive radiation*, when many species appear, and *mass extinction*, when many species disappear. Thus, evolutionary novelties, adaptive radiation, and mass extinction are important aspects of macroevolution.

Evolutionary novelties originate through modifications of pre-existing structures



New designs arise from structures already in existence. A change in the basic pattern of an organism produces something unique, such as wings on insects, flowers on plants, or feathered wings on birds. Usually, these evolutionary novelties are variations of some pre-existing structures, called **preadaptations**, that originally fulfilled one role but subsequently changed in a way that was adaptive for a different role. Feathers, which evolved from reptilian scales and may have originally provided thermal insulation in primitive birds and some dinosaurs, represent a preadaptation for flight. With gradual modification feathers evolved to function in flight as well as to fulfill their original thermoregulatory role. (Interestingly, a few feather-footed bird species exist; this phenotype is the result of a change in gene regulation that alters scales, normally found on bird feet, into feathers.)

How do such evolutionary novelties originate? Many are probably due to changes during development. *Regulatory genes* exert control over hundreds of other genes during development, and very slight genetic changes in regulatory genes could ultimately cause major structural changes in the organism (see Chapters 17 and 18).

For example, during development most organisms exhibit varied rates of growth for different parts of the body, known as **allometric growth** (from the Greek *allo*, "different," and

(a) A newly hatched ocean sunfish, only 1 mm long, has an extremely small tail.

(b) This allometric transformation is visualized by drawing rectangular coordinate lines through a picture of the juvenile fish and then changing the coordinate lines mathematically.

Richard Herrmann

(c) An ocean sunfish swims off the coast of southern California. The adult ocean sunfish may reach a length of 4 m (13 ft) and weigh about 1500 kg (3300 lb).

Figure 20-16 Allometric growth in the ocean sunfish
The tail end of an ocean sunfish (*Mola mola*) grows faster than the head end, resulting in the unique shape of the adult.

metr, "measure"). The size of the head in human newborns is large in proportion to the rest of the body. As a human grows and matures, the torso, hands, and legs grow more rapidly than the head. Allometric growth is found in many organisms, including the male fiddler crab with its single, oversized claw and the ocean sunfish with its enlarged tail (FIG. 20-16). If growth rates are altered even slightly, drastic changes in the shape of an organism may result, changes that may or may not be adaptive. For example, allometric growth may help explain the extremely small and relatively useless forelegs of the dinosaur *Tyrannosaurus rex* compared with those of its ancestors.

Sometimes novel evolutionary changes occur when a species undergoes changes in the *timing* of development. Consider, for example, the changes that would occur if juvenile characteristics were retained in the adult stage, a phenomenon

Stephen Dalton/Science Source

Figure 20-17 Paedomorphosis in a salamander
An adult axolotl salamander (*Ambystoma mexicanum*) retains the juvenile characteristics of external gills (feathery structures protruding from the neck) and a tail fin (*not visible*). Paedomorphosis allows the axolotl to remain permanently aquatic and to reproduce without developing typical adult characteristics.

known as **paedomorphosis** (from the Greek *paed*, "child," and *morph*, "form"). Adults of some salamander species have external gills and tail fins, features found only in the larval (immature) stages of other salamanders.

Retention of external gills and tail fins throughout life obviously alters the axolotl salamander's behavioral and ecological characteristics (FIG. 20-17). Perhaps such salamanders succeeded because they had a selective advantage over "normal" adult salamanders; that is, by remaining aquatic, they did not have to compete for food with the terrestrial adult forms of related species. The paedomorphic forms also escaped the typical predators of terrestrial salamanders (although they had other predators in their aquatic environment). Studies suggest that paedomorphosis in salamanders is probably the result of mutations in genes that block the production of hormones that stimulate metamorphic changes. When paedomorphic salamanders receive hormone injections, they develop into adults lacking external gills and tail fins.

Adaptive radiation is the diversification of an ancestral species into many species

Some ancestral species have given rise to far more species than have other evolutionary lineages. **Adaptive radiation** is the evolutionary diversification of many related species from one or a few ancestral species in a relatively short period.

Evolutionary innovations such as those we considered in the last section may trigger an adaptive radiation. Alternatively, an adaptive radiation may occur because the ancestral species happens to have been in the right place at the right time to exploit numerous ecological opportunities.

Biologists developed the concept of adaptive zones to help explain this type of adaptive radiation. **Adaptive zones** are new ecological opportunities that were not exploited

Key Point

Adaptive radiation occurs when a single ancestral species diversifies into a variety of species, each adapted to a different ecological niche.

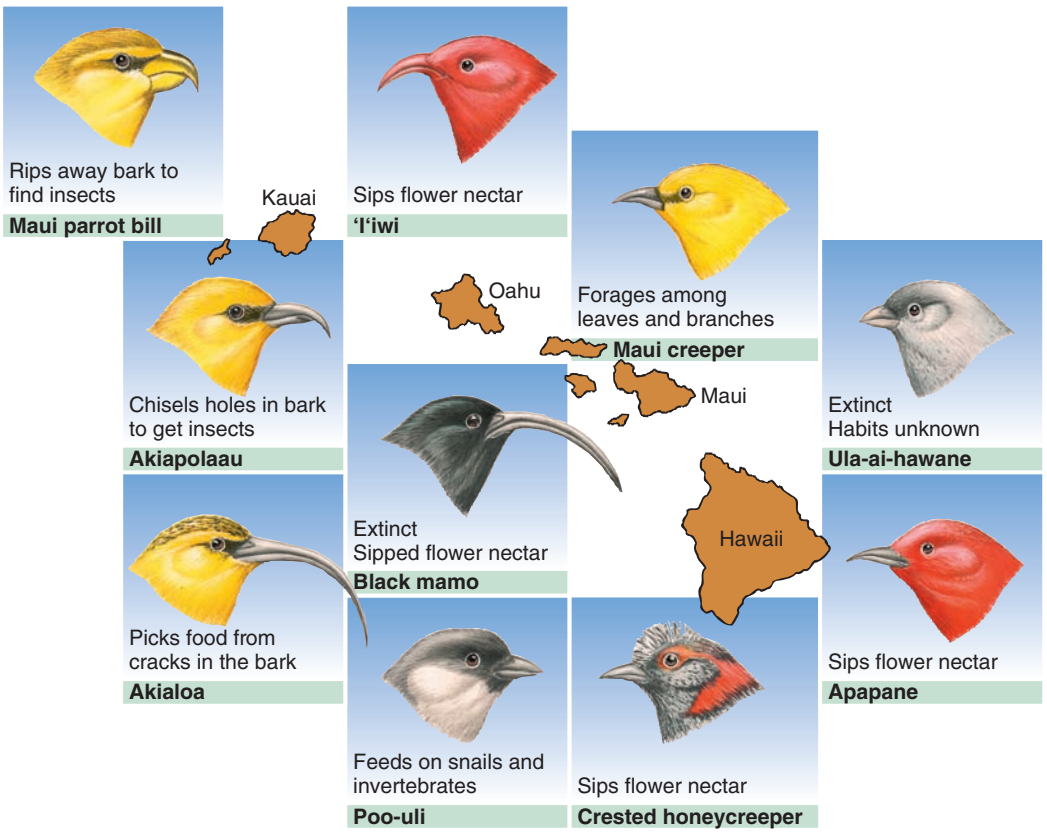

Figure 20-18 Adaptive radiation in Hawaiian honeycreepers
Compare the various beak shapes and methods of obtaining food. Many honeycreeper species are now extinct or nearing extinction as a result of human activities, including the destruction of habitat and the introduction of predators such as rats, dogs, and pigs.

CONNECT Do you think that adaptive radiation in the Hawaiian honeycreepers will continue in the future? Explain your answer.

by an ancestral organism. At the species level, an adaptive zone is essentially identical to one or more similar *ecological niches* (the functional roles of species within a community; see Chapter 54). Examples of adaptive zones include nocturnal flying to catch small insects, grazing on grass while migrating across a savanna, and swimming at the ocean's surface to filter out plankton. When many adaptive zones are empty, as they were in Lake Victoria when it refilled some 12,000 years ago (discussed earlier in the chapter), colonizing species such as the cichlids may rapidly diversify and exploit them.

Because islands have fewer species than do mainland areas of similar size, latitude, and topography, vacant adaptive zones are more common on islands than on continents. Consider the Hawaiian honeycreepers, a group of related birds found in the Hawaiian Islands. When the honeycreeper ancestors reached Hawaii, few other birds were present. The succeeding generations of honeycreepers quickly diversified into many new species and, in the process, occupied the many available adaptive zones that on the mainland are occupied by finches, honeyeaters, treecreepers, and woodpeckers. The diversity of honeycreeper bills is a particularly good illustration of adaptive radiation (FIG. 20-18). Some honeycreeper bills are curved to extract nectar out of tubular flowers, whereas others are short and thick for ripping away bark in search of insects.

Another example of vacant adaptive zones involves the Hawaiian silverswords, 28 species of closely related plants found only in the Hawaiian Islands. When the silversword ancestor, a California plant related to daisies, reached the Hawaiian Islands, many diverse environments—for example, cool, arid mountains; exposed lava flows; dry woodlands; shady, moist forests; and wet bogs—were present and more or less unoccupied. The succeeding generations of silverswords

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

quickly diversified in structure and physiology to occupy the many adaptive zones available to them. The diversity in their leaves, which changed during the course of natural selection as different populations adapted to various levels of light and moisture, is a particularly good illustration of adaptive radiation (FIG. 20-19). For example, leaves of silverswords that are adapted to shady, moist forests are large, whereas those of silverswords living in arid areas are small. The leaves of silverswords living on exposed volcanic slopes are covered with dense, silvery hairs that may reflect some of the intense ultraviolet radiation off the plant.

Adaptive radiation appears more common during periods of major environmental change, but it is difficult to determine how these changes are related to adaptive radiation. It is possible that major environmental change indirectly affects adaptive radiation by increasing the extinction rate. Extinction produces empty adaptive zones, which provide new opportunities for species that remain. Mammals, for example, diversified and exploited a variety of adaptive zones relatively soon after the dinosaurs' extinction. Flying bats, running gazelles, burrowing moles, and swimming whales all originated from early mammals that had coexisted with reptiles for millions of years.

Extinction is an important aspect of evolution

Extinction, the end of a lineage, occurs when the last individual of a species dies. The loss is permanent, for once a species is extinct, it never reappears. Extinctions have occurred continually since the origin of life; by one estimate, only one species is alive today for every 2000 that have become extinct. Extinction is the eventual fate of all species in the same way that death is the eventual fate of all individual organisms.

Although extinction has a negative short-term effect on the number of species, it facilitates evolution over a period of thousands to millions of years. As mentioned previously, when species become extinct, their adaptive zones become vacant. Consequently, surviving species are presented with new evolutionary opportunities and may diverge, filling in some of the unoccupied zones. In other words, the extinct species may eventually be replaced by new species.

During the long history of life, extinction appears to have occurred at two different rates. The continuous, low-level extinction of species is sometimes called **background extinction**. In contrast, five or possibly six times during Earth's history **mass extinctions** of numerous species and

higher taxonomic groups have taken place in both terrestrial and marine environments. The most recent mass extinction, which occurred about 66 million years ago (mya), killed off many marine organisms, terrestrial plants, and vertebrates, including the last of the dinosaurs. The time span over which a mass extinction occurs may be several million years, but that is relatively short compared with the 3.5 billion years or so of Earth's history of life. Each period of mass extinction has been followed by a period of adaptive radiation of some of the surviving groups.

The causes of past episodes of mass extinction are not well understood. Both environmental and biological factors seem to have been involved. Major changes in climate could have adversely affected those plants and animals that lacked the genetic flexibility to adapt. In particular, marine organisms are adapted to a steady, unchanging climate. If Earth's temperature were to increase or decrease by just a few degrees overall, many marine species would probably perish.

It is also possible that past mass extinctions were due to changes in the environment induced by catastrophes. If a large comet or small asteroid collided with Earth, the dust ejected into the atmosphere on impact could have blocked much of the sunlight. In addition to disrupting the food chain by killing many plants (and therefore terrestrial animals), this event would have lowered Earth's temperature, leading to the death of many marine organisms. Evidence exists that the extinction of dinosaurs was caused by an extraterrestrial object's collision with Earth (see Chapter 21).

Biological factors also trigger extinction. Competition among species may lead to the extinction of species that cannot compete effectively. The human species in particular has had a profound effect on the rate of extinction. The habitats of many animal and plant species have been altered or destroyed by humans, and habitat destruction can result in a species' extinction. Some biologists think that we have entered the greatest mass extinction episode in Earth's history. (Extinction is discussed further in Chapter 57.)

Is microevolution related to speciation and macroevolution?

The concepts presented in Chapters 18 and 19 represent the **modern synthesis**, in which mutation provides the genetic variation on which natural selection acts. The modern synthesis combines Darwin's scientific theory with important aspects of genetics. Many aspects of the modern synthesis have been tested and verified at the population and subspecies levels. Many biologists contend that microevolutionary processes explain macroevolution. They assert that natural selection, mutation, genetic drift, and gene flow account for not only the genetic variation within populations but also the origin of new species and higher taxa.

A considerable body of data from many fields supports the modern synthesis as it relates to speciation and macroevolution. Consider, for example, the *fish–tetrapod transition* (the evolution of four-legged amphibians from fishes), which was a major macroevolutionary event in the history of vertebrates (see Chapter 32). The fish–tetrapod transition is well documented in the fossil record. Studies of fossil intermediates show that the transition from aquatic fishes to terrestrial amphibians occurred as evolutionary novelties, such as changes in the limbs and skull roof, were added. These novelties accumulated as a succession of small changes over a period of 9 million to 14 million years. This time scale is sufficient to have allowed natural selection and other microevolutionary processes to produce the novel characters.

Although few biologists doubt the role of natural selection and microevolution in generating specific adaptations, some question the *extent* of microevolution's role in the overall pattern of life's history. These biologists ask whether speciation and macroevolution have been dominated by microevolutionary processes or by external, chance events, such as an impact by an asteroid. Chance events do not "care" about adaptive superiority but instead lead to the random extinction or survival of species. In the case of an asteroid impact, for example, certain species may survive because they were "lucky" enough to be in a protected environment at the time of impact. If chance events have been the overriding factor during life's history, microevolution cannot be the exclusive explanation for the biological diversity present today (see discussion of the role of chance in evolution in Chapter 18).

CHECKPOINT 20.5

- Why are evolutionary novelties important to scientists studying macroevolution?
- In what ways does preadaptation facilitate macroevolution?
- What are some potential selective advantages of paedomorphosis?
- **CONNECT** What is the relationship between mass extinction and adaptive radiation?

Summary: Focus on Learning Objectives

20.1 What Is a Species? *(page 422)*

1 Describe the biological species concept and list two potential problems with the concept.

- According to the **biological species concept**, a species consists of one or more populations whose members interbreed in nature to produce fertile offspring and do not interbreed with members of different species.
- One problem with the biological species concept is that it applies only to sexually reproducing organisms. Also, although individuals assigned to different species do not normally interbreed, they may occasionally successfully interbreed.

20.2 Reproductive Isolation *(page 423)*

2 Explain the significance of reproductive isolating mechanisms and distinguish among the various prezygotic and postzygotic barriers.

- **Reproductive isolating mechanisms** restrict gene flow between species.
- **Prezygotic barriers** are reproductive isolating mechanisms that prevent fertilization from taking place. **Temporal isolation** occurs when two species reproduce at different times of the day, season, or year. In **habitat isolation** two closely related species live and breed in different habitats in the same geographic area. In **behavioral isolation** distinctive courtship behaviors prevent mating between species. **Mechanical isolation** is due to incompatible structural differences in the reproductive organs of similar species. In **gametic isolation**, gametes from different species are incompatible because of molecular and chemical differences.

- **Postzygotic barriers** are reproductive isolating mechanisms that prevent gene flow after fertilization has taken place. **Hybrid inviability** is the death of interspecific embryos during development. **Hybrid sterility** prevents interspecific hybrids that survive to adulthood from reproducing successfully. **Hybrid breakdown** prevents the offspring of hybrids that survive to adulthood and successfully reproduce from reproducing beyond one or a few generations.

20.3 Speciation *(page 425)*

3 Explain the mechanism of allopatric speciation and give an example.

- **Speciation** is the evolution of a new species from an ancestral population. **Allopatric speciation** (e.g., in Death Valley pupfishes) occurs when one population becomes geographically isolated from the rest of the species and subsequently diverges. Speciation is more likely to occur if the original isolated population is small because **genetic drift** is more significant in small populations than in large populations.

4 Explain the mechanisms of sympatric speciation and give both plant and animal examples.

- **Sympatric speciation** does not require geographic isolation. In plants sympatric speciation can result when a **polyploid** individual (one with more than two sets of chromosomes) is an **allopolyploid** hybrid derived from two species. One example of sympatric speciation by allopolyploidy is the hemp nettle.
- Sympatric speciation occurs in animals, such as fruit maggot flies and cichlids, but how often it occurs and under what conditions remain to be determined.

20.4 The Rate of Evolutionary Change *(page 434)*

5 Discuss the pace of evolution by describing punctuated equilibrium and phyletic gradualism.

- According to the **punctuated equilibrium** model, evolution of species proceeds in spurts. Short periods of active speciation are interspersed with long periods of **stasis**. According to the **phyletic gradualism** model, populations slowly diverge from one another by the accumulation of adaptive characteristics within a population.

20.5 Macroevolution *(page 435)*

6 Define *macroevolution*.

- **Macroevolution** concerns large-scale phenotypic changes in populations that typically warrant the placement of the populations in taxonomic groups at the species level and higher, that is, new species, genera, families, orders, classes, and even phyla, kingdoms, and domains.

7 Discuss macroevolution in the context of novel features, including preadaptations, allometric growth, and paedomorphosis.

- Evolutionary novelties may be due to changes during **development**, the orderly sequence of events that occurs as an organism grows and matures. Slight genetic changes in regulatory genes could cause major structural changes in an organism.
- Evolutionary novelties may originate from **preadaptations**, structures that originally fulfilled one role but changed in a way that was adaptive for a different role. Feathers are an example of a preadaptation.
- **Allometric growth**, varied rates of growth for different parts of the body, results in overall changes in the shape of an organism. Examples include the expanded tail region of the ocean sunfish and the enlarged claw of the male fiddler crab.
- **Paedomorphosis**, the retention of juvenile characteristics in the adult, occurs because of changes in the timing of development. Adult axolotl salamanders, with external gills and tail fins, are an example of paedomorphosis.

Copyright 2019 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

8 Discuss the macroevolutionary significance of adaptive radiation and extinction.

- **Adaptive radiation** is the process of diversification of an ancestral species into many new species. **Adaptive zones** are new ecological opportunities that were not exploited by an ancestral organism. When many adaptive zones are empty, colonizing species may rapidly diversify and exploit them. Hawaiian honeycreepers and silverswords both underwent adaptive radiation after their ancestors colonized the Hawaiian Islands.

- **Extinction** is the death of a species. When species become extinct, the adaptive zones that they occupied become vacant, allowing other species to evolve and fill those zones. **Background extinction** is the continuous, low-level extinction of species. **Mass extinction** is the extinction of numerous species and higher taxonomic groups in both terrestrial and marine environments.

Test Your Understanding

Know and Comprehend

1. A prezygotic barrier prevents (a) the union of egg and sperm (b) reproductive success by an interspecific hybrid (c) the development of the zygote into an embryo (d) allopolyploidy from occurring (e) changes in allometric growth
2. The reproductive isolating mechanism in which two closely related species live in the same geographic area but reproduce at different times is (a) temporal isolation (b) behavioral isolation (c) mechanical isolation (d) gametic isolation (e) hybrid inviability
3. Interspecific hybrids, if they survive, are (a) always sterile (b) always fertile (c) usually sterile (d) usually fertile (e) never sterile
4. The first step leading to allopatric speciation is (a) hybrid inviability (b) hybrid breakdown (c) adaptive radiation (d) geographic isolation (e) paedomorphosis
5. The pupfishes in the Death Valley region are an example of which evolutionary process? (a) background extinction (b) allopatric speciation (c) sympatric speciation (d) allopolyploidy (e) paedomorphosis
6. Which of the following evolutionary processes is associated with allopolyploidy? (a) gradualism (b) allometric growth (c) sympatric speciation (d) mass extinction (e) preadaptation
7. According to the punctuated equilibrium model, (a) populations slowly diverge from one another (b) the evolution of species occurs in spurts interspersed with long periods of stasis (c) evolutionary novelties originate from preadaptations (d) reproductive isolating mechanisms restrict gene flow between species (e) the fossil record, being incomplete, does not accurately reflect evolution as it actually occurred
8. The evolutionary conversion of reptilian scales into feathers is an example of (a) allometric growth (b) paedomorphosis (c) gradualism (d) hybrid breakdown (e) a preadaptation
9. Adaptive radiation is common following a period of mass extinction, probably because (a) the survivors of a mass extinction are remarkably well adapted to their environment (b) the unchanging environment following a mass extinction drives the evolutionary process (c) many adaptive zones are empty (d) many ecological niches are filled (e) the environment induces changes in the timing of development for many species
10. The Hawaiian silverswords are an excellent example of which evolutionary process? (a) allometry (b) preadaptation (c) microevolution (d) adaptive radiation (e) extinction

Apply and Analyze

11. **VISUALIZE** Use two different colors to depict the unduplicated chromosomes of species C with larger chromosomes ($2n = 8$) and species D with slightly smaller chromosomes ($2n = 10$), and of their F_1 hybrid. Is the hybrid likely to be fertile?

Evaluate and Synthesize

12. **EVOLUTION LINK** Is allopatric speciation more likely to occur if the original isolated population is small or large? Explain your answer.
13. **EVOLUTION LINK** Could hawthorn and apple maggot flies be considered an example of assortative mating, which was discussed in Chapter 19? Explain your answer.
14. **EVOLUTION LINK** Because mass extinction is a natural process that may facilitate evolution during the period of thousands to millions of years that follow it, should humans be concerned about the current mass extinction we are causing? Why or why not?
15. **EVOLUTION LINK** Examine Figure 20-2c and predict which date is likeliest for researchers to have collected wood frogs and leopard frogs and interbred them in the lab: March 10, April 1, or April 15. Explain your answer.

21 The Origin and Evolutionary History of Life

KEY CONCEPTS

21.1 Although there is no direct fossil evidence of the origin of life, biochemical experiments have demonstrated how the complex organic molecules that are found in all living organisms may have formed.

21.2 The first cells were probably anaerobic and prokaryotic. Photosynthesis, aerobic respiration, and eukaryotic cell structure represent several major advances that occurred during the early history of life.

21.3 The fossil record tells us much of what we know about the history of life, such as what kinds of organisms existed and where and when they lived. Scientists identify and demonstrate relationships among fossils in rock layers from different periods of geologic time.

The preceding three chapters were concerned with biological evolution. However, we have not dealt with what many regard as a fundamental question: How did life begin? Although biologists generally accept the hypothesis that life developed from nonliving matter, exactly how this process, called **chemical evolution**, occurred is not certain. Current models suggest that small organic molecules first formed spontaneously and accumulated over time. Large organic macromolecules such as proteins and nucleic acids could have then assembled from the smaller molecules.

The macromolecules interacted, combining into more-complicated structures that could eventually metabolize and replicate, passing their genetic information on to their descendants, which eventually became the first true cells. After the first cells originated, they diverged over several billion years into the rich biological diversity that characterizes our planet today.

Initially, unicellular prokaryotes (archaea and bacteria) predominated, followed by unicellular eukaryotes. The first multicellular eukaryotes were soft-bodied marine animals that did not leave many fossils. Shelled animals and other marine invertebrates (animals without backbones) appeared next, as exemplified by trilobites, primitive aquatic arthropods. Marine invertebrates were followed by the first vertebrates (animals with backbones). The first fishes with jaws appeared and diversified, with some of them giving rise to amphibians, the first vertebrates with limbs that were capable of moving about on land. Amphibians gave rise to reptiles, which diversified and populated the land. Reptiles, in turn, gave rise independently to birds and to mammals (see photograph). Plants underwent a comparable evolutionary history and diversification.

In this chapter we survey life over a vast span of time, starting when our planet was relatively young. We first examine proposed models about how life began and then trace life's long evolutionary history.

21.1 Chemical Evolution on Early Earth

LEARNING OBJECTIVES

1. Describe the conditions that scientists think existed on early Earth.
2. Compare the prebiotic soup hypothesis with the iron–sulfur world hypothesis.

Scientists generally agree that life's beginnings occurred under environmental conditions quite different from those of today. Therefore, we must examine the conditions of early Earth to understand the origin of life. Evidence from many sources provides us with clues that help us formulate plausible scenarios of the steps in which life originated. Study of the origin of life is an active area of scientific research today, and many important contributions are adding to our understanding of how life began.

Astrophysicists and geologists estimate that Earth is about 4.6 billion years old. The atmosphere of early Earth apparently included carbon dioxide (CO_2), water vapor (H_2O), carbon monoxide (CO), and nitrogen (N_2). It may also have contained some ammonia (NH_3), hydrogen sulfide (H_2S), and methane (CH_4). The early atmosphere probably contained little or no free oxygen (O_2).

Four requirements must have existed for the chemical evolution of life: little or no free oxygen, a source of energy, the availability of chemical building blocks, and time. First, life could have begun only in the absence of free oxygen. Oxygen is quite reactive and would have oxidized the organic molecules that are necessary building blocks in the origin of life. Earth's early atmosphere was probably strongly reducing, which means that any free oxygen would have reacted with other elements to form oxides. Thus, oxygen would have been tied up in compounds.

The origin of life would also have required energy to do the work of building biological molecules from simple inorganic chemicals. Early Earth was a place of high energy with violent thunderstorms; widespread volcanic activity; bombardment from meteorites and other extraterrestrial objects; and intense radiation, including ultraviolet radiation from the sun (FIG. 21-1). The young sun probably produced more ultraviolet radiation than it does today, and ancient Earth had no protective ozone layer to filter it.

A third requirement would have been the presence of the chemical building blocks needed for chemical evolution, including water, dissolved inorganic minerals (present as ions), and the gases present in the early atmosphere. A final requirement for the origin of life was time for molecules to accumulate and react with one another. Earth is approximately 4.6 billion years old, and evidence suggests that life arose early in Earth's history.

Organic molecules formed on primitive Earth

Because organic molecules are the building materials for organisms, it is reasonable to first consider how they may have originated. Two main models seek to explain how the organic precursors of life originated: the **prebiotic soup hypothesis** proposes that these molecules formed near Earth's surface, whereas the **iron–sulfur world hypothesis** proposes that organic precursors formed at cracks in the ocean's floor.

Organic molecules may have been produced at Earth's surface The concept that simple organic molecules such as sugars, nucleotide bases, and amino acids could form spontaneously from simpler raw materials was first advanced in the 1920s by two scientists working independently: A.I. Oparin, a Russian biochemist, and J.B.S. Haldane, a Scottish physiologist and geneticist.

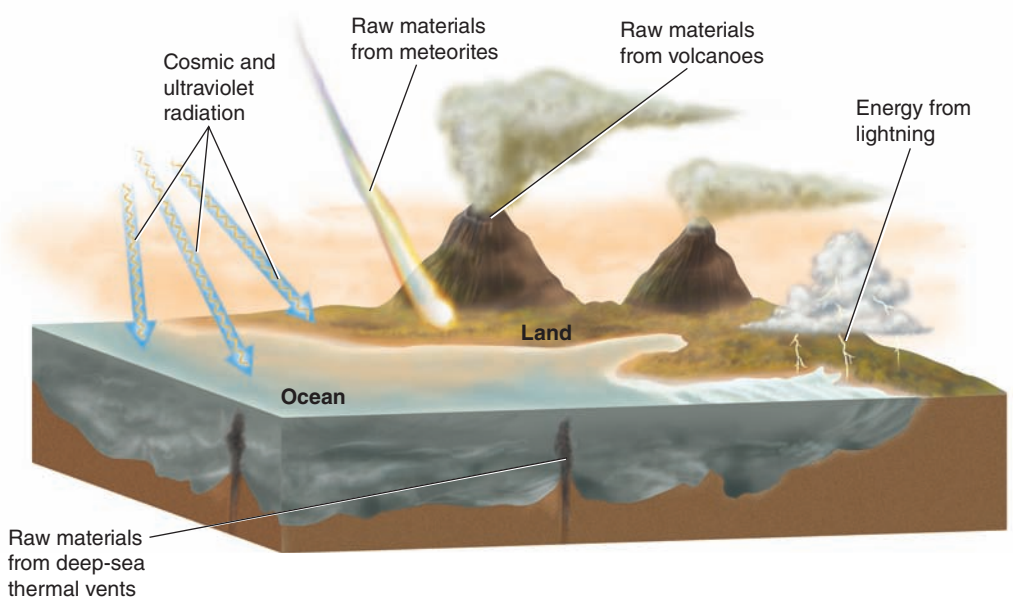

Figure 21-1 Conditions on early Earth

Volcanoes erupted, spewing gases that contributed to the atmosphere, and violent thunderstorms triggered torrential rainfall that washed molecules out of the atmosphere and eroded the land. Meteorites and other extraterrestrial objects bombarded Earth, cataclysmically changing the crust, ocean, and atmosphere. Deep-sea thermal vents, heated by Earth's internal heat, spewed forth chemicals. High-energy radiation from cosmic and ultraviolet rays blasted the planet.

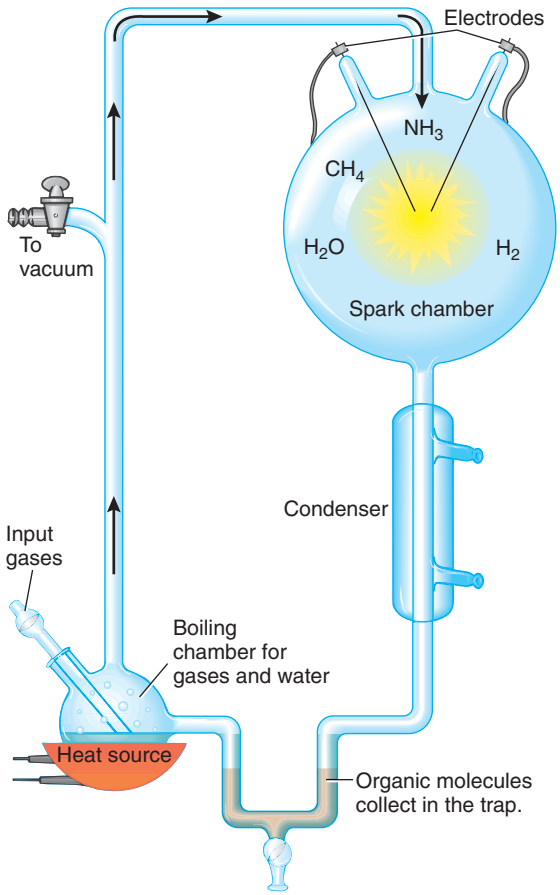
Their hypothesis was tested in the 1950s by U.S. biochemists Stanley Miller and Harold Urey, who designed a closed apparatus that simulated conditions that presumably existed on early Earth (FIG. 21-2). They exposed an atmosphere rich in H_2O, CH_4, NH_3, and H_2 to an electric discharge that simulated lightning. Their analysis of the chemicals produced during one week revealed that amino acids and other organic molecules had formed. Although more recent data suggest that Earth's early atmosphere was not rich in methane, ammonia, or hydrogen, similar experiments using different combinations of gases have produced a wide variety of organic molecules that are important in contemporary organisms. They include all 20 amino acids, several sugars, lipids, the nucleotide bases of RNA and DNA, and ATP (when phosphate is present). In 2015 British chemist John Sutherland and his colleagues at the University of Cambridge demonstrated that precursors of nucleic acids, amino acids, and lipids can all be produced by reacting hydrogen cyanide (HCN) and hydrogen sulfide (H_2S) in the presence of ultraviolet (UV) light. Scientists think that H_2S and UV were common on early Earth, and HCN is abundant in comets, which were bombarding Earth. Thus, before life began, its chemical building blocks were probably accumulating as a necessary step in chemical evolution.

Oparin envisioned that the organic molecules would, over vast spans of time, accumulate in the shallow seas to form a "sea of organic soup." He envisioned smaller organic molecules (monomers) combining to form larger ones (polymers) under such conditions. Evidence gathered since Oparin's time indicates that organic polymers may have formed and accumulated on rock or clay surfaces rather than in the primordial seas. Clay, which consists of microscopic particles of weathered rock, is particularly intriguing as a possible site for early polymerizations because it binds organic monomers and contains zinc and iron ions that may have served as catalysts. Laboratory experiments have confirmed that organic polymers form spontaneously from monomers on hot rock or clay surfaces.

Organic molecules may have formed at hydrothermal vents Some biologists hypothesize that early polymerizations leading to the origin of life may have occurred in cracks in the deep-ocean floor where hot water, carbon monoxide, and minerals such as sulfides of iron and nickel spew forth; this view is known as the iron–sulfur world hypothesis. Such **hydrothermal vents** would have been better protected than Earth's surface from the catastrophic effects of meteorite bombardment.

Today, these anaerobic hot springs produce precursors of biological molecules and of energy-rich "food," including the highly reduced compounds hydrogen sulfide and methane. These chemicals support a diverse community of microorganisms, clams, crabs, tube worms, and other animals (see *Inquiring About: Life without the Sun*, in Chapter 55).



Testing the iron–sulfur world hypothesis at hydrothermal vents is difficult, but laboratory experiments simulating the high pressures and temperatures at the vents have yielded intriguing results. For example, iron and nickel sulfides catalyze reactions between carbon monoxide and hydrogen sulfide, producing acetic acid and other simple organic compounds. Also, experiments show that ammonia, one of the precursors

Key Experiment

Could organic molecules have formed in the conditions of early Earth?

HYPOTHESIS: Organic molecules can form in a reducing atmosphere similar to that thought to be present on early Earth.

EXPERIMENT: The apparatus that Miller and Urey used to simulate the reducing atmosphere of early Earth contained water, methane, ammonia, and hydrogen. An electrical spark was produced in the upper right flask to simulate lightning.

RESULTS AND CONCLUSION: The gases present in the flask reacted together, and in one week a variety of simple organic compounds, such as amino acids, accumulated in the trap at the bottom. Thus, the formation of organic molecules—the first step in the origin of life—can be produced from simple precursors.

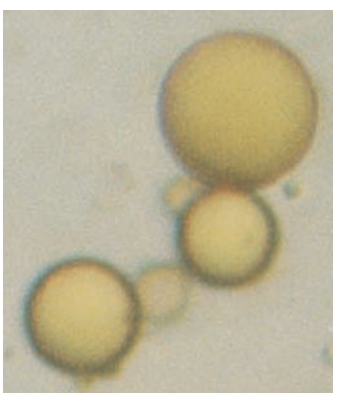
of proteins and nucleic acids, is produced in abundance, suggesting that vents were ammonia-rich environments in the prebiotic world and that the earliest organisms could have formed in this seemingly inhospitable environment.

CHECKPOINT 21.1



- What are the four requirements for chemical evolution, and why is each essential?
- **CONNECT** How does the iron–sulfur world hypothesis differ from the prebiotic soup hypothesis? What do these hypotheses have in common?

21.2 The First Cells

LEARNING OBJECTIVES

3 Outline the major steps hypothesized to have occurred in the origin of cells.
4 Explain how the evolution of photosynthetic autotrophs affected both the atmosphere and other organisms.
5 Describe the hypothesis of serial endosymbiosis.

After the first polymers formed, could they have assembled spontaneously into more complex structures with an outer membranous boundary? Scientists have synthesized several different **protobionts**, which are vesicle-like assemblages of abiotically produced (i.e., not produced by organisms) organic polymers. These protobionts resemble living cells in several ways, thus providing clues as to how aggregations of complex nonliving molecules took that "giant leap" and became living cells. These protobionts exhibit many functional and structural attributes of living cells. They often divide in half (binary fission) after they have sufficiently "grown." Protobionts maintain an internal chemical environment that is different from the external environment (homeostasis), and some of them show the beginnings of metabolism (catalytic activity). They are highly organized, considering their relatively simple composition.

Steven Brooke and Richard LeDuc

Figure 21-3 Microspheres
These tiny protobionts exhibit some of the properties of life.

Microspheres are a type of protobiont formed by adding water to abiotically formed polypeptides (FIG. 21-3). Some microspheres are excitable: they produce an electrical potential across their surfaces, reminiscent of electrochemical gradients in cells. Microspheres can also absorb materials from their surroundings (selective permeability) and respond to changes in osmotic pressure as though membranes enveloped them, even though they contain no lipid.

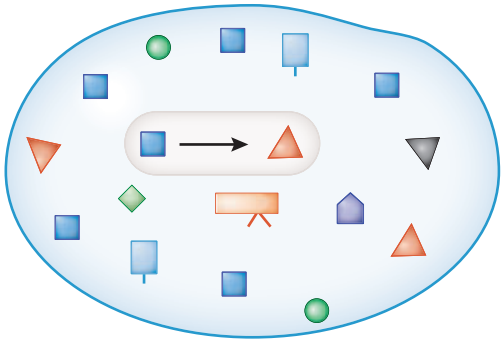
Scientists have constructed protobionts in which membranes of fatty acids and monoglycerides surround larger DNA-like molecules. These protobionts are impermeable to the genetic molecules but allow smaller organic molecules—that is, "nutrients"—to enter. This study is significant because it suggests how early cells could have held on to their "genes" and absorbed needed nutrients from their environment without the sophisticated membrane structure associated with contemporary cells.

The study of protobionts shows that relatively simple nonliving structures have some of the properties of life. However, it is a major step (or several steps) to go from simple molecular aggregates such as protobionts to living cells.

The origin of a simple metabolism within a membrane boundary may have occurred early in the evolution of cells

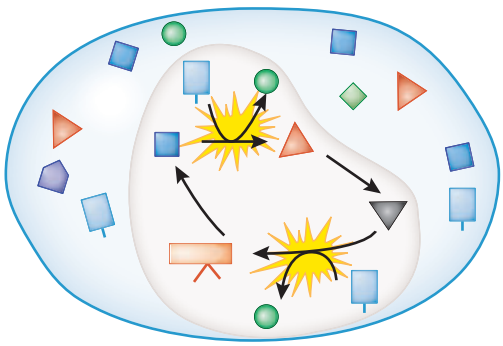
Although we have learned many things about how organic molecules may have formed on primitive Earth, the problem of how pre-cells evolved into living cells remains to be solved. Let's examine one possible scenario—the **metabolism first hypothesis**—supported by many chemists, including Robert Shapiro at New York University. Shapiro envisions life beginning as a self-sustaining, organized system consisting of chemical reactions between simple molecules that are enclosed within a boundary, that is, separated from the external environment (FIG. 21-4a).

A source of energy must be available to drive these chemical reactions (thereby maintaining an internal organization different from the external environment). To be self-sustaining, the energy source must be coupled to the chemical reaction sequence (FIG. 21-4b). (Recall how ATP links exergonic and endergonic reactions, shown in Figure 7-6.)



As the pre-cells continue to evolve, their organization increases (FIG. 21-4c). Finally, to survive, the pre-cell system must grow and reproduce. One of the most significant parts of the origin of living cells from pre-cells was the evolution of molecular reproduction (FIG. 21-4d).

Molecular reproduction was a crucial step in the origin of cells



In living cells genetic information is stored in the nucleic acid DNA, which is transcribed into messenger RNA (mRNA), which in turn is translated into the proper amino acid sequence in proteins. All three macromolecules in the DNA → RNA → protein sequence contain precise information. Of these macromolecules, only DNA and RNA are capable of self-replication (although only in the presence of the proper enzymes in cells today). Because both RNA and DNA can form spontaneously on clay in much the same way that other organic polymers do, the question becomes which molecule, DNA or RNA, first appeared in the prebiotic world.

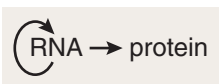
(a) Within a boundary, chemical reactions occur among simple molecules.

(b) A source of energy is coupled to the chemical reaction sequence.

(c) As the pre-cell system continues to evolve, its size and organization increase.

(d) The pre-cell system develops the ability to reproduce.

Figure 21-4 Origin of life: the metabolism first scenario



Many scientists have suggested that RNA was the first informational molecule to evolve in the progression toward a self-sustaining, self-reproducing cell and that proteins and DNA came along later. According to a model known as the **RNA world**, the chemistry of prebiotic Earth gave rise to self-replicating RNA molecules that functioned as both enzymes and substrates for their own replication. We represent the replication of RNA in the RNA world scenario as a circular arrow:

As discussed in Chapter 13, RNA often has catalytic properties; such enzymatic RNAs are called **ribozymes**. Before the evolution of true cells, ribozymes may have catalyzed their own replication in the clays, shallow rock pools, or hydrothermal vents where life originated. When RNA strands are added to a test tube containing RNA nucleotides but no enzymes, the nucleotides combine to form short RNA molecules.

The occurrence of an RNA world early in the history of life can never be proven, but experiments with **in vitro evolution**, also called **directed evolution**, have shown that it is feasible. These experiments address an important question about the RNA world, namely, could RNA molecules have catalyzed the many different chemical reactions needed for life? In directed evolution a large pool of RNA molecules with different sequences is mixed, and molecules are selected for their ability to catalyze a single biologically important reaction (FIG. 21-5). Those molecules that have at least some catalytic ability are selected by researchers, who then amplify them into many copies. The researchers use certain chemicals to cause mutations and then expose the molecules to another round of selection. After this cycle is repeated several times, the RNA molecules at the end of the selection process function efficiently as catalysts for the reaction. In vitro evolution studies have shown that RNA has a large functional repertoire—that is, RNA can catalyze a variety of biologically important reactions.

Biologists hypothesize that in the RNA world, ribozymes initially catalyzed protein synthesis and other important biological reactions; only later did protein enzymes catalyze these reactions.

Interestingly, in test-tube experiments RNA molecules that direct protein synthesis by catalyzing peptide bond formation have evolved. Some single-stranded RNA molecules fold back on themselves as a result of interactions among the nucleotides composing the RNA strand. Sometimes the conformation (shape) of the folded RNA molecule is such that it weakly binds to an amino acid (see discussion of peptidyl transferase in Chapter 13). Amino acids held close to one another by RNA molecules may bond, forming a polypeptide.

Key Experiment

Can in vitro natural selection result in chemical evolution of catalysts?

HYPOTHESIS: Self-replicating RNA molecules can undergo changes that make them more-efficient catalysts.

EXPERIMENT: RNA molecules are selected from a large pool, based on their ability to catalyze a specific reaction, and then amplified (see figure). Mutations occur as this process is repeated 7 to 20 additional times

RESULTS AND CONCLUSION: The final group of RNA molecules is the most efficient at catalyzing the chemical reaction selected for. Scientists have developed more than two dozen synthetic RNA catalysts by in vitro evolution.

SOURCE: Wright, M.C., and G.F. Joyce, "Continuous In Vitro Evolution of Catalytic Function," *Science*, 276 (1997): 614–617.

Figure 21-5 In vitro evolution of RNA molecules

PREDICT Would the same result have been obtained if no mutations had occurred during the amplification process?

We have considered how the evolution of informational molecules may have given rise to RNA and later to proteins. If a self-replicating RNA capable of coding for proteins appeared prior to DNA, how did DNA, the universal molecule of heredity in cells, become involved? Perhaps RNA made double-stranded copies of itself that eventually evolved into DNA.

DNA ← RNA → protein

The incorporation of DNA into the information transfer system was advantageous because the double helix of DNA is more stable (less reactive) than the single strand of RNA. Such stability in a molecule that stores genetic information would have provided a decided advantage in the prebiotic world (as it does today).

Thus, in the DNA/RNA/protein world, DNA became the information storage molecule, RNA remained involved in protein synthesis and various regulatory activities, and protein enzymes catalyzed most cell reactions, including DNA replication and RNA synthesis.

DNA → RNA → protein

RNA is still a necessary component of the information transfer system because DNA is not catalytic. Thus, natural selection at the molecular level favored the DNA → RNA → protein information sequence. Once DNA was incorporated into this sequence, RNA molecules assumed their present role as an intermediary in the transfer of genetic information.

Biological evolution began with the first cells

Several additional steps had to occur before a true living cell could evolve from macromolecular aggregations. For purposes of discussion, scientists have coined the acronym **LUCA** to refer to the hypothesized *l*ast *u*niversal *c*ommon *a*ncestor. The self-replicating genetic code that all known organisms possess is certainly a legacy from LUCA, but what else can be learned? Scientists are using varied approaches to address these questions.

No one knows exactly when or where the first cells appeared on Earth. No fossils have been found that undisputedly trace the transition from nonlife to life. Non-fossil evidence—isotopic "fingerprints" of organic carbon in ancient rocks in Greenland—suggests to some researchers that life existed as early as 3.8 billion years ago (bya). However, other scientists vigorously debate this conclusion.

Microfossils, ancient remains of microscopic life, suggest that the earliest cells were prokaryotic. **Stromatolites**, a type of fossil evidence of the earliest cells, are rocklike columns composed of many minute layers of prokaryotic cells, that is, microbial biofilms (FIG. 21-6). Over time, sediment collects around the cells and mineralizes. Meanwhile, a new layer of living cells grows over the older, dead cells. Fossil stromatolite

Figure 21-6 Stromatolites

reefs are found in several places in the world, including Great Slave Lake in Canada and the Gunflint Iron Formations along Lake Superior in the United States. Some fossil stromatolites are extremely ancient. One group in Western Australia, for example, has been dated at 3.48 billion years. In 2016 fossil stromatolites found in Greenland were dated to 3.7 billion years. If confirmed, they would be the earliest evidence of living cells. Living stromatolite reefs are rare but are found in certain hot springs and warm, shallow pools of fresh and salt water.

Proponents of the organic soup hypothesis argue that the earliest cells probably did not synthesize the organic molecules they needed but instead obtained them from the environment. These primitive **heterotrophs** may have consumed many types of organic molecules that had formed spontaneously, such as sugars, nucleotides, and amino acids. By fermenting these organic compounds, they obtained the energy they needed to support life. Of course, *fermentation*, discussed in Chapter 8, is an anaerobic process (performed in the absence of oxygen), and the first cells were almost certainly **anaerobes**.

In 2016 the hypothesis that the first cells arose in hydrothermal vents received support from the work of William F. Martin and his colleagues at the Heinrich Heine University in Germany. They used DNA data banks to analyze the DNA sequences of over 6 million protein-coding genes in living prokaryotes (archaea and bacteria). They assigned these sequences to gene families and found that 355 of these families occur in both archaea and bacteria and are hence a likely legacy from LUCA. These include genes required to fix CO_2 and obtain energy from H_2, making these organisms **chemoautotrophs** (see the discussion of metabolic diversity in Chapter 9). Furthermore, these families include genes found in present-day prokaryotes that live at high temperatures.

Photosynthesis was a further step in the evolution of cells

The first cells to obtain energy directly from sunlight probably used sunlight to make ATP, but like a few bacteria today, may have been **photoheterotrophs**, unable to carry out carbon fixation.

Photosynthesis requires both light energy and a source of electrons, which are used to reduce CO_2 to form organic molecules such as glucose. (Recall the discussion of photosynthesis as well as metabolic diversity in Chapter 9.) Most likely, the first **photoautotrophs** used the energy of sunlight to obtain electrons by splitting hydrogen-rich molecules such as H_2S, releasing elemental sulfur (not oxygen) in the process. Splitting H_2S is energetically much easier than splitting H_2O because sulfur is not electronegative like oxygen (see Chapter 9). Indeed, the green sulfur bacteria and the purple sulfur bacteria still use H_2S as a hydrogen (electron) source for photosynthesis.

The first photosynthetic autotrophs to obtain hydrogen electrons by splitting *water* were the **cyanobacteria**. Water was quite abundant on early Earth, as it is today, and the selective advantage of splitting water allowed cyanobacteria to thrive. The process of splitting water released oxygen as a gas (O_2). Initially, the oxygen released during photosynthesis oxidized minerals in the ocean and in Earth's crust, and oxygen did not begin to accumulate in the atmosphere for a long time. Eventually, however, oxygen levels increased in the ocean and the atmosphere.

Scientists estimate the timing of the events just described on the basis of geologic and fossil evidence. Fossils from that period, which include rocks containing traces of chlorophyll as well as the fossil stromatolites discussed earlier, indicate that the first photosynthetic organisms may have appeared as early as 3.5 bya. This evidence suggests that heterotrophic forms may have existed even earlier.

Aerobes appeared after oxygen increased in the atmosphere

Based on sulfur isotope data from ancient rocks in South Africa, it appears that cyanobacteria had produced enough oxygen to begin significantly changing the composition of the atmosphere by 2.4 bya. This date may be changed as more data accumulate. Geoscientists at Pennsylvania State University have found strong isotopic evidence in Australia that oxygen was present in the oceans as early as 3.46 bya, and scientists are now looking for the same kind of evidence in other sedimentary layers known to be older than 2.4 bya.

The increase in atmospheric oxygen affected life profoundly. The oxygen poisoned *obligate anaerobes* (organisms that cannot use oxygen for cellular respiration), and many species undoubtedly perished. Some anaerobes, however, survived in environments where oxygen did not penetrate; adaptations evolved in others that neutralized the oxygen so that it could not harm them. In some organisms, called **aerobes**, a respiratory pathway that *used* oxygen to extract more energy from food evolved. Aerobic respiration (see Chapter 8) was joined with the existing anaerobic process of glycolysis.

The evolution of organisms that could use oxygen in their metabolism had several consequences. Organisms that respire aerobically gain much more energy from a single molecule of glucose than anaerobes gain by fermentation. (Recall the comparison of fermentation and aerobic respiration in Table 8-2.) As a result, the newly evolved aerobic organisms were more efficient and more competitive than anaerobes. Coupled with the poisonous nature of oxygen to many anaerobes, the efficiency of aerobes forced anaerobes into relatively minor roles. Today, the vast majority of organisms—including plants, animals, and most fungi, protists, archaea, and bacteria—use aerobic respiration; only a few archaea and bacteria and even fewer protists and fungi are anaerobic.

The evolution of aerobic respiration stabilized both oxygen and carbon dioxide levels in the biosphere. Photosynthetic organisms used carbon dioxide as a source of carbon for synthesizing organic compounds. This raw material would have been depleted from the atmosphere in a relatively brief period without the advent of aerobic respiration, which released carbon dioxide as a waste product from the complete breakdown of organic molecules. Carbon thus started cycling in the biosphere, moving from the nonliving physical environment to photosynthetic organisms to heterotrophs that ate the photosynthetic organisms (see Chapter 55). Aerobic respiration released carbon back into the physical environment as carbon dioxide, and the carbon cycle continued. In a similar manner, molecular oxygen was produced by photosynthesis and used during aerobic respiration.

Another significant consequence of photosynthesis occurred in the upper atmosphere, where molecular oxygen reacted to form **ozone** (O_3) (FIG. 21-7). A layer of ozone eventually blanketed Earth, preventing much of the sun's ultraviolet radiation from penetrating to the surface. With the ozone layer's protection from the mutagenic effect of ultraviolet radiation, organisms could live closer to the surface in aquatic environments and eventually move onto land. Because the energy in ultraviolet radiation may have been necessary to form organic molecules, however, their abiotic synthesis decreased.

Key Point

Ozone (O_3) forms in the upper atmosphere when ultraviolet radiation from the sun breaks the double bonds of oxygen molecules.

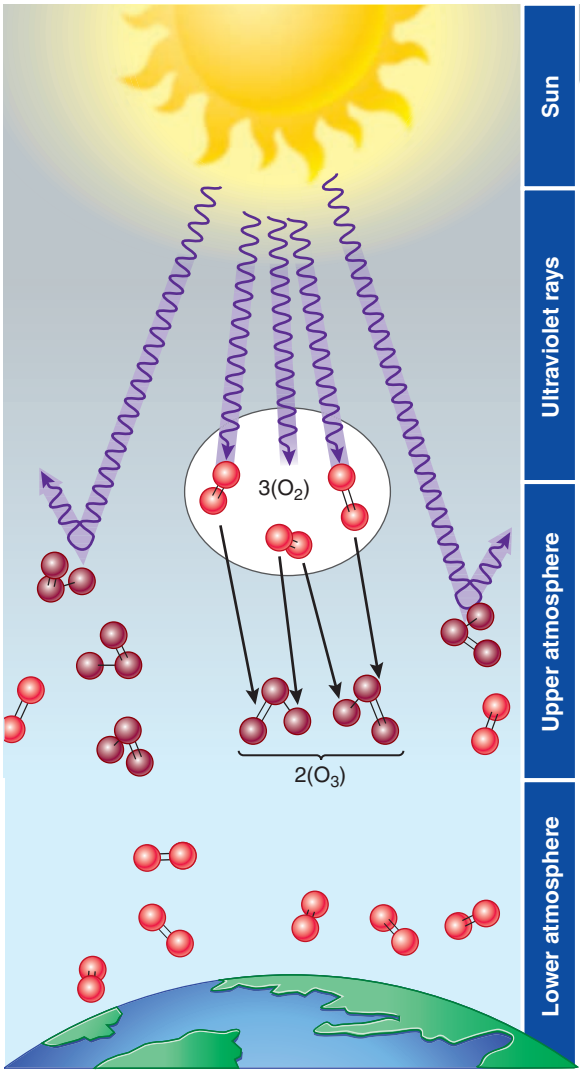

Figure 21-7 The formation of ozone

CONNECT As discussed in Chapter 57, certain human-produced chemicals rise to the stratosphere and react chemically with ozone. What consequences would you expect this reaction to have for organisms?

Eukaryotic cells descended from prokaryotic cells

Eukaryotes may have appeared in the fossil record as early as 2.2 bya, and geochemical evidence suggests that eukaryotes were present much earlier. *Steranes*, molecules derived from steroids, have been discovered in Australian rocks dated at 2.7 billion years old. Because bacteria are not known to produce steroids, the steranes may be biomarkers for eukaryotes. These ancient rocks lack fossil traces of ancient organisms because the rocks have since been exposed to heat and pressure that would have destroyed any fossilized cells. Steranes, however, are very stable in the presence of heat and pressure.

Eukaryotes arose from prokaryotes. Recall from Chapter 4 that archaeal and bacterial cells lack nuclear envelopes as well as other membranous organelles such as mitochondria and chloroplasts. How did these organelles arise? According to the hypothesis of **serial endosymbiosis**, organelles such as mitochondria and chloroplasts may have originated from mutually advantageous symbiotic relationships between two prokaryotic organisms (FIG. 21-8). Chloroplasts apparently evolved from photosynthetic bacteria (cyanobacteria) that lived inside larger heterotrophic cells, whereas mitochondria presumably evolved from aerobic bacteria (perhaps ancient purple bacteria) that lived inside larger anaerobic cells. See Chapter 25 for a discussion of the hypothesis that the larger host cells were derived from a group of ancient archaea. Thus, evidence is accumulating that early eukaryotic cells were assemblages of formerly free-living prokaryotes.

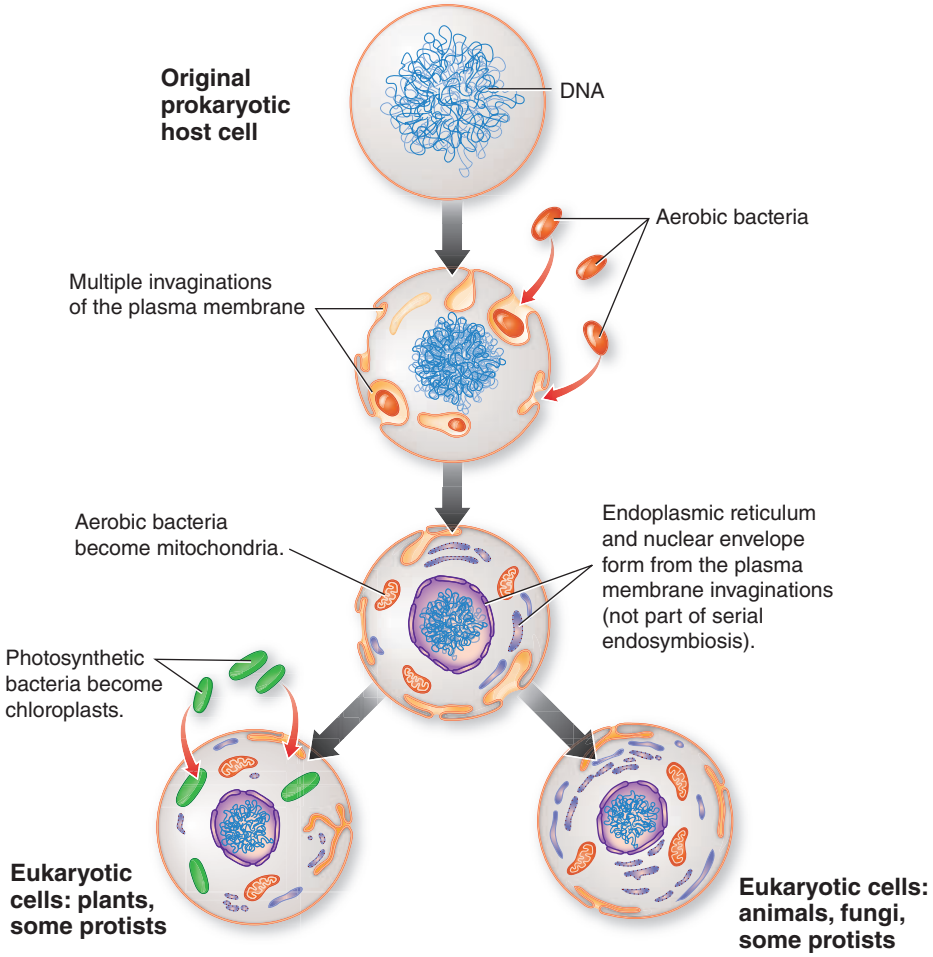

Figure 21-8 Serial endosymbiosis

How did these bacteria come to be **endosymbionts**, which are organisms that live symbiotically inside a host cell? They may originally have been ingested, but not digested, by a host cell. Once incorporated, they could have survived and reproduced along with the host cell so that future generations of the host also contained endosymbionts. A mutualistic relationship evolved between these two organisms in which each contributed something to the other. Eventually, the endosymbiont lost the ability to exist outside its host, and the host cell lost the ability to survive without its endosymbionts. This hypothesis stipulates that each of these partners brought to the relationship something that the other lacked. For example, mitochondria provided the ability to carry out the aerobic respiration lacking in the original anaerobic host cell. Chloroplasts provided the ability to use a simple carbon source (CO_2) to produce needed organic molecules. The host cell provided endosymbionts with a safe environment and raw materials or nutrients.

The principal evidence in favor of serial endosymbiosis is that mitochondria and chloroplasts possess some (although not all) of their own genetic material and translational components. They have their own DNA (as a circular molecule similar to that of archaea and bacteria; discussed in Chapter 25) and their own ribosomes (which resemble bacterial rather than eukaryotic ribosomes). Mitochondria and chloroplasts also possess some of the machinery for protein synthesis, including tRNA molecules, and conduct protein synthesis on a limited scale independent of the nucleus. Furthermore, it is possible to poison mitochondria and chloroplasts with an antibiotic that affects bacteria but not eukaryotic cells. As discussed in Chapter 4, double membranes envelope mitochondria and chloroplasts. The outer membrane apparently developed from the invagination (infolding) of the host cell's plasma membrane, whereas the inner membrane is derived from the endosymbiont's plasma membrane. (Serial endosymbiosis is discussed in greater detail in Chapter 26.)

Many endosymbiotic relationships exist today. Many corals have algae living as endosymbionts within their cells (see Fig. 54-12). Protozoa (*Myxotricha paradoxa*) live symbiotically

in the gut of termites; in turn, several different endosymbionts, including spirochete bacteria, attach to the protozoa and function as whiplike flagella, allowing the protozoa to move.

Although much evidence supports serial endosymbiosis, it does not completely explain the evolution of eukaryotic cells from prokaryotes. For example, serial endosymbiosis does not currently explain how a double membranous envelope came to surround the genetic material in the nucleus.

CHECKPOINT 21.2

- What major steps probably occurred in the origin of cells?
- **CONNECT** How did the presence of molecular oxygen in the atmosphere affect early life?
- **VISUALIZE** Draw a simple sketch illustrating the way in which aerobic bacteria are hypothesized to have become incorporated into an original prokaryotic host cell.

21.3 The History of Life

LEARNING OBJECTIVE

6 Briefly describe the distinguishing organisms and major biological events of the Ediacaran period and the Paleozoic, Mesozoic, and Cenozoic eras.

The sequence of biological, climate, and geologic events that make up the history of life is recorded in rocks and fossils. The sediments of Earth's crust consist of five major rock strata (layers), each subdivided into minor strata, lying one on top of the other. Very few places on Earth show all layers, but the strata present typically occur in the correct order, with younger rocks on top of older ones. These sheets of rock formed from the accumulation of mud and sand at the bottoms of the ocean, seas, and lakes. Each layer contains certain characteristic **index fossils** that identify deposits made at about the same time in different parts of the world.

Geologists divide Earth's history into units of time based on major geologic, climate, and biological events. **Eons** are the largest divisions of the geologic time scale. Eons are divided into **eras**; where fossil evidence exists, these divisions are based primarily on organisms that characterized each era. Eras are subdivided into **periods**, which in turn are composed of **epochs**.

Relatively little is known about Earth from its beginnings approximately 4.6 bya up to 2.5 bya. Life originated on Earth during the **Archaean eon**, the period between 4.0 bya when Earth's crust formed and 2.5 bya (TABLE 21-1). Signs of life date as early as 3.5 bya. Not much physical evidence is available because the rocks of the Archaean eon, being extremely ancient, are deeply buried in most parts of the world. Ancient rocks are exposed in a few places, including the bottom of the Grand Canyon and along the shores of Lake Superior. Many Archaean rock formations have revealed what appear to be microfossils of cyanobacteria and other bacteria.

Rocks from the Ediacaran period contain fossils of cells and simple animals

That part of time from 2500 mya to 541 mya is known as the **Proterozoic eon**. This enormous span of time is easier to study than the preceding Archaean eon because the rocks are less altered by heat and pressure. Life at the beginning of the Proterozoic eon consisted of prokaryotes such as cyanobacteria. Stromatolites were abundant. About 2.2 bya, the first eukaryotic cells appeared. By the end of the Proterozoic eon, multicellularity was evident in the abundant fossils of small, soft-bodied, invertebrate animals.

The **Ediacaran period** (pronounced "ee-dee-ack´-uh-run"), from 635 mya to 541 mya, is the last (most recent) period of the Proterozoic eon. It is named for the fossil deposits in the Ediacara Hills in South Australia, although Ediacaran fossils are also found in Newfoundland, the Mackenzie Mountains of northwestern Canada, the Doushantuo Formation of China, and other locations. Currently, more than 270 Ediacaran species have been identified and described.

Ediacaran fossils are the oldest known fossils of multicellular animals (FIG. 21-9). Experts have not yet identified all the simple, soft-bodied animals found in the Ediacara Hills and at other sites. Some paleontologists interpret many of these fossils as early sponges, jellyfish, corals, and comb jellies; however, other scientists think that the Ediacaran animals were not ancestral to modern-day species but instead became extinct at the end of the Ediacaran period.

A diversity of organisms evolved during the Paleozoic era

The **Paleozoic era** began approximately 541 mya and lasted about 289 million years. It is divided into six periods: Cambrian, Ordovician, Silurian, Devonian, Carboniferous, and Permian.

Chase Studio/Science Source

Figure 21-9 Reconstruction of life in an Ediacaran sea

The organisms shown here are based on fossils from the Ediacara Hills of South Australia, although similar associations have been found in Ediacaran rocks from every continent except Antarctica. Shown are organisms that some scientists have interpreted as jellyfish, flatworms, algae, and paddle-shaped organisms similar in appearance to soft corals.

Table 21-1 Some Important Biological Events in Geologic Time

Eon	Era	Period	Epoch	Time*	Some Important Biological Events
Phanerozoic eon	Cenozoic era	Quaternary period	Holocene epoch	0.01 (10,000 years ago)	Decline of some woody plants; rise of herbaceous plants; age of *Homo sapiens*
			Pleistocene epoch	2.6 mya	Extinction of some plant species; extinction of many large mammals at end
		Neogene period	Pliocene epoch	5 mya	Expansion of grasslands and deserts; many grazing animals
			Miocene epoch	23 mya	Flowering plants continue to diversify; diversity of songbirds and grazing mammals
		Paleogene period	Oligocene epoch	34 mya	Spread of forests; apes appear; present mammalian families are represented
			Eocene epoch	56 mya	Flowering plants dominant; modern mammalian orders appear and diversify; modern bird orders appear
			Paleocene epoch	66 mya	Semitropical vegetation (flowering plants and conifers) widespread; primitive mammals diversify
	Mesozoic era	Cretaceous period		145 mya	Rise of flowering plants; dinosaurs reach peak, then become extinct at end; toothed birds become extinct
		Jurassic period		201 mya	Gymnosperms common; large dinosaurs; first toothed birds
		Triassic period		252 mya	Gymnosperms dominant; ferns common; first dinosaurs; first mammals
	Paleozoic era	Permian period		299 mya	Conifers diversify; cycads appear; modern insects appear; mammal-like reptiles; extinction of many invertebrates and vertebrates at end of Permian
		Carboniferous period		359 mya	Forests of ferns, club mosses, horsetails, and gymnosperms; many insect forms; spread of ancient amphibians; first reptiles
		Devonian period		419 mya	First forests; gymnosperms appear; many trilobites; wingless insects appear; fishes with jaws appear and diversify; amphibians appear
		Silurian period		444 mya	Vascular plants appear; coral reefs common; jawless fishes diversify; terrestrial arthropods
		Ordovician period		485 mya	Fossil spores of terrestrial plants (bryophytes?); invertebrates dominant; coral reefs appear; first fishes appear
		Cambrian period		541 mya	Bacteria and cyanobacteria; algae; fungi; age of marine invertebrates; first chordates
Proterozoic eon		Ediacaran period		635 mya	Algae and soft-bodied invertebrates diversify
		Early Proterozoic period		2500 mya	Eukaryotes evolve
Archaean eon				4000 mya	Oldest known rocks; prokaryotes evolve; atmospheric oxygen begins to increase

* Time from beginning of eon, period, or epoch to present (millions of years). Dates from Walker, J.D., Geissman, J.W, Bowring, S.A., and Babcock, L.E., compilers, 2012, Geologic Time Scale v.4:0: Geological Society of America.

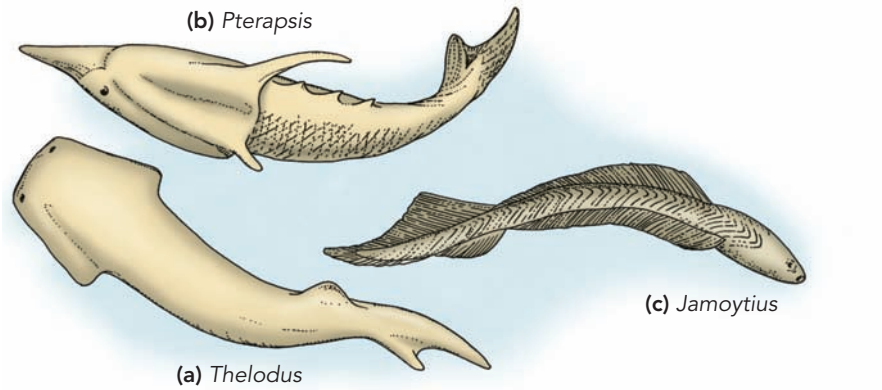
Rocks rich in fossils represent the oldest subdivision of the Paleozoic era, the **Cambrian period**. For about 40 million years, evolution was in such high gear, with the sudden appearance of many new animal body plans, that this period is called the **Cambrian radiation**, or more informally, **Cambrian explosion**. Fossils of all contemporary animal phyla are present, along with many bizarre, extinct phyla, in marine sediments. The seafloor was covered with sponges, corals, sea lilies, sea stars, snails, clamlike bivalves, primitive squidlike cephalopods, lampshells (brachiopods), and trilobites (see Fig. 31-26). In addition, small vertebrates—cartilaginous fishes—became established in the marine environment.

Scientists have not determined the factors responsible for the Cambrian radiation, a period unmatched in the evolutionary history of life. There is some evidence that oxygen concentrations, which had continued to gradually increase in the atmosphere, passed some critical threshold late in the Proterozoic eon. Scientists who advocate the *oxygen enrichment hypothesis* note that until late in the Proterozoic eon, Earth did not have enough oxygen to support larger animals. The most important fossil sites that document the Cambrian radiation are the *Chengjiang site* in China (for Early Cambrian fossils) and the *Burgess Shale* in British Columbia (for Middle Cambrian fossils) (FIG. 21-10).

According to geologists, seas gradually flooded the continents during the Cambrian period. In the **Ordovician period**, much land was covered by shallow seas, in which there was another burst of evolutionary diversification, although not as dramatic as the Cambrian radiation. The Ordovician seas were inhabited by giant cephalopods, squidlike animals with straight shells 5 to 7 m (16 to 23 ft) long and 30 cm (12 in.) in diameter. Coral reefs first appeared during this period, as did small, jawless, bony-armored fishes called *ostracoderms* (FIG. 21-11). Lacking jaws, these fishes typically had round or slitlike mouth openings that may have sucked in small food particles from the water or scooped up organic debris from the bottom. Ordovician deposits also contain fossil spores of terrestrial (land-dwelling) plants, suggesting that the colonization of land had begun.



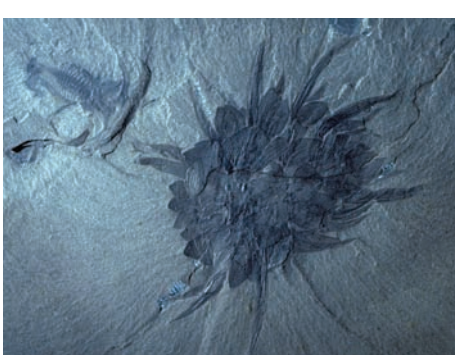


Figure 21-11 Ostracoderms
Ostracoderms, primitive jawless fishes that lived in the Ordovician, Silurian, and Devonian periods, ranged from 10 to 50 cm (4 to 20 in.) in length.

During the **Silurian period**, jawless fishes diversified considerably, and jawed fishes first appeared. Definitive evidence of two life-forms of great biological significance appeared in the Silurian period: terrestrial plants and air-breathing animals. The evolution of plants allowed animals to colonize the land because plants provided the first terrestrial animals with food and shelter. All air-breathing land animals discovered in Silurian rocks were arthropods: millipedes, spiderlike arthropods, and possibly centipedes. From an ecological perspective, the energy flow from plants to animals probably occurred via detritus, which is organic debris from decomposing organisms, rather than directly from living plant material. Millipedes eat plant detritus today, and spiders and centipedes prey on millipedes and other animals.

The **Devonian period** is frequently called the Age of Fishes. This period witnessed the explosive radiation of fishes with jaws, an adaptation that lets a vertebrate chew and bite. Armored *placoderms*, an extinct group of jawed fishes, diversified to exploit varied lifestyles (see Fig. 32-10). Appearing in Devonian deposits are sharks and the two predominant types of bony fishes: lobe-finned fishes and ray-finned fishes, which gave rise to the major orders of modern fishes (see Chapter 31).

Tiktaalik was a transitional form between fishes and *tetrapods*, which are vertebrates with four limbs (see Fig. 32-17). *Tiktaalik* is considered a fish because it had scales and fins. Like tetrapods, however, *Tiktaalik* had a movable neck and ribs that enclosed lungs. Upper (more recent) Devonian sediments contain fossil remains of salamander-like amphibians (*labyrinthodonts*) that were often quite large, with short necks and heavy, muscular tails. Wingless insects also originated in the Late Devonian period.

The early vascular plants (plants with specialized tissue to conduct water and nutrients) diversified during the Devonian period in a burst of evolution that rivaled that of animals during the Cambrian radiation. With the exception of flowering plants, all major plant groups appeared during the Devonian period. Forests of ferns, club mosses, horsetails, and seed ferns (an extinct group of ancient plants that had fernlike foliage but reproduced by forming seeds) flourished.

The **Carboniferous period** is named for the great swamp forests whose remains persist today as major coal deposits. Much of the land during this time was covered with low swamps filled with horsetails, club mosses, ferns, seed ferns, and gymnosperms, which are seed-bearing plants such as conifers (FIG. 21-12). Amphibians, which underwent an **adaptive radiation** and exploited both aquatic and terrestrial ecosystems, were the dominant terrestrial carnivores of the Carboniferous period. Reptiles first appeared and diverged to form two major lines at this time. One line consisted of mostly small and midsized insectivorous (insect-eating) lizards; this line later led to lizards, snakes, crocodiles, dinosaurs, and birds. The other reptilian line led to a diverse group of Permian and Early Mesozoic mammal-like reptiles. Two groups of winged insects, cockroaches and dragonflies, appeared in the Carboniferous period.

Amphibians continued in importance during the **Permian period**, but they were no longer the dominant carnivores in terrestrial ecosystems. During the Permian period, reptiles diversified and dominated both carnivorous and herbivorous terrestrial lifestyles. One important group of mammal-like reptiles, originating in the Permian and extending into the Mesozoic era, were the *therapsids*, a group that included the ancestor of mammals (see Fig. 32-24). During the Permian period, seed plants diversified and dominated most plant communities. Cone-bearing conifers were widespread, and cycads (plants with crowns of fernlike leaves and large, seed-containing cones) and ginkgoes (trees with fan-shaped leaves and exposed, fleshy seeds) appeared.

The greatest **mass extinction** of all time occurred at the end of the Paleozoic era, between the Permian and Triassic periods, 252 mya. More than 90% of all existing marine species became extinct at this time, as did more than 70% of the vertebrate genera living on land. There is also evidence of a major extinction of plants. Many causes for the Late Permian mass extinction have been suggested, from meteor impacts to global warming to changes in ocean chemistry. Recently a great deal of attention has been given to massive volcanic activity occurring at that time in a region of present-day Siberia known as the Siberian Traps. These giant eruptions are thought to have released not only corrosive sulfur dioxide into the atmosphere, but also vast quantities of carbon dioxide, capable of acidifying the oceans and affecting the calcium-containing shells of many types of sea life. Regardless of cause, evidence suggests that the extinction occurred globally in a very compressed period, within a few hundred thousand years. In the geologic time scale, this period is extremely short, suggesting that some sort of catastrophic event caused the mass extinction.

Dinosaurs and other reptiles dominated the Mesozoic era

The **Mesozoic era** began about 252 mya and lasted some 186 million years. It is divided into the Triassic, Jurassic, and Cretaceous periods. Fossil deposits from the Mesozoic era occur worldwide. Notable sites include the *Yixian Formation* in northeastern China,

the Solnhofen Limestone in Germany, northwestern Patagonia in Argentina, the Sahara in central Niger, the Badlands in South Dakota, and other sites in western North America.

The outstanding feature of the Mesozoic era was the origin, differentiation, and ultimately the extinction of a large variety of reptiles. For this reason, the Mesozoic era is commonly called the Age of Reptiles. Most of the modern orders of insects appeared during the Mesozoic era. Snails and bivalves (clams and their relatives) increased in number and diversity, and sea urchins reached their peak diversity. From a botanical viewpoint, the Mesozoic era was dominated by gymnosperms until the Mid-Cretaceous period, when the flowering plants first diversified.

During the **Triassic period**, reptiles underwent an adaptive radiation leading to the formation of many groups. On land, the dominant Triassic groups were the mammal-like therapsids, which ranged from small-sized insectivores (insect-eating reptiles) to moderately large herbivores (plant-eating reptiles), and a diverse group of *thecodonts*, early "ruling reptiles," which were primarily carnivores. Thecodonts are the ancestral reptiles that gave rise to crocodilians, flying reptiles, dinosaurs, and birds.

In the ocean several important marine reptile groups, the plesiosaurs and ichthyosaurs, appeared in the Triassic period. *Plesiosaurs* had bodies up to 15 m (about 49 ft) long and paddlelike fins. *Ichthyosaurs* had body forms superficially resembling those of sharks or porpoises, with short necks, large dorsal fins, and shark-type tails (FIG. 21-13). Ichthyosaurs had very large eyes, which may have helped them see at diving depths of 500 m (1650 ft) or more.

Pterosaurs, the first flying reptiles, appeared and underwent considerable diversification during the Mesozoic era (FIG. 21-14). This group produced some quite spectacular forms, most notably the giant *Quetzalcoatlus*, known from fragmentary Cretaceous fossils in Texas to have had a wingspan of 11 to 15 m (36 to 49 ft). Pterosaur wings were leathery membranes of skin that were supported by an elongated fourth finger bone. Claws extended from the other finger bones.

The first mammals to appear in the Triassic period were small insectivores that evolved from the mammal-like therapsids. Mammals diversified into a variety of mostly small, nocturnal insectivores during the remainder of the Mesozoic era, with marsupial and placental mammals appearing later in the Mesozoic.

During the **Jurassic** and **Cretaceous periods**, crocodiles, lizards, snakes, and birds appeared, and the dinosaurs diversified dramatically (FIG. 21-15). The *mosasaurs*, one group of lizards, were large, voracious marine predators during the Late Cretaceous period. The mosasaurs, which are now extinct, attained lengths of 10 m (33 ft) or more.

The evolutionary radiation of the dinosaurs expanded from one lineage to several dozen that ecologically filled a variety of adaptive zones. Dinosaurs are placed in two main groups based on their pelvic bone structure: the *saurischians* and the *ornithischians* (FIG. 21-16). Some saurischians were fast, bipedal (walking on two feet) forms ranging from those the size of a dog to the ultimate representatives of this group, the gigantic carnivores of the Cretaceous period: *Tyrannosaurus, Giganotosaurus*, and *Carcharodontosaurus*. Other saurischians were huge, quadrupedal (walking on four feet) dinosaurs that ate plants. Some of these dinosaurs were the largest terrestrial animals that have ever lived, including *Argentinosaurus*, with an estimated length of 30 m (98 ft) and an estimated weight of 72 to 90 metric tons (80 to 100 tons).

The other group of dinosaurs, the ornithischians, was entirely herbivorous. Although some ornithischians were bipedal, most were quadrupedal. Some had no front teeth and possessed stout, horny, birdlike beaks. In some species these beaks were broad and ducklike, hence the common name *duck-billed dinosaurs*. Other ornithischians had great armor plates, possibly as protection against carnivorous saurischians. *Ankylosaurus*, for example, had a broad, flat body covered with armor plates (actually bony scales embedded in the skin) and large, laterally projecting spikes.

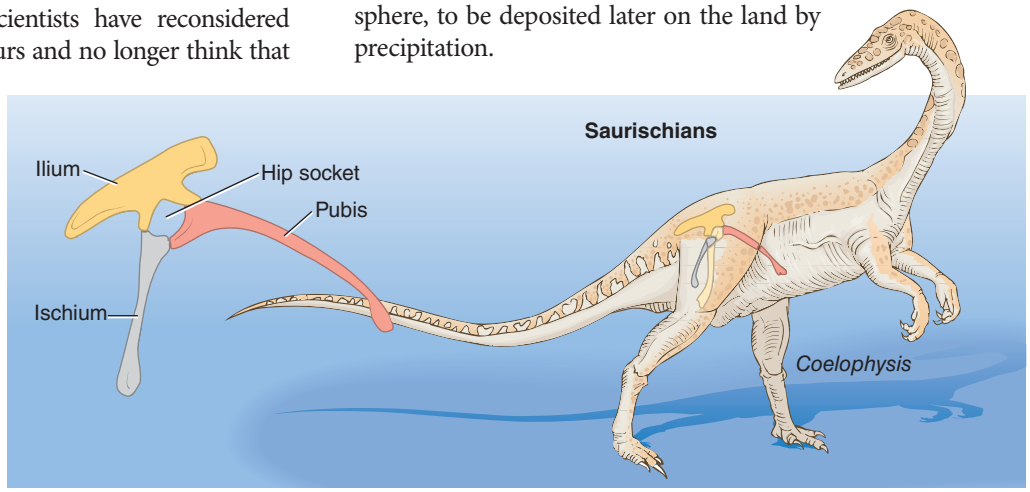
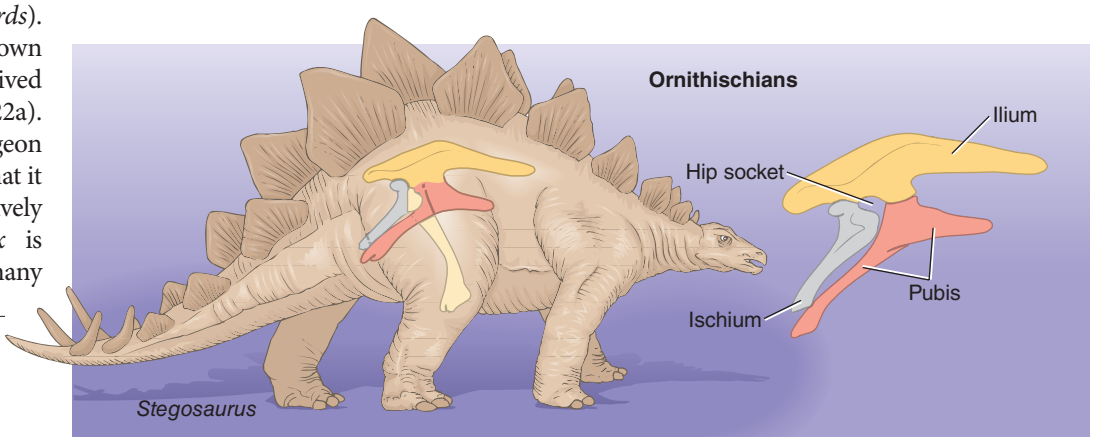
Figure 21-15 Dinosaurs



Three *Deinonychus* dinosaurs attack a larger *Tenontosaurus*. The name *Deinonychus* means "terrible claw" and refers to the enlarged, sharp claw on the second digit of its hind feet. *Deinonychus* dinosaurs were small (3 m, or 10 ft in length) but fearsome predators that hunted in packs. *Tenontosaurus* adults were as long as 7.5 m (24 ft).

Over the past few decades, scientists have reconsidered many traditional ideas about dinosaurs and no longer think that they were all cold-blooded, slow-moving monsters living in swamps. Recent evidence suggests that at least some dinosaurs were warm-blooded, agile, and able to move extremely fast. Many dinosaurs appear to have had complex social behaviors, including courtship rituals and parental nurturing of their young. Some species lived in social groups and hunted in packs.



Birds appeared by the Late Jurassic period, and fossil evidence indicates that they evolved directly from saurischian dinosaurs (see *Inquiring About: The Origin of Flight in Birds*). *Archaeopteryx*, the oldest known bird in the fossil record, lived about 150 mya (see Fig. 32-22a). It was about the size of a pigeon and had rather feeble wings that it used to glide rather than actively fly. Although *Archaeopteryx* is considered a bird, it had many reptilian features, including a mouthful of teeth and a long, bony tail.

Thousands of well-preserved bird fossils have been found in Early Cretaceous deposits in China. They include *Sinornis*, a 135-million-year-old sparrow-sized bird capable of perching; and the magpie-sized *Confuciusornis*, the earliest known bird with a toothless beak. *Confuciusornis* may date back as far as 142 mya.

At the end of the Cretaceous period, 66 mya, dinosaurs, pterosaurs, and many other animals abruptly became extinct. Many gymnosperms, with the exception of conifers, also perished. Evidence suggests that a catastrophic collision of a large extraterrestrial body with Earth dramatically changed the climate at the end of the Cretaceous period. Part of the evidence is a thin band of dark clay, with a high concentration of iridium, located between Mesozoic and Cenozoic sediments at more than two hundred sites around the world. Iridium is rare on Earth but abundant in meteorites. The force of the impact would have driven the iridium into the atmosphere, to be deposited later on the land by precipitation.

(a) The saurischian pelvis. Note the opening (hip socket), a trait possessed by no quadrupedal vertebrates other than dinosaurs.

(b) The ornithischian pelvis. Note that it has the hole in the hip socket but differs from the saurischian pelvis in that it has a backward-directed extension of the pubis.

Figure 21-16 Saurischian and ornithischian dinosaurs

In each dinosaur figure, the *pale yellow* femur is shown relative to the pelvic bone.

Inquiring About

The Origin of Flight in Birds

Do we know how birds evolved? The evolution of birds is arguably one of the most interesting chapters in Earth's history of life. Given the substantial fossil evidence, most paleontologists have concluded that the ancestors of birds were dinosaurs, specifically the *dromaeosaurs*, a group of ground-dwelling, bipedal theropods (carnivorous saurischians). Beginning in 1997, paleontologists made several discoveries of fossil dinosaurs with feathers, indicating that feathers appeared before birds. Scientists think that feathers evolved as one or a series of evolutionary novelties, or **preadaptations** (see Chapter 20). The first feathers may have provided thermal insulation but were subsequently modified for flight.

Once dinosaurs and early birds had feathers, how did they fly? Did tree-dwelling animals glide as an intermediate step in bird flight, or did ground-dwelling animals flap their wings and run to provide thrust and lift for a takeoff? The question about how flight originated in birds has intrigued biologists for more than a century. In 1915, U.S. zoologist William Beebe hypothesized that the ancestors of birds were probably tree-dwelling gliders that had feathers on all four limbs.[1] Because no fossil evidence supported his suggestion, scientists did not consider it seriously at the time.

Almost a century later, in 2003, a group of Chinese paleontologists announced the discovery of two nearly complete fossils of the organisms that Beebe had hypothesized.[2] The fossils of a small, feathered dromaeosaur dinosaur were found in Liaoning Province in northeastern China. The dinosaur, *Microraptor gui,* had feathers on both forelimbs and hind limbs as well as on its long tail. The figure depicts light-colored feathers to better illustrate their details, but analysis of melanosomes (pigment-containing bodies) in fossils has shown that the plumage was iridescent black, as in crows today. It was small—77 cm (about 30 in.) in length, including the tail—and appeared to be adapted to life in the trees. The feathers on *M. gui* were similar to those of modern-day birds. Downy feathers covered the body, and each limb had about 12 "primary" flight feathers and about 18 shorter, "secondary" feathers. *Microraptor gui*'s flight feathers were asymmetrical, a characteristic associated with flight or gliding in modern birds. The primary and secondary feathers followed a similar pattern on both the forelimbs and hind limbs, and this pattern resembles that on modern birds. In part because *M. gui*'s breastbone was not structured to attach large flight muscles, the dinosaur probably glided rather than flapped its wings.

Journal Nature/Portia Sloan/Getty Images

Microraptor gui, which is about 126 million years old, is not a direct ancestor of birds. Birds had already evolved when *M. gui* existed. The earliest known bird, *Archaeopteryx*, lived about 150 mya and therefore predates *M. gui* by about 25 million years. *Microraptor gui* is considered to have evolved from a *basal member*—that is, an earlier evolutionary branch—of the most recent ancestor of *Archaeopteryx* and other birds. Like *M. gui*, earlier feathered dinosaurs may have been four-winged organisms that lived and glided in the trees.

During the course of bird evolution, the feathered hind limbs may have become reduced and eventually lost. However, an alternative hypothesis is that feathered hind limbs may have been a failed evolutionary experiment restricted to dromaeosaurs and not important as an intermediate step in bird evolution. Further analysis of *M. gui* and future discoveries of earlier dromaeosaur fossils may shed some light on the importance of feathered hind limbs.

Microraptor gui has given paleontologists and biologists much to consider in the evolutionary transition from dinosaurs to birds. Scientists will continue to study and debate the evolution of flight in birds for many years.

The Chicxulub crater, buried under the Yucatán Peninsula in Mexico, is the apparent site of this collision. The impact produced giant tsunamis (tidal waves) that deposited materials from the extraterrestrial body around the perimeter of the Gulf of Mexico, from Alabama to Guatemala. It may have caused global forest fires and giant smoke and dust clouds that lowered global temperatures for many years.

Although scientists widely accept that a collision with an extraterrestrial body occurred 66 mya, they have reached no consensus about the effects of such an impact on organisms. The extinction of many marine organisms at or immediately after the time of the impact was probably the result of the environmental upheaval that the collision produced. However, many clam species associated with the mass extinction at the end of the Cretaceous period seem to have gone extinct *before* the impact, suggesting that other factors caused some of the massive extinctions occurring then.

The Cenozoic era is the Age of Mammals

With equal justice the Cenozoic era could be called the Age of Mammals, the Age of Birds, the Age of Insects, or the Age of Flowering Plants. This era is marked by the appearance of all these forms in great variety and numbers of species. The Cenozoic era extends from 66 mya to the present. It is subdivided into three periods: the **Paleogene period**, encompassing some 43 million years; the **Neogene period**, which was 20.4 million years in length; and the **Quaternary period**, which covers the last 2.6 million years. The Paleogene period is subdivided into three epochs, named from earliest to latest: Paleocene, Eocene, and Oligocene. The Neogene period is subdivided into two epochs: the Miocene and Pliocene. The Quaternary period is subdivided into the Pleistocene and Holocene epochs.

Flowering plants, which arose during the Cretaceous period, continued to diversify during the Cenozoic era. During

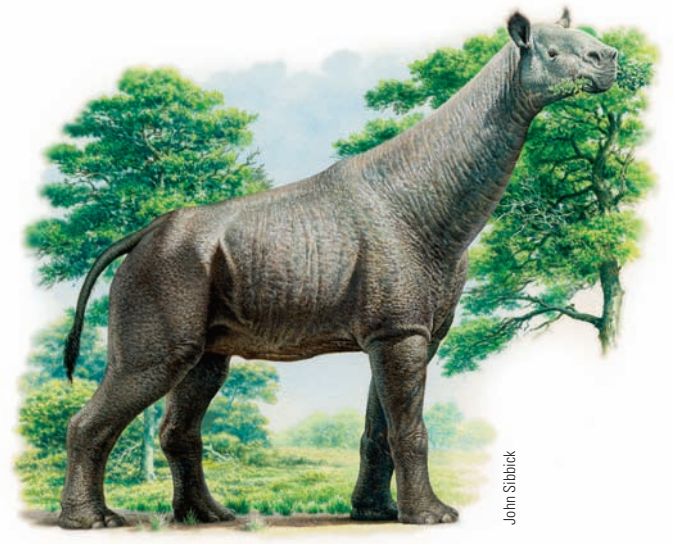
the Paleocene and Eocene epochs, fossils indicate that tropical and semitropical plant communities extended to relatively high latitudes. Palms, for example, are found in Eocene deposits in Wyoming. Later in the Cenozoic era, there is evidence of more open habitats. Grasslands and savannas spread throughout much of North America during the Miocene epoch, with deserts developing later in the Pliocene and Pleistocene epochs. During the Pleistocene epoch, plant communities changed dynamically in response to the fluctuating climates associated with the multiple advances and retreats of continental glaciers.

During the Paleocene epoch, an explosive radiation of primitive mammals occurred. Most of them were small forest dwellers that are not closely related to modern mammals. During the Eocene epoch, mammals continued to diverge, and all the modern orders first appeared. Again, many of the mammals were small, but there were also some larger herbivores.

During the Eocene epoch, there was an explosive radiation of birds, which acquired adaptations for different habitats. Paleontologists hypothesize that the jaws and beak of the flightless giant bird *Diatryma*, for example, may have been adapted primarily for crushing and slicing vegetation in Eocene forests, marshes, and grasslands. Other paleontologists hypothesize that these giant birds were carnivores that killed or scavenged mammals and other vertebrates (FIG. 21-17).



During the Oligocene epoch, many modern families of mammals evolved, including the first apes in Africa. Many lineages showed adaptations that suggest a more open type of habitat, such as grassland or savanna, than previously. Many mammals were larger than earlier mammals and had longer legs for running, specialized teeth for chewing coarse vegetation or for preying on animals, and increases in their relative brain sizes. The *indricotheres*, for example, are extinct relatives of the rhinoceros. These mammals, which lived on the grassless plains of Eurasia, became progressively larger during the Oligocene epoch (FIG. 21-18).

John Sibbick

Figure 21-17 A bird from the Eocene epoch

The flightless bird *Diatryma*, which stood 2.1 m (7 ft) tall and weighed about 175 kg (385 lb), may have been an herbivore or a formidable predator. In this picture *Diatryma* has captured a small, horselike perissodactyl.

John Sibbick

Figure 21-18 A mammal from the Oligocene epoch

Paraceratherium was an indricothere, a hornless relative of the rhinoceros. This huge land mammal was about 8 m (26 ft) long and weighed about 15 to 20 tons. It probably ate leaves and branches of deciduous trees, much as a modern-day giraffe does.

Human ancestors appeared in Africa during the Late Miocene and Early Pliocene epochs. *Homo*, the genus to which humans belong, appeared approximately 2.5 mya. (Primate evolution, including human evolution, is discussed in Chapter 22.)

The Pliocene and Pleistocene epochs witnessed the introduction of spectacular North and South American large-mammal fauna, including mastodons, saber-toothed cats, camels, giant ground sloths, and giant armadillos. However, many of the large mammals became extinct at the end of the Pleistocene epoch. This extinction was possibly due to climate change—the Pleistocene epoch was marked by several ice ages—or to the influence of humans, which had spread from Africa to Europe and Asia, and later to North and South America by crossing a land bridge between Siberia and Alaska. Archaeological evidence indicates that this mass extinction event was concurrent with the appearance of human hunters.

Recognition of the profound impact humans have had on Earth has led some scientists to propose a new geological epoch, the Anthropocene, or "Age of Humans." This hypothesis will be explored in more detail in Chapter 57.

CHECKPOINT 21.3

- **CONNECT** What is the correct order of appearance in the fossil record, starting with the earliest: eukaryotic cells, multicellular organisms, prokaryotic cells?
- **CONNECT** What is the correct order of appearance in the fossil record, starting with the earliest: reptiles, mammals, amphibians, fishes?
- **CONNECT** What is the correct order of appearance in the fossil record, starting with the earliest: flowering plants, ferns, gymnosperms?

Summary: Focus on Learning Objectives

21.1 Chemical Evolution on Early Earth *(page 443)*

1 Describe the conditions that scientists think existed on early Earth.

- Biologists generally agree that life originated from nonliving matter by **chemical evolution**. Hypotheses about chemical evolution are testable.
- Four requirements for chemical evolution are (1) the absence of oxygen, which would have reacted with and oxidized abiotically produced organic molecules; (2) energy to form organic molecules; (3) chemical building blocks, including water, minerals, and gases present in the atmosphere; and (4) sufficient time for molecules to accumulate and react.

2 Compare the prebiotic soup hypothesis with the iron–sulfur world hypothesis.

- During chemical evolution, small organic molecules formed spontaneously and accumulated. The **prebiotic soup hypothesis** proposes that organic molecules formed near Earth's surface in a "sea of organic soup" or on rock or clay surfaces. The **iron–sulfur world hypothesis** suggests that organic molecules were produced at **hydrothermal vents**, cracks in the deep-ocean floor.

21.2 The First Cells *(page 445)*

3 Outline the major steps hypothesized to have occurred in the origin of cells.

- After small organic molecules formed and accumulated, macromolecules assembled from the small organic molecules. Macromolecular assemblages called **protobionts** formed from macromolecules. Cells arose from the protobionts.
- According to a model known as the **RNA world**, RNA was the first informational molecule to evolve in the progression toward a self-sustaining, self-reproducing cell. Natural selection at the molecular level eventually resulted in the information sequence DNA → RNA → protein.

4 Explain how the evolution of photosynthetic autotrophs affected both the atmosphere and other organisms.

- The first cells were prokaryotes and were almost certainly **anaerobes**.
- The evolution of oxygen-generating photosynthesis ultimately changed early life. The accumulation of molecular oxygen in the atmosphere permitted the evolution of **aerobes**, organisms that could use oxygen for a more efficient type of cellular respiration.

5 Describe the hypothesis of serial endosymbiosis.

- Eukaryotic cells arose from prokaryotic cells. According to the hypothesis of **serial endosymbiosis**, certain eukaryotic organelles (mitochondria and chloroplasts) evolved from prokaryotic **endosymbionts** incorporated within larger prokaryotic hosts.

21.3 The History of Life *(page 451)*

6 Briefly describe the distinguishing organisms and major biological events of the Ediacaran period and the Paleozoic, Mesozoic, and Cenozoic eras.

- Life at the beginning of the **Proterozoic eon** (2500 mya to 541 mya) consisted of prokaryotes. About 2.2 bya, the first eukaryotic cells appeared. The **Ediacaran period**, from 635 mya to 541 mya, is the last period of the Proterozoic eon. Ediacaran fossils are the oldest known fossils of multicellular animals. Ediacaran fauna were small, soft-bodied invertebrates.
- During the **Paleozoic era**, which began about 541 mya and lasted approximately 289 million years, all major groups of plants, except flowering plants, and all animal phyla appeared. Fishes and amphibians flourished, and reptiles appeared. The greatest mass extinction of all time occurred at the end of the Paleozoic era, 252 mya. More than 90% of marine species and 70% of land-dwelling vertebrate genera as well as many plant species became extinct.
- The **Mesozoic era** began about 252 mya and lasted some 186 million years. Flowering plants appeared, and reptiles diversified. Dinosaurs, which descended from early reptiles, dominated. Insects flourished, and birds and early mammals appeared. At the end of the Cretaceous period, 66 mya, many species abruptly became extinct. A collision of a large extraterrestrial body with Earth may have resulted in dramatic climate changes that played a role in this mass extinction.

- In the **Cenozoic era**, which extends from 66 mya to the present, flowering plants, birds, insects, and mammals diversified greatly. Human ancestors appeared in Africa during the Late Miocene and Early Pliocene epochs.

Test Your Understanding

Know and Comprehend

1. Energy, the absence of molecular oxygen, chemical building blocks, and time were the requirements for (a) chemical evolution (b) biological evolution (c) the Cambrian radiation (d) the mass extinction episode at the end of the Cretaceous period (e) directed evolution
2. Many scientists think that _____ was the first information molecule to evolve. (a) DNA (b) RNA (c) a protein (d) an amino acid (e) a lipid
3. The first cells were probably (a) photosynthetic (b) aerobes (c) anaerobes (d) a and b (e) a and c

4. According to the hypothesis of serial endosymbiosis, (a) life originated from nonliving matter (b) the pace of evolution quickened at the start of the Cambrian period (c) chloroplasts, mitochondria, and possibly other organelles originated from intimate relationships among prokaryotic cells (d) banded iron formations reflect the buildup of sufficient oxygen in the atmosphere to oxidize iron at Earth's surface (e) the first photosynthetic organisms appeared 3.1 bya to 3.5 bya
5. During the Early _____, life consisted of prokaryotic cells, but by the end of this geologic time span, multicellular eukaryotic organisms had evolved. (a) Cenozoic era (b) Paleozoic era (c) Mesozoic era (d) Archaean eon (e) Proterozoic eon
6. Geologists divide the eons into (a) periods (b) epochs (c) eras (d) millennia (e) none of the preceding
7. Ediacaran fossils (a) are the oldest known fossils of multicellular animals (b) come from the Burgess Shale in British Columbia (c) contain remains of large salamander-like organisms (d) are the oldest fossils of early vascular plants (e) contain a high concentration of iridium
8. The time of greatest evolutionary diversification in the history of life occurred during the (a) Cambrian period (b) Ordovician period (c) Silurian period (d) Carboniferous period (e) Permian period
9. The greatest mass extinction episode in the history of life occurred at what boundary? (a) Pliocene–Pleistocene (b) Permian–Triassic (c) Mesozoic–Cenozoic (d) Cambrian–Ordovician (e) Triassic–Jurassic
10. The Age of Reptiles corresponds to the (a) Paleozoic era (b) Mesozoic era (c) Cenozoic era (d) Pleistocene epoch (e) Permian period
11. Evidence exists that a catastrophic collision between Earth and a large extraterrestrial body occurred 66 mya, resulting in the extinction of (a) worms, mollusks, and soft-bodied arthropods (b) jawless ostracoderms and jawed placoderms (c) dinosaurs, pterosaurs, and many gymnosperm species (d) mastodons, saber-toothed cats, and giant ground sloths (e) ferns, horsetails, and club mosses
12. Flowering plants and mammals diversified and became dominant during the (a) Paleozoic era (b) Mesozoic era (c) Cenozoic era (d) Devonian period (e) Cambrian period

Apply and Analyze

13. Which are thought to have evolved first, aerobic bacteria or photosynthetic bacteria? Explain.

Evaluate and Synthesize

14. **EVOLUTION LINK** If you were studying how protobionts evolved into cells and you developed a protobiont that was capable of self-replication, would you consider it a living cell? Why or why not?
15. **EVOLUTION LINK** If living cells were produced in a test tube from nonbiological components by chemical processes, would this accomplishment prove that life evolved in a similar manner billions of years ago? Explain your answer.
16. **EVOLUTION LINK** Why did the evolution of multicellular organisms such as plants and animals have to be preceded by the evolution of oxygen-producing photosynthesis?
17. **INTERPRET DATA** Evidence for the oldest cyanobacterial fossils (as stromatolites) dates to about 2 billion years, but molecular evidence inferred from lipids in ancient rocks puts the date for living cyanobacteria and eukaryotes at 2.7 billion years. Develop two opposing hypotheses to explain the discrepancy between the dates.

22 The Evolution of Primates

Twelve years after Darwin wrote *On the Origin of Species by Means of Natural Selection*, he published another controversial book, *The Descent of Man*, which addressed human evolution. In this later book, Darwin hypothesized that humans and apes share a common ancestry. For nearly a century after Darwin's studies, fossil evidence of human ancestry remained fairly incomplete. However, research during the last several decades, especially in Africa, has yielded a rapidly accumulating set of fossils that gives an increasingly clear answer to the question, Where did we come from?

Fossil evidence from **paleoanthropology**, the study of human evolution, has allowed scientists to infer not only the structure but also the habits of early humans and other primates. Teeth and bones are the main fossil evidence that paleoanthropologists study (see photograph). Much information can be obtained by studying teeth, which have changed dramatically during the course of primate and human evolution. Because tooth enamel is more mineralized (harder) than bone, teeth are more likely to fossilize. The teeth of each primate species, living or extinct, are distinctive enough to identify the species, approximate age, diet, and even sex of the individual.

Based on fossil evidence, paleontologists hypothesize that the first primates descended from small, shrewlike *placental mammals* that lived in trees and ate insects. (Placental mammals are the largest and most successful group of mammals. They have a **placenta**, an organ that exchanges materials between the mother and the embryo/fetus developing in the uterus.)

KEY CONCEPTS

22.1 Humans, along with lemurs, tarsiers, monkeys, and apes, are classified in the order Primates. This classification is based on close evolutionary ties.

22.2 The study of living primates provides clues to help scientists reconstruct the adaptations and lifestyles of early primates, some of which were ancestors of humans.

22.3 Fossil evidence indicates that the earliest human ancestors arose in Africa and shared many features with their apelike ancestors. The human brain did not begin to enlarge to its present size and complexity until long after bipedal locomotion had evolved.

22.4 Human culture began when human ancestors started making stone tools.

Many traits of the 233 generally recognized living primate species are related to their **arboreal** (tree-dwelling) past. This chapter focuses on humans and their ancestors, who differ from most other primates because they did not remain in the trees but instead adapted to a terrestrial way of life.

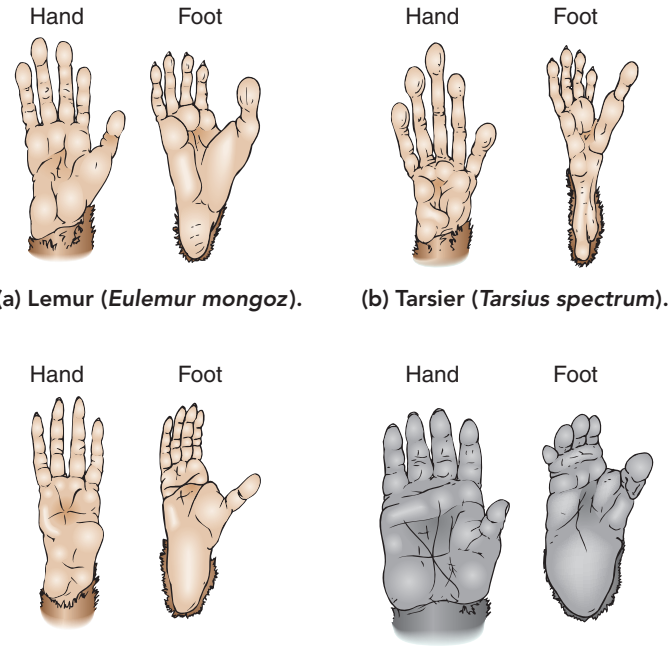
22.1 Primate Adaptations

LEARNING OBJECTIVE

1 Describe the structural adaptations that primates have for life in treetops.

Humans and other **primates**—including lemurs, tarsiers, monkeys, and apes—are mammals that share such traits as flexible hands and feet with five digits, a strong social organization, and front-facing eyes, which permit depth perception. Mammals (class Mammalia) evolved from mammal-like reptiles known as *therapsids* more than 200 million years ago (mya), during the Mesozoic era (see Fig. 32-24). These early mammals remained a minor component of life on Earth for almost 150 million years and then rapidly diversified during the Cenozoic era (from 66 mya to the present).

Fossil evidence indicates that the first primates with traits characteristic of modern primates appeared by the Early Eocene epoch about 56 mya. These early primates had digits with nails, and their eyes were directed somewhat forward on the head.



Several novel adaptations evolved in early primates that allowed them to live in trees. One of the most significant primate features is that each limb has five highly flexible digits: four lateral digits (fingers) plus a partially or fully opposable first digit (thumb and, in many primates, big toe; FIG. 22-1). An **opposable thumb** positions the fingers opposite the thumb, enabling primates to grasp objects such as tree branches with precision. Nails (instead of claws) provide a protective covering for the tips of the digits, and the fleshy pads at the ends of the digits are sensitive to touch. Another arboreal feature is long, slender limbs that rotate freely at the hips and shoulders, giving primates full mobility to climb and search for food in the treetops.

Having eyes located in the front of the head lets primates integrate visual information from both eyes simultaneously; they have *stereoscopic* (three-dimensional) vision, which is important in judging distance and in depth perception. Stereoscopic vision is vital in an arboreal environment, especially for species that leap from branch to branch, because an error in depth perception may cause a fatal fall. In addition to having sharp sight, primates hear acutely.

Primates share several other characteristics, including a relatively large brain. Biologists have suggested that the increased sensory input associated with primates' sharp vision and greater agility favored the evolution of larger brains. Primates are generally very social and intelligent animals that reach sexual maturity relatively late in life. They typically have long lifespans. Females usually bear one offspring at a time; the baby is helpless and requires a long period of nurturing and protection.

Key Point

Primates have five grasping digits at the end of each limb, and the thumb or first toe is often partially or fully opposable.

(a) Lemur (*Eulemur mongoz*). (b) Tarsier (*Tarsius spectrum*).

(c) Woolly spider monkey (*Brachyteles arachnoides*). (d) Gorilla (*Gorilla gorilla*).

CONNECT Compare the palm of your right hand to those illustrated here. To which is it most similar?

CHECKPOINT 22.1

- **CONNECT** What features of primate hands and feet are adaptations to an arboreal existence?
- **CONNECT** What anatomical feature confers stereoscopic vision on primates?

22.2 Primate Classification

LEARNING OBJECTIVES

2 List the three suborders of primates and give representative examples of each.

3 Distinguish among anthropoids, hominoids, and hominins.

Now that we have surveyed the general characteristics of primates, let us look at how they are classified. Many biologists currently divide the order Primates into three groups, or

Key Point

Several kinds of data support the hypothesis that chimpanzees are the closest living relative of humans.

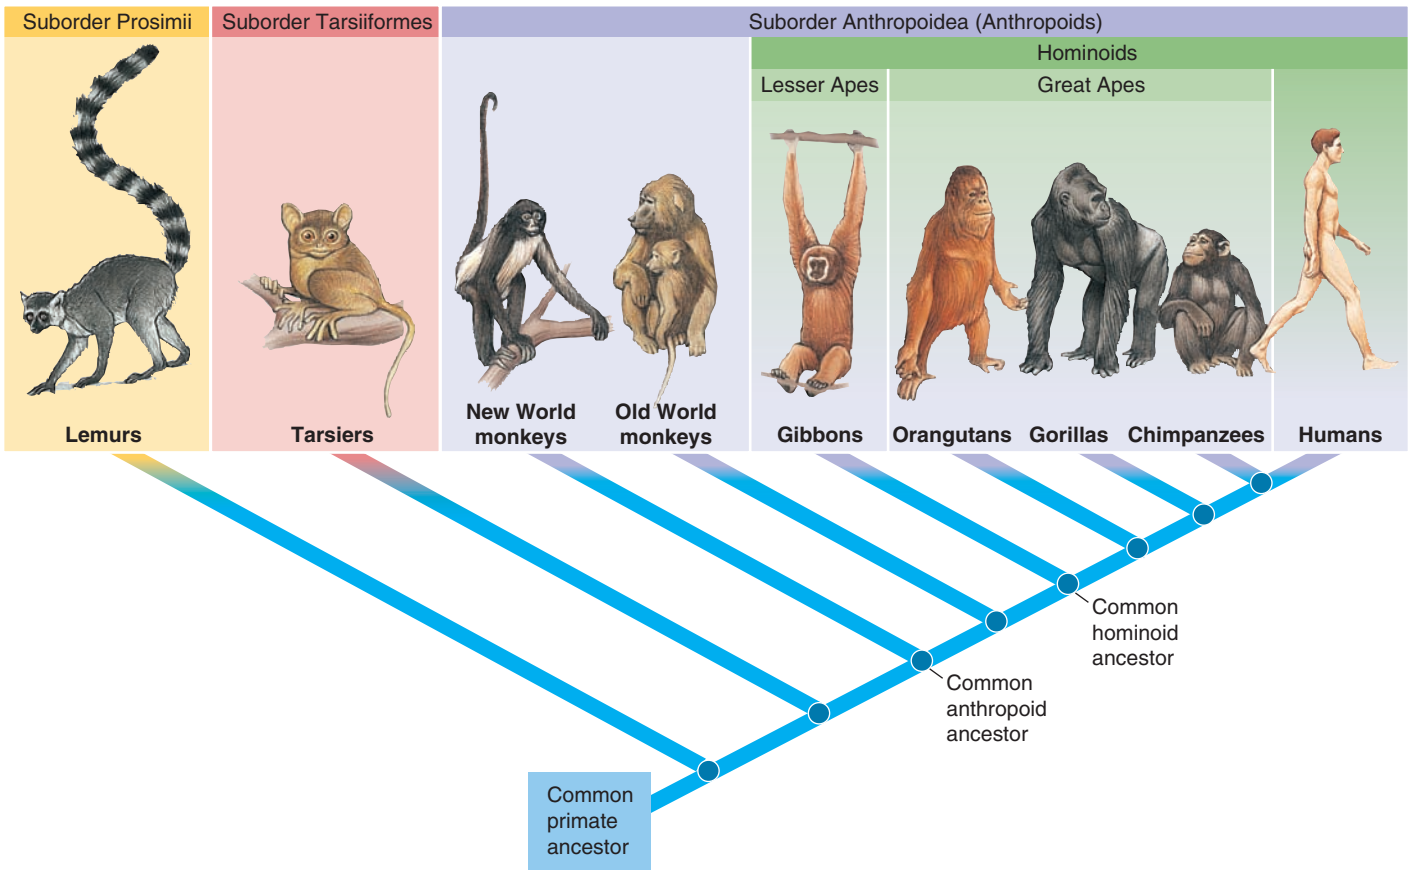

Figure 22-2 Primate evolution

This branching diagram, called a cladogram, shows evolutionary relationships among living primates, based on current scientific evidence. The nodes (*circles*) represent branch points where a species splits into two or more lineages. The divergence of orangutans from the ape/hominin line occurred some 12 mya to 16 mya. Gorillas separated from the chimpanzee/hominin line an estimated 8 mya, and the hominin (human) lineage diverged from that of chimpanzees about 6 mya. *Figures not drawn to scale.*

CONNECT According to the cladogram, which non-human primates are the closest living relatives of chimpanzees?

suborders (FIG. 22-2). The suborder Prosimii includes lemurs, galagos, and lorises; the suborder Tarsiiformes includes tarsiers; and the suborder Anthropoidea includes **anthropoids** (monkeys, apes, and humans).

All lemurs are restricted to the island of Madagascar off the coast of Africa. Because of extensive habitat destruction and hunting, they are very endangered. Lorises, which live in tropical areas of Southeast Asia and Africa, resemble lemurs in many respects, as do galagos, which live in sub-Saharan Africa. Lemurs, lorises, and galagos have retained several early mammalian features, such as elongated, pointed faces.

Tarsiers are found in rain forests of Indonesia and the Philippines (FIG. 22-3). They are small primates (about the size of a small rat) and are very adept leapers. These nocturnal primates resemble anthropoids in several ways, including their shortened snouts and forward-pointing eyes.

Suborder Anthropoidea includes monkeys, apes, and humans

Anthropoid primates arose during the Middle Eocene epoch, at least 45 mya. Several different fossil anthropoids have been identified, from Asia and North Africa, and there is a growing consensus about the relationships of these fossil groups to one another and to living anthropoids. Evidence indicates that anthropoids originated in Africa or Asia. The oldest known anthropoid fossils, such as 42-million-year-old *Eosimias*, have been found in China and Myanmar. Given details about their dentition and the few bones that have been discovered, scientists infer that *Eosimias* and other ancestral anthropoids were small, insect-eating arboreal primates that were active during the day. Once they evolved, anthropoids quickly spread throughout Europe, Asia, and Africa and

arrived in South America much later. (Paleoanthropologists date the oldest known South American primate, *Branisella*, from Bolivia, at 26 million years old.)

One significant difference between anthropoids and other primates is the size of their brains. The cerebrum in particular is more developed in monkeys, apes, and humans, where it functions as a highly complex center for learning, voluntary movement, and interpretation of sensation.

Monkeys are generally diurnal (active during the day) tree dwellers. They tend to eat fruit and leaves, with nuts, seeds, buds, insects, spiders, birds' eggs, and even small vertebrates playing a smaller part in their diets. The two main groups of monkeys, New World monkeys and Old World monkeys, are named for the hemispheres where they diversified. Monkeys in South America and Central America are called New World monkeys, whereas monkeys in Africa, Asia, and Europe are called Old World monkeys. New World and Old World monkeys have been evolving separately for tens of millions of years.

One of the most important and interesting questions in anthropoid evolution concerns *how* monkeys arrived in South America. Africa and South America had already drifted apart. (Continental drift is presented in Figure 18-11.) The ancestors of New World monkeys may have rafted from Africa to South America on floating masses of vegetation. The South Atlantic Ocean would have been about half as wide as it is today, and islands could have provided "stepping stones." Once established in the New World, these monkeys rapidly diversified.

New World monkeys are restricted to Central America and South America and include marmosets, capuchins, howler monkeys, squirrel monkeys, and spider monkeys. New World monkeys are arboreal, and some have long, slender limbs that permit easy movement in the trees (FIG. 22-4a). A few have **prehensile tails** capable of wrapping around branches and serving as fifth limbs. Some New World monkeys have shorter thumbs, and in certain cases the thumbs are totally absent (see Fig. 22-1c). Their facial anatomy differs from that of the Old World monkeys; New World monkeys have flattened noses with the nostrils opening to the side. They live in groups and engage in complex social behaviors.

Old World monkeys are distributed in tropical parts of Africa and Asia. In addition to baboons and macaques (pronounced "muh-kacks′"), the Old World group includes guenons, mangabeys, langurs, and colobus monkeys. Most Old World monkeys are arboreal, although some, such as baboons and macaques, spend much of their time on the ground (FIG. 22-4b). The ground dwellers, which are **quadrupedal** (four footed; they walk on all fours), arose from arboreal monkeys. None of the Old

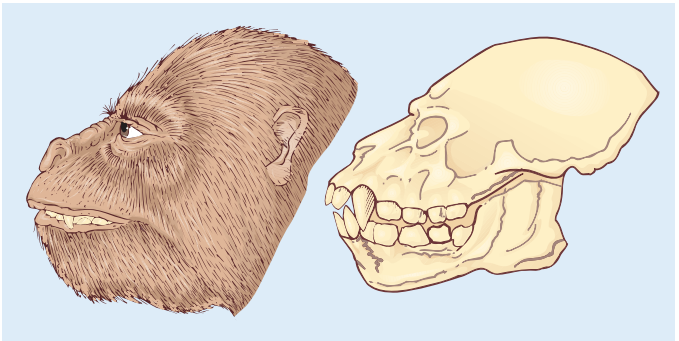
World monkeys has a prehensile tail, and some have extremely short tails. They have a fully opposable thumb, and unlike the New World monkeys, their nostrils are closer together and directed downward. Old World monkeys are intensely social animals.

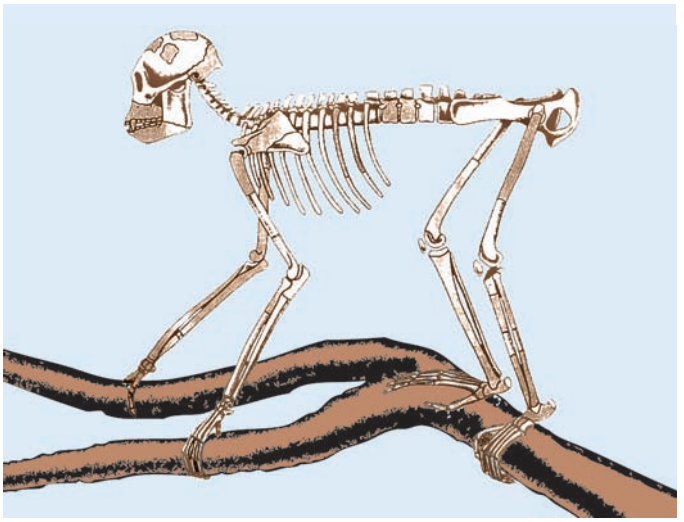
Apes are our closest living relatives

Old World monkeys shared a common ancestor with the **hominoids**, a group composed of apes and **hominins** (humans and their ancestors; also called *hominids*). A fairly primitive anthropoid, discovered in Egypt, was named *Aegyptopithecus* (FIG. 22-5a). A cat-sized, forest-dwelling arboreal monkey with a few apelike characteristics, *Aegyptopithecus* lived during the Oligocene epoch, approximately 34 mya.



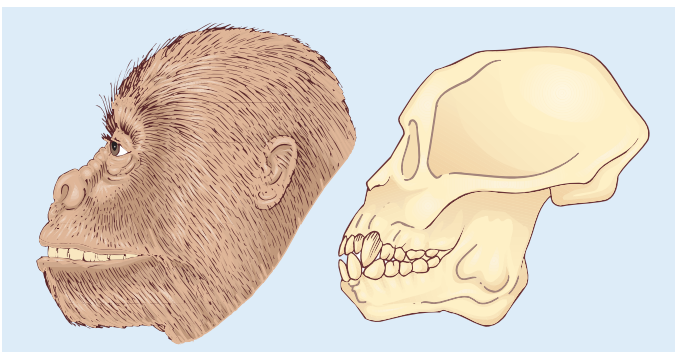
Fossil evidence reported in 2010 indicates that apes and Old World monkeys had diverged between 29 mya and 28 mya. During the Miocene epoch, as many as one hundred species of apes lived in Africa, Asia, and Europe.

Paleoanthropologists have discovered the oldest fossils with hominoid features in East Africa, mostly in Kenya. *Proconsul*, for example, appeared early in the Miocene epoch, about 20 mya (FIG. 22-5b). It had a larger brain than that of monkeys and apelike teeth and diet (fruits), but a monkeylike body. At least 30 other early hominoid species lived during the Miocene epoch, but most of them became extinct and were not the common ancestor of modern apes and humans.



Miocene fossils of forest-dwelling, chimpanzee-sized apes called *dryopithecines*, which lived about 15 mya, are of special interest because this hominoid lineage may have given rise to modern apes as well as to humans (FIG. 22-5c). The dryopithecines, such as *Dryopithecus*, *Kenyapithecus*, and *Morotopithecus*, were distributed widely across Europe, Africa, and Asia. As the climate gradually cooled and became drier, their range became more limited. These apes had highly modified bodies for swinging through the branches of trees, although there is also evidence that some of them may have left the treetops for the ground as dense forest gradually changed into open woodland. Many questions about the relationships among the various early apes have been generated by the discovery of these and other Miocene hominoids. As future fossil finds are evaluated, they may lead to a rearrangement of ancestors in the hominoid family tree.

Five genera of hominoids exist today: gibbons (*Hylobates*), orangutans (*Pongo*), gorillas (*Gorilla*), chimpanzees (*Pan*), and humans (*Homo*). Gibbons are known informally as lesser apes; orangutans, gorillas, and chimpanzees are known as great apes. Molecular evidence indicates a close relationship between humans and the great apes, particularly chimpanzees.



Gibbons are natural acrobats that can *brachiate*, or arm-swing, with their weight supported by one arm at a time (FIG. 22-6a). Orangutans are also tree dwellers, but chimpanzees and especially gorillas have adapted to life on the ground (FIGS. 22-6b–d). Gorillas and chimpanzees have retained long arms typical of brachiating primates but use them to assist in quadrupedal walking, sometimes known as *knuckle walking* because of the way they fold (flex) their digits when moving. Like humans, apes lack tails, a characteristic that makes them easy to distinguish from monkeys. They are generally much larger than monkeys, although gibbons are a notable exception.

(a) Fossils of *Aegyptopithecus*, a fairly primitive anthropoid, were discovered in Egypt.

(b) Skeletal reconstruction of *Proconsul*. (The reconstructed parts are *white*.) This anthropoid had the limbs and body proportions of a monkey but lacked a tail, like all apes.

(c) *Dryopithecus*, a more advanced ape, may have been ancestral to modern hominoids.

Figure 22-6 Apes

Molecular data provide clues about evolution of anthropoid primates Evidence of the close relatedness of orangutans, gorillas, chimpanzees, and humans is abundant at the molecular level. The amino acid sequence of the chimpanzee's hemoglobin is identical to that of the human; hemoglobin molecules of the gorilla and rhesus monkey differ from the human's by 2 and 15 amino acids, respectively. DNA sequence analyses indicate that chimpanzees are likely to be our nearest living relatives among the apes. (Figure 18-18 shows the percent divergence in a non-protein-coding sequence on the β-globin gene between various primates, including the apes, and humans.)

Researchers have sequenced the genomes of many primates, including all the great apes. Molecular evidence suggests that orangutans may have diverged from the gorilla, chimpanzee, and hominin lines about 12 mya to 16 mya. Gorillas may have diverged from the chimpanzee and hominin lines some 10 mya, whereas chimpanzee and hominin lines probably separated about 4 mya.

22.3 Hominin Evolution

LEARNING OBJECTIVES

4 Describe skeletal and skull differences between apes and hominins.

5 Briefly describe the following early hominins: *Orrorin*, *Ardipithecus*, *Australopithecus anamensis*, *Au. afarensis*, *Au. africanus*, and *Au. sediba*.

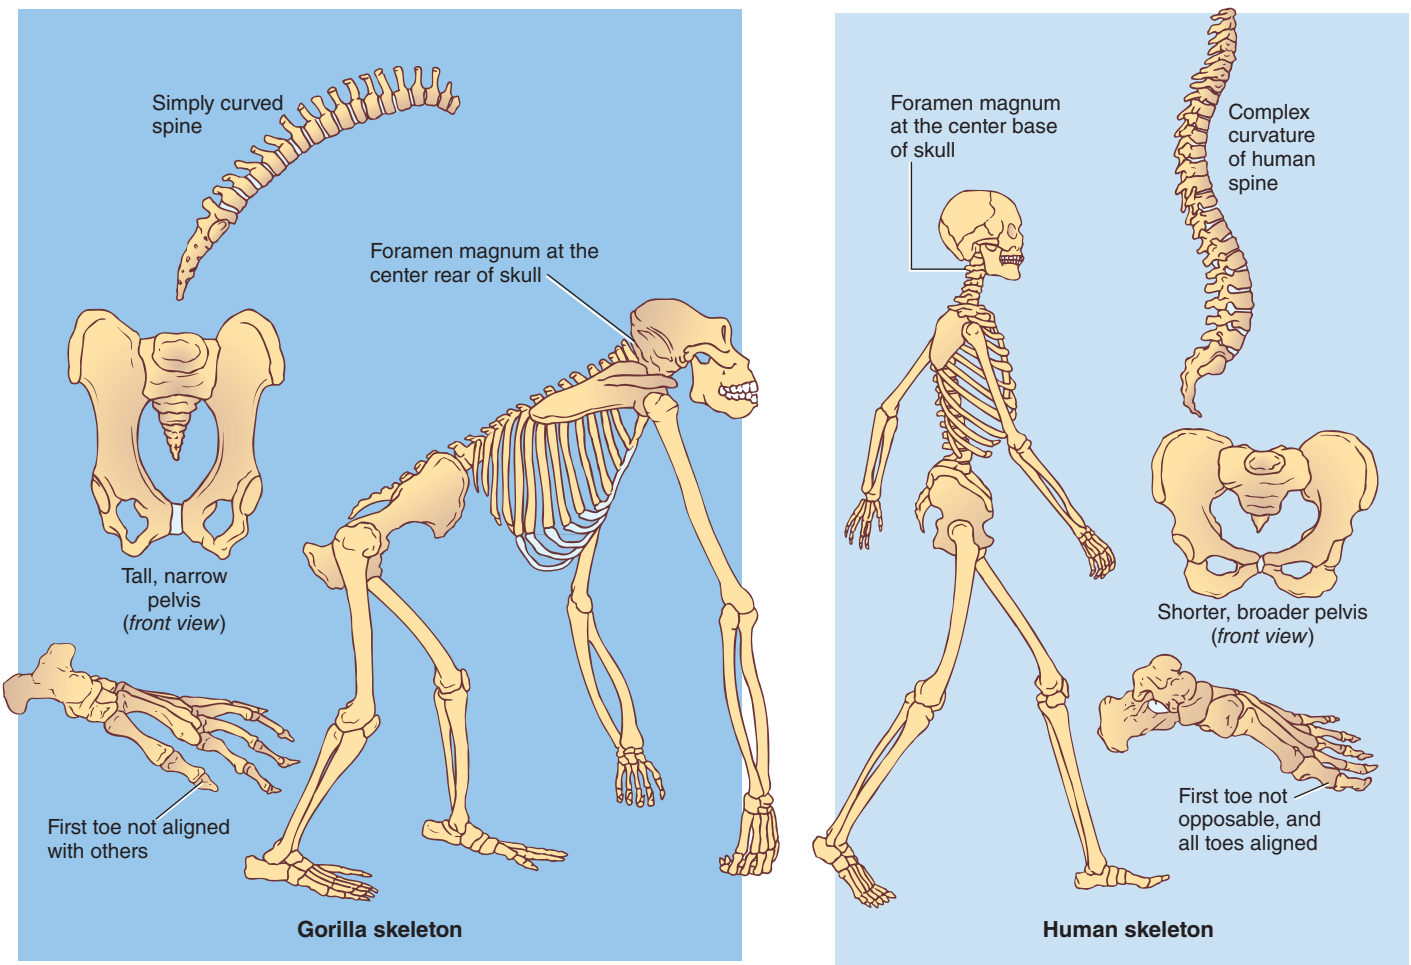
6 Distinguish among the following members of genus *Homo*: *H. habilis*, *H. ergaster*, *H. erectus*, *H. antecessor*, *H. heidelbergensis*, *H. neanderthalensis*, and *H. sapiens*.

7 Discuss the origin of modern humans.

Scientists have a growing storehouse of hundreds of hominin fossils, which provide useful data about general trends in the body design, appearance, and behavior of ancestral humans. Despite the wealth of fossil evidence and a growing body of molecular data, scientists continue to vigorously debate interpretations of hominin characteristics, classification, and evolution. New discoveries will continue to raise new questions.

Evolutionary changes from the earliest hominins to modern humans are evident in some of the characteristics of the skeleton and skull. For example, before their brains enlarged, early hominins clearly adopted a **bipedal** (two-footed) posture. Compared with the ape skeleton, the human skeleton shows distinct differences that reflect humans' ability to stand erect and walk on two feet (FIG. 22-7). These differences also reflect the habitat change for early hominins, from an arboreal existence in the forest to a life spent at least partly on the ground.

The curvature of the human spine provides better balance and weight distribution for bipedal locomotion than the spine of the ape. The human pelvis is shorter and broader than the ape pelvis, allowing better attachment of muscles used for upright walking. (The shape of the human pelvis also allows the birth of offspring with large brains.) In apes the **foramen magnum**, the hole in the base of the skull for the spinal cord, is located in the rear of the skull. In contrast, the human foramen magnum is centered in the skull base, positioning the head for erect walking. An increase in the length of the legs relative to the arms and alignment of the first toe with the rest of the toes further adapted the early hominins for bipedalism.



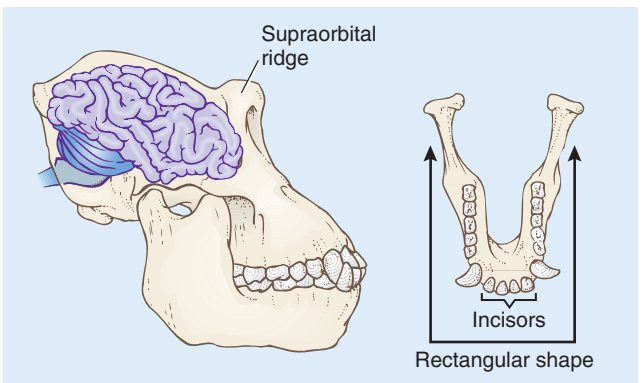


Figure 22-7 Gorilla and human skeletons
When gorilla and human skeletons are compared, the skeletal adaptations for bipedalism in humans become apparent.

Another major trend in hominin evolution was an increase in brain size relative to body size (FIG. 22-8). The ape skull has prominent **supraorbital ridges** above the eye sockets, whereas modern human skulls lack these ridges. Human faces are flatter than those of apes, and the jaws are different. The arrangement of teeth in the ape jaw is somewhat rectangular, compared with a rounded, or U-shaped, arrangement in humans. Apes have larger front teeth (canines and incisors) than do humans, and their canines are especially large. Gorillas and orangutans also have larger back teeth (premolars and molars) than do humans.

We now examine some of the increasing number of fossil hominins in the human lineage. As you read the following descriptions of human evolution, keep in mind that much of what is discussed is open to reinterpretation and major revision as additional discoveries are made. Although we present human evolution in a somewhat linear fashion, from ancient hominins to anatomically and behaviorally modern humans, the human family tree is not a single trunk; rather, it has several branches (FIG. 22-9). Perhaps it is most useful to think of the known hominin fossils as a sampling of human evolution instead of a continuous sequence.

(a) The ape skull has a pronounced supraorbital ridge.

(b) The human skull is flatter in the front and has a pronounced chin. The human brain, particularly the cerebrum (*purple*), is larger than that of an ape, and the human jaw is structured so that the teeth are arranged in a U shape. Human canines and incisors are also smaller than those of apes.

Figure 22-8 Gorilla and human heads

Homo sapiens is the only species of hominin in existence today, but more than one hominin species coexisted at any given time for most of the past 4 million years. In addition, do not make the mistake of thinking that your smaller-brained ancestors were inferior to yourself. Ancestral hominins were evolutionarily successful in that they were well adapted to their environment and survived for millions of years.

The earliest hominins may have lived 6 mya to 7 mya

Hominin evolution began in Africa. Although most hominin fossils have been discovered in Ethiopia and Kenya, French paleontologist Michel Brunet and an international team made a stunning discovery in 2002 in a dry lake bed in Chad, which is in central Africa. The fossil, which has been reliably dated at 6 million to 7 million years old, may be the earliest known hominin. Viewed from the back, the skull of *Sahelanthropus*, with its small braincase, resembles that of a chimpanzee. However, viewed from the front, the face and teeth have many characteristics of larger-brained human ancestors. Most paleoanthropologists place *Sahelanthropus* close to the base of the human family tree, that is, close to when genetic analyses suggest that the last common ancestor of hominins and chimpanzees existed. The discovery of *Sahelanthropus* is important in its own right, but it is also significant because it shows that early hominins exhibited more variation and lived over a larger area of Africa than had been originally hypothesized.

Orrorin, discovered in 2000 in Kenya, may also represent one of the earliest known hominins. The sediments in which fossils of *Orrorin* were found have been reliably dated at 6 million years old. In 2008, researchers studying the fossil leg bones of *Orrorin* concluded that it walked upright and was bipedal.

As with many aspects of human evolution, scientists have differing interpretations of *Sahelanthropus* and *Orrorin*. For example, some paleoanthropologists hypothesize that *Sahelanthropus* was a forerunner of modern apes, specifically the gorilla, and not one of the earliest ancestors of humans. Other researchers think the similar features of *Sahelanthropus*, *Orrorin*, and *Ardipithecus* (discussed in the next section) fossils mean that they are all members of the same genus, *Ardipithecus*. This point remains controversial, largely because there are currently no skeletal bones (leg, pelvis, and foot bones) to indicate if *Sahelanthropus* walked upright, a hallmark characteristic of hominins. (A 2005 reconstruction of the skull has features that strongly suggest *Sahelanthropus* was bipedal.) Future fossil discoveries and additional analyses of existing fossils should help clarify the evolutionary relationships among *Sahelanthropus*, *Orrorin*, and *Ardipithecus*.

Ardipithecus, *Australopithecus*, and *Paranthropus* are australopithecines, or "southern man apes"

After *Sahelanthropus* and *Orrorin*, the next-oldest hominin belongs to the genus *Ardipithecus*, which lived in eastern Africa between 4 mya and 6 mya. Although not as primitive

Key Point

Paleoanthropologists do not completely agree about certain specific details of the human family tree and hold many possible interpretations of classification lines of descent.

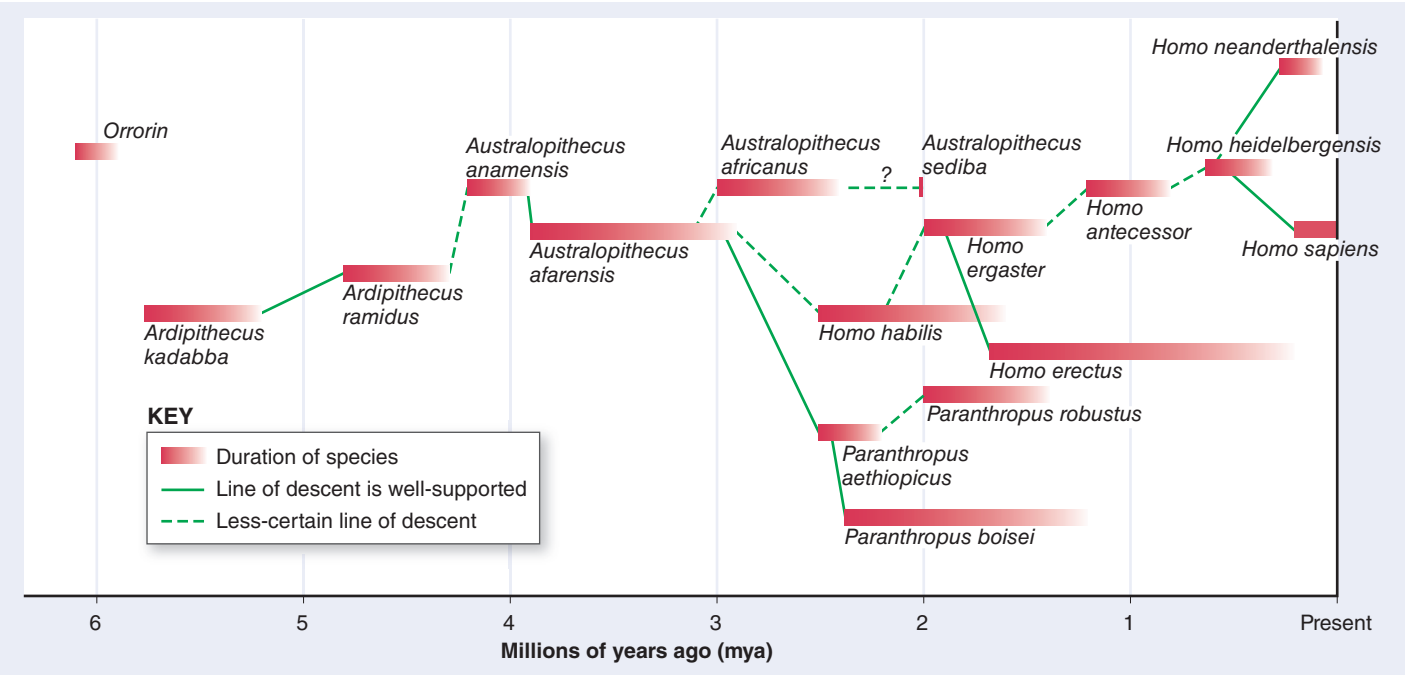

Figure 22-9 One interpretation of human evolution
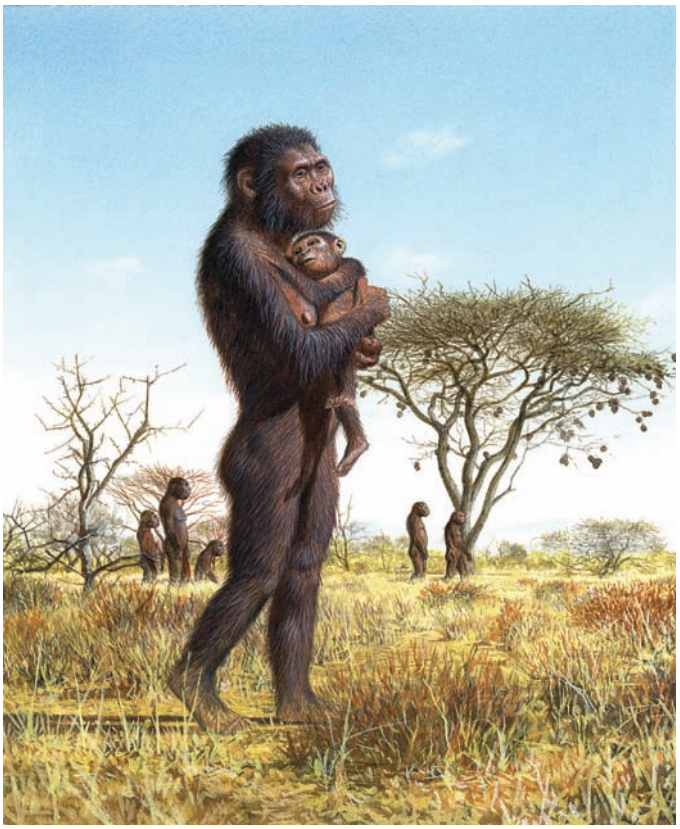
Please refer to this diagram as you read through Section 22.3. This interpretation, compiled by the author from multiple sources, will likely change as new evidence comes to light.

CONNECT If you were to add *Homo floresiensis* and the Denisovans to this chart, where would you place them? Justify your answers.

as *Sahelanthropus*, *Ardipithecus* is an **australopithecine** that is close to the "root" of the human family tree. The shape of the toe bones suggests that *Ardipithecus* walked upright.

Two species of *Ardipithecus* have been described. The canine teeth of the earliest species, *Ar. kadabba*, have certain primitive features similar to those of *Sahelanthropus* and *Orrorin*. The specific epithet *kadabba* comes from Afar words meaning "basal family ancestor." ***Ardipithecus ramidus*** appeared about 4.8 mya. A remarkably complete fossil of a female *Ar. ramidus*, nicknamed Ardi, was described in a series of scientific papers in 2009. Based on details of her anatomy, Ardi has been described as a "facultative biped," capable of walking upright but also able to climb.



Ardipithecus gave rise to *Australopithecus*, a genus that includes several species that lived between 4 mya and 1 mya. Both *Ardipithecus* and *Australopithecus* had longer arms, shorter legs, and smaller brains relative to those of modern humans.

Hominins that existed between 4.2 mya and 3.9 mya are assigned to the species ***Australopithecus anamensis***, first named by paleoanthropologist Meave Leakey and her co-workers in 1995 from fossils discovered in eastern Africa. This hominin species, which has a mixture of apelike and humanlike features, presumably evolved from *Ardipithecus ramidus*. A comparison of male and female *Australopithecus anamensis* body sizes and canine teeth reveals **sexual dimorphism**, marked phenotypic differences between the two sexes of the same species. (The modern-day gorilla is sexually dimorphic.) The back teeth and jaws of *Au. anamensis* are larger than those of modern chimpanzees, whereas the front teeth are smaller and more like those of later hominins. A fossil leg bone, the tibia, indicates that *Au. anamensis* had an upright posture and was bipedal, although it also may have foraged in the trees. Thus, bipedalism occurred early in human evolution and appears to have been the first human adaptation.

Australopithecus afarensis, another primitive hominin, probably evolved directly from *Au. anamensis*. Many fossils of *Au. afarensis* skeletal remains have been discovered in Africa, including a remarkably complete 3.2-million-year-old skeleton, nicknamed Lucy, found in Ethiopia in 1974 by a team led by U.S. paleoanthropologist Donald Johanson (FIG. 22-10). In 1978, British paleoanthropologist Mary Leakey and her co-workers discovered beautifully preserved fossil footprints of three *Au. afarensis* individuals who walked more than

This artist's rendition of a female australopithecine and child is based on the fossils of Lucy, discovered in 1974.

3.6 mya. In 1994, paleoanthropologists found the first adult skull of *Au. afarensis*. The skull, characterized by a relatively small brain, pronounced supraorbital ridges, a jutting jaw, and large canine teeth, is an estimated 3 million years old. It is probable that *Au. afarensis* did not construct tools or make fires because no evidence of tools or fire has been found at fossil sites. In 2016 an analysis of Lucy's skeleton provided evidence that she died due to injuries sustained in a fall from a great height. This finding has been taken as evidence that *Au. afarensis* had an arboreal existence.

Many paleoanthropologists think that *Au. afarensis* gave rise to several australopithecine species, including ***Australopithecus africanus***, which may have appeared as early as 3 mya. The first *Au. africanus* fossil was discovered in South Africa in 1924, and since then hundreds have been found. This hominin walked erect and possessed hands and teeth that were distinctly humanlike. Given the characteristics of the teeth, paleoanthropologists think that *Au. africanus* ate both plants and animals. Like *Au. afarensis*, it had a small brain, more like that of its primate ancestors than of present-day humans.

In 2010 and 2013, a series of papers in the journal *Science* described ***Australopithecus sediba*** based on studies of the well-preserved partial skeletons of an adult female and a young boy found in South Africa. Dated at 1.95 mya, these fossils exhibit a mixture of apelike and humanlike features. Like apes, they have small brains, long arms, and, in the female, a small birth canal. However, among their humanlike features are long legs, a pelvis consistent with bipedal posture, and long, opposable thumbs. Most perplexing of all, they have apelike feet, but their ankle joints are like those of humans. Many scientists think that *Au. sediba* was probably a descendant of *Au. africanus*, but there is considerable disagreement on other issues. Was *Au. sediba* part of the line leading to humans or an evolutionary dead end?

Three australopithecine species (*Paranthropus robustus* from South Africa and *P. aethiopicus* and *P. boisei*, both from East Africa) were larger than *Au. africanus* and had extremely large molars, very powerful jaws, relatively small brains, and bony skull crests. Most females lacked the skull crests and had substantially smaller jaws than *Au. africanus*, another example of sexual dimorphism in early hominins. The teeth and jaws suggest a diet, perhaps of tough roots, nuts, and seeds, that would require powerful grinding. (However, a 2008 study of fossil teeth of *P. boisei* found that the wear on the teeth suggested a softer diet, such as fruits. *P. boisei* apparently ate soft food during times of plenty but could eat hard items during food shortages.) These so-called *robust australopithecines* may or may not be closely related but are generally thought to represent evolutionary offshoots, or side branches, of human evolution. The first robust australopithecine, *P. aethiopicus*, appeared about 2.5 mya.

The actual number of australopithecine species for which fossil evidence has been found is under debate. In some cases, differences in the relatively few skeletal fragments could indicate either variation among individuals within a species or evidence of separate species.

Homo habilis is considered the oldest member of genus *Homo*

The first hominin to have enough uniquely human features to be placed in genus *Homo*, the same genus as modern humans, is ***Homo habilis***. It was first discovered in the early 1960s at Olduvai Gorge in Tanzania. Since then, paleoanthropologists have discovered other fossils of *H. habilis* in eastern and southern Africa. *Homo habilis* was a small hominin with a larger brain and smaller premolars and molars than those of the australopithecines. This hominin appeared approximately 2.5 mya and persisted for about 900,000 years. Fossils of *H. habilis* have been found in numerous areas in Africa. These sites contain primitive tools, stones that had been chipped, cracked, or hammered to make sharp edges for cutting or scraping. *Oldowan* pebble choppers and flakes, for example, were probably used to cut through animal hides to obtain meat and to break bones for their nutritious marrow.

The relationship between the australopithecines and *H. habilis* is not clear. Using physical characteristics of their fossilized skeletons as evidence, many paleoanthropologists have inferred that the australopithecines were ancestors of *H. habilis*. Some researchers do not think that *H. habilis* belongs in the genus *Homo*, and they suggest that it should be reclassified as *Australopithecus habilis*. The discovery of *Au. sediba*, described in the previous section, has added fuel to this debate.

The debate has become even more lively since 2015, following reports of the 2013 discovery of 1550 specimens from at least 15 individuals in the Rising Star cave system in South Africa. As with *Au. sediba*, the bones of *Homo naledi* exhibit a mixture of modern and primitive characteristics. These include small brains, upper limbs adapted for climbing and tool use, and lower limbs adapted for upright posture. Many questions arose: Was *H. naledi* actually an australopithecine? Did it evolve at the base of the *Homo* family tree, or did it exist much later? After subjecting the specimens to six methods of dating, scientists reported in 2017 that the remains are between 236,000 and 335,000 years old. Their findings support the hypothesis that *H. naledi* was not a direct ancestor of modern humans, but was instead a species that survived from a much earlier time and lived alongside humans in Africa.

Homo ergaster may have arisen from *H. habilis*

Initially, fossils that are now classified as *Homo ergaster* were considered by some scientists as early *H. erectus* (discussed in next section). With the discovery of additional fossils, however, many scientists hypothesized that the fossils classified as *H. erectus* really represent two species, ***Homo ergaster***, an earlier African species, and *H. erectus*, a later eastern Asian offshoot. The best-known fossils of *H. ergaster*, which existed from 2.0 mya to 1.4 mya, come from the Lake Turkana region in Kenya. Researchers who support the split speculate that *H. ergaster* may be the direct ancestor of later humans, whereas *H. erectus* may be an evolutionary dead end.

Homo erectus probably evolved from *H. ergaster*

Investigators found the first fossil evidence of ***Homo erectus*** in Indonesia in the 1890s. Since then, researchers have found numerous fossils of *H. erectus* throughout Africa and Asia. Paleoanthropologists think that *H. erectus* originated in Africa about 1.7 mya and then spread to Europe and Asia. Peking man and Java man, discovered in Asia, were later examples of *H. erectus*, which existed until at least 200,000 years ago; some populations of *H. erectus* may have persisted more recently.

Homo erectus was taller than *H. habilis*. Its brain, which was larger than that *of H. habilis*, got progressively larger during the course of its evolution. Its skull, although larger, did not possess totally modern features, retaining the heavy supraorbital ridge and projecting face that are more characteristic of its ape ancestors (FIG. 22-11). *Homo erectus* is the first hominin to have fewer differences between the sexes.

The increased intelligence associated with a larger brain enabled these early humans to make more advanced stone tools, known as *Acheulean* tools, including hand axes and other implements that scientists have interpreted as choppers, borers, and scrapers (FIG. 22-12). Their intelligence also allowed these humans to survive in cold areas. *Homo erectus* obtained food by hunting or scavenging and may have worn clothing, built fires, and lived in caves or shelters. Evidence of weapons (spears) has been unearthed at *H. erectus* sites in Europe. (For the remarkable story of an evolutionary offshoot from *H. erectus*, see *Inquiring About: The Smallest Humans*.)

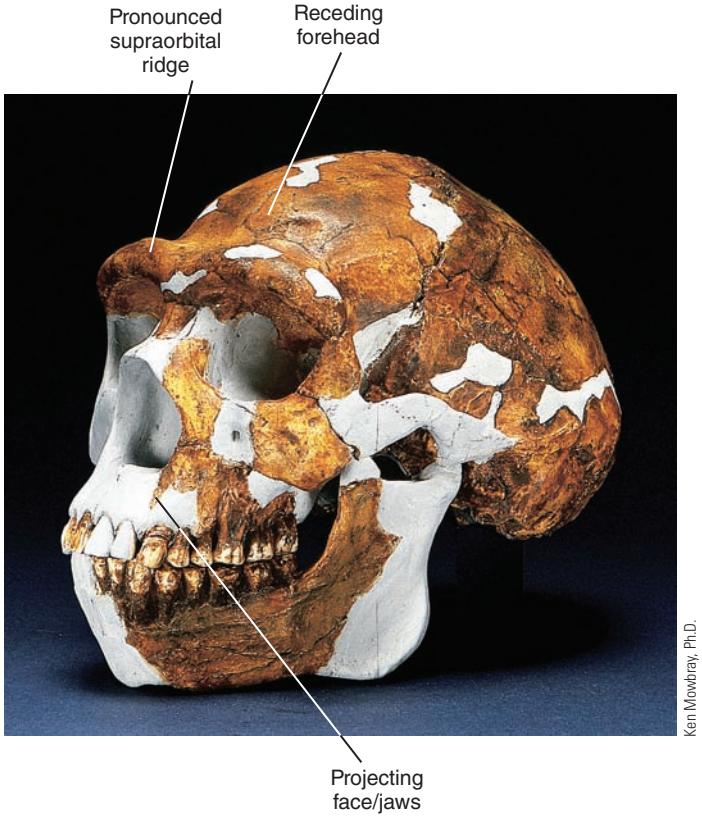

Figure 22-11 *Homo erectus* skull from China
The reconstructed parts are *white*. Note the receding forehead, pronounced supraorbital ridge, and projecting face and jaws.

Archaic humans date from about 1.2 mya to 200,000 years ago

Archaic humans are regionally diverse descendants of *H. ergaster* that lived in Africa, Asia, and Europe from about 1.2 mya to 200,000 years ago. The brains of archaic humans were essentially the same size as our brains, although their skulls retained some ancestral characters. Populations of archaic humans had rich and varied cultures (learned traditions) that included making many kinds of tools and objects with symbolic and ceremonial meaning.

Some researchers classify the oldest archaic human fossils discovered in Europe (in Spain) as ***Homo antecessor***. *Homo antecessor* existed from about 1.2 mya to 800,000 years ago. Sites where *H. antecessor* fossils have been found show numerous cuts on human bones that suggest that these early humans practiced cannibalism.

Homo heidelbergensis, which appeared about 600,000 years ago and existed until about 300,000 years ago, may have descended from *H. antecessor*. Fossils of *H. heidelbergensis*

Figure 22-12 Acheulean tool

This stone tool is a typical Acheulean tool. It was made about 800,000 years ago by striking both sides of the biface (*shown*) to make a teardrop shape. The tool was found with other fossils and tools in Gran Dolina, Sierra de Atapuerca, Spain.

were first discovered in Germany about one hundred years ago. This extinct hominin had a larger brain—similar in size to that of modern humans—than *H. ergaster* or *H. antecessor*.

Some scientists do not recognize *H. antecessor* and suggest that *H. antecessor* fossils should be classified as *H. heidelbergensis*. Classification of *H. heidelbergensis* is also controversial because many (but not all) of the scientists studying its fossil remains think that both Neandertals and modern humans descended from it.

Neandertals appeared approximately 250,000 years ago

Fossils of **Neandertals** were first discovered in the Neander Valley in Germany.[1] They lived throughout Europe and western Asia from about 250,000 to 28,000 years ago. Although at one time many scientists considered Neandertals as a subspecies of *H. sapiens*, increasing evidence suggests that Neandertals were a separate species from modern humans, carrying the name ***Homo neanderthalensis***.

[1] *Neandertal* was formerly spelled *Neanderthal*. The silent h has been dropped in modern German but not in the scientific name.

These early humans had short, sturdy builds. Their faces projected slightly, their chins and foreheads receded, they had heavy supraorbital ridges and jawbones, and their brains and front teeth were larger than those of modern humans. They had large nasal cavities and receding cheekbones. Scientists have suggested that the large noses provided larger surface areas in Neandertal sinuses, enabling them to better warm the cold air of Ice Age Eurasia as inhaled air traveled through the head to the lungs.

Neandertal tools, known as *Mousterian* tools, were more sophisticated than those of *H. erectus* (FIG. 22-13). Studies of Neandertal sites indicate that Neandertals hunted large animals. The existence of skeletons of elderly Neandertals and of some with healed fractures may demonstrate that Neandertals cared for the aged and the sick, an indication of advanced social cooperation. They apparently had rituals, possibly of religious significance, made jewelry, and sometimes buried their dead.

The disappearance of the Neandertals about 28,000 years ago is a mystery that has sparked debate among paleoanthropologists. Groups of *H. sapiens* with more modern features coexisted with the Neandertals for several thousand years. Perhaps the other humans outcompeted or exterminated the Neandertals, leading to their extinction. It is also possible that the Neandertals interbred with these humans, diluting their features beyond recognition.

Dirk Wiersma/Science Source

Figure 22-13 Mousterian tool

Mousterian tools are named after a Neandertal site in Le Moustier, France. Mousterian tools include a variety of skillfully made stone tools; this tool, with its sharp edges, was probably used to scrape hides and/or to form the point of a spear. Although Neandertals had spears, they did not develop bows and arrows and so had to get close to their prey when hunting.

Inquiring About

The Smallest Humans

Evolutionarily speaking, what are "hobbits"? In 2004, paleoanthropologists reported a startling discovery of fossils of seven humans in a cave on the Indonesian island of Flores. The finding was completely unexpected because the fossil bones and teeth were from adult humans that were about 1 m (about 3 ft) tall.

The tiny humans, which have been dubbed "hobbits" by the media, may represent a new species, *Homo floresiensis*. Although these hominins had small, ape-sized brains, sophisticated stone tools, fireplaces, and charred bones found with the fossils indicate that *H. floresiensis* was capable of complex thinking and activities. The charred bones were primarily from pygmy elephants (*Stegodon*) and Flores giant rats (*Papagomys*), and they provide clues about the food that *H. floresiensis* hunted and killed (see figure).

Detailed studies of the *H. floresiensis* braincase, published in 2005, revealed that it was similar in many ways to the larger brain of *H. erectus*, which is known to have lived on nearby islands. Many researchers have concluded from this and other evidence that *H. floresiensis* was an evolutionary offshoot of *H. erectus*.

Why was *H. floresiensis* so small? Biologists have often observed two evolutionary trends of mammals living on remote islands: large mammals tend to evolve into much smaller species, and small mammals tend to evolve into much larger species. It is not unreasonable to assume that the small population of *H. erectus* ancestors that colonized Flores, perhaps by rafting to the island on a log, underwent evolutionary dwarfing over the thousands of years that they were isolated on Flores. (If *H. erectus* had been a frequent visitor to Flores, gene flow between the indigenous population and the visitors would have prevented the indigenous population from becoming measurably smaller.)

Not everyone agrees with the hypothesis that *H. floresiensis* is a separate species of tiny humans. Some researchers have suggested that the fossils are from *H. sapiens* individuals suffering from a rare genetic defect (microcephaly) that causes small brains and bodies. This hypothesis has become less tenable as the cave fossils have been dated to at least 60,000 years ago, a time when no modern humans lived in that area. In 2014 researchers excavating at a different location on Flores found additional fossils: a fragment of a jaw and a skull, as well as adult and baby teeth. These individuals have been calculated to have been about 20% smaller than those whose remains were found in the cave. These fossils have been dated to 700,000 years ago, a finding consistent with the idea that *H. floresiensis* was a species with a very long history on Flores.

Peter Schouten

Increasingly sophisticated methods of DNA analysis contribute useful data for such controversies. Studies of nuclear DNA of Neandertals have indicated that between 1% and 5% of Neandertal DNA is shared with modern human populations outside of Africa, supporting the hypothesis that some human–Neandertal interbreeding did occur. Interestingly, Neandertal Y chromosome DNA is absent in modern human populations, indicating that there was a possible genetic incompatibility between *H. sapiens* mothers and hybrid male offspring.

In 2012, scientists reported on the genome of a Neandertal relative. DNA was extracted from fossil remains of a young girl excavated from Denisova Cave in Siberia. The fossils, consisting of a finger bone and two teeth, are from sediments that have been dated to 50,000 years. Additional human fossils from the cave are at least 110,000 years old, and possibly older. Scientists consider these archaic humans, provisionally known as the Denisovans, a sister group to the Neandertals. Again there is evidence for inbreeding between archaic humans and *H. sapiens*. Denisovan DNA sequences ranging from traces to as much as 3% have been found in some present-day Asian and Oceanic island populations.

Scientists have reached a near consensus on the origin of modern *H. sapiens*

Homo sapiens with a mixture of primitive and modern features existed in Africa by about 300,000 years ago. As anatomically modern humans later dispersed around the world, they displaced other hominins such as *H. erectus* and *H. neanderthalensis*. By about 30,000 years ago, anatomically modern humans were the only members of genus *Homo* remaining, excluding small, isolated populations.

Both recent fossil finds and extensive molecular analyses have promoted the **(recent) out-of-Africa model** (also called *Recent Africa Origin*, or *RAO*) as the main explanation for the origin of modern humans living around the world. New data include the discovery of the earliest fossilized remains of modern *H. sapiens* in Africa and analyses of DNA from mitochondria, the Y chromosome, and autosomes. In 2005, fossils of the earliest known modern *H. sapiens* were reliably dated at 195,000 years old; these fossils were found in southern Ethiopia. No *H. sapiens* fossils of comparable age have been found in Europe or Asia. The earliest fossils of anatomically modern *H. sapiens* in Europe and most parts

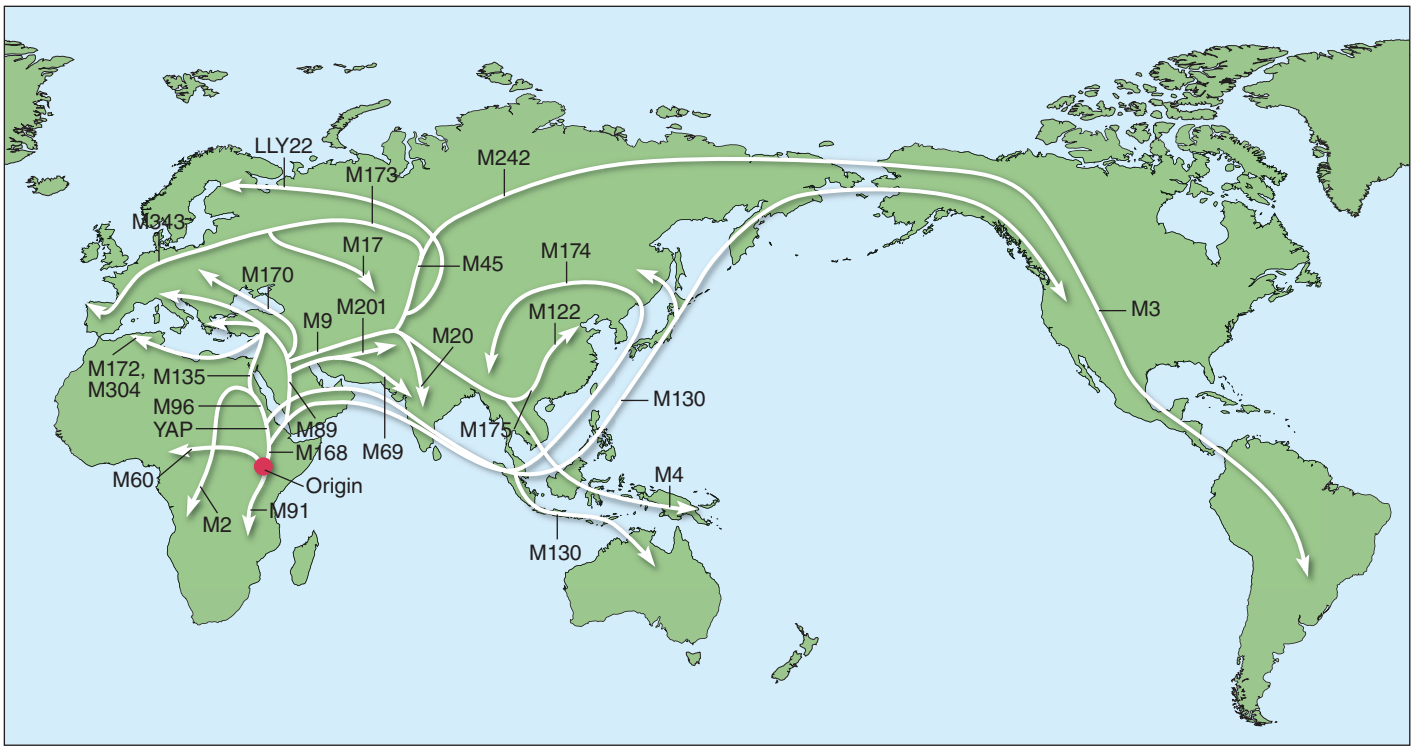

Figure 22-14 The path of human migrations, based on Y chromosome data

Homo sapiens originated in Africa and migrated from there throughout the world.

Adapted from G. Stix, "Traces of a Distant Past," *Scientific American* (July 2008): 59. Author credits information in *National Geographic* maps.

of Asia date to 45,000 to 40,000 years ago. One exception is in Israel, where *H. sapiens* fossils have been dated at 100,000 years before present.

Molecular anthropology, the comparison of biological molecules from present-day individuals of regional human populations, provides clues that help scientists unravel the origin of modern humans and trace human migrations. A series of genetic studies of mtDNA, the Y chromosome, and autosomal DNA has strengthened the case for Africa as the birthplace of modern humans (FIG. 22-14). These studies provide detailed comparisons of DNA in present-day populations around the world as well as ancient DNA extracted from Neandertal and early *H. sapiens* remains.

22.4 Cultural Change

LEARNING OBJECTIVE

8 What are the generally recognized cultural stages that human populations have experienced?

Genetically speaking, humans are not very different from other primates. At the level of our DNA sequences, we are roughly 98% identical to gorillas and 99% identical to chimpanzees. Our relatively few genetic differences, however, give rise to several important distinguishing features, such as greater intelligence and the ability to capitalize on it by transmitting knowledge from one generation to the next. Human culture is not inherited in the biological sense but instead is learned, largely through the medium of language.[2] It is dynamic and is modified as people obtain new knowledge. Human culture is generally divided into three stages: (1) the development of hunter–gatherer societies, (2) the development of agriculture, and (3) the Industrial Revolution.

Early humans were hunters and gatherers who relied on what was available in their immediate environment. They

[2] Humans are not the only animals to have culture. Chimpanzees have primitive cultures that include tool-using techniques, hunting methods, and social behaviors that vary from one population to another. These cultural traditions are passed to the next generation by teaching and imitation; see Figure 1-17.

were nomadic, and as the resources in a given area were exhausted or as the population increased, they migrated to a different area. These societies required a division of labor and the ability to make tools and weapons, which were needed to kill game, scrape hides, dig up roots and tubers, and cook food. Although scientists are not certain when hunting was incorporated into human society, they do know that it declined in importance approximately 15,000 years ago. This decline may have been due to a decrease in the abundance of large animals, triggered in part by overhunting. A few isolated groups of hunter–gatherer societies, such as the Inuit of the northern polar region and the Mbuti of Africa, survived into the 21st century.

Development of agriculture resulted in a more dependable food supply

Evidence that humans had begun to cultivate crops approximately 10,000 years ago includes the presence of agricultural tools and plant material at archaeological sites. Agriculture resulted in a more dependable food supply. Archaeological evidence suggests that agriculture arose in several steps. Although there is variation from one site to another, plant cultivation, in combination with hunting, usually occurred first. Animal domestication generally followed later, although in some areas, such as Australia, early humans did not domesticate animals.

Agriculture, in turn, often led to more permanent dwellings because considerable time was invested in growing crops in one area. Villages and cities often grew up around the farmlands, but the connection between agriculture and the establishment of villages and towns is complicated by certain discoveries. For example, Abu Hureyra in Syria was a village founded *before* agriculture arose. The villagers subsisted on the rich plant life of the area and the migrating herds of gazelle. Once people turned to agriculture, however, they seldom went back to hunting and gathering to obtain food.

Other advances in agriculture include the domestication of animals, which people kept to supply food, milk, and hides. Archaeological evidence indicates that wild goats and sheep were probably the first animals to be domesticated in southwestern Turkey, northern Iraq, and Iran. In the Old World, people also used animals to prepare fields for planting. Another major advance in agriculture was irrigation, which began more than 5000 years ago in Egypt.

Producing food agriculturally was more time-consuming than hunting and gathering, but it was also more productive. In hunter–gatherer societies, everyone shares the responsibility for obtaining food, but in agricultural societies, fewer people are needed to provide food for everyone. Thus, agriculture freed some people to pursue other endeavors, including religion, art, and various crafts.

Human culture has had a profound effect on the biosphere

Human culture has had far-reaching effects on both human society and on other organisms. The Industrial Revolution, which began in the 18th century, drew populations to concentrate in urban areas near centers of manufacturing. Advances in agriculture encouraged urbanization because fewer and fewer people were needed in rural areas to produce food for everyone. The spread of industrialization increased the demand for natural resources to supply the raw materials for industry. Chapter 53 discusses increases in human population size, and Chapter 57 investigates the effect of humans on the environment.

CHECKPOINT 22.4

- **CONNECT** Describe some of the transitions from hunter–gatherer societies to agricultural societies to the Industrial Revolution. Have all societies gone through these stages in this order?

Summary: Focus on Learning Objectives

22.1 Primate Adaptations *(page 462)*

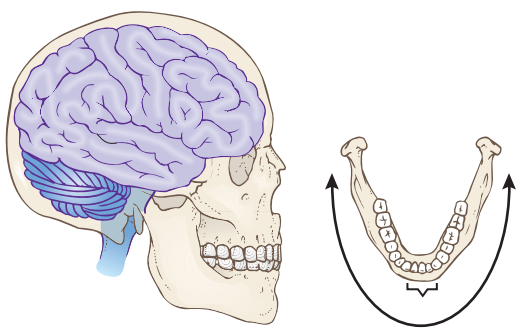
1 Describe the structural adaptations that primates have for life in treetops.

- **Primates** are *placental mammals* that arose from small, arboreal (tree-dwelling), shrewlike mammals. Primates possess five grasping digits, including an **opposable thumb** or toe; long, slender limbs that move freely at the hips and shoulders; and eyes located in front of the head.

22.2 Primate Classification *(page 462)*

2 List the three suborders of primates and give representative examples of each.

- Primates are divided into three suborders. The suborder Prosimii includes lemurs, galagos, and lorises. The suborder Tarsiiformes includes tarsiers. The suborder Anthropoidea includes anthropoids: monkeys, apes, and humans.



3 Distinguish among anthropoids, hominoids, and hominins.

- **Anthropoids** include monkeys, apes, and humans. Early anthropoids branched into two groups: New World monkeys and Old World monkeys.
- **Hominoids** include apes and humans. Hominoids arose from the Old World monkey lineage. There are four modern genera of apes: gibbons, orangutans, gorillas, and chimpanzees.
- The **hominin** line consists of humans and their ancestors.

22.3 Hominin Evolution *(page 467)*

4 Describe skeletal and skull differences between apes and hominins.

- Unlike ape skeletons, hominin skeletons have adaptations that reflect the ability to stand erect and walk on two feet. These adaptations include a complex curvature of the spine; a shorter, broader pelvis; repositioning of the **foramen magnum** to the base of the skull; and a first toe that is aligned with the other toes.
- The human skull lacks a pronounced **supraorbital ridge**, is flatter than ape skulls in the front, and has a pronounced chin. The human brain is larger than ape brains, and the jaw is structured so that the teeth are arranged in a U shape.

5 Briefly describe the following early hominins: *Orrorin, Ardipithecus, Australopithecus anamensis, Au. afarensis, Au. africanus*, and *Au. sediba*.

- *Orrorin* is an early hominin that arose about 6 mya. Researchers studying the fossil leg bones of *Orrorin* think that it walked upright and was **bipedal** (walked on two feet).
- *Ardipithecus, Australopithecus*, and *Paranthropus* species are often referred to as **australopithecines**. Australopithecines were bipedal, a hominin feature. The first *Ardipithecus* species, *Ar. kadabba*, appeared about 5.8 mya. ***Ardipithecus ramidus***, which appeared about 4.8 mya, may have given rise to ***Australopithecus anamensis***, which in turn probably gave rise to another primitive hominin, ***Australopithecus afarensis***. Many paleoanthropologists think that *Au. afarensis* gave rise to several australopithecine species, including ***Australopithecus africanus***, *Paranthropus* spp., and possibly *Homo habilis*. ***Australopithecus sediba*** may have descended from *Au. africanus*.

6 Distinguish among the following members of genus *Homo*: *H. habilis, H. ergaster, H. erectus, H. antecessor, H. heidelbergensis, H. neanderthalensis*, and *H. sapiens*.

- ***Homo habilis*** was the earliest known hominin with some of the human features lacking in the australopithecines, including a slightly larger brain. *Homo habilis* fashioned crude tools from stone.
- The best-known fossils of ***H. ergaster***, which existed from 2.0 mya to 1.4 mya, come from Kenya. *Homo ergaster* may be the direct ancestor of later humans.
- ***Homo erectus*** had a larger brain than *H. habilis*; made more sophisticated tools; and may have worn clothing, built fires, and lived in caves or shelters. *Homo erectus*, which is probably a later Asian offshoot of *H. ergaster*, appears to be an evolutionary dead end.
- Archaic humans are regionally diverse descendants of *H. ergaster* that lived in Africa, Asia, and Europe from about 1.2 mya to 200,000 years ago. The brains of archaic humans were essentially the same size as our brains, although their skulls retained some ancestral characters, and they had rich and varied cultures.
- Some researchers classify the oldest archaic human fossils discovered in Europe (in Spain) as *Homo antecessor*. ***Homo antecessor*** existed from about 1.2 mya to 800,000 years ago.
- ***Homo heidelbergensis***, which appeared about 600,000 years ago and existed until about 300,000 years ago, may have descended from *H. antecessor*. This extinct hominin had a larger brain—similar in size to that of modern humans—than either *H. ergaster* or *H. antecessor*. Many scientists studying *H. heidelbergensis* think that both Neandertals and modern humans descended from it.
- ***Neandertals*** lived from about 250,000 to 28,000 years ago. Neandertals had short, sturdy builds; receding chins and foreheads; heavy supraorbital ridges and jawbones; larger front teeth; and nasal cavities with unusual triangular bony projections. Many scientists think that Neandertals were a separate species, ***Homo neanderthalensis***.
- ***Homo sapiens*** with a mixture of primitive and modern features existed in Africa by about 300,000 years ago. By about 30,000 years ago, anatomically modern humans were the only members of genus *Homo* remaining, excluding small, isolated populations.

7 Discuss the origin of modern humans.

- Recent fossil finds and extensive molecular analyses have promoted the **(recent) out-of-Africa model** as the main explanation for the origin of modern humans living around the world. New data include the discovery of the earliest fossilized remains of modern *H. sapiens* in Africa and analyses of DNA from mitochondria, the Y chromosome, and autosomes.

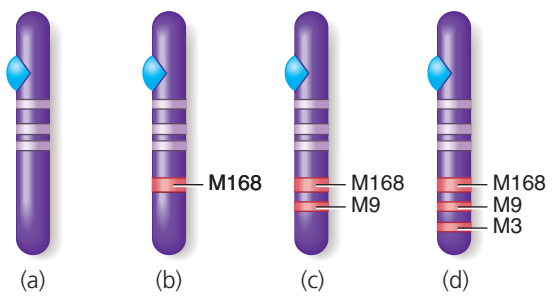
22.4 Cultural Change *(page 474)*

8 What are the generally recognized cultural stages that human populations have experienced?

- Large human brain size makes possible the transmission of knowledge from one generation to the next. Significant advances in human culture were the transition from a hunter–gatherer way of life to the development of agriculture and the Industrial Revolution.

Test Your Understanding

Know and Comprehend



1. The first primates evolved from (a) shrewlike monotremes (b) therapsids (c) shrewlike placental mammals (d) tarsiers (e) shrewlike marsupials
2. The anthropoids are more closely related to _____ than to _____. (a) tarsiers; lemurs (b) lemurs; monkeys (c) tree shrews; tarsiers (d) lemurs; tarsiers (e) tree shrews; monkeys
3. With what group do hominoids share the most recent common ancestor? (a) Old World monkeys (b) New World monkeys (c) tarsiers (d) lemurs (e) lorises and galagos
4. The _____ in humans is centered at the base of the skull, positioning the head for erect walking. (a) supraorbital ridge (b) foramen magnum (c) pelvis (d) bony skull crest (e) femur
5. Scientists collectively call humans and their *immediate* ancestors (a) mammals (b) primates (c) anthropoids (d) hominoids (e) hominins
6. The earliest hominin that most paleoanthropologists place in genus *Homo* is (a) *H. habilis* (b) *H. ergaster* (c) *H. erectus* (d) *H. heidelbergensis* (e) *H. neanderthalensis*
7. Some scientists now think that fossils identified as *Homo erectus* represent which two different species? (a) *H. habilis* and *H. erectus* (b) *H. ergaster* and *H. erectus* (c) *H. heidelbergensis* and *H. ergaster* (d) *H. neanderthalensis* and *H. erectus* (e) *H. neanderthalensis* and *H. sapiens*
8. Archaic humans appeared as early as _____ years ago. (a) 5 million (b) 1.2 million (c) 250,000 (d) 100,000 (e) 5000
9. _____ were an early group of humans with short, sturdy builds and heavy supraorbital ridges that lived throughout Europe and western Asia from about 250,000 to 28,000 years ago. (a) australopithecines (b) dryopithecines (c) archaic humans (d) Neandertals (e) Denisovans
10. The modern human skull *lacks* (a) small canines (b) a foramen magnum centered in the base of the skull (c) pronounced supraorbital ridges (d) a U-shaped arrangement of teeth on the jaw (e) a large cranium (braincase)
11. The comparison of genetic material from individuals of regional populations of humans, used to help unravel the origin and migration of modern humans, is known as (a) paleoarchaeology (b) cultural anthropology (c) molecular anthropology (d) cytogenetics (e) genetic dimorphism

Apply and Analyze

12. Place the following hominins in chronological order of appearance in the fossil record, beginning with the earliest: 1. *H. ergaster* 2. *H. sapiens* 3. *H. neanderthalensis* 4. *H. erectus* (a) 1, 4, 2, 3 (b) 4, 1, 2, 3 (c) 4, 1, 3, 2 (d) 3, 1, 4, 2 (e) 1, 4, 3, 2

Evaluate and Synthesize

13. If you were evaluating whether other early humans exterminated the Neandertals, what kinds of archaeological evidence might you look for?
14. The remains of *H. sapiens* have been found in southern Europe alongside reindeer bones, but reindeer currently exist only in northern Europe and Asia. Explain the apparent discrepancy.
15. **EVOLUTION LINK** What was the common ancestor of chimpanzees and humans: a chimpanzee, a human, or neither? Explain your answer.
16. **EVOLUTION LINK** Some scientists say that modern medicine and better sanitation are slowing down or altering the course of human evolution in highly developed countries today. As a result, evolution in humans today has gone from survival of the fittest to survival of almost everyone. Do you think that this idea is valid? Why or why not?
17. **INTERPRET DATA** Using the information in Figure 22-9, draw a simple cladogram that represents a reasonable hypothesis of human evolution at the genus level. (*Hint*: Your diagram will have three branches.)
18. **INTERPRET DATA** The four chromosomes depicted here are Y chromosomes from men in different parts of the world. The *light purple bands* represent specific genes that are identical in all four men. The *red bands* represent genetic mutations (M) that appeared at different times; M168 appeared about 50,000 years ago, M9 about 40,000 years ago, and M3 about 10,000 years ago. Based on what you have learned in this chapter, identify the geographic source of men carrying each of these chromosomes: African, Eurasian, Amerindian, and first migrants out of Africa. (You may wish to refer back to Figure 22-14.)

23 Understanding Diversity: Systematics

KEY CONCEPTS

23.1 Traditionally, biologists have named organisms using a binomial system (in which each species has a genus name followed by a specific epithet) and have classified organisms in taxonomic categories arranged in a hierarchy from most inclusive (domain) to least inclusive (species).

23.2 Based on current knowledge, the three main branches of the tree of life are the three domains: Bacteria, Archaea, and Eukarya.

23.3 Modern systematics seeks to reconstruct phylogeny (evolutionary history of a group of organisms) based on common ancestry inferred from shared characters (characteristics)—including structural, developmental, behavioral, and molecular similarities—as well as from fossil evidence.

23.4 Cladograms (a type of phylogenetic tree) are diagrams of hypothetical evolutionary relationships; they are constructed by analyzing shared derived characters.

23.5 Knowledge of modern systematics informs research in many other areas, including ecology and medicine.

PHOTO: A recently discovered peacock spider (*Maratus lobatus*). Peacock spiders are known for their elaborate courtship displays.
Jürgen Otto

The total number of living eukaryotic species on Earth is estimated to be between about 8.7 million and 100 million, but only about 1.9 million species have been described. Biologists estimate that to date they have identified less than 15% of terrestrial species and less than 10% of marine species. Many regions on our planet have not yet been carefully inventoried, including the forest canopy, soil, and the deep regions of the ocean.

Biologists discover thousands of new species each year. For example, Sydney biologist Jürgen Otto has identified several new species of peacock spider during the past few years (see photograph). Native to Australia, these brightly colored arachnids are very small, with an adult body length of only about 5 mm.

The variety of living organisms and the ecosystems they are part of are referred to as **biological diversity**, or **biodiversity**. The totality of life on Earth represents our biological heritage, and the quality of life for all organisms depends on the health and balance of this worldwide web of life-forms. For example, we depend on organisms to maintain the life-sustaining composition of gases in the atmosphere, form soil, break down wastes, recycle nutrients, and provide food for one another.

We humans exploit many species for economic benefit. One very anthropocentric (human-centered) example of the practical importance of biodiversity is that more than 40% of the prescriptions that pharmacists dispense in the United States derive from living organisms. Investigators continue to learn how to effectively screen organisms for potential drugs. Unfortunately, human activity is seriously reducing biodiversity, and species are becoming extinct faster than researchers can study them. (See the discussion on declining biodiversity in Chapter 57.)

Alarmed by these extinctions, biologists are mobilizing to more rapidly identify new species and to conserve biodiversity. Many biologists agree that describing and classifying all the surviving species of the world should be a major scientific goal of the 21st century. Important steps toward this goal are being taken by international research endeavors. For example, the *Catalogue of Life* is the work of a collaborative international research team that manages a comprehensive global database made available on the Internet. This team categorizes and lists all the world's known species. The *Encyclopedia of Life (EOL)*, a project launched in 2007, is an electronic database that includes a home page for each species. There are currently more than one million pages in this online resource, with information about more than 1.6 million species. Data include alternative names for each organism, classification, habitat, distribution, and diet. The Convention on Biological Diversity is an international treaty committed to reducing the "rate of loss of biodiversity." The 196 countries that make up this convention work to develop strategies for the conservation and sustainable use of Earth's biological diversity.

In this chapter we explore some of the approaches and methods used by biologists to classify organisms and infer their evolutionary history and relationships. (The evolution of species is discussed in Chapter 20.) Information comes from many sources, including fossils, and biogeography as well as homologies in structure, physiology, behavior, and patterns of development. Advances in DNA sequencing have generated huge amounts of data about molecular similarities and differences.

Systematics is the scientific study of the diversity of organisms and their evolutionary relationships. Recall from earlier chapters (e.g., see Chapter 18) that **evolution** is the accumulation of inherited changes within populations over time. *Systematists*, biologists who study systematics, organize information about groups of organisms ranging from a small number of populations to all life on Earth. They generate hypotheses regarding patterns of evolutionary relationships for these groups of organisms. As more sophisticated molecular methods and discovery of new fossils provide new data, old data are reinterpreted. As we gain greater understanding of how organisms are related, we revise the way we classify organisms. We can use the phylogenetic information for naming species as well as for investigating specific hypotheses about directions of evolutionary change and about the particular factors that may have caused certain evolutionary changes.

23.1 Classifying Organisms

LEARNING OBJECTIVES

1. State two justifications for the use of scientific names and classifications of organisms.
2. Describe the binomial system of naming organisms and arrange the Linnaean categories in hierarchical fashion from most inclusive to least inclusive.

Taxonomy, the science of naming, describing, and classifying organisms, is an important aspect of systematics. In biology the term **classification** means arranging organisms into groups based on similarities that reflect evolutionary relationships among lineages.

For hundreds of years, scientists have realized that certain groups of organisms share many features. Saying something like "Species X is some kind of cat," tells a person that species X falls somewhere between tigers and house cats. It also suggests that species X has many features shared with other cats, ranging from details of the heart, skin, muscles, and skeleton, to molecular traits like amino acid sequences in particular proteins and nitrogenous base sequences in DNA, and even to complex traits like behaviors and aspects of their physiology.

After the work of Charles Darwin, we came to realize that organisms within such groups share so many traits because they have all inherited those traits from the same ancestor. The living species are "related" via shared ancestors, and the traits they share are *homologous traits* (see Chapter 18). Modern systematists seek to name and classify organisms according to their evolutionary relationships. This work involves some careful investigations as we attempt to determine the patterns of relationships.

Organisms are named using a binomial system

In the mid-18th century, Carolus Linneaus developed a system of naming organisms to allow scientists to communicate more clearly. We will discuss his contributions to classification in the next section, but here we focus on his idea for naming species.

Before the mid-18th century, each species had a lengthy descriptive name, sometimes consisting of 10 or more Latin words! Linnaeus simplified scientific classification, developing a **binomial system of nomenclature** in which each species is assigned a unique two-part name. The first part of a binomial scientific name is a noun that designates the **genus** (pl., *genera*), and the second part, an adjective modifying that noun, is called the **specific epithet**.

The genus name is always capitalized, whereas the specific epithet is usually not. Both names are underlined or italicized. The genus, or generic, name can be used alone to designate all species in the genus (e.g., the genus *Quercus* includes all oak species). Note that the specific epithet alone is *not* the name of the species. In fact, the same specific epithet can be used as the second name of species in different genera. For example, *Quercus alba* is the scientific species name for the white oak, and *Salix alba* is the species name for the white willow (*alba* comes from a Latin word meaning "white"). Thus, both parts of the name must be used to identify the species accurately. The specific epithet is never used alone; it must always follow the full or abbreviated genus name, such as *Quercus alba* or *Q. alba*.

Scientific names are generally derived from Greek or Latin roots or from Latinized versions of the names of persons, places, or characteristics. For example, the generic name for the bacterium *Escherichia coli* is based on the name of the scientist, Theodor Escherich, who first described it. The specific epithet *coli* reminds us that *E. coli* lives in the colon (large intestine).

Scientific names permit biology to be a truly international science. Even though the common names of an organism may vary in different locations and languages, an organism can be universally identified by its scientific name. A researcher in Puerto Rico knows exactly which organisms were used in a study published by a Russian scientist and therefore can repeat or extend that scientist's experiments using the same species.

Each taxonomic level is more general than the one below it

Linnaeus devised a system for assigning species to a hierarchy of increasingly broader groups. As you move up the hierarchy, each group is more inclusive; that is, it includes the groups below it. When he set up his system, Linnaeus did not have a theory of evolution in mind, nor did he have any idea of the vast number of extant (living) and extinct organisms that would later be discovered. His system nonetheless ended up providing important evidence for evolution, and although some substantial modifications have been necessary, Linnaeus's basic system still forms a framework for much of our modern classifications.

The range of taxonomic categories from species to domain forms a hierarchy (TABLE 23-1 and FIG. 23-1). Closely related species are assigned to the same genus, and closely related genera are grouped in a single **family**. Families are grouped into **orders**, orders into **classes**, classes into **phyla**, phyla into **kingdoms**, and kingdoms into **domains**. A **taxon** (pl., *taxa*) is a formal grouping of organisms at any given level, such as species, genus, or phylum. Today we realize that classifying organisms requires many more classification levels than envisioned by Linnaeus, so between any two categories there could be additional levels. For example, the order Coleoptera (beetles) contains more than 400,000 species, and the class is divided into subclasses, with each subclass containing multiple infraorders, each infraorder containing multiple superfamilies, and each superfamily containing numerous families. Sometimes even these additional levels are not sufficient to categorize important groups.

Another difference between the current classifications and those of Linnaeus is even more substantial. Linnaeus grouped species into particular taxa because they shared certain *features*. In light of our modern understanding of shared ancestry and evolution, we seek to place organisms into particular taxa because they share particular *ancestry*. For example, a modern biologist would place a species within the taxon Mammalia if all the available evidence showed that the species evolved from the same recent ancestor as the rest of the mammals. This decision would not be based on whether or not members of the species had any one particular feature, like hair or mammary glands.

Table 23-1 Classification of Corn

Domain	**Eukarya** Organisms that have nuclei and other membrane-enclosed organelles
Kingdom	**Plantae** Terrestrial, multicellular, photosynthetic organisms
Phylum	**Anthophyta** Vascular plants with flowers, fruits, and seeds
Class	**Monocotyledones** Monocots: Flowering plants with one seed leaf (cotyledon) and flower parts in threes
Order	**Commelinales** Monocots with reduced flower parts, elongated leaves, and dry one-seeded fruits
Family	**Poaceae** Grasses with hollow stems; fruit is a grain; and abundant endosperm in seed
Genus	***Zea*** Tall annual grass with separate female and male flowers
Species	***Zea mays*** Corn

CHECKPOINT 23.1

- Eating a single "death cap" mushroom can be fatal. The specific epithet of this mushroom is *phalloides*. Its genus name is *Amanita*. Write its scientific name.
- What are the key features of the system of hierarchical classification?
- **VISUALIZE** Write a list of the following taxonomic categories in order from most inclusive to least inclusive: genus, order, domain, family, phylum, species, kingdom, class.

23.2 Determining the Major Branches in the Tree of Life

LEARNING OBJECTIVES

3 Describe the three domains and argue for and against classifying organisms in these domains. (Compare this approach with using kingdoms as the main rank of classification.)

4 Interpret a cladogram, describing the meaning of its specific nodes and branches.

5 Differentiate between vertical and horizontal gene transfer and explain their importance in understanding systematics.

The history of taxonomy at the kingdom and domain levels is a good example of the process of science. In this section we will review some highlights of this process.

Systematics is an evolving science

From the time of Aristotle (more than 2300 years ago) to the mid-19th century, biologists divided organisms into two kingdoms: **Plantae** and **Animalia**. After the development of microscopes, it became increasingly obvious that many organisms could not be easily assigned to either the plant or the animal kingdom. For example, the unicellular organism *Euglena* was classified at various times in the plant kingdom and in the animal kingdom, but did not really fit in either kingdom. *Euglena* carries on photosynthesis in the light, but in the dark, it uses its flagellum to move about in search of food (see Fig. 26-5). In 1866, a German biologist, Ernst Haeckel, proposed that a third kingdom, **Protista**, be established to accommodate bacteria and other microorganisms. However, biologists largely ignored this kingdom for about a hundred years.

In 1937, French marine biologist Edouard Chatton suggested the term *procariotique* ("before nucleus") to describe bacteria and the term *eucariotique* ("true nucleus") to describe all other cells. The distinction between prokaryotes and eukaryotes is now accepted by biologists as a fundamental evolutionary divergence.

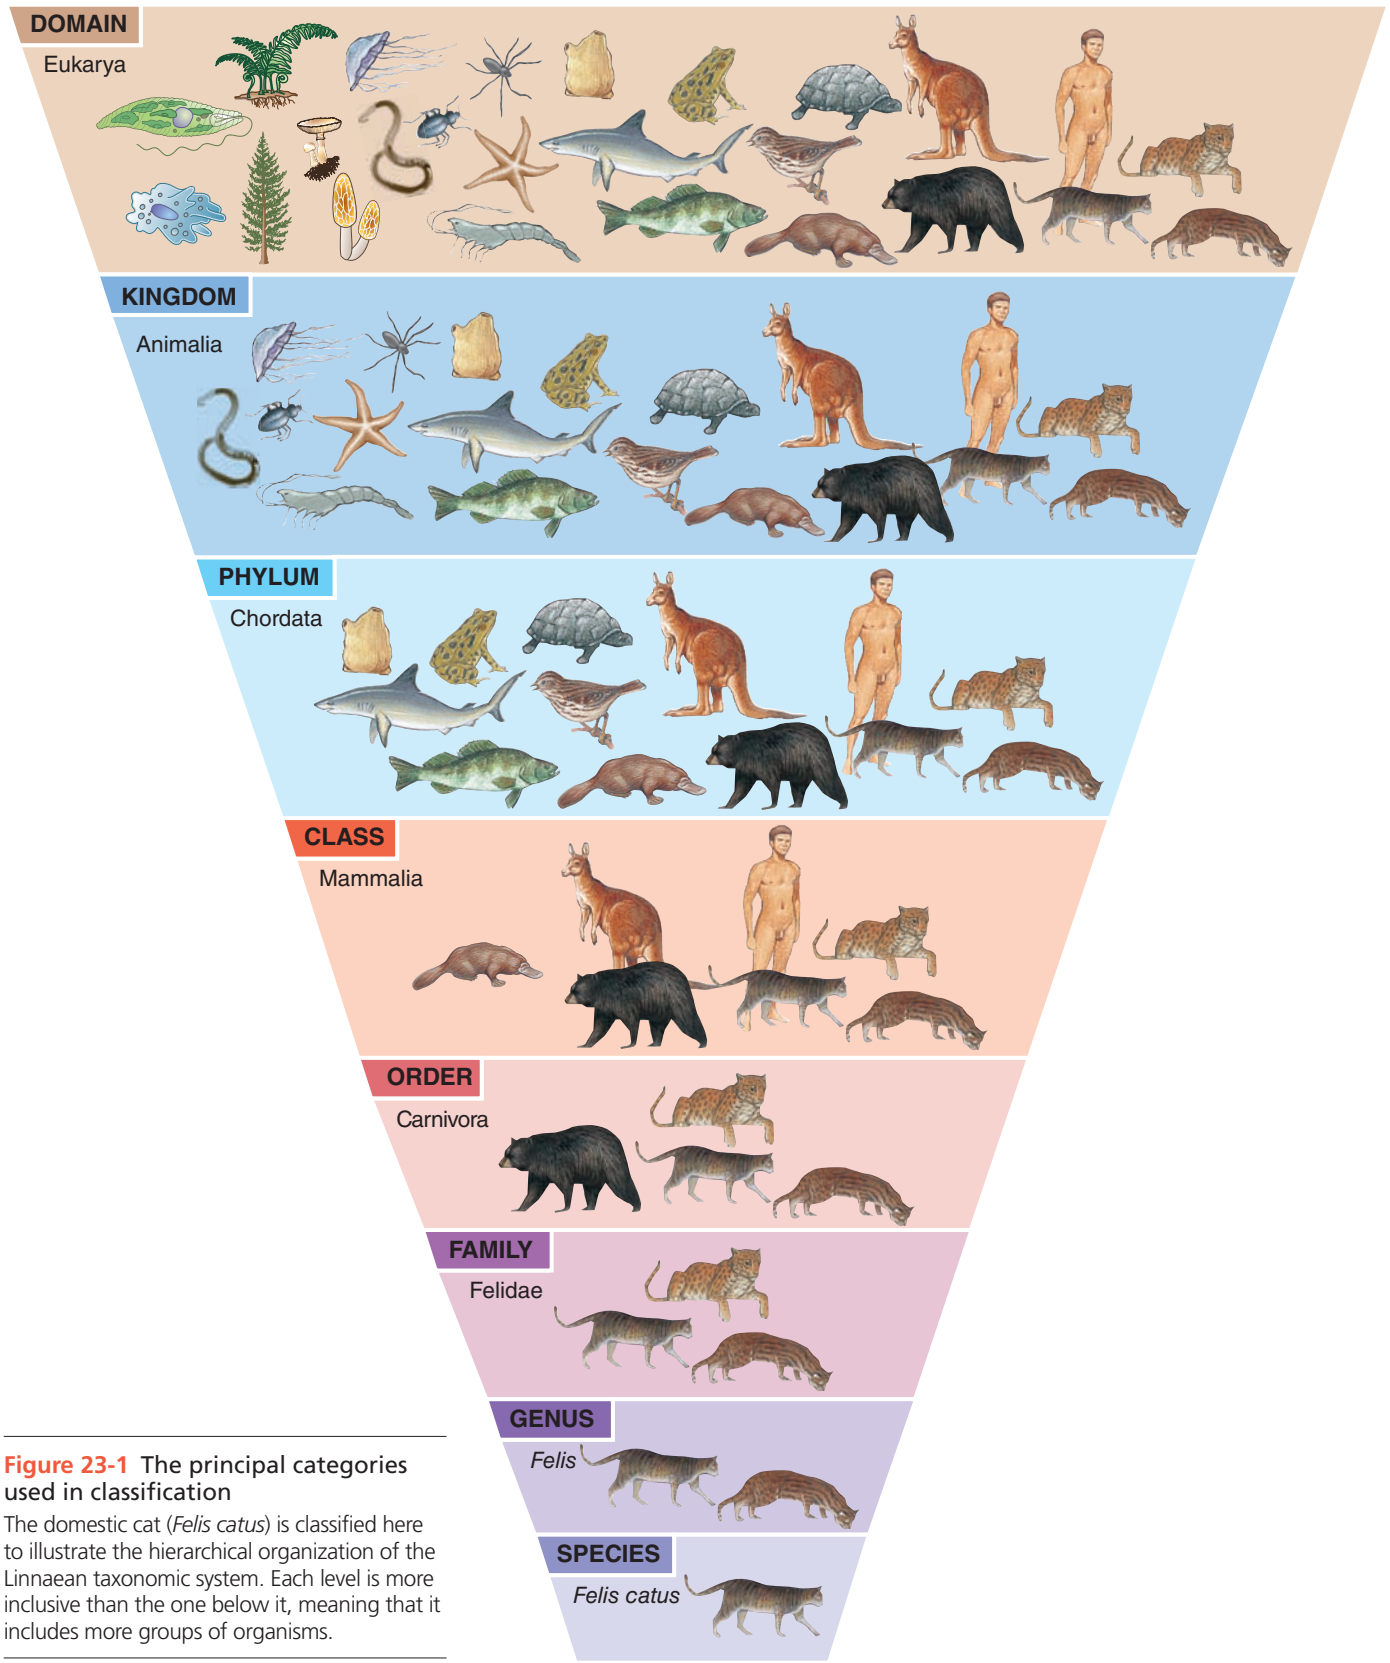

Figure 23-1 The principal categories used in classification

The domestic cat (*Felis catus*) is classified here to illustrate the hierarchical organization of the Linnaean taxonomic system. Each level is more inclusive than the one below it, meaning that it includes more groups of organisms.

In the 1960s, advances in electron microscopy and biochemical techniques revealed further cell differences that inspired many new proposals for classifying organisms. In 1969, R.H. Whittaker proposed a five-kingdom classification based mainly on cell structure and the way that organisms derive nutrition from their environment. (Although Whittaker is generally credited, the concept of five kingdoms was actually first proposed in 1949 by T.L. Jahn and F. Jahn in their book *How to Know the Protozoa*.)

Whittaker suggested that the fungi (which include the mushrooms, molds, and yeasts) be removed from the plant kingdom and classified in their own kingdom, **Fungi**. After all, fungi are not photosynthetic. They obtain their nutrition by absorbing nutrients produced by other organisms. Fungi also differ from plants in the composition of their cell walls, their body structures, and their modes of reproduction. Kingdom **Prokaryotae** was established to accommodate the bacteria, which are fundamentally different from all other organisms in that they do not have distinct nuclei and other membranous organelles and do not undergo mitotic division (see Fig. 4-8).

In the late 1970s, Carl Woese (pronounced "woes") of the University of Illinois and his colleagues began to study the evolutionary relationships among organisms by analyzing genes coding for their ribosomal RNA. Using sequence analysis, Woese used variations in this universal molecule to challenge the long-held view that all prokaryotes were closely related and very similar to one another. The analysis of ribosomal RNA is an important tool used by systematists. Woese showed that there are two fundamentally different groups of prokaryotes, archaea and bacteria. He and his colleagues proposed not only that the archaea are different from the bacteria, but also that the archaea are genealogically more closely related to the eukaryotes than they are to the bacteria.

Woese's hypothesis gained support in 1996 when Carol J. Bult of the Institute for Genomic Research in Rockville, Maryland, reported in the journal *Science* that she and her colleagues had sequenced the complete genome of a methane-producing archaea, *Methanococcus jannaschii*. When these researchers compared gene sequences with those of two previously sequenced bacteria, they found that fewer than half of the genes matched. Gene sequencing indicates that the archaea have a combination of bacteria-like and eukaryote-like genes. Biologists have identified other important differences between bacteria and archaea. For example, bacteria are characterized by the presence of a compound called peptidoglycan in their cell walls, whereas this compound is not present in archaea. Based on molecular evidence, biologists now divide the prokaryotes into two major groups: *bacteria* and *archaea*.

Kingdom Protista has had an interesting history. Biologists placed *Euglena*, along with other unicellular organisms traditionally referred to as protozoa, in kingdom Protista. At various times, they have also assigned algae (including multicellular forms), water molds, and slime molds to kingdom Protista. Thus, this kingdom became a diverse group of mainly unicellular, mainly aquatic eukaryotic organisms. During the past few years, systematists have established that the protist groups did not descend from one recent common ancestor. As we will discuss in Chapter 26, most biologists have abandoned kingdom Protista (as well as a kingdom classification for plants and animals) and now assign the eukaryotes to five "supergroups" based on molecular data. The word *protist* is currently used as an informal catch-all term.

The three domains form the three main branches of the tree of life

Based on fundamental molecular differences among the bacteria, archaea, and eukaryotes, biologists currently classify organisms in three domains: **Archaea**, **Bacteria**, and **Eukarya** (eukaryotes).

Key Point

Biologists classify organisms in three major groups called domains.

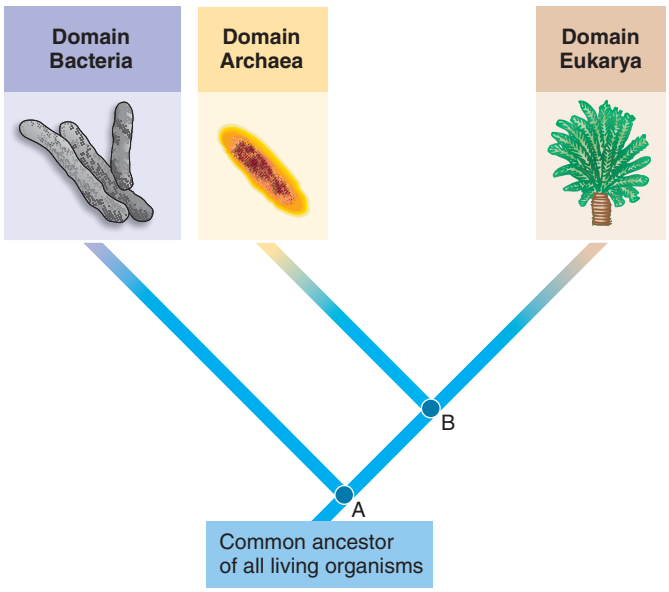

Figure 23-2 The three domains

This cladogram, a type of evolutionary tree, illustrates the evolutionary relationships among organisms in the three domains. Each branch of the cladogram represents a clade, a group of organisms with a recent common ancestor. Each node (*circle*) represents the point at which two groups diverged from each other.

PREDICT According to this cladogram, are the Archaea more closely related to the Bacteria or to the Eukarya?

Systematists have inferred that the three domains are the three main branches of the tree of life (FIG. 23-2). New data suggest that many core genes of eukaryotes came from archaea. The data support the hypothesis that an archaean was the host cell in the endosymbiosis that led to the evolution of eukaryotes. The hypothesized partnership between archaea and bacteria suggests that all life can be classified into a two-domain system, with eukaryotes as a subgroup. In Chapter 25 we will discuss characters that distinguish these domains. As we will discuss in Chapter 24, the viruses are a special case and are not classified in any of the three domains.

Some biologists are moving away from Linnaean categories

Because modern biologists are interested in having the classifications of living organisms reflect their patterns of relatedness as closely as possible, some of the terminology that has been used for decades is either being put aside or redefined. In addition, our increased ability to investigate the DNA sequences of organisms and improved techniques for analyzing these molecular data are providing many new discoveries regarding the patterns of relatedness among living species. We are in the midst of a time of transition.

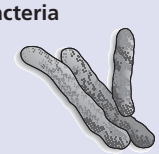
Students learning biology during this time of amazing new technology and research need to know that our understanding of many aspects of biology is rapidly changing. Biology textbooks may vary in the classification and terminology they present. For example, biologists are now using the classification system with three domains (Bacteria, Archaea, and Eukarya), with the Eukarya divided into a number of large taxa reflecting shared ancestry. Most biologists no longer recognize the kingdom Protista because many of the organisms within that group are actually more closely related to either plants or animals or fungi than they are to one another (see TABLE 23-2 and FIG. 23-3).

In this edition of *Biology*, we classify organisms using the three domains and also use many of the traditional taxonomic names. We discuss throughout the book instances where the traditional taxonomy is undergoing revision to better reflect our knowledge concerning patterns of common ancestry.



Phylogenetic trees show hypothesized evolutionary relationships

Systematists use **phylogenetic trees** to graphically represent hypothesized evolutionary relationships among organisms that have a common ancestor. In Figure 23-2 we use a phylogenetic tree to illustrate the relationship of the three domains, and the phylogenetic tree in Figure 23-3 illustrates the main branches that make up each of the three domains. This tree is one of the current versions of the tree of life.

The type of phylogenetic tree we use in this book is called a **cladogram**. Each *branch* in a cladogram represents a **clade**, a group of organisms with a common ancestor. Each branching point, referred to as a *node* (depicted by a circle), represents the divergence, or splitting, of two or more new groups from a common ancestor. Thus, the node represents the *most recent common ancestor* of each clade depicted by the branches. In this way, a cladogram uses the positions of branch points to illustrate the hypothesized evolutionary relationships among taxa. Each of the branches is formed based on evidence in terms of observable traits that are shared by the organisms at the end of the branch but are not found in organisms on other branches. (*Shared derived characters* are discussed in the next section.) These shared characteristics can be indicated by labels or by bars across the branches.

Cladograms are rooted if the most recent common ancestor is known. The *root*, or node at the base of the cladogram, represents the most recent common ancestor of all the clades

Table 23-2 Domains and Kingdoms

Domain	Kingdom	Characteristics	Ecological Role and Comments
Bacteria 	Bacteria	Prokaryotes (lack distinct nuclei and other membranous organelles); unicellular; microscopic; cell walls generally composed of peptidoglycan	Most are decomposers; some parasitic (and pathogenic); some chemosynthetic autotrophs; some photosynthetic; important in recycling nitrogen and other elements; some used in industrial processes.
Archaea 	Archaea	Prokaryotes; unicellular; microscopic; peptidoglycan absent in cell walls; differ biochemically from bacteria	Decomposers; important in recycling carbon, nitrogen, and other nutrients; methanogens are anaerobes that inhabit sewage, swamps, and animal digestive tracts; extreme halophiles inhabit salty environments; extreme thermophiles inhabit hot, sometimes acidic environments.
	Protists formerly classified in kingdom Protista; now assigned to a number of "supergroups"	Eukaryotes; mainly unicellular or simple multicellular	Protozoa are an important part of zooplankton. Algae are important producers, especially in marine and freshwater ecosystems; important oxygen source. Some protists cause diseases (e.g., malaria).
	Plantae	Eukaryotes; multicellular; photosynthetic; possess multicellular reproductive organs; alternation of generations; cell walls of cellulose	Terrestrial biosphere depends on plants in their role as primary producers; important source of oxygen in Earth's atmosphere.
Eukarya* 	Fungi	Eukaryotes; heterotrophic; absorb nutrients; do not photosynthesize; body composed of threadlike hyphae that form tangled masses that infiltrate food or habitat; cell walls of chitin	Decomposers; some parasitic (and pathogenic); some form important symbiotic relationships with plant roots (mycorrhizae) or algae (lichens); some used as food; yeast used in making bread and alcoholic beverages; some used to make industrial chemicals or antibiotics; responsible for much spoilage and crop loss.
	Animalia	Eukaryotes; multicellular heterotrophs; many exhibit tissue differentiation and complex organ systems; most able to move about by muscular contraction; nervous tissue coordinates responses to stimuli	Consumers; some specialized as herbivores, predators, or detritus feeders.

* For another approach to classification of Eukarya, see Figure 23-3.

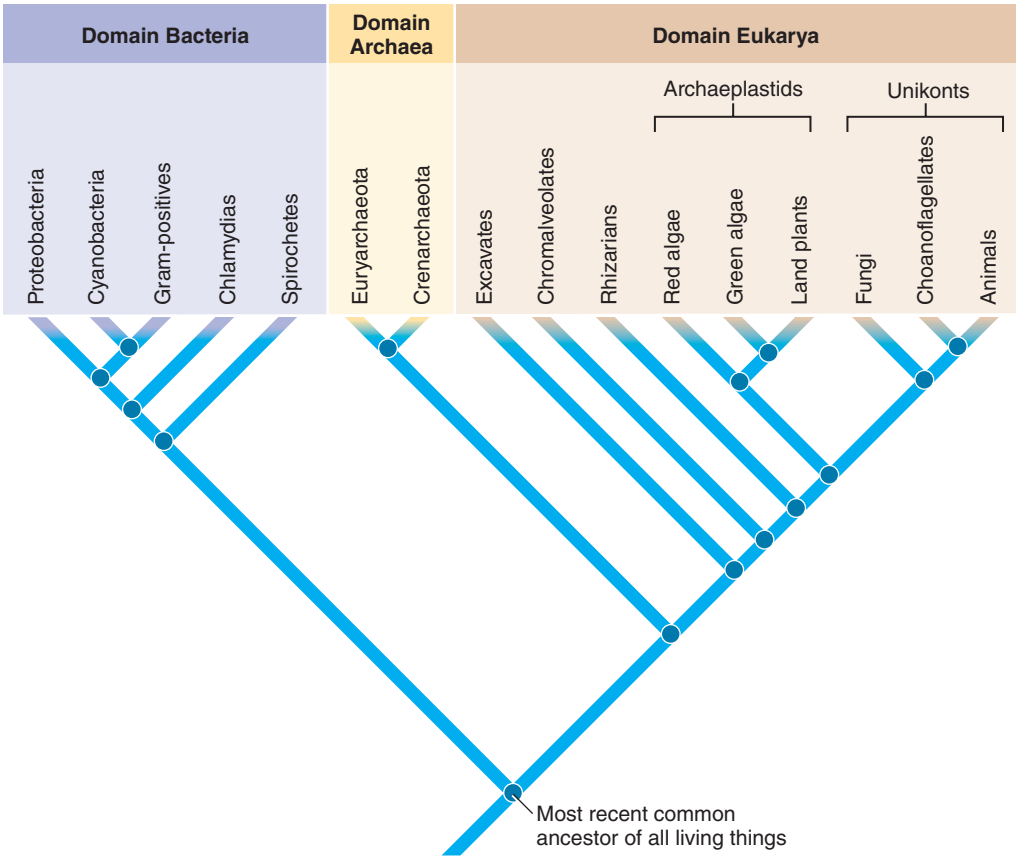

Figure 23-3 The tree of life, a work in progress

Some major branches of each of the three domains are shown. As new data are analyzed, the relationships of some of the branches will change.

depicted in the tree. We will discuss more about constructing cladograms as we proceed through this chapter.

Although a cladogram depicts the evolutionary relationships of each group through time, the *lengths* of the branches do not tell us *when* a particular species evolved. Other types of phylogenetic trees—for example, *phylograms*—can be constructed to indicate time, or rate of evolution, as well as the relationships among taxa. In a phylogram the length of the branches is proportional to the amount of inferred change in characteristics.

Systematists continue to consider other hypotheses

When we think of how organisms acquire their genes, we think of **vertical gene transfer** in which genes are transmitted from parent to offspring within the same species. We also usually attribute similarities among species in their heritable traits to be the result of shared ancestry, or **homology**. For example, if two species share the same sequence of nitrogenous bases in their DNA for a particular gene, we hypothesize that this sharing is due to the two species having inherited that particular gene from the same ancestor. As biologists have continued to investigate the evolution of genes, they have discovered that in some cases inheritance can occur outside the parent to offspring pathway.

Throughout the history of life, genes were not only passed down "vertically" from one generation to the next, but were also exchanged "laterally." In **horizontal gene transfer**, gene swapping takes place between one genome and another within one taxon or between genomes in different taxa. In this process, genes move from one individual to another or from one species to another species in the same generation.

Horizontal gene transfer can occur in several ways, such as by exchange of DNA among different populations or species of bacteria or archaea, or by interbreeding between closely related groups. One way that horizontal gene transfer has occurred in eukaryotes is by **endosymbiosis**, a process in which one organism lives inside the cell of another organism and the two become dependent on each other. Over time, such relationships may result in a complete loss of the separate identity of the symbionts. In fact, eukaryotic cells most likely evolved from prokaryotic cells that lived symbiotically, one within another. Recall that considerable evidence has been found supporting the hypothesis that mitochondria and chloroplasts originated from prokaryotes that lived as endosymbionts inside other cells (see Chapter 21).

Horizontal gene transfer occurs between free-living organisms classified in different domains. In 2013, a team of researchers reported that horizontal gene transfers from free-living bacteria and archaea enabled the unicellular red alga *Galdieria sulphuraria* to adapt to harsh environments that are too hot, acidic, or toxic for most other eukaryotes. The study suggests that horizontal gene transfer continues to be a very important mechanism in evolution.

Based on what is now known about horizontal gene transfer, some systematists argue that the common ancestor of all living things may have been a *community* of species that traded their genes. Many systematists suggest that there is no simple tree of life and have proposed alternative hypotheses (FIG. 23-4). Based on analyses of hundreds of genes, some systematists hypothesize that horizontal gene transfer between bacteria and archaea gave rise to the eukaryotes. Horizontal gene transfer appears to be a continuous process among members of the three domains.

The evolution of systematics reflects the creative and dynamic process of science. Systematists are very responsive

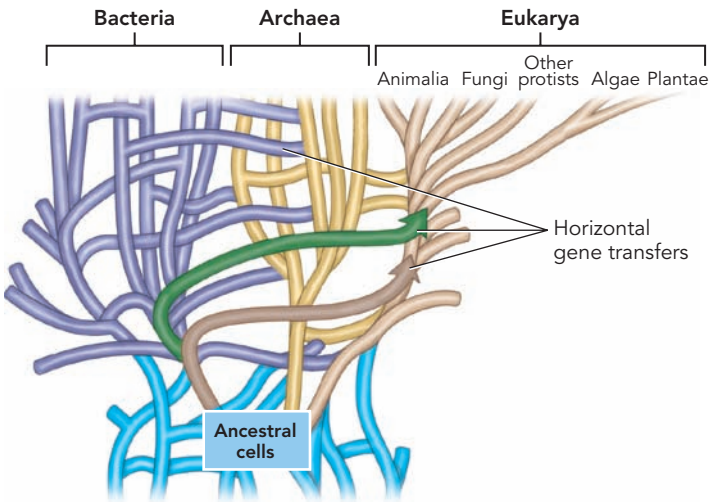

Figure 23-4 Another way to represent the tree of life

The three-domain approach has been drawn to show horizontal gene transfer as a continuous process between domains and also among groups within each domain. Only some of the branches are labeled. The diagonal *brown arrow* represents mitochondrial endosymbiosis; the diagonal *green arrow* represents chloroplast endosymbiosis.

to new data; consequently, classification of organisms at all levels is a continuously changing process. Although many biologists are moving away from a hierarchical system, some suggest adding new groups so that the classical approach keeps up with new findings. Whatever approach is used, the goal of systematics is to base classification on evolutionary change and relationships.

CHECKPOINT 23.2

- What are the major groups of organisms that belong to each of the three domains? In which domain and kingdom would you classify each of the following: white willow, the bacterium *Escherichia coli*, tapeworm, and black bread mold?
- **CONNECT** In what specific ways does a cladogram give us information about the evolutionary relationships of groups of organisms?
- Contrast the two mechanisms—vertical and horizontal gene transfer—by which genes are transferred from one genome to another.

23.3 Reconstructing Evolutionary History

LEARNING OBJECTIVES

6 Critically review the difficulties encountered in choosing taxonomic criteria.

7 Apply the concept of shared derived characters to the classification of organisms.

8 Describe how analyses of molecular homologies contribute to the science of systematics.

9 Contrast monophyletic, paraphyletic, and polyphyletic taxa.

A major goal of modern systematics is to reconstruct **phylogeny** (literally, "production of phyla"), the evolutionary history of any group of organisms from a common ancestor. In their efforts, systematists must employ a wide range of evidence, from shared traits (homologous traits) to geographic distributions to positions in strata (for fossils), and must incorporate our best understandings of evolutionary processes. As systematists determine evolutionary relationships among species and higher taxa, they build classifications based on the patterns of shared ancestry. Systematics is at the center of how we understand and explain the patterns of similarities and relationships of life-forms on Earth.

Once phylogenies are established, they help us answer other questions in biology. For example, phylogenies help us understand evolutionary patterns that might provide clues to the origin and spread of HIV and other pathogens (discussed later in this chapter). Phylogenies also help biologists identify new species and predict their characteristics, as well as understand biodiversity and ecological mechanisms. Systematists may classify a new species based on specific characters that it shares with other organisms in a particular taxon. They may then infer that the new species shares many other characters with organisms in that group.

As you read the following sections, remember that phylogenies are testable hypotheses. They are supported or falsified by the available data. Systematics proceeds by constantly re-evaluating data, hypotheses, and theoretical constructs. As new data are discovered and old data are reinterpreted, systematists modify their hypotheses. As a result, our understanding of how organisms are related and the way we classify organisms are continuously being revised. Systematics is a dynamic science that changes as biologists discover new species and use ever more sophisticated techniques to investigate the evolutionary relationships among organisms.

Recall that a **population** is made up of all the individuals of the same species that live in a particular area. A population has a dimension in space—its geographic range—and also a dimension in time. Each population extends backward in time. Somewhat like branches of a tree, a population may diverge from other populations enough to become a new species (which may be depicted by a new tree branch; see Chapters 19 and 20). Species have various degrees of evolutionary relationships with one another, depending on the degree of genetic divergence since their populations branched from a common ancestor.

Homologous structures are important in determining evolutionary relationships

The evidence suggests that some 380 to 400 million years ago a population of early fishlike vertebrates evolved. These animals, the early **tetrapods**, had four limbs instead of the pectoral and pelvic fins of their fish ancestors. Because all the modern amphibians, reptiles, birds, and mammals evolved from that group of early tetrapods, members of the modern taxa share

many traits. For example, the wings of bats, the front legs and paws of tigers, the front flippers of whales, and the front limbs of frogs all share similar bone structures because the genes for these bones were inherited from the same earliest tetrapods. We say that the bones are *homologous* among these animals (see Fig. 18-13). Based on their shared ancestry, the tetrapods are now classified in the group, **Tetrapoda**.

Although homologous similarities are very important to scientists for inferring phylogeny, similarities among species can occur for reasons other than homology. Similar structures sometimes evolve when unrelated or distantly related species become adapted to similar environmental conditions. Thus, wings may occur in two or more species not derived from a recent common ancestor. Recall from Chapter 18 that independent evolution of similar structures in distantly related organisms is known as **convergent evolution**. Sharks and dolphins have similar, but independently derived, body forms because they have become adapted to similar environments (aquatic) and lifestyles (predatory). Sometimes it is obvious that convergent evolution has occurred. In other cases, researchers must test their hypotheses using all available data.

Another challenge in deciding on homology is **reversal**, in which a trait reverts to its ancestral state. A reversal removes a similarity that had evolved. A characteristic that superficially appears homologous but is actually independently acquired by convergent evolution or reversal is described as exhibiting **homoplasy**. Distinguishing between homology and homoplasy can be challenging (FIG. 23-5).

Shared derived characters provide clues about phylogeny

Systematists rely on homologous traits for evidence of shared ancestry. However, they also distinguish among those homologous traits, determining which traits will help most for studying particular relationships. In making decisions about taxonomic relationships, the systematist first examines the homologous characteristics in the largest group (such as phylum or class) of organisms being studied and interprets them as indicating the most *remote* common ancestry. These **shared ancestral characters** are features that were present in an ancestral species and remain present in all groups descended from that ancestor. For example, the vertebrae, present in all vertebrates (with the exception of the hagfishes), is an ancestral character for study of classes within the subphylum Vertebrata. Studying the presence or absence of the vertebrae does not help us discriminate among various classes of vertebrates (e.g., between amphibians and mammals) because all individuals in these classes (except the hagfishes) have vertebrae.

When two populations become separated and begin to evolve independently, some of their homologous traits change as a result of mutation, natural selection, and genetic drift. The novel traits that evolve and remain present in the descendant taxa are referred to as **shared derived characters**, or *synapomorphies*. Note that shared derived characters originate in a *recent* common ancestor and are present in its descendants. Species that share derived characters form a clade. Systematists use *shared derived characters* (recently evolved homologies) to identify points where groups diverged from one another. A trait viewed as a derived character in a more inclusive (broader) taxon may also be considered an *ancestral character* in a less inclusive (narrower) taxon. For example, vertebrae are a shared derived character among vertebrates, but an ancestral character among mammals.

More recent common ancestry is indicated by classification into less and less inclusive taxonomic groups with more and more specific shared derived characters. For example, the small bones in the middle ear are useful in identifying a branch point between reptiles and mammals. All tetrapods (amphibians, reptiles, birds, and mammals) have one bone, the stapes, present in the middle ear, but mammals have two additional bones, the incus and malleus, in the middle ear. The evolution of this derived character (three bones rather than one bone) was a unique event, and only mammals have these

GEORGE GRALL/National Geographic Creative

Edmund Brodie

Figure 23-5 Homology and homoplasy

These two salamander species (*Notophthalmus viridescens*, red eft stage, and *Plethodon cinereus*, red-backed salamander) share many skeletal features because they inherited these features from the same early salamander species that was their shared ancestor. This is an example of homology. However, the bright red color of the two species has independently evolved, which is an example of homoplasy.

bones. However, if we compare mammals with one another, the three ear bones are a shared ancestral character because all mammals have them. Consequently, they have no value for distinguishing among mammalian taxa. Other characters must be used to establish branch points among the mammals.

If we compare dogs, goats, and dolphins (which are all mammals), we find that dogs and goats have two nostrils at the tip of their snouts, whereas dolphins have their nostrils at the tops of their heads as a single or paired blowhole. Having nostrils at the tip of the snout is an ancestral trait in mammals and therefore cannot be used as evidence that dogs and goats share a more recent common ancestor. In contrast, the presence of a blowhole in dolphins is a derived character within mammals. When we compare dogs, dolphins, and whales, we find that dolphins and whales share this derived character, providing evidence that these animals evolved from a common ancestor not shared by dogs.

Systematists base taxonomic decisions on recent shared ancestry

Both dolphins and many fishes have streamlined body forms, but this similarity is homoplastic and does not indicate close evolutionary relationships. In contrast, dolphins share important homologous derived characters (synapomorphies) with mammals: mammary glands, which produce milk for the young; three small bones in the middle ear; and a muscular diaphragm that helps move air into and out of the lungs, to name just a few traits. Thus, our evidence suggests that dolphins and mammals share a common ancestor, and we classify dolphins as mammals.

Historically, people have thought of higher taxonomic groups as being comprised of species that share certain defining features. For example, previously someone might say that mammals are defined as vertebrates that possess hair. Modern systematics, with its emphasis on recognizing taxonomic groups based on shared genealogy (ancestry), requires a different perspective. Systematists do use traits like mammary glands, muscular diaphragm, and hair as evidence that dolphins should be classified as mammals. Dolphins are included within the Mammalia because all the available evidence suggests that they evolved from the same recent ancestor as the rest of the mammals. Even if dolphins evolved to completely lose all body hair, they would still be classified within the Mammalia because of their ancestry.

Another example was mentioned earlier in this chapter. The tetrapods are all those vertebrates that evolved from the first fish-like vertebrates that had limbs with joints and digits instead of fins. As the name suggests, tetrapods are the "four-legged" vertebrates. However, the taxonomic group Tetrapoda is not defined by the presence of four legs; in fact, many groups of animals that are classified as tetrapods have either no limbs (e.g., snakes and limbless lizards) or greatly modified limbs (e.g., whales and birds).

Molecular homologies help clarify phylogeny

When a new species evolves, it does not always exhibit obvious phenotypic differences when compared to closely related species. For example, two distinct species of fruit flies may appear identical to us. Some of their DNA, proteins, and other molecules, however, are different. Such variations in the structure of specific macromolecules among species, just like differences in anatomical structure, result from mutations. Advances in molecular biology have provided the tools for biologists to compare the macromolecules of various organisms. In fact, organisms can now be identified by their molecular structure.

In 2003, scientists at the University of Guelph in Canada proposed in the British *Proceedings of the Royal Society* that we identify all living things by their unique sequences of nitrogenous bases in particular regions of DNA rather than by their physical structure. The DNA barcode initiative, directed by the Consortium for the Barcode of Life (CBOL), is based on the concept that scientists will find a particular region of DNA (1) that is present in all species, (2) that is relatively short and easy to sequence, and (3) for which each species has a unique sequence of nitrogenous bases. This DNA region would be a global tool for species identification. Currently, some scientists have agreed that the gene for the protein cytochrome oxidase subunit I may fit the requirements for eukaryotes, and they are attempting to determine the sequences for as many species as possible. The hope is that the relatively easy-to-determine DNA sequences will work like product barcodes, uniquely identifying each species at any stage of life, including eggs, seeds, or incomplete fragmented samples. More than 200 organizations worldwide are collaborators in CBOL's DNA barcode effort.

The science of **molecular systematics** focuses on molecular structure to clarify evolutionary relationships. DNA, RNA, and amino acid sequencing are used to compare the macromolecules of organisms being studied. Macromolecules that are functionally similar in two different types of organisms are considered homologous if their subunit sequence is similar. Such comparisons provide systematists with valuable information about the degree of relatedness among organisms. The more closely the subunit sequences of two species correspond, the more closely related the species are considered to be. The number of differences in certain DNA nucleotide sequences in two groups of organisms may approximately reflect how much time has passed since the groups branched from a common ancestor. (This can be true only when the mutations in DNA occur at a steady rate.) Thus, specific DNA sequences may be useful as **molecular clocks**.

Many systematists look to ribosomal RNA (rRNA) structure and the DNA sequences that code for the RNA in ribosomes (ribosomal DNA) to help determine phylogenies. All known organisms have ribosomes that function in protein synthesis, and the DNA nucleotide sequences coding for rRNA have been highly conserved during evolution. Recall that the division of organisms into three domains was based in large part on the comparison of rRNA by Carl Woese and his research team.

The ribosomes of archaea and bacteria contain three subunits of RNA, named in order of increasing size: 5S, 16S, and 23S. (These numbers are sedimentation coefficients, measures of relative size, used to characterize behavior of a particle when

centrifuged.) The DNA sequences for the 5S and 16S RNAs have been extensively used to determine evolutionary relationships among bacteria. These gene sequences for rRNA are useful because the number of base pairs is manageable, the DNA has shown little change over long evolutionary periods, and the genes show some species-specific variability among bacteria and archaea.

Researchers have also used comparison of the DNA sequences for rRNA to challenge the once widely accepted idea that fungi are closely related to plants. According to rRNA analysis, fungi are more closely related to animals than to plants. Animals and fungi share a more recent common ancestor, perhaps a flagellate, a one-celled protist that has one or more long, whiplike flagella (used for locomotion).

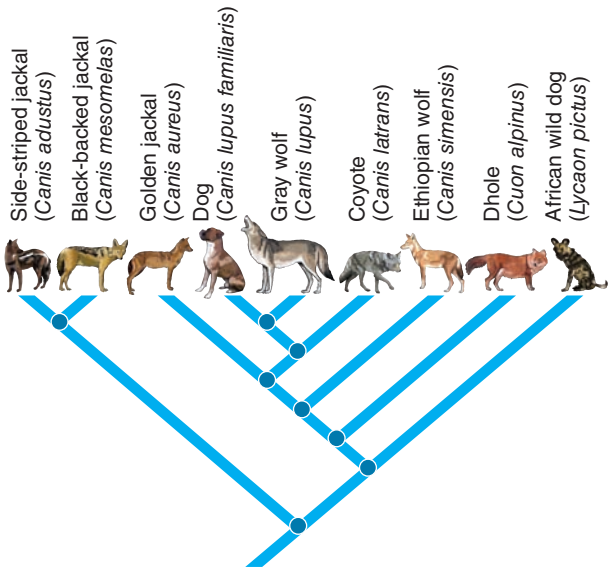
Because different genes can evolve at different rates, researchers now typically compare nitrogenous base sequences from many different genes of the organisms under study. Molecular sequence data have been sampled from the majority of all known species. The very precise tools provided by molecular biology have put systematics on the cutting edge of biological research.

Scientists at Broad's Genome Sequencing and Analysis program at the Massachusetts Institute of Technology (MIT) and at Harvard provided another example of applied molecular systematics (FIG. 23-6). They sequenced the genome of domestic dogs and compared 16 specific coding regions with the sequences found in 30 other living canids (members of the family Canidae to which the domestic dog belongs). The data they gathered enabled these investigators to construct a cladogram of the phylogenetic relationships of canids. They confirmed earlier research based on other DNA sequences as well as morphological traits showing that domestic dogs are most closely related to gray wolves.

Taxa are grouped based on their evolutionary relationships

Most known organisms were classified by biologists before the days of phylogenetics. Modern systematists use phylogenetic analysis to test these hypothesized relationships among groups of organisms. Based increasingly on molecular data, they either confirm or modify the work of earlier biologists. Using their data, systematists construct cladograms to reflect relationships among clades. Cladograms show that previous classifications reflect three different types of taxonomic relationships: monophyletic groups, paraphyletic groups, and polyphyletic groups.

A **monophyletic group** includes an ancestral species and all its descendants (FIG. 23-7a). It is defined by shared derived characters. Mammals, for example, have mammary glands that produce milk for the young, three small bones in the middle ear, and a muscular diaphragm. All mammals are thought to have evolved from a common ancestral mammal that had these shared derived characters, and all descendants of this ancestor are mammals. Monophyletic taxa are clades. They are referred to as "natural" groupings because they represent true evolutionary relationships and include all close relatives. **Sister taxa**, or sister groups, share a more recent common ancestor with one another than either taxon does with any other group shown on a cladogram. In Figure 23-7, taxon 2 and taxon 3 are sister taxa to each other; taxon 5 and taxon 6 are also sister taxa.



A **paraphyletic group** is a group that contains a common ancestor and some of, but not all, its descendants (FIG. 23-7b). Members of the group share ancestral characters. As discussed

Key Experiment

How is the dog related to other canids?

HYPOTHESIS: Analysis of molecular data from a variety of canids will clarify the evolutionary relationships of canids.

EXPERIMENT: Researcher Kerstin Lindblad-Toh and her colleagues sequenced the genome of the domestic dog. They compared coding regions of more than 13,000 dog genes with corresponding human and mouse genes. Then they selected 12 exons and 4 introns and sequenced them in 30 of 34 living canids.

RESULTS AND CONCLUSION: Analysis of the comparisons of exon and intron nucleotide sequences allowed these researchers to build a cladogram of Canidae species. The data indicated that the dog is most closely related to the gray wolf. (Sequence divergences of nuclear exon and intron sequences are 0.04% and 0.21%, respectively.) The two African jackals (*branch at left*) are the sister group of this clade, suggesting an African origin for the canids.

SOURCE: Lindblad-Toh, K., et al., "Genome Sequence, Comparative Analysis and Haplotype Structure of the Domestic Dog," *Nature*, Vol. 438 (Dec. 8, 2005).

Figure 23-6 Molecular phylogeny
Molecular similarities indicate that the domestic dog is closely related to the gray wolf. Note that some biologists list the scientific name for the domestic dog as *Canis familiaris*, but others, including the Smithsonian Institution and the American Society of Mammalogists, consider the dog a subspecies of the gray wolf (*Canis lupus*) and list its name as *Canis lupus familiaris*.

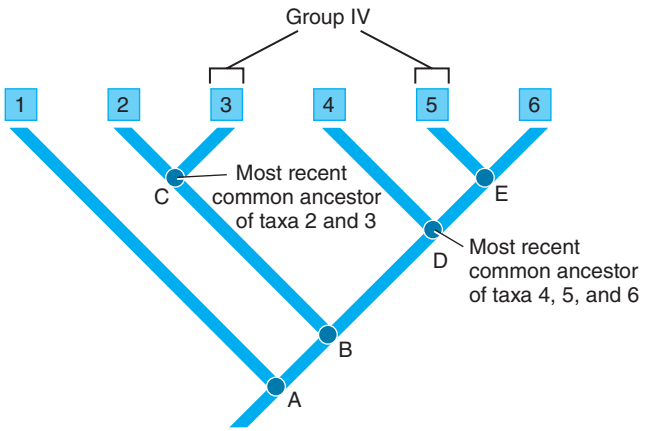
Key Point



Groups of organisms can be described as monophyletic, paraphyletic, or polyphyletic. Only monophyletic groups are considered clades.

(a) Taxa 2 and 3 are a monophyletic group or clade (Group I). Taxa 1 through 6 also make up a monophyletic group (Group II). Each group includes a common ancestor and all its descendants.

(b) Taxa 4 and 5 make up a paraphyletic group (Group III). This group includes some of, but not all, the descendants of the recent common ancestor indicated at node D. Which taxon is not included?

(c) Group IV is polyphyletic. Members of this group (taxa 3 and 5) do not share the same recent common ancestor.

Figure 23-7 Evolutionary relationships

In all three figures, the branch point at node A represents the common ancestor of all taxa shown. Node B represents the common ancestor of taxa 2 through 6. Node C represents the common ancestor of taxa 2 and 3. Node D represents the common ancestor of taxa 4, 5, and 6. Node E represents the common ancestor of taxa 5 and 6. Common ancestry is the basis for making decisions about classification.

CONNECT Look at part (b). Consider the organisms that evolved from the ancestor at node D. Which of the taxa shown form a monophyletic group?

later in this chapter, the traditional class Reptilia is paraphyletic because it does not include all descendants of the most recent common ancestor of reptiles. Birds share a recent common ancestor with reptiles.

A **polyphyletic group** consists of several evolutionary lines that do not share the same recent common ancestor (FIG. 23-7c). Biologists might have mistakenly classified the members of such a group together because these organisms share similar (homoplastic) features arising from convergent evolution. Systematists try to avoid constructing polyphyletic taxa because they are unnatural and misrepresent evolutionary relationships. Polyphyletic taxa are sometimes accepted temporarily until research provides additional data.

CHECKPOINT 23.3

- How are shared ancestral characters and shared derived characters different? How is the concept of homology related to these concepts?
- Why don't shared ancestral characters provide evidence for relationships between organisms within a taxon that has those traits? Give an example.
- **CONNECT** How is molecular biology contributing to the science of systematics?
- Systematists prefer to recognize monophyletic taxa rather than polyphyletic taxa. Why?

23.4 Constructing Phylogenetic Trees

LEARNING OBJECTIVES

10 Contrast the traditional classification with the current classification of reptiles and birds.
11 Describe the construction of a cladogram by using outgroup analysis.
12 Apply the principle of parsimony to cladogram construction.

In the second half of the 20th century, several methodological and philosophical schools of systematics were in a sense competing for supremacy among biologists. Three major schools emerged—*phenetics* (also known as numerical taxonomy), *evolutionary taxonomy*, and **phylogenetic systematics**, also known as **cladistics**. Their approaches differed in terms of broad goals, the methodologies used, and the accepted naming systems. The debate among followers of these three approaches was at times quite forceful and animated. What has emerged is a loosely defined consensus that borrows modified techniques from all three approaches but largely adopts many of the concepts from phylogenetic systematics.

Biologists today generally agree that ideally the goal of systematics should be to reconstruct the genealogical (evolutionary) relationships among species and that the best evidence for such relationships can be found in the patterns of traits shared by organisms (homologous traits). For many traits, the differences between shared derived characters and shared ancestral characters can be distinguished, and these traits can be analyzed as outlined below following many approaches derived from phylogenetic systematics. Aspects of these approaches are described in the next few sections. In some cases, however, systematists cannot clearly separate ancestral and derived states for certain traits; there, the more statistical approaches derived from phenetics are employed to construct phylogenies.

One conflict from the 20th century that has persisted into the present concerns the naming of taxonomic groups. Most modern systematists agree that scientific names should reflect monophyletic groups because such names will generally carry the most meaning. For example, when someone uses a taxonomic name that reflects a monophyletic group, we immediately understand that the name reflects an ancestor and all its descendants. We understand that because of their relatedness, the species included in the monophyletic group are likely to share many homologous similarities. Although this approach seems almost intuitive, it is not without controversy, mostly because full adoption of this approach will require changes to traditional taxonomy.

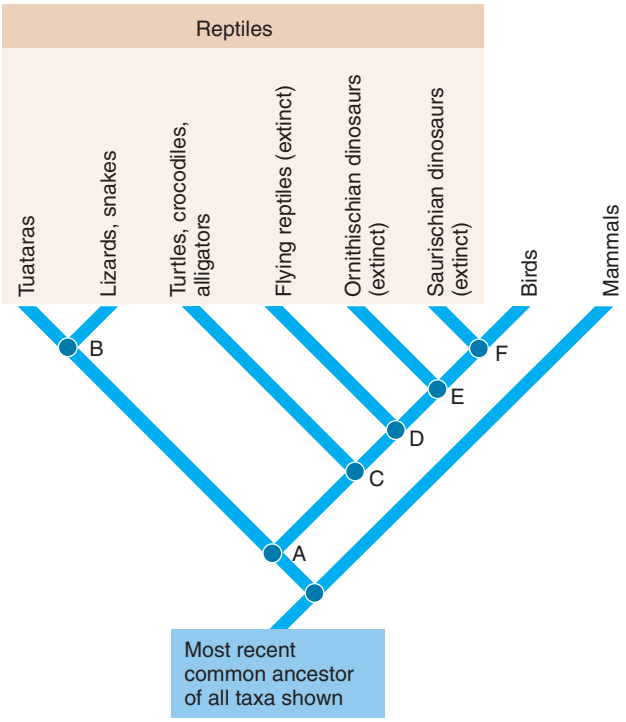
As additional evidence is discovered, new monophyletic groups must be recognized. At the same time, systematists find that some traditional group names do not reflect monophyletic groups. These groups need to be discarded or redefined. For example, a new taxon is needed for Tetrapoda (discussed earlier in this chapter). The tetrapods include amphibians, reptiles (including birds), and mammals, and their ancestors can be traced back to the first vertebrate with four legs. All available evidence suggests that the tetrapods are a monophyletic group and should be recognized as the group Tetrapoda.

More controversial is how traditional names that do not reflect monophyletic groups should be handled. Traditionally, the class Reptilia has been defined to include turtles, lizards, snakes, crocodilians, and dinosaurs. The phylogenetic evidence suggests that this group is paraphyletic because birds share a common ancestor with the saurischian dinosaurs yet are not included in the traditional Reptilia (FIG. 23-8a).

One solution would be to redefine the group Reptilia to include birds. Another solution is to abandon Reptilia as a taxon. Reptiles, birds, and mammals all have an **amnion**, a membrane that forms a fluid-filled sac around the embryo. Reptiles, birds, and a few mammals lay eggs. The fluid within the amnion prevents them from drying out. Thus, the amnion allows development in terrestrial environments. Animals with an amnion make up a monophyletic group, the **amniotes**, or Amniota (FIG. 23-8b).

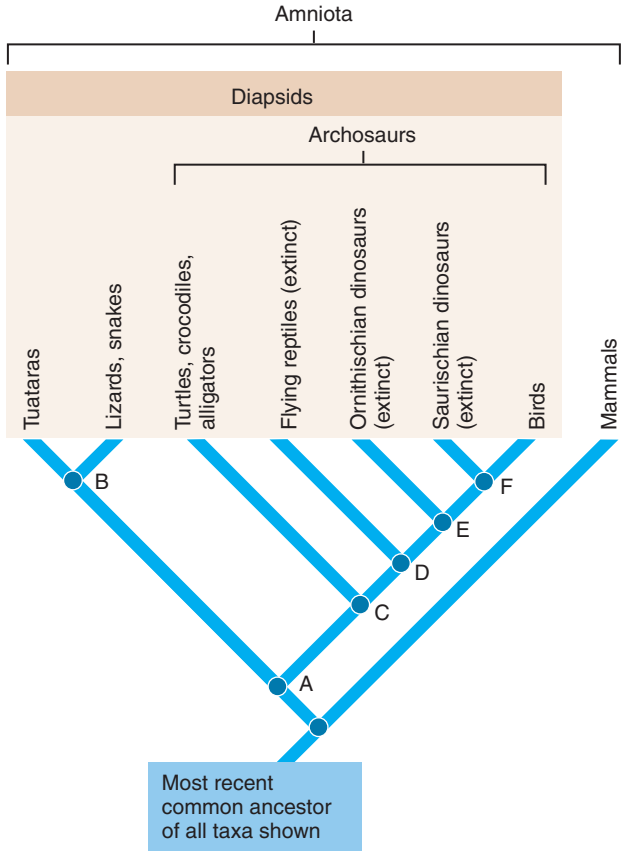
Two large monophyletic groups within the Amniota are the **diapsids** (traditional reptiles and birds) and the mammals. Within the diapsid group, the **archosaurs** include the crocodiles, flying reptiles (the extinct pterosaurs), the extinct dinosaurs, and the birds. These groups are discussed in more detail in Chapter 32.

Outgroup analysis is used in constructing and interpreting cladograms



A crucial step in most cladistic analyses is **outgroup analysis**, a research method for estimating which attributes are shared derived characters in a given group of organisms (FIG. 23-9). An **outgroup** is a taxon that is considered to have branched off earlier than the taxa under investigation, the **ingroup**. An ideal outgroup is the closest relative of the group being studied, its sister taxon, and has not been highly modified since its origin. Recall that sister taxa evolved from the same recent common ancestor. Systematists argue that an outgroup is likely to retain the ancestral state for characters being used in the analysis, allowing the researchers to identify the evolutionary changes leading to derived characters. To help you understand outgroup analysis, we describe the specific example illustrated in Figure 23-9.

The first step in constructing a cladogram is to select the taxa, which may consist of individuals, species, genera, or other taxonomic levels. Here we use a representative group of eight chordates: the lancelet, lamprey, sunfish, frog, lizard, bear, chimpanzee, and human. (Chordates are animals that, at some time in their lives, have a cartilaginous, dorsal skeletal structure called a notochord; a dorsal, tubular nerve cord; and grooves in the wall of the pharynx.) The next step is to select the homologous characters to be analyzed. In our example we use seven characters. For each character, we must define all the different conditions, or states, as they exist in our taxa. For simplicity, we consider our characters to have only two different states: *present* or *absent*. Keep in mind that many characters used in cladistics have more than two states. For example, black, brown, yellow, and red may be only a few of the many possible states for the character of hair color.



The last, and often the most difficult, step in preparing the data is to organize the character states into their correct evolutionary order. For this step, we use outgroup analysis. In our example the

(a) The traditional approach to classification recognized the common ancestry of birds and reptiles, but assigned them to different classes. In this approach reptiles are a paraphyletic group.

(b) Phylogenetic systematists (cladists) classify birds and reptiles together because they have a recent common ancestor and are a monophyletic group. The cladogram shows the branching points in the evolution of the major groups of reptiles. Lizards, snakes, and crocodiles are phenotypically similar, but crocodiles, dinosaurs, and birds are most closely related because they evolved most recently from a common ancestor (node C). Node E represents the branching of two clades of dinosaurs from a common ancestor and the subsequent branching of birds from the lineage of the saurischian dinosaurs.

Figure 23-8 Two approaches to the classification of reptiles and birds

Phylogenetic systematics, also known as cladistics, recognizes reptiles and birds as a monophyletic group.

lancelet, a small marine chordate with a fishlike appearance, is the chosen outgroup. It belongs to a taxon that is considered to have diverged earlier than any of the other taxa under investigation but to be closely related to vertebrates; thus, the lancelet represents an approximation of the ancestral condition for vertebrates. Therefore, the character state "absent" for a particular character state such as vertebrae is the ancestral condition, and the character state "present" is the derived condition for the characters in Figure 23-9.

A cladogram is constructed by considering shared derived characters

Our objective is to construct a cladogram that requires the fewest number of evolutionary changes in the characters. Taxa are grouped by the presence of shared derived characters. To form a valid monophyletic group, all members must share at least one derived character. Membership in a clade cannot be established by shared ancestral characters.

In our example notice that all taxa, except the outgroup lancelet, have vertebrae. We can therefore conclude that these seven vertebrate taxa form a valid clade. Next, among the seven vertebrate taxa, note that jaws are present in all groups except lampreys (a group of jawless vertebrates). Using these data, we construct a preliminary cladogram (see Fig. 23-9a).

Recall that the root, or base, of the cladogram represents the common ancestor for all taxa being analyzed. In Figure 23-9a, node A represents the common chordate ancestor from which the outgroup (lancelet) and the seven vertebrate taxa evolved. Similarly, node B represents the common ancestor of the vertebrates, and node C represents the common ancestor of the jawed vertebrates. Continuing with this procedure, note that among the six jawed taxa, all but sunfish have four limbs with digits (see Fig. 23-9b). Among the five groups with limbs, all but frogs have an amnion (see Fig. 23-9c). The branching process is continued, using the data in the table in the top center of the figure, until all clades are established (see Fig. 23-9d).

Each branch point represents a major evolutionary step

Notice that humans and chimpanzees share a recent common ancestor at node G in Figure 23-9d. This hypothesis is supported by the derived characters they share (synapomorphies).

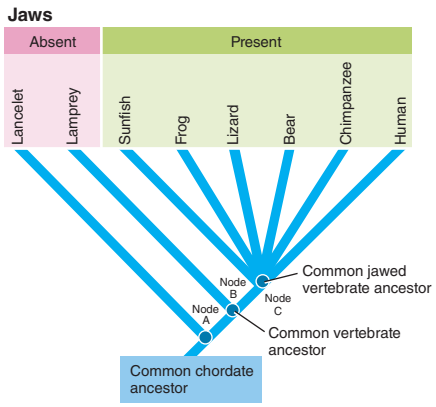
WHY IS IT USED? Outgroup analysis is used to organize character states into their evolutionary order, that is, to reconstruct phylogeny.

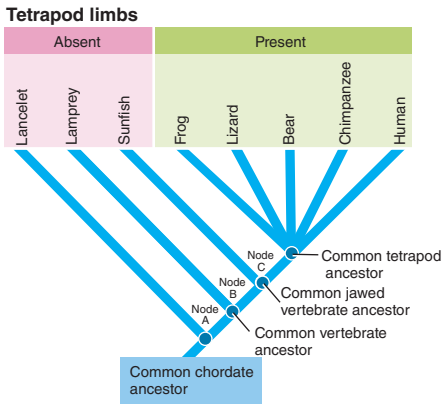
HOW IS IT DONE?

1. Select the taxa of interest and the homologous characters to be analyzed.
2. Define the possible conditions, for example, present (P) or absent (A).
3. Here, the lancelet is selected as the outgroup; this taxon diverged earlier than any of the other taxa being considered. The lancelet represents an approximation of the ancestral condition.
4. Refer to the table at *right* as you follow steps (a) through (d) to build a cladogram.

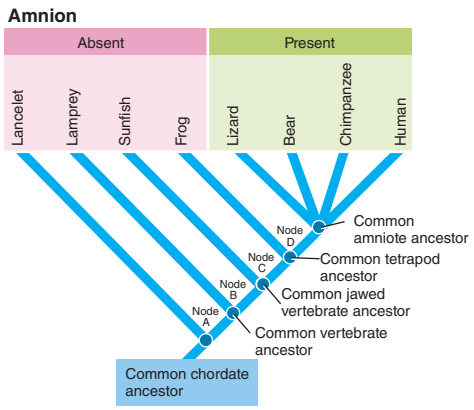


KEY

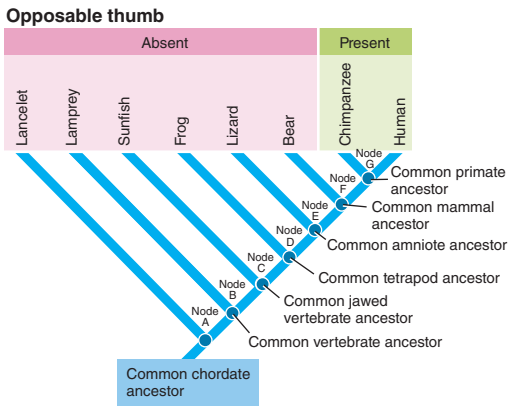
A = Absent



P = Present



TAXA	CHARACTERS						
	Vertebrae	Jaws	Tetrapod (4 limbs)	Amnion	Mammary glands	Opposable thumb	Upright posture
Lancelet (outgroup)	A	A	A	A	A	A	A
Lamprey	P	A	A	A	A	A	A
Sunfish	P	P	A	A	A	A	A
Frog	P	P	P	A	A	A	A
Lizard	P	P	P	P	A	A	A
Bear	P	P	P	P	P	A	A
Chimpanzee	P	P	P	P	P	P	A
Human	P	P	P	P	P	P	P



(a) All seven vertebrate taxa shown here have jaws, except the lamprey. Jaws are a shared derived character for these six taxa.

(b) Tetrapod limbs are a shared derived character for all vertebrate taxa shown here except the lamprey and sunfish.

(c) Lizards, bears, chimpanzees, and humans have amnions, a shared derived character. Therefore, they are members of the clade Amniota.

(d) Of the vertebrate taxa shown here, only the chimpanzee and human share the derived character opposable thumb.

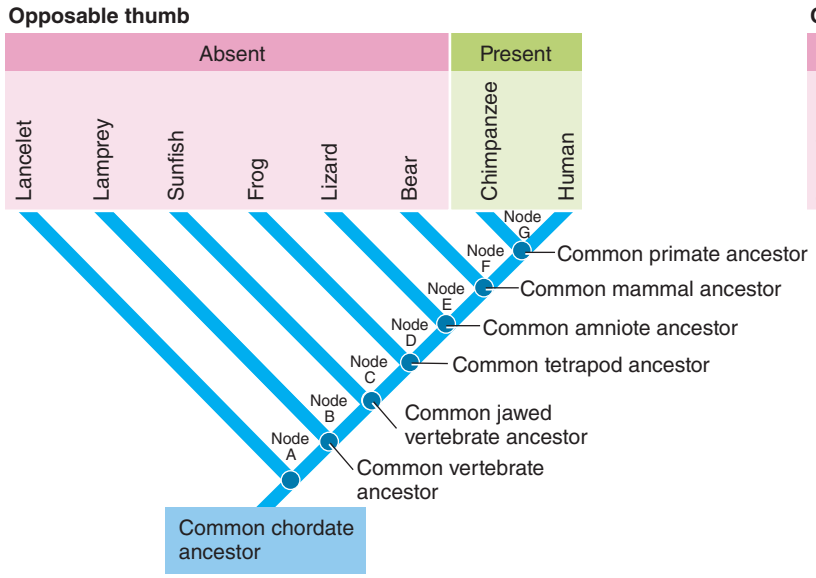


Figure 23-9 Constructing a cladogram using outgroup analysis

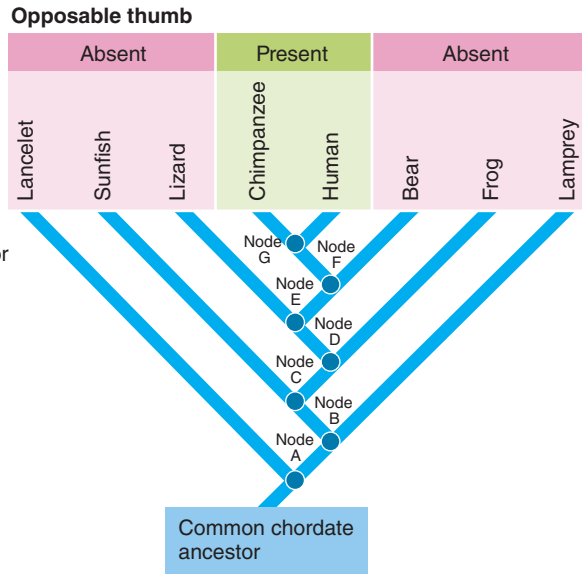
In the same way, bears are more closely related to the human–chimpanzee clade than to any other clade considered in our example, as indicated by the common ancestor at node F.



Note that shared derived characters are nested. As you trace the tree from its root to its tips, each branch reflects the addition of one or more shared derived characters. When we compare the nodes, the order of divergence (branching) is indicated by relative distance from the base of the diagram. The farther a node is located from the base of the cladogram, the more recently the group diverged. In our example node G represents the most recent divergence, and node A represents the most ancient divergence. Thus, in our example humans are closely related to chimpanzees (through node G) but more distantly related to bears (through node F). Therefore, biologists

(a) This cladogram, with its diagonal branches, illustrates the style most commonly used in this book.

(b) This cladogram is another way to depict the same relationships shown in (a).

(c) This cladogram has rectangular branches and is rotated 90 degrees. However, it illustrates the same relationships as the cladograms in (a) and (b).

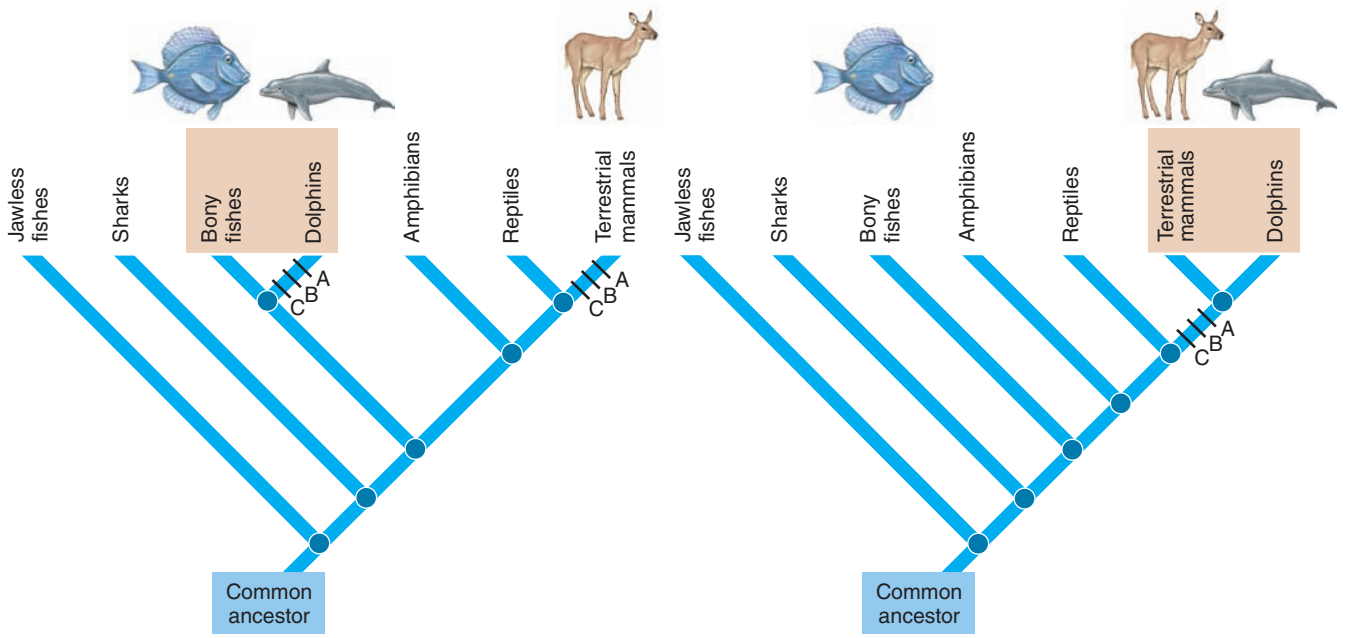
Figure 23-10 Cladogram styles

These three cladograms look very different, but they depict the same relationships. Remember that the relationships are depicted by which groups branch at the nodes. The length of the branches is not important.

assign humans and chimpanzees to a less inclusive taxon (order Primates), whereas humans, chimpanzees, and bears are assigned to a broader, more inclusive taxon (class Mammalia). In addition, the cladogram reveals that lizards are more closely related to the mammal clade than to frog, sunfish, or any other clade in our example. Can you explain why?

Two important concepts guide interpretation of cladograms. First, the relationships among taxa are determined only by tracing along the branches back to the most recent common ancestor and *not* by the relative placement of the branches along the horizontal axis. It is possible to represent the same relationships with many different types of branching diagrams (FIG. 23-10). Note that all three cladograms in this figure are equivalent. (Verify this fact by comparing the nodes and checking the relationships described earlier.) Thus, a tree can be rotated around its nodes. The branching relationships, not the order of the taxa or the size of the branches, are important.

A second important concept is that the cladogram tells us which taxa shared a common ancestor and how recently they shared a common ancestor. The ancestor itself remains unspecified. The cladogram does not establish direct ancestor–descendant relationships among taxa. In other words, a cladogram does not suggest that a taxon gave rise to any other taxon. Very specifically, the cladograms in Figures 23-9 and 23-10 do not suggest that the lampreys evolved before the other vertebrates or that the other vertebrates evolved from the lampreys, only that the lineage that eventually evolved into the lampreys separated from the rest of the vertebrates before the separation of the tetrapods from the fishes.



Note that any particular cladogram, such as those shown in Figures 23-8, 23-9, and 23-10, depicts only some of the nodes and branches in the tree of life. For example, in Figure 23-10a the single branch from node C that leads toward sunfish could be drawn to show thousands of nodes and tens of thousands of branches representing all the species of modern bony fishes. Cladograms used throughout this book will by necessity illustrate only particular nodes and branches of interest. The reader is always encouraged to think about which organisms have been left off any cladograms and where their favorite organisms might be placed. Where on Figure 23-10a should salamanders be placed?

Research Method

WHY IS IT USED? Cladogram construction is used to choose between alternative hypotheses of evolutionary relationships by selecting the most accurate branching pattern.

(a) Hypothesis 1: Dolphins and bony fishes are close relatives.

(b) Hypothesis 2: Dolphins and terrestrial mammals are close relatives.

HOW IS IT DONE? Systematists choose the simplest explanation to interpret the data.

1. Draw the possible cladograms.
2. Examine the relevant characters. In this example, character A = hair, B = mammary glands, and C = middle ear bones.
3. Note that in the first cladogram (hypothesis 1) all three characters examined had to evolve independently twice.
4. Hypothesis 2 is chosen because it requires that each character evolve only once.

Figure 23-11 Applying the principle of parsimony to cladogram construction

Systematists use the principles of parsimony and maximum likelihood to make decisions

When systematists consider the evolutionary relationships of organisms, they must choose between multiple, competing cladograms. How do they choose the most accurate branching pattern? The most common criterion is the principle of **parsimony**: they choose the simplest explanation to interpret the data. Parsimony, a guiding principle in many areas of research, is based on the experience that the simplest explanation is probably the correct one. Applied to choice of cladograms, parsimony requires that the cladogram with the fewest changes in characters (the one with the fewest homoplasies) be accepted as most probable (FIG. 23-11).

In actual practice it is often possible to generate several cladograms that are equally parsimonious. The cladograms that are selected are the ones with more shared derived characters. The cladograms with more homoplasies are excluded because homoplasies are less likely to evolve than shared derived characters.

Systematists also use **maximum likelihood** to make decisions, especially when analyzing molecular data. Maximum likelihood is a statistical method that depends on probability (e.g., the probability that nucleotide sequences in DNA change at a constant rate over time). Complex computer programs analyze large data sets and report the probability of a particular tree.

CHECKPOINT 23.4

23.5 Applying Phylogenetic Information

LEARNING OBJECTIVE

13 Describe how phylogenetic information can be applied to problems in other disciplines.

Modern systematics offers much more than simply a set of consistent species names and organized categories. The phylogenetic trees that are constructed contain useful information about the relationships among the organisms involved. This information can be applied to problems in many disciplines, including in ecology, evolution, and medicine.

When combined with other data, phylogenetic trees can be used to investigate the evolutionary histories of entire groups of organisms as well as the evolutionary changes that have occurred in specific traits. For example, phylogenetic trees based on the DNA sequences of modern humans combined with information on the geographic homelands of those humans are helping us understand the pathways used by humans as they originally dispersed out of Africa to inhabit the rest of the world (see Chapter 22).

Phylogenetic information has proven important in medical research and often has public health implications. **Human immunodeficiency virus (HIV)**, the virus that causes **acquired immunodeficiency syndrome (AIDS)** in humans, has had a devastating effect on humans since it first became prevalent in the 1980s. A major medical question concerned the origin of this virus. HIV is a **lentivirus**, a group of retroviruses (viruses that use RNA as their genetic material). Scientists have been able to determine the sequences of nucleotides in the RNA of many strains of HIV that have infected humans around the world. Researchers have sequenced somewhat similar viruses, called SIV viruses, that infect other primate species. Systematists have used these nucleotide sequences to generate phylogenetic trees for the viruses (FIG. 23-12).

When researchers mapped the primate host species onto the phylogeny for the viruses, they found that HIV-2, the somewhat less virulent virus, is most closely related to an SIV virus in a species of monkey (sooty mangabey). The more virulent HIV-1 strains have evolved from a virus that infected chimpanzees. The phylogenetic data were critically important in showing that precursors to HIV probably jumped from other primates to humans several times before the onset of the HIV epidemic. (HIV is discussed further in Chapter 45.)

This type of phylogenetic research has important public health implications. Many primate species are hosts for human pathogens that have spread into human populations, causing epidemics. Understanding the source and spread of these infections may lead to prevention measures that mitigate or prevent future epidemics.

Many evolutionary questions remain. New hypotheses about how organisms are related suggest new taxonomic schemes. Systematics offers tools to help us test these hypotheses. In Chapters 24 through 32, we explore many evolutionary puzzles and discuss current hypotheses about relationships and classifications of organisms.

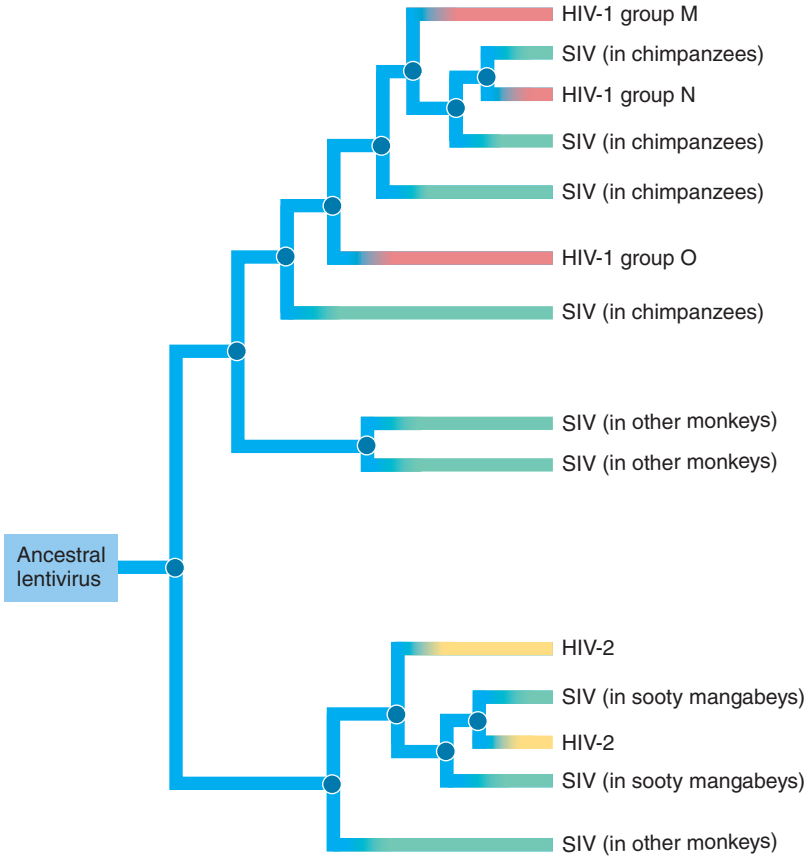

Figure 23-12 Understanding the origins of HIV infection in humans

The human immunodeficiency viruses (HIVs) and the related simian immunodeficiency viruses (SIVs) are lentiviruses. A phylogenetic analysis of nucleotide sequences for this group of viruses gives insight into the origins of HIV infection in humans. There are two major types of HIV, HIV-1 and HIV-2, with multiple strains within each of these types. Groups M, N, and O of HIV-1 are shown in the cladogram. HIV-1, group M, has affected millions of people around the world. Although all the HIV types and strains are from humans, different strains of SIV have been isolated from other species of primates. The cladogram shows four different strains of SIV isolated from chimpanzees, two SIV strains isolated from sooty mangabey monkeys, and three SIV strains isolated from other species of monkeys. The branching pattern derived from this phylogenetic analysis shows that the different strains of HIV-1 and HIV-2 have evolved separately from the various strains of SIV. Chimpanzees were the original source of the HIV-1 viral strains and sooty mangabey monkeys were the original source of the HIV-2 viral strains.

Summary: Focus on Learning Objectives

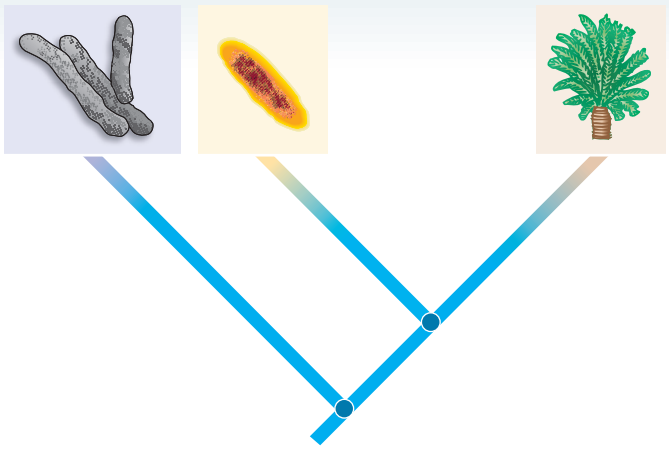
23.1 Classifying Organisms *(page 479)*

1 State two justifications for the use of scientific names and classifications of organisms.

- **Systematics** is the scientific study of the diversity of organisms and their evolutionary relationships. **Taxonomy** is the branch of systematics devoted to naming, describing, and classifying organisms. **Classification** is the process of arranging organisms into groups based on similarities that reflect evolutionary relationships.
- Scientific names allow biologists from different countries with different languages to communicate about organisms. Biologists in distant locations must know with certainty that they are studying the same (or different) organisms.
- Classifications help biologists organize their knowledge.

2 Describe the binomial system of naming organisms and arrange the Linnaean categories in hierarchical fashion from most inclusive to least inclusive.

- In the **binomial system of nomenclature**, the basic unit of classification is the species.
- The name of each species has two parts: the **genus** name followed by the **specific epithet**. Both names are italicized.
- The hierarchical system of classification includes **domain**, **kingdom**, **phylum**, **class**, **order**, **family**, **genus**, and **species**. Each formal grouping at any given level is a **taxon**.



23.2 Determining the Major Branches in the Tree of Life *(page 480)*

3 Describe the three domains and argue for and against classifying organisms in these domains. (Compare this approach with using kingdoms as the main rank of classification.)

- The three-domain classification system assigns organisms to domains **Archaea**, **Bacteria**, or **Eukarya**. The domain classification is based on molecular data.
- Domain Eukarya includes the fungi, plants, animals, and protists.
- Some systematists recognize the kingdoms **Archaea**, **Bacteria**, **Fungi**, **Plantae**, and **Animalia**. Several "supergroups" composed of mainly unicellular, mainly aquatic eukaryotic organisms were formerly classified as kingdom Protista. Members of Archaea and Bacteria are prokaryotes. The fungi, which include molds, yeasts, and mushrooms, absorb nutrients produced by other organisms. Kingdoms Plantae and Animalia both consist of multicellular eukaryotes. For additional characteristics of the kingdoms, refer to Table 23-2. As new data are interpreted, organisms assigned to these kingdoms often must be reclassified.

4 Interpret a cladogram, describing the meaning of its specific nodes and branches.

- In a **cladogram**, each *branch* represents a **clade**, a group of organisms with a common ancestor. Each *node*, or branching point, represents the splitting of two or more new groups from a common ancestor. The node represents the *most recent common ancestor* of the clade represented by the branches. The *root* represents the most recent common ancestor of all the clades shown in the tree.

- We can determine the relationships among taxa by tracing along the branches back to the nodes. The cladogram indicates which taxa shared a recent common ancestor and how recently they shared that ancestor compared to other groups.

5 Differentiate between vertical and horizontal gene transfer and explain their importance in understanding systematics.

- In **vertical gene transfer**, genes are transmitted from parent to offspring within the same species.
- In **horizontal gene transfer**, genes are exchanged between one genome and another within one taxon or between genomes in different taxons. Genes move from one individual to another or from one species to another species in the same generation.

23.3 Reconstructing Evolutionary History *(page 485)*

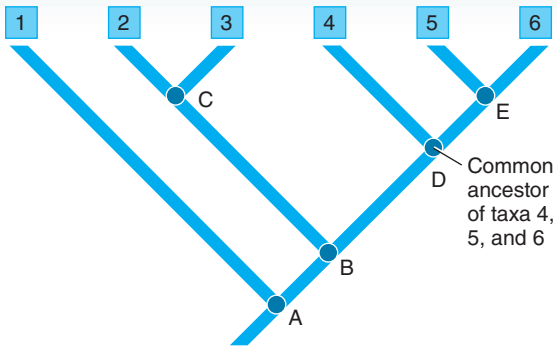
6 Critically review the difficulties encountered in choosing taxonomic criteria.

- Systematists seek to determine evolutionary relationships, or **phylogeny**, based on shared characteristics. **Homology**, the presence in two or more species of a trait derived from a common ancestor, implies evolution from a common ancestor.
- Some seemingly homologous characters are acquired independently by **convergent evolution**, independent evolution of similar structures in distantly related organisms, or by **reversal**, reversion of a trait to its ancestral state. The term **homoplasy** refers to superficially similar characters that are not homologous.

7 Apply the concept of shared derived characters to the classification of organisms.

- **Shared ancestral characters** suggest a distant common ancestor.
- **Shared derived characters** (synapomorphies) indicate a more recent common ancestor and can be used as evidence for constructing cladograms.

8 Describe how analyses of molecular homologies contribute to the science of systematics.



- **Molecular systematics** depends on molecular structure to clarify phylogeny. Comparisons of nucleotide sequences in DNA and RNA, and of amino acid sequences in

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

proteins, provide important information about how closely organisms are related.

9 Contrast monophyletic, paraphyletic, and polyphyletic taxa.

- A **monophyletic group**, or clade, includes all the descendants of the most recent common ancestor.
- A **paraphyletic group** consists of a common ancestor and some of, but not all, its descendants.
- A **polyphyletic group** consists of organisms that evolved from different recent ancestors.

23.4 Constructing Phylogenetic Trees *(page 490)*

10 Contrast the traditional classification with the current classification of reptiles and birds.

- Modern systematists agree that taxa must be monophyletic. Each monophyletic group consists of a common ancestor and all its descendants. Phylogenetic systematists (cladists) use shared derived characters to determine relationships among groups of organisms.
- Contemporary systematists classify reptiles and birds in a single clade.

11 Describe the construction of a cladogram by using outgroup analysis.

- Cladists use shared derived characters to reconstruct evolutionary relationships and diagram these relationships in cladograms. They use **outgroup analysis** to determine which characters in a given group of taxa are ancestral and which are derived.
- An **outgroup** is a taxon that diverged earlier than any of the other taxa being investigated.

12 Apply the principle of parsimony to cladogram construction.

- **Systematists** choose the simplest explanation to interpret the data—the principle of **parsimony**.

23.5 Applying Phylogenetic Information *(page 495)*

13 Describe how phylogenetic information can be applied to problems in other disciplines.

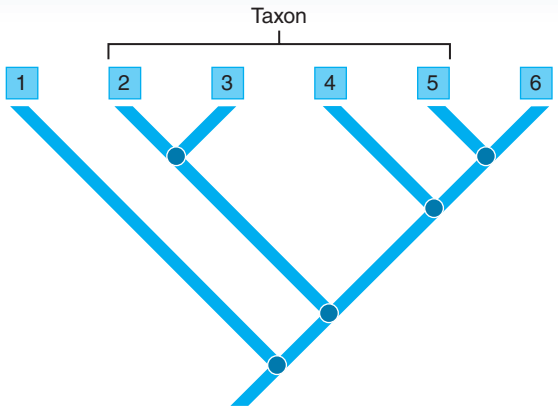
- Understanding how species are related can help scientists answer questions and solve problems in other disciplines. For example, phylogenetic information has helped us better understand the origin and transmission of HIV.

Test Your Understanding

Know and Comprehend

1. The mold that produces penicillin is *Penicillium notatum*. *Penicillium* is the name of its (a) genus (b) order (c) family (d) species (e) specific epithet
2. Decomposers such as molds and mushrooms belong to which domain and kingdom? (a) Eukarya, Plantae (b) Bacteria, Archaea (c) Archaea, Fungi (d) Eukarya, Archaea (e) Eukarya, Fungi
3. Each branching point in a cladogram (a) is called a root (b) represents a clade (c) represents the divergence of two or more groups from a common ancestor (d) represents horizontal gene transfer (e) marks the divergence of two kingdoms
4. The presence of homologous structures in two different groups of organisms suggests that (a) the organisms evolved from a common ancestor (b) convergent evolution has occurred (c) they belong to a polyphyletic group (d) homoplasy has occurred (e) independently acquired characters may evolve when organisms inhabit similar environments
5. Dolphins and humans both have the ability to nurse their young, whereas the less closely related sharks do not. The ability to nurse their young is (a) a shared derived character of fish and mammals (b) a shared ancestral character of all vertebrates (c) a shared derived character of mammals (d) an example of homoplastic behavior (e) an example of reversal
6. A group of organisms that includes a recent common ancestor and all its descendants is (a) polyphyletic (b) paraphyletic (c) monophyletic (d) an example of horizontal gene transfer (e) a sister group
7. In cladistic analysis, (a) ancestral characters are used to reconstruct phylogenies (b) characters must be homoplastic (c) polyphyletic groups are preferred (d) outgroup analysis is rarely used (e) shared derived characters are the preferred evidence for relatedness
8. When systematists apply the principle of parsimony, they (a) choose the cladogram that requires the fewest changes in characters as the most probable explanation to interpret the data (b) select multiple hypotheses to explain each relationship (c) do not use outgroups (d) typically use a polyphyletic approach (e) hypothesize that the most complex explanation is most probably the correct one

Apply and Analyze



9. In interpreting a cladogram, (a) we can identify the specific ancestor of each taxon by tracing each branch back to the node closest to the root (b) taxa on the right side of a cladogram have evolved from the taxa on the left side (c) the relative placement of smaller branches allows us to determine the number of years since a particular taxon has evolved (d) we can determine relationships by tracing along the branches back to the most recent common ancestor (e) we must first identify horizontal gene transfer
10. What are some of the criteria and tools biologists might use to assign the different types of protists to monophyletic groups?
11. What are the advantages of using domains, rather than kingdoms, as the highest rank of classification?

Evaluate and Synthesize

12. **EVOLUTION LINK** Are members of a clade similar because they share a common ancestor, or do they belong to the same clade because they are similar?
13. **EVOLUTION LINK** The TATA-binding protein (TBP) is thought to be necessary for transcription in all eukaryotic cell nuclei. Studies show that archaea, but not bacteria, have a protein structurally and functionally similar to TBP. What does this similarity suggest regarding the evolution of archaea, bacteria, and eukaryotes? How might knowledge of this similarity affect how systematists classify these organisms?
14. **VISUALIZE** Construct a cladogram based on the following data. Mosses are plants with no vascular tissue. Horsetails, ferns, gymnosperms (pines and other plants with naked seeds), and angiosperms (flowering plants) are all vascular plants. Seeds are absent in all but the gymnosperms and angiosperms. Angiosperms are the only seed plants with flowers. (*Hint*: To help you construct the cladogram, draw a simple table showing which characters are present in each group. See Fig. 23-9.)
15. **INTERPRET DATA** What kind of grouping is represented by the bracketed area in the illustration? What type of group is formed by taxon 2 and taxon 3? What type of group is formed by taxa 2, 4, and 6?

24 Viruses and Subviral Agents

During the late 1800s, botanists searched for the cause of tobacco mosaic disease, which stunts the growth of tobacco plants and gives the infected tobacco leaves a spotted, mosaic appearance. The investigators found that they could transmit this disease to healthy plants by daubing their leaves with the sap of diseased plants. In 1892, Dmitri Ivanowsky, a Russian botanist, showed that the sap was still infective after it had been passed through porcelain filters designed to filter out all known bacteria. A few years later, in 1898, Martinus Beijerinck, a Dutch microbiologist, provided evidence that the agent that caused tobacco mosaic disease had many characteristics of a living organism. However, it appeared that the infective agent could reproduce only within a living cell. Beijerinck named the infective agent *virus* (from the Latin word "virus," which means "poison"). Tobacco mosaic virus was the first virus to be recognized.

Early in the 20th century, scientists discovered other infective agents, like those responsible for tobacco mosaic disease, that could cause disease in animals or kill bacteria. These pathogens were so small that they could not be seen with the light microscope. They also passed through filters that removed bacteria. Curiously, they could not be grown in laboratory cultures unless living cells were present. The development of the electron microscope in the 1930s made it possible to see viruses for the first time.

Most of the viruses that infect animals, plants, and bacteria were identified during the second half of the 20th century.

KEY CONCEPTS

24.1 A virus is a small particle consisting of a nucleic acid core surrounded by a protein coat; a virus must infect a living cell in order to reproduce.

24.2 Viruses can be classified based on their host range, what type of nucleic acid they have, and whether the nucleic acid is single-stranded or double-stranded.

24.3 In a lytic reproductive cycle, a virus uses the host cell's molecular machinery to replicate itself, destroying the host cell in the process. In a lysogenic cycle, the viral genome becomes integrated into the host DNA and is then called a "provirus."

24.4 Viruses infect the cells of organisms in each domain; most viruses are not harmful and many are beneficial to their host. However, some viruses cause serious diseases in plants and animals.

24.5 Three different hypotheses suggest how viruses may have originated and evolved.

24.6 Subviral agents, which include satellites, viroids, prions, and defective interfering particles (DIPs), are smaller and simpler than viruses.

Viruses cause many plant diseases and are responsible for billions of dollars in crop losses each year. You may recognize some of the many human viral diseases, such as rabies, influenza, and herpes. You have probably received vaccinations for many childhood viral diseases, including polio, rubella (German measles), mumps, and chickenpox. *Emerging viruses* are new viruses that appear suddenly or move into new areas. They may cause epidemics or even pandemics (global epidemics). HIV (human immunodeficiency virus), which causes AIDS, is an important example. More recent emerging viruses include Zika virus and Ebola virus (see photograph).

Viruses make up a large component of Earth's biomass. Their huge numbers make up for their small size and weight. Viruses influence many ecological processes. For example, they kill large amounts of marine biomass each day, contributing significantly to the recycling of carbon and nutrients. Viruses adapt to their environments through evolution. They also influence the biodiversity of other organisms by transferring their own genes into the genetic material of their hosts. Viruses can also transfer eukaryotic genes from one organism to another, crossing species boundaries. The discovery of giant viruses has raised new questions about the structure, genomes, origin, and phylogenetic relationships of viruses.

In this chapter we examine the characteristics and diversity of viruses as well as the smaller subviral agents, viroids, prions, and defective interfering particles. Although biologists do not consider viruses to be living things, we include them in the diversity unit of *Biology* because they have some characteristics of life and because they impact all living organisms.

24.1 The Status and Structure of Viruses

LEARNING OBJECTIVES

1. Contrast a virus with a cellular organism.
2. Describe the structure of a virus.

A **virus** is a very small infective agent that consists of a core of nucleic acid and is dependent on a living host. The study of viruses is called *virology*, and biologists who study viruses are *virologists*. Most biologists view viruses as nonliving particles because they are not composed of cells and they cannot carry on metabolic activities or reproduce on their own. They do not have the components necessary to carry on cellular respiration or to synthesize proteins and other molecules.

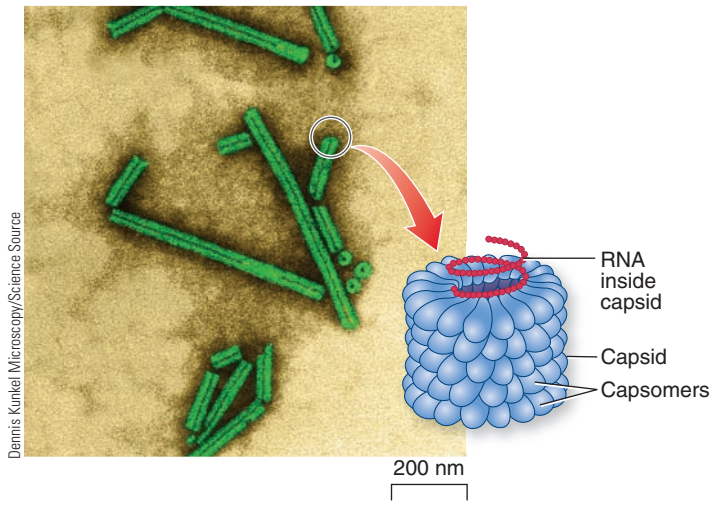
Viruses do contain the nucleic acids necessary to make copies of themselves. They replicate by invading living cells and commandeering their metabolic machinery. To multiply, a virus must *infect* a cell in which it can replicate. Thus, viruses are *obligate intracellular parasites*; they survive only by using the resources of a *host cell*, the cell the virus invades. Viruses infect all types of organisms, including bacteria, archaea, protists, plants, fungi, and animals. Some viruses even infect other viruses. Interestingly, viruses evolve by natural selection. For these reasons, most biologists view viruses as being at the edge of life, although a few argue that they are very simple life-forms.

Viruses are very small

Most known viruses are very small, ranging in size from 20 to 300 nm. (Recall that a nanometer is one-thousandth of a micrometer.) The poliovirus is about 30 nm in diameter (about the size of a ribosome). If we could line these viruses up end to end, it would take about 100 of them to reach the length of an average bacterium! A poxvirus that causes smallpox can measure up to 300 nm long and 200 nm wide.

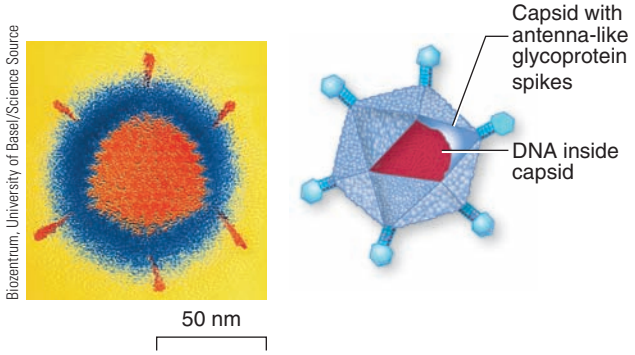
The paradigm that all viruses are very small and simple, with very small genomes, has been challenged by the discovery of giant viruses. The genus *Mimivirus* was discovered in 2004, followed by *Megavirus* in 2011 and *Pandoravirus* in 2013. *Pandoravirus salinas* approaches 1 μm in length and is about 0.5 μm wide, larger than many bacteria and some eukaryotic cells. Only 7% of the genes from *Pandoravirus salinas* match with existing gene databases. *Pandoravirus* was first discovered by French researchers in sediment off the coast of Chile and, like the other giant viruses, it infects amoebas.

A virus consists of nucleic acid surrounded by a protein coat



The nucleic acid core of the virus is surrounded by a protein coat called a **capsid**. Microbiologists use the term *virion* to refer to the complete virus particle that is outside a host cell in a dormant state. The virion is the form in which the virus moves from the cell in which it was produced to a new host cell in which it can replicate its genome. However, here we will use the term *virus* in a broad sense, even when referring to virions.

A typical virus contains *either* deoxyribonucleic acid (DNA) or ribonucleic acid (RNA), not both. In 2012, however, researchers discovered an RNA–DNA hybrid virus in a high temperature acidic California lake. Further studies have found a few other similar RNA–DNA hybrids in marine environments.



The nucleic acid of a virus can be single-stranded or double-stranded. Thus, a virus can have single-stranded (ss) DNA, double-stranded (ds) DNA, ssRNA, or dsRNA. As we will discuss, the type of nucleic acid is important in classifying viruses. The virus genome typically consists of 5000 to more than 100,000 bases or base pairs (depending on whether it is single-stranded or double-stranded). Again, the giant viruses are exceptions. *Megavirus* has seven transfer RNAs and some metabolic genes never before identified in any other virus. Researchers have sequenced the double-stranded DNA genomes of two species of *Pandoravirus* and reported that they range from 1.9 to 2.5 million base pairs. The species with

(a) TEM of tobacco mosaic virus. This rod-shaped virus has a helical arrangement of capsid proteins.

(b) Color-enhanced TEM of an adenovirus. The capsid is composed of 252 subunits (visible as tiny ovals) arranged into a 20-sided polyhedron. Twelve of the subunits have projecting glycoprotein spikes that permit the virus to recognize host cells.

(c) Color-enhanced TEM of HIV, the virus that causes AIDS. The virus is leaving a host cell (*pink*). The virus is enclosed in an envelope (*green*) derived from the host's plasma membrane. Viral proteins project from the envelope. The capsid of the virus is shown in *yellow*.

(d) Color-enhanced TEM of T4 bacteriophage. This virus has a polyhedral head and a helical tail. The virus attaches to the cell wall of the bacterial host by its tail fibers.

Figure 24-1 The structure of a virus

A virus consists of a DNA or RNA core surrounded by a protein coat called a capsid. The capsid is made up of protein subunits called capsomers. Some viruses have an outer membranous envelope surrounding the capsid.

the largest genome has 2556 proposed protein-coding genes (only 6% of which match known proteins).

The capsid is a protective protein coat

The capsid consists of protein subunits called *capsomers*. The capsomers determine the shape of the virus. Capsids generally are helical, polyhedral, or a combination of both shapes. Helical viruses, such as the tobacco mosaic virus (TMV), appear as long rods or threads (FIG. 24-1a). Its capsid is a hollow cylinder made up of proteins that form a groove into which the RNA fits.

Polyhedral viruses, such as the adenoviruses (which cause a number of human illnesses, including some respiratory infections), appear somewhat spherical (FIG. 24-1b). Its capsomers are organized in equilateral triangles. The capsid of a large virus can consist of several hundred capsomers. The most common polyhedral structure is an *icosahedron*, a structure with 20 identical surface faces (each face is a triangle). The human immunodeficiency virus (HIV) that causes AIDS is an enveloped virus (see next section) (FIG. 24-1c).

Some viruses have both helical and polyhedral components. Viruses that infect bacteria are called *bacteriophages*, or simply *phages* (FIG. 24-1d). The T4 phage that infects the bacterium *Escherichia coli* consists of a polyhedral "head" attached to a helical "tail." Many phages have this shape. Many phages also have tail fibers that attach to the host cell.

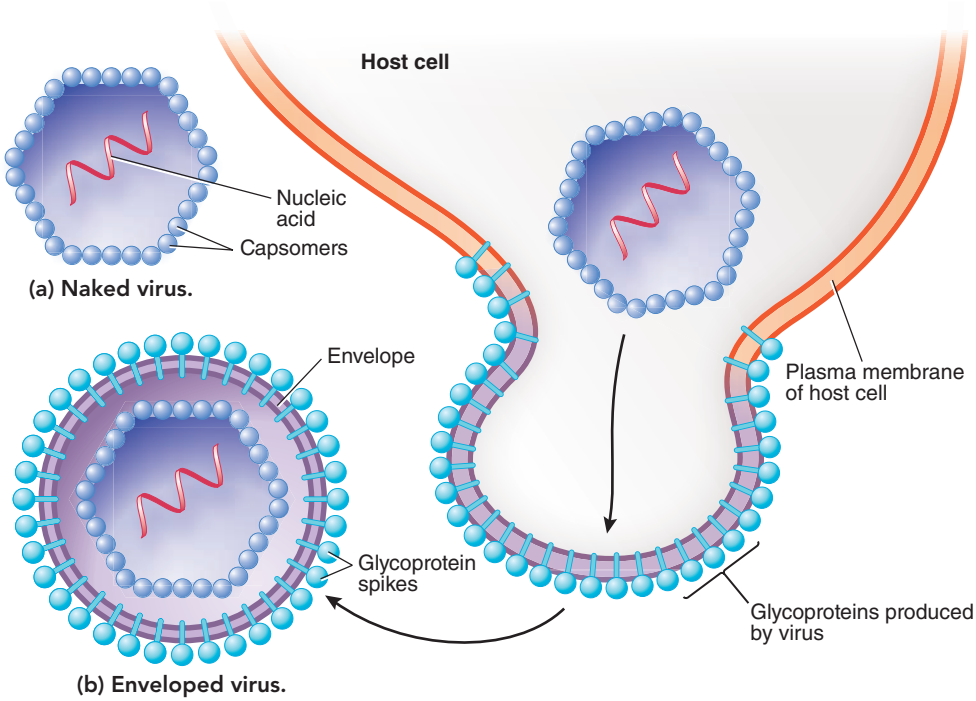

Figure 24-2 Comparison of naked and enveloped viruses

As the virus leaves the host cell, the host's plasma membrane wraps around the virus, forming the envelope. The envelope contains proteins encoded by the virus.

Some viruses are surrounded by an envelope

Some viruses, called *enveloped viruses*, have an outer membranous envelope that surrounds the capsid. Typically, the virus acquires the envelope from the host cell's plasma membrane as it leaves the host cell (FIG. 24-2). Interestingly, while inside the host cell, the virus directs the synthesis of certain proteins, which are then inserted into the host's plasma membrane. Thus, the viral envelope consists of phospholipids and proteins of the host's plasma membrane as well as distinctive proteins encoded by the virus itself. Some viruses possess envelope glycoproteins that extend out from the envelope as spikes. As we will discuss, these glycoprotein spikes can be very important in the virus's interaction with the host cell.

CHECKPOINT 24.1

- **CONNECT** What characteristics of a living organism are absent in a virus?
- What are the structural components of a virus?

24.2 Classification of Viruses

LEARNING OBJECTIVE

3 Identify three characteristics used to classify viruses.

Viruses present a taxonomic challenge to biologists because they do not have the characteristics that define living organisms (see Chapter 1). They are not cellular, they do not carry on metabolic activities, and they reproduce only by taking over the reproductive machinery of other cells. Viruses do not manufacture proteins and so do not have distinctive rRNA. For these reasons, viruses are not classified in any of the three domains.

Viruses can be classified based on their **host range**, the types of host species a specific virus (or other type of infectious agent) can infect. They may be referred to as plant viruses, animal viruses, bacterial viruses, and so on. Viruses are more formally classified into taxa from species to orders. The International Committee on Taxonomy of Viruses (ICTV), a group of virologists, decides on specific criteria for classifying and naming viruses. Recently, based on host range and other characteristics, the ICTV classified viruses into 7 orders, 111 families, 488 genera, and nearly 3000 species. Virus family names include the suffix *-viridae*. Note that this classification system is not a traditional Linnaean system; it does not assign viruses to domains, kingdoms, or phyla.

The Baltimore classification system classifies viruses based on the type of nucleic acid the virus contains, whether the nucleic acid is single-stranded or double-stranded, and how mRNA is produced. Other traits considered in viral classification are the size and shape of the virus, the presence of an envelope, and the method by which the virus is transmitted from host to host.

CHECKPOINT 24.2

- What criteria would you use to classify a virus?

24.3 Viral Replication

LEARNING OBJECTIVES

4 Characterize bacteriophages.
5 Contrast a lytic cycle with a lysogenic cycle.

As we have discussed, viruses reproduce, but only within the complex environment of the living host cells they infect. Viruses use their genetic information to force their host cells to replicate their viral nucleic acid and make the proteins they need. They take over the transcriptional and translational mechanisms of the host cell.

Bacteriophages infect bacteria

Much of our knowledge of viruses has come from studying **bacteriophages** ("bacteria eaters"), more simply referred to as **phages**. These viruses can be cultured easily within living bacteria in the laboratory. Microbiologists have identified more than 5000 phages. Bacteriophages are among the most complex viruses (see Fig. 24-1d). Their most common structure consists of a long nucleic acid molecule (usually dsDNA) coiled within a polyhedral head. Most have a tail, which may be contractile and may function in penetration of the host cell.

Archaeal viruses, first described in 1974, attack archaea in a manner similar to bacteriophages. Over 50 archaeal viruses have been identified, with most having dsDNA and a head and tail structure similar to bacteriophages. Some archaeal viruses, however, have unique forms different from any other viruses (making them more morphologically diverse than bacteriophages). As more archaeal viruses are identified and studied, we will better understand evolutionary relationships between viruses and their hosts across domains.

Phages have been clinically used to treat infection for close to a century. Although abandoned in Western countries after the discovery of sulfa drugs and antibiotics in the 1940s, they have continued to be commonly used in member countries of the former Soviet Union to treat patients. Antibiotics, which have long been more dependable and easier to use, are increasingly less effective than in the past due to the widespread and escalating problem of bacterial resistance. Phage therapy, alone and paired with antibiotics, is again a focus of research in the United States as well as in Europe.

Phages are being engineered to specifically destroy particular bacteria due to their ability to target specific host species. Scientists are also genetically engineering phages so that bacteria will be slower to evolve resistance to them. A fast-acting blood culture test uses bacteriophages to identify and determine if *Staphylococcus aureus* bacteria are present and if they have resistance to methicillin. This new test yields results from in vitro testing in 5 hours compared to standard testing methods, which require 2 to 3 days.

Phage therapy also has applications in dentistry, veterinary medicine, agriculture, and food science. For example, certain phages can kill deadly strains of *E. coli* in cattle. These bacteria do not appear to make cattle ill but can cause illness and death in people who eat contaminated, undercooked ground beef.

Bacteriophages are now commonly used to identify and eradicate target bacteria present in food products and food preparation facilities. Sprays containing bacteriophages are being used to destroy surface bacteria in clinical settings and to prevent bacterial growth on medical instruments, catheters, and surgical materials.

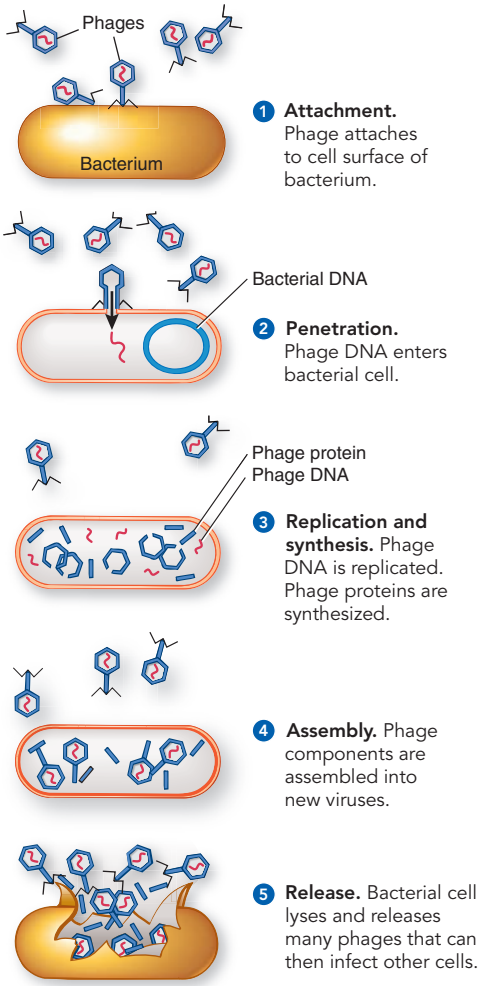
Viruses replicate inside host cells

Viruses infect bacterial, archaeal, plant, and animal cells in basically similar ways. We will focus on phage infection of bacteria because this process is best understood. The reproductive cycle of viruses begins with a virus coming into contact with a host cell. The virus typically attaches to the surface of the host cell. The viral nucleic acid must enter the host cell and synthesize the components it needs to reproduce itself. Then viral components are assembled, and viruses are released from the cell, ready to invade other cells. Two types of viral reproductive cycles are lytic and lysogenic cycles.

Lytic reproductive cycles destroy host cells In a **lytic cycle**, the virus lyses (destroys) the host cell. When the virus infects a susceptible host cell, it forces the host to use its metabolic machinery to replicate viral particles. Viruses that have only a lytic cycle are described as *virulent*, which means that they cause disease and often death.

Five steps are typical in lytic viral reproduction (FIG. 24-3):

1. **Attachment (or adsorption).** The virus attaches to specific receptors on the host cell. This process ensures that the virus infects only its specific host.
2. **Penetration.** The virus penetrates the host plasma membrane and moves into the cytoplasm. Many viruses that infect animal cells enter the host cell intact. Some phages inject only their nucleic acid into the cytoplasm of the host cell; the capsid remains on the outside.
3. **Replication and synthesis.** The viral genome contains all the information necessary to produce new viruses. Once inside a host cell, the virus degrades the host-cell nucleic acid. The virus then uses the molecular machinery of the host cell to replicate its own nucleic acid and produce viral proteins. Many antiviral drugs interfere with replication of viral nucleic acid.
4. **Assembly.** The newly synthesized viral components are assembled into new viruses.
5. **Release.** Assembled viruses are released from the cell. Generally, lytic enzymes, produced by the phage late in the replication process, destroy the host plasma membrane. Phage release typically occurs all at once and results in rapid cell lysis. In contrast, animal viruses are often released slowly or bud off from the plasma membrane.



Once released, the viruses infect other cells, and the process begins anew. The time required for viral reproduction, from attachment to the release of new viruses, varies from less than 20 minutes to more than 1 hour.

Key Point

Viruses reproduce by seizing control of the metabolic machinery of a host cell. In a lytic infection, the viruses destroy the host cell.

(a) The sequence of events in a lytic infection.

Eye of Science/Science Source

(b) Color-enhanced TEM of phages infecting a bacterium, *Escherichia coli*.

Figure 24-3 The sequence of events in a lytic infection

Virulent bacteriophages kill their host cell during each cycle of infection.

PREDICT Would the phage components be able to infect other bacteria if they were released prior to assembly?

How do bacteria protect themselves from phage infection? You may recall from Chapter 15 that bacteria produce *restriction enzymes*, enzymes that cut up the foreign DNA of the phage. This action prevents the phage DNA from duplicating. The bacterial cell protects its own DNA by slightly modifying it after replication so that the restriction enzyme does not recognize the sites it would cut.

In lysogenic cycles, temperate viruses integrate into the host DNA **Temperate phages** do not immediately destroy their hosts. These phages alternate between a lytic cycle and a lysogenic cycle. In a **lysogenic cycle**, the viral genome becomes integrated into the host bacterial DNA. The integrated virus is called a **prophage**, or **provirus**. When the bacterial DNA replicates, the prophage also replicates (FIG. 24-4). In this way, the prophage is passed on to new generations of the original infected cell. The viral genes that code for viral structural proteins may be repressed indefinitely. The temperate phage lambda (designated by the Greek letter λ) is a model organism used to study temperate viruses.

Certain external conditions (such as ultraviolet light and X-rays) cause temperate viruses to revert to a lytic cycle and then destroy their host. Sometimes temperate viruses become lytic spontaneously.

Bacterial cells carrying prophages are called *lysogenic cells*. Such bacterial cells may exhibit new properties. This type of change is called **lysogenic conversion**. An interesting example involves the bacterium *Corynebacterium diphtheriae*, which causes diphtheria. Two strains of this species exist, one that produces a toxin (and causes diphtheria) and one that does not. The only difference between these two strains is that the toxin-producing bacteria are infected by a specific temperate phage. The phage DNA codes for the powerful toxin that causes the symptoms of diphtheria. Similarly, the bacterium *Clostridium botulinum*, which causes botulism, a serious form of food poisoning, is harmless unless it contains certain prophage DNA that induces synthesis of the toxin.

CHECKPOINT 24.3

- **VISUALIZE** What are the steps in a lytic cycle? Draw diagrams to illustrate your answer.
- How is a lysogenic cycle different from a lytic cycle?

24.4 Viral Diseases

LEARNING OBJECTIVES

6 Contrast viral infection of plants and animals, and identify specific diseases caused by viruses.

7 Describe the reproductive cycle of a retrovirus, such as human immunodeficiency virus (HIV).

Key Point

In a lysogenic cycle, temperate phages integrate their nucleic acid into the host genome. The prophage replicates when the bacterial DNA replicates.

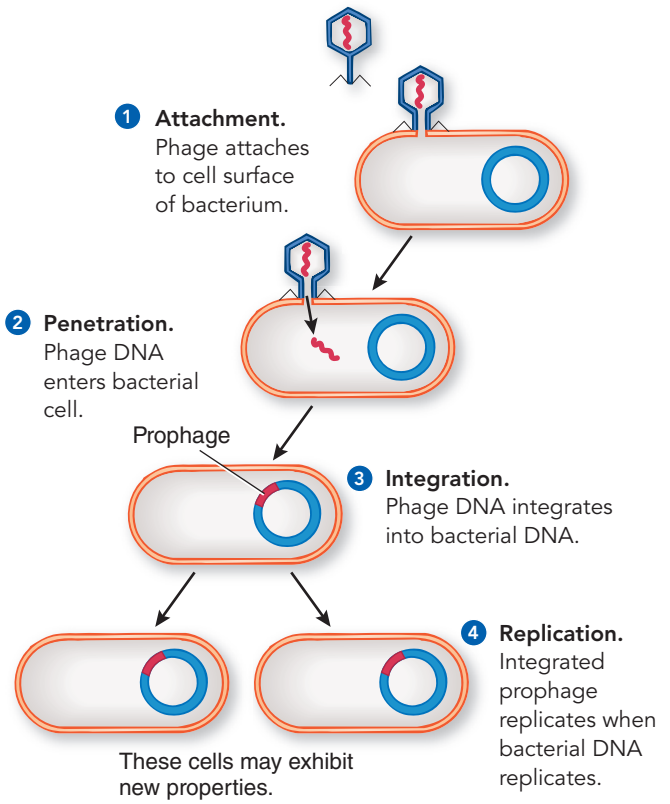

Figure 24-4 The sequence of events in a lysogenic cycle

Temperate phages integrate their nucleic acid into the DNA of their bacterial host. The integrated viral DNA is called a prophage. The bacterium is called a lysogenic cell.

PREDICT How do temperate phages benefit from integrating into the bacterial DNA?

Sir Peter Medawar, a winner of the 1960 Nobel Prize in Physiology or Medicine, defined a *virus* as "a piece of bad news wrapped in protein." Viruses that are **pathogens** are responsible for some very serious diseases, including Ebola hemorrhagic fever, rabies, influenza (flu), hepatitis, and AIDS. However, although viruses must infect cells to reproduce, most known viruses do *not* cause disease. Most viruses, including those that normally inhabit the human body, are harmless or are symbionts. Interestingly, viral genes from retroviruses comprise 8% of the human genome; some of these genes code for proteins essential to human life. Here we focus on viral infection of plants and animals.

Viruses cause serious plant diseases

Viruses cause many important plant diseases and are responsible for an estimated $60 billion in agricultural crop losses worldwide each year. Infected crops almost always produce lower yields and are less profitable than non-infected crops.

Viral infections do not usually kill plants, but they do stunt their growth; cause changes in the shape of the foliage; and may cause spots, streaks, or mottled patterns on leaves, flowers, or fruits (FIG. 24-5). Most plant viruses have capsids, but not envelopes. The genome of 75% of plant viruses consists of ssRNA. Plant viruses are typically named according to the type of host plant they infect and their effects on the plant. Tobacco mosaic virus, described at the beginning of this chapter, was the first virus ever discovered.

Insects are important vectors of plant disease. As they feed on plant tissues, aphids, leaf-hoppers, and many other insects spread viral diseases among plants. Some plant viruses can replicate within certain insects as well as in the host plant. These plant viruses may have originally existed in insects and evolved to replicate in plants. Some soil-borne nematodes and parasitic protozoa are vectors of viral infections in plant roots. They feed on infected roots and transmit the virus to surrounding roots.

Because plants have thick cell walls, viruses cannot penetrate plant cells unless the cells are damaged. Sap from virus-infected plants can be transmitted to healthy plants by injury from hands or agricultural equipment. Natural predation by animals can also transfer contaminated sap to healthy plants. About 20% of plant viruses can be transmitted from one generation to the next through infected seeds or pollen. Natural and artificial asexual propagation can also pass plant viruses to succeeding generations. Once a plant is infected, the virus spreads through the plant body by passing through *plasmodesmata*, cytoplasmic channels that connect adjacent plant cells. Some defenses against viral infection have evolved in plants. When a plant is injured, it reduces transport through the damaged plasmodesmata and quickly grows callus-like tissue, which covers the injured area. Plants can also mount a defense against viruses, called *RNA silencing*, using small interfering RNAs (siRNAs), which are stimulated in the presence of viral dsRNA. Unfortunately, plant viruses have evolved genes to code for proteins to repress the plant's defense.

There are no known cures for most viral diseases of plants, so infected plants are commonly burned. Vectors of plant virus transmission are controlled or eradicated following chemical or biological protocols. Many agricultural scientists are focusing their efforts on preventing viral disease by developing virus-resistant strains of important crop plants.

Viruses cause serious diseases in animals

Hundreds of different viruses infect animals, including humans. Animal viruses cause hog cholera, foot-and-mouth disease, canine distemper, avian influenza, and certain types

of cancer (such as feline leukemia and cervical cancer). In humans, viruses cause herpes simplex (one type causes genital herpes), mumps, rubella (German measles), rubeola (measles), warts, infectious mononucleosis, influenza, viral hepatitis, Ebola hemorrhagic fever, and AIDS (**TABLE 24-1** and *Inquiring About: Emerging Viruses*). Most humans suffer from two to six viral infections each year, including common colds and gastrointestinal disorders.

Norwalk virus is responsible for most worldwide viral gastroenteritis outbreaks and epidemics, affecting more than 200 million and killing more than 200,000 people each year. Norwalk virus is transmitted directly from person to person and indirectly by fecal contamination of water and food. The virus is also spread when infected people sneeze or cough, sending particles into the air; that is, virus particles become aerosolized. Infected individuals can shed viral particles for many weeks after symptoms abate. Norwalk virus infections are a serious concern, especially in closed communities, such as health care institutions, prisons, and cruise ships where people are in prolonged close contact. The genetically diverse strains of the Norwalk virus species make up the noroviruses.

Human activity, including social factors such as urbanization, global travel, immigration, and war, contributes to epidemics of infectious disease. Climate change increasingly impacts human health as mosquitoes and other vectors of viral infection expand their range into warmer areas (discussed in Chapter 57). As habitats expand and human travel facilitates greater movement, introduction and reintroduction of viruses and their carriers increases. Viruses such as Zika, chikungunya, and the virus that causes yellow fever continue to extend their range and become endemic in new parts of the world.

Living conditions, including sanitation, nutrition, physical stress, quality of health care, intravenous drug use, and sexual practices, are important factors in the spread of disease. In the United States and other, more developed countries, infectious disease accounts for about 4% to 8% of deaths compared with death rates of 30% to 50% in developing regions. Even at the level of our current knowledge about viruses and epidemiology, just how prepared are we to contain a particularly virulent virus? For example, how well are we containing HIV (the virus that causes AIDS), which continues to infect and kill millions of people worldwide every year?

Since the September 11, 2001, terrorist attacks in the United States, bioterrorism has become a critical concern worldwide. **Bioterrorism** is the intentional use of microorganisms or toxins derived from living organisms to cause death or disease in humans, animals, or plants on which humans depend. Terrorists could conceivably initiate epidemics of smallpox, anthrax, plague, yellow fever, Ebola hemorrhagic fever, and other potentially fatal diseases. (Note that anthrax and plague are caused by bacteria; see Table 25-4.) Rapid identification, effective treatments, and the development and deployment of vaccines for these diseases continue to be a critical global mission for scientists, health care officials, and governmental strategists.

Animal viruses have varied structure and life cycles

Most viruses cannot survive very long outside a living host cell. Their survival depends on being transmitted from one animal to another. However, their host range may be quite limited because attachment to a host cell is very specific.

The type of attachment proteins on the surface of a virus determines what type of cell it can infect. Receptors typically vary with each species and sometimes with each type of tissue. Thus, many human viruses can infect only humans because the viral attachment proteins combine only with receptor sites found on human cell membranes. The measles virus and poxviruses infect many types of human tissue because their attachment proteins combine with receptor sites on a variety of cells. In contrast, the poliovirus attaches to specific types of human cells, such as those that line the digestive tract and motor neurons of the brain and spinal cord.

Some viruses, such as the adenoviruses, have fibers that project from the capsid and adhere to complementary receptors on the host cell. Other viruses, such as those that cause herpes and rabies, are surrounded by a lipoprotein envelope

Table 24-1 Some Viruses That Infect Vertebrates

Group	Diseases Caused	Characteristics
DNA VIRUSES WITH ENVELOPE		
Herpesviruses	Cold sores (herpes simplex virus type 1); genital herpes, a sexually transmitted disease (herpes simplex virus type 2); chickenpox and shingles (herpes varicella–zoster virus); infectious mononucleosis and Burkitt's lymphoma (Epstein–Barr virus)	**dsDNA**; medium to large, enveloped viruses; replicate in the host nucleus*
Poxviruses	Smallpox, cowpox,† monkeypox, and economically important diseases of domestic fowl	**dsDNA**; large, complex viruses; replicate in the cytoplasm of the host cell
DNA VIRUSES WITH NO ENVELOPE		
Adenoviruses	Respiratory tract disorders (e.g., sore throat, tonsillitis), conjunctivitis, and gastrointestinal disorders are caused by more than 40 types of adenoviruses in humans; other varieties infect other animals	**dsDNA**; replicate in the host nucleus
Papovaviruses	Human warts and some degenerative brain diseases; some cancers, including cervical cancer‡‡	**dsDNA**
Parvoviruses	Infections in dogs, swine, arthropods, rodents; gastroenteritis in humans (transmitted by consumption of infected shellfish)	**ssDNA**; some require a helper virus to multiply
RNA VIRUSES WITH ENVELOPE		
Bunyaviruses	St. Louis encephalitis; hantavirus pulmonary syndrome (caused by Sin Nombre virus, a hantavirus)	**ssRNA**
Coronaviruses	Upper respiratory infections; SARS	**ssRNA**; largest known RNA virus
Filoviruses	Hemorrhagic fever, including that caused by the Ebola virus	**ssRNA**
Flaviviruses	Yellow fever; West Nile infection; Zika virus infection; hepatitis C (the most common reason for liver transplants in the United States)	**ssRNA**
Orthomyxoviruses	Influenza (flu) in humans and other animals	**ssRNA**; serve as a template for mRNA synthesis; medium-sized viruses that often exhibit projecting glycoprotein spikes
Paramyxoviruses	Rubeola (measles) and mumps in humans; distemper in dogs	**ssRNA**; resemble orthomyxoviruses but somewhat larger
Retroviruses	AIDS; some types of cancer	**ssRNA** viruses that contain reverse transcriptase for transcribing the RNA genome into DNA; two identical molecules of ssRNA
Rhabdoviruses	Rabies	**ssRNA**
Togaviruses	Rubella (German measles)	**ssRNA**; can serve as mRNA; large diverse group of medium-sized enveloped viruses; many transmitted by arthropods
RNA VIRUSES WITH NO ENVELOPE		
Noroviruses (made up of strains of Norwalk virus)	Most common cause of viral gastroenteritis in humans	**ssRNA**
Picornaviruses	Polio (poliovirus); hepatitis A (hepatitis A virus); intestinal disorders (enteroviruses); common cold (rhinoviruses); aseptic meningitis (coxsackievirus, echovirus)	**ssRNA** that can serve as mRNA; diverse group of small viruses
Reoviruses	Vomiting and diarrhea (rotaviruses); encephalitis (coltiviruses, orbiviruses)	**dsRNA**

* These viruses frequently cause latent infections; some cause tumors.

† The vaccinia (cowpox) virus is used to produce genetically engineered vaccines.

‡‡ The virus SV40 has been used as a vector to transport genes into cells.

with projecting glycoprotein spikes that attach to a host cell. The influenza virus has rodlike, glycoprotein spikes that project from its envelope. These spikes bind with specific receptors present only on cells lining the respiratory tract of certain vertebrates, including wild and domestic birds, horses, swine, and humans. Influenza vaccine prevents attachment by stimulating the host's antibodies to cover the glycoprotein spikes projecting from the virus.

Viruses have several ways to penetrate animal cells (FIG. 24-6). After attachment to a host-cell receptor, some enveloped viruses fuse with the animal cell's plasma membrane. The entire virus, including the capsid and nucleic acid, is released into the animal cell. Other viruses enter the host cell by *endocytosis*. In this process the plasma membrane of the animal cell invaginates, forming a membrane-enclosed vesicle that contains the virus. Endocytosis is advantageous

Inquiring About

Emerging Viruses

An **emerging virus** is one that is new to a population or that is rapidly increasing in incidence. The best-known example is HIV, the virus that causes AIDS. Other emerging viruses include the coronavirus that causes severe acute respiratory syndrome (SARS); chikungunya, a viral disease transmitted by mosquitos; Ebola virus that causes hemorrhagic fever (see chapter-opening photograph); and Zika virus, which causes serious birth defects, including microcephaly (small brain). Many new, continual, or re-emerging pathogens appear suddenly and can strike globally.

Re-emerging viruses are those that have been almost eradicated and then suddenly recur, causing an epidemic, sometimes in a new geographic area. Many familiar diseases, such as influenza, malaria, tuberculosis, and bacterial pneumonias, continue to infect large numbers of people and increasingly reappear in forms that are resistant to drug therapy. Drug-resistant pathogens are a major challenge to public health and other health care professionals.

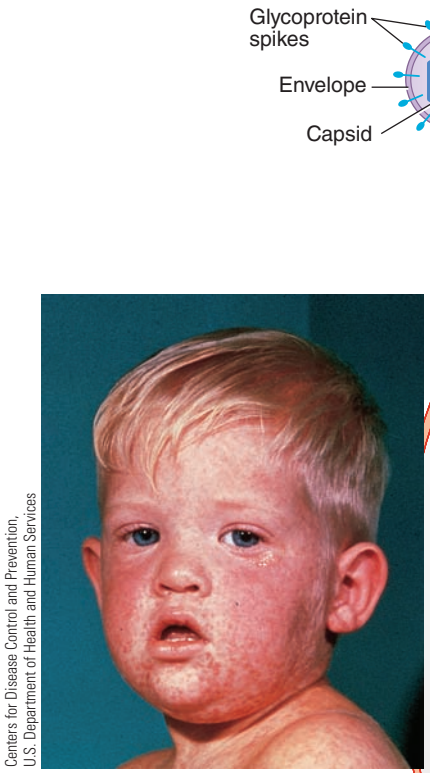
Historically, new viral strains have claimed many human lives. In 1918, for example, an influenza (flu) **pandemic** (global epidemic) killed more than 20 million people. Flu pandemics also occurred in 1957 and 1968. Each year new strains of influenza virus evolve and become infectious. If the new combination of viral genes is unfamiliar to the human immune system, the virus may spread easily, resulting in a pandemic. New strains of influenza are thought to infect one species, such as a species of birds. At first, they are not able to spread among mammals. However, because viruses can evolve, the avian strain can mutate and become virulent. The avian virus can also exchange RNA with a virus that has the genetic material necessary to spread among swine or other mammals. Swine can be susceptible to both avian and human strains of the virus. Inside a swine's body, the viruses can exchange bits of RNA and develop the ability to infect humans. When an animal disease crosses the species barrier and infects humans, it is called a **zoonotic disease**. (We discuss zoonosis further in Chapter 25.) Reassortment of genetic material can also occur inside a human host, producing a viral strain that can spread from person to person (see figure). H1N1 influenza evolved in this way.

An influenza virus such as H1N1 evolves as it mutates and its RNA reassorts in the bodies of birds, swine, and humans. Eventually, it becomes virulent.

to the virus because the endocytotic vesicle delivers the virus deep into the cytosol.

In DNA animal viruses, replication of viral DNA and protein synthesis are similar to the processes by which the host cell would normally carry out its own DNA replication and protein synthesis. In most RNA viruses, RNA synthesis takes place with the help of an RNA-dependent RNA polymerase.

Retroviruses are RNA viruses that have a DNA polymerase called **reverse transcriptase**, which transcribes the RNA genome into a DNA intermediate (FIG. 24-7). This DNA becomes integrated into the host DNA by an enzyme also carried by the virus. Copies of the viral RNA are synthesized as the incorporated DNA is transcribed by host RNA polymerases. The **human immunodeficiency virus (HIV)** that causes AIDS is a retrovirus. Some retroviruses can cause cancer directly or by interacting with other cancer-causing viruses.



After viral genes are transcribed, the viral structural proteins are synthesized. The capsid is produced, and then assembly of new virus particles takes place. Finally, release occurs. Viruses that do not have an outer envelope exit by

Key Point

Viruses bind to specific receptor proteins on the animal cell's plasma membrane. Enveloped viruses then enter the cell by membrane fusion.

Centers for Disease Control and Prevention, U.S. Department of Health and Human Services

(a) This unvaccinated child's rash is a symptom of rubella (German measles), which is caused by an RNA virus spread by close contact.

(b) An enveloped virus enters an animal cell by fusing with its plasma membrane. After it makes copies of itself, new viruses are released. A new envelope forms around each virus as it leaves the host cell.

Figure 24-6 Viral infection in animals

CONNECT Why can't new viruses be completely assembled in the nucleus of the host?

cell lysis. The plasma membrane ruptures, releasing many new viral particles. Enveloped viruses obtain their lipoprotein envelopes by picking up a fragment of the host plasma membrane as they leave the infected cell (see Figs. 24-6b and 24-7).

Viral proteins damage the host cell in several ways. These proteins may alter the permeability of the plasma membrane or may inhibit synthesis of host nucleic acids or proteins. Viruses sometimes damage or kill their host cells by their sheer numbers. A poliovirus can produce 100,000 new viruses within a single host cell!

Viruses quickly become resistant to antiviral drugs

Antibiotics are specific for fighting bacteria; they do not kill

Key Point

Retroviruses use reverse transcriptase to transcribe their RNA into DNA; the viral DNA becomes part of the host DNA. When activated, viral DNA uses host enzymes to transcribe viral RNA.

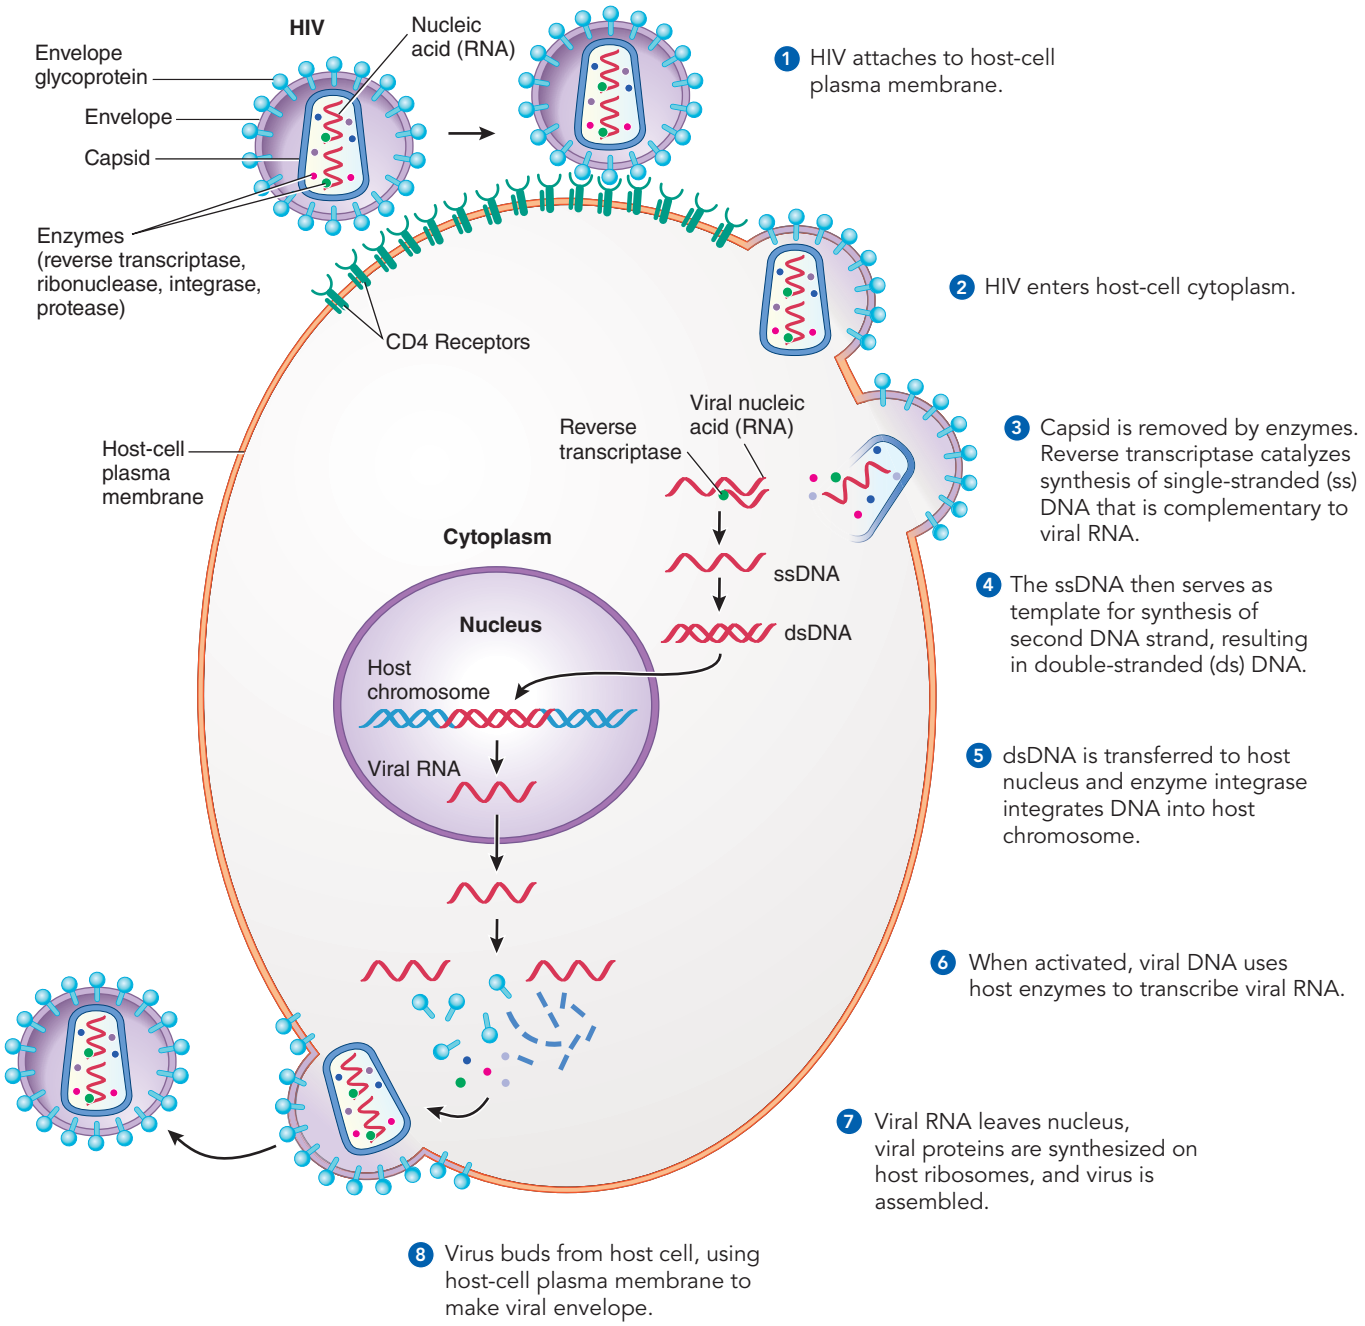

Figure 24-7 Life cycle of HIV, the retrovirus that causes AIDS

HIV infects T helper cells, specialized cells of the host's immune system. The virus attaches to protein receptors, known as CD4, on the plasma membrane of T helper cells. HIV has two identical single-stranded RNA molecules.

CONNECT What advantage does the retrovirus that causes AIDS have compared to an RNA virus?

viruses. Fortunately, researchers continue to develop antiviral drugs. These drugs are currently used to treat many diseases, including HIV, hepatitis B and C, herpes, and influenza A and B.

Antiviral drugs do not typically destroy viruses. Rather, they inhibit the development, or replication, of many types of RNA and DNA viruses. Unfortunately, viruses rapidly

develop resistance, making antiviral drug design and therapy a constantly changing, competitive endeavor. For example, amantadine, which inhibits penetration or uncoating of viral nucleic acids, had been effective in treating patients with influenza. Unfortunately, most strains of influenza virus have become resistant to amantadine, perhaps as a result of common use of the drug in poultry feed in certain areas of Asia, such as China.

Another type of antiviral drug (e.g., Tamiflu) inhibits a viral enzyme (neuraminidase) necessary for the virus to leave the host cell. Certain viral strains are becoming resistant to Tamiflu. A single mutation that occurs spontaneously is apparently responsible for this resistance. New antiviral drugs are being designed or are currently in clinical trials. Some inhibit viral attachment to host cells, and others interfere with replication of viral nucleic acid.

Viruses are being genetically modified to treat diseases such as cancer. Viruses can be reprogrammed to enter, reproduce, and destroy cancer cells. For example, researchers have deleted a replication gene from herpes simplex virus and replaced it with a human gene that stimulates immunity. This virotherapy procedure is now being used to destroy melanoma, a type of skin cancer. Researchers are developing strategies using RNA-targeted CRISPR to target and inhibit the hepatitis C virus (a ssRNA virus) in cells. Ongoing research suggests that these strategies may be effective against several other viruses, including HIV.

24.5 Evolution of Viruses

LEARNING OBJECTIVE

8 Trace the evolutionary origin of viruses according to current hypotheses and describe research regarding the evolution of polydnaviruses.

Scientists have been debating the origin of viruses ever since they were discovered. Currently, there are three main hypotheses: the progressive (or escape) hypothesis, the regressive (or reduction) hypothesis, and the virus-first hypothesis.

According to the *progressive hypothesis*, also known as the *escape hypothesis*, viruses may have originated as mobile genetic elements such as *transposons* (see Chapter 13) or plasmids (small, circular DNA fragments discussed in Chapters 15 and 25). Such fragments could have escaped from one cell and entered another cell through damaged cell membranes. According to this hypothesis, the origin of viruses may be traced back to archaeal, bacterial, protist, plant, or animal cells. Their multiple origins may explain why many viruses are species specific; perhaps they infect only those species that are closely related to the organisms from which they originated. This hypothesis is supported by the genetic similarity between some viruses and their host cells—a closer similarity than exists between one type of virus and another.

The *regressive hypothesis*, also called the *reduction hypothesis*, asserts that viruses are remnants of cellular organisms and evolved from small cells that were parasites in larger cells. Genes that they did not need, like those for protein synthesis, were gradually lost through evolution. This hypothesis is supported by certain bacteria (chlamydia and rickettsia) that are able to reproduce only inside the cells of their hosts (see Table 25-4).

The regressive hypothesis is also supported by the discovery that some giant viruses have genes that code components for protein translation. Proponents of the regressive hypothesis suggest that these giant viruses evolved from a free-living, complex cellular ancestor. Later, they became parasitic and gradually lost some of the genes necessary for protein synthesis. This hypothesis explains how viruses could have existed before their present-day hosts evolved.

The *virus-first hypothesis* states that viruses predate or coevolved with their current cellular hosts even before the life-forms assigned to the three domains diverged. One research team recently suggested that viruses initially existed in a pre-cellular world as self-replicating units. Gradually, these small units became more organized and more complex. Eventually they evolved to produce enzymes for the synthesis of membranes and cell walls, leading to the origin of the first cells.

Evidence for this hypothesis comes from similarities found in the protein structures of some viral capsids and in genetic similarities between some viruses that infect archaea and some that infect bacteria. Molecular biologists studying this hypothesis consider it improbable that these similarities evolved independently. They hypothesize that viruses diverged very early—before archaea, bacteria, or eukaryotes.

Recent studies on the origin of polydnaviruses contribute to our understanding of viral evolution. **Polydnaviruses** are particles that consist of multiple circles of dsDNA encased in capsid proteins and an envelope. Each circle of DNA contains part of the virus genome. These viruses are found in ovary cells of many species of parasitic wasps. The polydnaviruses are unusual in that their circular DNA does not have genes for making the proteins needed to replicate and produce new viruses. Genes needed for these viruses to replicate are found only in the wasp genome; the viruses can replicate only in the wasp ovary cells.

The wasp injects polydnaviruses along with her eggs into certain caterpillars. The polydnaviruses express toxins that

interfere with the caterpillar's immune defenses and development. The wasp eggs hatch and develop inside the caterpillar. The young wasps feed on the caterpillar.

Biologists wondered whether the polydnaviruses were really viruses. Were the polydnaviruses simply particles derived from wasp genes? An alternative hypothesis was that millions of years ago a particular virus infected wasps. The virus genome became integrated into the wasp genome and lost the capacity to enter virus particles. Instead, wasp DNA was incorporated into the particles. Read the Key Experiment, FIGURE 24-8, to learn which hypothesis is supported by the research of Jean-Michel Drezen, Annie Bézier, and their colleagues.

Today's viruses may have originated multiple times, through many mechanisms, or by a mechanism not yet discovered. No matter how viruses came to be and how they continue to evolve, they have important roles in evolution. They mutate constantly, producing many new alleles. They replicate rapidly, and some of their genes are incorporated into the genomes of host cells through horizontal gene transfer. In fact, viruses can provide a major source of new genes for their host cells.

- **CONNECT** How could viruses have evolved before their hosts? Explain your answer.
- **CONNECT** In what way are polydnaviruses mutualistic partners with certain wasps?

24.6 Subviral Agents

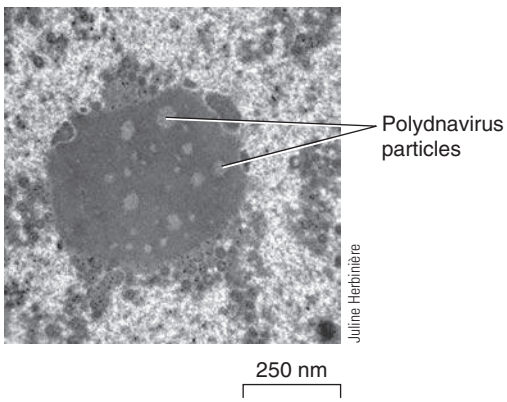
LEARNING OBJECTIVE

9 Compare satellites, viroids, prions, and defective interfering particles (DIPs).

Subviral agents are infective agents that are smaller and simpler than viruses. Subviral agents include satellites, viroids, prions, and defective interfering particles (DIPs).

Satellites depend on helper viruses

Satellites are subviral agents that depend on co-infection of a host cell with a helper virus. The satellite, which consists of either DNA or RNA, cannot reproduce without the helper virus. A satellite is called a satellite virus when the satellite encodes the coat protein in which it is encapsulated.



Sputnik is a satellite that infects *Mimivirus*, which in turn infects an amoeba. Sputnik is dependent on the replication and assembly machinery set up by Mimivirus. Many researchers now refer to Sputnik as a *virophage*. The term implies that Sputnik, and perhaps other satellites, impair the reproduction of Mimivirus, its helper virus.

Key Experiment

What is the origin of polydnaviruses?

HYPOTHESIS: Polydnaviruses evolved from ancient viruses that infected wasps.

EXPERIMENT: Annie Bézier, Jean-Michel Drezen, and their colleagues searched for virus-related genes in the wasp genome. The team analyzed DNA from three different wasp species. They compared nucleotide sequences with sequences of public databases containing sequences of all organisms and viruses studied.

RESULTS AND CONCLUSION: The researchers identified 22 genes expressed in wasp ovaries where viral particles are produced. These genes are present in the wasp genome and resemble key genes of nudiviruses, a family of insect viruses. The investigators found that many of these genes code for proteins that are part of the polydnavirus particles. These genes have been conserved in several different wasp families that have polydnaviruses.

The research team concluded that the polydnavirus evolved from a nudivirus that infected wasps millions of years ago. In time, the virus genome became incorporated into the wasp genome. Proteins needed for viral replication are now part of the wasp's DNA, and the virus can replicate only in the wasp's ovaries.

At the same time, the wasps depend on the virus. The wasps inject their eggs into certain caterpillars along with polydnaviruses. The viruses depress the caterpillar's immune defenses, allowing the wasp larvae to develop in the caterpillar. Thus, a mutualistic relationship has evolved between the wasp and the polydnavirus.

The investigators suggested that the polydnavirus acts as a gene vector, transporting large chunks of DNA to the caterpillar. Might learning more about this mechanism have clinical applications?

SOURCE: Bézier, Annie, et al., "Polydnaviruses of Braconid Wasps Derive from an Ancestral Nudivirus," *Science*, Vol. 323, No. 5916 (Feb. 13, 2009): 926–930.

Figure 24-8 Exploring the evolution of polydnaviruses

Viroids are short, single strands of naked RNA

In 1971, Theodor Otto Diener, a plant pathologist, discovered an infective agent in potatoes that he named a **viroid**. Since then, more than 30 species of viroids have been identified. Smaller than a virus, a viroid consists of a very short, circular, single strand of naked RNA (only 250 to 400 nucleotides). The viroid has no protective protein coat and no associated proteins to assist in duplication. Its RNA serves as a template that is copied by host RNA polymerases. Viroids are extremely hardy and can resist heat and ultraviolet radiation because of the condensed folding of their RNA. Until recently it was thought that viroids only infect plants. However, it is now known that a viroid enclosed in a hepatitis B virus capsid causes the human disease hepatitis D.

Many viroids that cause plant diseases—including potato spindle tuber viroid, apple scar skin viroid, avocado sunblotch viroid, and tomato chlorotic dwarf viroid—have been identified. Viroids cause stunted or distorted growth and sometimes kill the plant. For example, cadang-cadang disease has killed more than 30 million coconut palm trees in the Philippines. Viroids are transmitted by infected pollen or seeds.

Viroids are generally found within the host-cell nucleus and appear to interfere with gene regulation. Molecular biologists have hypothesized that viroids mirror gene sequences in their hosts and silence critically important host genes. The viroid's ssRNA replicates, forming dsRNA. The plant's defense response cleaves this viroid RNA, producing small interfering RNAs (siRNAs), discussed in Chapters 13 and 14. However, the viroid siRNAs then cause host ribonucleases to selectively cleave host mRNAs with complementary base sequences. This action inactivates host mRNA and silences specific host genes. The viroids themselves are resistant to RNA silencing.

Prions are protein particles

Motivated by the death of a patient from Creutzfeldt–Jakob disease (CJD), a degenerative brain disease, Stanley Prusiner, professor of neurology and biochemistry at the University of California, San Francisco, began his studies of prions in the early 1970s. Prusiner discovered that the infective agent was not affected by radiation (which typically mutates nucleic acids), and he could not find DNA or RNA in the particles. In 1982, he named the infective agent **prion**, for "proteinaceous infectious particle."

Prusiner's hypothesis that an infectious agent could cause disease without nucleic acids was not readily accepted because there was no known mechanism by which this action could occur. However, Prusiner and other researchers continued to study prions and discovered how they can cause cells to malfunction. In 1997, Prusiner was awarded the Nobel Prize in Physiology or Medicine for his discovery of prions.

Prusiner and others have shown that animals have a gene that encodes a normally harmless protein known as PrP. Normal forms of the protein are found on the surfaces of brain cells and many other types of cells. The PrP protein, which consists of 208 amino acids, helps neurons transport copper and may play a role in the sense of smell in animals. Researchers have discovered that normal PrP interacts with the peptides associated with Alzheimer's disease.

Sometimes, the PrP protein folds into a different shape, an insoluble form that can cause disease. This misfolded protein is the prion. Mutations in the gene that encodes the PrP protein increase the risk that the protein will misfold and become a prion. The prion then somehow induces other PrP molecules to misfold into the pathogenic form (FIG. 24-9). Prions apparently can aggregate and accumulate in the brain and in certain other tissues and cause serious damage.

Prions are found in the brains of patients with *transmissible spongiform encephalopathies (TSEs)*. This group of fatal degenerative brain diseases has been identified in birds and mammals. These diseases are called TSEs because when infected, the brain appears to develop holes and becomes somewhat spongelike. The TSEs are in some ways like viral illnesses. However, there is a long latency period (about 5 years in cows and up to 10 years in humans) between contracting the infection and developing symptoms of the illness. Also, the TSEs have proven very difficult to treat. Genetically engineered mice that lack the prion protein gene are immune to TSE infection.

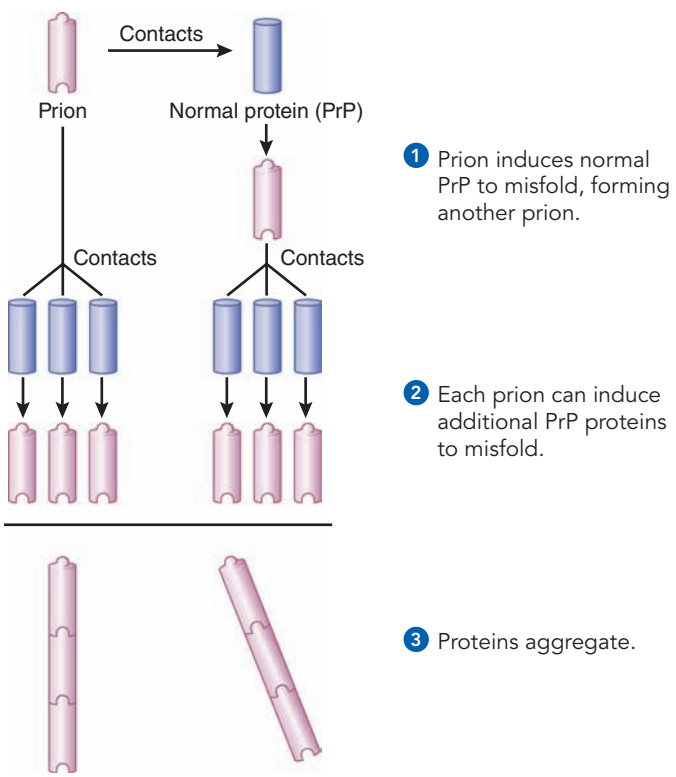

Figure 24-9 A model for how prion populations expand

Prions contact normal PrP proteins and induce them to misfold and become prions. Each new prion can then contact additional PrP molecules and induce them to misfold, thus expanding the prion population. Prions can form clumps by aggregating.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

The oldest known prion disease is *scrapie* in sheep and goats. When infected, animals lose coordination, become irritable, and itch so severely that they scrape off their wool or hair. Bovine spongiform encephalopathy (BSE) is a related prion disease popularly referred to as "mad cow disease" because some diseased cattle become aggressive. In the 1990s, BSE became epidemic in cattle in the United Kingdom.

More than 200 people have died from a human variety of BSE, providing evidence that the disease is transmissible from cow to human. The human disease is called vCJD because it is a variant of CJD, which is caused by the transformation of PrP proteins into prions. The infectious agent of vCJD has been recovered from infected human neural tissue and appears similar to the prion that causes scrapie in sheep. New regulations have been instituted in many countries to safeguard the food supply. Human-to-human transmission of vCJD has been associated with tissue and organ transplants and with transfusion with contaminated blood.

Chronic wasting disease, an illness related to mad cow disease, has spread among deer and elk populations in North America. Studies are under way to determine whether chronic wasting disease can infect livestock or humans. In 2015 researchers in Texas discovered that plants can act as a vector for prions when they attach to a plant and the plant is then consumed. Feline spongiform encephalopathy is a prion disease of domestic and captive felines. With this disease, large deposits of a misfolded protein accumulate in the liver and spleen.

Like viruses, prions exhibit variability. Different strains of prions may differ from one another in the conformation of their proteins, in their properties, and in the diseases they cause. Prions are different from viruses in that they can arise spontaneously, mostly as a result of mutation. Researchers are studying ways to block prions from forming. They are also looking for ways to stimulate cells to destroy prions. Early diagnosis is critical, and the search for an assay, or test, to detect prion disease is ongoing.

Defective interfering particles are virus mutants

Defective interfering particles (DIPs) are naturally occurring viral mutants that are spontaneously generated when part of the viral genome is lost due to defective replication. DIPs can only penetrate a host cell when accompanied by a helper virus. DIPs can occur in all types of DNA and RNA viruses. The particles compete with non-defective viruses, which is why they are called "interfering." DIPs are being studied as a possible virus therapy. Researchers have used DIPs to make a "protecting virus," which rendered influenza A non-lethal in research with mice.

Summary: Focus on Learning Objectives

24.1 The Status and Structure of Viruses *(page 500)*

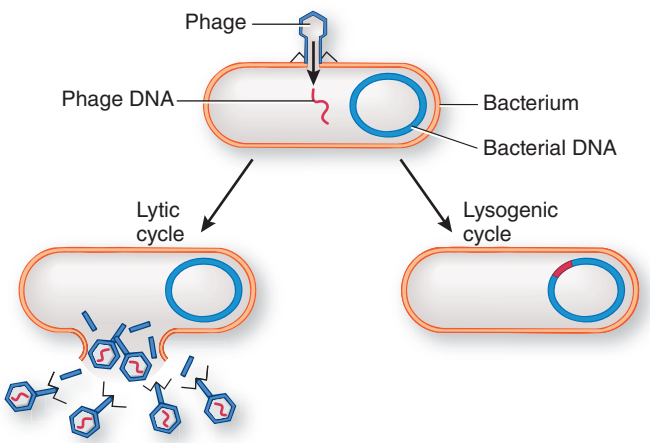
1 Contrast a virus with a cellular organism.

- A **virus** is a very small infective agent that consists of a core of nucleic acid and is dependent on a living host. Viruses contain the nucleic acids necessary to make copies of themselves, but to reproduce they must invade living cells and commandeer their metabolic machinery.

2 Describe the structure of a virus.

- A virus is a subcellular particle consisting of a DNA or RNA genome surrounded by a protein coat, called a **capsid**. In some viruses the capsid is surrounded by an outer envelope.

24.2 Classification of Viruses *(page 502)*



3 Identify three characteristics used to classify viruses.

- Viruses are classified based on **host range**, the types of host species they can infect; the type of nucleic acid they contain; and whether the nucleic acid is single-stranded or double-stranded. Other factors used to classify viruses include size and shape, presence of an envelope, and method of transmission from host to host.

24.3 Viral Replication *(page 503)*

4 Characterize bacteriophages.

- **Bacteriophages**, or **phages**, are complex viruses that infect bacteria. They typically consist of a long molecule of dsDNA coiled within a polyhedral head.

5 Contrast a lytic cycle with a lysogenic cycle.

- In a **lytic cycle**, the virus destroys the host cell. The five steps in a lytic cycle are *attachment* to the host cell, *penetration* of viral nucleic acid into the host cell, *replication* of the viral nucleic acid, *assembly* of newly synthesized components into new viruses, and *release* from the host cell.
- The nucleic acid of some phages becomes integrated into the DNA of its bacterial host. The phage is then called a **prophage**. A **temperate virus** alternates between a lytic and a lysogenic cycle. In a **lysogenic cycle**, the genome of a temperate virus is replicated along with replication of the host's DNA without causing death of the host cell.
- Bacterial cells that carry prophages are lysogenic cells. In **lysogenic conversion**, bacterial cells containing certain temperate viruses exhibit new properties.

24.4 Viral Diseases *(page 504)*

6 Contrast viral infection of plants and animals, and identify specific diseases caused by viruses.

- Most plant viruses are ssRNA viruses that do not have envelopes. Plant viruses penetrate plants through damaged cells and are also transmitted by infected seeds. Viruses can be spread among plants by insect vectors. Viruses spread through the plant via plasmodesmata.
- Viruses enter animal cells by membrane fusion or by endocytosis. Diseases caused by DNA viruses include herpes, respiratory infections, and gastrointestinal disorders. RNA viruses cause influenza, upper respiratory infections, AIDS, and some types of cancer.

7 Describe the reproductive cycle of a retrovirus, such as human immunodeficiency virus (HIV).

- **Retroviruses**, such as HIV, use **reverse transcriptase** to transcribe their RNA genome into a DNA intermediate that becomes integrated into the host DNA. Copies of the viral RNA are then synthesized.

24.5 Evolution of Viruses *(page 511)*

8 Trace the evolutionary origin of viruses according to current hypotheses and describe research regarding the evolution of polydnaviruses.

- According to the *progressive*, or *escape, hypothesis*, viruses may have originated as mobile genetic elements that could have escaped and moved from one cell and entered another through damaged cell membranes. Viruses may trace their origin to animal cells, plant cells, bacterial cells, or archaeal cells.
- The *regressive*, or *reduction, hypothesis* asserts that viruses are remnants of cellular organisms; they evolved from free-living, complex cellular ancestors. As they became parasitic, some of the genes necessary for protein synthesis were lost through evolution. According to the *virus-first hypothesis*, viruses predate or coevolved with their current cellular hosts. Viruses may have initially existed as self-replicating units. As they evolved, viruses produced enzymes for the synthesis of membranes and cell walls, leading to the formation of the first cells.
- Evidence suggests that **polydnaviruses** evolved from viruses that infected wasps. They have become mutualistic partners with their wasp hosts.

24.6 Subviral Agents *(page 512)*

9 Compare satellites, viroids, prions, and defective interfering particles (DIPs).

- Satellites, viroids, and prions are smaller than viruses. Satellites reproduce only with the help of a helper virus. A **viroid** consists of a short strand of RNA with no protein coat. Many viroids cause plant diseases.
- A **prion** consists only of protein. Prions cause fatal degenerative brain diseases, such as *transmissible spongiform encephalopathies (TSEs)*. A **DIP** can only penetrate a host cell accompanied by a helper virus.

Test Your Understanding

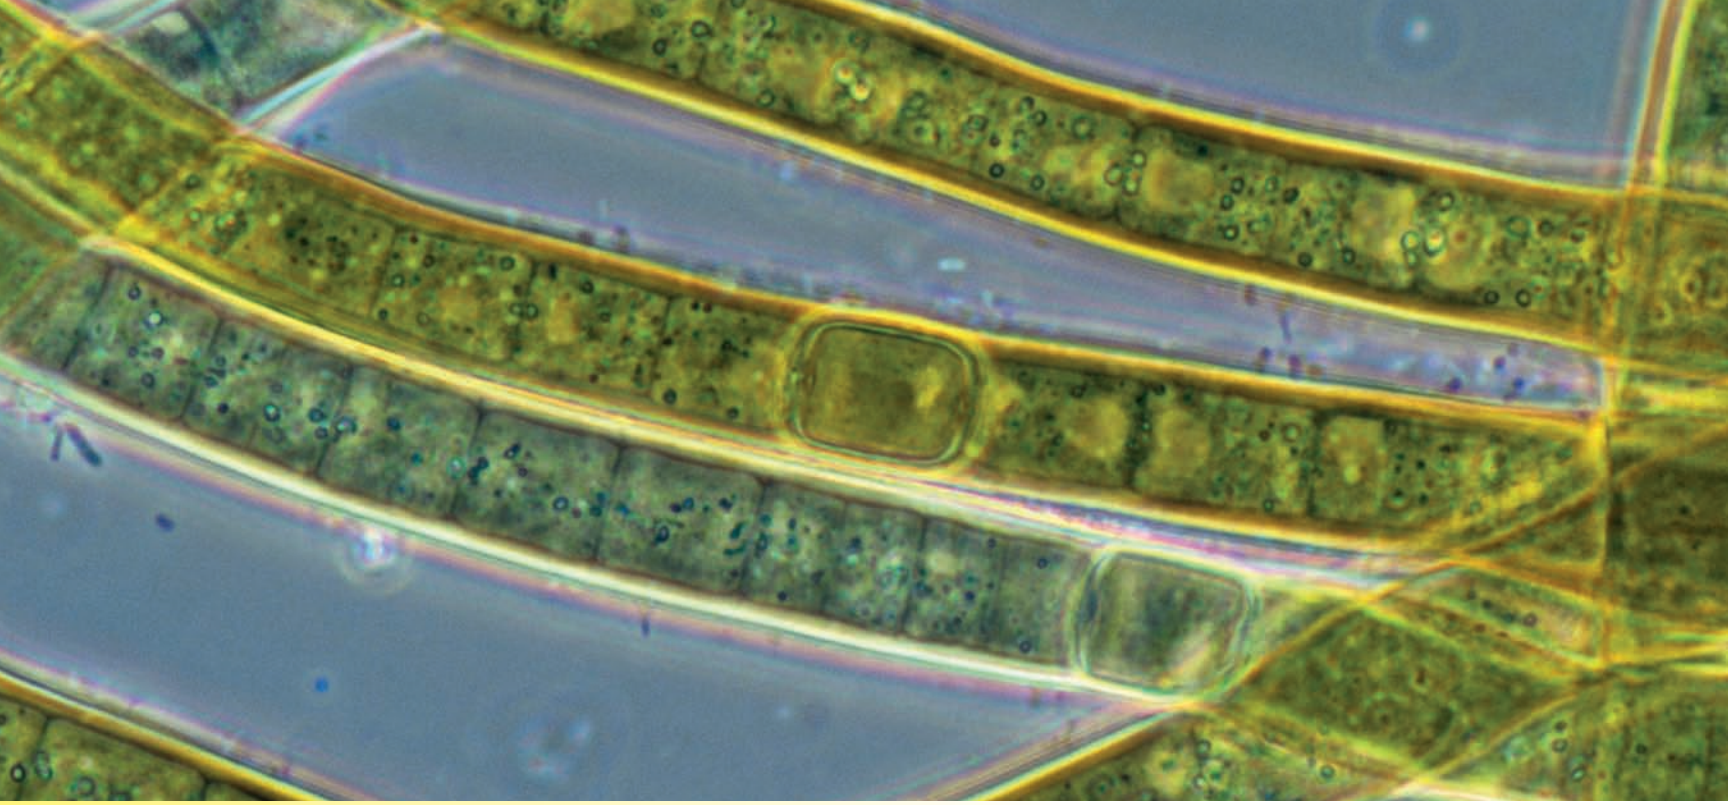
Know and Comprehend

1. The genome of a virus consists of (a) DNA (b) RNA (c) prions (d) DNA and RNA (e) DNA or RNA
2. The capsid of a virus consists of (a) protein subunits (b) nucleic acid (c) helical lipids (d) a carbohydrate envelope (e) RNA and lipid
3. Viruses that kill host cells are (a) lysogenic (b) lytic (c) viroids (d) prophages (e) temperate
4. In lysogenic conversion, (a) bacterial cells may exhibit new properties (b) the host cell dies (c) prions sometimes convert to viroids (d) reverse transcriptase transcribes DNA into RNA (e) lytic viruses become temperate
5. The types of host species a particular virus can infect are referred to as its (a) assembly (b) commensal cohort (c) host range (d) prophage factor (e) virulence factor
6. Plant viruses (a) typically cause rapid death of infected plants (b) are mainly retroviruses (c) can be killed with antibiotics (d) are transmitted throughout the plant body by insects (e) can be transmitted from one generation to the next through infected seeds
7. According to the progressive, or escape, hypothesis, viruses (a) appeared before the three domains diverged (b) came from mobile genetic elements and had multiple origins (c) evolved from early plant cells (d) are bits of nucleic acid that escaped from animal cells (e) evolved from cells that were parasites in larger cells
8. Prions (a) consist of RNA with no protein coat (b) are misfolded proteins (c) cause several important plant diseases (d) are the infective agents of several emerging diseases (e) consist of proteins that stimulate host RNA to produce DNA

Apply and Analyze

9. Arrange the following list into the correct sequence for viral reproduction: 1. penetration 2. assembly 3. replication 4. attachment 5. release (a) 1, 2, 3, 4, 5 (b) 5, 2, 3, 4, 1 (c) 4, 1, 3, 2, 5 (d) 4, 1, 2, 3, 5 (e) 3, 1, 2, 4, 5
10. Arrange the following list into the correct sequence for part of the cycle of a retrovirus: 1. dsDNA integrated into host DNA 2.viral proteins synthesized on host ribosomes 3. viral DNA uses host enzymes to transcribe viral RNA 4. reverse transcriptase catalyzes synthesis of ssDNA 5. synthesis of second DNA strand (a) 5, 2, 1, 3, 4 (b) 5, 2, 3, 4, 1 (c) 4, 5, 1, 3, 2 (d) 4, 1, 2, 3, 5 (e) 2, 1, 3, 4, 5
11. **VISUALIZE** What does this diagram illustrate? Complete the labels.

12. **CONNECT** How are viral genomes different from those of plant or animal cells?
13. **CONNECT** How do viroids and prions differ from viruses?



Evaluate and Synthesize

14. **EVOLUTION LINK** Discuss the coevolution of polydnaviruses and their mutualistic partners. (See the discussion and Key Experiment on polydnaviruses.)
15. **EVOLUTION LINK** Based on what you have learned about viruses, present an argument for one of the three hypotheses of virus origin.
16. **SCIENCE, TECHNOLOGY, AND SOCIETY** What is the continuous challenge that the influenza virus presents to scientists and public health officials? How can they use technology and work together to meet this challenge?

25 Bacteria and Archaea

In this chapter we examine the diversity and characteristics of the members of domain Bacteria and domain Archaea, two of the three main branches of the tree of life. These organisms, informally called prokaryotes, have inhabited our planet for more than 3.5 billion years, much longer than eukaryotes, which evolved about 2.2 billion years ago. Although prokaryotes are microscopic, they are so numerous that they probably account for more than half of Earth's biomass, the mass of living material. Thus, the biomass of prokaryotes is greater than that of all the eukaryotes: fungi, plants, and animals. As scientists discover new prokaryotes and explore new niches and habitats, the percentage of bacteria and archaea in the Earth's total biomass continues to increase.

Anton van Leeuwenhoek, a Dutch microscopist, discovered bacteria and other microorganisms in 1674 when he looked at a drop of lake water through a glass lens. During the late 1800s, many microorganisms, including some bacteria, fungi, and protozoa, were identified as **pathogens**, agents that cause disease. Bacteria cause many diseases, such as tuberculosis, tetanus, respiratory infections, and food poisoning in humans. However, only a small minority of bacterial species are pathogens. (Although some archaea have been associated with disease, no pathogenic archaea have been identified.)

Both bacteria and archaea play essential roles in the biosphere. As decomposers they break down organic molecules into their components. Along with fungi, prokaryotes are nature's chief recyclers. Without these microorganisms, elements such as carbon, nitrogen, phosphorus, and sulfur would remain locked

KEY CONCEPTS

25.1 Bacteria and archaea are single-celled organisms; their prokaryotic cells do not have membrane-enclosed organelles; most have a cell wall that surrounds the plasma membrane; and most have a single, circular DNA molecule.

25.2 Evolution occurs rapidly in prokaryotes; natural selection acts on the genetic variation provided by mutations and genetic recombination and is facilitated by rapid reproduction.

25.3 The great diversity that has evolved in their metabolism and mode of nutrition allows prokaryotes to thrive in all kinds of habitats.

25.4 Prokaryotes make up two of the three domains: Bacteria and Archaea.

25.5 Prokaryotes form intimate relationships with other organisms and play critical roles in ecology, commerce, and technology.

25.6 The many adaptations that have evolved in pathogenic bacteria contribute to their great success.

up in the wastes and dead bodies of plants, animals, and other organisms and would be unavailable for the synthesis of new cells and organisms.

One group of prokaryotes, the cyanobacteria, are producers that carry on photosynthesis, which generates oxygen (see photograph). In fact, 70% to 80% of the oxygen on planet Earth is generated by cyanobacteria and algae. Other prokaryotes convert atmospheric nitrogen to ammonia and then to nitrates, forms that are used by plants (see Fig. 55-8). This conversion enables plants and animals (because they eat plants) to manufacture essential nitrogen-containing compounds such as proteins and nucleic acids.

We begin this chapter with a description of the structure of bacteria and archaea, and then we discuss prokaryote reproduction and evolution. We outline some of the nutritional and metabolic adaptations of these organisms and describe the phylogeny of the two prokaryote domains. We then present an overview of prokaryote relationships with other organisms and the effect of prokaryotes on ecology, technology, and commerce. We end the chapter with a discussion of bacteria and disease.

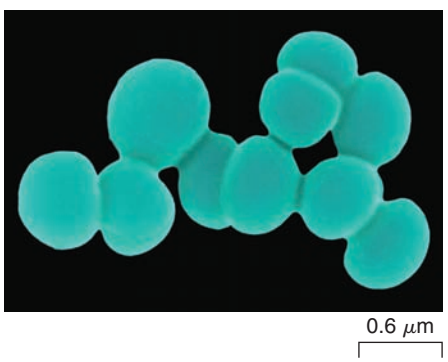
25.1 The Structure of Bacteria and Archaea

LEARNING OBJECTIVES

1. Describe the structure and common shapes of prokaryotic cells.
2. Compare the bacterial cell wall in gram-positive and gram-negative bacteria.
3. Describe movement in prokaryotes and describe the structure of the bacterial flagellum.

In contrast to viruses, viroids, and prions, which consist only of nucleic acid and/or protein, **prokaryotes**, assigned to domain Archaea or Bacteria, are cellular organisms. However, recall from Chapters 4 and 23 that the cell structure of prokaryotes is fundamentally different from that of the eukaryotic cells of other living organisms.

Most prokaryotic cells are very small. Typically, their diameter ranges from 0.5 to 1.0 μm, and their length ranges from 1.0 to 5.0 μm. Their cell volume is only about one-thousandth that of small eukaryotic cells, and their length is only about one-tenth. Most prokaryotes are unicellular, but some form colonies or filaments containing specialized cells.



Prokaryotes have several common shapes

Three common prokaryote shapes are spherical, rod-shaped, and spiral. Spherical prokaryotes, known as **cocci** (sing., *coccus*), occur singly in some species and in groups of independent cells in others (FIG. 25-1a). Cells may be grouped in twos (*diplococci*), in long chains (*streptococci*), or in irregular clumps that look like bunches of grapes (*staphylococci*). Rod-shaped prokaryotes, called **bacilli** (sing., *bacillus*), may occur as single rods or as long chains of rods (FIG. 25-1b). Some prokaryotes form spirals. If the spiral-shaped cell is flexible, it is a **spirochete**; if rigid, it is a **spirillum** (pl., *spirilla*) (FIG. 25-1c). A spirillum shaped like a comma is called a **vibrio**. Some archaea have unusual shapes, such as triangular or square-shaped cells.

Prokaryotic cells do not have membrane-enclosed organelles

In contrast to eukaryotic cells, prokaryotic cells do not have a nucleus or other membrane-enclosed organelles (FIG. 25-2; see Chapter 4). Although the prokaryotic cell does not have a membrane-enclosed nucleus, it does have a **nuclear area**, also referred to as the **nucleoid**, which contains DNA.

The dense cytoplasm of the prokaryotic cell contains ribosomes (smaller than those found in eukaryotic cells) and storage granules that hold glycogen, lipid, and phosphate compounds. Enzymes needed for metabolic activities may be located in the cytoplasm. Although the membranous organelles of eukaryotic cells are absent, in some prokaryotic cells the plasma membrane is extensively folded inward. Enzymes needed for cellular respiration and photosynthesis may be associated with the plasma membrane or its folds.

Key Point

In contrast to eukaryotic cells, prokaryotic cells lack organelles enclosed by membranes; the DNA is not surrounded by a nuclear envelope.

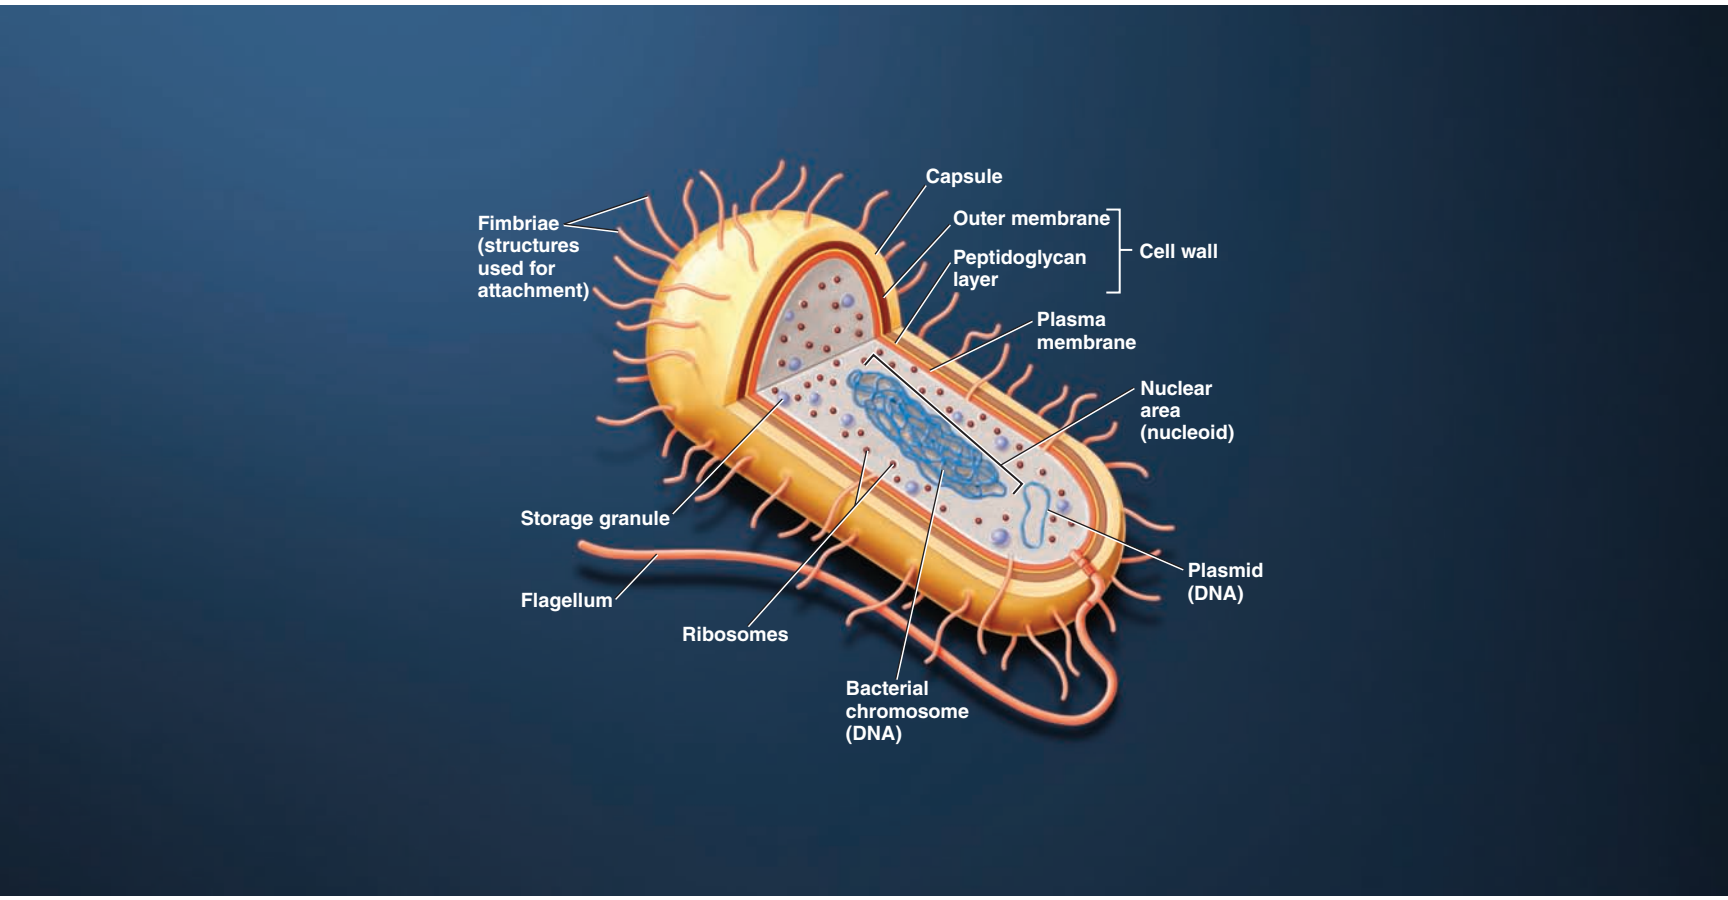

Figure 25-2 Structure of a prokaryotic cell

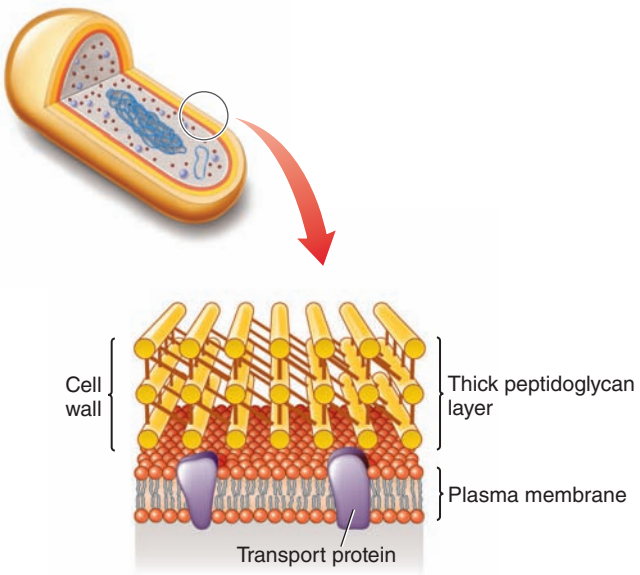
This bacillus is a gram-negative bacterium (discussed in text). Prokaryotic cells typically have a nuclear area with a single, circular DNA molecule. They may also have one or more plasmids, small rings of DNA that replicate independently.

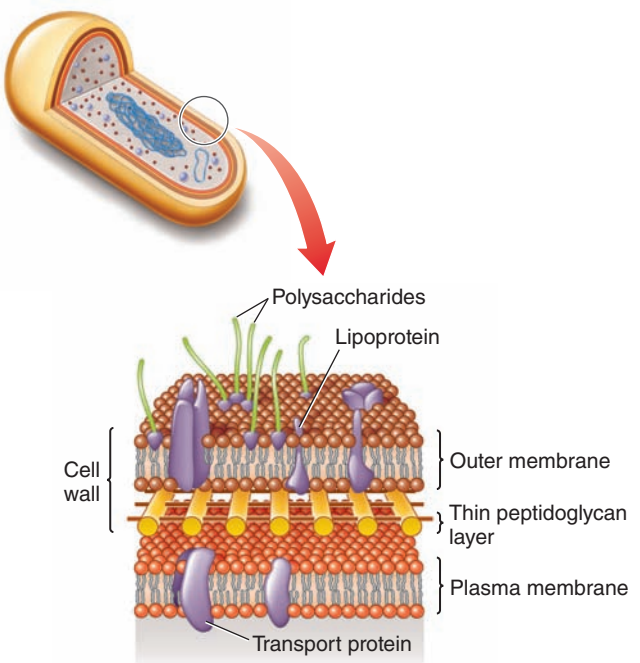
PREDICT Why might the absence of a nucleus be an advantage for prokaryotes?

A cell wall protects most prokaryotes



Most prokaryotic cells have a **cell wall** surrounding the plasma membrane. The cell wall provides a rigid framework that supports the cell and maintains its shape. Bacterial cells have a high concentration of dissolved solutes. The cell wall keeps the cell from bursting under hypotonic conditions (see Chapter 5). Thus, most bacteria are adapted to hypotonic surroundings. When wall-less forms of bacteria are produced experimentally, they must be maintained in isotonic solutions to keep them from bursting. However, cell walls are of little help when a bacterium is in a hypertonic environment, as in food preserved by a high sugar or salt content. For this reason, most bacteria grow poorly in jellies, jams, salted fish, and other foods preserved in these ways.

The bacterial cell wall includes **peptidoglycan**, a complex polymer that consists of two unusual types of sugars (amino sugars) linked with short polypeptides. The sugars and polypeptides are cross-linked to form a crystalline lattice that surrounds the entire plasma membrane. Peptidoglycan is absent in the archaeon cell wall.



Differences in bacterial cell wall composition are of great interest to microbiologists and are important clinically. In 1888, Danish physician Christian Gram developed the Gram staining procedure. Bacteria that absorb and retain crystal violet stain in the laboratory are referred to as **gram-positive bacteria**. Bacteria that do not retain the stain when rinsed with alcohol are **gram-negative bacteria**. The cell walls of gram-positive bacteria are very thick and consist primarily of peptidoglycan. The cell walls of gram-negative bacteria have two layers: a thin peptidoglycan layer and a thick outer membrane. The outer membrane resembles the plasma membrane but contains polysaccharides bonded to lipids (FIG. 25-3).

(a) Gram-positive cell wall. A thick layer of peptidoglycan molecules is held together by amino acids.

(b) Gram-negative cell wall. A thin layer of peptidoglycan is covered by an outer membrane.

Figure 25-3 Bacterial cell walls

If present, the capsule (shown only in the locater cells) is outside the cell wall.

Distinguishing between gram-positive and gram-negative bacteria is important in treating certain diseases. For example, the antibiotic penicillin interferes with peptidoglycan synthesis, ultimately resulting in a fragile cell wall that cannot protect the cell (see Chapter 7 discussion of drugs that are enzyme inhibitors). Predictably, penicillin works most effectively against gram-positive bacteria.

Some bacteria produce capsules or slime layers

Many prokaryote species produce a **capsule** or **slime layer** that surrounds the cell wall. A slime layer is more loosely attached to the cell wall than a capsule. These outer layers are made of polysaccharide or protein.

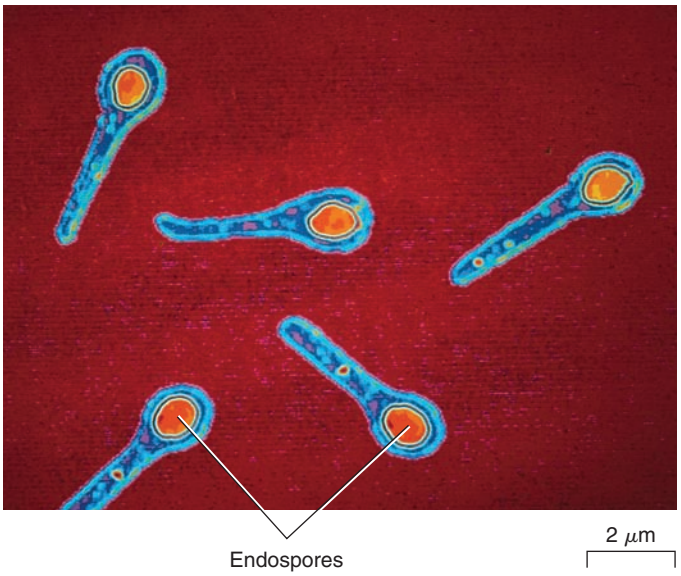
In free-living species, the outer covering may provide the cell with added protection against phagocytosis (engulfment; see Chapter 5) by other microorganisms. In disease-causing bacteria, a capsule or slime layer may protect against phagocytosis by the host's white blood cells. The ability of *Streptococcus pneumoniae* to cause bacterial pneumonia depends on its capsule. A strain of *S. pneumoniae* that lacks a capsule does not cause the disease. Bacteria also use their capsules to attach to surfaces such as rocks, plant roots, and human teeth (where they cause dental plaque).

Some prokaryotes have fimbriae or pili

Some prokaryotes have hundreds of hair-like appendages called **fimbriae** (sing., *fimbria*). Fimbriae, which are made of protein, are shorter than flagella. **Pili** (sing., *pilus*) are usually longer than fimbriae. There are typically fewer pili on the cell surface than fimbriae. Prokaryotes use fimbriae and pili to attach to cell surfaces and, in the case of pathogenic bacteria, to the surfaces of cells they infect. These protein structures also help bacteria adhere to one another. Some elongated pili, called *sex pili*, are important in transmitting DNA between bacteria.

Some bacteria survive unfavorable conditions by forming endospores

When the environment becomes unfavorable—for example, when nutrients are limited or the environment becomes very dry or hot—some types of bacteria produce extremely durable, dormant cells called **endospores**. To form an endospore, the bacterial cell divides by binary fission, forming a large cell that surrounds a smaller cell containing the genome. After an endospore forms, the cell wall of the original cell disintegrates, releasing the endospore.



Endospores survive in very dry, hot, or frozen environments or at times when food is scarce. Some endospores are so resistant that they can survive an hour or more of boiling or centuries of freezing. When environmental conditions are again suitable for growth, the endospore germinates, forming an active, growing bacterial cell.

Several types of bacteria that form endospores cause disease (FIG. 25-4). The endospore of *Bacillus anthracis*, the bacterium that causes anthrax, is so hardy that this pathogen has become a concern as an agent of biological warfare. The bacteria (*Clostridium tetani*) that cause tetanus and the bacteria (*C. perfringens*) that cause gas gangrene typically enter the body with soil when a person suffers a deep cut or puncture wound. Patients may also be exposed to these serious diseases when surgical instruments are not effectively sterilized, allowing endospores to survive.

Formation of endospores is not a type of reproduction in bacteria; endospores are not comparable to the reproductive spores of fungi and plants. Only one endospore is formed per original

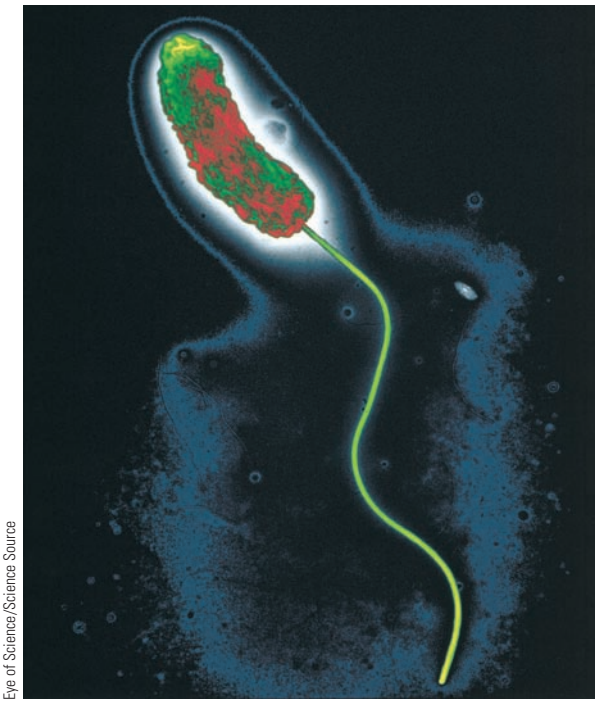
cell, so the total number of individuals does not increase. Archaea do not form endospores; they produce unique enzymes on the cell surface that protect them from cold, heat, and desiccation.

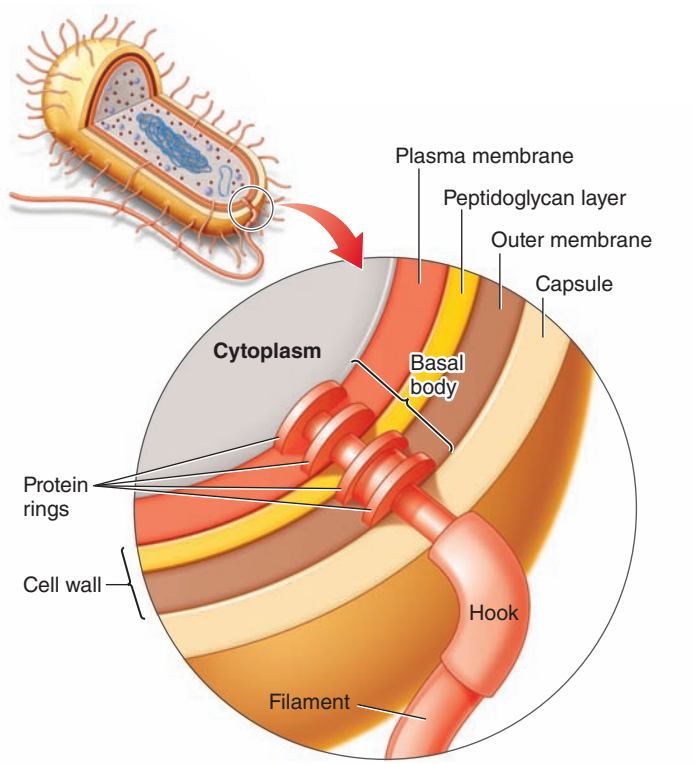
Many types of prokaryotes are motile



Can you imagine trying to swim through molasses? Water has the same relative viscosity to prokaryotes that molasses has to humans. Most motile prokaryotes manage to move by means of rotating **flagella**. The number and location of flagella are important in classifying some bacterial species.

Unlike eukaryotic flagella, prokaryotic flagella do not consist of microtubules (see Chapter 4). A bacterial flagellum is a long, thin appendage consisting of three parts: a basal body, a hook, and a single filament (FIG. 25-5). The basal body is a complex structure that anchors the flagellum into the cell wall by disc-shaped plates. The curved hook connects the basal body to the long, hollow filament that extends into the outside environment.

The basal body is a motor, somewhat like the propeller of a boat motor. The bacterium uses energy from ATP to pump protons out of the cell. Diffusion of these protons back into the cell powers the motor that spins the flagellum. The rotary motion generated pushes the cell much like a propeller pushes a boat through the water. The flagellum rotates counterclockwise, pushing the cell forward.



Archaea have a rotating appendage for motility called an *archaellum* (formerly referred to as an archaeal flagellum). The archaellum is thinner than a bacterial flagellum. In fact, it is more similar to a type of bacterial pili than to bacterial flagella. Biologists have determined that the structure of the motor and the assembly of the flagellum in archaea evolved differently from those of bacteria.

Prokaryotic flagella and archaella perform other functions in addition to swimming. Some prokaryotes use their

flagella or archaella to swarm, to adhere to surfaces, and to participate in *biofilm* formation (a biofilm is a community of microorganisms attached to a surface). Researchers have documented that bacteria use flagella to sense wetness. A recent study reported that some archaea can interact with one another by their archaella, resulting in the formation of a biofilm composed of more than one species. Prokaryotes that lack flagella or archaella may move by gliding or twitching.

Cannulae and *hami* are extracellular structures that are unique to archaea. Cannulae are hollow glycoprotein tubes that extend from cells forming a network. Cannulae are extremely resistant to heat. They are produced by *Pyrodictium*, a genus of archaea that live in marine hydrothermal habitats. Hami are complex archaeal cell appendages that have been discovered entwined with bacterial filaments in sulfurous springs. Hami are helical, have barbs along the length of the filament, and have a three-part hook at the distal end, which facilitates attachment to surfaces. Cannulae and hami are adaptations to the extreme environments that many archaea inhabit.

Prokaryotes that propel themselves do not move aimlessly. Many prokaryotes exhibit *chemotaxis*, movement in response to chemicals in the environment. For example, prokaryotes move toward food and may also move toward one another using diverse signaling mechanisms. Some bacteria and archaea move away from certain harmful chemicals. In addition, many prokaryotes exhibit *phototaxis*, movement in response to light in the environment.

CHECKPOINT 25.1

- **CONNECT** How do bacteria and archaea differ from each other? Contrast prokaryotic cells with eukaryotic cells.
- **CONNECT** How do gram-positive and gram-negative bacteria differ? Why is this difference important to humans?
- **CONNECT** Contrast a bacterial flagellum with a eukaryotic flagellum.

25.2 Prokaryote Reproduction and Evolution

LEARNING OBJECTIVES

4 Describe asexual reproduction in prokaryotes and summarize three mechanisms (transformation, transduction, and conjugation) that may lead to genetic recombination.

5 State specific factors that contribute to the rapid evolution of bacteria and archaea.

The genetic material of a prokaryote is located in the nuclear area but is not surrounded by a nuclear envelope. In most species the genetic material consists of a single, circular DNA molecule. If stretched out to its full length, this molecule would be about 1000 times as long as the cell itself. Unlike the DNA in eukaryotic chromosomes, prokaryote DNA has little protein associated with it.

In addition to their genomic DNA, most bacteria and archaea have one or more **plasmids**, smaller circular fragments of DNA. Bacterial plasmids often have genes that code for catabolic enzymes, for genetic exchange, or for resistance to antibiotics. Bacterial plasmids replicate independently of the genomic DNA or become integrated into it (see Chapter 15). Replication mechanisms for archaeal plasmids have not yet been discovered.

Rapid reproduction contributes to prokaryote success

Prokaryotes are extremely successful organisms in terms of their numbers and distribution. Their success is in large part due to their remarkable ability to reproduce rapidly. Prokaryotes reproduce asexually, generally by **binary fission**, a process in which one cell divides into two similar cells (see Fig. 10-12). First the circular DNA replicates, and then an ingrowth of both the plasma membrane and the cell wall forms a transverse wall.

Binary fission occurs with remarkable speed. Under ideal conditions, some bacterial species divide in less than 20 minutes. At this rate, if nothing interfered, one bacterium could give rise to more than one billion bacteria within 10 hours! Prokaryotes cannot reproduce at this rate for very long, however, before lack of food or the accumulation of waste products slows their population expansion.

Bacteria and archaea also commonly reproduce by **budding**. In budding a cell develops a bulge, or bud, that enlarges, matures, and eventually separates from the mother cell. Some prokaryotes divide by **fragmentation**. In this process, walls develop within the cell, which then separates into several new cells.

Prokaryotes transfer genetic information

Although sexual reproduction involving the fusion of gametes does not occur in prokaryotes, genetic material can be exchanged among bacteria and among archaea and also between domains. Such exchange of genes, called *gene transfer*, results in genetic recombination. Transfer of genetic material from parent to offspring is called **vertical gene transfer**. **Horizontal gene transfer** occurs when an organism (or virus) transfers genetic material to another organism that is not its offspring. Gene transfer among prokaryotes takes place by three different mechanisms: transformation, transduction, and conjugation.

1. When prokaryotes die, they release DNA that can be taken in by certain other prokaryotes. In **transformation** a prokaryotic cell takes up fragments of foreign DNA (or RNA) released by another prokaryotic cell. The foreign DNA must bind to DNA-binding proteins on the surface of the host cell. Once it enters the host cell, segments of the foreign DNA may be exchanged with homologous segments of the host DNA (reciprocal recombination) (FIG. 25-6). Recall from Chapter 12 that Oswald T. Avery and his colleagues identified DNA as the agent that transformed bacterial cells and showed that DNA is the chemical basis of heredity.

   Foreign DNA can also be taken up as plasmids. When that occurs, DNA does not undergo recombination; instead, it remains as a plasmid separate from the prokaryotic chromosome.

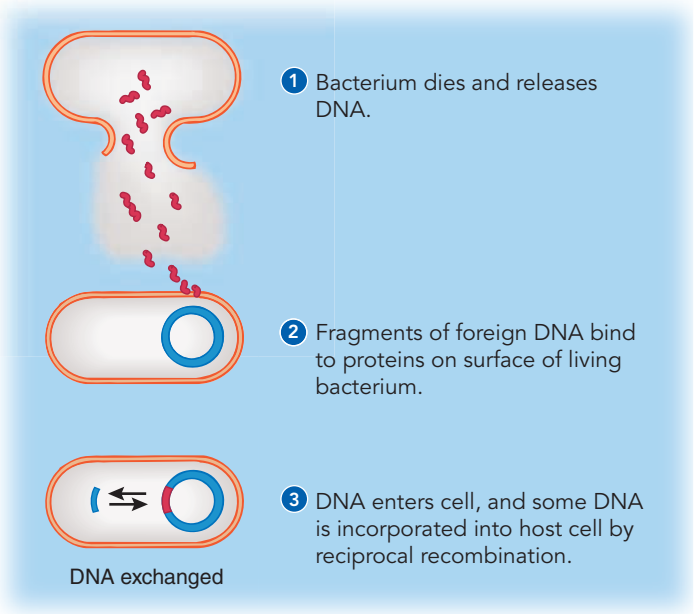

Figure 25-6 Transformation

In transformation a prokaryote takes in foreign DNA from its environment. The host cell exchanges some of its own DNA with homologous segments of the foreign DNA, resulting in a recombinant cell.

2. In a different process of horizontal gene transfer, **transduction**, a phage carries bacterial or archaeal genes from one bacterial or archaeal cell into another (FIG. 25-7). Normally, a phage contains only its own DNA. However, sometimes a phage incorporates some of the DNA of its host. Then, when the phage infects another bacterium or archaeon, it transfers that DNA to its new host. The chromosome of this new host then becomes a recombination of its own original DNA and DNA from another bacterium or archaeon.
3. In **conjugation**, two cells of different mating types come together, and genetic material is transferred from one to the other (FIG. 25-8). In contrast to transformation and transduction, conjugation involves contact between two cells.

Conjugation has been most extensively studied in the bacterium *Escherichia coli*. In the *E. coli* population, there are *donor cells*, or F^+ *cells*, which have DNA that can be transmitted to *recipient cells*, or F^- *cells*. F^+ cells have a DNA sequence known as the *F factor* (*F* stands for fertility) that is necessary for a bacterium to serve as a donor during conjugation. The F factor can be in the form of a plasmid, or it can be part of the DNA in the bacterial chromosome.

F genes encode enzymes essential for transferring DNA. Certain F genes encode **sex pili**, long, hair-like extensions that project from the cell surface. The sex pilus of an F^+ cell recognizes and binds to the surface of an F^- cell, forming a cytoplasmic conjugation bridge between the two cells. The F plasmid replicates itself, and DNA is transferred from donor to recipient bacterium through the conjugation bridge. F plasmids may also have other types of genes, including those that determine resistance to antibiotics.

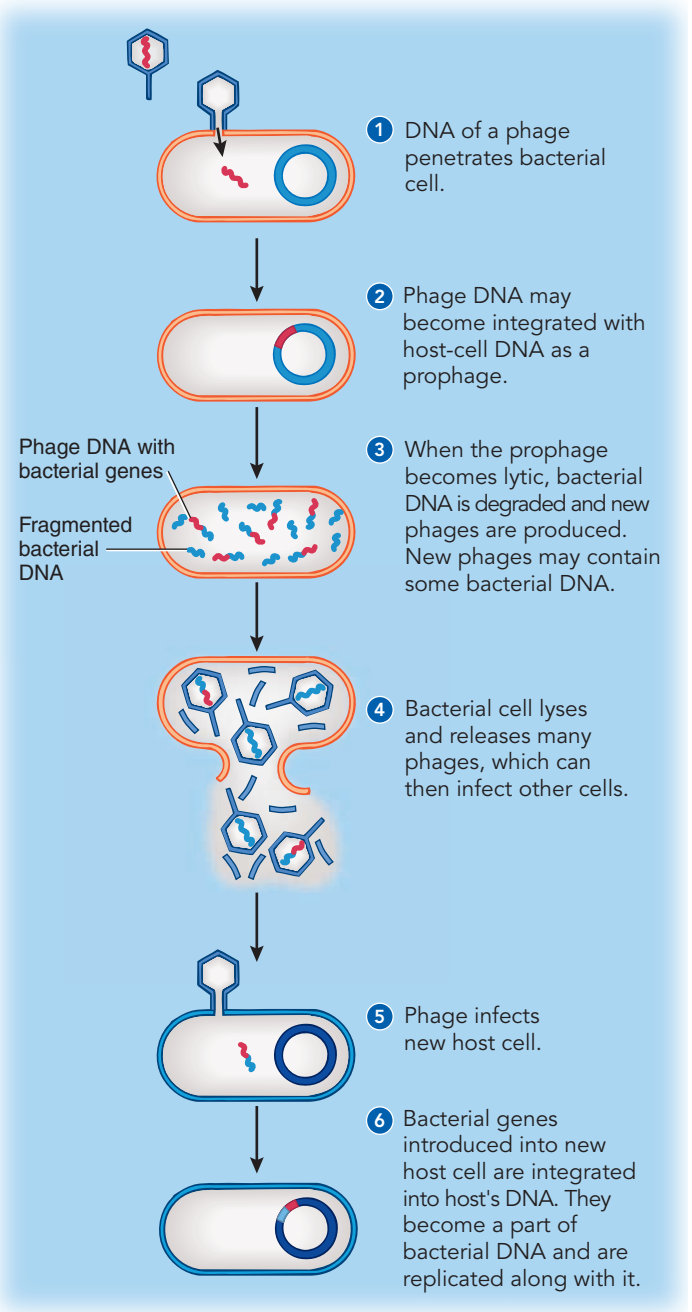

Figure 25-7 Transduction

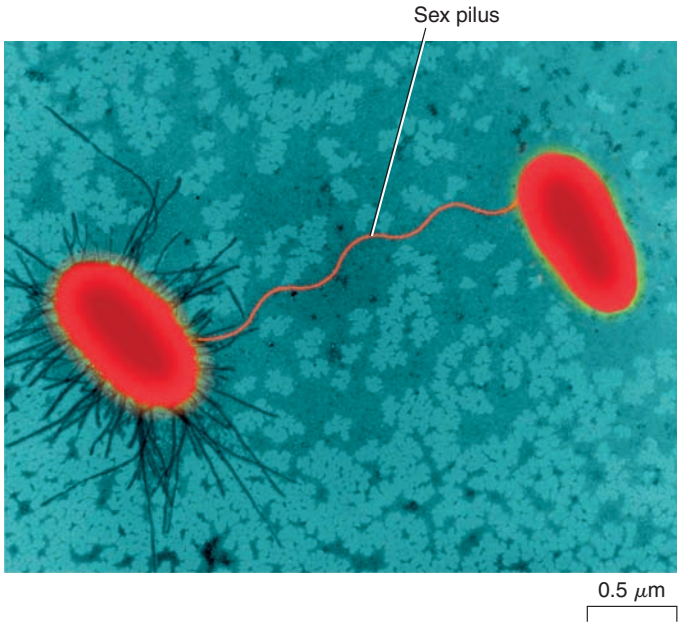
In transduction a phage transfers bacterial DNA from one bacterium to another, resulting in genetic recombination. Transduction is an important means of horizontal gene transfer.

Evolution proceeds rapidly in prokaryote populations

Because prokaryotes reproduce rapidly by binary fission, mutations are quickly passed on to new generations. Mutations that confer some advantage spread through the population, and the effects of natural selection are quickly evident.



Horizontal gene transfer greatly contributes to the rapid evolution that takes place in prokaryotes. Acquisition of new DNA and genetic recombination are important sources of the

Key Point

During conjugation, horizontal gene transfer takes place, resulting in genetic recombination.

DENNIS KUNKEL MICROSCOPY/SCIENCE PHOTO LIBRARY/Science Source

(a) Color-enhanced SEM of *E. coli* bacteria conjugating. The bacteria are connected by a sex pilus. When stimulated by the contact, the cells pull close together and form a conjugation bridge between donor and recipient cells (*shown in* **b**).

(b) The process of conjugation.

Figure 25-8 Conjugation

In conjugation, a donor bacterium transfers plasmid DNA to a recipient bacterium. Conjugation requires cell-to-cell contact.

CONNECT Why might it be advantageous for a bacterial cell to receive the F plasmid from another cell?

genetic variation required for diversification and adaptation. New DNA introduced into a prokaryote's genome represents raw material for evolution. New genes are subject to mutation and are acted on by the forces of natural selection. The changes in the genetic material are passed to succeeding generations by binary fission. Changes that result in adaptation can quickly spread through future bacterial and archaeal populations.

CHECKPOINT 25.2

- How do prokaryotes reproduce? What mechanisms result in gene transfer?
- **CONNECT** How does transduction contribute to the rapid evolution of bacterial populations?
- **VISUALIZE** Draw the steps that take place during conjugation.

25.3 Nutritional and Metabolic Adaptations

LEARNING OBJECTIVE

6 Describe the principal modes by which prokaryotes carry on nutrition and energy capture, and compare their requirements for oxygen.

Some prokaryotes are *autotrophs* (*-troph* comes from a Greek word that means "nutrition"), and others are *heterotrophs*. **Autotrophs** are able to use inorganic compounds, such as carbon dioxide, as a source of carbon for manufacturing their organic molecules. Most prokaryotes are **heterotrophs** that obtain carbon atoms from the organic compounds of other organisms.

Based on *two principal ways of capturing energy*, an autotroph is classified as a chemotroph or a phototroph. **Chemotrophs** obtain their energy from chemical compounds. **Phototrophs** capture energy from light. As early as 3.5 billion years ago,

the ability to use the sun as an energy source evolved in early prokaryotes. These early phototrophs used hydrogen sulfide to reduce carbon dioxide. They released sulfur as a waste product. About 2.7 billion years ago, the ability to use water rather than hydrogen sulfide to reduce carbon dioxide evolved in early cyanobacteria, and oxygen was released as a waste product. When we consider the source of carbon *and* the source of energy, we can classify prokaryotes into four main groups (TABLE 25-1):

1. **Photoautotrophs**, such as cyanobacteria, use the energy from sunlight to synthesize organic compounds from carbon dioxide and other inorganic compounds.
2. The majority of archaea and some bacteria are **chemoautotrophs**, which use carbon dioxide as a carbon source, but do not use sunlight as their energy source. Instead, they obtain energy by oxidizing inorganic chemical substances such as ammonia (NH_3) or hydrogen sulfide (H_2S).
3. **Photoheterotrophs**, such as the purple nonsulfur bacteria, obtain their carbon from other organisms but use chlorophyll and other photosynthetic pigments to trap energy from sunlight.
4. The majority of bacteria are **chemoheterotrophs**. They depend on organic molecules for both their carbon and energy. Many prokaryote chemoheterotrophs are free-living **decomposers** that obtain their carbon and energy from dead organic matter. These organisms are sometimes called *saprotrophs*. Some bacterial chemoheterotrophs are pathogens, which obtain their nourishment from the organisms they infect. They harm their hosts by causing diseases. Other heterotrophic bacteria benefit their hosts. For example, some of the bacteria that inhabit the human large intestine produce vitamin K and certain B vitamins that benefit their hosts.

Most prokaryotes require oxygen

Whether they are heterotrophs or autotrophs, most bacterial cells and many archaeal cells are **aerobic** and require oxygen for cellular respiration. Many are **facultative anaerobes** that use oxygen for cellular respiration if it is available but can carry on metabolism anaerobically when necessary. Other prokaryotes are **obligate anaerobes** that carry on anaerobic respiration; they respire with terminal electron acceptors other than oxygen, such as sulfate (SO_4^{2-}), nitrate (NO_3^-), or iron (Fe^{2+}). Some obligate anaerobes, including certain archaea, are actually killed by even low concentrations of oxygen.

Some prokaryotes fix and metabolize nitrogen

All organisms require nitrogen to manufacture amino acids and nucleic acids. Some bacteria (e.g., certain cyanobacteria) and archaea (e.g., methanogens) can reduce nitrogen in the atmosphere to ammonia. This process is called **nitrogen fixation**. Ammonia produced by nitrogen fixation is converted to ammonium ions (NH_4^+). Nitrogen-fixing prokaryotes can use these simple forms of nitrogen to produce organic compounds.

Certain prokaryotes convert ammonia or ammonium ions to nitrite (NO_2^-), and others convert nitrite to nitrate (NO_3^-). This process, called **nitrification**, converts nitrogen to a form that can be used by plants and fungi. Animals obtain nitrogen from organic compounds when they eat other organisms. As we will discuss in a later section, all other organisms ultimately depend on nitrogen fixation and nitrification by prokaryotes for their survival (discussed further in Chapter 55).

CHECKPOINT 25.3

- How do chemoheterotrophs obtain energy?
- CONNECT How do facultative anaerobes differ from obligate anaerobes? How do they differ from aerobes?
- How do prokaryotes obtain nitrogen needed to produce amino acids and nucleic acids?

25.4 The Phylogeny of the Two Prokaryote Domains

LEARNING OBJECTIVES

7 Compare characteristics of the three domains: Archaea, Bacteria, and Eukarya.
8 Distinguish between the main groups of archaea and identify specific types of archaea belonging to each group.
9 Describe the main groups of bacteria discussed in this chapter.

Under a microscope, most prokaryotes appear rather similar in size and form. However, using sequence analysis of small subunit 16S ribosomal RNA (SSU rRNA), Carl Woese and his coworkers demonstrated that there are two fundamentally different

Table 25-1 Modes of Nutrition and Energy Capture

Mode of Nutrition	Energy Source	Carbon Source	Examples of Organisms
AUTOTROPH			
Photoautotroph	Sunlight	CO_2	Cyanobacteria; purple sulfur bacteria
Chemoautotroph	Inorganic chemicals (e.g., NH_3, H_2S, Fe^{2+})	CO_2	Certain proteobacteria; most archaea (e.g., methanogens, extreme halophiles)
HETEROTROPH			
Photoheterotroph	Sunlight	Organic compounds	Purple and green nonsulfur bacteria
Chemoheterotroph	Organic compounds	Organic compounds	Free-living decomposers; most bacterial pathogens

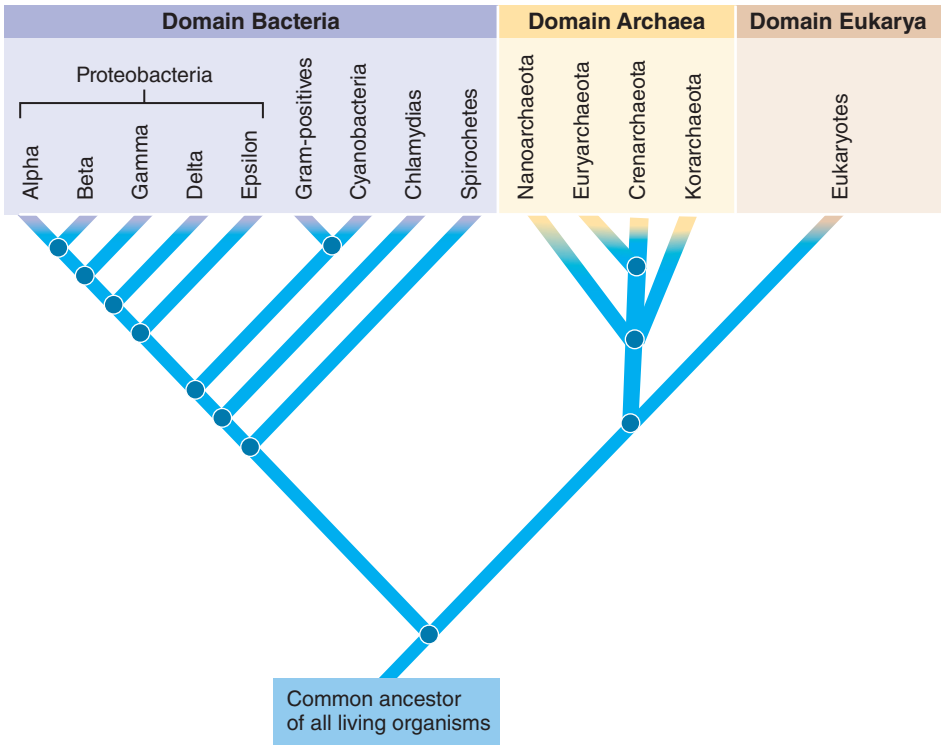
groups of prokaryotes (see Chapter 23). Each group has regions of SSU rRNA that have unique nucleotide sequences. These differences are present because after they diverged, prokaryote populations diversified, and mutations occurred that affect RNA sequences. Using such analyses, Woese hypothesized that ancient prokaryotes split into two lineages early in the history of life.

Based on Woese's work and on other recent data, systematists now classify the modern descendants of these two ancient lines in two domains: **Archaea** and **Bacteria** (FIG. 25-9). These groups are thought to have diverged from a common ancestor about 4 billion years ago. Archaea and bacteria were the only living organisms on our planet for about 2 billion years. Thus, archaea and bacteria have had a very long time to evolve and adapt to all types of environments. Their diversity is staggering. Horizontal gene transfer has contributed to the diversity of these organisms. As a result of gene transfer, sometimes from distantly related species, the genomes of archaea and bacteria are actually a mix of genes from many prokaryotes.



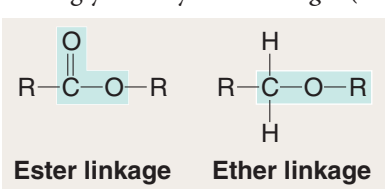


Figure 25-9 Three domains

This highly simplified diagram depicts some representative taxa of domain Bacteria and domain Archaea. The relationships illustrated are based on molecular data. As taxonomists consider additional data, these relationships will likely be modified.

Key characters distinguish the three domains

Several key characters distinguish archaea from bacteria. In contrast to bacteria, archaea do not have peptidoglycan in their cell walls. Although their plasma membranes are structurally similar, they are chemically unique. In the plasma membranes of bacteria and eukaryotes, straight-chain fatty acids are linked to glycerol molecules by *ester linkages*. In contrast, fatty acid components are not found in archaea. Instead, branched-chain hydrocarbons (synthesized from isoprene units) are bonded to glycerol by *ether linkages* (TABLE 25-2).

The absence of a second electronegative oxygen atom makes ether linkages stronger than ester linkages. This unique membrane structure may contribute to the ability of archaea to survive and thrive in harsh environments.

In some ways, archaea are more like eukaryotes than like bacteria. For example, archaea do not have the simple RNA polymerase found in bacteria. Like eukaryotes, their translation process begins with methionine, whereas in bacteria, translation begins with formylmethionine (see Chapter 13). In addition, several antibiotics that affect bacteria do not affect archaea or eukaryotes.

Bacteria also share some characteristics (that are absent in archaea) with eukaryotes. For example, as stated above, bacteria and eukarya both have ester-linked membrane lipids, whereas archaea have ether-linked membrane lipids. Some microbiologists hypothesize that eukaryotes are a product of fusion between an archaeon, which contributed components for transcription and translation, and a bacterial symbiont, which contributed enzymes necessary for energy metabolism.

Using molecular data analyses, researchers further hypothesize that eukaryotes arose from an archaeal ancestor. That ancestor may have been a member of a recently discovered clade of archaea, **Lokiarchaeota**. Because members of this clade have several eukaryotic characteristics, some systematists propose that the eukaryotes branched from the Lokiarchaeotes. If accurate, this hypothesis would make the eukaryotes part of domain Archaea, eliminating the domain Eukarya!

Taxonomy of archaea and bacteria continuously changes

Prokaryote taxonomy is based largely on molecular data, mainly RNA sequencing and more recently on sequencing entire genomes. Groups that branched off earlier had more time to accumulate mutations in their SSU rRNA. Their nucleotide sequences are less similar than those of groups that

Table 25-2 Comparison of the Three Domains

Characteristic	Bacteria	Archaea	Eukarya
Nuclear envelope	Absent	Absent	Present
Membrane-enclosed organelles	Absent	Absent	Present
Circular chromosome	Present (linear in some species)	Present	Absent
Number of chromosomes	Typically one (may also have plasmids)	Typically one (may also have plasmids)	Typically many
Histones associated with DNA	Absent	Present	Present
Peptidoglycan in cell wall	Present	Absent	Absent
Structure of lipids in plasma membrane	Straight-chain fatty acids bonded to glycerol by ester linkages	Branched-chain hydrocarbons linked to glycerol by ether linkages	Straight-chain fatty acids bonded to glycerol by ester linkages
Size of ribosomes	70S[1]	70S	80S except in mitochondria and chloroplasts
RNA polymerase	One relatively simple RNA polymerase	One relatively complex RNA polymerase	Several relatively complex RNA polymerases
Translation	Begins with formylmethionine	Begins with methionine	Begins with methionine
Growth above 70°C	Yes	Yes	No

[1] The numbers 70S and 80S refer to the sedimentation coefficient (a measure of relative size) when centrifuged.

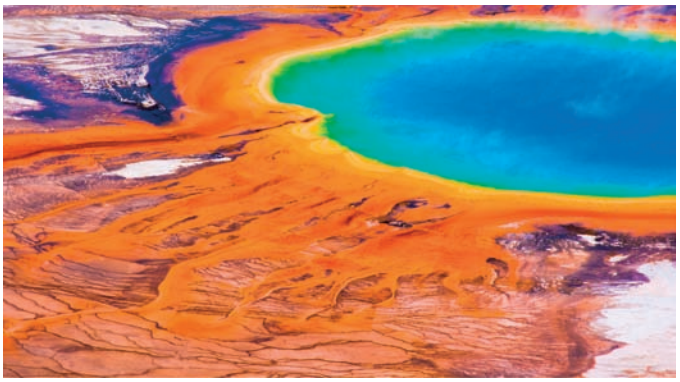
diverged more recently. Microbiologists who are developing phylogenetic trees based on sequencing entire genomes argue that there may be 1000 genes that code proteins for every 1 gene that codes an rRNA. These researchers prefer to consider the proportions of genes (or proteins) that genomes of various groups have in common. Taxonomy of archaea and bacteria continuously changes as systematists study new molecular data that provide new clues to the phylogeny of these groups.

Although prokaryotic taxonomy is controversial and continuously changing, about 14,000 species of prokaryotes have been classified. Hundreds of thousands of additional species are thought to exist. The editors of *Bergey's Manual of Systematic Bacteriology*, considered the definitive reference text by microbiologists, have divided archaea into 4 groups (phyla) and bacteria into more than 30 groups (phyla) based on 16S rRNA analyses. Systematists, however, have proposed additional groups (phyla) of archaea based on the numerous and continuing discoveries of previously unidentified organisms.

Most archaea live in marine and soil habitats, and many thrive in harsh environments

Domain Archaea consists of several widely recognized groups (phyla, clades), including *Crenarchaeota, Euryarchaeota, Nanoarchaeota*, and *Korarchaeota*. This phylogeny is based on 16S rRNA and on sequencing of entire genomes. Based on continued detection of previously unidentified archaea and sequencing of archaeal genomes, systematists estimate that more than a dozen additional groups may be added.

The **Crenarchaeota** include **extreme thermophiles**, archaea that require a very high temperature or very low temperature for growth. The optimum temperature for many is greater than 80°C (176°F) and some thrive at temperatures greater than 100°C. Some crenarcheotes have the highest growth temperatures known of any organisms. Some species inhabit acidic environments. One species is found in the hot sulfur springs of Yellowstone National Park at temperatures near 80°C and pH values of 1 to 2, the pH of concentrated sulfuric acid (FIG. 25-10a). Other crenarchaeotes inhabit volcanic areas under the sea. One species, found near deep-sea hydrothermal vents on the seafloor of the Pacific Ocean, lives at temperatures ranging from 80°C to 120°C. In contrast, some Crenarchaeota species live in very cold environments (1.8°C).



Studies have identified many diverse species of Crenarchaeota in soil and fresh water, demonstrating that members of this clade are common to most environments. Crenarchaeotes are a main contributor to carbon fixation. They are also an important part of the plankton in cold, oxygen-rich seas. A few are photoheterotrophs.

The **Euryarchaeota** also include many archaea that inhabit extreme environments. This group includes methanogens, extreme aerobic and anaerobic thermophiles, acidophiles, and halophiles (some extreme) (FIG. 25-10b). The **methanogens** (methane producers) are a large, diverse group that inhabit oxygen-free environments in sewage, swamps, and the digestive tracts of humans and other animals. They are obligate anaerobes that produce methane gas from simple carbon compounds. The methanogens are important in recycling components of organic products of organisms that inhabit swamps. Methanogens that inhabit the digestive tracts of cows and other grazing animals produce methane, which is belched out by the animals. Methanogens produce more than 80% of the methane (more than 2 billion tons each year) in Earth's atmosphere. Methanogens are also found in marine sediments (FIG. 25-10c). Methane is an important greenhouse gas (discussed in Chapter 57).

Extreme halophiles are heterotrophs that require large amounts of Na^+ for their growth. They live in saturated brine solutions such as salt ponds, the Dead Sea, and Great Salt Lake. The extreme halophiles use aerobic respiration to make ATP. However, they also carry out a form of the Calvin cycle (a part of photosynthesis) in which they capture the energy of sunlight using a purple pigment (*bacteriorhodopsin*). This pigment is very similar to the pigment rhodopsin involved in animal vision.

(a) Extreme thermophiles. Orange, yellow, and green colonies of extreme thermophiles thrive in the Grand Prismatic Spring in Yellowstone National Park in Wyoming. Thermophilic red algae contribute the green color.

Nancy Nehring/Getty Images

(b) Extreme halophiles. These seawater salt-evaporation ponds are colored from the large number of extreme halophiles that inhabit them. The colors come from pigments in the cell membranes. These archaea are harmless, and the ponds are used to produce salt commercially.

Eye of Science / Science Source

(c) SEM of *Pyrococcus furiosus*, an anaerobe that inhabits marine sediments. This methanogen is highly resistant to heat; its optimum temperature is 100°C. *Pyrococcus* is classified as a euryarchaeote.

Figure 25-10 Archaea that inhabit extreme environments

Korarchaeota is a clade of Archaea that appears to have branched before the Crenarchaeota and Euryarchaeota branches separated. Korarchaeota have some characteristics of Crenarchaeota and some features of Euryarchaeota. Korarchaeotes have been found in terrestrial hot springs.

The first member of the **Nanoarchaeota**, *Nanoarchaeum equitans*, was discovered in a hydrothermal vent in 2002. This marine microbe is a very small (400 nm) anaerobic, extreme thermophile with a very small genome (less than 500,000 nucleotides). It lives attached to another archaeon, an autotroph, and depends on its host for many of its metabolic needs. A few other nanoarchaeotes have been identified in hot springs throughout Yellowstone National Park.

Two supergroups have recently been proposed. Supergroup "TACK" includes four groups (Thaumarchaeota, Aigarchaeota, Crenarchaeota, and Korarchaeota). The "Asgard" clade includes the Lokiarchaeota, discussed previously, along with three other newly discovered archaea groups (Thorarchaeota, Odinarchaeota, and Heimdallarchaeota). Asgard archaea appear to be closely related to TACK archaea.

As more archaea have been discovered and studied, it has become evident that there are more archaea in marine and soil environments than in extreme habitats. The archaea are important in biogeochemical cycles and in marine food chains. Although archaea continue to be discovered on and in humans, no pathogenic archaea have been identified.

Bacteria are the most familiar prokaryotes

Bacteria have been known and studied much longer than the archaea. Bacteria are also widely distributed in the environment. Five major groups are considered here: proteobacteria (gram-negative), cyanobacteria (gram-negative), gram-positive bacteria, chlamydias (gram-negative), and spirochetes (gram-negative). These groups are summarized in TABLE 25-3.

CHECKPOINT 25.4

- **CONNECT** How does each of the following groups of bacteria (described in Table 25-3) affect the biosphere: alpha proteobacteria, cyanobacteria, and chlamydias?

25.5 Impact on Ecology, Technology, and Commerce

LEARNING OBJECTIVES

10 Identify the critical ecological roles played by prokaryotes and briefly describe their relationships with other organisms.

11 Describe some of the important roles played by prokaryotes in commerce and technology.

Prokaryotes inhabit virtually every environment on Earth and are vital members of the biosphere. They affect other organisms directly and by the ecological roles they play. Prokaryotes produce nitrogen in forms usable by other organisms, and they are a reservoir for nutrients. These microscopic organisms recycle nutrients and are key players in biogeochemical cycles.

Prokaryotes form intimate relationships with other organisms

Some prokaryote species have coevolved with eukaryotes and are interdependent with them. All plants and animals harbor a community of microorganisms referred to as **microbiota**. (This term has replaced *microflora*, which is a misnomer because "flora" refers to plants.) An estimated 37 to more than 100 trillion symbiotic bacteria, archaea, and (a few) eukaryotic microorganisms normally inhabit the human body! This number is equal to or up to triple the number of the body's own cells (more than 37 trillion).

Normal microbial populations have been shown to have multiple effects, including preventing harmful microorganisms from flourishing. The term **microbiome** refers to the community of these microorganisms, including their genomes and all of their interactions. Rapid DNA sequencing has greatly facilitated microbiome research because there are thousands of species of these organisms and many are difficult to grow in culture. Through the *Human Microbiome Project* supported by the National Institutes of Health, investigators have mapped the human **microbiome**, creating a database of more than 10,000 microorganisms. Through continued research, we are developing an ever-increasing understanding of the critical control and effects these symbionts have on human health and disease.

Prokaryotes interact with other organisms in both beneficial and harmful ways. An intimate relationship between members of two or more species is called **symbiosis**. The partners in a symbiotic relationship are called **symbionts**. Symbiotic relationships arise by coevolution. Three forms of symbiosis are mutualism, commensalism, and parasitism.

Mutualism is a symbiotic relationship in which both partners benefit. Cows and other ruminants (cud-chewing animals) have mutualistic relationships with bacteria and archaea that inhabit their digestive tracts. Ruminants lack enzymes for digesting cellulose. They provide the prokaryotes with a nutrient-rich home, and the prokaryotes digest the cellulose for them.

Trillions of bacteria and some archaea inhabit the nutrient-rich human intestine. Some of them are mutualistic bacteria. For example, in exchange for nutrients and a place to live, *Bacteroides* break down indigestible complex carbohydrates into sugars that their human host can absorb. These bacteria also produce certain vitamins that their host absorbs and uses. In addition, *Bacteroides* promote proliferation of blood vessels that improve intestinal function. Investigators have reported that these bacteria can turn on specific genes in cells of the host's intestine, inducing synthesis of a compound that kills competing bacteria.

In **commensalism**, one partner benefits, and the other is neither harmed nor helped. Many prokaryotes that inhabit the human intestine are commensals that live on unused food. In **parasitism**, one partner lives on or in the other. The **parasite** benefits, and the **host** is harmed. Disease-causing bacteria are usually not considered obligate parasites because these *pathogens* typically can survive in other ways.

Some types of bacteria may influence evolution of other species The proteobacteria *Wolbachia* infect many invertebrates, including insects, spiders, crustaceans, and nematodes (roundworms). *Wolbachia* are transmitted from generation to generation in the eggs of their hosts, so male hosts are not useful to them. Consequently, these parasites limit or eradicate males from the population. In some insect species, infected males can reproduce only when they mate with infected females carrying the same *Wolbachia* strain. In some other species, these parasites convert male insects into females. In some wasp species, *Wolbachia* induces **parthenogenesis**, the development of unfertilized eggs into adult organisms. Because they affect reproduction in their hosts, *Wolbachia* and other reproductive parasites may influence evolutionary divergence and even extinction in some species. *Wolbachia* may also affect evolution by horizontal gene transfer.

Many prokaryotes form biofilms Many types of bacteria and archaea that inhabit watery environments form **biofilms**, dense communities of microorganisms that attach to solid surfaces. The prokaryotes secrete a slimy, gluelike substance rich in polysaccharides and become embedded in this matrix. A biofilm may consist of layers up to 200 μm thick. Biofilms are communities of many microorganisms and may consist of many species of bacteria, archaea, fungi, and protists. Scientists have found evidence of ancient biofilms in sediments from coastal marine environments 3.5 billion years old.

The dental plaque that forms on teeth is a familiar example of a biofilm (FIG. 25-11 on page 532). Dental plaque consists of several hundred different types of bacteria and archaea. Biofilms also commonly form on the surfaces of contact lenses and catheters. They sometimes develop on surgical implants such as pacemakers and joint replacements. Biofilms, which form on and inside plants, cause considerable crop loss.

Prokaryotes play key ecological roles

Bacteria, especially actinomycetes and myxobacteria, are the most numerous inhabitants of soil. As described earlier in this chapter, many prokaryotes are essential decomposers, chemoheterotrophs that break down dead organic matter and wastes. They use the products of decomposition as an energy source. When prokaryotes break down organic compounds, many of their components, including nitrogen, oxygen, carbon, phosphorus, sulfur, and certain trace elements, are recycled. (The roles of bacteria and archaea in biogeochemical cycles, particularly the nitrogen cycle, are discussed in Chapter 55.)

Nitrogen is constantly removed from the soil by plants and other natural processes as well as by human activities such as agriculture. Plant growth depends on the availability of usable nitrogen, so it must be continually added to the soil. Several types of bacteria, including cyanobacteria, and some archaea transform atmospheric nitrogen to forms that can be used by plants (see Table 25-3). Marine archaea that carry out nitrification are important in the ocean nitrogen cycle.

Rhizobial prokaryotes, motile inhabitants of the soil, form mutualistic relationships with the roots of legumes, a large family of plants that includes important crops such as beans, peas, and peanuts. The infected plant cells form tumorlike nodules in which the microbes reside and fix nitrogen (see Fig. 55-9). The prokaryotes supply the plant with the nitrogen it requires, and

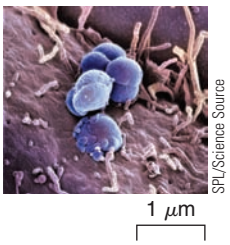
Table 25-3 Major Groups of Bacteria

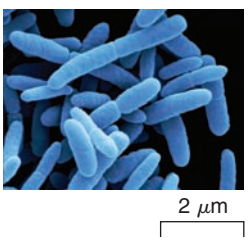
Proteobacteria (Gram-Negative)



A large, very diverse clade of gram-negative bacteria. Based on rRNA sequences, the group is divided into five subgroups designated as alpha, beta, gamma, delta, and epsilon.

***Rhizobia* (*Rhizobium leguminosarum*) in root nodule**
Rhizobia are nitrogen-fixing bacteria.

ALPHA PROTEOBACTERIA



Includes many symbionts of plants and animals, and some pathogens. *Rhizobium* species live symbiotically in root nodules of legumes (e.g., beans) and convert atmospheric nitrogen to a form usable by plants (nitrogen fixation). **Rickettsias** are very small, rod-shaped bacteria. A few species are pathogenic to humans and other animals; transmitted by arthropods through bites or through contact with their excretions. Rickettsias cause typhus (transmitted by fleas and lice) and Rocky Mountain spotted fever (transmitted by ticks). Members of the SAR11 clade are extremely abundant in the ocean.

SEM of bacteria (*Neisseria gonorrhoeae*) that cause gonorrhea
In this colorized SEM, these beta proteobacteria (*blue*) are infecting a human epithelial cell (*purple*).

BETA PROTEOBACTERIA

Several diverse groups, including *Nitrosomonas*, which oxidizes ammonia. Pathogenic bacteria in this group include *Neisseria gonorrhoeae*, which causes gonorrhea.

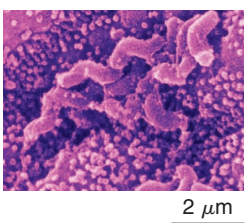
SEM of *Escherichia coli* colony
E. coli are gamma proteobacteria.

GAMMA PROTEOBACTERIA

Includes the **enterobacteria**, decomposers that live on decaying plant matter, pathogens, and a variety of bacteria that inhabit humans. Although *Escherichia coli* is a normal inhabitant of the animal intestinal tract, certain strains can cause moderate to severe diarrhea. One species of *Salmonella* infects food and produces a toxin that causes a form of food poisoning; another species causes typhoid fever.

Vibrios are mainly marine; some are bioluminescent. *Vibrio cholerae* causes cholera.

Pseudomonads are heterotrophs that produce nonphotosynthetic pigments; cause disease in plants and animals, including humans.



Purple sulfur bacteria are photoautotrophs that do not produce oxygen.

SEM of fruiting body of the myxobacterium *Stigmatella aurantiaca*
Protective resting cells within the fruiting bodies are very resistant to heat and drying. Myxobacteria are delta proteobacteria.

DELTA PROTEOBACTERIA

Includes the **myxobacteria** (slime bacteria), which secrete slime and glide or creep along. When nutrients are exhausted, these bacteria aggregate into stalked, multicellular reproductive structures called fruiting bodies. Bacterial cells within the fruiting body enter a resting stage. When conditions are favorable, resting cells become active.

SEM of *Helicobacter pylori* attached to the epithelial lining of the stomach

EPSILON PROTEOBACTERIA

A small group of bacteria that inhabit the animal digestive tract. *Helicobacter* can cause peptic ulcers.

Table 25-3 Major Groups of Bacteria (*continued*)

Gram-Positive Bacteria

SEM of *Actinomycetes mashuensis* (color-enhanced)

These soil-dwelling bacteria form filamentous colonies.

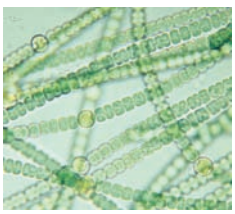
SEM of *Mycoplasma* on fibroblast cells

Actinomycetes superficially resemble fungi. However, they have peptidoglycan in their cell walls, lack nuclear envelopes, and have other prokaryotic characteristics. Most actinomycetes are saprotrophs that decompose organic materials in soil. Some are anaerobic. Some actinomycetes cause serious lung disease and other infections in humans and other animals.

Several species of the genus ***Streptomyces*** produce antibiotics such as streptomycin, erythromycin, chloramphenicol, and the tetracyclines. *A. mashuensis* produces streptomycin, as well as an antifungal antibiotic.

Lactic acid bacteria ferment sugar, producing lactic acid as the main end product. Inhabit decomposing plant material, milk, and other dairy products; responsible for the characteristic taste of yogurt, pickles, sauerkraut, and green olives. Among the normal inhabitants of the human mouth and vagina.

Mycobacteria are slender, irregular rods; contain a waxy substance in their cell walls. One species causes tuberculosis; another causes leprosy.



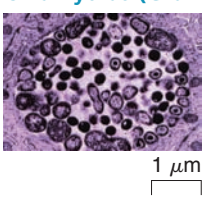
Streptococci inhabit the mouth and digestive tract of humans and some other animals. Among the harmful species are those that cause "strep throat," dental caries, a form of pneumonia, scarlet fever, and rheumatic fever.

Staphylococci normally live in the nose and on skin. Opportunistic pathogens that cause disease when the immunity of the host is lowered. *Staphylococcus aureus* causes boils and skin infections (some extremely serious); may infect wounds. Certain strains of *S. aureus* cause a form of food poisoning; other strains cause toxic shock syndrome (see Fig. 25-14).

Clostridia are anaerobic. One species causes tetanus; another causes gas gangrene. *Clostridium botulinum* can cause botulism, an often fatal type of food poisoning.

The **mycoplasmas** are a group of very small bacteria that lack cell walls. They may have evolved from bacteria with gram-positive cell walls. They inhabit soil and sewage; some are parasitic on plants or animals. Some inhabit human mucous membranes but do not generally cause disease; one species causes a mild type of bacterial pneumonia in humans.

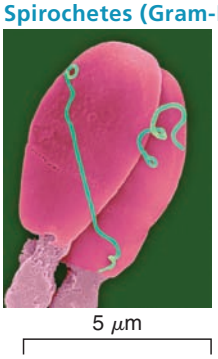
Cyanobacteria (Gram-Negative)



LM of *Anabaena*, a filamentous cyanobacterium that fixes nitrogen

Nitrogen fixation takes place in the rounded cells, called *heterocysts*.

Cyanobacteria contain chlorophyll *a* and are the only prokaryotes that, like plants and algae, carry on photosynthesis that generates oxygen. Cyanobacteria were the first organisms that carried on oxygen-generating photosynthesis; very important in the evolution of life-forms because their photosynthesis changed the early reducing atmosphere on Earth to an oxidizing atmosphere. Chloroplasts are thought to have evolved from endosymbiotic cyanobacteria. Inhabit ponds, lakes, swimming pools, moist soil, dead logs, and tree bark. Some form filaments; other species are solitary. As primary producers, they are an important source of food for marine and freshwater organisms. Some species have special structures that fix nitrogen.

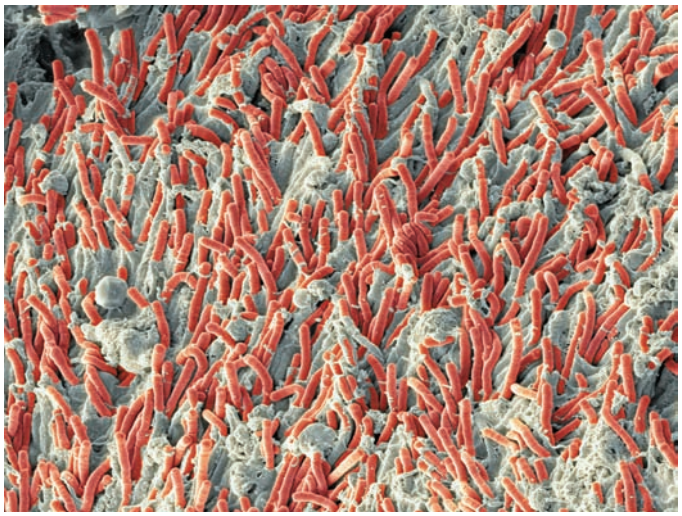


Chlamydias (Gram-Negative)

TEM of *Chlamydia trachomatis* in human oviduct cell

Chlamydias lack peptidoglycan in their cell walls. They are energy parasites, completely dependent on their hosts for ATP. Infect almost every species of bird and mammal. A strain of *Chlamydia* causes trachoma, the leading cause of blindness in the world. Sexually transmitted chlamydias are the major cause of pelvic inflammatory disease in women.

Spirochetes (Gram-Negative)



LM of *Treponema pallidum*, the spirochete that causes syphilis

Spirochetes are spiral-shaped bacteria with flexible cell walls; move by means of unique internal flagella called *axial filaments*. Some species are free-living, whereas others form symbiotic associations; a few are parasitic. *Treponema pallidum* causes syphilis.

Steve Gschmeissner/Science Source

Figure 25-11 A familiar biofilm: dental plaque

Colorized SEM of dental plaque, which consists of a film of bacteria (*red*) embedded in a matrix of glycoprotein (*blue*). Bacteria in the plaque can produce acids that erode tooth enamel, leading to tooth decay.

the plant provides the prokaryotes with organic compounds, including sugar needed for cellular respiration. Because many soils are deficient in nitrogen, legumes that have formed mutualistic associations with rhizobial microbes have a decided advantage over other plants. When the legumes die and are decomposed, the fixed nitrogen is released and enriches the soil.

Cyanobacteria are the only prokaryotes that carry on photosynthesis using water as the electron source and generating oxygen. During this process they fix huge amounts of carbon dioxide into organic molecules.

Microbiologists are only beginning to unravel the mysteries of prokaryote ecology. For example, alpha proteobacteria in the SAR11 clade are among the most successful organisms on Earth. Although they are one of the most abundant organisms in the Atlantic Ocean, they were not successfully cultured until 2002, and very little is known about their ecological role. There is evidence that they are important in cycling carbon, nitrogen, and sulfur in the ocean.

Prokaryotes are important in many commercial processes and in technology

Some microorganisms produce *antibiotics*. These compounds limit competition for nutrients by inhibiting or destroying other microorganisms. By the 1950s, antibiotics had become important clinical tools that transformed the treatment of infectious disease. Today, more than 100 clinically useful antibiotics are available, and literally tons of antibiotics are produced annually. Pharmaceutical companies obtain most antibiotics from three groups of microorganisms: a large group of gram-positive soil bacteria, the *actinomycetes*; gram-positive bacteria of the genus *Bacillus*; and molds (eukaryotes belonging to kingdom Fungi). Researchers have discovered that some archaea also produce antimicrobial substances, called **archaeocins**, which may someday be used in the production of new antibiotics.

Because of their prolific reproduction rates, bacteria are ideal "factories" for the production of biomolecules. Microbiologists have genetically engineered bacteria to produce certain vaccines, human growth hormone, insulin, and many other clinically important compounds (see Chapter 15). Researchers are developing genetically engineered bacteria for production of many other medically and agriculturally useful products.

Microbial fermentation helps produce many foods and beverages. Lactic acid bacteria are used in producing acidophilus milk, yogurt, pickles, olives, and sauerkraut. Several types of bacteria are used in the production of cheese. Bacteria are involved in making fermented meats such as salami and in producing vinegar, soy sauce, chocolate, and certain B vitamins (B_{12} and riboflavin).

Bacteria are used in **bioremediation**, the process of using microorganisms (and sometimes other organisms) to detoxify or remove oil, gasoline, and other pollutants or toxic chemicals from the environment. Microorganisms break down certain toxins, leaving behind harmless metabolic byproducts such as carbon dioxide and chlorides (FIG. 25-12). More than 1000 different species of bacteria and fungi have been used to clean up various forms of pollution, and microbiologists are searching for others. For example, bacteria and other microorganisms are used in oil spills to break down oil, oxidizing it to CO_2. Microorganisms are also used in sewage treatment and to break down solid wastes in landfills.

Archaea are also economically important. Archaea that are adapted to high temperatures or extremely acidic conditions, for example, are a source of enzymes that can be used under these extreme conditions. Archaeal enzymes have been added to laundry and industrial detergents and to organic solvents to increase performance at higher temperatures and pH levels. Methanogens are important in the biogas production industry and in sewage treatment. Another archaeal enzyme has been useful in the food industry to convert cornstarch to dextrins (low molecular weight carbohydrates produced by hydrolysis of starch or glycogen).

Molecular biology and forensic biology have greatly benefited from heat-resistant DNA polymerase, derived from the archaeon *Pyrococcus furiosus* (see Fig. 25-10c). Like heat-resistant Taq polymerase, derived from a bacterium, it is used in the polymerase chain reaction (PCR) discussed in Chapter 15. Acidophilic archaea are promising as resources for extracting metal from ores and remediating toxic mining sites.

CHECKPOINT 25.5

- **CONNECT** In what ways do bacteria form relationships with other organisms?
- Where would you expect to find biofilms? Name organisms you would expect to find in biofilms.
- **CONNECT** Describe how prokaryotes are ecologically important. Give specific examples.
- Describe the process of bioremediation.

As they feed on gasoline and certain other waste products in contaminated soil, certain microorganisms convert hydrocarbons in these pollutants to carbon dioxide and water. Photographed at an oil refinery and chemical plant in the United Kingdom.

25.6 Bacteria and Disease

LEARNING OBJECTIVES

12 Describe the roles played by Louis Pasteur and Robert Koch in understanding infectious disease; list Koch's postulates.

13 Identify adaptations that have contributed to pathogen success.

A small percentage of bacterial species are important pathogens of plants and animals. Some of the normal bacterial inhabitants are opportunistic pathogens that cause disease only under certain conditions. For example, when the immune system is compromised, opportunistic bacteria increase in number and cause disease. Some important bacterial diseases and the pathogens that cause them are briefly described in TABLE 25-4.

Many scientists have contributed to our understanding of infectious disease

The idea that some unknown agent caused disease was debated long before Leeuwenhoek discovered microorganisms with his microscope in the late 1600s. However, not until much later did scientists develop the tools and methods needed to accurately understand the relationships between bacteria and disease. During the late 19th century, several physicians, microbiologists, and chemists working independently laid the foundations for the science of microbiology. French chemist Louis Pasteur disproved the prevailing views of spontaneous generation by demonstrating that sterilization of a sugar and protein culture prevented bacterial growth. Pasteur also developed a rabies vaccine, showing that people can be stimulated to develop immunity to disease.

German physician Robert Koch was the first to clearly demonstrate that bacteria cause infectious disease. In 1876, he showed that *Bacillus anthracis* caused anthrax. Using a microscope, Koch observed the bacteria in the blood and spleens of dead sheep. When he inoculated mice with the infected sheep blood, he was able to identify *B. anthracis* in the blood of the mice. He also cultured *B. anthracis* and showed that when he injected the bacteria into healthy mice they developed anthrax.

Koch proposed a set of guidelines, now known as **Koch's postulates**, that are still used to demonstrate that a specific pathogen causes specific disease symptoms: (1) the pathogen must be present in every individual with the disease, (2) a sample of the microorganism taken from the diseased host can be grown in pure culture, (3) a sample of the pure culture causes the same disease when injected into a healthy host, and (4) the microorganism can be recovered from the experimentally infected host. Sometimes these guidelines cannot be met, as, for example, when certain microorganisms cannot be grown in pure culture. In those situations, other criteria must be used.

Many adaptations contribute to pathogen success

Pathogenic microorganisms can enter the body in food, dust, or droplets, or through wounds. Many diseases are transmitted by insect or animal bites. To cause disease, a pathogen must adhere to a specific cell type, multiply, and produce toxic substances. Adherence and multiplication occur only when the pathogen competes successfully with the normal microbiota and counteracts the host's defenses against invasion.

Helicobacter pylori, the most common cause of peptic ulcers (ulcers of the stomach and duodenum), is an extremely successful pathogen (FIG. 25-13). It is also associated with chronic gastritis (stomach inflammation) and with stomach cancer, the second most common type of cancer in the world. *Helicobacter pylori* inhabits the gastrointestinal tracts of an estimated 40% of adults in developed countries and 80% of adults in developing countries. Among its many adaptations is its ability to produce an alkaline shield around itself that protects it from stomach acid. Also contributing to its success are several powerful flagella used to propel the pathogen through the thick mucus lining the stomach.

Pathogens produce a variety of substances that increase their success. Some bacteria produce **exotoxins**, strong poisons that are either secreted from the cell or leak out when the bacterial cell is destroyed. The toxin, not the presence of

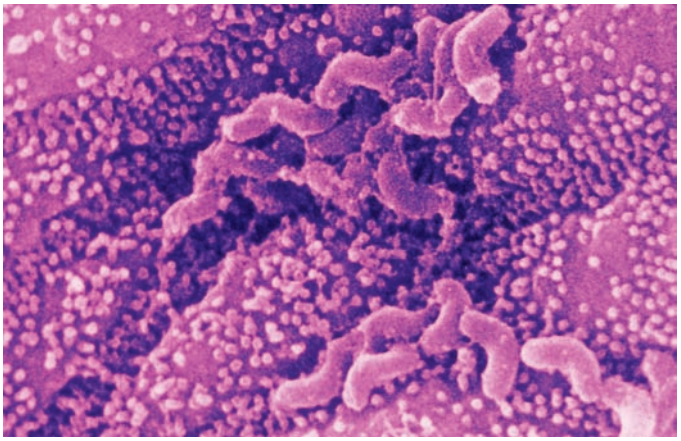
Table 25-4 Important Bacterial Diseases and Their Causative Agents

Disease	Pathogen	Epidemiology/Comments
Anthrax	*Bacillus anthracis*	Most commonly occurs in domestic animals such as cattle. Can be transmitted to humans from infected animals or animal products. Endospores can live in soil for many years. Anthrax is not spread from person to person. Infection can occur in three ways: cutaneous, by inhalation, and gastrointestinal.
Antibiotic-associated diarrhea; and inflammation of colon	*Clostridium difficile* (common name: *C. dif*)	Risk greatest for older people taking antibiotics, people with compromised immune systems, and patients in hospitals and health care facilities for extended periods
Botulism	*Clostridium botulinum*	Contracted by eating foods that contain the exotoxin or from infected wound. Infant botulism is caused by ingesting endospores. Causes muscle paralysis and can cause death from respiratory failure.
Chlamydia	*Chlamydia trachomatis*	One of the most frequently reported sexually transmitted infections in the U.S. About 75% of infected women and 50% of infected men have no symptoms. If untreated, infection spreads and can lead to infertility. Chlamydia can also infect eyes; causes millions of cases of blindness worldwide each year.
Cholera	*Vibrio cholerae*	Contracted by eating food or drinking water contaminated with the bacteria. Common in areas with inadequate sewage treatment and impure water. Infects intestine and can cause severe diarrhea. Rapid fluid loss can lead to dehydration and death.
Diphtheria	*Corynebacterium diphtheriae*	Transmitted from person to person by intimate respiratory and physical contact. Endemic in developing countries. Not common in U.S. since vaccine became available in 1920s. Infects the heart muscle and respiratory passageways.
Epidemic typhus	*Rickettsia prowazekii*	Transmitted by infected body lice. After an 8- to 12-day incubation period, symptoms include fever, severe headache, muscle aches, and chills. Several days later, a rash appears. About 40% of untreated patients die.
Gonorrhea	*Neisseria gonorrhoeae*	Common sexually transmitted disease.
Hansen disease (leprosy)	*Mycobacterium leprae*	Thought to be spread from person to person in nasal secretions. Worldwide, this disease has disabled up to 2 million people.
Lyme disease	*Borrelia burgdorferi*	Transmitted to humans by bite of infected blacklegged ticks. Symptoms include skin rash, headache, fever, and fatigue. If untreated, infection can spread to joints, heart, and nervous system.
Peptic ulcer disease	*Helicobacter pylori*	Causes peptic ulcer, a lesion in the lining of the stomach or duodenum (upper part of small intestine).
Pertussis (whooping cough)	*Bordetella pertussis*	Highly communicable from person to person. Causes spasms of severe coughing. Vaccination available.
Plague	*Yersinia pestis*	Transmitted from wild rodents, squirrels, and cats to people by infected fleas. If untreated, can be fatal. Killed millions of people in Europe during the Middle Ages.
Pneumonia	*Streptococcus pneumoniae*	Transmitted from person to person. Strains of *S. pneumoniae* are resistant to some antibiotics. Incidence has decreased since introduction of a vaccine.
Salmonella (salmonellosis)	*Salmonella* sp.	Transmitted via contaminated chicken, eggs, or other food; also from feces of infected animals. Symptoms include fever, diarrhea, and stomach pain.
Syphilis	*Treponema pallidum*	Sexually transmitted disease passed through direct contact with a syphilis sore. If untreated, eventually damages brain, liver, bone, and spleen; can cause death.
Travelers' diarrhea	Certain strains of *Escherichia coli* are the most common cause.	Ingested in contaminated food and water. Affects 30% to 50% of travelers in high-risk areas (Central America, South America, Africa, Middle East, and most of Asia). Infecting bacteria produce toxins in gastrointestinal tract.
Tuberculosis	*Mycobacterium tuberculosis*	Transmitted from person to person through inhalation of air containing the pathogen. Symptoms include fatigue, cough, fever, and weight loss. Not common in U.S., but multidrug-resistant form is a growing threat.
Typhoid fever	*Salmonella typhi*	Transmitted from person to person in food or water contaminated with feces. Risk greatest for travelers in developing countries, but vaccine available. Symptoms include high fever, headache, and loss of appetite. Can cause death if not treated.

the bacteria themselves, is responsible for the disease. Diphtheria is caused by a gram-positive bacillus (*Corynebacterium diphtheriae*) that produces a toxin only when lysogenized by a phage. The diphtheria toxin kills cells and causes inflammation.



Botulism, a type of food poisoning that can lead to paralysis and sometimes death, can result from eating improperly canned food. Botulism is caused by an exotoxin released by the gram-positive, endospore-forming *Clostridium botulinum*. During the canning process, food must be heated sufficiently to kill any highly heat-resistant endospores that may be present. If not, the endospores can germinate. The resulting bacterial population grows and releases an exotoxin so powerful that 1 g could kill one million humans! Like many exotoxins, the one that causes botulism is inactivated by heating. (Food must be heated to 80°C for 10 minutes or boiled for 3 to 4 minutes to inactivate the exotoxin.)

The botulism exotoxin, marketed under the trade name Botox, is used in extremely tiny amounts to treat several medical conditions involving spasms (involuntary muscle contractions). Botox injections are used to treat migraines, excessive sweating, overactive bladder/incontinence, and crossed eyes. Because Botox is a neurotoxin that works by paralyzing muscles, it can also relax facial wrinkles caused by contraction of the underlying muscles. However, its effects last for only about three months.

Another gram-positive, endospore-forming bacterium, *Clostridium difficile*, is an anaerobe that produces two exotoxins. It is a common cause of antibiotic-associated diarrhea (AAD), accounting for 15% to 25% of all episodes of AAD. *C. difficile* has recently become more virulent and more resistant to antibiotics. It has been linked to more than 500,000 cases and more than 29,000 deaths in the United States each year (see Table 25-4).

Veronika Burmeister/Visuals Limited

Figure 25-13 SEM of *Helicobacter pylori* attached to the epithelial lining of the stomach

Helicobacter pylori causes peptic ulcers.

NIAID/Science Source

Figure 25-14 Colorized SEM of methicillin-resistant *Staphylococcus aureus* (MRSA; *purple*) interacting with human white blood cells (*blue*)

These bacteria also show increased resistance to vancomycin. This strain of MRSA is a leading cause of infections associated with hospitals and nursing homes in the United States and United Kingdom.

Endotoxins are not secreted by pathogens but instead are components of the cell walls of most gram-negative bacteria. These compounds affect the host only when they are released from dead bacteria. Endotoxins bind to the host's macrophages (large phagocytic cells of the immune system) and stimulate them to release substances that cause fever and other symptoms of infection. Unlike exotoxins, which cause specific symptoms, endotoxins appear to affect the entire body. Endotoxins are not destroyed by heating.

Antibiotic resistance is a major public health problem

Bacteria mutate frequently and reproduce rapidly, often developing resistance to antibiotics. Many antibiotics target protein synthesis in bacteria. For example, streptomycin and related antibiotics block the initiation of protein synthesis. The tetracyclines block aminoacyl tRNA from binding to the A site on the ribosome.

Drug resistance may result from an accumulation of mutations in plasmid or chromosomal DNA. Plasmids that have genes for antibiotic resistance are called *R factors*. They have genes for resistance to a specific drug and for transferring the resistance to other bacteria. Some R factors have several genes for drug resistance, each encoding resistance to a different drug.

Methicillin-resistant *Staphylococcus aureus* (SA), referred to as *MRSA*, and vancomycin-resistant *Staphylococcus aureus*, or *VRSA*, have been directly linked to the horizontal transfer of antibiotic-resistance genes by plasmids during conjugation. An estimated 2 in every 100 healthy people in the United States now carries MRSA (FIG. 25-14). This "superbug" can cause infection in individuals with compromised immune systems. The Centers for Disease Control and Prevention estimates that MRSA causes more than 70,000 serious infections each year, resulting in death for many elderly and immune-compromised people. Overuse of antibiotics is the principal contributing factor to drug resistance. In any bacterial population, there are likely at least a few bacteria that are genetically resistant to a particular antibiotic. The bacteria that are *not* resistant are killed by the antibiotic, leaving the resistant bacteria to multiply and produce a resistant population. Note that this process is a common, present-day example of natural selection.

The practice of feeding low-dose antibiotics to farm animals to promote growth has also resulted in many types of antibiotic-resistant bacteria that survive and multiply after susceptible bacteria are killed. Many countries have banned some antibiotics in animal feed. Antibiotic resistance has significantly reduced the effectiveness of most common, inexpensive antibiotics. Scientists and pharmaceutical companies are challenged to rapidly develop new antibiotics to treat bacterial infections that were formerly easily cured.

Another type of drug resistance explains why some infections, such as urinary tract infections, are difficult to cure. When *E. coli* infect the bladder, the immune system launches a powerful defense. The bacteria subvert the attack by forming *biofilms* (discussed earlier in this chapter). Each biofilm is surrounded by a matrix rich in polysaccharides and by a protective shell. The bacteria in the biofilm are resistant to antibiotics as well as to host defenses. By one estimate, bacteria growing in a biofilm are up to 1000 times as resistant to antibiotics as are the same type of bacteria that have not formed a biofilm. Within biofilms, differential gene expression and mutation lead to diverse bacterial colonies. The biofilm strategy also explains some other types of chronic or recurrent infections. A high percentage of infections acquired in hospitals involve biofilms.

CHECKPOINT 25.6

- **CONNECT** Why are Koch's postulates important?
- Contrast endotoxins with exotoxins.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Summary: Focus on Learning Objectives

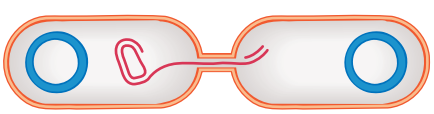
25.1 The Structure of Bacteria and Archaea *(page 518)*

1 Describe the structure and common shapes of prokaryotic cells.

- Prokaryotic cells are very small and do not have membrane-enclosed organelles such as nuclei and mitochondria.
- Prokaryotic cells have several common shapes: spherical (**cocci**), rod-shaped (**bacilli**), and spiral. Spiral bacteria include the **spirillum**, which is a rigid helix, and **spirochete**, which is a flexible helix.

2 Compare the bacterial cell wall in gram-positive and gram-negative bacteria.

- Most bacteria have **cell walls** composed of **peptidoglycan**. The walls of **gram-positive** bacteria are very thick and consist mainly of peptidoglycan. The cell walls of **gram-negative** bacteria consist of a thin peptidoglycan layer and an outer membrane resembling the plasma membrane. Some species of bacteria produce a **capsule** or **slime layer** that surrounds the cell wall.
- Some prokaryotes have hairlike appendages called **fimbriae**. **Pili** also extend from the surface of some prokaryotes. Both fimbriae and pili help cells adhere to one another or to certain other surfaces, including cells they infect. *Cannulae* and *hami* are recently discovered hairlike appendages unique to archaea.



3 Describe movement in prokaryotes and describe the structure of the bacterial flagellum.

- Bacterial **flagella** are structurally different from eukaryotic flagella; each flagellum consists of a basal body, hook, and filament. They produce a rotary motion. Many archaea have an *archaellum* that functions similarly to the bacterial flagellum.

25.2 Prokaryote Reproduction and Evolution *(page 522)*

4 Describe asexual reproduction in prokaryotes and summarize three mechanisms (transformation, transduction, and conjugation) that may lead to genetic recombination.

- The genetic material of a bacterium typically consists of a circular DNA molecule and one or more **plasmids**, smaller circular fragments of DNA.
- Prokaryotes reproduce asexually by **binary fission** (the cell divides, forming two cells), **budding** (a bud forms and separates from the mother cell), or **fragmentation** (walls form inside the cell, which then separates into several cells).
- In prokaryotes, genetic material can be exchanged by transformation, transduction, or conjugation. In **transformation**, a prokaryotic cell takes in foreign DNA released by another cell. Homologous segments of foreign and host DNA are exchanged. In **transduction**, a phage carries bacterial DNA from one bacterial cell into another. In **conjugation**, a donor cell transfers plasmid DNA to a recipient cell.

5 State specific factors that contribute to the rapid evolution of bacteria and archaea.

- Rapid reproduction ensures that mutations are rapidly passed to new generations. **Horizontal gene transfer**—by transformation, transduction, or conjugation—contributes to rapid evolution in prokaryotes.

25.3 Nutritional and Metabolic Adaptations *(page 524)*

6 Describe the principal modes by which prokaryotes carry on nutrition and energy capture, and compare their requirements for oxygen.

- Most prokaryotes are **heterotrophs** that obtain carbon from other organisms; some are **autotrophs** that make their own organic molecules from simple raw materials.
- **Chemotrophs** obtain energy from chemical compounds; **phototrophs** capture energy from light.
- Autotrophs may be **photoautotrophs**, which obtain energy from sunlight, or **chemoautotrophs**, which obtain energy by oxidizing inorganic chemicals such as ammonia.
- **Photoheterotrophs** obtain carbon from other organisms but use chlorophyll and other photosynthetic pigments to trap energy from sunlight. The majority of bacteria are **chemoheterotrophs**. They are mainly free-living **decomposers** that obtain both carbon and energy from dead organic matter.
- Most bacteria are **aerobic**; that is, they require oxygen for cellular respiration. Some prokaryotes are **facultative anaerobes** that metabolize anaerobically when necessary; others are **obligate anaerobes** that can carry on metabolism only anaerobically.
- Some bacteria and archaea carry on **nitrogen fixation**; that is, they reduce nitrogen in the atmosphere to ammonia. Other prokaryotes convert ammonia to nitrite or nitrate in a process called **nitrification**.

25.4 The Phylogeny of the Two Prokaryote Domains *(page 525)*

7 Compare characteristics of the three domains: Archaea, Bacteria, and Eukarya.

- Prokaryotes are assigned to domain **Archaea** and domain **Bacteria**.
- Unlike those of bacteria, the cell walls of archaea do not have peptidoglycan. The translational mechanisms of eukaryotes more closely resemble those of archaea than those of bacteria.

8 Distinguish between the main groups of archaea and identify specific types of archaea belonging to each group (see Fig. 25-9).

- The **Crenarchaeota** include many **extreme thermophiles**, archaea that can inhabit very hot, sometimes acidic, environments and archaea that are marine dwellers. **Euryarchaeota** include methanogens, extreme halophiles, and some extreme thermophiles. **Methanogens** are obligate anaerobes that produce methane gas from simple carbon compounds. **Extreme halophiles** inhabit saturated salt solutions. **Korarchaeota** have been found in terrestrial hot springs. **Nanoarchaeota** include extreme thermophiles.

Copyright 2019 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

- Two supergroups have recently been proposed: "TACK" and the "Asgard" clade, which includes Lokiarchaeota. There is some evidence that this group gave rise to the eukaryotes.

9 Describe the main groups of bacteria discussed in this chapter.

- Major groups of bacteria include proteobacteria, gram-positive bacteria, cyanobacteria, chlamydias, and spirochetes (see Table 25-3).

25.5 Impact on Ecology, Technology, and Commerce *(page 528)*

10 Identify the critical ecological roles played by prokaryotes and briefly describe their relationships with other organisms.

- Prokaryotes form intimate relationships with other organisms. All plants and animals have a community of microorganisms referred to as **microbiota**. The human **microbiome** consists of more than 10,000 different microorganisms.
- Many bacteria are symbiotic with other organisms. **Mutualism** is a symbiotic relationship in which both partners benefit. In **commensalism**, one partner benefits, and the other is neither harmed nor helped. In **parasitism**, the **parasite** benefits, and the host is harmed. Bacterial **pathogens** cause disease, but are usually not considered obligate parasites. **Biofilms** are dense communities of microorganisms, in which cells adhere to one another on a surface. Biofilms may include bacteria, archaea, protists, and fungi.
- Prokaryotes play essential ecological roles as decomposers and are important in recycling nitrogen and other nutrients. Some bacteria carry out photosynthesis.

11 Describe some of the important roles played by prokaryotes in commerce and technology.

- Some prokaryotes produce antibiotics. We have developed the technology for using certain bacteria to produce vaccines, insulin, and other important compounds. We use bacteria in the production of many foods, including cheese, yogurt, vinegar, and chocolate. We also use microbes in sewage treatment and in bioremediation.

25.6 Bacteria and Disease *(page 533)*

12 Describe the roles played by Louis Pasteur and Robert Koch in understanding infectious disease; list Koch's postulates.

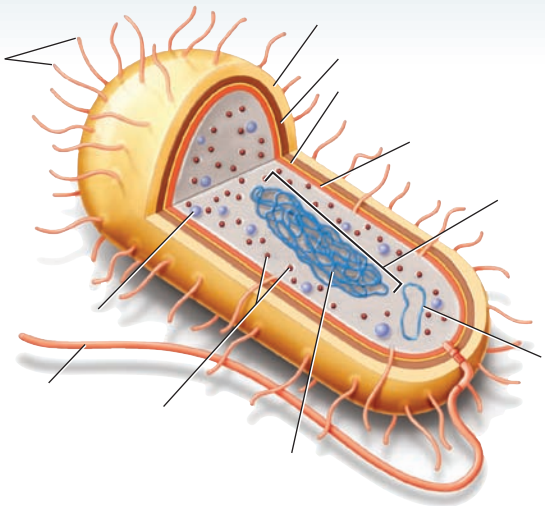
- Louis Pasteur demonstrated that sterilization prevented bacterial growth. **Koch's postulates** are a set of guidelines developed by Robert Koch to demonstrate that a specific pathogen causes specific disease symptoms: (1) the pathogen must be present in every individual with the disease, (2) a sample of the microorganism taken from the diseased host can be grown in pure culture, (3) a sample of the pure culture causes the same disease when injected into a healthy host, and (4) the microorganism can be recovered from the experimentally infected host.

13 Identify adaptations that have contributed to pathogen success.

- Some pathogenic bacteria release strong poisons called **exotoxins**; others produce **endotoxins**, poisonous components of their cell walls that are released when bacteria die. Many bacteria have become resistant to antibiotics. Plasmids that have genes for antibiotic resistance are called *R factors*. See Table 25-4 for a description of some pathogenic bacteria.

Test Your Understanding

Know and Comprehend



1. Peptidoglycan is a chemical compound found in the cell walls of (a) most viroids (b) most archaea (c) all prokaryotes (d) most bacteria (e) most eukarya
2. Bacterial flagella (a) are homologous with eukaryotic flagella (b) exhibit a rotary motion (c) consist of a basal body and nine pairs of microtubules (d) are important in transduction (e) are characteristic of gram-positive bacteria
3. Endospores (a) are formed by some viruses (b) are extremely durable cells (c) are comparable to the reproductive spores of fungi and plants (d) cause fever and other symptoms in the host (e) are vulnerable to infection by archaea
4. In conjugation, (a) two bacterial cells of different mating types come together, and genetic material is transferred from one to another (b) a bacterial cell develops a bulge that enlarges and eventually separates from the mother cell (c) fragments of DNA released by a broken cell are taken in by another bacterial cell (d) a phage carries bacterial genes from one bacterial cell into another (e) walls develop in the cell, which then divides into several new cells
5. The majority of heterotrophic bacteria are (a) free-living chemoheterotrophs (b) photoautotrophs (c) chemoautotrophs (d) facultative anaerobes (e) obligate anaerobes
6. Bacteria that are autotrophs (a) do not require atmospheric oxygen for cellular respiration (b) must obtain organic compounds from other organisms (c) manufacture their own organic molecules from simple raw materials (d) get their nourishment from dead organisms (e) produce endospores when oxygen levels are too low for active growth
7. Bacteria that thrive in puncture wounds are likely to be (a) aerobes (b) photoautotrophs (c) chemoautotrophs (d) endospores (e) obligate anaerobes
8. Which of the following do *not* belong to domain Archaea? (a) prokaryotes that produce methane from carbon dioxide and hydrogen (b) thermophiles (c) halophiles (d) bacteriophages (e) prokaryotes with cell walls that lack peptidoglycan
9. Rhizobial bacteria (a) are used in the production of yogurt (b) produce antibiotics (c) cause peptic ulcers (d) are the pathogens that cause syphilis (e) form mutualistic relationships with the roots of legumes and fix nitrogen
10. Robert Koch (a) proposed a set of guidelines to demonstrate that a specific pathogen causes specific disease symptoms (b) discovered *Helicobacter* (c) showed that biofilms consist of microorganisms (d) proposed a hypothesis for antibiotic resistance (e) demonstrated that people can be stimulated to develop immunity to disease
11. Which group of bacteria contains the gram-positive, anaerobic bacterium that causes botulism? (a) clostridia (b) actinomycetes (c) enterobacteria (d) spirochetes (e) streptococci

26 Protists

Protists are an informal group of primarily aquatic eukaryotic organisms with diverse body forms, types of reproduction, modes of nutrition, and lifestyles. Protists, which include algae, water molds, slime molds, and protozoa, are unicellular, colonial, or simple multicellular organisms that have a eukaryotic cell organization (see photograph). The word *protist*, from the Greek for "the very first," reflects the idea that protists were the first eukaryotes to evolve.

Protists are members of domain Eukarya, the third domain on the tree of life. (Recall the three domains depicted in Figure 23-2.) Eukaryotic cells are characteristic of protists as well as of complex multicellular organisms belonging to the kingdoms Fungi, Animalia, and Plantae. However, having a eukaryotic cell structure clearly differentiates protists from members of the prokaryotic domains Bacteria and Archaea. Recall from Chapter 4 that unlike prokaryotic cells, eukaryotic cells have nuclei and other membrane-enclosed organelles such as mitochondria and plastids, 9 + 2 flagella, and multiple chromosomes in which DNA and proteins form a complex called chromatin. Sexual reproduction, meiosis, and mitosis are also characteristic of eukaryotes.

Until recently, all protists were classified as the kingdom Protista, but this classification was by default: protists included any eukaryotes that were not land plants, fungi, or animals. Based largely on recent molecular data that have clarified many evolutionary relationships among eukaryotes, kingdom Protista

KEY CONCEPTS

26.1 Protists are a diverse group of eukaryotic organisms that vary in body plan (unicellular, colonial, coenocytic, multicellular), method of motility (pseudopodia, cilia, flagella), nutrition type (autotrophic, heterotrophic), and mode of reproduction (asexual, sexual).

26.2 Much uncertainty surrounds eukaryote evolution, but eukaryote organelles such as chloroplasts probably descended from engulfed cells that survived and became organelles. Current scientific evidence supports splitting the protists and other eukaryotes (land plants, fungi, and animals) into five informal "supergroups."

26.3 Excavates are a supergroup of unicellular protists with atypical, greatly modified mitochondria; they get their name because many have a deep, or excavated, oral groove.

26.4 Chromalveolates are a supergroup of diverse protists that may have originated as a result of secondary endosymbiosis in which an ancestral cell engulfed a red alga.

26.5 Rhizarians are a supergroup of amoeboid cells that often have tests (shells) through which cytoplasmic projections extend; forams, actinopods, and certain shell-less amoebas are rhizarians.

26.6 Archaeplastids are a supergroup that includes red algae, green algae, and land plants, all of which have plastids enclosed by two external membranes.

26.7 Unikonts are a supergroup that includes amoebozoa and choanoflagellates as well as fungi and animals.

is no longer a recognized clade. Although we have made great progress in understanding the evolutionary relationships among protists, many relationships remain uncertain.

Biologists currently recognize dozens of protist taxa, which, along with other eukaryotes, are classified into five "supergroups." Consideration of all protist taxa is beyond the scope of this text, but we discuss several representative examples of each supergroup and provide insights into how such diverse eukaryotes may have evolved.

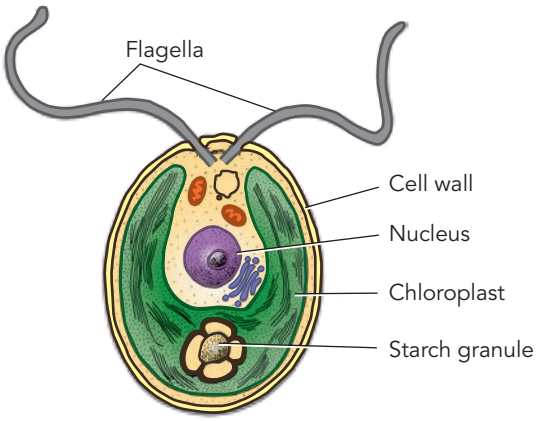
26.1 Diversity in the Protists

LEARNING OBJECTIVE

1 Discuss in general terms the diversity inherent in protists, including means of locomotion, modes of nutrition, interactions with other organisms, habitats, and modes of reproduction.

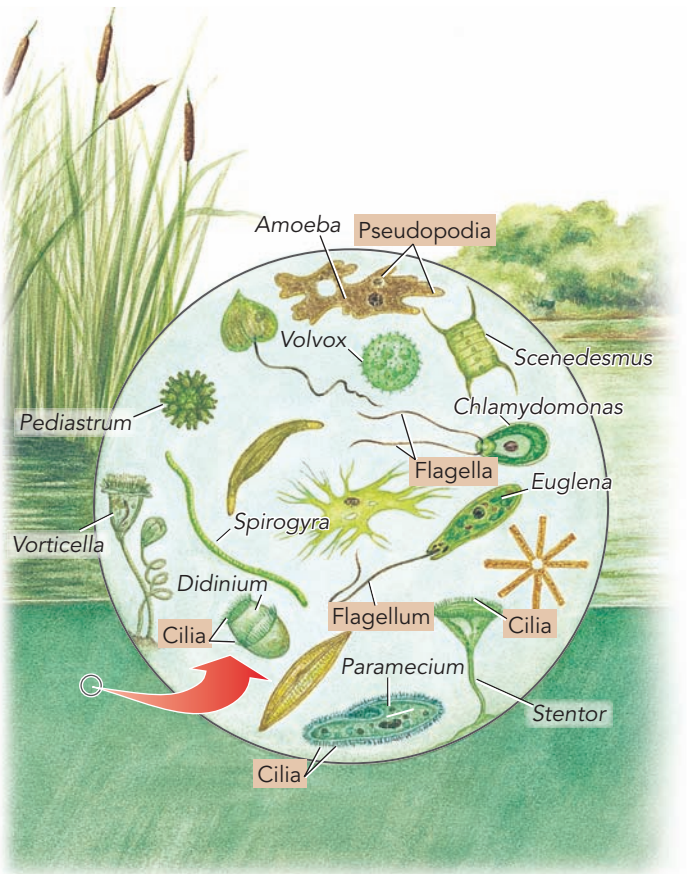
Because of their huge numbers, protists are crucial to the natural balance of the living world. Protists are an important source of food for other organisms, and photosynthetic protists supply oxygen to aquatic and terrestrial ecosystems. Certain protists are economically important, and others cause devastating diseases such as malaria.

Body plan varies considerably among protists. Most protists are *unicellular*, with each cell forming a complete organism capable of performing all the functions characteristic of life. Some protists form **colonies**, loosely connected groups of cells; some are **coenocytes**, consisting of a multinucleate mass of cytoplasm; and some are *multicellular*, composed of many cells. Unlike animals, plants, and many fungi, most multicellular protists have relatively simple body forms without specialized tissues.



Size and structural complexity are not the only variable features of protists. During the course of the long evolutionary history of protists, diversity has evolved in their means of locomotion, ways of obtaining nutrients, interactions with other organisms, habitats, and modes of reproduction.

Protists, most of which are motile at some point in their life cycle, have various means of locomotion. Some move by pushing out cytoplasmic extensions called **pseudopodia** along the leading edge and retracting the cytoplasm that trails behind, as an amoeba does. Other protists move by flexing individual cells; by gliding over surfaces; by waving **cilia**, short, hairlike organelles; or by lashing **flagella**, long, whiplike organelles. Some protists have two or more means of locomotion, such as both flagella and pseudopodia.



Methods of obtaining nutrients differ widely among protists. Most algae are autotrophic and photosynthesize as plants do (FIG. 26-1a). Some heterotrophic protists obtain their nutrients by absorption, as fungi do, whereas others resemble animals in that they ingest food. Some protists switch their modes of nutrition and are autotrophic at certain times and heterotrophic at others.

Although many protists are free-living, others form stable symbiotic associations with unrelated organisms. These intimate associations range from **mutualism**, a more or less equal partnership where both partners benefit; to **commensalism**, where one partner benefits and the other is unaffected; to **parasitism**, where one partner (the parasite) lives on or in another (the host) and metabolically depends on it (see Chapter 54). Some parasitic protists are important *pathogens* (disease-causing agents) of plants or animals. Throughout this chapter, we describe specific examples of symbiotic associations involving protists.

Most protists are aquatic and live in the ocean or in freshwater streams, lakes, and ponds (FIG. 26-1b). They make up most of the **plankton**, the floating, often microscopic

(a) *Chlamydomonas* is a photosynthetic organism with two flagella and a cup-shaped chloroplast.

(b) Protists in a drop of pond water. Several modes of locomotion are shown.

organisms that inhabit surface waters and are the base of the food web in aquatic ecosystems. Other aquatic protists attach to rocks or other surfaces in the water. Even parasitic protists are aquatic because they live in the watery environments of other organisms' body fluids. Terrestrial protists are restricted to damp places such as soil, cracks in bark, and leaf litter.

Reproduction is varied among protists. Almost all protists reproduce asexually, and many also reproduce sexually. However, most protists do not develop multicellular reproductive organs, nor do they form embryos the way more complex organisms do.

CHECKPOINT 26.1

- How do protists vary in their means of obtaining nutrients?
- What are some of the ways protists interact with other organisms?

26.2 How Did Eukaryotes Evolve?

LEARNING OBJECTIVES

2 Discuss the hypothesis of serial endosymbiosis and briefly explain some of the evidence that supports it.

3 Describe the kinds of data biologists use to classify eukaryotes.

For many years biologists have hypothesized that protists were the first eukaryotic cells and that they evolved from ancestral prokaryotes. However, the more we study eukaryote origins, the more uncertain we are. One thing we can say with absolute certainty is that the evolution of eukaryotes was a complex process.

Eukaryotes may have appeared in the fossil record as early as 2.2 billion years ago. Other than a few protists with hard shells, such as diatoms and forams, most ancient protists did not leave many fossils because their bodies were too soft to leave permanent traces. Evolutionary studies of protists focus primarily on molecular and structural comparisons of present-day organisms, which contain many clues about their evolutionary history.

Mitochondria and chloroplasts probably originated from endosymbionts

Throughout evolutionary history, one organism has engulfed another to the mutual benefit of both. According to the hypothesis of **serial endosymbiosis**, certain eukaryotic organelles, particularly mitochondria and chloroplasts, arose from symbiotic relationships between larger cells and smaller bacteria that were incorporated and lived within them. (You might want to review serial endosymbiosis in Figure 21-8.) Cell biologists hypothesize that mitochondria originated from aerobic bacteria. Studies of mitochondrial DNA suggest that it is a remnant from the mitochondrion's past, when it was an independent organism. Ribosomal RNA (rRNA) sequences from mitochondria closely match rRNAs found in purple bacteria, suggesting that ancient purple bacteria were the ancestors of mitochondria.

Chloroplast evolution is more complex given that there were probably several endosymbiotic events (FIG. 26-2). Molecular evidence supports the view that incorporation of an ancient cyanobacterium within a host cell, known as *primary endosymbiosis*, resulted in the chloroplasts in today's red algae, green algae, and land plants. (The host cell was eukaryotic because mitochondria almost certainly evolved before chloroplasts.) Biologists hypothesize that these chloroplasts, which are enclosed by two external membranes (known as the outer and inner chloroplast membranes; see Chapter 9), later provided other eukaryotes with their chloroplasts during *secondary endosymbiosis*.

Secondary endosymbiosis occurred frequently in eukaryote evolution, as evidenced by the presence of additional chloroplast membranes. For example, *three* membranes envelop the chloroplasts of euglenoids and dinoflagellates, and *four* membranes surround the chloroplasts of diatoms, golden algae, and brown algae. Understanding how these membranes originated is an essential aspect of serial endosymbiosis, and many researchers are studying the origin of chloroplasts in different organisms.

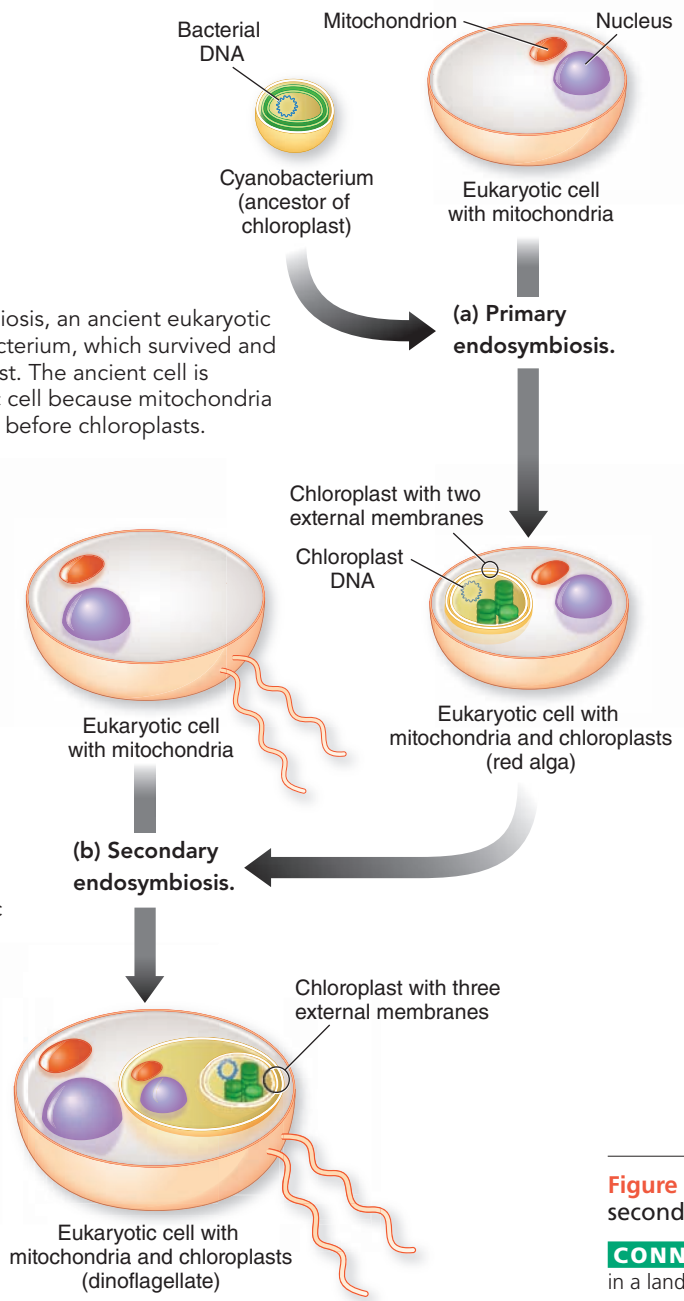
Even non-photosynthetic protists may contain chloroplast relics from secondary endosymbiotic events. Apicomplexans—protists such as *Plasmodium*, which causes malaria—have a non-photosynthetic chloroplast derived from a red alga, surrounded by four external membranes. Because this plastid carries out certain functions essential to the survival of the parasite, it has become a target of ongoing research focused on the development of antimalarial drugs.

A consensus in eukaryote classification is beginning to emerge

Scientists re-evaluate evolutionary relationships among the eukaryotes as additional evidence becomes available. Two types of modern research, molecular analysis and ultrastructural studies, have contributed substantially to scientific understanding of the phylogenetic relationships among protists. Molecular data were initially obtained for the gene that codes for small subunit ribosomal RNA in different eukaryotes (SSU rRNA; see Chapter 25). More recently, biologists have compared other nuclear genes, many of which code for proteins, in different protist taxa.

Ultrastructure is the fine details of cell structure revealed by electron microscopy. In many cases, ultrastructure data complement molecular data. Electron microscopy reveals similar structural patterns among those protist taxa that comparative molecular evidence suggests are **monophyletic**; that is, they evolved from a common ancestor (see Chapter 23). For example, molecular and ultrastructure data suggest that water molds, diatoms, golden algae, and brown algae—protist taxa that at first glance seem to share few characteristics—are a monophyletic group.

Given the diversity in protist ultrastructure and molecular data, biologists regard the protists as a **paraphyletic group**; that is, protists contain some, but not all, of the descendants of a common eukaryote ancestor. Molecular and ultrastructural analyses continue to help biologists clarify relationships among the various protist phyla and among protists and the other eukaryotic kingdoms.



Biologists use these data to develop various classification schemes. A current scheme that is used in this edition

Key Point

Scientists hypothesize that plastids have evolved through both primary and secondary endosymbiosis.

(a) In primary endosymbiosis, an ancient eukaryotic cell engulfed a cyanobacterium, which survived and evolved into a chloroplast. The ancient cell is depicted as a eukaryotic cell because mitochondria almost certainly evolved before chloroplasts.

(b) In a secondary endosymbiotic event, a heterotrophic eukaryotic cell (with mitochondria) engulfed a eukaryotic cell with chloroplasts (a red alga is depicted). The red alga survived and evolved into a chloroplast surrounded by three membranes (a dinoflagellate chloroplast is depicted). Other secondary endosymbiotic events resulted in more complex chloroplast membrane structures.

Figure 26-2 Chloroplast evolution by primary and secondary endosymbiosis

CONNECT How many external membranes are present in a land plant chloroplast? Use Figure 9-4b to check your answer.

splits the protists and other eukaryotes (land plants, fungi, and animals) into five informal supergroups (FIG. 26-3 and TABLE 26-1). This classification scheme will almost certainly be modified as new information becomes available.

Now that we have a basic understanding of evolution of the protists and other eukaryotes, let's examine representative protists within the five supergroups.

CHECKPOINT 26.2

- How does serial endosymbiosis explain the origin of chloroplasts?
- What kinds of scientific evidence support the hypothesis that protists are a paraphyletic group?

Key Point

Unraveling phylogenetic relationships among the protists has been difficult, but progress is occurring. Many biologists currently classify eukaryotes into five major "supergroups."

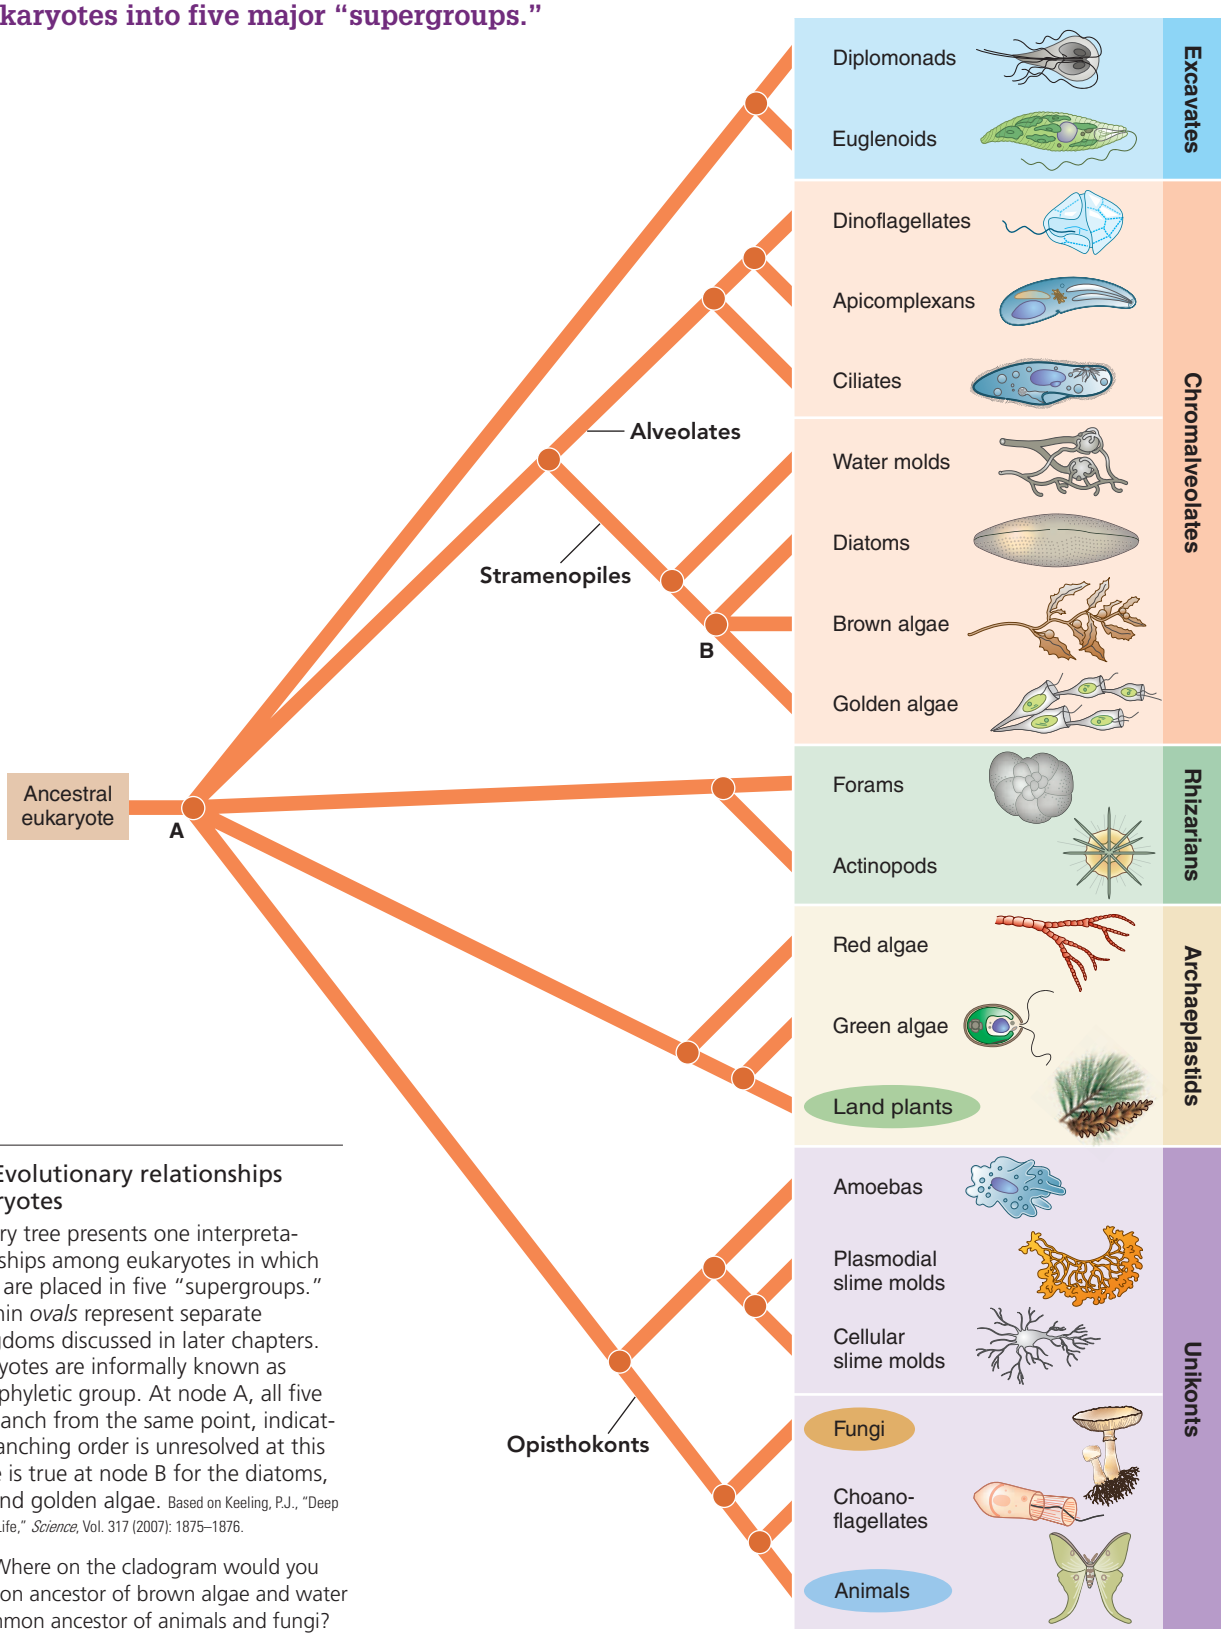

Figure 26-3 Evolutionary relationships among eukaryotes

This evolutionary tree presents one interpretation of relationships among eukaryotes in which the eukaryotes are placed in five "supergroups." Organisms within *ovals* represent separate eukaryotic kingdoms discussed in later chapters. All other eukaryotes are informally known as protists, a paraphyletic group. At node A, all five supergroups branch from the same point, indicating that the branching order is unresolved at this time. The same is true at node B for the diatoms, brown algae, and golden algae. Based on Keeling, P.J., "Deep Questions in the Tree of Life," *Science*, Vol. 317 (2007): 1875–1876.

Table 26-1 "Protist" Clades

Eukaryote "Supergroup"	Representative "Protist" Clades	Key Characters
EXCAVATES Unicellular protists with atypical, greatly modified mitochondria; bikonts	**Diplomonads and parabasalids**	Two or more flagella; ventral oral (feeding) groove
	Euglenoids and trypanosomes	Some with plastids; crystalline rod in flagella
CHROMALVEOLATES Diverse protists that may have originated as a result of secondary endosymbiosis in which an ancestral cell engulfed a red alga; bikonts	**Alveolates** Dinoflagellates, ciliates, apicomplexans	Alveoli (flattened vesicles) just inside the plasma membrane
	Stramenopiles Water molds, diatoms, brown algae, golden algae	Most have two flagella, one with hairs; no flagella in some
RHIZARIANS Amoeboid cells that often have tests (shells); bikonts	**Forams**	Porous tests (hard shells) through which cytoplasmic projections (pseudopods) extend
	Actinopods	Endoskeletons (internal shells) through which axopods (filamentous pseudopods) extend
ARCHAEPLASTIDS Plastids bounded by outer and inner membranes; include land plants; bikonts	**Red algae**	Chloroplast pigments include phycoerythrin (red pigment) and phycocyanin (blue pigment)
	Green algae	Chloroplast pigments identical to those in land plants
UNIKONTS Cells that have a single flagellum or are amoebas with no flagella; have a triple-gene fusion that is lacking in other eukaryotes; include animals and fungi	**Amoebozoa** Amoebas, plasmodial slime molds, cellular slime molds	Naked amoebas (no tests) with lobelike pseudopods
	Opisthokonts Choanoflagellates	No flagella or single posterior flagellum on motile cells

26.3 Excavates

LEARNING OBJECTIVE

4 Summarize the basic features of excavates and distinguish among diplomonads, parabasilids, and euglenoids.

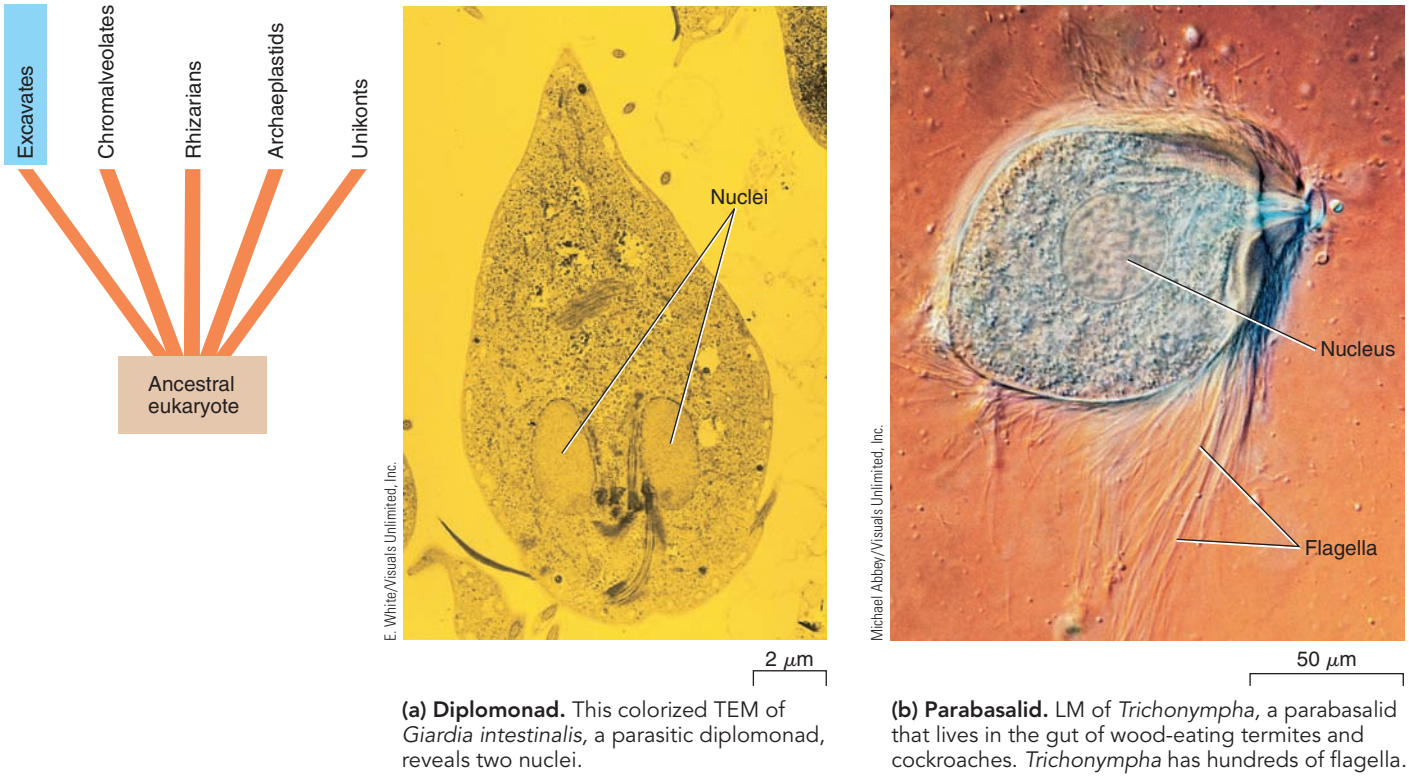
Excavates are a diverse group of unicellular protists with flagella. These protists are so named because many have a deep, or *excavated*, oral groove. Unlike other protists, excavates have atypical, greatly modified mitochondria. Many excavates are endosymbionts and live in anoxic (without oxygen) environments. These excavates do not carry out aerobic respiration; they obtain energy by the anaerobic pathway of glycolysis (presumably by fermentation).

Currently, excavates include diplomonads, parabasalids, euglenoids, and trypanosomes. The inclusion of these organisms into a single superfamily is somewhat controversial because their relationships to one another are uncertain. Additional studies are needed to determine if the excavates as currently presented are a monophyletic group.

Diplomonads are small, mostly parasitic flagellates

Diplomonads are excavates that have one or two nuclei, no functional mitochondria, no Golgi complex, and up to eight flagella. *Giardia* is a parasitic diplomonad (FIG. 26-4a). Interestingly, *Giardia* has two haploid nuclei, each of which contains a complete copy of *Giardia*'s genome. *Giardia* lacks functional mitochondria, although it contains certain genes that code for proteins associated with mitochondria in other organisms. *Giardia* also has reduced structures that somewhat resemble mitochondria. This information suggests to some biologists that an early eukaryotic ancestor of *Giardia* may have possessed mitochondria, which were somehow lost or reduced at a later time during its evolutionary history.

Giardia intestinalis is a major cause of water-borne diarrhea throughout the world. *Giardia* is eliminated as a resistant cyst in the feces of many vertebrate animals. These cysts are a common contaminant in untreated drinking water, even in environments considered relatively pristine, such as isolated mountain streams. In a heavy infection, much of the wall of the small intestine is coated with these flagellates, which interfere with the absorption of digested nutrients and cause weight loss, abdominal cramps, and diarrhea.



Parabasilids are anaerobic endosymbionts that live in animals

Parabasilids are anaerobic, flagellated excavates that often live in animals. Trichonymphs and trichomonads are examples of parabasilids. *Trichonymphs*, which have hundreds of flagella, live in the guts of termites and wood-eating cockroaches (FIG. 26-4b). Trichonymphs ingest wood chips from the wood that termites or roaches eat. The trichonymphs rely on endosymbiotic bacteria to digest cellulose in the wood. Thus, in an excellent example of mutualism, the insects, trichonymphs, and bacteria all obtain their nutrients from cellulose.

The most well-known trichomonad is probably *Trichomonas vaginalis*, which causes trichomoniasis, a curable sexually

Figure 26-4 Diplomonads and parabasalids

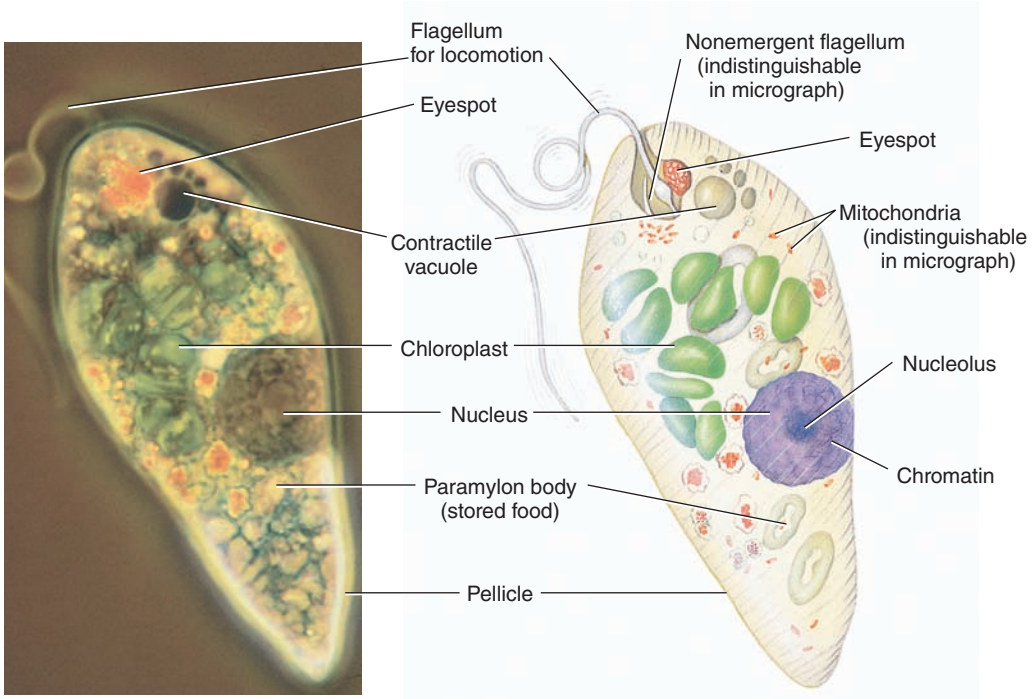
transmitted disease (STD) in humans. Trichomoniasis affects both men and women, although the symptoms are more obvious in women. According to the Centers for Disease Control and Prevention, about 7.4 million new cases occur in the United States each year.

Euglenoids and trypanosomes include both free-living species and parasites

Euglenoids and *trypanosomes* are characterized by an unusual flagellum: in addition to the 9 + 2 arrangement of microtubules characteristic of all eukaryotic flagella, these excavates have a crystalline rod in their flagella; the function of this rod is unknown. Like other excavates, euglenoids and trypanosomes also have atypical mitochondria.

Most **euglenoids** are unicellular flagellates, and about one-third of them are photosynthetic (FIGS. 26-5a and b). They generally have two flagella: one long and whiplike and one that is often so short that it does not extend outside the cell. Some euglenoids, such as *Euglena*, change shape continually as they move through the water because their **pellicle**, or outer covering, is flexible.

Autotrophic euglenoids have chloroplasts with the same photosynthetic pigments that green algae and plants have. However, these chloroplasts were acquired by secondary endosymbiosis; euglenoids are not closely related to either group, as shown in Figure 26-3. Some photosynthetic euglenoids lose their chlorophyll when grown in the dark, and they obtain their nutrients heterotrophically, by ingesting organic matter. Other euglenoids are always colorless and heterotrophic. Some heterotrophic species absorb organic compounds from the surrounding water, whereas others engulf bacteria and protists by **phagocytosis**; they digest the prey within food vacuoles.



Trypanosomes are excavates with a single mitochondrion that has an organized deposit of DNA called a **kinetoplastid**. Trypanosomes are colorless, and many are parasitic and cause disease. In vertebrates, including humans, trypanosomes live in the blood. For example, *Trypanosoma brucei* is a human parasite that causes African sleeping sickness (FIG. 26-5c). It is transmitted by the bite of infected tsetse flies. Early symptoms include recurring attacks of fever. Later, when the trypanosomes have invaded the central nervous system, infected people are lethargic, have difficulty speaking or walking, and may die if the disease is untreated. Control efforts are showing significant success; the incidence of the disease has dropped from about 300,000 new cases in 1998 to an estimate of below 20,000 in 2014.

26.4 Chromalveolates

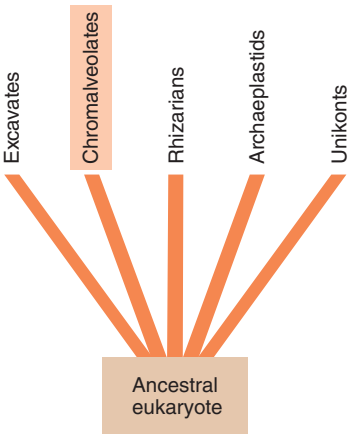
LEARNING OBJECTIVES

5 Contrast the two main groups of chromalveolates: alveolates and stramenopiles.
6 Distinguish among the alveolates: dinoflagellates, apicomplexans, and ciliates.
7 Distinguish among the stramenopiles: water molds, diatoms, golden algae, and brown algae.

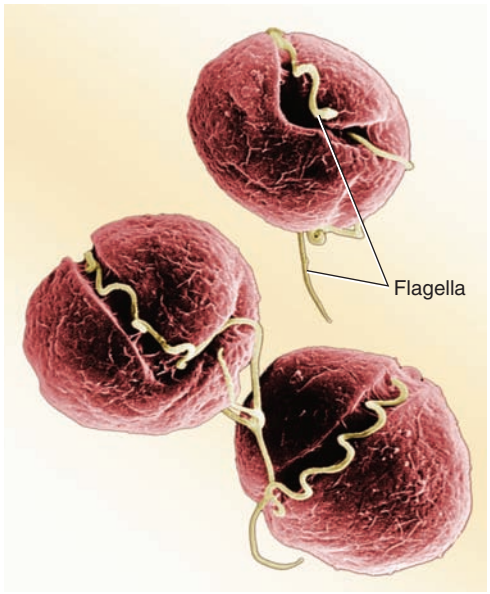
The **chromalveolates** are a supergroup composed of extremely diverse protists with few shared characters. Chromalveolates probably originated as a result of secondary endosymbiosis in which an ancestral cell engulfed a red alga (which itself was the result of primary endosymbiosis). Most chromalveolates are photosynthetic, and evidence suggests that heterotrophic chromalveolates, such as the water molds and ciliates, descended from autotrophic ancestors. Classification of the chromalveolates as a monophyletic supergroup is controversial because some DNA sequence data have indicated that they are not monophyletic. The chromalveolates are divided into two main groups: alveolates and stramenopiles.

The unifying features of protists classified as **alveolates** include similar ribosomal DNA sequences and **alveoli** (sing., *alveolus*), flattened vesicles located just inside the plasma membrane. In some alveolates the vesicles contain plates of cellulose. Alveolates include the dinoflagellates, apicomplexans, and ciliates.

The **stramenopiles** include water molds, diatoms, golden algae, and brown algae. At first glance stramenopiles appear too diverse to classify together. However, most stramenopiles have motile cells with two flagella, one of which has tiny hairlike projections extending from the shaft. The word *stramenopile* comes from Latin words referring to "straw" (i.e., the shaft of the flagellum) and "hairs."



Most dinoflagellates are a part of marine plankton



Dinoflagellates are generally unicellular, although a few are colonial. Their alveoli contain interlocking cellulose plates impregnated with silicates. The typical dinoflagellate has two flagella. One flagellum wraps around a transverse groove in the center of the cell like a belt, and the other lies in a longitudinal groove (perpendicular to the transverse groove), projecting behind the cell (FIG. 26-6a). The undulation of these flagella propels the dinoflagellate through the water like a spinning top. Indeed, the name is derived from the Greek *dinos*, meaning "whirling." Many marine dinoflagellates are bioluminescent.

Many dinoflagellates are photosynthetic, but others are heterotrophic and ingest other microorganisms for food. Some dinoflagellates are endosymbionts that live in the

(b) Red tide in Mexico. Billions of dinoflagellates produce the orange cloudiness

Figure 26-6 Dinoflagellates

bodies of marine invertebrates such as mollusks, jellyfish, and corals (see Fig. 54-12). These symbiotic dinoflagellates, called **zooxanthellae**, photosynthesize and provide carbohydrates for their invertebrate partners. Zooxanthellae contribute substantially to the productivity of coral reefs. Other dinoflagellates that are endosymbionts lack pigments and are parasites that live off their hosts.

Ecologically, dinoflagellates are important producers in marine ecosystems. A few dinoflagellates are known to have occasional population explosions, or blooms. These blooms, known as **red tides**, frequently color coastal waters orange, red, or brown (FIG. 26-6b). Dinoflagellate blooms are particularly common in warm, nutrient-enriched water. Some dinoflagellate species that form red tides produce a toxin that attacks the nervous systems of fishes, leading to fish kills. Birds sometimes die after eating contaminated fish. Research has also linked red tides to manatee and dolphin deaths in Florida.

Apicomplexans are spore-forming parasites of animals

Apicomplexans are a large group of parasitic, spore-forming alveolates, some of which cause serious diseases in humans. As discussed earlier in the chapter, they contain the unpigmented remnant of a chloroplast derived from a red alga. Apicomplexans lack specific structures for locomotion (cilia, flagella, or pseudopodia) and move by flexing.

Apicomplexans have an *apical complex* of microtubules that attaches the parasite to its host cell; the apical complex is visible only by using electron microscopy. They also have the ability to form a structure known as a *moving junction*, which enables them to form a vacuole that encloses and protects them as they invade a host cell. At some stage in their life cycle, apicomplexans produce **sporozoites**, small infective agents transmitted to the next host. Many apicomplexans spend part of their complex life cycle in one host species and part in a different host species.

Malaria is caused by an apicomplexan (FIG. 26-7). According to the World Health Organization, there were approximately 212 million new cases of malaria worldwide in 2015; about 429,000 people, mostly children in developing countries, died from the disease. Although for centuries Chinese, Greek, Arabic, and Roman writings described the disease, its causative agent and mode of transmission by means of mosquitoes were not identified until the end of the 19th century. British scientist Ronald Ross received the Nobel Prize in Physiology or Medicine in 1902 for his role in elucidating the life cycle of *Plasmodium*, the apicomplexan that causes malaria.

Control measures that have lost effectiveness due to the evolution of chemotherapy resistance on the part of *Plasmodium* and pesticide resistance on the part of the mosquitoes are currently being replaced by newer methods, but the battle is ongoing. For example, chemotherapies that include the drug artemisinin in combination with other drugs have emerged as the standard of care, but there are signs that resistance of the parasite to artemisinin is beginning to evolve in some countries. Researchers

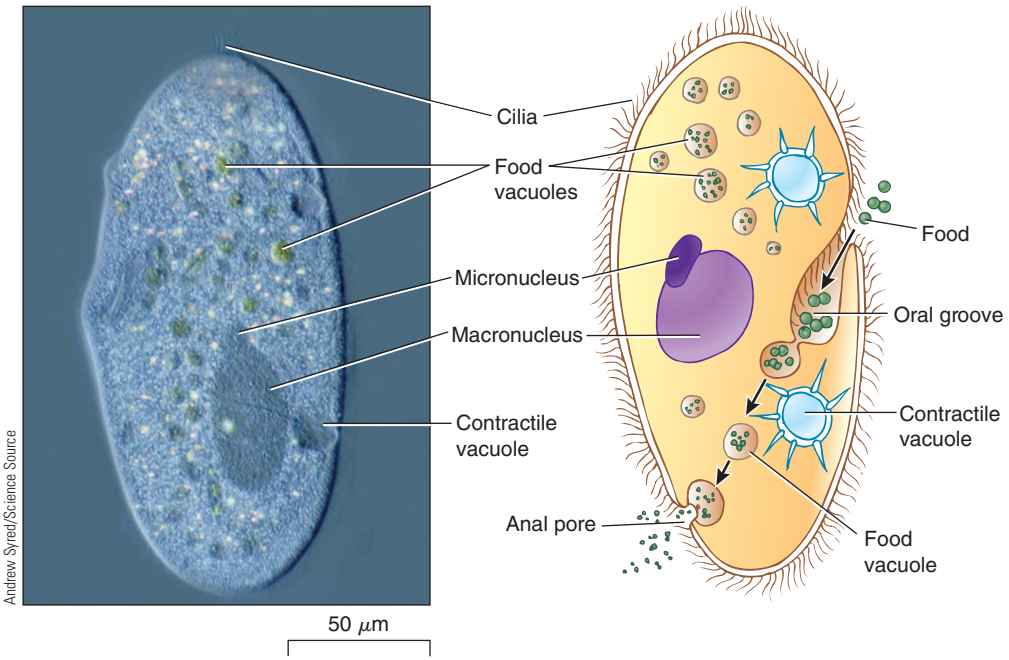
are currently testing new antimalarial drugs and several possible vaccines against malaria. Advanced sequencing of the genomes of *P. falciparum* and the *Anopheles* mosquito may lead to new diagnostics, drugs, and vaccines.

Ciliates use cilia for locomotion



Ciliates are among the most complex of eukaryotic cells. These unicellular alveolates have a pellicle that gives them a definite but changeable shape. In *Paramecium* the surface of the cell is covered with several thousand fine, short, hair-like cilia that extend through pores in the pellicle to facilitate movement (FIGS. 26-8a and b; also see Fig. 4-5c). The cilia beat with such precise coordination that the organism can back up and turn around as well as move forward.

Not all ciliates are motile. Some sessile forms have stalks, and others, although capable of some swimming, are more likely to remain attached to a rock or other surface at one spot. Their cilia set up water currents that draw food toward them.

Ciliates differ from other protists in having two kinds of nuclei: one or more small, diploid **micronuclei** that function in reproduction; and a larger, polyploid **macronucleus** that controls cell metabolism and growth. Most ciliates are capable of a sexual process called **conjugation**, in which two individuals come together and exchange genetic material (FIG. 26-8c). Conjugation results in two "new" cells that are genetically identical to each other but different from what they were before conjugation. Mitosis and cell division need not follow immediately after conjugation. Ciliates usually divide perpendicularly to their longitudinal axis.

Water molds produce biflagellate reproductive cells

Water molds are stramenopiles that were once classified as fungi because of their superficial resemblance. Both water molds and fungi have a body, called a **mycelium**, that grows over organic material, digesting it and then absorbing the predigested nutrients (FIG. 26-9). The threadlike **hyphae** that make up the mycelium in water molds are *coenocytic*, meaning that there are no cross walls; the body consists of a single multinucleate cell. The cell walls of water molds are composed of cellulose (as in plants), chitin (as in fungi), or both.

When food is plentiful and environmental conditions are favorable, water molds reproduce asexually. A hyphal tip swells, and a cross wall is formed, separating the hyphal tip from the rest of the mycelium. Within this structure, called a **zoosporangium**,

tiny biflagellate **zoospores** form, each of which swims about, lands and encysts, and eventually develops into a new mycelium. When environmental conditions worsen, water molds initiate sexual reproduction. After fusion of male and female nuclei, thick-walled **oospores** develop from the oospheres (female gametes). Water molds often spend the winter as oospores.

Some water molds have played a profound role in human history. For example, the Irish potato famine of the 19th century was precipitated by the water mold *Phytophthora infestans*, which causes late blight of potatoes. (The genus *Phytophthora* is named from Greek words meaning "plant destruction.") During several rainy, cool summers in Ireland in the 1840s, the water mold multiplied unchecked, causing potato tubers to rot in the fields. Because potatoes were the staple of the Irish peasants' diet, as many as one million people starved. The famine prompted a mass migration out of Ireland to the United States and other countries.

A close relative of the late blight water mold, *P. ramorum*, causes sudden oak death, which is killing oak forests in several western states. Plant pathologists are concerned that the disease may spread to midwestern and eastern forests. This particular water mold also attacks redwoods, Douglas firs, bay trees, maples, and several other plant species, but most have only twig and leaf infections, not the rapid death observed in oaks.

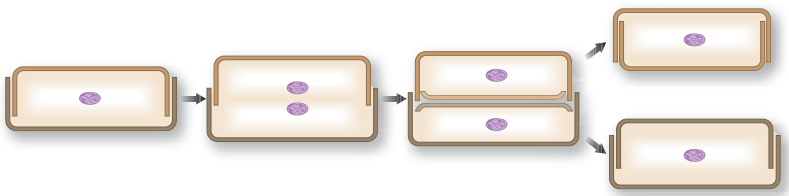
Diatoms are stramenopiles with shells composed of two parts

Most **diatoms** are unicellular, although a few exist as colonies. The cell wall of each diatom consists of two shells that overlap where they fit together, much like a petri dish. Silica is deposited in the shell, and this glasslike material is laid down in intricate patterns (FIG. 26-10a). There are two basic groups of diatoms: those with radial symmetry (wheel shaped) and those with bilateral symmetry (boat shaped or needle shaped). Although some diatoms are part of the floating plankton, others live on rocks and sediments, where they move by gliding. This gliding movement is facilitated by the secretion of a slimy material from a small groove along the shell.



Diatoms most often reproduce asexually by mitosis. When a diatom divides, the two halves of its shell separate, and each becomes the larger half of a new diatom shell (FIG. 26-10b). Because the glass shell cannot grow, some diatom cells get progressively smaller with each succeeding generation. When a diatom reaches a fraction of its original size, sexual reproduction occurs, with the production of shell-less gametes. Sexual reproduction restores the diatom to its original size because the resulting *zygote*, a *2n* cell that results from the fusion of *n* gametes, grows substantially before producing a new shell.

Diatoms are common in fresh water but are especially abundant in relatively cool ocean water. They are ecologically significant as major producers in aquatic ecosystems. At least one species is toxic and linked to shellfish poisonings, marine mammal strandings, and the deaths of sea lions along the central California coast.

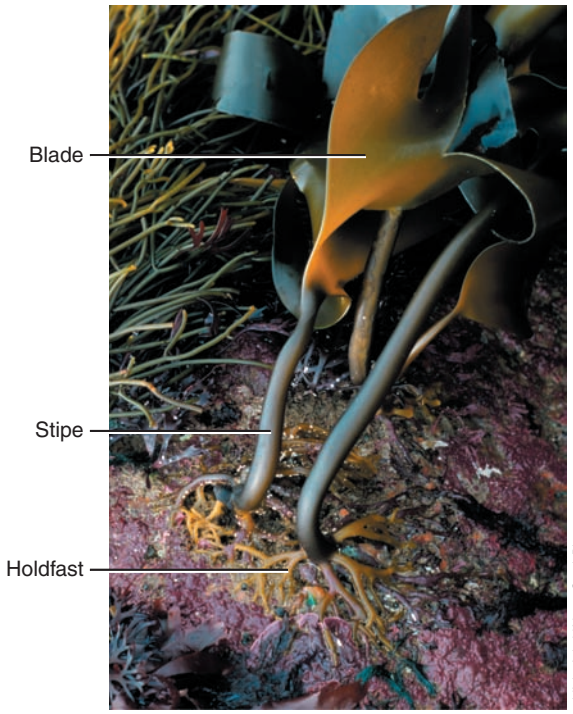
(b) Asexual reproduction in diatoms. After cell division, each new cell retains half of the original shell. The newly synthesized half of the shell always fits *inside* the original half. As a result, one of the new cells is slightly smaller than the other.

Figure 26-10 Diatoms

When diatoms die, their shells trickle to the ocean floor and accumulate in layers that eventually become sedimentary rock. After millions of years, geologic upheaval has exposed some of these deposits on land. Called *diatomaceous earth*, these deposits are mined and used as filtering, insulating, and soundproofing materials. As a filtering agent, diatomaceous earth is used to refine raw sugar and process vegetable oils. Because of its abrasive properties, diatomaceous earth is a common ingredient in scouring powders and metal polishes; it is no longer added to most toothpastes because it is too abrasive for tooth enamel. The intricately detailed diatom shells are often used to test microscope resolution down to 1 μm.

Brown algae are multicellular stramenopiles

Brown algae are the largest and most complex of all algae commonly called seaweeds. All brown algae are multicellular and range in size from a few centimeters (about an inch) to 75 m (about 260 ft). Their body forms are branched filaments; tufts; fleshy "ropes"; or thick, flattened branches. The largest brown algae, called *kelps*, are tough and leathery in appearance.



Many kelps have leaflike **blades** in which most photosynthesis occurs, stemlike **stipes**, and rootlike anchoring **holdfasts** (FIG. 26-11a). They often have gas-filled *bladders* that provide buoyancy. (The blades, stipes, and holdfasts of brown algae are not homologous to the leaves, stems, and roots of plants. Brown algae and plants arose from different unicellular ancestors, as shown in Figure 26-3.)

Reproduction is varied and complex in the brown algae. Their reproductive cells, both asexual zoospores and sexual gametes, are usually biflagellate. Most have a life cycle that exhibits **alternation of generations**, in which they spend part of their life as multicellular haploid organisms and part as multicellular diploid organisms (see Fig. 10-19c).

Brown algae are commercially important for several reasons. Their cell walls contain a polysaccharide called *algin* that is harvested from kelps such as *Macrocystis* and used as a thickening and stabilizing agent in ice cream, toothpaste, shaving cream, hair spray, and hand lotion. Brown algae are an important human food, particularly in eastern Asia, and they are rich sources of certain vitamins and minerals such as iodine.

(b) A kelp (*Macrocystis pyrifera*) bed is ecologically important to aquatic organisms, including the sea lion shown here. Photographed off the coast of California.

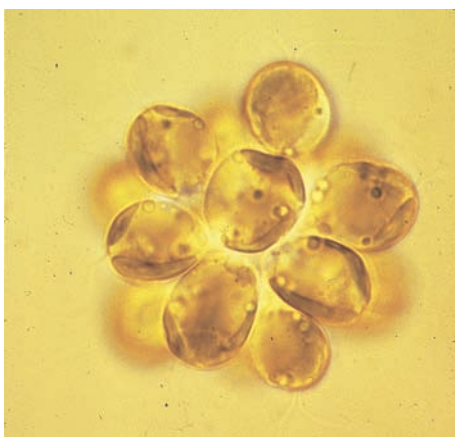

Figure 26-11 Brown algae

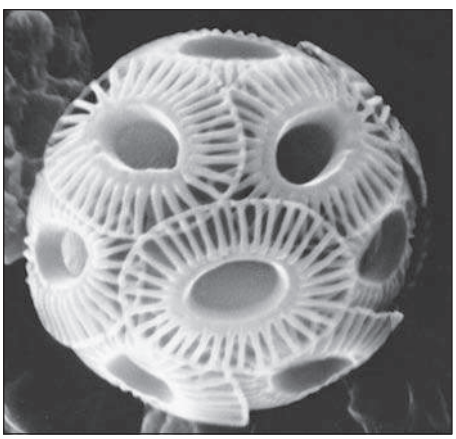
Brown algae are common in cooler marine waters, especially along rocky coastlines, where they live mainly in the intertidal zone or relatively shallow offshore waters. Kelps form extensive underwater "forests," or kelp beds (FIG. 26-11b). They are essential in that ecosystem as important food producers, and they provide habitat for many marine invertebrates, fishes, and mammals. The diversity of life supported by kelp beds rivals that found in coral reefs.

Most golden algae are unicellular biflagellates



Golden algae are found in both freshwater and marine environments. Most species are biflagellate, unicellular organisms, although some are colonial (FIG. 26-12a). A few of these stramenopiles lack flagella and are similar to amoebas in appearance except that golden algae contain chloroplasts. Tiny scales of either silica or calcium carbonate may cover the cells. Reproduction in golden algae is primarily asexual and involves the production of biflagellate, motile *zoospores*.

Most golden algae are photosynthetic, and the pigment composition of golden algae gives them a golden or golden brown color. A few species ingest bacteria and other particles of food. Ecologically, golden algae are important producers in marine environments. They compose a significant portion of the ocean's **nanoplankton**, extremely minute algae (2 to 10 μm) that are major producers because of their great abundance.

Classification of golden algae is controversial. Some biologists lump diatoms and golden algae in a single phylum, whereas others classify both groups as brown algae. At the other extreme, some biologists divide the golden algae into two phyla by placing many of the marine species, such as *coccolithophorids* (FIG. 26-12b), in a separate phylum.

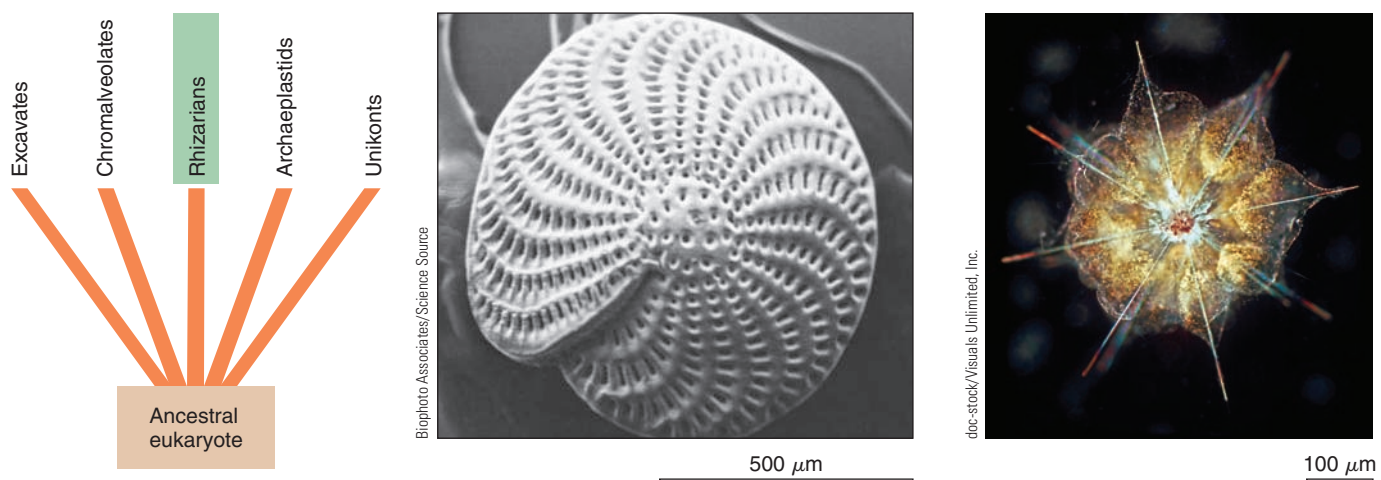
- Why do some biologists think that the apicomplexans descended from dinoflagellates?
- Which water mold has influenced human history? Explain your answer.
- What is the ecological significance of the diatoms? The brown algae?

26.5 Rhizarians

LEARNING OBJECTIVE

8 Describe the forams and actinopods, and explain why many biologists classify them in the rhizarian supergroup.

Rhizarians are a diverse supergroup of amoeboid cells that often have hard outer shells, called **tests**, through which cytoplasmic projections extend. The threadlike cytoplasmic projections suggest the name *rhizarian*, from the Greek *rhiza*, meaning "root." Forams and actinopods are rhizarians, as are certain shell-less amoebas. Not all amoebas are rhizarians, however, and many amoeba species are more closely related to other eukaryotic clades. Current molecular evidence indicates that the rhizarian supergroup is monophyletic.



Forams extend cytoplasmic projections that form a threadlike, interconnected net

Almost all **foraminiferans (forams)** are marine rhizarians that produce elaborate tests (FIG 26-13a). The ocean contains enormous numbers of forams, which secrete chalky, many-chambered tests with pores through which cytoplasmic projections are extended. (*Foraminifera* is derived from the Latin for "bearing openings.") The cytoplasmic projections form a sticky, interconnected net that entangles prey. Many forams contain unicellular algal endosymbionts (green algae, red algae, or diatoms) that provide food by photosynthesis. Many foram species live on the ocean floor, but others are part of the plankton.

Dead forams settle on the bottom of the ocean, where their tests form a gray mud that is gradually transformed into chalk. With geologic uplifting, these chalk formations become part of the land, as in the White Cliffs of Dover in England. (The White Cliffs of Dover are the remains of a variety of carbonate organisms, not only forams.) Because foram tests often appear in rock layers covering oil deposits, geologists exploring for oil look for foram tests in rock strata. Forams are well preserved in the fossil record, and biologists use some as **index fossils**, markers to help identify ancient sedimentary rock layers (see Chapter 18).

Actinopods project slender axopods

Actinopods are mostly marine plankton rhizarians with long, filamentous cytoplasmic projections called **axopods** that protrude through pores in their shells (FIG. 26-13b). A cluster of

microtubules strengthens each axopod. Unicellular algae and other prey become entangled in these axopods and are engulfed outside the main body of the actinopod; cytoplasmic streaming carries the prey inside the body. Many actinopods contain algal endosymbionts that provide them with the products of photosynthesis.

Some actinopods, called **radiolarians**, secrete elaborate, beautiful glassy shells made of silica. Radiolarians are an important constituent of marine plankton. When radiolarians and other actinopods die, their shells settle and become an ooze (sediment) that may be several meters thick on the ocean floor.

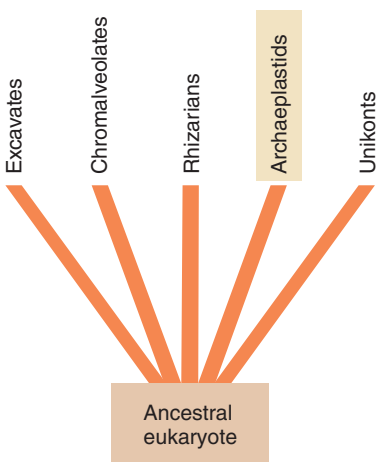
CHECKPOINT 26.5

- What character does the term rhizarian indicate about the forams and actinopods?

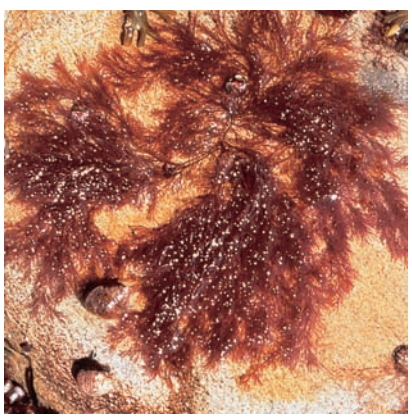
26.6 Archaeplastids

LEARNING OBJECTIVE

9 Describe evidence supporting the hypothesis that red algae and green algae should be included in a monophyletic group with land plants.



In the classification scheme adopted in this text, the monophyletic group of **archaeplastids** includes red algae and green algae, which are discussed here, and land plants, which are in a separate kingdom (see Chapters 27 and 28). Biologists classify these groups together based on molecular data and on the presence of chloroplasts bounded by outer and inner membranes, suggesting that they developed directly from a cyanobacterial endosymbiont. All photosynthetic protists other than archaeplastids have plastids surrounded by three or four membranes.



Red algae do not produce motile cells

The vast majority of **red algae** are multicellular organisms, although there are a few unicellular species. The multicellular body form of red algae commonly consists of complex, interwoven filaments that are delicate and feathery (FIG. 26-14a); a few red algae are flattened sheets of cells. Most multicellular red algae attach to rocks or other substrates by a basal holdfast. Reproduction in the red algae is remarkably complex, with an alternation of sexual and asexual stages. No flagellate cells develop during the life cycle. Some unicellular red algae may exhibit unusual features. For example, in 2013 a team of scientists working in the United States, Germany, and France reported on the genome of a unicellular extremophilic red alga adapted to toxic hot sulfur springs. The genome includes at least 75 genes acquired from archaea and bacteria needed for this extreme lifestyle, providing a striking example of horizontal gene transfer involving a eukaryote. (See Chapter 23 and Figure 23-4 for a discussion of the evolutionary significance of horizontal gene transfer.)

Red algae primarily live in warm tropical ocean waters, although a few species occur in fresh water and in soil. Some red algae, known as *coralline algae*, incorporate calcium carbonate in their cell walls from the ocean water (FIG. 26-14b). The hard calcium carbonate may protect coralline algae from the rigors of wave action. These coralline red algae build "coral" reefs and are perhaps as crucial as coral animals in this process.

The cell walls of red algae often contain thick, sticky polysaccharides that have commercial value. For example, *agar* is a polysaccharide extracted from certain red algae used as a food thickener and culture medium, a substrate on which to grow microorganisms and propagate some plants, such as

Philip Sze / Visuals Unlimited, Inc.

(a) *Polysiphonia*, which is widely distributed throughout the world, has a highly branched body of interwoven filaments.

(c) *Chara*, a green alga commonly called a stonewort, is closely related to land plants. *Chara* is widely distributed in fresh water.

Figure 26-15 Green algae

orchids. Another polysaccharide extracted from red algae, *carrageenan*, is a food additive used to stabilize chocolate milk; it also provides a thick, creamy texture to ice cream and other soft processed foods. Carrageenan is also used to stabilize paints and cosmetics. Red algae are a source of vitamins (particularly A and C) and minerals, especially in Japan and other eastern Asian countries where people eat red algae fresh, dried, or toasted in such traditional foods as sushi and nori.

Green algae share many similarities with land plants

Green algae have pigments, energy reserve products, and cell walls that are chemically identical to those of land plants. Green algae are photosynthetic, with chloroplasts of a wide variety of shapes. Most green algae have cell walls with cellulose, although some lack walls. Because of these and other similarities, biologists generally accept that land plants arose from ancestral green algae (see Fig. 26-3). Based on recent molecular and ultrastructure data, some biologists classify this diverse group in the plant kingdom.

Green algae exhibit a variety of body types, from single cells to colonial forms, to coenocytic algae (multinucleate), to multicellular filaments and sheets (FIG. 26-15). The multicellular forms do not have cells differentiated into tissues, a characteristic that separates them from land plants. Most green algae have, or produce, flagellate cells during their life cycle, although a few are totally nonmotile.

Reproduction in the green algae is as varied as their body forms, with both sexual and asexual reproduction. Many green algae have life cycles with an alternation of multicellular haploid and multicellular diploid generations. Asexual reproduction is by mitosis and cell division in single cells or by fragmentation in multicellular forms. Many green algae produce spores asexually by mitosis; if these spores have flagella and are motile, they are called *zoospores* (FIG. 26-16). Sexual reproduction in the green algae involves gamete formation in unicellular **gametangia** (sing., *gametangium*), reproductive structures in which gametes are produced. Green algae are found in both aquatic and terrestrial environments. Aquatic green algae primarily inhabit fresh water, although there are many marine species. Terrestrial green algae are restricted to damp soil, cracks in tree bark, and other moist places. Many green algae are symbionts with other organisms; some live as endosymbionts in body cells of invertebrates, and a few grow together with fungi as "compound organisms" called *lichens* (discussed in Chapter 29). Regardless of where they live, green algae are ecologically important as producers.

CHECKPOINT 26.6

- Why do many biologists classify red algae and green algae with land plants?

26.7 Unikonts

LEARNING OBJECTIVE

10 Briefly describe and compare the following unikonts: amoebas, plasmodial slime molds, cellular slime molds, and choanoflagellates.

Unikonts are a supergroup composed of certain amoebas, plasmodial slime molds, cellular slime molds, choanoflagellates, fungi (discussed in Chapter 29), and animals (discussed in Chapters 30 through 32). Unikonts share a single posterior flagellum in flagellate cells such as sperm and motile spores, although some extant organisms in this supergroup have lost the flagellum. Many unikonts also have a single centriole.

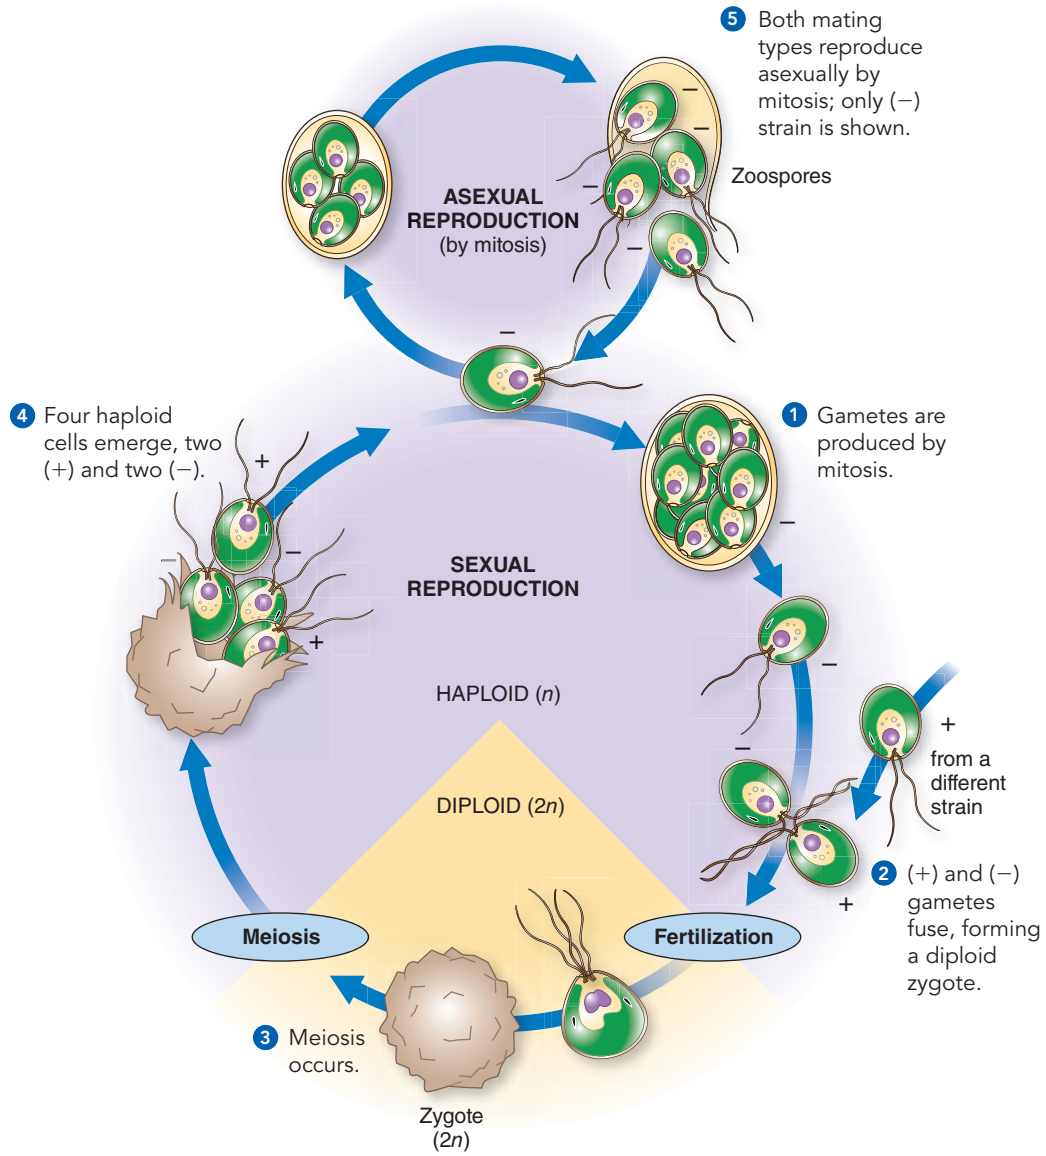

Figure 26-16 The life cycle of *Chlamydomonas*

Chlamydomonas is a unicellular, haploid green alga with two mating types, (+) and (–). The only diploid cell in the life cycle is the zygote.

Examine Figure 26-3 again and note that the unikonts are divided into two clades. One clade is the **opisthokonts**, which consist of fungi, choanoflagellates, and animals. You will learn more about the opisthokonts in Chapters 29 and 30.

Unikonts also have a **triple-gene fusion** that has major evolutionary significance. In a triple-gene fusion, three separate genes fused into a single unit early in the course of eukaryote evolution; the fused gene codes for a multienzyme protein. You may recall that Figure 26-3 showed all five supergroups branching from the same point, indicating that the branching order is unresolved. However, triple-gene fusion provides evidence of a bifurcation, or branch of the eukaryotes into two main clades, close to the root of the common ancestor of all eukaryotes (FIG 26-17). The two branches consist of (1) unikonts, which had a common ancestor with a single posterior flagellum; and (2) all other eukaryotes, collectively called **bikonts**, which had a common ancestor with two flagella.

Amoebozoa are unikonts with lobose pseudopodia

Most **amoebozoa** produce temporary cytoplasmic projections called **pseudopodia** (sing., *pseudopodium*, meaning "false foot") at some point in their life cycle. The pseudopodia of amoebozoa are *lobose*—that is, rounded and wide—as opposed to the slender cytoplasmic projections characteristic of rhizarians. Many biologists currently classify amoebas, plasmodial slime molds, and cellular slime molds as amoebozoa.

Key Experiment

How do we deduce details of eukaryote evolution near the root of the evolutionary tree?

HYPOTHESIS: Derived gene fusions, which have occurred rarely during the course of evolution, can provide insights into eukaryote evolutionary relationships.

EXPERIMENT: Alexandra Stechmann and Thomas Cavalier-Smith of Oxford University sequenced a double-gene fusion that codes for two enzymes: dihydrofolate reductase (DHFR) and thymidylate synthase (TS). In a second experiment, they sequenced a triple-fused gene involved in the enzymatic synthesis of pyrimidine nucleotides. They tested for the presence of these two gene fusions in various eukaryote groups as well as in bacteria and archaea.

RESULTS AND CONCLUSION: The double-gene fusion is present in all eukaryotes examined except for unikonts; bacteria and archaea also lack the double-gene fusion. The unikonts have the triple-gene fusion that is lacking in all other eukaryotes, bacteria, and archaea. These gene fusions suggest a fundamental division of eukaryotes into two main clades, the unikonts and all other eukaryotes, which are collectively called bikonts.

SOURCE: Stechmann, A., and T. Cavalier-Smith, "The Root of the Eukaryote Tree Pinpointed," *Current Biology*, Vol. 13 (2003): R665–R666.

CONNECT Are you a bikont or a unikont?

Amoebas move by forming pseudopodia **Amoebas** are unicellular amoebozoa found in soil, fresh water, the ocean, and other organisms (as parasites). Because of the extreme flexibility of their outer plasma membrane, many members of this group have an asymmetrical body form and continually change shape as they move. (The word *amoeba* derives from a Greek word meaning "change.") An amoeba moves by pushing out lobose pseudopodia from the surface of the cell. More cytoplasm flows into the pseudopodia, enlarging them until all the cytoplasm has entered and the organism as a whole has moved. Pseudopodia also capture and engulf food by surrounding and forming a vacuole around it (FIG. 26-18). Food particles are digested when the food vacuole fuses with a lysosome containing digestive enzymes. Digested materials are absorbed from the food vacuole, which gradually shrinks as it empties. Amoebas reproduce asexually, splitting into two equal parts after mitotic division of the nucleus; sexual reproduction has not been observed.

Parasitic amoebas include *Entamoeba histolytica*, which causes *amoebic dysentery*, a serious human intestinal disease characterized by severe diarrhea, bloody stools, and ulcers in the intestinal wall. In especially severe cases the organism spreads from the large intestine and causes abscesses in the liver, lungs, or brain. *Entamoeba histolytica* is transmitted as cysts in contaminated drinking water. A *cyst* is a thick-walled, resistant, resting stage in the life cycle of some protists. Other amoebas, such as *Acanthamoeba*, are usually free-living but produce opportunistic infections such as eye infections in wearers of contact lenses.

Plasmodial slime molds feed as multinucleate plasmodia The feeding stage of a **plasmodial slime mold** is a **plasmodium**, a multinucleate mass of cytoplasm that can grow up to 30 cm (1 ft) in diameter (FIG. 26-19a). The slimy plasmodium streams over damp, decaying logs and leaf litter, often forming a network of channels that covers a large surface area. As it creeps along, it ingests bacteria, yeasts, spores, and decaying organic matter.

When the food supply dwindles or there is insufficient moisture, the plasmodium crawls to an exposed surface and starts reproducing. Stalked structures of intricate complexity and beauty usually form from the drying plasmodium (FIG. 26-19b). Within these structures, called **sporangia**, meiosis produces haploid spores that are extremely resistant to adverse environmental conditions.

When conditions become favorable, the spores germinate, and a haploid reproductive cell emerges from each. This haploid cell is either a biflagellate *swarm cell* or an amoeboid *myxamoeba*, depending on available moisture; flagellate cells form in wet conditions. Swarm cells and myxamoebas act as gametes, which fuse to form a zygote with a diploid nucleus. The resultant diploid nucleus divides many times by mitosis, but the cytoplasm does not divide, so the result is a multinucleate plasmodium.

The plasmodial slime mold *Physarum polycephalum* is a model organism that researchers use to study many fundamental biological processes, such as growth, cytoplasmic streaming, and the function of the cytoskeleton.

Cellular slime molds feed as individual amoeboid cells The **cellular slime molds** are amoebozoa with close affinities to amoebas and plasmodial slime molds. During its feeding stage, each cellular slime mold is an individual amoeboid cell that behaves as a separate, solitary organism (FIG. 26-20). Each cell creeps over rotting logs and soil or swims in fresh water, ingesting bacteria and other particles of food as it goes. Each amoeboid cell has a haploid nucleus and reproduces by mitosis, as a true amoeba does.

When moisture or food becomes inadequate, certain cells send out a chemical signal, cyclic adenosine monophosphate (cAMP; see Fig. 3-26), that causes them to aggregate by the hundreds or thousands. During this stage the cells creep about

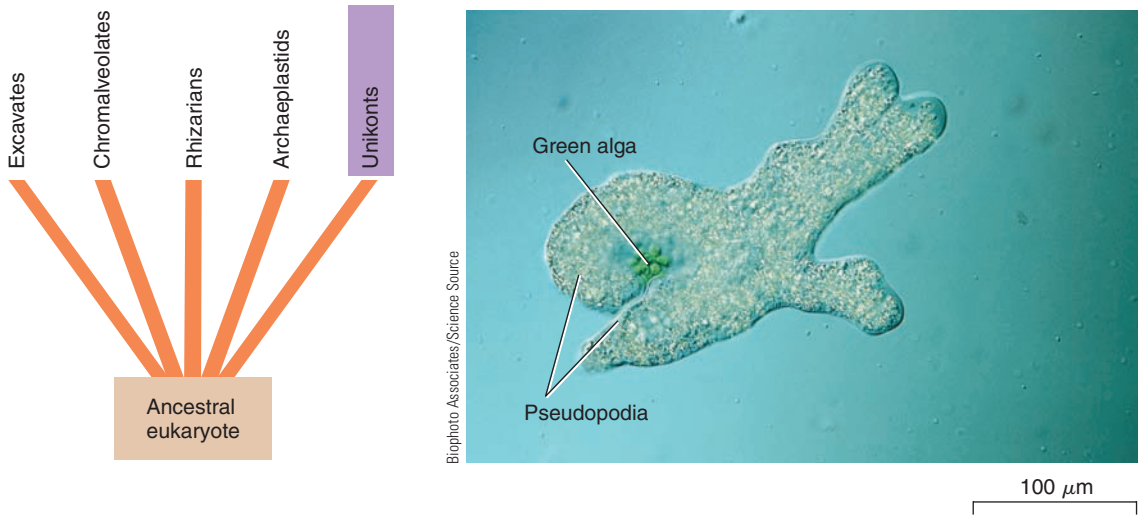

Figure 26-18 Amoeba

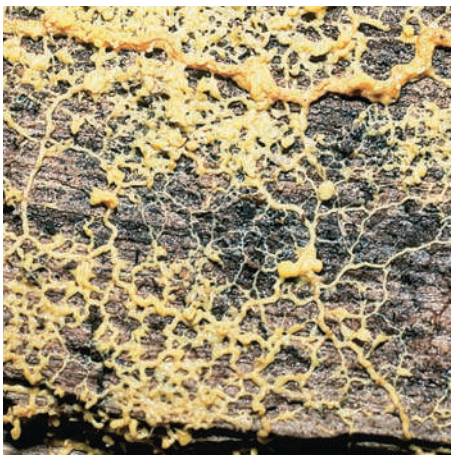
LM of a giant amoeba (*Chaos carolinense*). This unicellular protist, which moves and feeds by pseudopodia, is surrounding and ingesting a colonial green alga. *Chaos* amoebas are generally scavengers that feed on debris in freshwater habitats, but they ingest living organisms when the opportunity arises.



for short distances as a single multicellular aggregate, or slug. Each cell of the slug retains its plasma membrane and individual identity. Eventually, the slug settles and reorganizes, forming a stalked fruiting body containing spores. After being released each spore opens, and a single haploid amoeboid cell—the feeding stage—emerges. The spore-forming reproductive cycle is asexual, although sexual reproduction is observed occasionally. The life cycles of most cellular slime molds lack a flagellate stage.

The cellular slime mold *Dictyostelium discoideum* is a model organism for the study of cell differentiation, cell communication, and cell motility and adhesion. Its biology has been studied intensively, particularly as it relates to **cell signaling** molecules, such as cAMP, which are found in many organisms in addition to the cellular slime molds (see Chapter 6).

Choanoflagellates are opisthokonts closely related to animals

Choanoflagellates are collared flagellates in the opisthokont clade, which also includes fungi and animals. These small, inconspicuous unikonts are found globally in both freshwater and marine environments. Choanoflagellates include both free-swimming and **sessile** species that are permanently attached by a thin stalk to bacteria-rich debris. Their single flagellum is surrounded at its base by a delicate collar of microvilli that trap food (FIG. 26-21).

Choanoflagellates are of special interest because of their striking resemblance to collar cells in sponges (see Fig. 31-1b). Other animal phyla, such as cnidarians, flatworms, and echinoderms, also contain choanoflagellate-like cells, but no other group of protists has been observed to possess these cells. Evidence supporting the close relationship

(a) The brightly pigmented plasmodium, shown on a dead log, feeds on bacteria and other microorganisms.

(b) The reproductive structures are sporangia on stalks.

Figure 26-19 The plasmodial slime mold *Physarum polycephalum*

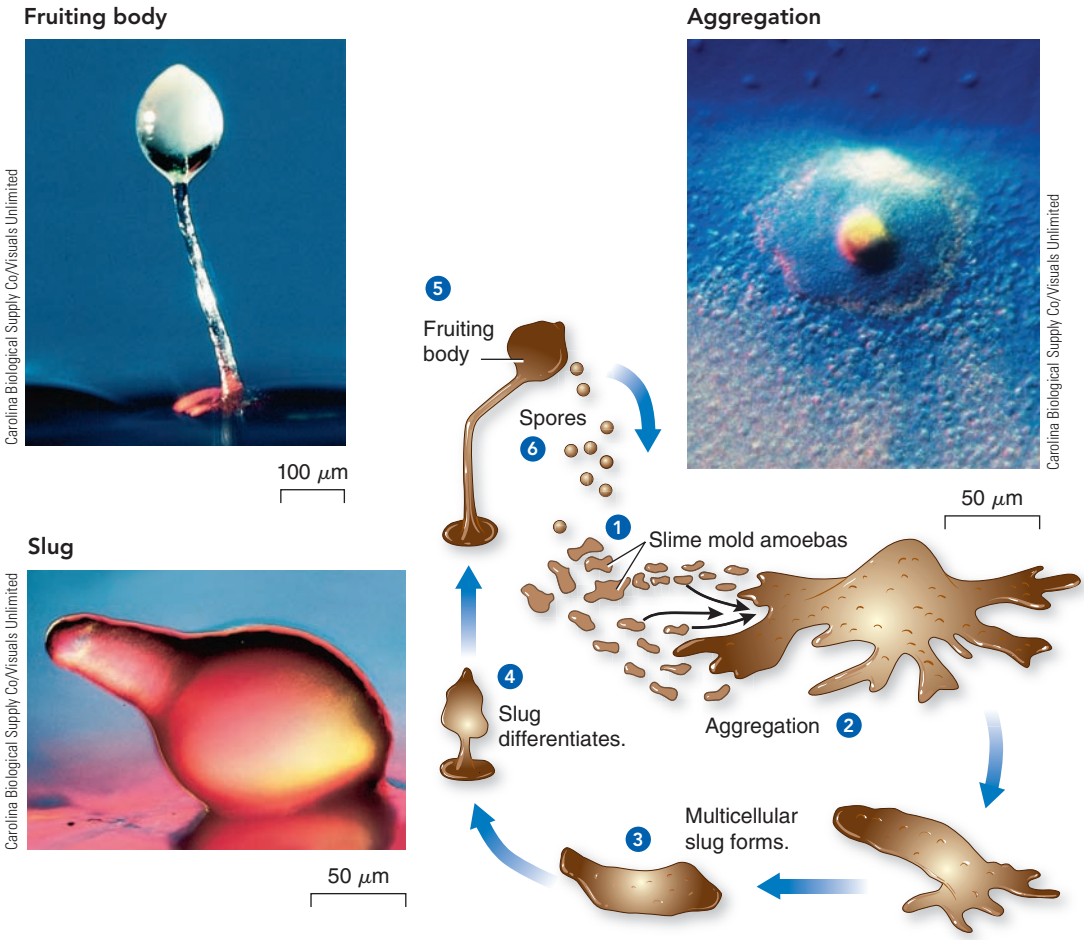

Figure 26-20 The cellular slime mold *Dictyostelium discoideum*

Slime mold amoebas ingest food, grow, and reproduce by cell division. After their food is depleted, hundreds of amoeboid cells stream together (*inset in upper right*) and form a migrating slug-like aggregate (*inset in lower left*). When it stops migrating, the aggregate forms a fruiting body on a stalk (*inset in upper left*). The fruiting body releases spores, each of which opens in a favorable environment to liberate an amoeboid cell.

between choanoflagellates and animals includes comparative DNA sequence data of mitochondrial and nuclear genes. Given the similarities in structure and molecular genomics that has accumulated in recent years, many biologists hypothesize that choanoflagellates are the closest living non-animal relative of animals. Thus, living choanoflagellates and animals probably share a common choanoflagellate-like ancestor.

CHECKPOINT 26.7

- What features distinguish the amoebozoa from the rhizarians?
- **CONNECT** Which group of unikonts is structurally and genetically most similar to animals?

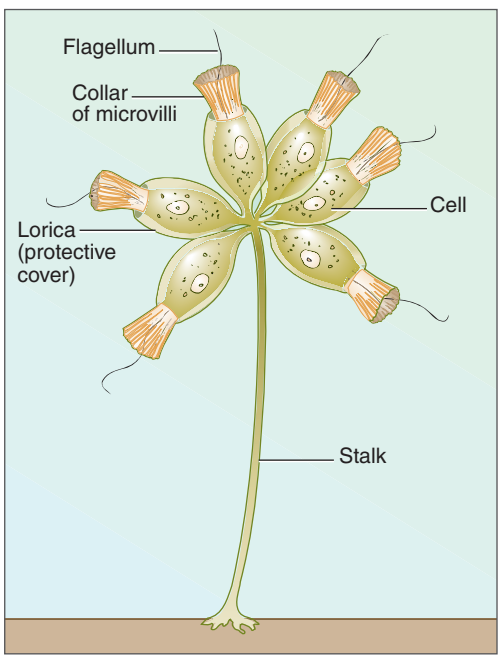

Figure 26-21 Choanoflagellates

Choanoflagellates are free-living flagellates that obtain food by waving their flagella, causing water currents to carry bacteria and other small particles of food into the collar of microvilli. A colonial form is shown. Each cell is 5 to 10 μm long, not including the flagellum.

Summary: Focus on Learning Objectives

26.1 Diversity in the Protists *(page 540)*

1 Discuss in general terms the diversity inherent in protists, including means of locomotion, modes of nutrition, interactions with other organisms, habitats, and modes of reproduction.

- Protists have various means of locomotion, including **pseudopodia**, **flagella**, and **cilia**; a few are nonmotile.

- Protists obtain their nutrients autotrophically or heterotrophically. Protists are free-living or symbiotic, with symbiotic relationships ranging from **mutualism** to **parasitism**.
- Most protists live in the ocean or in freshwater ponds, lakes, and streams. Parasitic protists live in the body fluids or cells of their hosts.
- Many protists reproduce both sexually and asexually; others reproduce only asexually.

26.2 How Did Eukaryotes Evolve? *(page 541)*

2 Discuss the hypothesis of serial endosymbiosis and briefly explain some of the evidence that supports it.

- According to the hypothesis of **serial endosymbiosis**, mitochondria and chloroplasts arose from symbiotic relationships between larger cells and the smaller bacteria that were incorporated and lived within them.
- Chloroplasts of red algae, green algae, and plants probably arose in a single primary endosymbiotic event in which a cyanobacterium was incorporated into a cell. Multiple secondary endosymbioses led to chloroplasts in euglenoids, dinoflagellates, diatoms, golden algae, and brown algae and to the nonfunctional chloroplasts in apicomplexans.

3 Describe the kinds of data biologists use to classify eukaryotes.

- Relationships among protists are determined largely by **ultrastructure**, which is the fine details of cell structure revealed by electron microscopy, and by comparative molecular data. Biologists have compared nuclear genes, many of which code for proteins, in different protist taxa.

26.3 Excavates *(page 544)*

4 Summarize the basic features of excavates and distinguish among diplomonads, parabasilids, and euglenoids.

- **Excavates** are a diverse group of unicellular protists with flagella, an excavated oral groove, and atypical, greatly modified mitochondria. The inclusion of diplomonads, parabasalids, and euglenoids in the excavate superfamily is controversial.
- **Diplomonads** are excavates with one or two nuclei, no functional mitochondria, no Golgi complex, and up to eight flagella.
- **Parabasilids** are anaerobic, flagellated excavates that often live in animals. Trichonymphs and trichomonads are examples of parabasilids.
- **Euglenoids** are unicellular and flagellate. Some euglenoids are photosynthetic.

26.4 Chromalveolates *(page 546)*

5 Contrast the two main groups of chromalveolates: alveolates and stramenopiles.

- **Chromalveolates** probably originated as a result of secondary endosymbiosis in which an ancestral cell engulfed a red alga. Some DNA sequence data suggest that the chromalveolates are not monophyletic.
- **Alveolates** have similar ribosomal DNA sequences and alveoli, flattened vesicles located just inside the plasma membrane. Most **stramenopiles** have motile cells with two flagella, one of which has tiny hairlike projections off the shaft.

6 Distinguish among the alveolates: dinoflagellates, apicomplexans, and ciliates.

- **Dinoflagellates** are mostly unicellular, biflagellate, photosynthetic alveolates of great ecological importance as producers in marine ecosystems. Their **alveoli**, flattened vesicles under the plasma membrane, often contain cellulose plates impregnated with silicates. Some dinoflagellates produce toxic blooms known as **red tides**.
- **Apicomplexans** are parasites that produce **sporozoites** and are nonmotile. An apical complex of microtubules attaches the apicomplexan to its host cell. The apicomplexan *Plasmodium* causes malaria.
- **Ciliates** are alveolates that move by hairlike cilia, have **micronuclei** (for sexual reproduction) and **macronuclei** (for controlling cell metabolism and growth), and undergo a sexual process called **conjugation**.

7 Distinguish among the stramenopiles: water molds, diatoms, golden algae, and brown algae.

- **Water molds** have a coenocytic **mycelium**. They reproduce asexually by forming biflagellate **zoospores** and sexually by forming **oospores**.
- **Diatoms** are mostly unicellular, with shells containing silica. Some diatoms are part of floating **plankton**, and others live on rocks and sediments where they move by gliding.
- **Brown algae** are multicellular stramenopiles that are ecologically important in cooler ocean waters. The largest brown algae (kelps) possess leaflike **blades**, stemlike **stipes**, anchoring **holdfasts**, and gas-filled bladders for buoyancy.
- **Golden algae** are mostly unicellular, biflagellate freshwater and marine stramenopiles that are of ecological importance as a component of the ocean's extremely minute **nanoplankton**.

26.5 Rhizarians *(page 553)*

8 Describe the forams and actinopods, and explain why many biologists classify them in the rhizarian supergroup.

Copyright 2019 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in

Copyright 2019 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

- **Rhizarians** are amoeboid cells that often have hard outer shells, called **tests**, through which cytoplasmic projections extend; molecular evidence indicates that this group is monophyletic.
- **Forams** secrete many-chambered tests with pores through which cytoplasmic projections extend to move and obtain food.
- **Actinopods** are mostly marine plankton that obtain food by means of **axopods**, slender cytoplasmic projections that extend through pores in their shells.

26.6 Archaeplastids *(page 554)*

9 Describe evidence supporting the hypothesis that red algae and green algae should be included in a monophyletic group with land plants.

- Red algae, green algae, and land plants, collectively called **archaeplastids**, are considered a monophyletic group based on molecular data and on the presence of chloroplasts bounded by outer and inner membranes.
- **Red algae**, which are mostly multicellular seaweeds, are ecologically important in warm tropical ocean waters.
- **Green algae** exhibit a wide diversity in size, structural complexity, and reproduction. Botanists hypothesize that ancestral green algae gave rise to land plants.

26.7 Unikonts *(page 555)*

10 Briefly describe and compare the following unikonts: amoebas, plasmodial slime molds, cellular slime molds, and choanoflagellates.

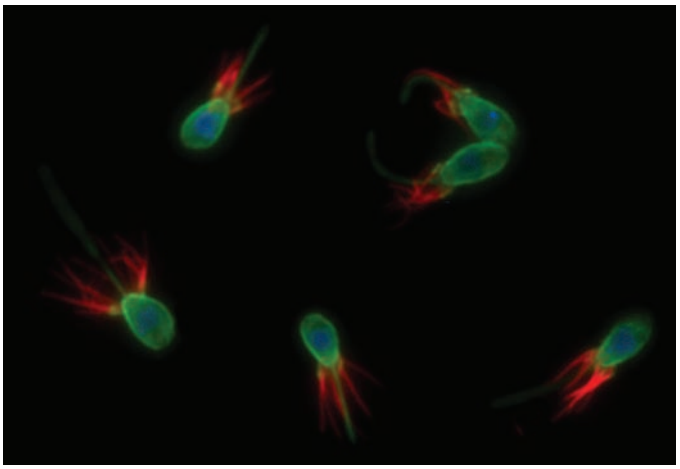
- **Unikonts** have a single posterior flagellum in flagellate cells.
- **Amoebas** move and obtain food using cytoplasmic extensions called pseudopodia.
- The feeding stage of **plasmodial slime molds** is a multinucleate **plasmodium**. Reproduction is by haploid spores produced within **sporangia**.
- **Cellular slime molds** feed as individual amoeboid cells. They reproduce by aggregating into an aggregate (slug) and then forming asexual spores.
- **Choanoflagellates** are unikonts that are probably the closest living nonanimal relative of animals. A collar of microvilli surrounds their single flagellum at its base. Choanoflagellates are included with animals in the **opisthokont** clade, which also includes fungi.

Test Your Understanding

Know and Comprehend

1. Which of the following is *not* true of the protists? (a) they are unicellular, colonial, coenocytic, or simple multicellular organisms (b) their cilia and flagella have a 9 + 2 arrangement of microtubules (c) they are prokaryotic, as bacteria and archaea are (d) some are free-living, and some are endosymbionts (e) most are aquatic and live in the ocean or in freshwater ponds
2. Molecular evidence supports the view that all plastids evolved from an ancient (a) cyanobacterium (b) archaean (c) diplomonad (d) apicomplexan (e) unikont
3. Forams (a) are endosymbionts that live in many marine invertebrates (b) were responsible for the Irish potato famine in the 19th century (c) secrete many-chambered tests with pores through which cytoplasmic extensions project (d) have numerous axopods that may aid in trapping and holding prey (e) have numerous cilia to direct food into the oral groove
4. *Paramecium* and other ciliates often display a sexual phenomenon called (a) oogamy (b) conjugation (c) serial endosymbiosis (d) red tide (e) alternation of generations
5. Parasitic alveolates that form spores at some stage in their life belong to which group? (a) actinopods (b) ciliates (c) coccolithophorids (d) apicomplexans (e) dinoflagellates
6. Malaria (a) is transmitted by the bite of a female tsetse fly (b) is caused by a parasitic flagellate, *Giardia intestinalis* (c) is a serious form of amoebic dysentery caused by *Entamoeba histolytica* (d) is caused by an apicomplexan that spends part of its life cycle in the *Anopheles* mosquito and part in humans (e) is transmitted when people drink water tainted by a red tide
7. Photosynthetic protists with shells composed of two halves that fit together like a petri dish are (a) golden algae (b) diatoms (c) euglenoids (d) brown algae (e) forams
8. The pigments, energy reserve products, and cell walls found in land plants are also characteristic of (a) green algae (b) brown algae (c) golden algae (d) diatoms (e) euglenoids and diatoms
9. Kelps are _____ with multicellular bodies differentiated into blades, stipes, holdfasts, and gas-filled floats. (a) golden algae (b) diatoms (c) euglenoids (d) brown algae (e) red algae
10. Cellular slime molds (a) include *Physarum* and *Phytophthora* (b) are more closely related to bacteria than are any other protists (c) are responsible for late blight of potatoes, which led to starvation in Ireland in the 1840s (d) have double-gene fusion (e) form a slug when cells aggregate in response to cyclic AMP
11. Water molds reproduce asexually by forming _____ and sexually by forming _____. (a) oospores; holdfasts (b) zoospores; zooxanthellae (c) zoospores; oospores (d) holdfasts; oospores (e) oospores; zoospores

Apply and Analyze



12. **VISUALIZE** Draw simple sketches of a *Euglena* and a *Paramecium*. Choose the appropriate structures for each organism from the following list and label them in your drawings: flagellum, cilia, chloroplast, mitochondrion, nucleus, macronucleus, micronucleus, contractile vacuole, pellicle, food vacuole.

27 Seedless Plants

About 445 million years ago (mya), planet Earth would have seemed an inhospitable place because even though life abounded in the ocean, it did not yet exist in abundance on land. Occasionally, perhaps, an animal would crawl out of the water onto land, but it never stayed there permanently because there was little to eat on land: not a single blade of grass, no fruit, and no seeds.

During the next 30 million years, a time corresponding roughly to the Silurian period in geologic time (see Table 21-1), plants appeared in abundance and colonized the land. Where did they come from? Although plants living today exhibit great diversity in size, form, and habitat (see photograph), biologists hypothesize that they all evolved from a common ancestor that was an ancient green alga.

Modern green algae share many biochemical and metabolic traits with modern plants. Both green algae and plants contain the same photosynthetic pigments: chlorophylls *a* and *b* and carotenoids, including xanthophylls (yellow pigments) and carotenes (orange pigments). Both store excess carbohydrates as starch and have cellulose as a major component of their cell walls. In addition, plants and some green algae share certain details of cell division, including formation of a cell plate during cytokinesis (see Chapter 10).

What exactly is a plant? A **plant** is a complex multicellular eukaryote that has cellulose cell walls, chlorophylls *a* and *b* in plastids, and starch as a storage product and that may have cells with two anterior flagella. In addition, all plants develop from multicellular *embryos* that are enclosed in maternal tissues; this last character is one that distinguishes plants from green algae. Many botanists refer to land plants as *embryophytes* because of this character.

Plants range in size from minute, almost microscopic duckweeds and water-meal to massive giant sequoias, some of the largest organisms that have ever lived. Plants include hundreds of thousands of species that live in varied habitats, from frozen arctic tundra to lush tropical rain forests to harsh deserts to moist stream banks.

KEY CONCEPTS

27.1 Adaptations of land plants include a waxy cuticle to prevent water loss; multicellular gametangia; stomata; and for most plants, vascular tissues containing lignin. Plants undergo an alternation of generations between multicellular gametophyte and sporophyte generations.

27.2 Mosses and other bryophytes lack vascular tissues and do not form true roots, stems, or leaves.

27.3 In club mosses and ferns, lignin-hardened vascular tissues that transport water and dissolved substances throughout the plant body have evolved.

PHOTO: Land plants. Note the ferns and the moss-covered tree trunk. Both mosses and ferns are seedless plants. Panoramic Images/Getty Images

27.1 Adaptations of Plants to Life on Land

LEARNING OBJECTIVES

1. Discuss some environmental challenges of living on land and describe how several plant adaptations meet these challenges.
2. Name the green algal group from which plants are hypothesized to have descended and describe supporting evidence.

How were plants modified during the transition from life in the water to life on land? What are some features of plants that have let them colonize so many types of environments? One important difference between plants and algae is that a waxy **cuticle** covers the aerial portion of a plant. Essential for existence on land, the cuticle helps prevent desiccation, or drying out, of plant tissues by evaporation. Plants that are adapted to moister habitats may have a very thin layer of wax, whereas those adapted to drier environments often have a thick, crusty cuticle. (Many desert plants also have a reduced surface area, particularly of leaves, which minimizes water loss.)

Plants obtain the carbon they need for photosynthesis from the atmosphere as carbon dioxide (CO_2). To be fixed into organic molecules such as sugar, CO_2 must first diffuse into the chloroplasts that are inside green plant cells. Because a waxy cuticle covers the external surfaces of leaves and stems, however, gas exchange through the cuticle between the atmosphere and the interior of cells is negligible. Tiny pores called **stomata** (sing., *stoma*), which dot the surfaces of leaves and stems of almost all plants, facilitate gas exchange.

The sex organs, or **gametangia** (sing., *gametangium*), of most plants are multicellular, whereas the gametangia of algae are unicellular (FIG. 27-1). Each plant gametangium has a layer of sterile (nonreproductive) cells that surrounds and protects the delicate gametes (eggs and sperm cells). In plants the fertilized egg develops into a multicellular **embryo** (young plant) within the female gametangium. Thus, the embryo is protected during its development. In algae the fertilized egg develops away from its gametangium; in some algae the gametes are released before fertilization, whereas in others the fertilized egg is released.

The plant life cycle alternates between haploid and diploid generations

Plants have a clearly defined **alternation of generations** in which they spend part of their lives in a multicellular haploid stage and part in a multicellular diploid stage (FIG. 27-2).[1] The haploid portion of the life cycle is called the **gametophyte generation** because it gives rise to haploid gametes by mitosis. When two gametes fuse, the diploid portion of the life cycle, called the **sporophyte generation**, begins. The sporophyte generation produces haploid spores by the process of meiosis; these spores represent the first stage in the gametophyte generation.

Let us examine alternation of generations more closely. The haploid gametophytes produce male gametangia, known as **antheridia** (sing., *antheridium*), in which sperm cells form (FIG. 27-3a). Gametophytes also produce female gametangia, known as **archegonia** (sing., *archegonium*), each bearing a single egg (FIG. 27-3b). Sperm cells reach the female gametangium in a variety of ways, and one sperm cell fertilizes the egg to form a **zygote**, or fertilized egg.

The diploid zygote is the first stage in the sporophyte generation. The zygote divides by mitosis and develops into a multicellular embryo, the young sporophyte plant. Embryo development takes place within the archegonium; thus, the embryo is protected as it develops. Eventually, the embryo grows into a mature sporophyte plant. The mature sporophyte has special cells called *sporogenous cells* (spore-producing cells, also called *spore mother cells*) that divide by meiosis to form haploid **spores**.

fertilization of egg by sperm cell → zygote → embryo → mature sporophyte plant → sporogenous cells → meiosis → spores

All plants produce spores by meiosis, in contrast with algae and fungi, which may produce spores by meiosis or mitosis. The spores represent the first stage in the gametophyte generation. Each spore divides by mitosis to produce a multicellular gametophyte, and the cycle continues. Plants therefore alternate between a haploid gametophyte generation and a diploid sporophyte generation.

spores → mature gametophyte plants → archegonia → eggs
mature gametophyte plants → antheridia → sperm cells

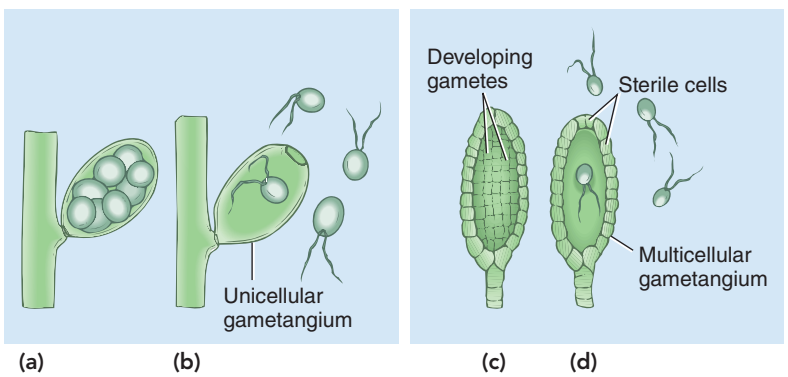

Figure 27-1 Generalized reproductive structures of algae and plants
(a, b) In algae, gametangia are generally unicellular. When the gametes are released, only the wall of the original cell remains. **(c, d)** In plants, the gametangia are multicellular, but only the inner cells become gametes. The gametes are surrounded by a protective layer of sterile (nonreproductive) cells.

[1] For convenience, we limit our discussion to plants that are not polyploid, although polyploidy is very common in land plants. We therefore use the terms *diploid* and $2n$ (and *haploid* and n) interchangeably, but these terms are not actually synonymous.

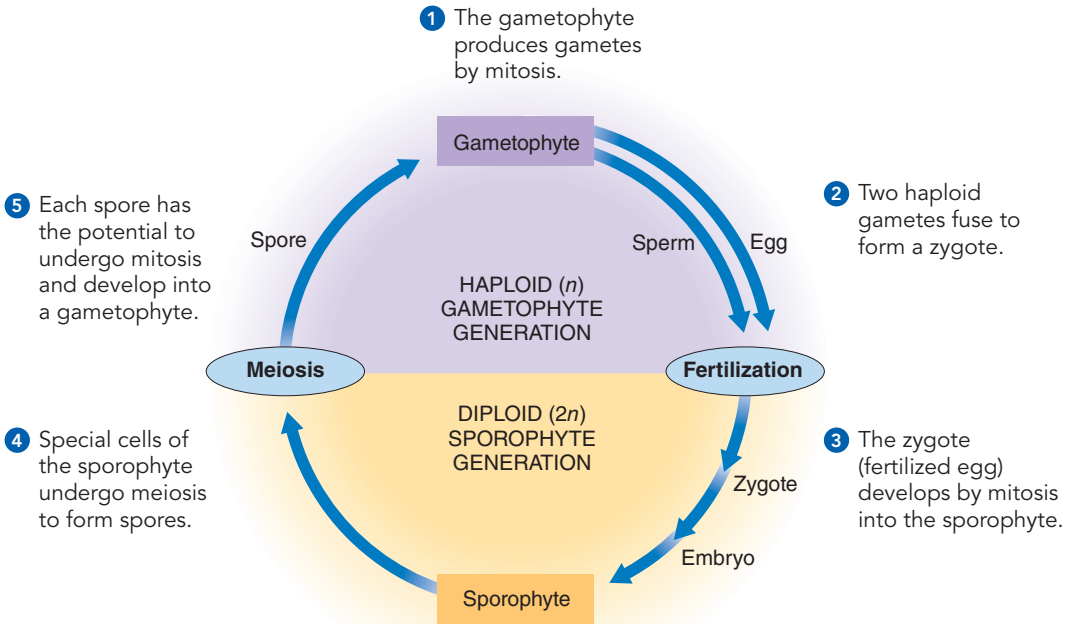
Key Point

Plants have an alternation of generations, spending part of the cycle in a haploid gametophyte stage and part in a diploid sporophyte stage.



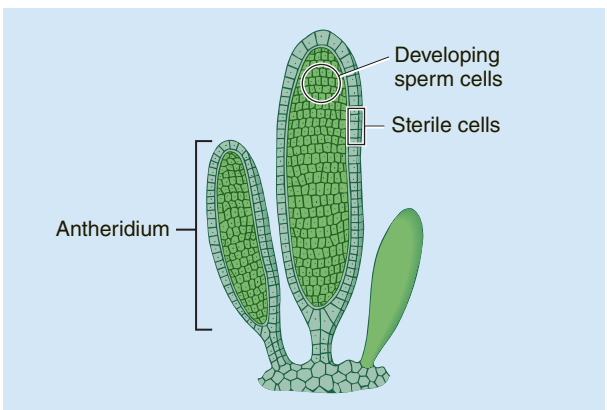


Figure 27-2 The basic plant life cycle

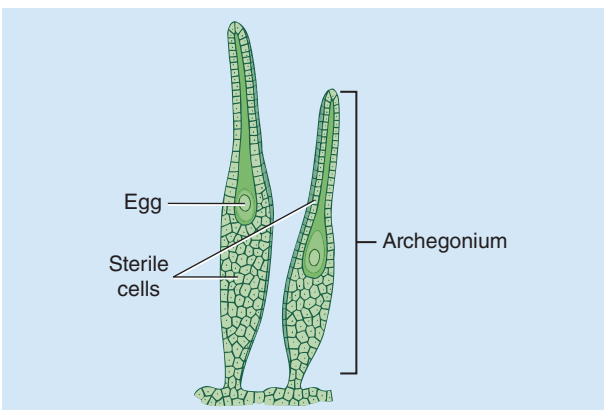
Depending on the plant group, the haploid or the diploid stage may be greatly enlarged or reduced; as you will learn, this fact has evolutionary significance.



CONNECT Do diploid cells undergo mitosis in this life cycle? haploid cells?

Four major groups of plants exist today

Structural and molecular data indicate that land plants probably descended from a group of green algae called **charophytes** or *stoneworts* (see Figure 26-15c, which shows a charophyte). Recall from Chapter 26 that red algae, green algae, and land plants are collectively classified as **archaeplastids**. Molecular comparisons, particularly of DNA and RNA sequences, provide compelling evidence that green algae are closely allied to plants (FIG. 27-4). These comparisons among plants and various green algae include sequences of chloroplast DNA, certain nuclear genes, and ribosomal RNA. In each case, the closest match

(a) Each antheridium, the male gametangium, produces numerous sperm cells.

(b) Each archegonium, the female gametangium, produces a single egg.

Figure 27-3 Plant gametangia

Shown are generalized moss gametangia.

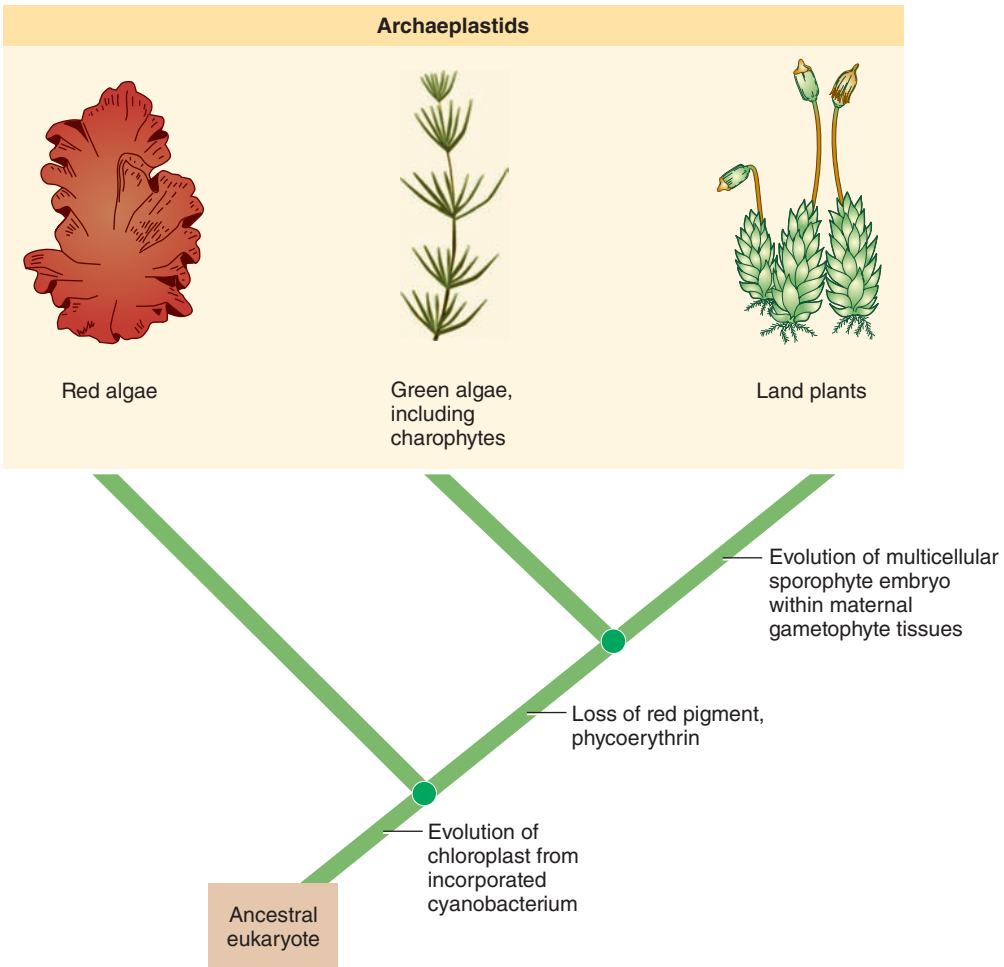

Figure 27-4 Evolution of land plants
Cladograms such as this one represent an emerging consensus that is open to change as new discoveries are made.

occurs between charophytes and plants, indicating that modern charophytes and plants probably share a recent common ancestor.

Plants consist of four major groups: bryophytes; seedless vascular plants; and two groups of seeded vascular plants, the gymnosperms and angiosperms (flowering plants). Their relationships are illustrated in FIGURE 27-5; see also TABLE 27-1, which is an overview of the ten extant (living) plant phyla.

The mosses and other bryophytes are small nonvascular plants that lack a specialized vascular, or conducting, system to transport nutrients, water, and essential minerals (inorganic nutrients) throughout the plant body. In the absence of such a system, bryophytes rely on diffusion and osmosis to obtain needed materials. This reliance means that bryophytes are restricted in size; if they were much larger, some of their cells could not obtain enough necessary materials. Bryophytes do not form seeds, the reproductive structures discussed in Chapter 28. Bryophytes reproduce and disperse primarily via haploid spores. Recent molecular and fossil evidence, discussed later in this chapter, suggests that bryophytes may have been the earliest plants to colonize land.

The other three groups of plants—seedless vascular plants, gymnosperms, and flowering plants—have vascular tissues and are thus known as vascular plants. The two vascular tissues are **xylem**, for conducting water and dissolved minerals, and **phloem**, for conducting dissolved organic molecules such as sugar. A key step in the evolution of vascular plants was the ability to produce **lignin**, a strengthening polymer in the walls of cells that function for support and conduction (see Chapter 33 for a discussion of plant cell wall chemistry, including lignin). The stiffening property of lignin enabled plants to grow tall, which let them maximize light interception. The successful occupation of the land by plants, in turn, made the evolution of terrestrial animals possible by providing them with both habitat and food.

Club mosses and ferns (which include whisk ferns and horsetails) are seedless vascular plants that, like the bryophytes, reproduce and disperse primarily via spores. Seedless vascular plants arose and diversified during the Silurian and Devonian periods of the Paleozoic era, between 444 mya and 359 mya. Club mosses and ferns extend back more than 420 million years and were of considerable importance as Earth's dominant

Key Point

Based on recent evidence, scientists are beginning to reach a consensus about the evolutionary relationships among living plants.

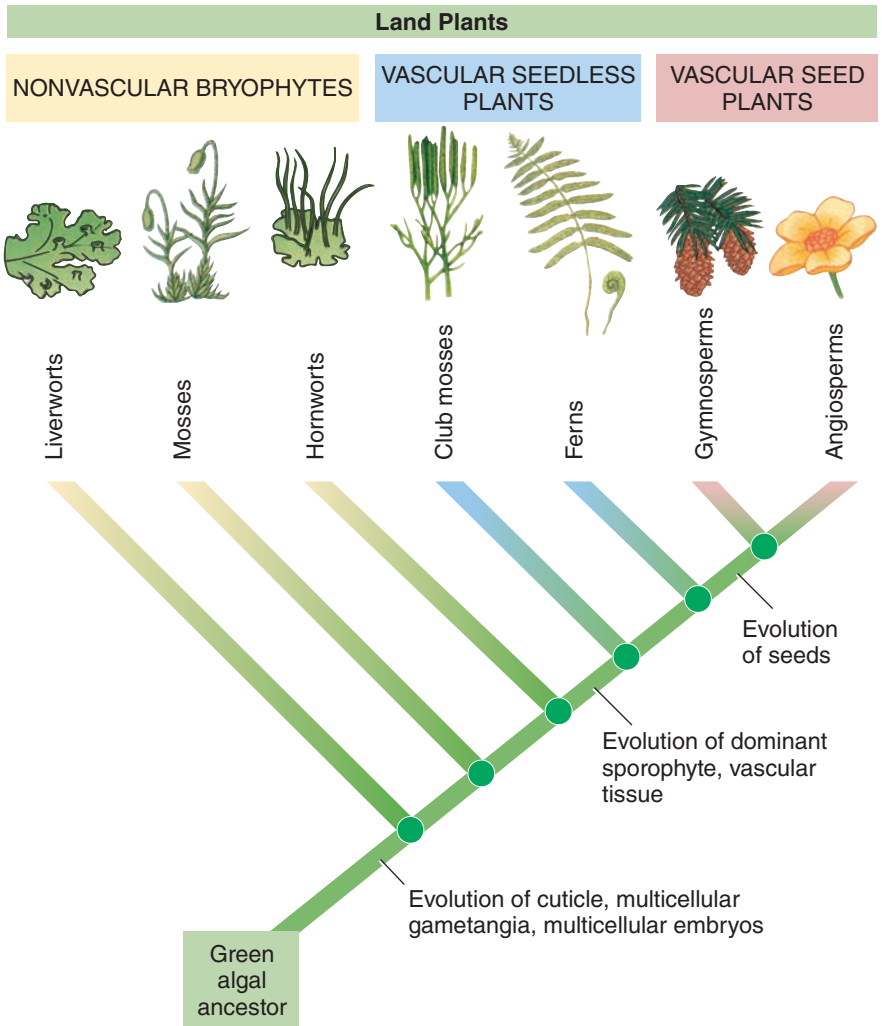

Figure 27-5 Plant evolution

The four major groups of plants are bryophytes, seedless vascular plants, and two groups of seed plants: gymnosperms and angiosperms. The seed plants are covered in Chapter 28.

CONNECT How does the cladogram relate to many botanists referring to land plants as embryophytes?

plants in past ages. Fossil evidence indicates that many species of these plants were the size of immense trees. Most living representatives of club mosses and ferns are small.

The gymnosperms are vascular plants that reproduce by forming seeds. Gymnosperms produce seeds borne exposed (unprotected) on a stem or in a cone. Plants with seeds as their primary means of reproduction and dispersal first appeared about 359 mya, at the end of the Devonian period. These early seed plants diversified into many varied species of gymnosperms.

The most recent plant group to appear is the flowering plants, or angiosperms, which arose during the early Cretaceous period of the Mesozoic era, about 130 mya. Like gymnosperms, flowering plants reproduce by forming seeds. Flowering plants, however, produce seeds enclosed within a fruit.

CHECKPOINT 27.1

- What are the most important environmental challenges that plants face living on land?
- What adaptations do plants have to meet these environmental challenges?
- What types of evidence support the hypothesis that land plants descended from the group of green algae known as charophytes?
- **VISUALIZE** Draw a simple diagram illustrating alternation of generations in plants, including the sporophyte and gametophyte generations, spores, gametes (eggs and sperm), meiosis, and fertilization. Be sure to indicate whether each generation or kind of cell is haploid or diploid.

Phylum Gnetophyta (gnetophytes)

Seeds enclosed within a fruit (angiosperms)

Phylum Anthophyta (angiosperms or flowering plants)
Class Eudicotyledones (eudicots)
Class Monocotyledones (monocots)

27.2 Bryophytes

LEARNING OBJECTIVES

3 Summarize the features that distinguish bryophytes from other plants.
4 Name and briefly describe the three phyla of bryophytes.
5 Describe the life cycle of mosses and compare their gametophyte and sporophyte generations.

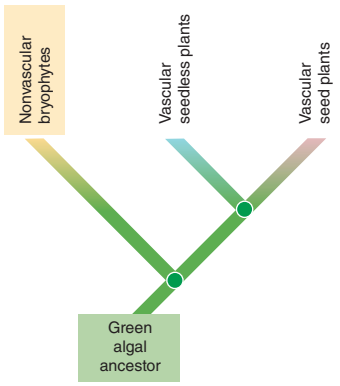
The **bryophytes** (from the Greek words meaning "moss plant") consist of about 16,000 species of mosses, liverworts, and hornworts; bryophytes are the only living nonvascular plants (TABLE 27-2). Because they have no means for extensive internal transport of water, sugar, and essential minerals, bryophytes are typically small. They generally require a moist environment for active growth and reproduction, but some bryophytes tolerate dry areas.

The bryophytes are divided into three distinct phyla: mosses (phylum Bryophyta), liverworts (phylum Hepatophyta), and hornworts (phylum Anthocerophyta). These three groups differ in many ways and may or may not be closely related. They are usually studied together because they lack vascular tissues and have similar life cycles.

Moss gametophytes are differentiated into "leaves" and "stems"

Mosses (phylum Bryophyta), which include about 9900 species, usually live in dense colonies or beds (FIG. 27-6). Each individual gametophyte plant has tiny, hairlike absorptive structures called *rhizoids* and an upright, stemlike structure that bears leaflike blades, each normally consisting of a single layer of undifferentiated cells except at the midrib. Because mosses lack vascular tissues, they do not have true roots, stems, or leaves; the moss structures are not homologous to roots, stems, or leaves in vascular plants. Some moss species have water-conducting cells and sugar-conducting cells, although these cells are not lignified, nor are they as specialized or effective as the conducting cells of vascular plants.

Alternation of generations is clearly defined in the life cycle of mosses (FIG. 27-7). The green moss gametophyte often bears its gametangia at the top of the plant. Many moss species have separate sexes: male plants that bear antheridia and female plants that bear archegonia. Other mosses produce antheridia and archegonia on the same plant.



Fertilization occurs when one of the sperm cells fuses with the egg within the archegonium. Sperm cells, which have flagella, are transported from antheridium to archegonium by flowing water, such as splashing rain droplets. A raindrop lands on the top of a male gametophyte, and sperm cells are released into it from the antheridia. Another raindrop landing on the male plant may splash the sperm-laden droplet into the air and onto the top of a nearby female plant. Alternatively, arthropods such as insects and mites may touch the

Table 27-2 A Comparison of Major Groups of Seedless Plants

Plant Group	Dominant Stage of Life Cycle	Representative Genera
NONVASCULAR; REPRODUCE BY SPORES (BRYOPHYTES)		
Liverworts (phylum Hepatophyta)	Gametophyte: thalloid or leafy plant	*Marchantia*
Mosses (phylum Bryophyta)	Gametophyte: leafy plant	*Polytrichum, Sphagnum, Physcomitrella*
Hornworts (phylum Anthocerophyta)	Gametophyte: thalloid plant	*Anthoceros*
VASCULAR; REPRODUCE BY SPORES		
Club mosses (phylum Lycopodiophyta)	Sporophyte: roots, rhizomes, erect stems, and leaves (microphylls)	*Lycopodium, Selaginella*
Ferns (phylum Pteridophyta)	Sporophyte: roots, rhizomes, and leaves (megaphylls)	*Pteridium, Polystichum, Azolla, Platycerium*
Whisk ferns (phylum Pteridophyta)	Sporophyte: rhizomes and erect stems; no true roots or leaves	*Psilotum*
Horsetails (phylum Pteridophyta)	Sporophyte: roots, rhizomes, erect stems, and leaves (reduced megaphylls)	*Equisetum*

Figure 27-6 Bryophytes: mosses

sperm-laden fluid and inadvertently carry it for considerable distances. Once in a film of water on the female moss, a sperm cell swims into the archegonium, which secretes chemicals to attract and guide the sperm cells, and fuses with the egg.

The diploid zygote, formed by fertilization, grows by mitosis into a multicellular embryo that develops into a mature moss sporophyte. This sporophyte grows out of the top of the female gametophyte and remains attached and nutritionally dependent on the gametophyte throughout its existence (see Fig. 27-6b). Initially green and photosynthetic, the sporophyte becomes golden brown at maturity. It consists of three main parts: a *foot*, which anchors the sporophyte to the gametophyte and absorbs minerals and nutrients from it; a *seta*, or stalk; and a *capsule*, which contains sporogenous cells (spore mother cells). The capsule of some species is covered by a caplike structure, the *calyptra*, which is derived from the archegonium.

The sporogenous cells undergo meiosis to form haploid spores. When the spores are mature, the capsule opens and releases them, and they are then transported by wind or rain. If a moss spore lands in a suitable spot, it germinates and grows into a filament of cells called a **protonema**. The protonema, which superficially resembles a filamentous green alga, forms buds, each of which grows into a green gametophyte, and the life cycle continues.

Biologists consider the haploid gametophyte generation the dominant generation in mosses because it lives independently of the diploid sporophyte. In contrast, the moss sporophyte is attached to and nutritionally dependent on the gametophyte.

Mosses make up an inconspicuous but significant part of their environment. They play an important role in forming soil. Mosses, which form mats that cover the rock, eventually die, forming a thin layer of organic matter in which grasses and other plants can grow. Because they grow tightly packed in dense colonies, mosses hold soil in place and help prevent erosion. At the same time, they retain moisture that they and other organisms need. Waxwings and other birds use moss, along with twigs and grass, as nesting material.

Commercially, the most important mosses are the peat mosses in the genus *Sphagnum*. One of the distinctive features of *Sphagnum* "leaves" is the presence of many large, empty cells that absorb and hold water. This feature makes peat moss a useful packing material for shipping live plants as well as a good soil conditioner. Added to sandy soils, for example, peat moss helps absorb and retain moisture.

The acidic and anaerobic conditions of a peat bog retard the growth of bacterial and fungal decomposers. As a result, dead peat mosses accumulate as thick deposits—some several meters in depth—under the growing mat of living peat mosses.

Key Point

The dominant phase in the life cycle of mosses, like that of other bryophytes, is the gametophyte.

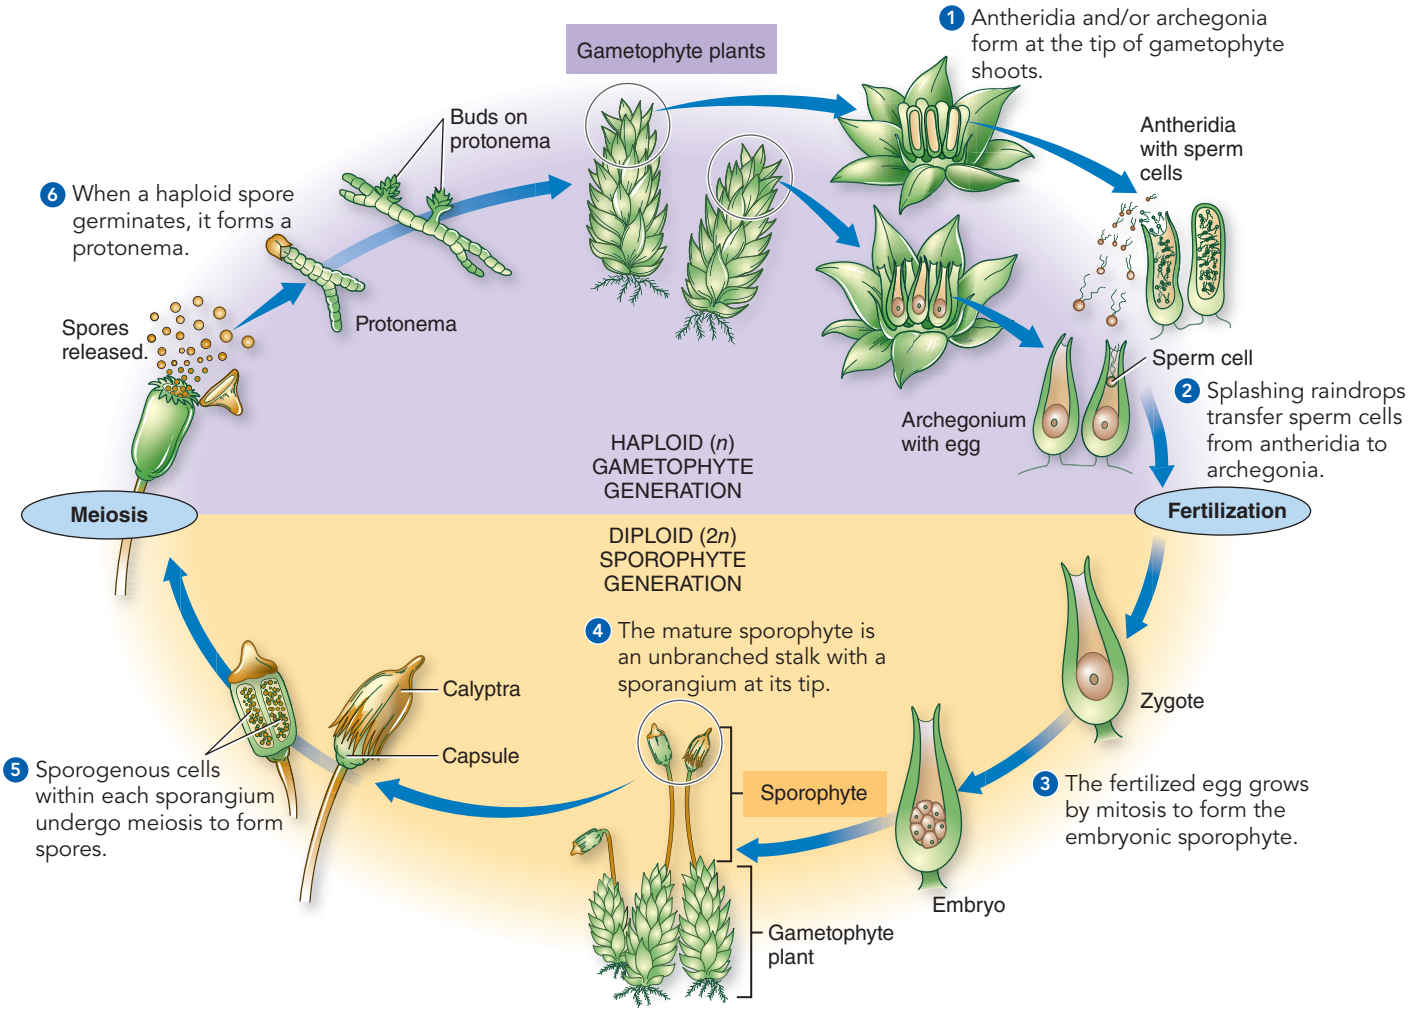

Figure 27-7 The life cycle of mosses

The gametophyte generation is dominant in the moss life cycle. After sexual reproduction, the sporophyte grows out of the gametophyte.

VISUALIZE Sketch an embryo developing in an archegonium. Indicate to what generation each belongs and whether the tissue is haploid or diploid.

Robin Weaver/Alamy Stock Photo

Over time, the organic material compresses to form *peat*. In some countries, such as Ireland and Scotland, people cut out blocks of peat that has accumulated for hundreds of years in peat bogs, dry them, and burn them for fuel. Occasionally, the remains of well-preserved humans have been uncovered during the excavations of old peat bogs in Ireland and other parts of Europe (FIG. 27-8).

The name *moss* is often misused to refer to plants that are not truly mosses. For example, reindeer "moss"

Figure 27-8 Preserved human remains in a peat bog in Denmark

The clothing and features of the Tollund man, estimated to be about two thousand years old, are remarkably well preserved because the bog's acidic conditions inhibited decay.

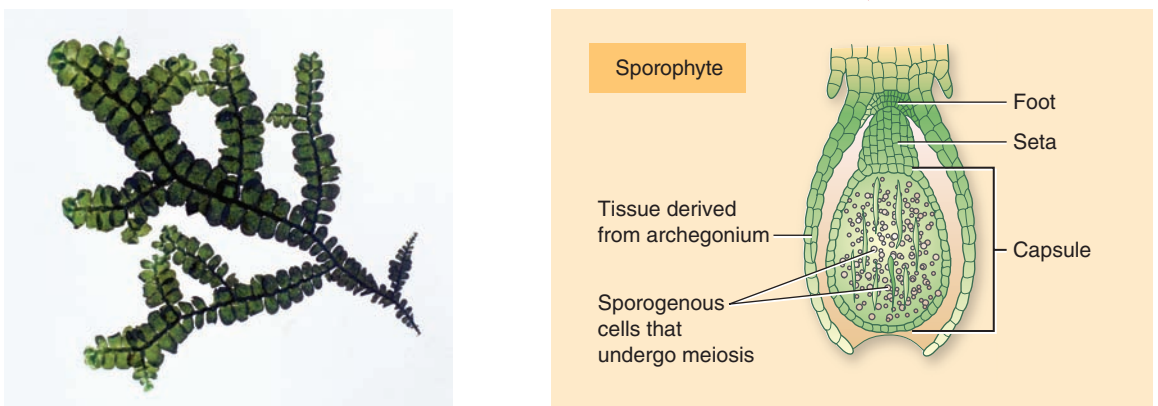
is a lichen that is a dominant form of vegetation in the arctic tundra, Spanish "moss" is a flowering plant, and club "moss" (discussed later in this chapter) is a relative of ferns.

Liverwort gametophytes are either thalloid or leafy



Liverworts (phylum Hepatophyta) consist of about 6000 species of nonvascular plants with a dominant gametophyte generation, but the gametophytes of some liverworts are quite different from those of mosses. Their body form is often a flattened, lobed structure called a **thallus** (pl., *thalli*) that is not differentiated into leaves, stems, or roots. The common liverwort, *Marchantia polymorpha*, is thalloid (FIGS. 27-9a and b). Liverworts are so named because the lobes of their thalli superficially resemble the lobes of the human liver; *wort* is derived from the Old English word *wyrt*, meaning "plant." On the underside of the liverwort thallus are hairlike rhizoids that anchor the plant to the soil.

(a) Flattened, ribbon-like lobes characterize the gametophyte of the common liverwort (*Marchantia polymorpha*). This male gametophyte thallus has both asexual gemmae cups and sexual antheridiophores, which produce sperm-bearing antheridia.

(b) Archegoniophores on the female gametophyte thallus of *M. polymorpha* produce egg-bearing archegonia. Liverwort sporophytes, which are always attached to and dependent on the gametophyte plant, consist of a foot, seta, and capsule. Meiosis occurs in the capsule and produces haploid spores.

(c) *Porella* is a leafy liverwort. The leafy plant is the gametophyte. It bears antheridia and archegonia on special branches that look quite similar to the nonreproductive branches. After fertilization, a small sporophyte develops that produces spores following meiosis.

Figure 27-9 Bryophytes: liverworts

Other liverworts, known as *leafy liverworts*, superficially resemble mosses, with leaflike blades, "stems," and rhizoids rather than a lobed thallus (FIG. 27-9c). As in the mosses, leafy liverwort "leaves" consist of a single layer of undifferentiated cells. Like other bryophytes, liverworts are small, generally inconspicuous plants that are largely restricted to damp environments. Unlike mosses, hornworts, and other plants, liverworts lack stomata, although some liverworts have surface pores thought to be analogous to stomata.

Liverworts reproduce both sexually and asexually (see Figs. 27-9a and b). Their sexual reproduction involves production of archegonia and antheridia on the haploid gametophyte. In some liverworts these gametangia are borne on stalked structures called *archegoniophores*, which bear archegonia, and *antheridiophores*, which bear antheridia. Their life cycle is basically the same as that of mosses, although some of the structures look quite different. Splashing raindrops transport sperm cells to the archegonia, where fertilization takes place. The resulting zygote develops into a multicellular embryo that becomes a mature sporophyte. The liverwort sporophyte is attached to the gametophyte, as in mosses. Sporogenous cells in the capsule of the sporophyte undergo meiosis, producing haploid spores. Each spore has the potential to develop into a green gametophyte, and the cycle continues.

Some liverworts reproduce asexually by forming tiny balls of tissue called **gemmae** (sing., *gemma*), which are borne in a saucer-shaped structure, the gemmae cup, directly on the liverwort thallus (see Fig. 27-9a). Splashing raindrops and small animals help disperse gemmae. When a gemma lands in a suitable place, it grows into a new liverwort thallus. Liverworts may also reproduce asexually by thallus branching and growth. The individual thallus lobes elongate, and each becomes a separate plant when the older part of the thallus that originally connected the individual lobes dies.

Hornwort gametophytes are inconspicuous thalloid plants

Hornworts (phylum Anthocerophyta) are a small group of about 100 species of bryophytes whose gametophytes superficially resemble those of the thalloid liverworts. Hornworts live in disturbed habitats such as fallow fields and roadsides.

Hornworts may or may not be closely related to other bryophytes. For example, their cell structure, particularly the presence of a single large chloroplast in each cell, resembles certain algal cells more than plant cells. In contrast, mosses, liverworts, and other plants have many disc-shaped chloroplasts per cell.

In the common hornwort (*Anthoceros natans*), archegonia and antheridia are embedded in the gametophyte thallus rather than on archegoniophores and antheridiophores. After fertilization and development, the needlelike sporophyte projects out of the gametophyte thallus, forming a spike or "horn," hence the name *hornwort*. A single gametophyte often produces multiple sporophytes (FIG. 27-10). Meiosis occurs, forming spores within each **sporangium** (pl., *sporangia*), or spore case. The sporangium splits open from the top to release the spores; each spore can give rise to a new gametophyte thallus. A unique feature of hornworts is that the sporophytes, unlike those of mosses and liverworts, continue to grow from their bases for the remainder of the gametophyte's life, a characteristic known as **indeterminate growth**. Some botanists think that indeterminate growth may indicate that hornworts evolved from plants with larger, more complex sporophytes.

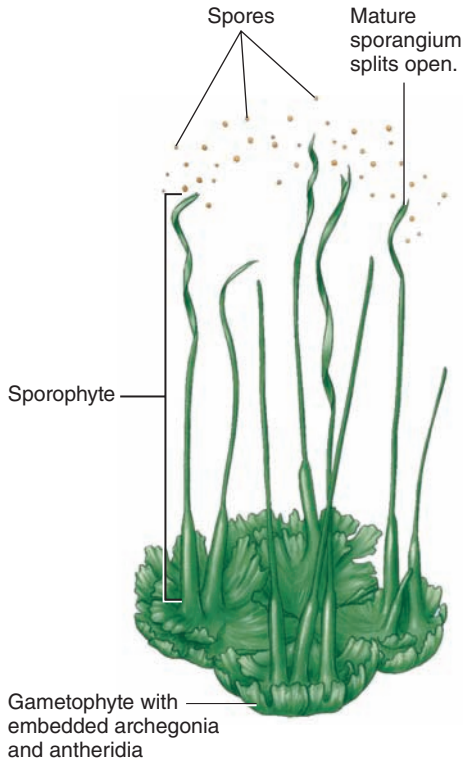

Figure 27-10 Bryophytes: hornworts
The gametophyte of the common hornwort (*Anthoceros natans*) is a small thallus with unicellular rhizoids on the lower (ventral) surface. After fertilization, sporophytes project up out of the gametophyte, forming "horns."

Bryophytes are used for experimental studies

Botanists use certain bryophytes as experimental models to study many fundamental aspects of plant biology, including genetics, growth and development, plant ecology, plant hormones, and *photoperiodism*, which is plant responses to varying periods of night and day length.

The moss *Physcomitrella patens* is a particularly important research organism for studying plant evolution because its features and genome can be compared with those of algae and flowering plants (FIG. 27-11). In this regard *Physcomitrella* is a plant equivalent of the fruit fly *Drosophila*, which is an important model organism for studies of animal inheritance, development, and evolution. As experimental organisms,

Key Experiment

Does the Physcomitrella *genome reveal any insights in plant evolution?*

HYPOTHESIS: Comparing the genome of the model organism *Physcomitrella* with genomes of other land plants as well as green algae will provide details of genes that were probably associated with the colonization of land.

EXPERIMENT: Several dozen scientists in Germany, the United States, Japan, the United Kingdom, Australia, Canada, and Belgium collaborated to produce the draft genome sequence for the model organism *Physcomitrella* (see photograph). This bryophyte was selected because researchers have used *Physcomitrella* in a wide variety of experiments and have a good understanding of its biology.

After sequencing the genome of *Physcomitrella*, it was compared with available genomes of green algae (*Ostreococcus* and *Chlamydomonas*) and land plants: the model flowering plant *Arabidopsis*, rice (*Oryza sativa*), and western balsam poplar (*Populus trichocarpa*).

Courtesy of David J. Cove, University of Leeds

RESULTS AND CONCLUSION: Researchers found that *Physcomitrella* has lost some genes needed for life in the water and gained new genes needed for life on land. Every land plant has to meet the same environmental challenges, such as obtaining enough water and preventing excessive water loss, tolerating high and low temperatures, and adapting to increased levels of solar radiation. These challenges have resulted in many modifications in plant body plans and physiological processes.

Bryophytes and vascular plants living today represent remnants of the first plants that colonized land some 450 mya. Compared with green algae, *Physcomitrella* lacks the genes needed to survive in aquatic environments but has gained genes involving plant signaling molecules (auxin, abscisic acid, and cytokinins) needed to adapt to drought, extremes of temperature, and light reception. Compared with *Physcomitrella*, other land plants have gained additional signaling molecules (gibberellins, jasmonic acid, and brassinosteroids) that enable a more complex tolerance of environmental stressors.

Because of its intermediary position in evolution (i.e., between green algae and vascular land plants), *Physcomitrella's* genome allows biologists to reconstruct which genes may have been acquired and lost during the colonization of land by the last common ancestor of all land plants.

PREDICT Would you expect *Physcomitrella* to possess genes required to produce xylem or phloem?

Physcomitrella and other bryophytes are easy to grow on artificial media and do not require much space because they are so small.

Recap: details of bryophyte evolution are based on fossils and on structural and molecular evidence

Plants are a **monophyletic group**; that is, all plants probably evolved from a common ancestral green alga. Fossil evidence indicates that bryophytes are ancient plants, probably the first group of plants to arise from the common plant ancestor. The fossil record of ancient bryophytes is incomplete, consisting mostly of spores and small tissue fragments, and can be interpreted in different ways. As a result, it does not provide a definite answer on bryophyte evolution.

The oldest known recognizable plant fossils are dated at about 425 million years old. These fossils resemble modern liverworts in many respects, but the spores are virtually identical to those in 470-million-year-old rocks. Fossil fragments of tiny liverwort-like plants associated with ancient spores have been discovered in Oman. This evidence suggests that liverwort-like plants may have been the earliest plants to colonize land.

CHECKPOINT 27.2

- Which of the following are parts of the gametophyte generation in mosses: antheridia, zygote, embryo, capsule, archegonia, sperm cells, egg cell, spores, and protonema?
- **CONNECT** How are mosses, liverworts, and hornworts similar? How is each group distinctive?

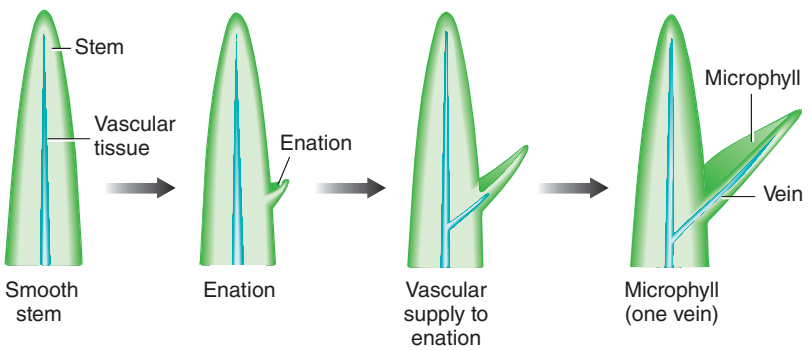
27.3 Seedless Vascular Plants

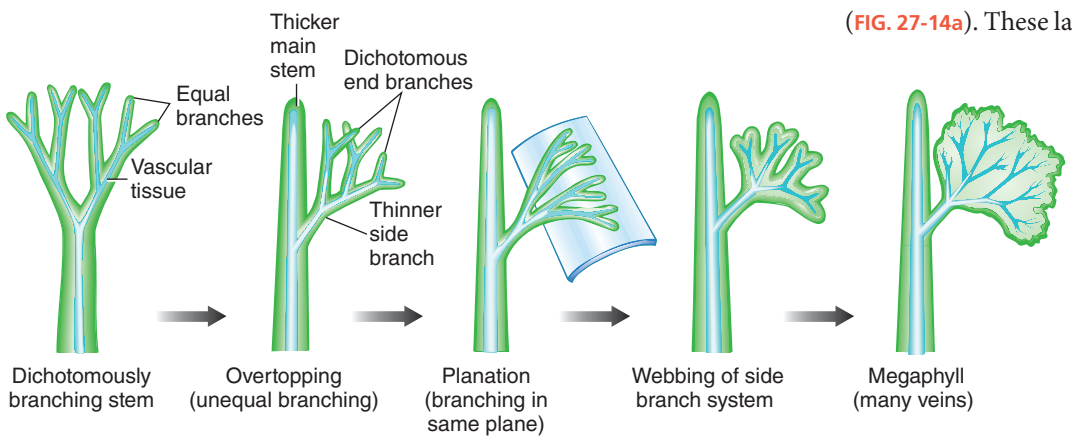
LEARNING OBJECTIVES

6 Discuss the features that distinguish seedless vascular plants from algae and bryophytes.
7 Name and briefly describe the two phyla of seedless vascular plants.
8 Describe the life cycle of ferns and compare their sporophyte and gametophyte generations.
9 Compare the generalized life cycles of homosporous and heterosporous plants.



The most important adaptation found in seedless vascular plants, although absent in algae and bryophytes, is specialized vascular tissues—xylem and phloem—for support and conduction. This system of conduction lets vascular plants grow larger than bryophytes because water, minerals, and sugar are transported to all parts of the plant. Although seedless vascular plants in temperate environments are relatively small, tree ferns in the tropics may grow to heights of 18 m (60 ft). All seedless vascular plants have true stems with vascular tissues, and most also have true roots and leaves.

Botanists have extensively studied the evolution of the leaf as the main organ of photosynthesis. The two basic types of true leaves—microphylls and megaphylls—evolved independently of each other (FIG. 27-12). The **microphyll**, which is usually small and has a single vascular strand, probably evolved from small, projecting extensions of stem tissue (*enations*). Only one group of living plants, the club mosses, has microphylls.



In contrast, **megaphylls** probably evolved from stem branches that gradually filled in with additional tissue (*webbing*) to form most leaves as we know them today. Megaphylls have more than one vascular strand, as we would expect if they evolved from branch systems. Ferns (with the exception of whisk ferns, discussed later in this chapter), gymnosperms, and flowering plants have megaphylls.

Recent evidence suggests megaphylls evolved over a 40-million-year period in the Late Paleozoic era in response to a gradual decline in the level of atmospheric CO_2. As CO_2 declined, plants developed a flattened blade with more stomata for gas exchange. (More stomata allowed cells inside the leaf to get enough CO_2.)

There are two main clades of seedless vascular plants: the club mosses and the ferns. Biologists originally considered horsetails and whisk ferns distinct enough to be classified in separate phyla. However, many kinds of evidence, such as DNA comparisons and similarities in sperm structure, have resulted in their being reclassified as ferns. As shown in FIGURE 27-13, ferns, including horsetails and whisk ferns, are a monophyletic group and the closest living relatives of seed plants (also see Table 27-2).

(a) Microphyll evolution. Microphylls probably originated as outgrowths (enations) of stem tissue that developed a single vascular strand later. Club mosses have microphylls.

(b) Megaphyll evolution. Megaphylls probably evolved from the evolutionary modification of side branches. Webbing is the evolutionary process in which the spaces between close branches become filled with chlorophyll-containing cells. Ferns, horsetails, gymnosperms, and flowering plants have megaphylls.

Figure 27-12 Evolution of microphylls and megaphylls

Club mosses are small plants with rhizomes and short, erect branches

Club mosses (phylum Lycopodiophyta) were important plants millions of years ago, when species that are now extinct often reached great size (FIG. 27-14a). These large, treelike plants were major

Key Point

Seedless vascular plants include lycophytes and ferns.

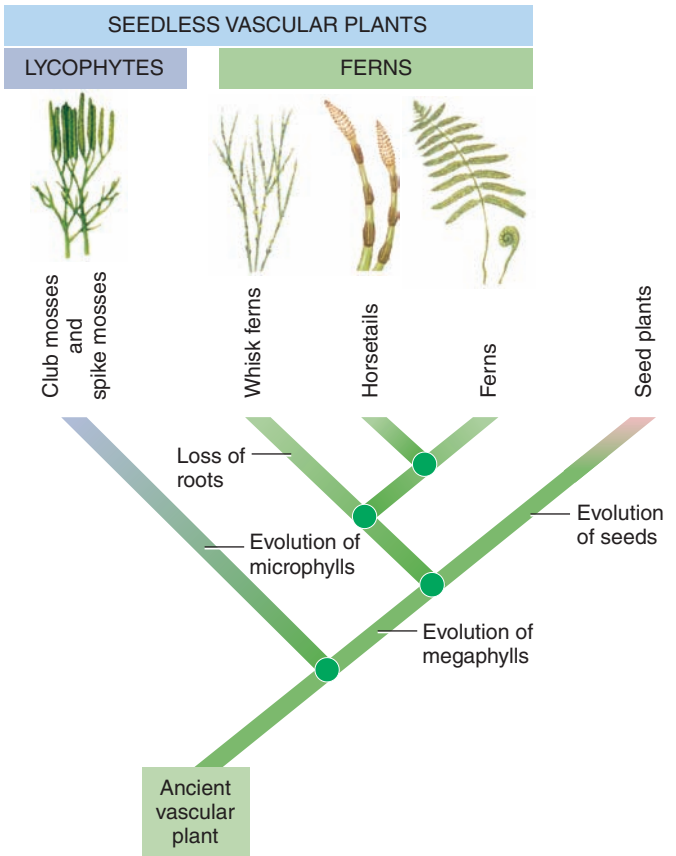

Figure 27-13 Evolutionary relationships among extant seedless vascular plants

These relationships are based on structural and molecular comparisons.

CONNECT According to the cladogram, which group, the lycophytes or the ferns, is most closely related to the seed plants?

contributors to our present-day coal deposits (see *Inquiring About: Ancient Plants and Coal Formation* on page 579).

The 1200 or so species of club mosses living today, such as *Lycopodium* (FIG. 27-14b), are small (less than 25 cm, or 10 in., tall), attractive plants common in temperate woodlands. They possess true roots, both rhizomes and erect aerial stems, and small, scalelike leaves (microphylls). Sporangia are borne on reproductive leaves that are either clustered in conelike strobili at the tips of stems or scattered in reproductive areas along the stem. Club mosses are evergreen and often fashioned into wreaths and other decorations. In some areas they are endangered by overharvesting.

That common names are sometimes misleading in biology is vividly evident in this group of plants. The most common names for the phylum Lycopodiophyta are "club mosses" and "ground pines," yet these plants are neither mosses, which are nonvascular, nor pines, which are seed plants.

Ferns are a diverse group of spore-forming vascular plants

Most of the 11,000 species of **ferns** (phylum Pteridophyta) are terrestrial, although a few have adapted to aquatic habitats. Ferns range from the tropics to the Arctic Circle, with most species living in tropical rain forests, where they perch high in the branches of trees. In temperate regions ferns commonly inhabit swamps, marshes, stream banks, and moist woodlands (FIG. 27-15a). Some species grow in fields, rocky crevices on cliffs or mountains, or even deserts.

The life cycle of ferns involves a clearly defined alternation of generations. The ferns grown as houseplants (e.g., Boston fern, maiden-hair fern, and staghorn fern) represent the larger, more conspicuous sporophyte generation.

The fern sporophyte consists of a horizontal underground stem, or *rhizome*, that bears leaves, called *fronds*, and true roots. As each young frond first emerges from the ground, it is tightly coiled and resembles the top of a violin, hence the name *fiddlehead* (FIG. 27-15b). As fiddleheads grow, they unroll and expand to form fronds. Fern fronds are usually compound (the blade is divided into leaflets), with the leaflets forming beautifully complex leaves. Fronds, roots, and rhizomes all contain vascular tissues.

Spore production usually occurs in certain areas on the fronds, which develop sporangia. Many species bear the sporangia in clusters, called **sori** (sing., *sorus*) (FIGS. 27-15c and d). Within sporangia, sporogenous cells (spore mother cells) undergo meiosis to form haploid spores. The sporangia burst open and discharge spores that may germinate and grow by mitosis into gametophytes.

The mature fern gametophyte, which bears no resemblance to the sporophyte, is a tiny (less than half the size of one of your fingernails), green, often heart-shaped structure that grows flat against the ground. Called a **prothallus** (pl., *prothalli*), the fern gametophyte lacks vascular tissues and has tiny, hairlike absorptive rhizoids to anchor it (FIG. 27-15e). The prothallus usually produces both archegonia and antheridia on its underside. Each archegonium contains a single egg, whereas numerous sperm cells are produced in each antheridium.

Ferns use water as a transport medium. The flagellate sperm cells swim, usually from a nearby prothallus, to the neck of an archegonium through a thin film of water on the ground underneath the prothallus. After one of the sperm cells fertilizes the egg, a diploid zygote grows by mitosis into a multicellular embryo (an immature sporophyte). At this stage, the sporophyte embryo is attached to and dependent on the gametophyte. As the embryo matures, however, the prothallus withers and dies, and the sporophyte becomes free-living.

The fern life cycle alternates between the dominant, diploid sporophyte with its rhizome, roots, and fronds and the haploid gametophyte (prothallus) (FIG. 27-16 on page 578). The sporophyte generation is dominant not only because it is larger than the gametophyte but also because it persists for an extended period (most fern sporophytes are perennials), whereas the gametophyte dies soon after reproducing.

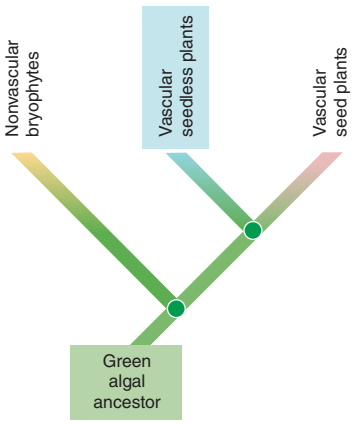
Whisk ferns are classified as reduced ferns

Only about 12 species of **whisk ferns** (phylum Pteridophyta) exist today, and the fossil record contains several extinct species. Whisk ferns, which live mainly in the tropics and subtropics, are relatively simple in structure and lack true roots and leaves but have vascularized stems. *Psilotum nudum*, a representative whisk fern, has both a horizontal underground rhizome and vertical aerial stems (FIG. 27-17a). Whenever the stem forks, or branches, it always divides into two equal halves. Botanists call this forking **dichotomous branching**. In contrast, when most plant stems branch, one stem is more vigorous and becomes the main trunk.

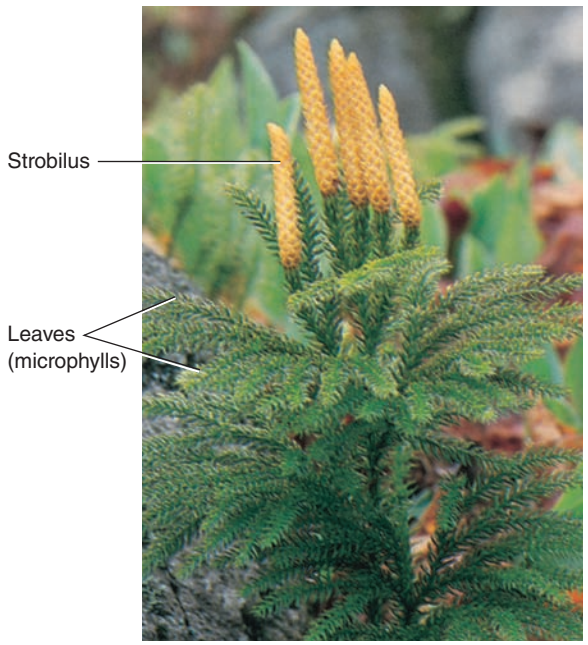
The upright stems of *Psilotum* are green and are the main organs of photosynthesis. Tiny, round sporangia, borne directly on the erect, aerial stems, contain sporogenous cells that undergo meiosis to form haploid spores. After dispersal, the spores germinate to form haploid prothalli. Because they grow underground, the prothalli of whisk ferns are difficult to study (FIG. 27-17b). They are nonphotosynthetic as a result of their subterranean location, and they apparently have a symbiotic relationship with mycorrhizal fungi that provides them with sugar and essential minerals (see Chapter 29).



Botanists have carefully studied whisk ferns in recent years. Molecular data, including comparisons of nucleotide sequences of ribosomal RNA, chloroplast DNA, and mitochondrial DNA in living species, support the hypothesis that the whisk ferns should be classified as reduced ferns rather than as surviving representatives of extinct vascular plants (see discussion of rhyniophytes later in this chapter).

Horsetails are an evolutionary line of ferns

About 300 mya, the **horsetails** (phylum Pteridophyta) were among the dominant plants and grew as large as modern trees (FIG. 27-18a on page 580). Because they contributed to Earth's vast coal deposits, these ancient horsetails, like ancient club mosses, are still significant today.



The few surviving horsetails, about 15 species in the genus *Equisetum*, grow mostly in wet, marshy habitats and are less than 1.3 m (4 ft) tall, but extremely distinctive (FIG. 27-18b on page 580). They are widely distributed on every continent except Australia. Traditionally classified in their own phylum, horsetails are now grouped with ferns. This reclassification is based on molecular similarities between horsetails and other ferns.

Horsetails have true roots, stems (both rhizomes and erect aerial stems), and small leaves. The hollow, jointed stems are impregnated with silica, which gives them a gritty texture. Small leaves, interpreted as reduced megaphylls, are fused in whorls at each node (the area on the stem where leaves attach). The

Figure 27-15 Seedless vascular plants: ferns

green stem is the main organ of photosynthesis. Horsetails are so named because certain vegetative (nonreproductive) stems have whorls of branches that give the appearance of a bushy horse's tail. In the past, horsetails were called "scouring rushes" and were used to scrub pots and pans along stream banks.

Each reproductive branch of a horsetail bears a terminal conelike **strobilus** (pl., *strobili*). The strobilus consists of several stalked, umbrella-like structures, each of which bears five to ten sporangia in a circle around a common axis.

The horsetail life cycle is similar in many respects to the fern life cycle. In horsetails, as in ferns, the sporophyte is the conspicuous plant, whereas the gametophyte is a minute, lobed thallus ranging in width from the size of a pinhead to about 1 cm across. The sporophyte and gametophyte are both photosynthetic and nutritionally independent at maturity. Like ferns, horsetails require water as a medium for flagellate sperm cells to swim to the egg.

Some ferns and club mosses are heterosporous

In the life cycles examined thus far, plants produce only one type of spore as a result of meiosis. This condition, known as **homospory**, is characteristic of bryophytes, horsetails, whisk ferns, and most ferns and club mosses. However, certain ferns and club mosses (known as spike mosses) exhibit **heterospory**, in which they produce two types of spores: microspores and megaspores.

FIGURE 27-19 on page 581 illustrates the generalized life cycle of a heterosporous plant. The sporophyte plant produces sporangia within a conelike strobilus. Each strobilus usually bears two kinds of sporangia: microsporangia and megasporangia. *Microsporangia* are sporangia that produce *microsporocytes* (also called *microspore mother cells*), which undergo meiosis to form microscopic, haploid **microspores**. Each microspore develops into a male gametophyte that produces sperm cells within antheridia.

Key Point

The dominant phase in the life cycle of ferns, like that of all other vascular plants, is the sporophyte.

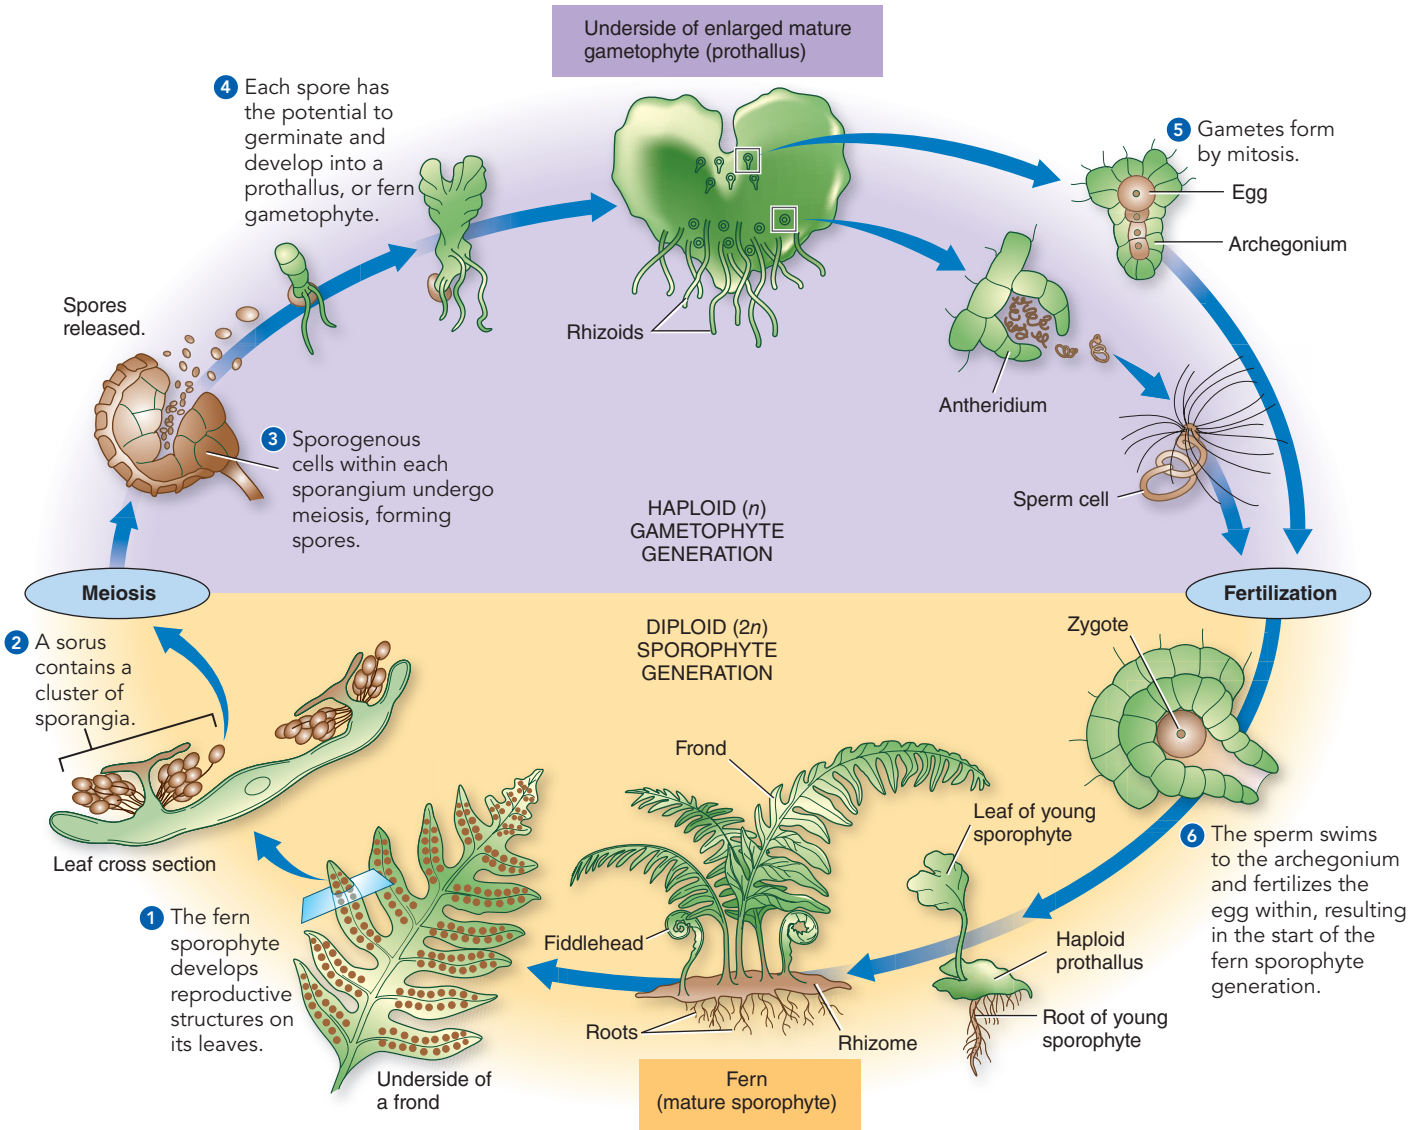

Figure 27-16 The life cycle of ferns

Note the clearly defined alternation of generations between the gametophyte (prothallus) and sporophyte (leafy plant) generations.

CONNECT What is the most fundamental difference between the fern life cycle and that of mosses?

Megasporangia produce *megasporocytes* (also called *megaspore mother cells*). When megasporocytes undergo meiosis, they form haploid **megaspores**, each of which develops into a female gametophyte that produces eggs in archegonia.

The development of male gametophytes from microspores and of female gametophytes from megaspores occurs within their respective spore walls, using stored food provided by the sporophyte. As a result, and unlike the gametophytes of other seedless vascular plants, the male and female gametophytes are not truly free-living. Fertilization is followed by the development of a new sporophyte.

Heterospory evolved several times during the history of land plants. It was a significant development in plant evolution because it was the forerunner of the evolution of seeds. Heterospory characterizes the two most successful groups of plants existing today, the gymnosperms and the flowering plants, both of which produce seeds.

Seedless vascular plants are used for experimental studies

Botanists use many seedless vascular plants as experimental models to study certain aspects of plant biology, such as

Inquiring About

Ancient Plants and Coal Formation

How did the coal that industrial society uses as an energy source form? Coal, which is burned to produce electricity and to manufacture items of steel and iron, is one of the most important fossil fuels. Although mined, coal is not an inorganic mineral like gold or aluminum but rather is an organic material formed from the remains of ancient vascular plants, particularly those of the Carboniferous period, approximately 320 mya. Four main groups of plants contributed to coal formation. Two were seedless vascular plants: the club mosses and ferns (see figure), including horsetails. The other two were seed plants: seed ferns (now extinct) and early gymnosperms.

It is hard to imagine that relatives of the small, relatively inconspicuous club mosses, ferns, and horsetails of today were so significant in forming vast beds of coal. However, many members of these groups that existed during the Carboniferous period were giants compared with their modern counterparts and formed immense forests. (Figure 21-12 shows a reconstruction of a Carboniferous forest.)

The climate during the Carboniferous period was warm, moist, and mild. Plants in most locations could grow year-round because of the favorable conditions. Forests of these plants often grew in low-lying, swampy areas that periodically flooded when the sea level rose. As the sea level receded, these plants would re-establish.

When these large plants died or were blown over in storms, they decomposed incompletely because they were covered by swamp water. (The anaerobic conditions of the water prevented wood-rotting fungi from decomposing the plants, and anaerobic bacteria do not decompose wood rapidly.) Thus, over time the partially decomposed plant material accumulated and consolidated.

Layers of sediment formed over the plant material each time the water level rose and flooded the low-lying swamps. With time, heat and pressure built up in these accumulated layers and converted the plant material to coal and the sediment layers to sedimentary rock. Much later, geologic upheavals raised the layers of coal and sedimentary rock. Coal is usually found in seams, underground layers that vary in thickness from 2.5 cm (1 in.) to more than 30 m (100 ft).

The various grades of coal (lignite, the lowest grade; subbituminous; bituminous; and anthracite, the highest grade) formed as a result of the different temperatures and pressures to which the layers were exposed. Coal exposed to high heat and pressure during its formation is drier, is more compact (and therefore harder), and has a higher heating value (i.e., a higher energy content) than coal exposed to lower heat and temperature conditions.

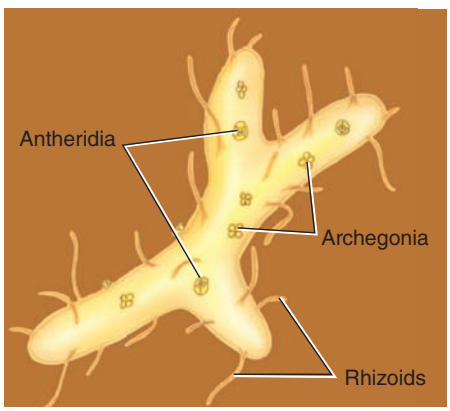
This piece of Carboniferous coal contains a fossilized fern. The coal and fossil are about 300 million years old.



physiology, growth, and development. Ferns and other seedless vascular plants are useful in studying how apical meristems give rise to plant tissues. An **apical meristem** is the area at the tip (apex) of a root or shoot where growth—cell division, elongation, and differentiation—occurs. Ferns and other seedless vascular plants have a single large *apical cell* located at the center tip of the apical meristem. This apical cell is the source, by mitosis, of all the cells that eventually make up the root or shoot. The apical cell divides in an orderly fashion, and the smaller daughter cells produced by the apical cell, in turn, divide and give rise to different parts of the root or shoot. It is possible to trace mature cells in the root or shoot back to their origin from the single apical cell.

Ferns are interesting research plants for studies in genetics because they are **polyploids** and have multiple sets of chromosomes. (Many ferns have hundreds of chromosomes.) However, gene expression in ferns is exactly what one would expect of a *diploid* plant. Apparently, genes in the extra sets of chromosomes are gradually silenced and therefore not expressed.

John Arnaldi

(a) The sporophyte of the whisk fern *Psilotum nudum*. The stem is the main organ of photosynthesis in this rootless, leafless, vascular plant. Sporangia, which turn yellow as they mature, are borne on short lateral branches directly on the stems.

(b) The gametophyte of the whisk fern *Psilotum nudum*. The gametophyte (prothallus) lives underground, nourished by mycorrhizal fungi.

(b) *Equisetum telematia*, a horsetail with a wide distribution in Eurasia, Africa, and North America, has unbranched reproductive shoots bearing conelike strobili and separate, highly branched vegetative (nonreproductive) shoots. In some horsetail species, both reproductive and vegetative shoots are unbranched.

Figure 27-18 Horsetails

Seedless vascular plants arose more than 420 mya

Currently, the oldest known megafossils of early vascular plants are from Silurian (420 mya) deposits in Europe. (Plant *megafossils* are fossilized roots, stems, leaves, and reproductive structures.) Megafossils of several kinds of small, seedless vascular plants also occur in Silurian deposits in Bolivia, Australia, and northwestern China. Microscopic spores of early vascular plants appear in the fossil record earlier than megafossils, suggesting that even older megafossils of simple vascular plants may be discovered.

Botanists assign the oldest vascular plants to phylum Rhyniophyta, which, according to the fossil record, arose some 420 mya and became extinct about 380 mya. The rhyniophytes are so named because many fossils of these extinct plants were found in fossil beds near Rhynie, Scotland. *Rhynia gwynne-vaughanii* is an example of an early vascular plant that superficially resembled whisk ferns in that it consisted of leafless upright stems that branched dichotomously from an underground rhizome (FIG. 27-20). *Rhynia* lacked roots, although it had absorptive rhizoids. Sporangia formed at the ends of short branches. The internal structure of its rhizome contained a central core of xylem cells for conducting water and minerals.

For many years, botanists considered *Rhynia major*, a plant that grew about 50 cm (20 in.) tall and probably lived in marshes, a classic example of a rhyniophyte. Fossils indicate that this plant had rhizoids, dichotomously branching rhizomes, and upright stems that terminated in sporangia. However, recent microscopic studies of fossil rhizomes indicate that the central core of tissue lacked the xylem cells characteristic of vascular plants. For that reason, *R. major* was reclassified into a new genus, *Aglaophyton*, and is no longer considered a rhyniophyte (FIG. 27-21).

The oldest known megafossils of fernlike trees, discovered in New York, are dated at 380 million years old. These trees, which were about 8 m (26 ft) tall, had vascular tissues but no leaves and a minimal root system. They grew vertically and reproduced by forming spores. The trunks were discovered in the late 1800s (and named *Eospermatopteris*), but not until 2007 was a fossil of an entire tree pieced together. The treetops had previously been found separate from the trunks and named *Wattieza*.

CHECKPOINT 27.3

- What adaptations do ferns have that both algae and bryophytes lack?
- **CONNECT** How does one distinguish between megaphylls and microphylls?
- Which of the following are parts of the sporophyte generation in ferns: frond, sperm cells, egg cell, roots, sorus, sporangium, spores, prothallus, rhizome, antheridium, archegonium, and zygote?
- Why are whisk ferns and horsetails now classified as ferns?
- How does heterospory modify the plant life cycle?

Summary: Focus on Learning Objectives

27.1 Adaptations of Plants to Life on Land *(page 564)*

1 Discuss some environmental challenges of living on land and describe how several plant adaptations meet these challenges.

- The colonization of land by plants required the evolution of many anatomical, physiological, and reproductive adaptations. Plants have a waxy **cuticle** to protect against water loss and **stomata** for gas exchange needed for photosynthesis.
- Plant life cycles have an **alternation of generations** in which they spend part of their life cycle in a multicellular haploid **gametophyte generation** and part in a multicellular diploid **sporophyte generation**. The gametophyte plant produces gametes by mitosis. During fertilization these gametes fuse to form a **zygote**, the first stage of the sporophyte generation. The zygote develops into a multicellular **embryo** that the gametophyte protects and nourishes. The mature sporophyte plant develops from the embryo and produces sporogenous cells (spore mother cells). These cells undergo meiosis to form **spores**, the first stage in the gametophyte generation.
- Most plants have multicellular **gametangia** with a protective jacket of sterile cells surrounding the gametes. **Antheridia** are gametangia that produce sperm cells, and **archegonia** are gametangia that produce eggs.
- Ferns and other vascular plants have **xylem** to conduct water and dissolved minerals and **phloem** to conduct dissolved sugar.

2 Name the green algal group from which plants are hypothesized to have descended and describe supporting evidence.

- Plants probably arose from a group of green algae called **charophytes**. This conclusion is based in part on molecular comparisons of DNA and RNA sequences, which show the closest match between charophytes and plants.

27.2 Bryophytes *(page 568)*

3 Summarize the features that distinguish bryophytes from other plants.

- Unlike other land plants, **bryophytes** are nonvascular and lack xylem and phloem. Bryophytes are the only plants with a dominant gametophyte generation. Their sporophytes remain permanently attached and nutritionally dependent on the gametophytes.

4 Name and briefly describe the three phyla of bryophytes.

- **Mosses** (phylum Bryophyta) have gametophytes that are green plants that grow from a filamentous **protonema**.
- Many **liverworts** (phylum Hepatophyta) have gametophytes that are flattened, lobelike **thalli**; others are leafy.
- **Hornworts** (phylum Anthocerophyta) have thalloid gametophytes.

5 Describe the life cycle of mosses and compare their gametophyte and sporophyte generations.

- The green moss gametophyte bears archegonia, antheridia, or both at the top of the plant. During fertilization, a sperm cell fuses with an egg cell in the archegonium. The zygote grows into an embryo that develops into a moss sporophyte, which is attached to the gametophyte. Meiosis occurs within the capsule of the sporophyte to produce spores. When a spore germinates, it grows into a protonema that forms buds that develop into gametophytes.

27.3 Seedless Vascular Plants *(page 574)*

6 Discuss the features that distinguish seedless vascular plants from algae and bryophytes.

- Seedless vascular plants have several adaptations that algae and bryophytes lack, including vascular tissues and a dominant sporophyte generation. As in bryophytes, reproduction in seedless vascular plants depends on water as a transport medium for motile sperm cells.

7 Name and briefly describe the two phyla of seedless vascular plants.

- Sporophytes of **club mosses** (phylum Lycopodiophyta) consist of roots, rhizomes, erect branches, and leaves that are **microphylls**.
- **Ferns** (phylum Pteridophyta) are the largest and most diverse group of seedless vascular plants. The fern sporophyte consists of a rhizome that bears fronds and true roots. Phylum Pteridophyta also includes whisk ferns and horsetails. Sporophytes of **whisk ferns** have **dichotomously branching** rhizomes and erect stems; they lack true roots and leaves. **Horsetail** sporophytes have roots, rhizomes, aerial stems that are hollow and jointed, and leaves that are reduced **megaphylls**.

8 Describe the life cycle of ferns and compare their sporophyte and gametophyte generations.

- Fern sporophytes have roots, rhizomes, and leaves that are megaphylls. Their leaves, or fronds, bear sporangia in clusters called **sori**. Meiosis in sporangia produces haploid spores. The fern gametophyte, called a **prothallus**, develops from a haploid spore and bears both archegonia and antheridia.

9 Compare the generalized life cycles of homosporous and heterosporous plants.

- **Homospory**, the production of one kind of spore, is characteristic of bryophytes, most club mosses, and most ferns, including whisk ferns and horsetails. In homospory, spores give rise to gametophyte plants that produce both egg cells and sperm cells.
- **Heterospory**, the production of two kinds of spores (microspores and megaspores), occurs in certain club mosses, certain ferns, and all seed plants. **Microspores** give rise to male gametophytes that produce sperm cells. **Megaspores** give rise to female gametophytes that produce eggs. The evolution of heterospory was an essential step in the evolution of seeds.

Test Your Understanding

Know and Comprehend

1. Plants probably descended from a group of green algae called (a) rhyniophytes (b) *Calamites* (c) epiphytes (d) charophytes (e) club mosses
2. Which of the following is *not* a characteristic of plants? (a) cuticle (b) unicellular gametangia (c) stomata (d) multicellular embryo (e) alternation of generations
3. In plant life cycles, (a) the first products of meiosis are gametes (b) spores are part of the diploid sporophyte generation (c) the embryo gives rise to a zygote (d) the first stage in the diploid sporophyte generation is the zygote (e) the first stage in the haploid gametophyte generation is the prothallus
4. The bryophytes (a) include mosses, liverworts, and hornworts (b) include whisk ferns, horsetails, and club mosses (c) are small plants that lack a vascular system (d) a and c (e) b and c
5. The waxy layer that covers aerial parts of plants is the (a) cuticle (b) archegonium (c) protonema (d) stoma (e) thallus
6. A strengthening compound found in cell walls of vascular plants is (a) chitin (b) lignin (c) cutin (d) cellulose (e) carotenoid
7. Stomata (a) help prevent desiccation of plant tissues (b) transport water and minerals through plant tissues (c) allow gas exchange for photosynthesis (d) strengthen cell walls (e) produce male gametes
8. The green, gametangia-bearing moss plant (a) is the haploid gametophyte generation (b) is the diploid sporophyte generation (c) is called a protonema (d) contains cells with single large chloroplasts (e) b and c
9. A(n) _____ is a leaf that arose from a branch system. (a) antheridium (b) microphyll (c) megaphyll (d) sorus (e) microspore
10. These plants have vascularized stems but lack true roots and leaves. (a) mosses (b) club mosses (c) horsetails (d) whisk ferns (e) hornworts
11. These plants have hollow, jointed stems that are impregnated with silica. (a) mosses (b) club mosses (c) horsetails (d) whisk ferns (e) hornworts
12. Which of the following statements about ferns is *not* true? (a) ferns have motile sperm cells that swim through water to the egg-containing archegonium (b) ferns are vascular plants (c) ferns are the most economically important group of bryophytes (d) the fern sporophyte consists of a rhizome, roots, and fronds (e) the diversity of ferns is greatest in the tropics

Apply and Analyze

13. **VISUALIZE** Draw a simple diagram illustrating a heterosporous life cycle. Include the sporophyte generation, megaspore, female gametophyte, egg, microspore, male gametophyte, sperm, meiosis, and fertilization. Be sure to indicate whether each generation or kind of cell is haploid or diploid.

Evaluate and Synthesize

14. **EVOLUTION LINK** How may the following trends in plant evolution be adaptive to living on land?
    (a) dependence on water for fertilization → no need for water as a transport medium
    (b) homospory → heterospory
15. **INTERPRET DATA** According to the cladogram in Figure 27-5, which plants evolved first: nonvascular bryophytes, seedless vascular plants, or seed plants?
16. **EVOLUTION LINK** Where would you position the rhyniophytes on Figure 27-13? Would the line for rhyniophytes extend to the tips of the rest of the cladogram? Why or why not?

28 Seed Plants

KEY CONCEPTS

28.1 Seed plants, which produce young sporophytes enclosed within seeds, include gymnosperms and angiosperms.

28.2 Gymnosperms produce exposed ovules that, following fertilization, develop into seeds that are usually borne in cones on the sporophytes. Conifers are the most diverse and numerous of the four living gymnosperm phyla.

28.3 Angiosperms produce ovules enclosed within carpels; following fertilization, seeds develop from the ovules, and the ovaries of carpels become fruits. Angiosperms dominate the land and exhibit great diversity in both vegetative and reproductive structures.

28.4 Gymnosperms evolved from ancestral seedless vascular plants; angiosperms evolved from ancestral gymnosperms, possibly an ancient conifer.

Chapter 27 focused on plants that reproduce by means of *spores*, haploid cells that disperse and germinate to produce gametophytes. Although gymnosperms and angiosperms also produce spores, their primary means of reproduction and dispersal is by **seeds**, which represent an important adaptation for life on land (see photograph). Each seed consists of an embryonic sporophyte, nutritive tissue, and a protective coat. Seeds develop from the fertilized egg cell, the female gametophyte, and its associated tissues. The two groups of seed plants, gymnosperms and angiosperms (flowering plants), exhibit the greatest evolutionary complexity of land plants and are the dominant plants in most terrestrial environments.

Seeds are reproductively superior to spores for several reasons. First, a seed is further along in its development before it is released to survive on its own: a seed contains a multicellular young plant with embryonic root, stem, and one or more leaves already formed, whereas a spore is a single cell. Second, a seed contains an abundant food supply. After germination, food stored in the seed nourishes the plant embryo until it becomes self-sufficient. Because a spore is a single cell, few food reserves exist for the plant that develops from a spore. Third, a seed is protected by a multicellular **seed coat** that is very thick and hard in some plants, as, for example, in lima beans. Like spores, seeds live for extended periods at reduced rates of metabolism and germinate when conditions become favorable.

Seeds and seed plants are intimately connected with the development of human civilization. From prehistoric times, early humans collected and used seeds for food. Seeds often contain a

PHOTO: Wild tamarind (*Cojoba arborea*) seeds. The black seeds develop in the seed pods (fruits), which turn orange as they ripen.

concentrated source of proteins, oils, carbohydrates, and vitamins, which are nourishing for humans as well as for germinating plants. Seeds are easy to store (if kept dry), so humans can collect them during times of plenty to save for times of need. Few other foods are stored as conveniently or for as long. Although flowering plants produce most seeds that humans consume, the seeds of certain gymnosperms—the piñon pine, for example—are edible.

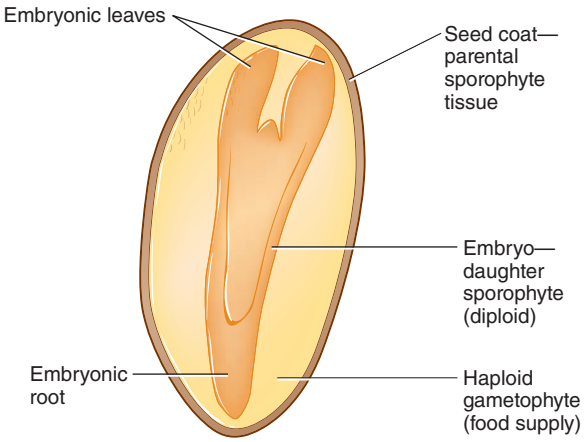
In this chapter we present the diversity in seed plants—both gymnosperms and angiosperms—followed by an examination of what we know about how seed plants evolved.

28.1 An Introduction to Seed Plants

LEARNING OBJECTIVE

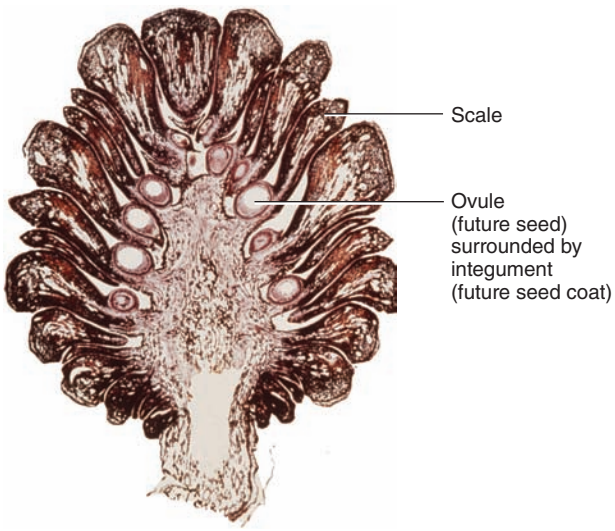
1 Compare the features of gymnosperms and angiosperms.

Like the bryophytes and seedless vascular plants introduced in Chapter 27, seed plants have life cycles with an **alternation of generations**; they spend part of their lives in the multicellular diploid sporophyte stage and part in the multicellular haploid gametophyte stage. The sporophyte generation is the dominant stage in seed plants, and the gametophyte generation is significantly reduced in size and entirely dependent on the sporophyte generation. Unlike the bryophytes and ferns, seed plants do not have free-living gametophytes. Instead, the female gametophyte is attached to and nutritionally dependent on the sporophyte generation.



In Chapter 27 you learned that some seedless vascular plants are heterosporous. (Figure 27-19 shows a generalized life cycle for heterosporous plants.) However, *all* seed plants are heterosporous and produce two types of spores: microspores and megaspores. In fact, heterospory is a requirement of seed production.

Seed plants produce **ovules**, each of which is a *megasporangium* surrounded by **integuments**, layers of sporophyte tissue that enclose the megasporangium. After fertilization takes place, the ovule develops into a seed, and the integuments develop into the seed coat (FIG. 28-1a).



Botanists divide seed plants into two groups based on whether or not an ovary wall surrounds their ovules (an *ovary* is a structure that contains one or more ovules). The two groups of seed plants are the **gymnosperms** and the **angiosperms** (TABLE 28-1). The word *gymnosperm* is derived from the Greek for "naked seed." Gymnosperms produce seeds that are totally exposed or borne on the scales of cones (FIG. 28-1b). In other words, an ovary wall does not surround the ovules of gymnosperms. Pine, spruce, fir, hemlock, and ginkgo are examples of gymnosperms.

The term *angiosperm* is derived from the Greek expression that means "seed enclosed in a vessel or case." Angiosperms are flowering plants that produce their seeds within a *fruit* (a mature ovary) (FIG. 28-1c). Thus, the ovules of angiosperms are protected. Flowering plants, which are extremely diverse, include corn, oaks, water lilies, cacti, apples, grasses, palms, and buttercups.

Both gymnosperms and flowering plants have vascular tissues: **xylem**, for conducting water and dissolved minerals (inorganic nutrients), and **phloem**, for conducting dissolved sugar.

Table 28-1 A Comparison of Gymnosperms and Angiosperms

Characteristic	Gymnosperms	Angiosperms
		
Growth habit	Woody trees and shrubs	Woody or herbaceous
Conducting cells in xylem	Tracheids	Vessel elements and tracheids
Reproductive structures	Cones (usually)	Flowers
Pollen grain transfer	Wind (usually)	Animals or wind
Fertilization	Egg and sperm → zygote	Double fertilization: egg and sperm → zygote; two polar nuclei and sperm → endosperm
Seeds	Exposed or borne on scales of cones	Enclosed within fruit derived from ovary
Nutritive material	Female gametophyte	Endosperm
Number of species	About 840	More than 300,000
Geographic Distribution	Worldwide	Worldwide

CHECKPOINT 28.1

- What is an ovule?
- What kinds of seeds are surrounded by an ovary wall?

28.2 Gymnosperms

LEARNING OBJECTIVES

2 Trace the steps in the life cycle of a pine and compare its sporophyte and gametophyte generations.

3 Summarize the features that distinguish gymnosperms from bryophytes and ferns.

4 Name and briefly describe the four phyla of gymnosperms.

The gymnosperms include some of the most interesting plants. For example, a giant sequoia (*Sequoiadendron giganteum*) known as the General Sherman Tree, in Sequoia National Park in California, is one of the world's most massive organisms. It is 84.2 m (275 ft) tall and has a girth of 24.1 m (79 ft) measured 1.5 m (5 ft) above ground level. Another gymnosperm, a coast redwood (*Sequoia sempervirens*) nicknamed "Hyperion" after a giant in Greek mythology, is possibly the world's tallest tree, measuring 115.7 m (379 ft) in 2007. Botanists using tree-ring analysis determined that one of Earth's oldest living organisms, a bristlecone pine (*Pinus longaeva*) in the White Mountains of California, is about 5000 years old.

Gymnosperms are usually classified into four phyla, which branch from a single evolutionary line (FIG. 28-2). Numbering 630 species, the largest phylum of gymnosperms is Coniferophyta, commonly called conifers. Two phyla of gymnosperms, Ginkgophyta (the ginkgoes) and Cycadophyta (the cycads), are evolutionary remnants of groups that were more significant in the past. The fourth phylum, Gnetophyta (gnetophytes), is a collection of some unusual plants that share certain traits not found in other gymnosperms; until recently, the gnetophytes were thought to be more closely related to flowering plants than were other gymnosperm clades. Current evidence, however, suggests that gnetophytes are probably most closely related to conifers (see Fig. 28-2).

Conifers are woody plants that produce seeds in cones

The **conifers** (phylum Coniferophyta), which include pines, spruces, hemlocks, and firs, are the most familiar group of gymnosperms (FIG. 28-3a). These 630 species of woody trees or shrubs produce annual additions of secondary tissues (wood and bark); there are no herbaceous (nonwoody) conifers. The wood (*secondary xylem*) consists of **tracheids**, which are long, tapering cells with pits through which water and dissolved minerals move from one cell to another.

Many conifers produce **resin**, a viscous, clear or translucent substance consisting of several organic compounds that may protect the plant from attack by fungi or insects. The resin collects in resin ducts, tubelike cavities that extend throughout the roots, stems, and leaves. Cells lining the resin ducts produce and secrete resin.

Conifers generally have leaves called *needles* that are long, narrow, tough, and leathery (FIG. 28-3b). Most pines bear clusters of two to five needles, depending on the species. In a few conifers, such as American arborvitae, the leaves are scale-like and cover the stem (FIG. 28-3c). Most conifers are evergreen and bear their leaves throughout the year. Only a few, such as the dawn redwood, larch, and bald cypress, are deciduous and shed their needles at the end of each growing season.

Most conifers are **monoecious**: they have separate male and female reproductive parts in different locations on the same plant. These reproductive parts are generally borne in *strobili* (commonly called *cones*), hence the name *conifer*, which means "cone-bearing."

Conifers occupy extensive areas, ranging from the Arctic to the tropics, and are the dominant vegetation in the forested regions of Alaska, Canada, northern Europe, and Siberia. In addition, they are important in the Southern Hemisphere, particularly in wet, mountainous areas of temperate and tropical regions in South America, Australia, New Zealand, and Malaysia. Southwestern China, with more than 60 species of conifers, has the greatest regional diversity of conifer species

Key Point

Seed plants include four gymnosperm phyla and one phylum of flowering plants (angiosperms).

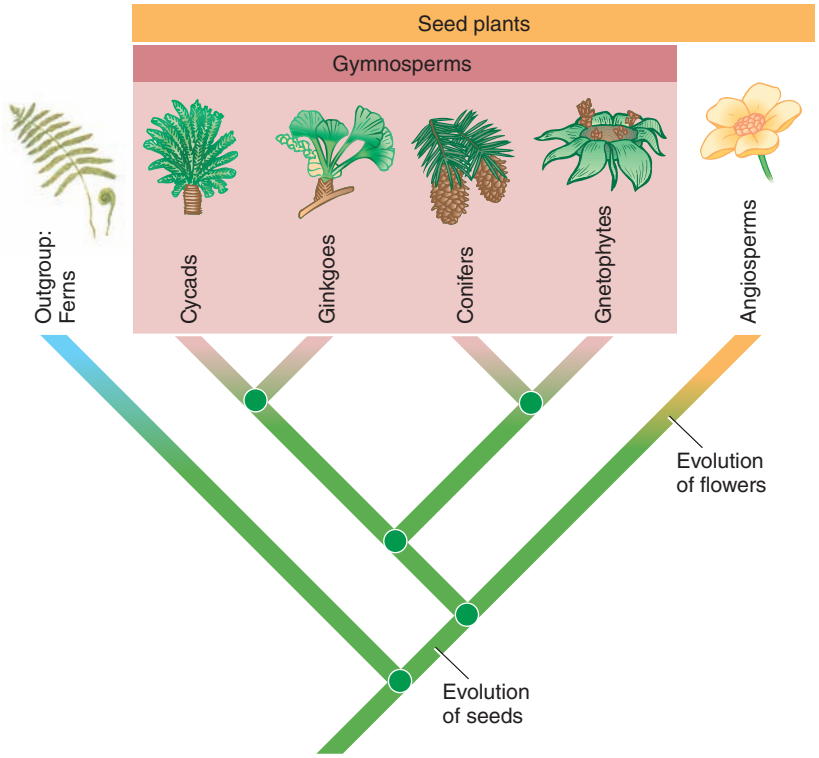

Figure 28-2 Gymnosperm and angiosperm evolution

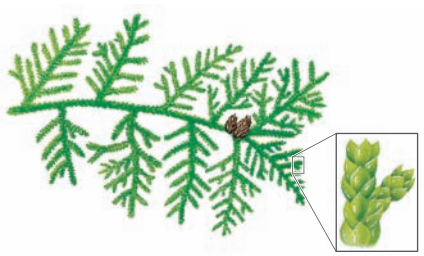
This cladogram shows a current hypothesis of phylogenetic relationships among living seed plants, based on structural evidence, molecular comparisons, and fossils. Relationships among extant gymnosperm clades and angiosperms remain controversial. The arrangement of the phyla shown here may change as future analyses help clarify relationships.

CONNECT According to the cladogram, which group is most closely related to the conifers?



Michael P. Gadomski/Science Source

Key Point

Gymnosperms, like all seed plants, are heterosporous.

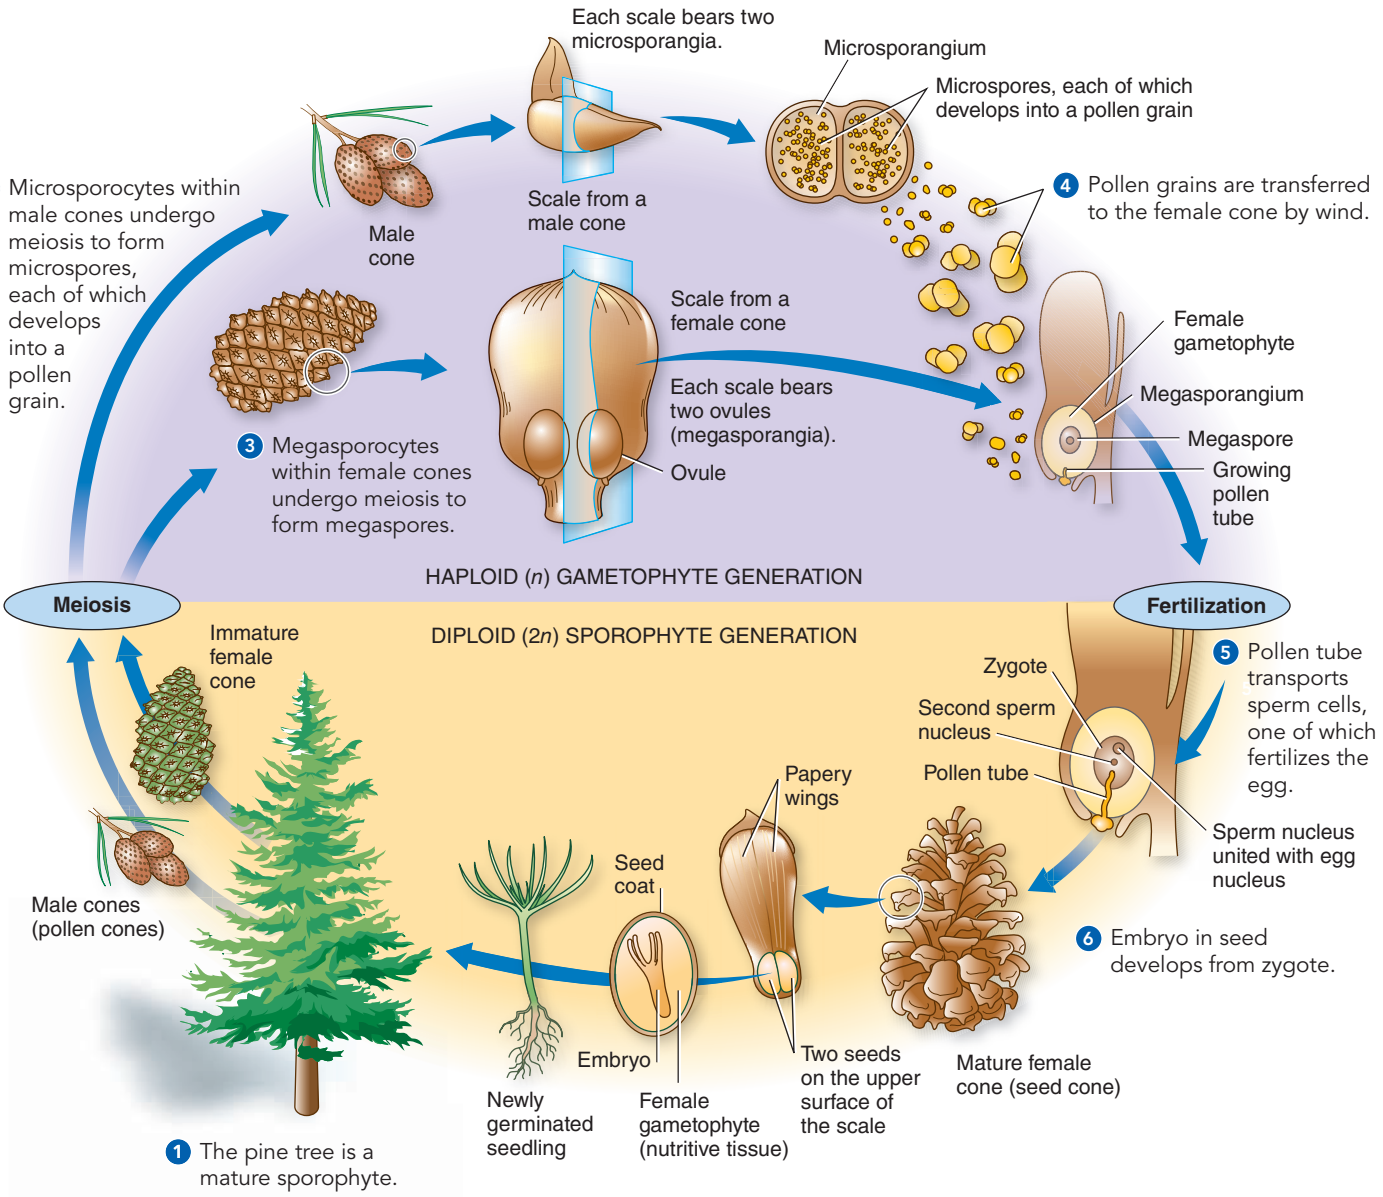

Figure 28-4 Life cycle of pine

One major advantage of gymnosperms over the seedless vascular plants is the production of wind-borne pollen grains.

CONNECT Is a pine pollen grain haploid or diploid? Is it a gamete? Explain your answer.

in the world. California, New Caledonia (an island east of Australia), southeastern China, and Japan also have considerable diversity of conifer species. Ecologically, conifers contribute food and shelter to animals and other organisms, and their roots hold the soil in place and help prevent soil erosion.

Humans use conifers for their wood (for building materials as well as paper products), medicinal value (such as the anticancer drug Taxol from the Pacific yew), turpentine, and resins. Because of their attractive appearance, conifers such as firs, spruces, pines, and cedars are grown for landscape design and decorative holiday trees and wreaths.

Pines represent a typical conifer life cycle

The genus *Pinus*, by far the largest genus in the conifers, consists of about 100 species. A pine tree is a mature sporophyte (FIG. 28-4). Pine is heterosporous and therefore produces

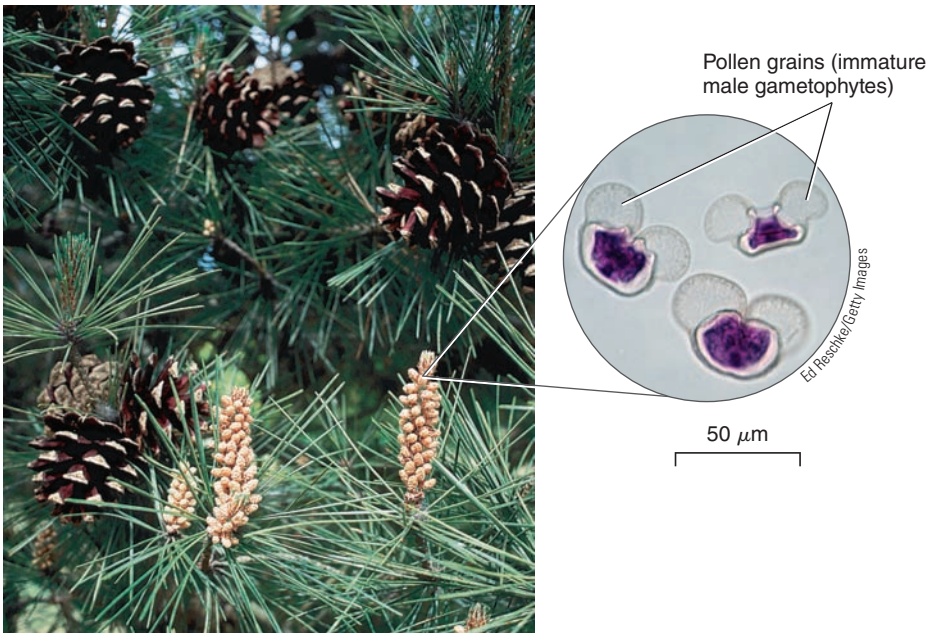

Figure 28-5 Male and female cones in lodgepole pine (*Pinus contorta*)
Mature woody female cones (*top*) have opened to shed their seeds. Clusters of male cones (*bottom*) produce copious amounts of pollen grains in the spring. (*Inset*) Each pollen grain develops from a microspore.

microspores and megaspores in separate cones. Male cones, usually 1 cm or less in length, are smaller than female cones and are generally produced on the lower branches each spring (FIG. 28-5). The more familiar, woody female cones, which are on the tree year-round, are usually found on the upper branches of the tree and bear seeds after reproduction. Female cones vary considerably in size. The sugar pine (*P. lambertiana*) that grows in California produces the world's longest female cones, which reach lengths of 60 cm (2 ft).

Each male cone, also called a *pollen cone*, consists of **sporophylls**, leaflike scales that bear sporangia on the underside. At the base of each sporophyll are two **microsporangia**, which contain numerous **microsporocytes**, also called *microspore mother cells*. In Figure 28-4, each microsporocyte undergoes meiosis to form four haploid microspores. **Microspores** then develop into extremely reduced male gametophytes. Each immature male gametophyte, also called a **pollen grain**, consists of four cells, two of which—a *generative cell* and *a tube cell*—are involved in reproduction. The other two cells soon degenerate. Two large air sacs on each pollen grain provide buoyancy for wind dissemination. Male cones shed pollen grains in great numbers, and wind currents carry some to the immature female cones.

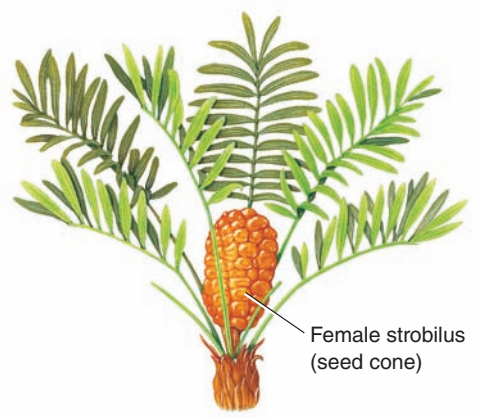
Many botanists think that the female cones (also called *seed cones*) are modified branch systems. Each cone scale bears two **ovules**, or **megasporangia**, on its upper surface. Within each megasporangium, meiosis of a **megasporocyte**, or *megaspore mother cell*, produces four haploid **megaspores**. One of them divides mitotically, developing into the female gametophyte, which produces an egg within each of several archegonia. The other three megaspores are nonfunctional and soon degenerate.

When the ovule is ready to receive pollen, it produces a sticky droplet at the opening where the pollen grains land. **Pollination**, the transfer of pollen to the female cones, occurs in the spring for a week or ten days, after which the pollen cones wither and drop off the tree. One of the many pollen grains that adhere to the sticky female cone grows a **pollen tube**, an outgrowth that digests its way through the megasporangium to the egg within the archegonium. The germinated pollen grain with its pollen tube is the mature male gametophyte.

Ultimately, two nonmotile (nonflagellate) sperm cells form within the germinated pollen grain. When it reaches the female gametophyte, the pollen tube discharges the two sperm cells near the egg. One of these sperm cells fuses with the egg, in the process of **fertilization**, to form a zygote, or fertilized egg, which subsequently grows into a young pine embryo in the seed. The other sperm cell degenerates.

The developing embryo consists of an embryonic root and an embryonic shoot with several cotyledons (embryonic leaves). Haploid female gametophyte tissue surrounds the embryo and becomes the nutritive tissue in the mature pine seed. A tough, protective seed coat derived from the integuments encloses the embryo and nutritive tissue. The seed coat forms a thin, papery wing at one end that enables dispersal by air currents. Some seeds remain within the female cones for several years before being shed.

In the pine life cycle, the sporophyte generation is dominant, and the gametophyte generation is restricted in size to microscopic structures in the cones. Although the female gametophyte produces archegonia, the male gametophyte is so reduced that it does not produce antheridia. The gametophyte generation in pines, as in all seed plants, depends totally on the sporophyte generation for nourishment.



A major adaptation in the pine life cycle is elimination of the need for external water as a sperm transport medium. Instead, air currents carry pine pollen grains to female cones, and nonflagellate sperm cells move through a pollen tube to the egg. Pine and other conifers are plants whose reproduction is totally adapted for life on land.

Cycads have seed cones and compound leaves

Cycads (phylum Cycadophyta) were very important during the Triassic period, which began about 251 million years ago (mya) and is sometimes referred to as the "Age of Cycads." Most cycad species are now extinct, and the few surviving ones, about 140 species, are tropical and subtropical plants

(b) This female cycad (*Encephalartos princeps*) native to South Africa bears three seed cones.

Figure 28-6 Cycads

with stout, trunklike stems and compound leaves that resemble those of palms or tree ferns (FIG. 28-6). Many cycads are endangered, primarily because they are popular as ornamentals and are gathered from the wild and sold to collectors. In the United States, cycads can be found in Florida, Texas, and California.

Cycad reproduction is similar to that in pines except that cycads are **dioecious** and therefore have seed cones on female plants and pollen cones on male plants. Their seed structure is most like that of the earliest seeds found in the fossil record. Cycads have also retained motile sperm cells, each of which has many hairlike flagella. Motile sperm cells are a vestige retained from the ancestors of cycads, in which sperm cells swam from antheridia to archegonia. In cycads specialized insects (almost exclusively beetles) carry pollen grains to the female plants and their cones. Following transfer to the female cone, the pollen grain germinates and grows a pollen tube. The sperm cells are released into this tube and swim to the egg.

Ginkgo biloba is the only living species in its phylum

Ginkgo (phylum Ginkgophyta) is represented by a single *extant* (living) species, the maidenhair tree, *Ginkgo biloba* (FIG. 28-7). This native of eastern China grew in the wild in only two locations, although people had cultivated it for its edible seeds in China and Japan for centuries. *Ginkgo* is the oldest genus (and species) of *extant* trees. Fossil ginkgoes 200 million years old have been discovered that are strikingly similar to the modern ginkgo.

People often plant ginkgo in North America and Europe today, particularly in parks and along city streets, because it is hardy and somewhat resistant to air pollution. Its leaves are deciduous and turn a beautiful yellow before being shed in the fall.

Like cycads, ginkgo is dioecious, with separate male and female trees. It has flagellate sperm cells, an evolutionary vestige that is not required because ginkgo produces airborne pollen grains. Ginkgo seeds are completely exposed rather than contained within cones. Male trees are usually planted because the female trees bear seeds whose fleshy outer coverings give off a foul odor that smells like rancid butter. In China and Japan, where people eat the seeds, the female trees are more common.

Ginkgo has been an important medicinal plant for centuries and is still a common herbal remedy today. Extracts from the leaves may enhance neurological functioning by increasing blood flow to the brain, although several recent studies have concluded that ginkgo does not improve memory or prevent dementia in elderly people. In 2013 scientists from the National Toxicology Program of the National Institutes of Health reported the development of cancers in rats and mice fed high doses of *Gingko biloba* extract.

Gnetophytes include three unusual genera

The **gnetophytes** (nee´ toe phites) (phylum Gnetophyta) consist of about 70 species in three diverse and obscure genera (*Gnetum*, *Ephedra*, and *Welwitschia*). Gnetophytes share certain features that make them unique among the gnetophytes. For example, gnetophytes have more efficient water-conducting cells, called *vessel elements*, in their xylem (see Chapter 33). Flowering plants also have vessel elements in their xylem, but of the gnetophytes, only the gnetophytes do. In addition, the cone clusters that some gnetophytes produce resemble flower clusters, and certain details in their life cycles resemble those of flowering plants. Despite these similarities, most botanists now think that gnetophytes represent evolutionary diversity in gymnosperms and are not in a direct line to flowering plants (see Fig. 28-2).

Dr. John D. Cunningham/Visuals Unlimited, Inc.

(a) The leaves of *Gnetum gnemon* resemble those of flowering plants. Note the exposed seeds. The species is native to southern Asia and the Maldives.

Bob Gibbons/Alamy Stock Photo

(b) A male joint fir (*Ephedra*) has pollen cones clustered at the nodes. In the 19th century, European pioneers used species native to the American Southwest to make a beverage, Mormon tea.

The genus *Gnetum* contains tropical vines, shrubs, and trees with broad leaves (FIG. 28-8a). Species in the genus *Ephedra* include many shrubs and vines that grow in deserts and other dry temperate and tropical regions. Some *Ephedra* species resemble horsetails in that they have jointed green stems with tiny leaves (FIG. 28-8b). Commonly called *joint fir*, *Ephedra* has been used medicinally for centuries. An Asiatic *Ephedra* is the source of ephedrine, which stimulates the heart and raises blood pressure. At one time, ephedrine was commonly sold over the counter in weight-control medications and herbal energy boosters; several deaths were reported from chronic use or overdose of products containing ephedrine, so its use has been restricted.

The third gnetophyte genus, *Welwitschia*, contains a single species found in deserts of southwestern Africa (FIG. 28-8c). Most of *Welwitschia*'s body—a long taproot—grows underground. Its short, wide stem forms a shallow disc, up to 0.9 m (3 ft) in diameter, from which two ribbonlike leaves extend. These two leaves continue to grow from the stem throughout the plant's life, but their ends are usually broken and torn by the wind, giving the appearance of numerous leaves. Each leaf grows to about 2 m (6.5 ft) in length. When *Welwitschia* reproduces, cones form around the edge of its disclike stem.

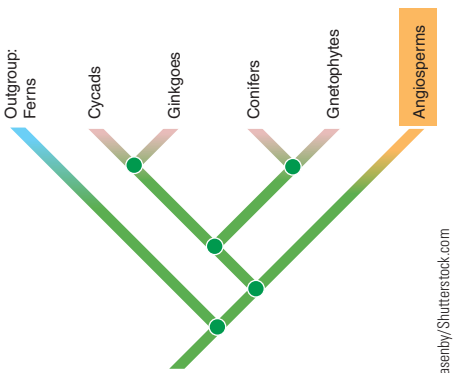
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

importance. They have adapted to almost every habitat and, with at least 300,000 species, are Earth's dominant plants. Flowering plants come in a wide variety of sizes and forms, from herbaceous violets to massive eucalyptus trees. Some flowering plants—tulips and roses, for example—have large, conspicuous flowers; others, such as grasses and oaks, produce small, inconspicuous flowers.

Flowering plants are vascular plants that reproduce sexually by forming flowers and, following a unique double fertilization process, seeds within fruits. The fruit protects the developing seeds and often aids in their dispersal (see Chapter 37). Flowering plants have efficient water-conducting cells called **vessel elements** in their xylem and efficient sugar-conducting cells called **sieve tube elements** in their phloem (see Chapter 33).

Flowering plants are extremely important to humans because our survival as a species literally depends on them. All our major food crops are flowering plants; examples include rice, wheat, corn, potatoes, tomatoes, beans, apples, and citrus fruits. Woody flowering plants such as oak, cherry, and walnut provide valuable lumber. Flowering plants give us fibers, such as cotton and linen, and medicines, such as digitalis and codeine. Products as diverse as rubber, tobacco, coffee, chocolate, wine, and aromatic oils for perfumes come from flowering plants. *Economic botany* is the subdiscipline of botany that deals with plants of economic importance.

Monocots and eudicots are the two largest classes of flowering plants

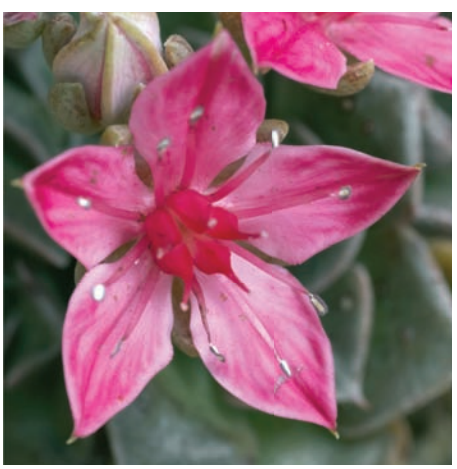


Phylum Anthophyta is divided into several classes with only a few members each and two very large classes: the monocots (class Monocotyledones) and the eudicots (class Eudicotyledones). The smaller classes will be discussed later in this chapter in the context of their evolutionary significance. For now, we restrict our discussion of flowering plants to the monocots and eudicots, which collectively represent about 97% of all flowering plant species. Eudicots are more diverse and include many more species (at least 200,000) than the monocots (at least 90,000). TABLE 28-2 provides a comparison of some of the general features of the two classes.

Table 28-2 Distinguishing Features of Monocots and Eudicots

Feature	Monocots	Eudicots
Flower parts	Usually in threes	Usually in fours or fives
Pollen grains	One furrow or pore	Three furrows or pores
Leaf venation	Usually parallel	Usually netted
Vascular bundles in stem cross section	Usually scattered or more complex arrangement	Arranged in a circle (ring)
Roots	Fibrous root system	Taproot system
Seeds	Embryo with one cotyledon	Embryo with two cotyledons
Secondary growth (wood and bark)	Absent	Often present

Monocots include palms, grasses, orchids, irises, onions, and lilies. Monocots are mostly herbaceous plants with long, narrow leaves that have parallel veins (the main leaf veins run parallel to one another). The parts of monocot flowers usually occur in threes (FIG. 28-9a). For example, a flower may have three sepals, three petals, six stamens, and a compound pistil consisting of three fused carpels (these flower parts are discussed shortly). Monocot seeds have a single **cotyledon**, or embryonic seed leaf; **endosperm**, a nutritive tissue, is usually present in the mature seed.



Eudicots include oaks, roses, mustards, cacti, blueberries, and sunflowers. Eudicots are either herbaceous (such as a tomato plant) or woody (such as a hickory tree). Their leaves vary in shape but usually are broader than monocot leaves, with netted (finely branched) veins. Flower parts usually occur in fours or fives or multiples thereof (FIG. 28-9b). Two cotyledons are present in eudicot seeds, and endosperm is usually absent in the mature seed, having been absorbed by the two cotyledons during seed development.

Brian Lasenby/Shutterstock.com

(a) Monocot. *Trillium erectum*, like most monocots, has floral parts in threes. Note the three green sepals, three red petals, six stamens, and three stigmas (the compound pistil consists of three fused carpels).

Glenn Harper/AgeFotostock

(b) Eudicot. Most eudicots, such as this *Tacitus*, have floral parts in fours or fives. Note the five petals, ten stamens, and five separate pistils. Five sepals are also present but barely visible against the background.

Figure 28-9 Flowering plants

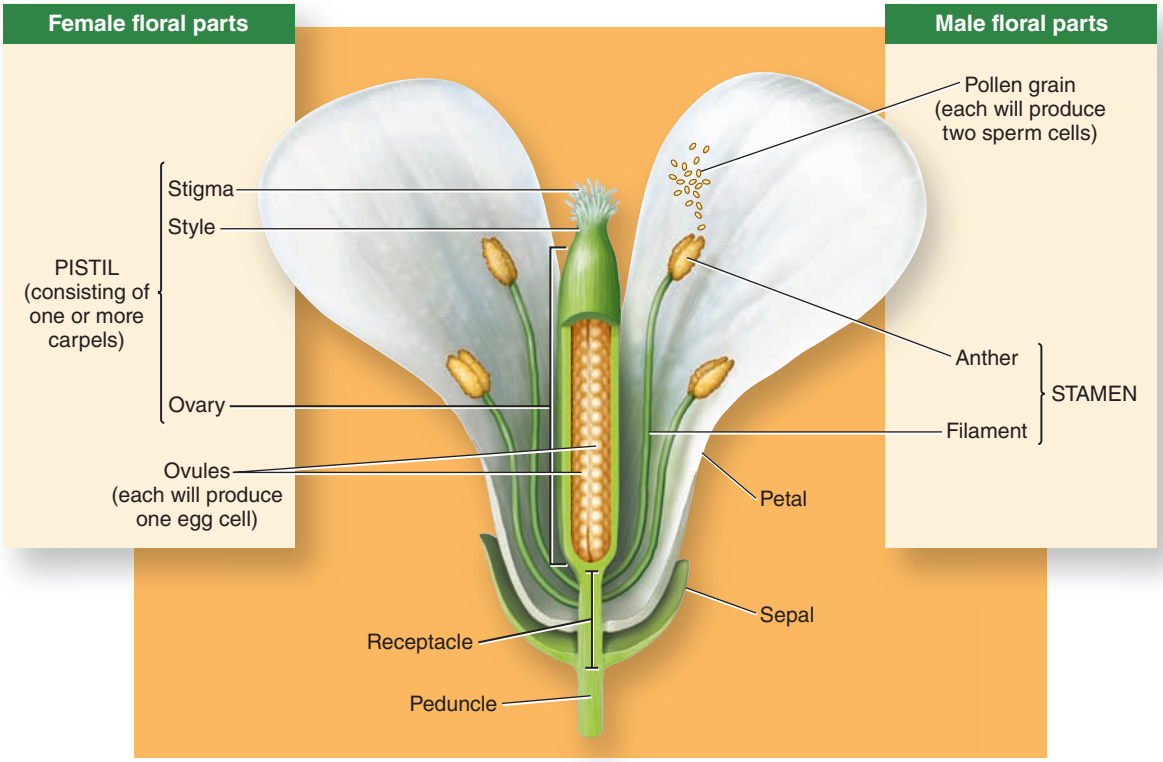

Figure 28-10 Floral structure

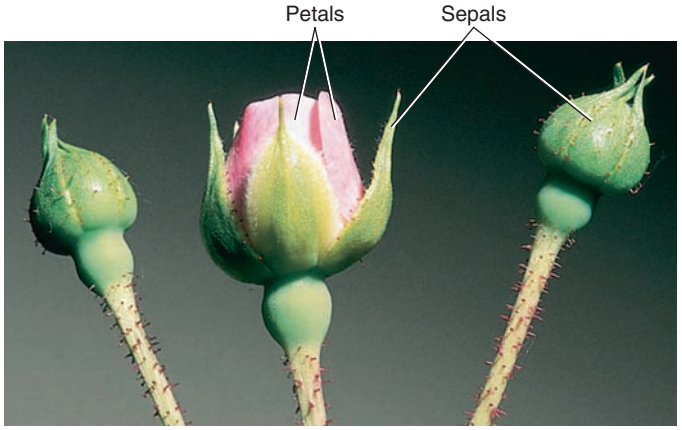
This cutaway view of an *Arabidopsis* flower shows the details of basic floral structure. Each flower has four sepals (two are shown), four petals (two are shown), six stamens, and one long pistil. Four of the stamens are long, and two are short (two long and two short are shown). Pollen grains develop within sacs in the anthers. In *Arabidopsis*, the compound pistil consists of two carpels that each contain numerous ovules.

Sexual reproduction takes place in flowers

Flowers are reproductive shoots usually composed of four parts—sepals, petals, stamens, and carpels—arranged in whorls (circles) on the end of a flower stalk, or **peduncle** (FIG. 28-10). The peduncle may terminate in a single flower or a cluster of flowers known as an **inflorescence**. The tip of the flower stalk that bears the flower parts is known as the **receptacle**.

All four floral parts are important in the reproductive process, but only the stamens (the "male" organs) and carpels (the "female" organs) produce gametes. A flower that has all four parts is a **complete flower**, whereas an **incomplete flower** lacks one or more of these four parts. A flower with both stamens and carpels is a **perfect flower**, whereas an **imperfect flower** has stamens or carpels, but not both.

Sepals, which make up the lowermost and outermost whorl on a floral shoot, are leaflike in appearance and often green (FIG. 28-11a). Sepals cover and protect the other flower parts when the flower is a bud. As the flower opens, the sepals fold back to reveal the more conspicuous petals. The collective term for all the sepals of a flower is the **calyx**.



The whorl just above the sepals consists of **petals**, which are broad, flat, and thin (like sepals and leaves) but vary in shape and are frequently brightly colored. Petals attract animal pollinators to the flower (see Chapter 37). Sometimes petals are fused to form a tube (as in trumpet honeysuckle flowers) or other floral shape (as in snapdragons, whose petals form two lips). The petals of a flower are referred to collectively as the **corolla**.

Just inside the petals is a whorl of **stamens** (FIG. 28-11b). Each stamen is composed of a thin stalk, called a **filament**, and a saclike **anther**, where meiosis occurs to form microspores that develop into pollen grains. Each pollen grain produces two cells surrounded by a tough outer wall. One cell eventually divides to form two male gametes, or sperm cells, and the other produces a pollen tube through which the sperm cells travel to reach the ovule.

In the center of most flowers are one or more closed **carpels**, the "female" reproductive organs. Carpels bear ovules, which, as you may recall, are structures with the potential to develop into seeds. The carpels of a flower can be separate or fused into a single structure. The female part of the flower is also called a **pistil** (see Fig. 28-11b). A pistil may consist of a single carpel (a simple pistil) or a group of fused carpels (a compound pistil) (FIG. 28-12). Each pistil generally has three sections: a **stigma**, on which the pollen grain lands; a **style**, a necklike structure through which the pollen tube grows; and an **ovary**, an enlarged structure that contains one or more ovules. Each young ovule contains a female gametophyte that forms one female gamete (an egg), two *polar nuclei*, and several other haploid cells. After fertilization, the ovule develops into a seed, and the ovary develops into a fruit.

Figure 28-12 Simple and compound pistils

The life cycle of flowering plants includes double fertilization

Flowering plants undergo alternation of generations in which the sporophyte generation is larger and nutritionally independent (FIG. 28-13). The gametophyte generation in flowering plants is microscopic and nutritionally dependent on the sporophyte. Flowering plants, like gymnosperms and certain other vascular plants, are heterosporous and produce two kinds of spores: microspores and megaspores. Sexual reproduction occurs in the flower.

Each young ovule within an ovary contains a megasporocyte (megaspore mother cell) that undergoes meiosis to produce four haploid megaspores. Three of them usually disintegrate, and one divides mitotically and develops into a mature female gametophyte, also called an **embryo sac**.

Embryo sacs in the vast majority of angiosperms contain seven cells with eight haploid nuclei. Six of these cells, including the egg cell, contain a single nucleus each, and a central cell has two nuclei, called **polar nuclei**. The egg and the central cell with two polar nuclei are directly involved in fertilization; the other five cells in the embryo sac apparently have no direct role in the fertilization process and disintegrate. As the *synergids* (the two cells flanking the egg) disintegrate, however, they release chemicals that may affect the direction of pollen tube growth.

Each pollen sac, or microsporangium, of the anther contains numerous microsporocytes (microspore mother cells), each of which undergoes meiosis to form four haploid microspores. Every microspore develops into an immature male gametophyte, also called a *pollen grain*. Pollen grains are small, and each consists of two cells: the *tube cell* and the *generative cell*.

The anthers split open and begin to shed pollen. A variety of agents—including wind, water, insects, and other animal pollinators—transfer pollen grains to the stigma (see

Key Point

A significant feature of the flowering plant life cycle is double fertilization, in which one sperm cell unites with the egg, forming a zygote; the other sperm cell unites with the two polar nuclei, forming a triploid cell that gives rise to endosperm.

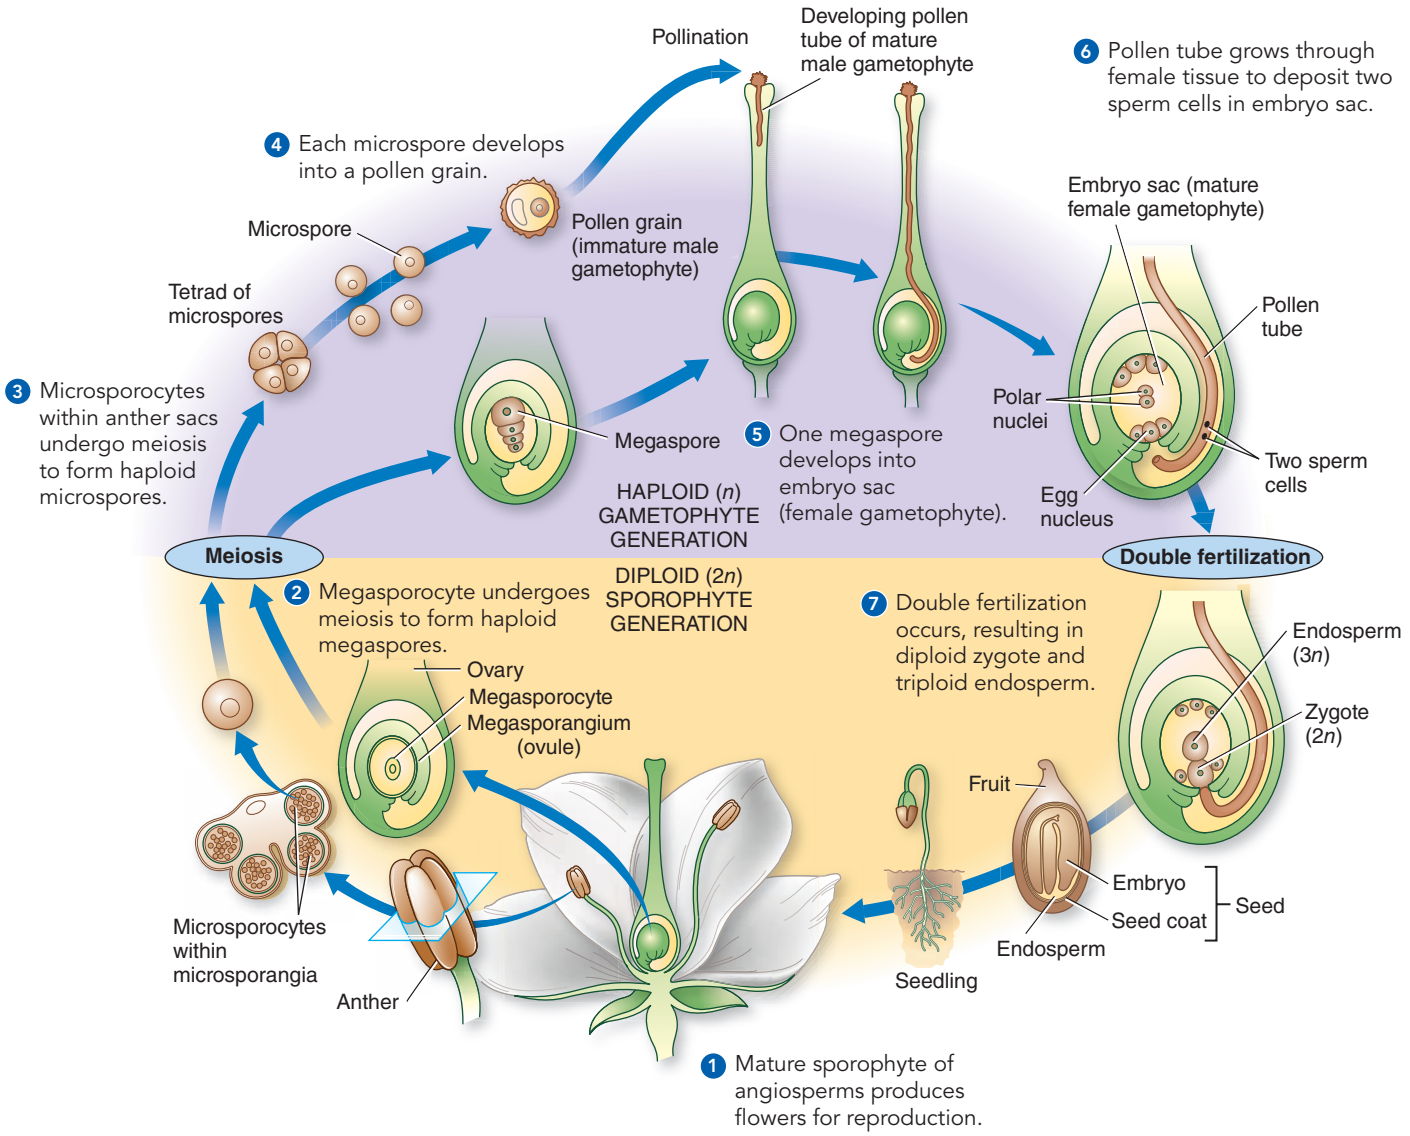

Figure 28-13 Life cycle of flowering plants

CONNECT Are microspores and megaspores haploid or diploid? Are they gametes? Explain your answer.

Chapter 37). If compatible with the stigma, the pollen grain germinates, and a pollen tube grows down the style and into the ovary. The germinated pollen grain with its pollen tube is the mature male gametophyte. Next, the generative cell divides to form two nonflagellate sperm cells. The sperm cells move down the pollen tube and are discharged into the embryo sac.

When the two sperm cells enter the embryo sac, *both* participate in fertilization. One sperm cell fuses with the egg, forming a zygote that divides by mitosis and develops into a multicellular embryo in the seed. The second sperm cell fuses with the two haploid polar nuclei of the central cell to form a triploid ($3n$) cell that divides by mitosis and develops into **endosperm**, a nutrient tissue rich in lipids, proteins, and carbohydrates that nourishes the growing embryo. This fertilization process, which involves two separate nuclear fusions, is called **double fertilization** and is, with two exceptions, unique to flowering plants. (Double fertilization has been reported in the gymnosperms *Ephedra nevadensis* and *Gnetum gnemon*. This process differs from double fertilization in flowering plants in that an additional zygote, rather than endosperm, is produced. The second zygote later disintegrates.)

Seeds and fruits develop after fertilization

As a result of double fertilization and subsequent growth and development, each seed contains a young plant embryo and nutritive tissue (the endosperm), both of which are surrounded by a protective seed coat. In monocots, the endosperm persists and is the main source of food in the mature seed. In most eudicots, the endosperm nourishes the developing embryo, which subsequently stores food in its cotyledons.

As a seed develops from an ovule following fertilization, the ovary wall surrounding it enlarges dramatically and develops into a **fruit**. In some instances, other tissues associated with the ovary also enlarge to form the fruit (see discussion of fruits in Chapter 37). Fruits serve two purposes: to protect the developing seeds from desiccation as they grow and mature and to aid in the dispersal of seeds. For example, dandelion fruits have feathery plumes that are lifted and carried by air currents. Animals often assist in dispersing seeds found in edible fruits (FIG. 28-14). Once a seed lands in a suitable place, it may germinate and develop into a mature sporophyte that produces flowers, and the life cycle continues as described.

Flowering plants have many adaptations that account for their success

The evolutionary adaptations of flowering plants account for their success in terms of their ecological dominance and their great number of species. Seed production as the primary means of reproduction and dispersal, an adaptation shared with the gymnosperms, is clearly significant and provides a definite advantage over seedless vascular plants. Closed carpels, which give rise to fruits surrounding the seeds, and the process of double fertilization with its resulting endosperm increase the likelihood of reproductive success. The evolution of a variety of interdependencies with many types of insects, birds, and bats, which disperse pollen from one flower to another of the same species, is another reason for angiosperm success. Pollen transfer results in cross-fertilization, which mixes the genetic material and promotes genetic variation among the offspring.

irabelB/Shutterstock.com

Figure 28-14 Guava fruit and seeds

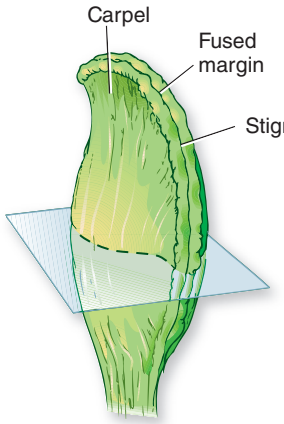
Animals eat fleshy fruits such as guava. The seeds are frequently swallowed whole and pass unharmed through the animals' digestive tracts.

Several distinctive features have contributed to the success of flowering plants in addition to their highly successful reproduction involving flowers, fruits, and seeds. Recall that most flowering plants have very efficient water-conducting vessel elements in their xylem, as well as tracheids. In contrast, the xylem of almost all seedless vascular plants and gymnosperms consists exclusively of tracheids. Most flowering plants also have efficient carbohydrate-conducting sieve tube elements in their phloem. Vascular plants other than flowering plants and gnetophytes lack vessel elements and sieve tube elements.

The leaves of flowering plants, with their broad, expanded blades, are very efficient at absorbing light for photosynthesis. Abscission (shedding) of these leaves during cold or dry periods reduces water loss and has enabled some flowering plants to expand into habitats that would otherwise be too harsh for survival. The stems and roots of flowering plants are often modified for food or water storage, another feature that helps flowering plants survive in severe environments.

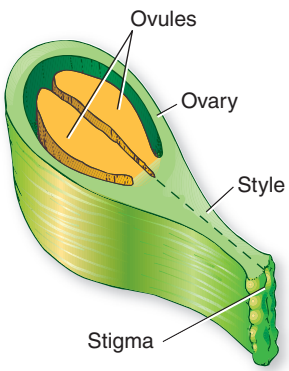
Probably most crucial to the evolutionary success of flowering plants, however, is the overall adaptability of the sporophyte generation. As a group, flowering plants readily adapt to new habitats and changing environments. This adaptability is evident in the great diversity of growth forms exhibited by the various species of flowering plants. For example, the cactus is remarkably well-adapted to desert environments. Its stem stores water; its leaves (spines) have a reduced surface area available for transpiration (loss of water vapor; see Chapter 34) and may also protect against thirsty herbivorous animals; and its thick, waxy cuticle reduces water loss. In contrast, the water lily is well-adapted for wet environments, in part because it has air channels that provide adequate oxygen to stems and roots living in oxygen-deficient water and mud.

Floral structure provides insights into the evolutionary process



In evolution new structures or organs often originate by modification of previously existing structures or organs. (See Chapter 20 for the discussion of preadaptations.) Much evidence supports the classical interpretation that the four organs of a flower—sepals, petals, stamens, and carpels—arose from highly modified leaves. This evidence includes comparisons of the arrangement of vascular tissues in both flowers and leafy stems and of the developmental stages of floral parts and leaves.

Sepals are the most leaflike of the four floral organs, and botanists generally agree that sepals are specialized leaves. Although petals of many flowering plant species are leaflike in appearance, botanists generally view petals as modified stamens that later became sterile and leaflike. Cultivated roses and camellias provide evidence supporting this hypothesis; in some varieties the stamens have been transformed into petals, forming showy flowers with large numbers of petals.



The remarkably leaflike stamens and carpels of certain tropical trees and other species support the origin of stamens and

(a) The carpel resembles a folded leaf in which the ovules borne on its upper surface are enclosed.

(b) A cross section of the carpel, cut along the dashed line in **(a)**.

Figure 28-15 Carpel of *Drimys piperita*

carpels from leaves or leaflike organs. Consider, for example, the carpel of *Drimys*, a genus of flowering trees and shrubs native to Southeast Asia, Australia, and South America. This carpel resembles a leaf that is folded inward along the midrib, thereby enclosing the ovules, and joined along the entire length of the leaf's margin (FIG. 28-15).

The fundamental question is whether these leaflike stamens and carpels are shared ancestral characters that were conserved (retained) during the course of evolution or instead are highly specialized organs (i.e., shared derived characters) that do not resemble early stamens and carpels. Many botanists who have studied this question have concluded that stamens and carpels are probably derived from leaves. Not all botanists accept the origin of stamens and carpels from highly modified leaves, however.

During the course of more than 130 million years of angiosperm evolution, floral structure diversified as floral organs fused or became reduced in size or number. These changes led to greater complexity in floral structure in some species and greater simplicity in other species. Interpreting the floral structures of so many different angiosperm species is sometimes difficult, but it is important because correct interpretations are essential to devising a phylogenetic classification scheme.

CHECKPOINT 28.3

- How do nonreproductive adaptations of flowering plants differ from those of gymnosperms?
- **CONNECT** How does the flowering plant life cycle differ from that of the gymnosperms?
- What are the two major classes of flowering plants, and how can one distinguish between them?
- **CONNECT** How does fertilization differ in gymnosperms and flowering plants?

28.4 The Evolution of Seed Plants

LEARNING OBJECTIVE

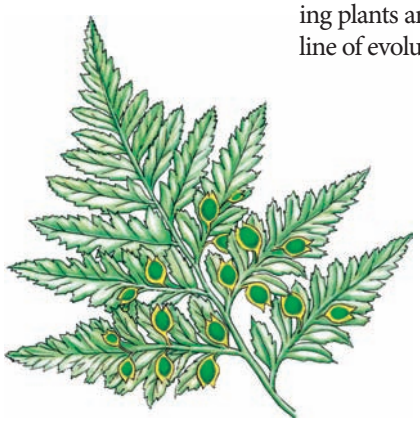
9 Summarize the evolution of gymnosperms from seedless vascular plants and trace the evolution of flowering plants from gymnosperms.

One group that descended from ancestral seedless vascular plants was the **progymnosperms**, all of which are now extinct. Progymnosperms had two derived features: leaves with branching veins (*megaphylls*) and woody tissue (*secondary xylem*) similar to that of modern gymnosperms. Progymnosperms, however, reproduced by spores, not seeds. *Archaeopteris*, a progymnosperm that lived about 370 mya, is one of the earliest known trees with "modern" woody tissue (FIG. 28-16a).

Fossils of several progymnosperms with reproductive structures intermediate between those of spore plants and seed plants have been discovered. For example, the evolution of microspores into pollen grains and of megasporangia into ovules (seed-producing structures) can be traced in fossil progymnosperms. Plants producing seeds appeared during the late Devonian period, more than 359 mya. The fossil record indicates that different groups of seed plants apparently arose independently several times.

As mentioned previously, fossilized remains of ginkgo are found in 200-million-year-old rocks, and other groups of gymnosperms were well established by 160 mya to 100 mya. Although the gymnosperms are an ancient group, some questions persist about the exact pathways of gymnosperm evolution. The fossil record indicates that progymnosperms probably gave rise to conifers and to another group of extinct plants called **seed ferns**, which were seed-bearing woody plants with fernlike leaves (FIG. 28-16b). The seed ferns, in turn, probably gave rise to cycads and ginkgo as well as to several gymnosperm groups now extinct. The origin of gnetophytes remains unclear, although molecular data indicate that they are closely related to conifers.

Our understanding of the evolution of flowering plants has made great progress in recent years



Flowering plants are the most recent clade of plants to evolve. The fossil record, although incomplete, suggests that flowering plants descended from gymnosperms. By the middle of the Jurassic period, about 180 mya, several gymnosperm lines existed with some features resembling those of flowering plants. Among other traits, these derived gymnosperms possessed leaves with broad, expanded blades and the first modified seed-bearing leaves, which nearly enclose the ovules. Beetles were evidently visiting these plants, and biologists have suggested that perhaps this relationship was the beginning of **coevolution**, a mutual adaptation between plants and their animal pollinators (see Chapter 37).

(a) Progymnosperm. *Archaeopteris*, which existed about 370 mya, had some features in common with modern seed plants but did not produce seeds.

(b) Seed fern. *Emplectopteris* produced seeds on fernlike leaves. Seed ferns existed from about 360 mya to 250 mya.

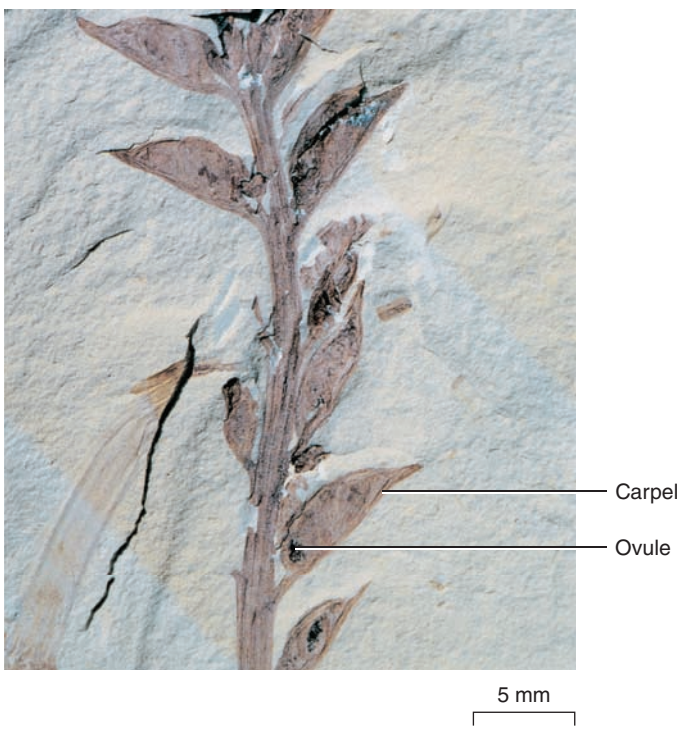

Figure 28-16 Evolution of seed plants

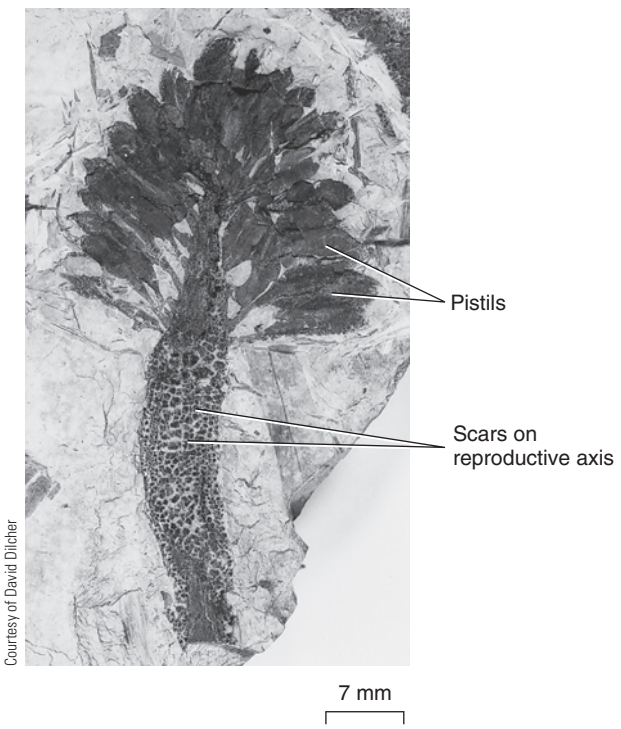
(a) Redrawn from Beck, C.B., "Reconstructions of *Archaeopteris* and Further Consideration of Its Phylogenetic Position," *American Journal of Botany*, Vol. 49 (1962); **(b)** Redrawn from Andrews, H.N., *Ancient Plants and the World They Lived In* (Comstock, New York, 1947).

One important task facing paleobotanists (biologists who study fossil plants) is determining which of the ancient gymnosperms are in the direct line of evolution leading to the flowering plants. Given the structural data, most botanists hypothesize that flowering plants arose only once; that is, they think that there is only one line of evolution from the gymnosperms to the flowering plants.



Based largely on structural data, many evolutionary botanists previously thought that the gnetophytes were the gymnosperm clade most closely related to flowering plants. However, new hypotheses of angiosperm origin have been proposed in recent years with advances in molecular comparisons, genetic studies (particularly as gene function relates to reproductive development), and additional fossil discoveries. Currently, many botanists think that the closest extant gymnosperms related to flowering plants are probably conifers, but this hypothesis is far from certain, and the origin and early evolution of flowering plants continue to challenge botanists.

The oldest definitive trace of flowering plants in the fossil record consists of ovules enclosed in tiny podlike fruits interpreted as carpels in Jurassic and Lower Cretaceous rocks some 125 million to 145 million years old (FIG. 28-17a). The oldest fossilized flowers are about 118 million to 120 million years old.

David Dilcher and Ge Sun

(a) The oldest known fossil angiosperm. This fossil of *Archaefructus* shows a carpel-bearing stem. Discovered in northeastern China, it is about 125 million years old.

Key Point

Flowering plants evolved from ancient gymnosperms. Basal angiosperms are early diverging clades that still survive today.

(a) One hypothesis of relationships among the flowering plants, based on fossil and molecular evidence. *Amborella*, water lilies, and star anise are living plants whose ancestors apparently branched off of the angiosperm family tree early. These early clades were followed by the magnoliids, the monocots, and the eudicots.

(e) *Magnolia*, a core angiosperm.

Figure 28-18 Evolution of flowering plants

CONNECT According to the cladogram, do all basal angiosperms possess vessel elements?

By 90 mya, during the Cretaceous period, flowering plants had diversified and had begun to replace gymnosperms as Earth's dominant plants. Fossils of flowering plant leaves, stems, flowers, fruits, and seeds are numerous and diverse. They outnumber fossils of gymnosperms and ferns in Late Cretaceous deposits, indicating the rapid success of flowering plants once they appeared (FIG. 28-17b). Many angiosperm species apparently arose from changes in chromosome number. (See discussion of allopolyploidy and sympatric evolution in Chapter 20.)

The basal angiosperms comprise three clades

Beginning in 1999, a series of cladistic analyses of structural features and molecular comparisons have helped clarify relationships among the angiosperm classes. In the process many long-held assumptions about early angiosperm lineages have been discarded. The evidence indicates that several clades of basal (early-diverging) angiosperms evolved before the divergence of core angiosperms (FIG. 28-18a). The 170 species of

Key Experiment

Plants commonly known as hydatellas were incorrectly classified as grasses until recent molecular evidence indicated that they are basal angiosperms closely related to water lilies. Do these plants have any reproductive features that may indicate that they are one of the most ancient surviving lineages of angiosperms?

EXPERIMENT: *Trithuria inconspicua* (formerly *Hydatella inconspicua*), a small aquatic plant, was collected at a lake in Northland, New Zealand, and its embryo sacs were carefully analyzed.

© Justin Goh, School of Biological Sciences, University of Auckland, Auckland, New Zealand

RESULTS AND CONCLUSION: As in gymnosperms, the mother plant turns over nutrients to the seed *before* fertilization has occurred. This gymnosperm-like reproductive feature may represent a shared ancestral character that was retained during the transition from gymnosperms to flowering plants, thus supporting the view that hydatellas are representative of an ancient angiosperm lineage. Alternatively, this feature may represent a shared derived character not found in earlier hydatella ancestors.

SOURCE: Friedman, W.E., "Hydatellaceae Are Water Lilies with Gymnospermous Tendencies," *Nature*, Vol. 453 (May 1, 2008).

Figure 28-19 The basal angiosperm *Trithuria*

Trithuria inconspicua belongs to an ancient clade that consists of about 10 species native to Australia, New Zealand, and India.

CONNECT How is the nutritive tissue in the seeds of gymnosperms formed?

basal angiosperms represent groups thought to be ancestral to all other flowering plants.

The oldest surviving clade of basal angiosperms is represented by a single extant species, *Amborella trichopoda* (FIG. 28-18b). A shrub native to New Caledonia, an island in the South Pacific, *Amborella* may be the nearest living relative to the ancestor of all flowering plants. The water lilies and related families compose the second clade of basal angiosperms (FIG. 28-18c and FIG. 28-19). This clade, which contains about 70 species of aquatic or wetland herbs, may be the second-oldest surviving lineage. Star anise and relatives—the third clade of basal angiosperms—consist of about 100 species of vines, trees, and shrubs found mostly in warmer climates. Star anise is important economically because it is a source of spice used by confectioners and anise oil (FIG. 28-18d). Star anise is also used to make Tamiflu, a treatment for influenza.

The core angiosperms comprise magnoliids, monocots, and eudicots

Most angiosperm species belong to a clade of **core angiosperms**, which is divided into three subclades: magnoliids, monocots, and eudicots. **Magnoliids** include species in the magnolia, laurel, and black pepper families as well as several related families (FIG. 28-18e). Although magnoliids were traditionally classified with the eudicots as "dicots," molecular evidence such as DNA sequence comparisons indicates that the magnoliids are neither eudicots nor monocots. Native to tropical or warm temperate regions, magnoliids include several economically important plants, such as avocado, black pepper, nutmeg, and bay laurel.

CHECKPOINT 28.4

- What features distinguish progymnosperms from seed ferns?
- Describe the significant features of the oldest known fossil angiosperm.
- Are monocots considered basal or core angiosperms? Explain your answer.

Summary: Focus on Learning Objectives

28.1 An Introduction to Seed Plants *(page 585)*

1 Compare the features of gymnosperms and angiosperms.

- The two groups of seed plants are the **gymnosperms** and the **angiosperms**. Gymnosperms produce seeds that are totally exposed or borne on the scales of cones; an ovary wall does not surround the ovules of gymnosperms. Angiosperms are flowering plants that produce their seeds within a fruit (a mature ovary).

28.2 Gymnosperms *(page 586)*

2 Trace the steps in the life cycle of a pine and compare its sporophyte and gametophyte generations.

- A pine tree is a mature sporophyte; pine gametophytes are extremely small and nutritionally dependent on the sporophyte generation. Pine is heterosporous and produces microspores and megaspores in separate cones.
- Male cones produce **microspores** that develop into **pollen grains** (immature male gametophytes) that are carried by air currents to female cones.
- Female cones produce **megaspores**. One of each four megaspores produced by meiosis develops into a female gametophyte within an **ovule** (**megasporangium**).
- After **pollination**, the transfer of pollen to the female cones, a **pollen tube** grows through the megasporangium to the egg within the archegonium. After **fertilization**, the zygote develops into an embryo encased inside a seed adapted for wind dispersal.

3 Summarize the features that distinguish gymnosperms from bryophytes and ferns.

- Unlike bryophytes, gymnosperms are vascular plants. Unlike bryophytes and ferns, gymnosperms produce seeds. Gymnosperms also produce wind-borne pollen grains, a feature absent in ferns and other seedless vascular plants.

4 Name and briefly describe the four phyla of gymnosperms.

- **Conifers** (phylum Coniferophyta), the largest phylum of gymnosperms, are woody plants that bear *needles* (slender leaves that are usually evergreen) and produce seeds in cones. Most conifers are **monoecious** and have male and female reproductive parts in separate cones on the same plant.
- **Cycads** (phylum Cycadophyta) are palmlike or fernlike in appearance. They are **dioecious**—they have male and female reproductive structures on separate plants—but reproduce with pollen and seeds in conelike structures.
- *Ginkgo biloba*, the only surviving species in phylum Ginkgophyta, is a deciduous, dioecious tree. The female **ginkgo** produces fleshy seeds directly on branches.
- **Gnetophytes** (phylum Gnetophyta) are an obscure clade of gymnosperms that has a few traits associated with angiosperms.

28.3 Flowering Plants *(page 591)*

5 Summarize the features that distinguish flowering plants from other plants.

- **Flowering plants**, or angiosperms (phylum Anthophyta), constitute the phylum of vascular plants that produce flowers and seeds enclosed within a **fruit**. They are the most diverse and most successful group of plants.
- The flower, which may contain **sepals**, **petals**, **stamens**, and **carpels**, functions in sexual reproduction. Unlike those of gymnosperms, the ovules of flowering plants are enclosed within an **ovary**. After fertilization, the ovules become seeds, and the ovary develops into a fruit.

6 Briefly explain the life cycle of a flowering plant and describe double fertilization.

- The sporophyte generation is dominant in flowering plants; gametophytes are extremely reduced in size and nutritionally dependent on the sporophyte generation. Flowering plants are heterosporous and produce microspores and megaspores within the flower.
- Each microspore develops into a pollen grain (immature male gametophyte). One of each four megaspores produced by meiosis develops into an **embryo sac** (female gametophyte). Within the embryo sac, the egg cell and the central cell with two **polar nuclei** participate in fertilization.
- **Double fertilization**, which results in the formation of a diploid zygote and triploid **endosperm**, is characteristic of flowering plants.

7 Contrast monocots and eudicots, the two largest classes of flowering plants.

- Most **monocots** (class Monocotyledones) have floral parts in threes, and their seeds each contain one **cotyledon**. The nutritive tissue in their mature seeds is endosperm.
- **Eudicots** (class Eudicotyledones) usually have floral parts in fours or fives or multiples thereof, and their seeds each contain two cotyledons. The nutritive organs in their mature seeds are usually the cotyledons, which have absorbed the nutrients in the endosperm.

8 Discuss the evolutionary adaptations of flowering plants.

- Flowering plants reproduce sexually by forming flowers. After double fertilization, seeds form within fruits. Flowering plants have efficient water-conducting **vessel elements** in their xylem and efficient carbohydrate-conducting **sieve tube elements** in their phloem. Wind, water, insects, or other animals transfer pollen grains in various flowering plants.

28.4 The Evolution of Seed Plants *(page 597)*

9 Summarize the evolution of gymnosperms from seedless vascular plants and trace the evolution of flowering plants from gymnosperms.

- Seed plants arose from seedless vascular plants. **Progymnosperms** were seedless vascular plants that had megaphylls and "modern" woody tissue. Progymnosperms probably gave rise to conifers as well as to **seed ferns**, which in turn likely gave rise to cycads and ginkgo.
- The evolution of the gnetophytes is unclear, although molecular data indicate that they are closely related to conifers.
- Flowering plants probably descended from ancient gymnosperms that had specialized features, such as leaves with broad, expanded blades and closed carpels. Flowering plants likely arose only once; that is, there is only one line of evolution from the gymnosperms to the flowering plants.

Test Your Understanding

Know and Comprehend

1. Seed plants *lack* which of the following structure(s)? (a) ovules surrounded by integuments (b) microspores and megaspores (c) vascular tissues (d) a large, nutritionally independent sporophyte (e) a large, nutritionally independent gametophyte
2. Conifers, cycads, ginkgo, and gnetophytes are collectively called (a) club mosses (b) gymnosperms (c) angiosperms (d) eudicots (e) seedless vascular plants
3. The immature male gametophytes of pine are called (a) ovules (b) stamens (c) seed cones (d) pollen grains (e) polar nuclei
4. The transfer of pollen grains from the male to the female reproductive structure is known as (a) pollination (b) fertilization (c) embryo sac development (d) seed development (e) fruit development
5. Motile sperm cells are found as vestiges in these two gymnosperm groups: (a) monocots, eudicots (b) gnetophytes, conifers (c) gnetophytes, flowering plants (d) cycads, conifers (e) cycads, ginkgo
6. There are at least _____ species of flowering plants worldwide. (a) 300 (b) 3000 (c) 30,000 (d) 300,000 (e) 3,000,000
7. A simple pistil consists of a single (a) calyx (b) carpel (c) ovule (d) filament (e) petal
8. A flower that lacks stamens is both _____ and _____. (a) complete; imperfect (b) incomplete; perfect (c) complete; perfect (d) incomplete; imperfect
9. After fertilization, the _____ develop(s) into a fruit and the _____ develop(s) into a seed. (a) ovary; ovule (b) polar nuclei; ovule (c) ovary; endosperm (d) ovule; ovary (e) ovule; polar nuclei
10. The female gametophyte in flowering plants is also called the (a) polar nuclei (b) anther (c) embryo sac (d) endosperm (e) sporophyll
11. This flowering plant may be the nearest living relative to the ancestor of all flowering plants. (a) *Amborella* (b) *Archaeopteris* (c) *Gnetum* (d) water lily (e) magnolia

Apply and Analyze

12.  This cross section through an ovary reveals that the pistil is (a) simple, with one carpel (b) compound, with two fused carpels (c) compound, with three fused carpels (d) compound, with six separate carpels (e) compound, with six fused carpels
13. You are given a plant that you have never seen before (see figure). Is it a gymnosperm or angiosperm? A monocot or eudicot? What are the features that helped you make these determinations?

Carlyn Iverson

14. **VISUALIZE** Sketch a seed of a gymnosperm and of a monocot. Label the embryo, seed coat, and nutritive tissue (giving its specific name). Indicate the ploidy of each structure (haploid, diploid, or triploid).
15. **CONNECT** How do the life cycles of seedless plants (see Chapter 27) and seed plants differ? In what fundamental ways are they alike?

Evaluate and Synthesize

16. **EVOLUTION LINK** Most flowers contain both male and female reproductive structures, in contrast to the cones of gymnosperms, which are either male or female. Explain how bisexual flowers might be an advantageous evolutionary adaptation to the flowering plants that possess them.
17. **EVOLUTION LINK** Contrast the algae, mosses, ferns, gymnosperms, and angiosperms with respect to their dependence on water as a transport medium for reproductive cells. Suggest a hypothesis to explain how the differences might be adaptive to living on land.
18. **EVOLUTION LINK** Where would you place the progymnosperms on Figure 28-2? Explain your reasoning.

29 The Fungi

Mushrooms, morels, and truffles, delights of the gourmet, share a recent common ancestry with baker's yeast, the black mold that forms on stale bread, and the mildew that collects on damp shower curtains. The science of **mycology**, the study of fungi, is concerned with all these diverse life-forms. Mycologists have described about 100,000 species, most of which are terrestrial, but they estimate that there are more than 1.5 million species. Biologists who use the kingdom as a taxon group these organisms in kingdom Fungi, one of the eukaryotic kingdoms.

Fungi grow best in moist habitats, but they are found universally wherever organic material is available. They require moisture to grow, and they can obtain water from a humid atmosphere as well as from the medium on which they live. When the environment becomes dry, fungi survive by going into a resting stage or by producing spores (see photograph) that resist desiccation (drying out).

Some fungi grow to enormous size. In Washington State a fungal clone (*Armillaria ostoyae*) has been identified that covers more than 1500 acres. This giant fungus, which is mainly underground, developed from a single spore that germinated more than a thousand years ago. The fungus has fragmented and is no longer one continuous body.

Like prokaryotes, most fungi are decomposers that obtain nutrients and energy from dead organic matter. They are vital members of ecosystems because they break down the organic compounds found in dead organisms, leaves, garbage, sewage, and other waste. When they decompose organic compounds, carbon and other elements are released into the environment, where they are recycled.

Many fungi form vital symbiotic associations. For example, most terrestrial plants have fungal partners that live in close association with their roots. The fungi help the plants obtain phosphate ions and other needed minerals from the soil. In exchange, the plants provide the

KEY CONCEPTS

29.1 Fungi are eukaryotic heterotrophs that absorb nutrients from their surroundings; most grow as multicellular filaments called hyphae that form a tangled mass called a mycelium.

29.2 Most fungi have complex life cycles and reproduce both asexually and sexually by means of spores.

29.3 According to current hypotheses, fungi evolved from a unicellular, flagellate protist and diverged into several groups.

29.4 Fungi are of major ecological importance; they are decomposers, and they form symbiotic relationships with other organisms.

29.5 Fungi are of major economic, biological, and medical importance.

PHOTO: Fungal spores. These collared earthstars (*Geastrum triplex*) are releasing puffs of microscopic spores after their sacs, which are about 1.3 cm (0.5 in.) wide, were hit by raindrops. This fungus is common in leaf litter under trees throughout North America.

fungi with organic nutrients. Some fungi live symbiotically with algae and cyanobacteria as lichens. Others are parasites and pathogens that cause disease in animals or plants.

29.1 Characteristics of Fungi

LEARNING OBJECTIVES

1. Describe the distinguishing characteristics of fungi.
2. Describe the body plan of a fungus.

All **fungi** (sing., *fungus*) are eukaryotes; their cells contain membrane-enclosed nuclei, mitochondria, and other membranous organelles. Although they vary strikingly in size and shape, fungi share certain key characters, including their way of obtaining nutrition.

The optimum pH for most fungal species is about 5.6, but various fungi can tolerate and grow in environments where the pH ranges from 2 to 9. Many fungi are less sensitive to high osmotic pressures than are bacteria. As a result, they can grow in concentrated salt solutions or in sugar solutions such as jelly, which discourage or prevent bacterial growth. Fungi also thrive over a wide temperature range. Even refrigerated food may be invaded by fungi.

Fungi absorb food from the environment

Like animals, fungi are heterotrophs. For their nutritional and energy needs, they depend on preformed carbon molecules produced by other organisms. However, fungi do not ingest food and then digest it in the body as animals do. Instead, they infiltrate a food source and secrete digestive enzymes onto it. Digestion takes place outside the body. When complex molecules are broken down into smaller compounds, the fungus absorbs the predigested food into its body.

The fungus is very efficient at absorbing nutrients and growing. It rapidly converts nutrients into new cell material. If excessive amounts of nutrients are available, fungi store them, usually as lipid droplets or glycogen.

Fungi have cell walls that contain chitin

Like the cells of bacteria, certain protists, and plants, fungal cells are enclosed by cell walls during at least some stage in their life cycle. Fungal cell walls, however, have a different chemical composition from cell walls of other organisms. In most fungi the cell wall consists of complex carbohydrates, including **chitin**, a polymer that consists of subunits of a nitrogen-containing sugar (see Fig. 3-11). Chitin is also a component of the external skeletons of insects and other arthropods. It is resistant to breakdown by most microorganisms.

Most fungi consist of a network of filaments

The simplest fungi are the **yeasts**, which are unicellular, with a round or oval shape. Yeasts are widely distributed in the soil; on leaves, fruits, and cured meats; and on and in our bodies. The importance of some yeasts in medicine, biological research, and the food industry is discussed later in this chapter.

Most fungi are multicellular. The body consists of long, branched, threadlike filaments called **hyphae** (sing., *hypha*) (FIGS. 29-1a and b). Hyphae consist of tubular cell walls surrounding the plasma membranes of the fungal cells. They are an adaptation to the fungal mode of nutrition. Growth occurs at the tips of the hyphae; as the hyphae elongate, the fungus grows into and infiltrates food sources. The fungus absorbs nutrients through its very large surface area.

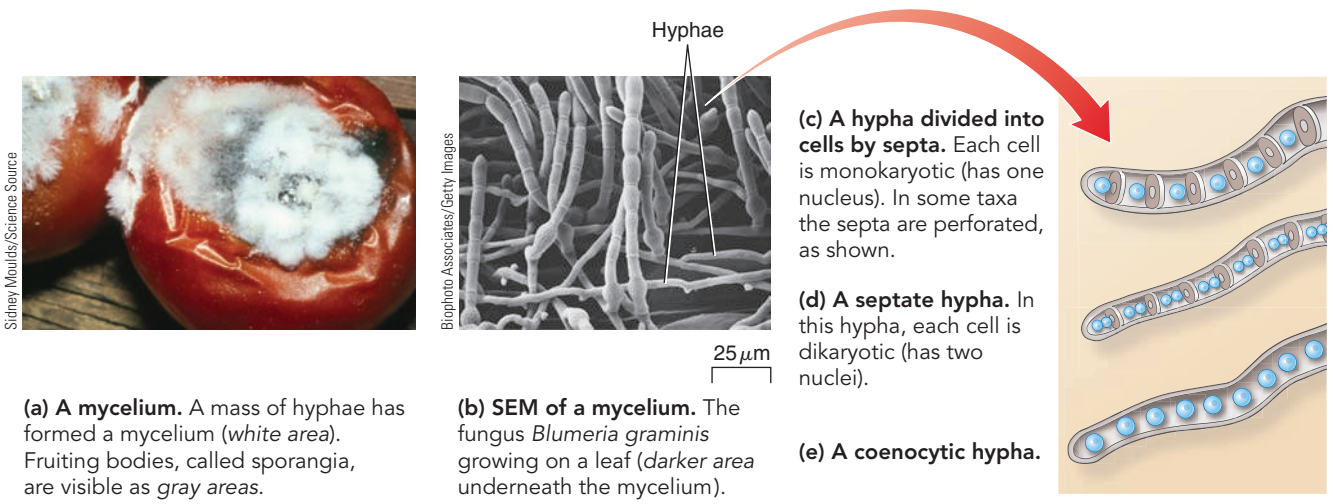

Figure 29-1 Fungus body plan

Spores carried by the air settle on food. They germinate and produce a mass of threadlike filaments called hyphae. The hyphae penetrate the food to obtain nourishment and produce a mass of hyphae called the mycelium. Eventually, specialized hyphae grow from the mycelium, giving rise to erect stalks with fruiting bodies (sporangia) at their tops. When the walls of the sporangia rupture, new spores are released into the air.

As hyphae grow they form a tangled mass or tissuelike network, called a **mycelium** (pl., *mycelia*). Fungi that form mycelia are commonly called *molds*. The cobweb-like mold sometimes seen on bread is the mycelium of a fungus. What is not seen is the extensive mycelium that grows into the bread. Depending on environmental conditions, some fungi can alternate between a yeast phase and a phase in which they produce hyphae.

In most fungi hyphae are divided by cross walls, called **septa** (sing., *septum*), into individual cells containing one or more nuclei (FIGS. 29-1c and d). As we will discuss, the presence of septa is an important character in the two largest fungal phyla (which include the most complex fungi). The septa of many fungi are perforated by a pore that may be large enough to permit organelles to flow from cell to cell. Some fungi are **coenocytes**, which lack septa. In these species nuclear division is not followed by cytoplasmic division. As a result, a coenocytic fungus is one elongated, multinucleated, giant cell (FIG. 29-1e).

CHECKPOINT 29.1

- **CONNECT** What characters distinguish fungi from other organisms?
- How does the body of a yeast differ from that of a mold?

29.2 Fungal Reproduction

LEARNING OBJECTIVE

3 Describe the life cycle of a typical fungus, including sexual and asexual reproduction.

Most fungi reproduce by means of microscopic **spores**, reproductive cells that can develop into new organisms. In most groups spores are nonmotile. They are dispersed by wind, water, or animals. The air we breathe is filled with hundreds of thousands of fungal spores. When a spore germinates, it gives rise to a hypha, which then develops into a mycelium (FIG. 29-2).

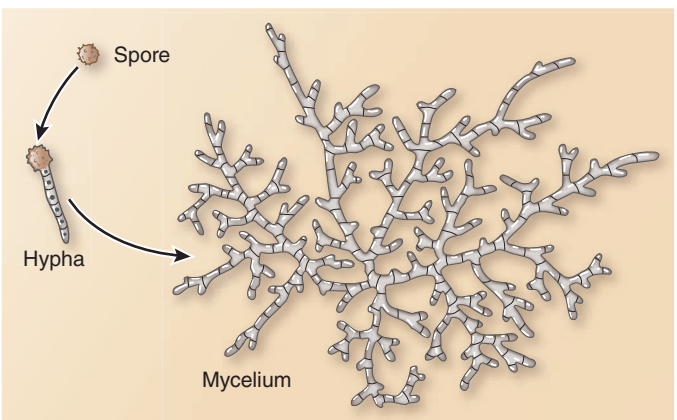

Figure 29-2 Germination of a spore to form a mycelium

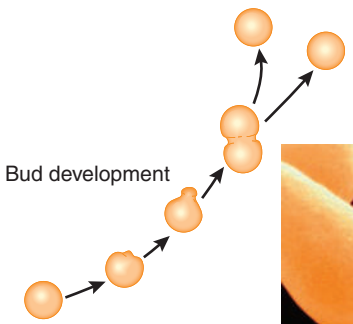
Fungi produce spores either sexually or asexually. With asexual reproduction new individuals are produced quickly, but there is little genetic variability. Sexual reproduction involves meiosis and generates new genotypes.



Spores are usually produced on specialized aerial hyphae or in fruiting structures. When positioned up above the ground, spores can be easily dispersed. Structures in which spores are produced are called **sporangia** (sing., *sporangium*). The aerial hyphae of some fungi produce spores in large, complex reproductive structures, referred to as **fruiting bodies**. The familiar part of a mushroom is a large fruiting body. We do not normally see the bulk of the fungus, a nearly invisible mycelium buried out of sight in the rotting material or soil on which it grows.

Many fungi reproduce asexually

Yeasts reproduce asexually, primarily by forming buds that pinch off from the parent cell (FIG. 29-3). Many species of multicellular fungi also reproduce asexually. Spores are produced by mitosis and then released into the air or water. **Conidiophores** (from the Greek, meaning "dust-bearers") are specialized hyphae that produce asexual spores called **conidia** (sing., *conidium*). The arrangement of conidia on conidiophores varies from species to species.

Most fungi reproduce sexually

Fungi are a diverse group with many variations in their life cycles. Most fungi (but not all) reproduce both asexually and sexually. FIGURE 29-4 illustrates a generalized life cycle. Many fungal species reproduce sexually when they come into

(a) Yeasts can reproduce asexually by budding.

Key Point

Most fungi can reproduce both asexually (which allows rapid proliferation) and sexually (which produces new genotypes).

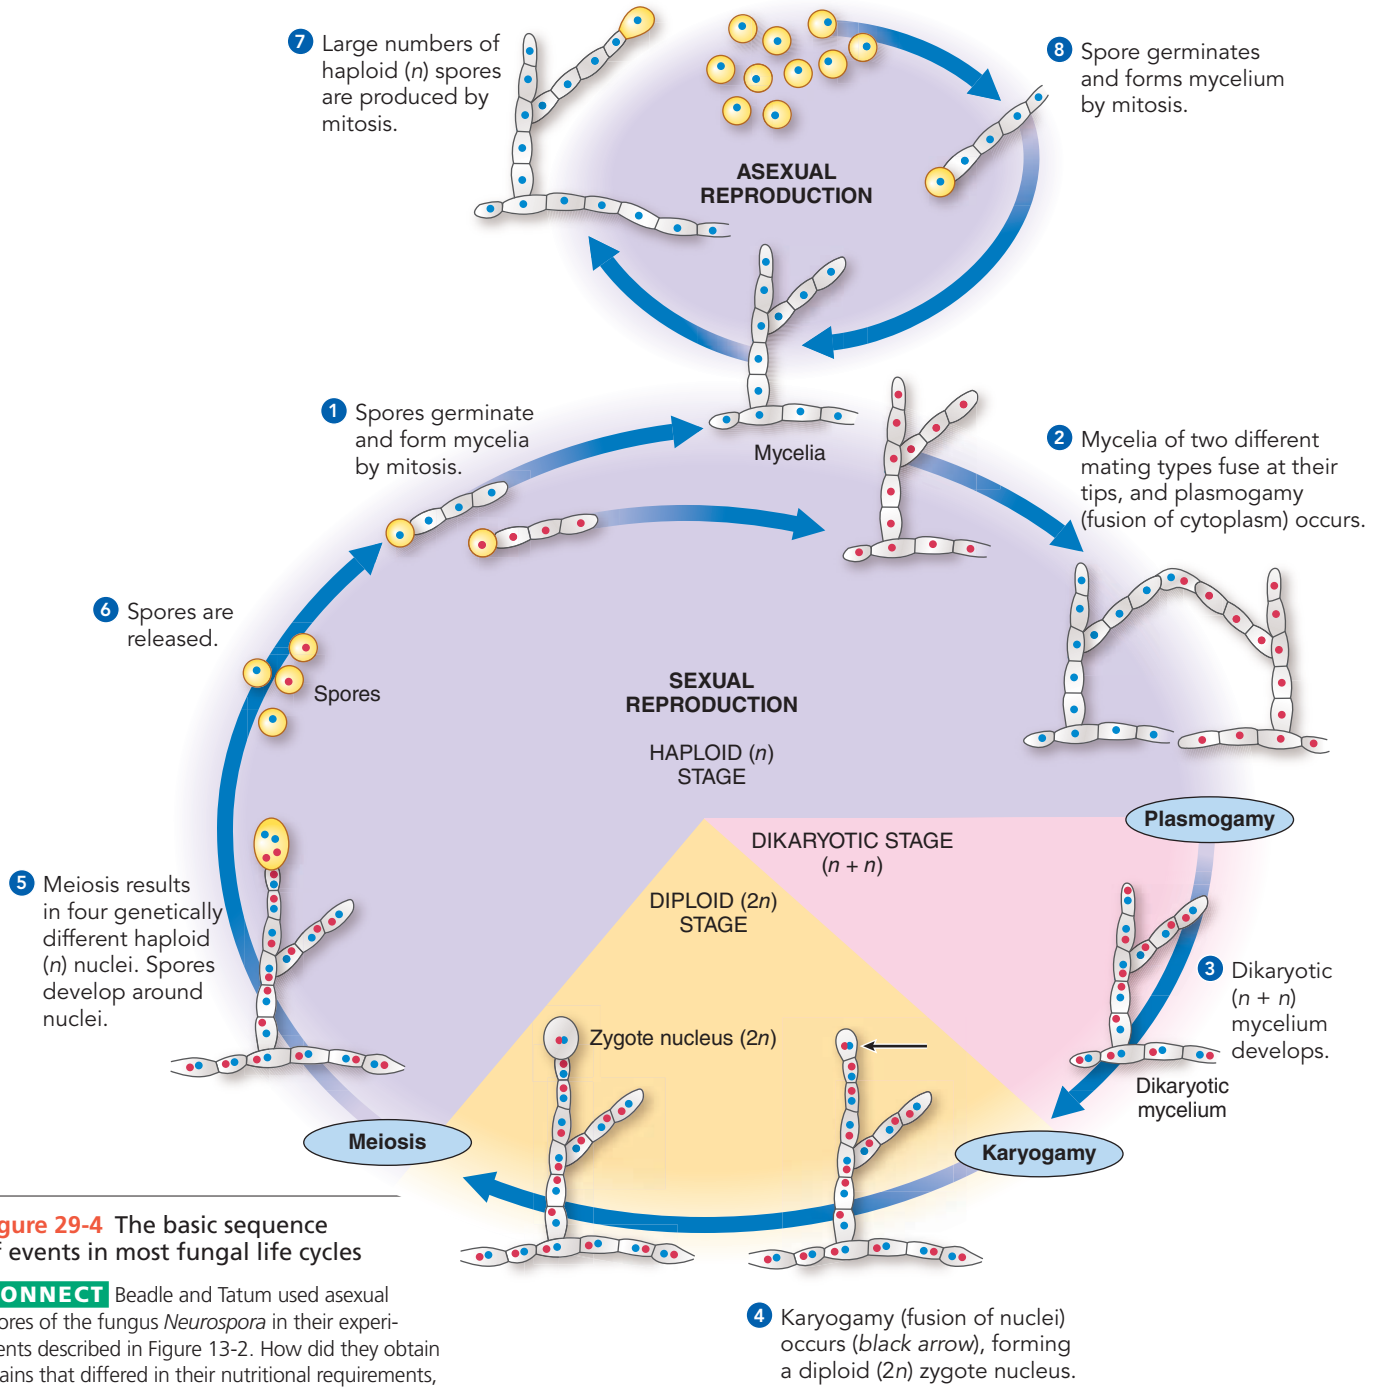

Figure 29-4 The basic sequence of events in most fungal life cycles

CONNECT Beadle and Tatum used asexual spores of the fungus *Neurospora* in their experiments described in Figure 13-2. How did they obtain strains that differed in their nutritional requirements, given that asexual spores derived from the same parent are expected to be genetically identical?

contact with other mating types. In contrast to the majority of animal and plant cells, most fungal cells contain haploid nuclei. In sexual reproduction the hyphae of two genetically compatible mating types come together, and their cytoplasm fuses, a process called **plasmogamy**. The resulting cell has two haploid nuclei, one from each fungus. This cell gives rise by mitosis to other cells with two nuclei. At some point the two haploid nuclei fuse. This process, called **karyogamy**, results in a cell containing a diploid nucleus known as a *zygote nucleus*. In some groups the zygote nucleus is the only diploid nucleus.

In the two largest fungal phyla, the ascomycetes and basidiomycetes (discussed later in this chapter), plasmogamy occurs (hyphae fuse), but karyogamy (fusion of the two different nuclei) does not follow immediately. For a time, the nuclei remain separate within the fungal cytoplasm. Hyphae that contain two genetically distinct, sexually compatible nuclei within each cell are described as **dikaryotic** (see Fig. 29-1d). This condition is referred to as $n + n$ rather than $2n$ because there are two separate haploid nuclei. Hyphae that contain only one nucleus per cell are described as **monokaryotic**. The presence of a dikaryotic stage is an important defining character of the ascomycetes and basidiomycetes.

Fungi communicate chemically by secreting signaling molecules called **pheromones**. At least one pheromone has been identified in each major fungal group. The pheromone binds with a compatible receptor on a different mating type. For example, in the zygomycetes, a pheromone induces the formation of specialized aerial hyphae. Another pheromone causes the tips of aerial hyphae of opposite mating types to grow toward each other and fuse prior to sexual reproduction.

CHECKPOINT 29.2

- **CONNECT** How is a diploid cell different from a dikaryotic cell?
- **VISUALIZE** Draw a generalized life cycle of a fungus. Include asexual and sexual reproduction as well as haploid, diploid, and dikaryotic stages.

29.3 Fungal Diversity

LEARNING OBJECTIVES

4 Give arguments to support the hypothesis that fungi are opisthokonts, more closely related to animals than to plants.
5 Give arguments to support the hypothesis that chytrids may have been the earliest fungal group to evolve from the most recent common ancestor of fungi.
6 List distinguishing characteristics, describe a typical life cycle, and give examples of each of the following fungal groups: chytridiomycetes, zygomycetes, glomeromycetes, ascomycetes, and basidiomycetes.

For centuries biologists classified fungi in the plant kingdom. Like plants, fungi have cell walls and vacuoles and are sessile; that is, they cannot move around from place to place. Also, like plants, many types of fungi inhabit the soil. However, systematists began to question this classification, and in 1969, R.H. Whittaker proposed that fungi be assigned to a separate kingdom, Fungi.

Unlike plants, fungal cell walls do not contain cellulose. Rather, they contain chitin, a polysaccharide found in insect skeletons. The fungal mode of nutrition is also very different from that of plants. Unlike plants, fungi cannot produce their own organic materials from a simple carbon source (carbon dioxide). Like animals, fungi are heterotrophs.

As with systematics for other kingdoms, fungal systematics is a challenging and continuously changing process. For example, slime molds and water molds were formerly classified as fungi but are now included among the protists (see Chapter 26).

Fungi are assigned to the opisthokont clade

Systematists hypothesize that the common ancestor of all plants, fungi, and animals was an ancient flagellate protist. As discussed in Chapter 26, amoebozoa (a group of amoebas), fungi, animals, and a few protists, including the choanoflagellates (a group of flagellate protists), form a monophyletic "supergroup," the **unikonts**. Within this supergroup, the clade **opisthokonts** includes the choanoflagellates, the animals, and the fungi. Both genetic and structural similarities support this grouping. Like animals, fungi have platelike cristae in their mitochondria. Another key character shared by members of this clade is that flagellate cells propel themselves with a single posterior flagellum. In other eukaryote groups, flagellate cells move by means of one or more anterior flagella. Based on structural characters and on molecular data, systematists now view fungi as more closely related to animals than to plants.

Diverse groups of fungi have evolved

Fossil evidence has not been very helpful to systematists studying evolutionary relationships among fungal groups. Most fossilized fungi recovered to date have been microscopic. For example, fossilized fungal spores have been found in amber more than 225 million years old, and fossils of hyphae associated with cyanobacteria or algae have been dated as more than 550 million years old. Few large fungal fossils, such as mushrooms, have been found.

Historically, fungi have been classified mainly on the characteristics of their sexual spores and fruiting bodies. More recently, molecular data, such as comparative DNA and RNA sequences, have helped clarify relationships among fungal groups. Currently, many mycologists assign fungi to five main groups: Chytridiomycota, Zygomycota, Glomeromycota, Ascomycota, and Basidiomycota (FIG. 29-5 and TABLE 29-1). Some biologists consider each of these groups to be a phylum. However, some of these groups are not monophyletic (see Chapter 23), and mycologists are in the process of assigning fungi to additional clades.

In this edition of *Biology*, we will discuss fungi in the five phyla shown in Figure 29-5 and listed in Table 29-1. Microsporidia, a group of intracellular parasites, are classified in this text with the zygomycetes, although in the future they may be assigned to their own taxon. About 95% of all named fungi have been assigned to phyla Ascomycota and Basidiomycota. These phyla are considered *sister taxa* because they share a more recent common ancestor with each other than either does with any other group. Fungi of phyla Ascomycota and Basidiomycota have septate hyphae and a dikaryotic stage during the sexual part of their life cycle.

Until recently, mycologists had assigned about 25,000 species of fungi that did not fit into the major groups to a group called deuteromycetes (phylum Deuteromycota). It was a polyphyletic group (members did not share a recent common

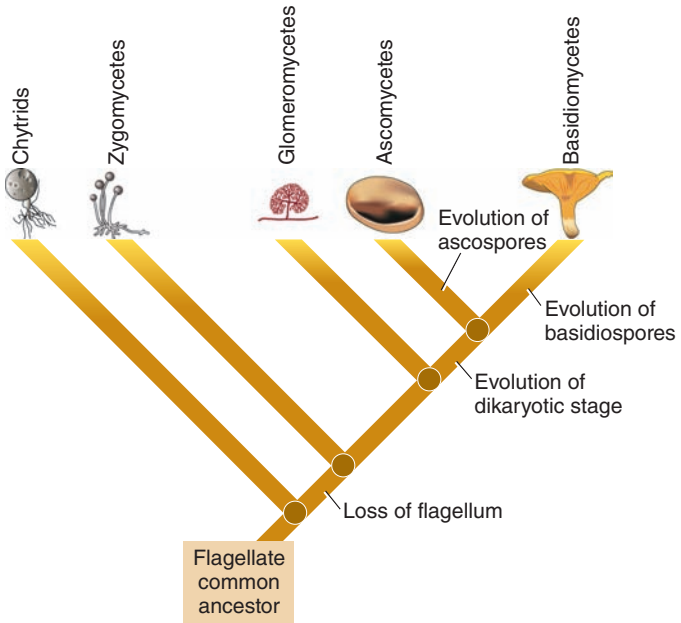

Figure 29-5 Cladogram of currently recognized groups of fungi

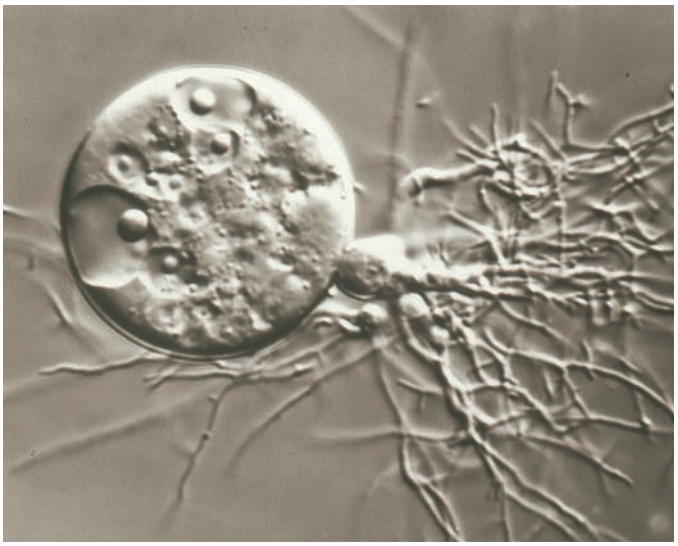
This cladogram shows phylogenetic relationships among living fungi, based on comparisons of ribosomal and nuclear gene sequence data for many species. The chytrids were the lineage that branched off first during fungal evolution. Note that ascomycetes and basidiomycetes are sister clades. Remember that the phylogeny of fungi is a work in process.

ancestor) lumped together simply as a matter of convenience. Mycologists classified fungi as deuteromycetes if no sexual stage had been observed for them at any point during their life cycle. Some of these fungi have lost the ability to reproduce sexually, whereas others reproduce sexually only rarely. Most fungi classified as deuteromycetes reproduce only by means of asexual spores. Mycologists have identified relationships between deuteromycetes and their sexually reproducing relatives, based on DNA comparisons among various species. Most of the deuteromycetes have been reassigned to phylum Ascomycota, and a few have been reassigned to phylum Basidiomycota. (By convention, the asexual stage is still identified as a deuteromycete.)

Chytrids have flagellate spores

At one time, biologists considered the **chytrids**, also known as **chytridiomycetes** (phylum Chytridiomycota), to be funguslike protists, similar in many respects to the water molds. However, both structural and molecular characters indicate that the approximately 1000 species of chytridiomycetes are members of kingdom Fungi. Like fungi, their cell walls contain chitin, and molecular comparisons—particularly of DNA and RNA sequences—have provided compelling evidence that chytrids are indeed fungi. However, recent comparisons of rRNA sequences suggest that chytrids are not a monophyletic group, and they may be divided into four clades.

Chytrids are small, relatively simple fungi that inhabit ponds and damp soil. A few species have been found in salt water. Most chytrids are decomposers that degrade organic matter. However, a few species cause disease in plants and animals. A parasitic chytrid has been partly responsible for declining amphibian populations. Infected frogs have been identified in many parts of the world (see *Inquiring About: Declining Amphibian Populations*, in Chapter 57).



Most chytrids are unicellular or composed of a few cells that form a simple body, called a **thallus**. The term *thallus* describes the simple body plan of certain algae, fungi, and plants. The thallus may have slender extensions, called *rhizoids*, that anchor it to a food source and absorb food (FIG. 29-6). Chytrids are the only fungi that have flagellate cells. Their spores bear a single, posterior flagellum. Sexual reproduction has not been identified in most chytrids. Species that do reproduce sexually have flagellate gametes.

Table 29-1 Characteristics of Currently Recognized Phyla of Fungi

	Phylum and Common Types	Asexual Reproduction	Sexual Reproduction	Other Key Characters
	**Chytridiomycota** (chytrids or chytridiomycetes) *Allomyces*	Flagellate, diploid zoospores produced by mitosis in zoosporangia	Flagellate, haploid gametes in some species	Haploid zoospores produced in resting sporangia; form haploid thallus
	**Zygomycota** (zygomycetes) Black bread mold Microsporidia are classified with the zygomycetes.	Haploid spores produced in sporangia	Zygospores develop in zygosporangia.	Important decomposers; some are insect parasites. Microsporidia are opportunistic pathogens that infect animals.
	**Glomeromycota** (glomeromycetes)	Large, multinucleate blastospores	Has not been observed	Form arbuscular mycorrhizae with plant roots
	**Ascomycota** (ascomycetes) Yeasts, powdery mildews, molds, morels, truffles	Conidia pinch off from conidiophores.	Ascospores develop in asci.	Have a dikaryotic stage; form important symbiotic relationships as lichens and mycorrhizae
	**Basidiomycota** (basidiomycetes or club fungi) Mushrooms, bracket fungi, puffballs, rusts, smuts	Uncommon	Basidiospores develop on club-shaped basidia.	Have a dikaryotic stage; many form mycorrhizae with tree roots

John Taylor/Visuals Unlimited

Figure 29-6 Chytrid

Nomarski differential interference micrograph of a common chytrid (*Chytridium convervae*). Many chytrids have a microscopic body form consisting of a rounded, coenocytic thallus and branched rhizoids that superficially resemble roots. The rhizoids may anchor the chytrid thallus and absorb predigested food.

Some chytrids produce branched, coenocytic mycelia. *Allomyces*, a large, common chytrid, has an unusual life cycle compared with that of most fungi. It undergoes an **alternation of generations** (common in plants, but rare in fungi), spending part of its life as a multicellular haploid (n) thallus and part as a multicellular diploid ($2n$) thallus (FIG. 29-7). The haploid and diploid thalli are similar in appearance. At the tips of its branches, the haploid thallus bears two types of sporangia, structures in which gametes form by mitosis. Each sporangium produces a different type of flagellate gamete.

Each type of gamete secretes a pheromone that attracts the other type. The two gametes fuse, and plasmogamy and karyogamy occur, resulting in a motile zygote. Each zygote can develop into a diploid thallus. The thallus bears two kinds of spore cases: zoosporangia and resting sporangia. Zoosporangia produce flagellate diploid **zoospores** that develop into new diploid thalli. Meiosis occurs within resting sporangia, producing haploid zoospores. Each zoospore has the potential to develop into a haploid thallus.

Molecular evidence suggests that chytrids were probably the earliest fungal group to evolve. Chytrids produce flagellate cells at some stage in their life history, a character that systematists trace to the protist that was the common ancestor of all opisthokonts. No other fungal group has flagellate cells. At some point in their evolutionary history, other fungal groups apparently lost the ability to produce motile cells, perhaps during the transition from aquatic to terrestrial habitats.

Zygomycetes reproduce sexually by forming zygospores

Mycologists have named more than 1100 species of **zygomycetes** (phylum Zygomycota). Of all the fungi, members of this taxon appear most closely related to the chytrids. However, zygomycetes are not a monophyletic group, and as mycologists learn more about fungal relationships, they may divide this phylum into several taxa or reassign its members to other existing phyla.

Most zygomycetes are decomposers that live in the soil on decaying plant or animal matter (FIG. 29-8). Some zygomycetes form a type of symbiotic association (mycorrhizal relationship) with plant roots. (Recall that a symbiotic association is an intimate relationship between organisms of different species.) A few species cause disease in plants and animals, including humans.

During sexual reproduction, zygomycetes produce sexual spores, called **zygospores**. The zygospores are typically produced in spore sacs called **zygosporangia**. The hyphae in zygomycetes are coenocytic; that is, they lack regularly spaced septa. However, septa do form to separate the hyphae from reproductive structures.

Perhaps the most familiar zygomycete is the black bread mold, *Rhizopus stolonifer*, a decomposer that breaks down bread and other foods. If preservatives are not added, bread left at room temperature for a few days often becomes covered with a black, fuzzy growth. Bread becomes moldy when a spore falls on it and then germinates and grows into a mycelium (FIG. 29-9 on page 612). Hyphae penetrate the bread and absorb nutrients. Eventually, certain hyphae grow upward and develop sporangia at their tips. Clusters of more than 50,000 black asexual spores can develop within each sporangium. The spores are released when the delicate sporangium ruptures. The spores give the black bread mold its characteristic color.

Sexual reproduction in the black bread mold occurs when the hyphae of two different mating types, designated plus (+) and minus (–), grow into contact with one another. The bread mold is **heterothallic**, meaning that an individual fungal hypha mates only with a hypha of a different mating type. That is, sexual reproduction occurs only between a member of a (+) strain and one of a (–) strain, not between members of two (+) strains or members of two (–) strains. Because there are no physical differences between the two mating types, it is not appropriate to refer to them as "male" and "female."

When hyphae of opposite mating types grow in close proximity, they signal one another with pheromones. In response to these chemical signals, the tips of the hyphae come together and form **gametangia**, which serve as gametes. Plasmogamy occurs as the gametangia fuse. Then karyogamy occurs as the (+) and (–) nuclei fuse to form the diploid zygote nucleus. The zygote develops into a zygospore. Zygospores are encased in a thick protective zygosporangium. The zygospore may lie dormant for several months. It can survive desiccation and extreme temperatures. Meiosis probably occurs at or just before germination of the zygospore.

When the zygospore germinates, an aerial hypha develops with a sporangium at the tip. Mitosis within the sporangium produces haploid spores. These spores may be all (+) spores, all (–) spores, or a mixture of (+) and (–) spores. When released, the spores germinate to form new hyphae. Only the zygote and zygospore of a black bread mold are diploid; all the hyphae and the asexual spores are haploid.

Key Point

Chytrids have flagellate reproductive cells.

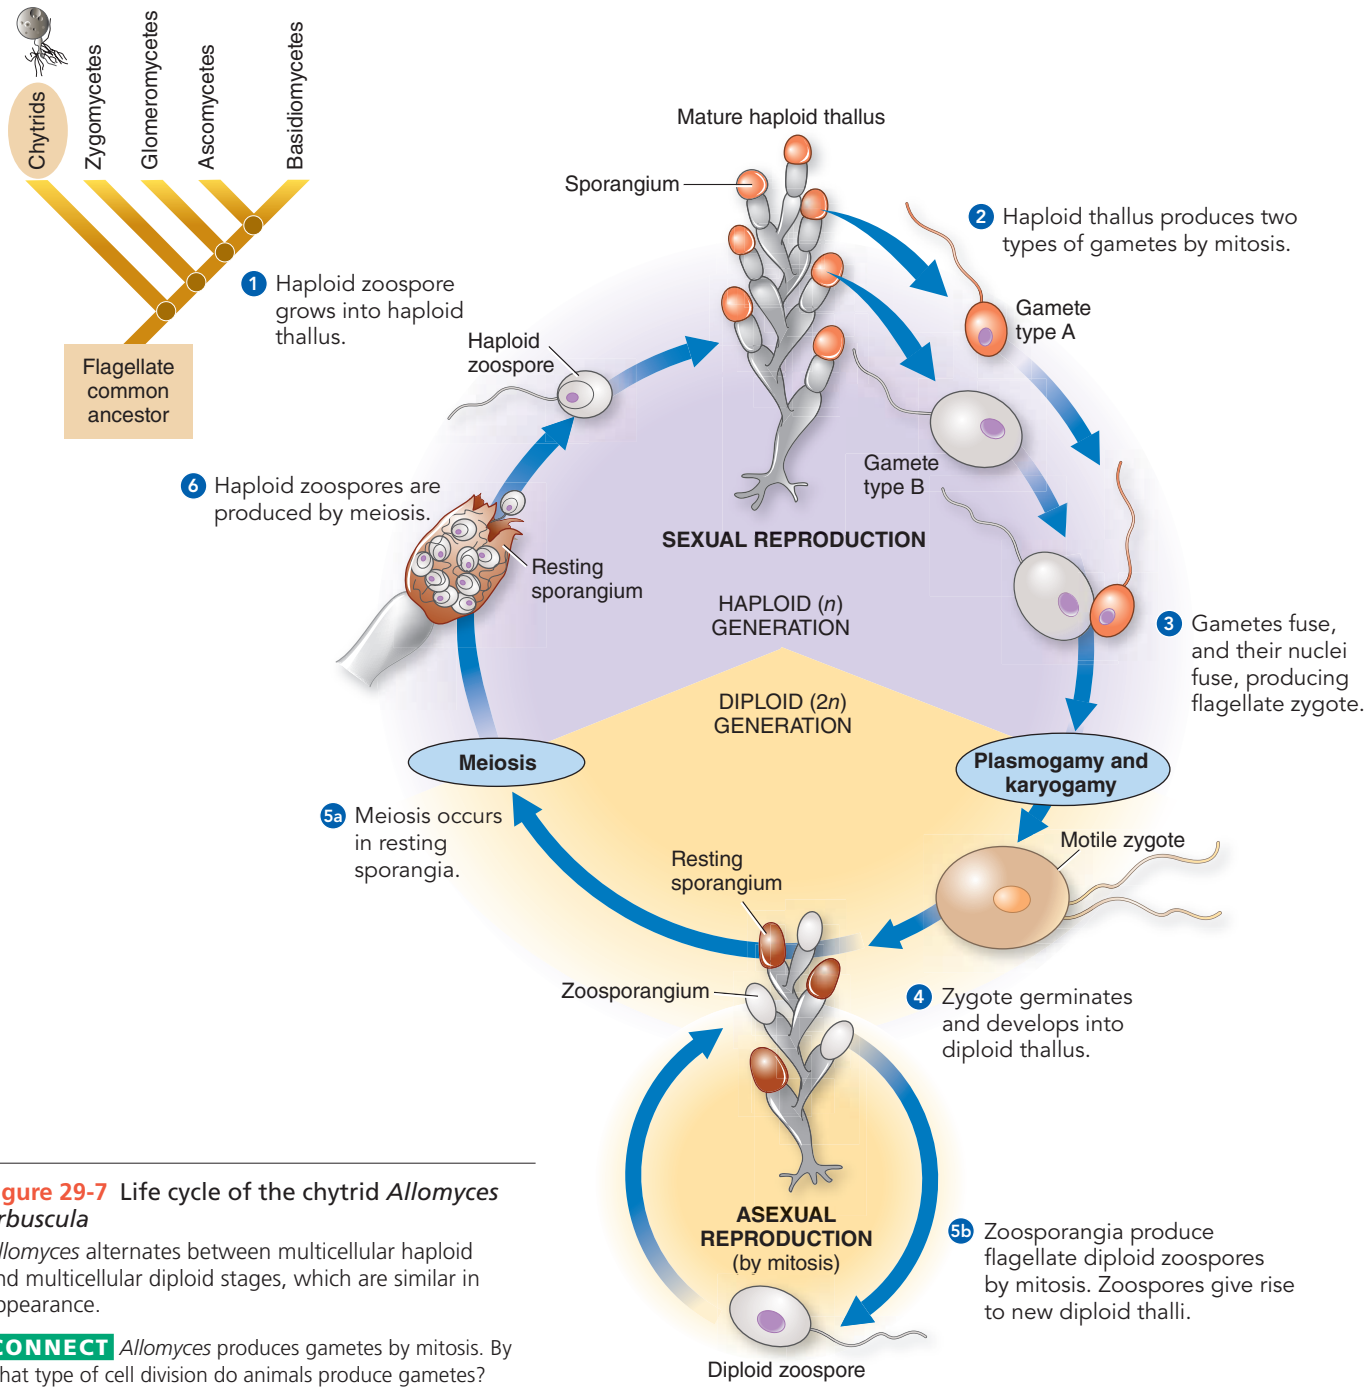

Figure 29-7 Life cycle of the chytrid *Allomyces arbuscula*

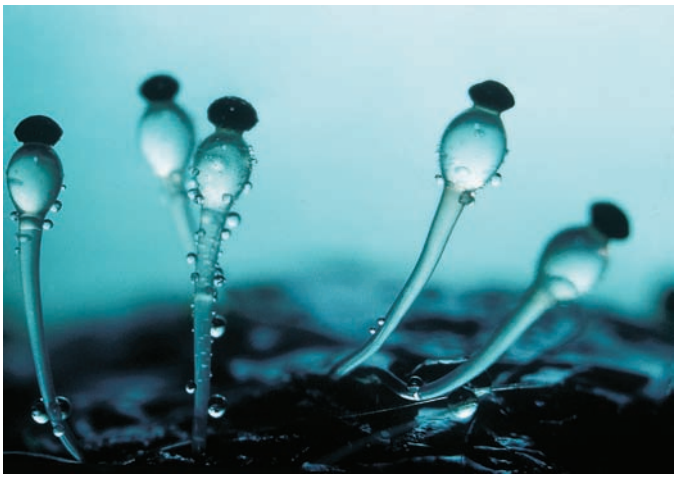
Allomyces alternates between multicellular haploid and multicellular diploid stages, which are similar in appearance.

CONNECT *Allomyces* produces gametes by mitosis. By what type of cell division do animals produce gametes?



Microsporidia have been a taxonomic mystery

Microsporidia are small, unicellular parasites that infect eukaryotic cells. They are opportunistic pathogens that infect animals. For example, microsporidia infect people with compromised immune systems, such as HIV-infected individuals. Microsporidia cause a variety of diseases involving many organ systems, and some species cause lethal infections. Some species of microsporidia appear to be host-specific.

Microsporidia have two developmental stages inside their host: a feeding stage and a reproductive stage. Some microsporidian species divide into two cells by binary fission, and others divide into several cells. Some species undergo nuclear fusion

Figure 29-8 *Pilobolus*, a zygomycete that grows in animal dung

Stalked sporangia of *Pilobolus* protruding from a pile of dung, which contains an extensive mycelium of the fungus. The stalked sporangia, which are 5 to 10 mm tall, act like shotguns and forcefully discharge sporangia (the black tips) away from the dung onto nearby grass. When animals such as cattle or horses eat the grass, the spores pass unharmed through the animal's digestive tract and are deposited in a fresh pile of dung.

and meiosis before producing spores. The spores, which have thick protective walls, can pass from cell to cell inside the host or can be excreted in urine or through the skin. The spores, the only stage with distinct characters, are used to identify groups.

Each spore is equipped with a unique structure, a long, threadlike *polar tube*. When the spore enters the gut of a new host, it discharges its polar tube and penetrates the lining of the gut. Acting as a hypodermic needle, the polar tube injects the contents of the spore into the host cell (FIG. 29-10).

Microbiologists estimate that there may be more than one million species of microsporidia, but only about 1500 species have been named. Microsporidia were originally classified with yeasts and bacteria. In 1976, they were assigned to the protozoa. In the 1980s, biologists viewed microsporidia as the most primitive example of a eukaryote. They were the smallest and simplest known eukaryotes, and the genomes of some species are smaller than most bacterial genomes. Microsporidia lack mitochondria, flagella, and Golgi complexes. Their ribosomes resemble those of prokaryotes.

In 1998, British biologist Thomas Cavalier-Smith reassigned microsporidia to kingdom Fungi. Molecular studies show that microsporidia have gene sequences that indicate that they originally had mitochondria. Microbiologists now generally agree that these organisms have become simpler as they adapted to their parasitic way of life. Other molecular studies have provided additional evidence for their taxonomic relationship with fungi. Establishing that they are closely related to fungi is important in developing medications that will be effective in treating microsporidian infections. Recent genome studies suggest that microsporidia descended from a zygomycete ancestor. For now, we classify the microsporidia with the zygomycetes, but in the future they may be assigned to a separate taxon.

Glomeromycetes have a symbiotic relationship with plant roots

Glomeromycetes (phylum Glomeromycota) have coenocytic (no septa) hyphae. They reproduce asexually with large, multinucleate spores called *blastospores*. Sexual reproduction has not been documented. About 230 species of glomeromycetes have been described. Glomeromycetes were previously considered zygomycetes, but taxonomists using molecular data have determined that they form a separate monophyletic group.

Glomeromycetes are symbionts that form intracellular associations with the roots of most trees and herbaceous plants. These symbiotic associations between the hyphae of certain fungi and the roots of plants are called **mycorrhizae** (from Greek words meaning "fungus roots") (FIG. 29-11). Glomeromycetes extend their hyphae through the cell walls of root cells but often may not penetrate the plasma membrane. As each hypha pushes forward, the plasma membrane of the root cell surrounds it. Thus, the hyphae can be thought of as fingers pushing into a glove formed by the plasma membrane. Because they penetrate the cell wall, these fungi are referred to as **endomycorrhizal fungi**.

The most widespread endomycorrhizae are called *arbuscular mycorrhizae* because the hyphae inside the root cells form branched, tree-shaped structures known as **arbuscules** (see Fig. 29-11 and Fig. 36-11b). The arbuscules are the sites of nutrient exchange between the plant and the fungus. Arbuscular mycorrhizae live entirely underground.

In mycorrhizal relationships the roots supply the fungus with sugars, amino acids, and other organic substances. The mycorrhizal fungus decomposes organic material in the soil and also benefits the plant by extending the reach of its roots. The slender mycelia are far thinner than roots and can extend into narrow spaces, absorbing nutrients that the plant could not capture on its own. Thus, with the help of the mycorrhizal fungus, the plant can also take in more nutrient minerals such as phosphorus and nitrogen.

What we have just described is a mutualistic symbiotic association: both partners benefit. Studies show that if a plant grows in phosphate-deficient soil or has a limited root system, its growth is enhanced by having a fungal partner. However, a plant in a phosphate-rich soil with a well-developed root system may not need fungal partners. For these plants, the fungus may be a parasite.

Much remains to be learned about mycorrhizal associations. Other, yet unknown, benefits of the symbiosis may further define the association as mutualistic. For example, some fungi release alkaloids that protect the plants from herbivores and pathogens. Plants also exchange nutrients with one another through fungi that connect them.

Scientists have discovered mycorrhizal fungi within ancient plant fossils in rocks that are about 400 million years old. These findings suggest that when plants moved onto the land, their fungal partners moved with them. In fact, the fungal partners may have been critical for early vascular plants to colonize the land because the fungal hyphae may have provided plants with water and minerals before their own root systems evolved.

Key Point

Like most fungi, most zygomycetes reproduce both asexually and sexually.

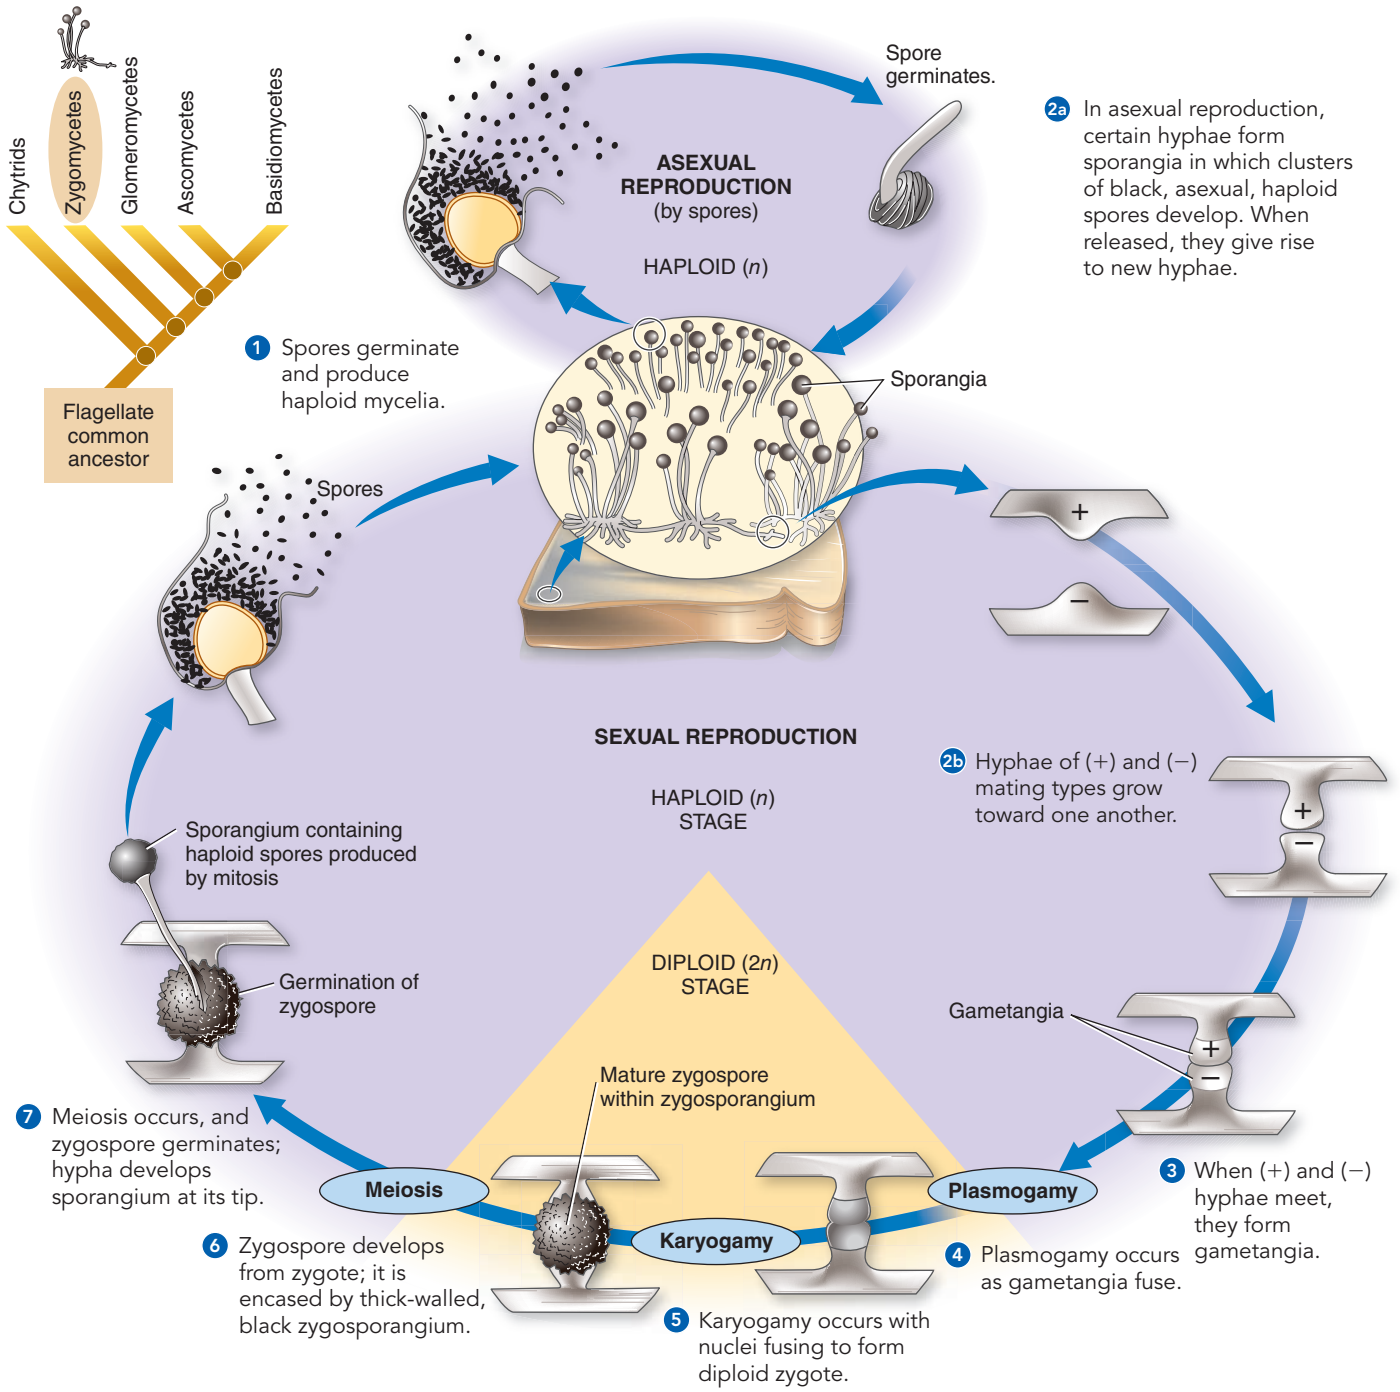

Figure 29-9 Life cycle of a zygomycete, the black bread mold (*Rhizopus stolonifer*)

CONNECT Identify the structures that function as the equivalent of gametes in the zygomycete life cycle. Are they haploid, diploid, or dikaryotic?

Ascomycetes reproduce sexually by forming ascospores

Ascomycetes (phylum Ascomycota) comprise a large group of fungi consisting of more than 32,000 described species. The diverse ascomycetes include most yeasts; the powdery mildews; most of the blue-green, pink, and brown molds that cause food to spoil; decomposer cup fungi; and the edible morels and truffles.

The ascomycetes, more than any other group of fungi, affect humans. As we will discuss in a later section,

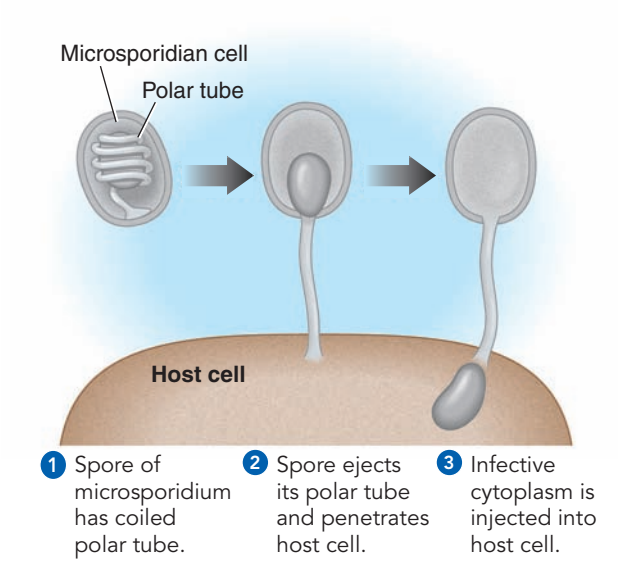

Figure 29-10 Infection by a microsporidium

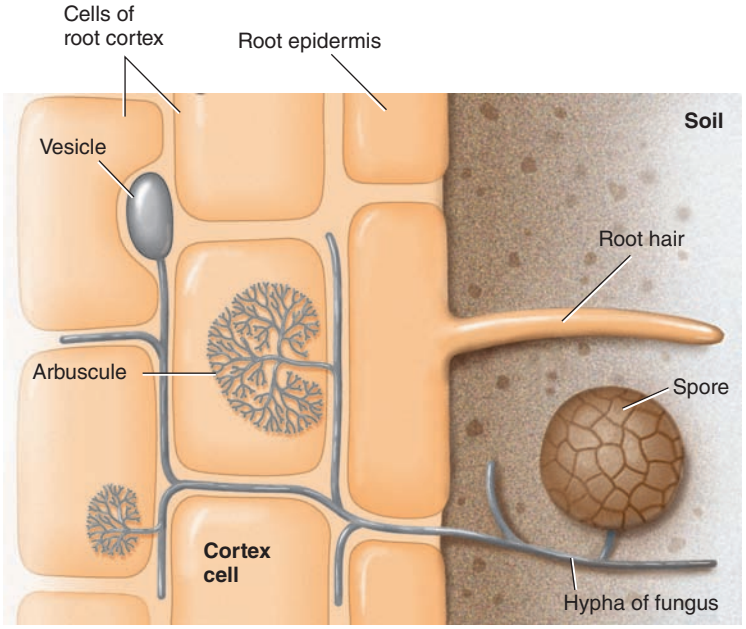

Figure 29-11 Arbuscular mycorrhizae

This mycelium has grown into a plant root. Its hyphae branch between the cells of the root. Hyphae have penetrated through the cell walls of two root cells and have branched extensively to form arbuscules. The tip of one hypha between root cells has enlarged and serves as a vesicle that stores food. The tip of a hypha in the soil has enlarged, forming a spore. The spaces between the root cells have been magnified for clarity.

ascomycetes are used to flavor cheeses, to bake bread (yeast), and to ferment alcohol. Some are enjoyed as foods (morels and truffles). Ascomycetes are used to produce antibiotics. They have also served as valuable model organisms for biologists studying cellular processes, including protein synthesis. Many fungi in this group form mycorrhizae with tree roots, and about 40% join with green algae or cyanobacteria to form lichens. On the negative side, ascomycetes cause most fungal diseases of plants and animals, including humans. For example, ascomycetes cause serious plant diseases such as Dutch elm disease, ergot disease on rye, powdery mildew on fruits and ornamental plants, and chestnut blight.

Ascomycetes are sometimes referred to as *sac fungi* because their sexual spores are produced in microscopic sacs called **asci** (sing., *ascus*). Their hyphae usually have septa, but these cross walls have pores so that cytoplasm is continuous from one cell compartment to another.

In most ascomycetes asexual reproduction involves production of spores called **conidia**, which form at the tips of certain specialized hyphae known as *conidiophores* (FIG. 29-12). Production of these spores is a means of rapidly propagating new mycelia when environmental conditions are favorable. Conidia occur in various shapes, sizes, and colors in different species. The color of the conidia produces the characteristic blue-green, pink, brown, or other tints of many of these molds.

Some species of ascomycetes are heterothallic. (Recall that heterothallic means that an individual fungal hypha mates only with a hypha of a different mating type.) Others are **homothallic**, which means that they are self-fertile and have the ability to mate with themselves. In both heterothallic and homothallic ascomycetes, sexual reproduction takes place after two gametangia come together and their cytoplasm mingles.

Let us examine the life cycle of a typical ascomycete (FIG. 29-13). In our example plasmogamy takes place as hyphae

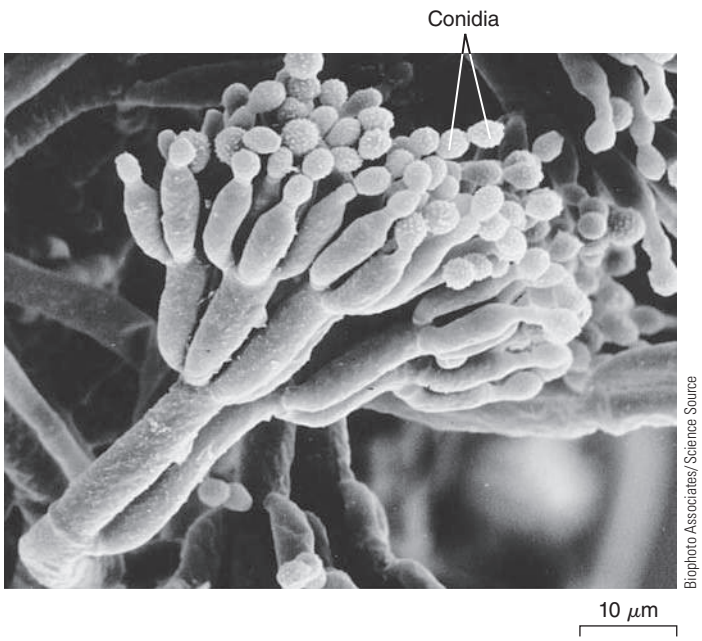

Figure 29-12 Conidia

of two different mating types come together and fuse. Within this fused structure, pairs of haploid nuclei, one from each parent hypha, associate but do not fuse. New hyphae, with dikaryotic cells, develop from the fused structure. The hyphae branch repeatedly until the hyphal tips reach the site where asci will be produced. As the many sac-shaped asci develop, each containing two dissimilar nuclei (one from each parent), they are surrounded by intertwining haploid (monokaryotic) hyphae. These hyphae help make a fruiting body known as an **ascocarp** (FIG. 29-14a).

Karyogamy occurs in each ascus. The two nuclei fuse and form a diploid zygote nucleus. The zygote nucleus then undergoes meiosis to form four haploid nuclei with different genotypes. One mitotic division of each of the four nuclei usually follows, resulting in eight haploid nuclei. Each haploid nucleus becomes incorporated into a thick-walled **ascospore**; thus, there are typically eight haploid ascospores within the ascus (FIG. 29-14b). The ascospores are usually released through a pore, slit, or hinged lid at the tip of the ascus. Air currents carry individual ascospores, often for long distances. If one lands in a suitable location, it germinates and forms a new mycelium. The fungus can reproduce asexually by producing conidia that can develop into new mycelia.

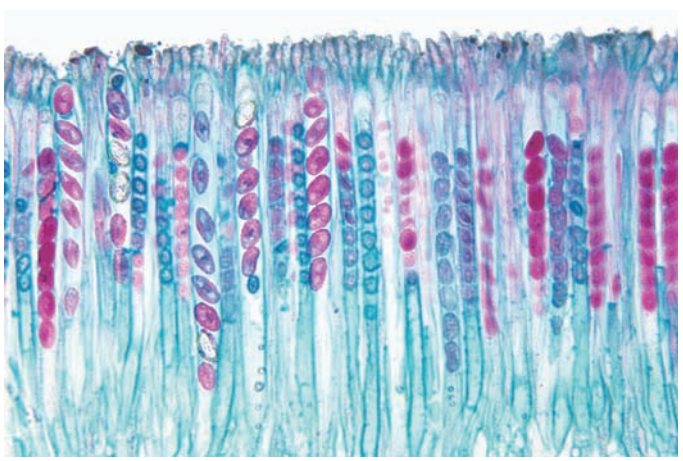
Phylum Ascomycota includes more than 300 species of unicellular yeasts. Asexual reproduction of yeasts is mainly by **budding**; in this process, a small protuberance (bud) grows and eventually separates from the parent cell (see Fig. 29-3). Each bud can grow into a new yeast cell.

Yeasts reproduce sexually by forming ascospores. During sexual reproduction, two haploid yeasts fuse, forming a diploid zygote. The zygote undergoes meiosis, and the resulting haploid nuclei are incorporated into ascospores. These spores remain enclosed for a time within the original cell wall, which corresponds to an ascus.

Basidiomycetes reproduce sexually by forming basidiospores

The more than 30,000 species of **basidiomycetes** (phylum Basidiomycota) include the largest and most familiar of the fungi: the mushrooms, bracket fungi, and puffballs (FIG. 29-15). Many basidiomycetes are decomposers that obtain nutrients by breaking down organic matter. Some species cause great economic loss because they cause dry rot in buildings. Certain basidiomycetes form mycorrhizae. Others, such as wheat rust and corn smut, infect important crops. A few basidiomycetes cause human disease.

Sometimes called *club fungi*, basidiomycetes derive their name from their microscopic club-shaped **basidia** (sing., *basidium*). Basidia are comparable in function to the asci of ascomycetes. Each basidium is an enlarged hyphal cell that undergoes meiosis to form four **basidiospores** (FIG. 29-16). Note that basidiospores develop on the *outside* of a basidium, whereas ascospores develop *within* an ascus.



Each individual fungus produces millions of basidiospores, and each basidiospore has the potential to give rise to a new **primary mycelium**. Hyphae of a primary mycelium consist of monokaryotic cells. The mycelium of a basidiomycete, such as the commonly cultivated mushroom *Agaricus brunnescens*, consists of a mass of white, branching, threadlike hyphae that live mostly underground. Septa divide the hyphae into cells, but as in ascomycetes, the septa are perforated and allow cytoplasmic streaming between cells.

Let us examine the life cycle of a typical basidiomycete. Asexual reproduction is less common in basidiomycetes than in other groups, so we will focus here on sexual reproduction. We begin with two compatible primary mycelia (FIG. 29-17). When in the course of its growth a hypha of a primary mycelium encounters a compatible monokaryotic hypha, typically of a different mating type, the two hyphae fuse (plasmogamy).

(c) Turkey-tail (*Trametes versicolor*) is a common bracket fungus. Bracket fungi grow on both dead and living trees and produce shelf-like fruiting bodies. Basidiospores are produced in pores located underneath each shelf.

Figure 29-15 Basidiomycete fruiting bodies

As in the ascomycetes, the two haploid nuclei remain separate within each cell. In this way a **secondary mycelium** with dikaryotic hyphae, in which each cell contains two haploid nuclei, is produced. The $n + n$ hyphae of the secondary mycelium grow rapidly and extensively.

When environmental conditions are favorable, the hyphae form compact masses, called *buttons*, along the mycelium. Each button grows into a fruiting body that we know as a mushroom. A mushroom is more formally referred to as a **basidiocarp**. Each basidiocarp consists of intertwined, matted hyphae and has a stalk and a cap. The lower surface of the cap usually consists of many thin, perpendicular plates called **gills** that radiate from the stalk to the edge of the cap.

Biophoto Associates/Science Source

Figure 29-16 SEM of a basidium
Each basidium produces four basidiospores.

Karyogamy takes place within the young basidia on the gills of the mushroom. The haploid nuclei fuse in the dikaryotic cells, forming diploid zygote nuclei. They are the only diploid cells that form during a basidiomycete's life cycle. Meiosis then takes place, forming four haploid nuclei with different genotypes. These nuclei move to the outer edge of the basidium. Finger-like extensions of the basidium develop, into which the nuclei and some cytoplasm move; each of these extensions becomes a basidiospore. A septum forms that separates the basidiospore from the rest of the basidium by a delicate stalk that breaks when the basidiospore is forcibly discharged. Each basidiospore can germinate and give rise to a primary mycelium.

Many basidiomycetes produce "fairy rings" in lawns and forests (FIG. 29-18). A fairy ring may first appear as a dark green ring surrounding an inner brown circle. The size of the ring ranges from a few centimeters to more than 15 m (about 51 ft) in diameter. The green ring consists of grass, well nourished by the nutrients released as the fungi decompose organic material. Grass dies, producing the inner brown circle, because the mass of mycelia decreases the movement of water into the area. As the fungi grow outward, the circle widens. The rings grow a few centimeters to more than a meter per year. After rainfall or irrigation, a ring of mushrooms may appear just outside the green circle. The name "fairy ring" comes from a legend that a ring of mushrooms appeared where fairies had danced in a circle the night before.

CHECKPOINT 29.3

- What evidence supports the hypothesis that chytrids were the earliest fungal group to evolve from the common ancestor of fungi?
- What are the distinguishing characteristics of each of the following fungal groups: zygomycetes, glomeromycetes, ascomycetes, and basidiomycetes?
- **VISUALIZE** Use simple diagrams to illustrate how the life cycle of a typical basidiomycete differs from that of a typical ascomycete.
- Distinguish among (1) ascocarp, ascus, and ascospore and among (2) basidiocarp, basidium, and basidiospore.

29.4 Ecological Importance of Fungi

LEARNING OBJECTIVES

7 Summarize the ecological significance of fungi as decomposers.
8 Describe the important ecological role of mycorrhizae.
9 Characterize the unique nature of a lichen.

Fungi make vital contributions to the ecological balance of our planet. Like bacteria, most fungi are free-living decomposers, chemoheterotrophs that absorb nutrients from organic wastes and dead organisms. For example, many fungal decomposers degrade cellulose and lignin, the main components of plant cell walls. When fungi degrade wastes and dead organisms, they release water, carbon (as CO_2), and mineral components of organic compounds, and these elements are recycled (see biogeochemical cycles in Chapter 55). Without this continuous decomposition, essential nutrients would remain locked up in huge mounds of animal carcasses, feces, branches, logs, and leaves. These nutrients would be unavailable for use by new generations of organisms, and life would eventually cease.

Fungi form important symbiotic relationships with animals, plants, bacteria, and protists. A three-way symbiotic relationship involving a fungus, a grass, and a virus has recently been reported. In the geothermal hot spots of Yellowstone National Park, a fungus infects the roots of the host grass. When infected with a specific virus, the fungus is heat tolerant and confers heat tolerance to the grass. When not infected by the virus, the fungus does not confer heat tolerance. The symbiotic relationships of fungi with other organisms have major effects on ecosystems.

Fungi form symbiotic relationships with some animals

Because animals do not have the enzymes necessary to digest cellulose and lignin, cattle and other grazing animals cannot, by themselves, obtain needed nutrients from the plant material they eat. Their survival depends on fungi that inhabit their guts because fungi, like many other microorganisms, do have the enzymes that break down these organic compounds. The fungi benefit by living in a nutrient-rich environment.

Fungi also form symbiotic associations with ants and termites. More than 200 species of ants farm fungi. Leaf-cutting ants bring leaves to their fungi and protect them from competitors and predators. The ants also disperse the fungi to new locations. In exchange, the fungi digest the leaves, providing nutrients for the ants. This symbiosis can involve other organisms. The farmed fungi can be infested by fungal parasites. In response, the ants culture bacteria (actinomycetes) that produce antibiotics to control these parasites. These symbiotic relationships, the most complex known, are the product of 50 million years of coevolution.

Mycorrhizae are symbiotic associations between fungi and plant roots

Mycorrhizae occur in about 80% of plants (and more than 90% of all plant families). As discussed in the section on glomeromycetes, mycorrhizal fungi decompose organic material in the soil and increase the surface area of a plant's roots so that the plant can absorb more water and mineral nutrients. In exchange, the roots supply the fungus with organic nutrients.

To establish and maintain a symbiotic relationship, cells of the fungi and cells of the plant roots must communicate. For example, signaling molecules from the plant root cells stimulate fungal cells to shift to a presymbiotic growth phase in which their energy metabolism increases and their hyphae branch. The fungal cells then signal the root cells, activating a signaling pathway that activates gene expression in the root cells.

The importance of mycorrhizae first became evident when horticulturalists observed that orchids do not grow unless an appropriate fungus lives with them. Similarly, many forest trees, such as pines, decline and eventually die from

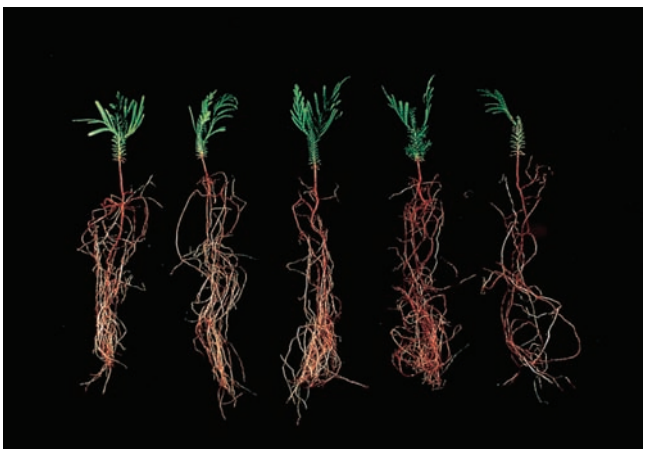
Key Experiment



Is plant growth affected by fungi in the soil?

HYPOTHESIS: In low-phosphorus soils, plants that form mycorrhizal associations with fungi exhibit enhanced growth.

EXPERIMENT: Western red cedar seedlings (*Thuja plicata*) were selected for this study. Control seedlings were grown in low-phosphorus soil in the absence of the fungus. Experimental seedlings of the same age as the control plants were grown under the same conditions as the controls except that their roots formed mycorrhizal associations.

RESULTS AND CONCLUSION: Growth of the plants that formed mycorrhizal associations was significantly enhanced. Mycorrhizal associations enhance the growth of western red cedar plants. Many similar studies using other types of plants and other types of soil have confirmed the importance of mycorrhizal association to plant growth.

SOURCE: Kough, J.L., R. Molina, and R.G. Linderman, "Mycorrhizal Responsiveness of *Thuja, Calocedrus, Sequoia*, and *Sequoiadendron* Species of Western North America," *Canadian Journal of Forest Research*, Vol. 15 (1985): 1049–1054.

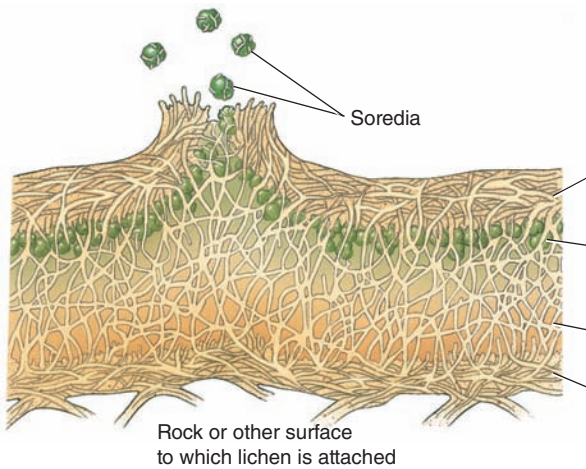
Figure 29-19 The effect of mycorrhizae on western red cedar (*Thuja plicata*) seedlings

CONNECT Biologists have discovered that many mycorrhizal fungi are sensitive to a low pH. What human-caused environmental problem may prove catastrophic for these fungi? How may this problem affect their plant partners? What measures could we take to decrease the problem?

mineral deficiencies when transplanted to mineral-rich grassland soils that lack the appropriate mycorrhizal fungi. When forest soil containing the appropriate fungi or their spores is added to the soil around these trees, they quickly resume normal growth. Studies performed with various types of plants, including cedar, have confirmed the role of mycorrhizae in plant growth (FIG. 29-19).

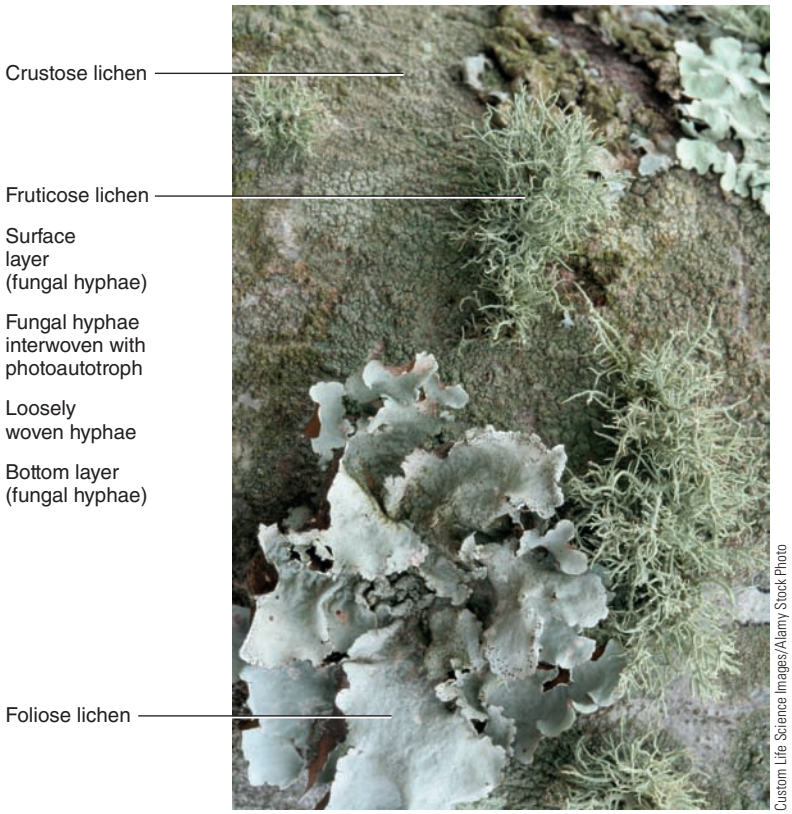
As we have discussed, glomeromycetes form *endomycorrhizal* connections; they infiltrate the cells of plant roots. At least 5000 species of ascomycetes and basidiomycetes also form mycorrhizal connections, but their hyphae coat the plant root rather than penetrate its cells. These species are referred to as **ectomycorrhizal fungi**. Interestingly, researchers have shown that some mycorrhizal fungi harbor bacteria in their cytoplasm. Although the role of the bacteria is not yet clear, their presence suggests that they may be members of a three-way partnership: fungus, plant, and bacteria.

Mycorrhizal fungi connect plants, allowing nutrient transfer among them. Scientists have measured the movement of organic materials from one tree species to another through shared mycorrhizal connections. Mycorrhizal fungi also release chemicals that protect the plant against herbivores and pathogens.



Mycorrhizae improve the soil by decreasing water loss and erosion. Ecologists are studying the role of mycorrhizal fungi in reclaiming soils damaged by pollution. For example, mycorrhizae can modify toxic heavy metals, such as cadmium, so that plants cannot absorb them.

A lichen consists of one or more fungi and a photoautotroph



Although a **lichen** looks like a single organism, it is actually a compound organism, a combination of one or more fungi and a *photoautotroph* (FIG. 29-20a). Almost one-fifth of all known fungal species form these symbiotic relationships. About 14,000 kinds of lichens have been described. Fossils suggest that fungi developed symbiotic partnerships with photoautotrophs before the evolution of vascular plants.

(a) This cross section of a typical lichen shows distinct layers. The soredium (pl., *soredia*), an asexual reproductive structure, consists of clusters of algal or cyanobacterial cells enclosed by fungal hyphae.

Custom Life Science Images/Alamy Stock Photo

(b) Lichens vary in color, shape, and overall appearance. Three growth forms—crustose, foliose, and fruticose—are shown on a tree trunk in Massachusetts.

Figure 29-20 Lichens
These organisms are a combination of a fungus and an alga or cyanobacterium.

The photoautotrophic component of a lichen is a green alga, a cyanobacterium, or both. The fungus is typically an ascomycete, although a basidiomycete is the fungal partner in some tropical lichens. In 2016 it was reported that many lichens may include both an ascomycete and a unicellular basidiomycete (a yeast) as the fungal partners. Most photoautotrophic organisms found in lichens also occur as free-living species in nature, but the fungal components are generally found only as a part of the lichen. Typically, the fungus forms most of the lichen thallus (body). The fungus surrounds hundreds of photosynthetic partners and holds them in place. Lichens are named for the fungal component.

In the laboratory, researchers can isolate the fungal and photoautotrophic components of some lichens and grow them separately in appropriate culture media. The photoautotroph grows more rapidly when separated, whereas the fungus grows more slowly and requires many complex carbohydrates. Neither organism resembles a lichen in appearance when grown separately. The photoautotroph and fungus can be sometimes reassembled as a lichen thallus, but only if they are placed in a culture medium under conditions that cannot support either of them independently.

What is the nature of this partnership? The lichen was originally considered a definitive example of mutualism. The photoautotroph carries on photosynthesis, producing energy-rich carbon compounds for both members of the lichen. It is unclear how the photoautotroph benefits from the relationship. Some biologists have suggested that the photoautotroph obtains water and nutrient minerals from the fungus as well as protection against desiccation. More recently, researchers have suggested that the lichen partnership is not really a case of mutualism but one of controlled parasitism of the photoautotroph by the fungus.

Lichens typically exhibit one of three different growth forms (FIG. 29-20b). *Crustose lichens* are flat and grow tightly against their substrate (the surface they are growing on). *Foliose lichens* are also flat, but they have leaflike lobes and are not as tightly pressed to the substrate. *Fruticose lichens* grow erect and have many branches.

Able to tolerate extremes of temperature and moisture, lichens grow in almost all terrestrial environments except polluted cities. They exist farther north than any plants of the arctic region and are equally at home in the steaming equatorial rain forest. They grow on tree bark, leaves, and exposed rock surfaces, from solidified lava to tombstones. In fact, lichens are often the first organisms to inhabit rocky areas, and their growth in these areas is important in forming soil from rock. They secrete acid that gradually etches tiny cracks in the rock, releasing minerals. This process sets the stage for further disintegration of the rock by wind and rain. When the lichens themselves die and are decomposed, they become part of the soil.

Reindeer mosses of the arctic region, which serve as the main source of food for migrating herds of caribou, are actually lichens, not mosses. Some lichens produce colored pigments. One of them, orchil, is used to dye wool; another, litmus, is widely used in chemistry laboratories as an acid–base (pH) indicator.

Lichens vary greatly in size. Some are almost invisible, whereas others, such as the reindeer mosses, may cover many square kilometers of land with an ankle-deep growth. Growth proceeds slowly; the radius of a lichen may increase by less than 1 mm each year. Some mature lichens are thought to be thousands of years old.

Lichens absorb minerals from the air, rainwater, and the surface on which they grow. They cannot excrete the elements they absorb, and perhaps for this reason they are extremely sensitive to toxic compounds. This sensitivity was first reported in 1866 by a Finnish biologist who observed that lichens growing on tree trunks in Paris were poorly developed or sterile. He deduced that lichens could be used to measure air purity. Today, reduction in lichen growth is used as a sensitive indicator of air pollution, particularly from sulfur dioxide. In one study, investigators demonstrated a relationship between lung cancer and air pollution by comparing the locations of low lichen biodiversity (and therefore of air pollution) with the locations of lung cancer deaths in young males. The return of lichens to an area indicates an improvement in air quality.

Lichens reproduce mainly by asexual means, usually by fragmentation, a process in which special dispersal units of the lichen, called **soredia** (sing. *soredium*), break off and, if they land on a suitable surface, establish themselves as new lichens. Soredia contain cells of both partners. In some lichens the fungus produces ascospores, which may be dispersed by wind and find an appropriate algal partner only by chance.

CHECKPOINT 29.4

- **CONNECT** What is the ecological importance of fungal decomposers?
- What are some ways in which the relationship between a plant root and a mycorrhizal fungus is mutualistic?
- Many biologists consider a lichen an example of controlled parasitism. In this view, which component is the likely parasite, and which is the likely host?

29.5 Economic, Biological, and Medical Impact of Fungi

LEARNING OBJECTIVES

10 Summarize some specific ways that fungi affect humans economically.

11 Summarize the importance of fungi to biology and medicine; describe how fungi infect plants and humans, describing at least one fungal animal disease and one fungal plant disease.

The same powerful digestive enzymes that fungi use to decompose wastes and dead organisms can also be used with great efficiency to reduce wood, fiber, and food to their basic components. Many species of basidiomycetes have enzymes that break down the lignin in wood. (Lignin is the second most abundant organic compound on Earth, second only to cellulose.) From the human perspective, various fungi cause incalculable damage to stored goods and building materials each year. Bracket fungi, for example, cause enormous losses by decaying wood, both in living trees and in stored lumber.

Some fungi cause serious diseases in animals and plants, yet fungi also contribute to our quality of life. They are responsible for economic gains as well as losses. People eat them and grow them to make various medications, such as penicillin. We use them to make certain industrial chemicals and for bioremediation. Renewable fuel companies are actively searching for fungi and other microbes that can produce fuel. For example, a fungus has been discovered that synthesizes 55 hydrocarbons, perhaps to inhibit the growth of other organisms. Researchers may be able to use the genes of this fungus to engineer other microorganisms to produce fuel more efficiently.

Fungi provide beverages and food

Humans exploit the ability of yeasts to produce bread and alcoholic beverages. Yeasts produce ethyl alcohol and carbon dioxide from glucose and other sugars by fermentation (see Chapter 8).

Yeast species of the genus *Saccharomyces* (ascomycetes) are used to produce wine, beer, and other fermented beverages. Wine is produced when yeasts ferment fruit sugar, and beer results when yeasts ferment sugar derived from starch in grains (usually barley).

Saccharomyces cerevisiae, referred to as baker's yeast, is used to bake bread, pizza, and other wheat products. During the process of making bread, carbon dioxide produced by yeast becomes trapped in dough as bubbles, causing the dough to rise and giving leavened bread its light quality. Both the carbon dioxide and the alcohol produced by the yeast escape during baking.

The unique flavor of cheeses such as Roquefort, Brie, Gorgonzola, and Camembert is produced by species of *Penicillium*. For example, *P. roquefortii*, found in caves near the French village of Roquefort, is used to make Roquefort cheese. By French law, only cheeses produced in this area can be called Roquefort cheese. (The blue spots in Roquefort and certain other cheeses are masses of conidia.)

Aspergillus tamarii and certain other fungi are used to produce traditional soy sauce by fermenting soybeans with the fungi for at least three months. Soy sauce enriches other foods with more than just its special flavor. It also adds vital amino acids from both the soybeans and the fungi themselves, which, in some parts of the world, supplement a low-protein rice diet.

Among the basidiomycetes, there are some 200 kinds of edible mushrooms and about 70 species of poisonous ones. Many edible mushrooms are cultivated commercially. The mushroom *Agaricus brunnescens* is the principal fungal species grown extensively for food. About 30 other mushroom species, such as oyster, shiitake, portobello, and straw mushrooms, are available in supermarkets. Morels, which superficially resemble mushrooms, and truffles, which produce underground fruiting bodies, are ascomycetes (FIG. 29-21). Truffles are now cultivated as mycorrhizal fungi on the roots of tree seedlings.

(a) The yellow morel (*Morchella esculenta*). This morel grows 6 to 10 cm (2.5 to 4 in.) tall. It is found throughout North America. Photographed in Michigan.

John D. Cunningham/Visuals Unlimited

(b) The Oregon white truffle (*Tuber gibbosum*). This truffle, which is found underground near Douglas firs and possibly oak trees in British Columbia and northern California, is 1 to 5 cm (0.4 to 2 in.) wide. People find these subterranean ascocarps with the help of trained dogs or pigs. Here, truffles are shown whole and sectioned to show the conspicuous white, marbled tissue.

Figure 29-21 Edible ascomycetes

Edible and poisonous mushrooms can look very much alike and may even belong to the same genus. There is no simple way to tell them apart; an expert must identify them. Some of the most poisonous mushrooms belong to the genus *Amanita* (FIG. 29-22). Toxic species of this genus have been appropriately called such names as "destroying angel" (*A. virosa*) and "death cap" (*A. phalloides*). Eating a single mushroom of either species can be fatal.

Certain species of mushrooms cause intoxication and hallucinations. The sacred mushrooms of the Aztecs—*Conocybe* and *Psilocybe*—are still used in religious ceremonies by native peoples of Central America for their hallucinogenic properties. The chemical ingredient *psilocybin* is responsible for the trances and visions experienced by those who eat these mushrooms. Ingestion of psychoactive mushrooms is dangerous because negative reactions vary considerably, from mild indigestion, sweating, and heart palpitations, to death. In addition, the possession and use of such mushrooms are illegal in the United States and some other countries.

Fungi are important to modern biology and medicine

As discussed in Chapter 17, yeast *Saccharomyces cerevisiae* has served as a model eukaryotic cell (see Fig. 29-3). It was the first eukaryote whose genome was sequenced, and with its 6275 genes, it has the smallest genome of any eukaryotic model organism. Molecular biologists are in the process of determining the functions of the proteins encoded by its genes. Biologists have used *S. cerevisiae* to study molecular genetics, including how genes regulate cell division. Researchers continue to use this yeast to study such problems as genetic recombination and the correlation between cell age and cancer. *Saccharomyces cerevisiae* is also being used to study the mechanism of action of antifungal drugs and resistance to these drugs.

Biologists have used the ascomycete *Aspergillus nidulans*, an opportunistic pathogen of humans, to study mitosis and other cell processes. This fungus has provided valuable knowledge about the genetics of microtubules. Biologists are using recombinant DNA techniques to manipulate yeasts and certain filamentous fungi to produce important biological molecules, such as hormones. Among the many genes that have been cloned in yeast are those for insulin, human growth hormone, and molecules important in immune function. These procedures allow researchers to produce unlimited amounts of these compounds for study and eventual medical use.

Fungi produce useful drugs and chemicals. Discovered in 1928 by British bacteriologist Alexander Fleming, penicillin, produced by the mold *Penicillium notatum*, is still among the most widely used and effective antibiotics (see Chapter 1). Other drugs derived from fungi include the cephalosporin antibiotics (produced by *Cephalosporium*), statins (used to lower blood cholesterol levels), and cyclosporine (used to suppress immune responses in patients who receive organ transplants). Fumagillin, a chemical produced by the ascomycete *Aspergillus fumigatus*, inhibits the formation of new blood vessels. Because solid tumors need a rich blood supply, fumagillin shows promise as an anticancer agent. Fumagillin is also used to treat diseases caused by microsporidia. Researchers have identified several other promising compounds produced by fungi that are antiviral or that destroy cancer cells.

The ascomycete *Claviceps purpurea* infects the flowers of rye plants and other cereals. It produces a structure called an *ergot* where a seed would normally form in the grain head. When livestock eat this grain or when humans eat bread made from ergot-contaminated rye flour, they may be poisoned by the extremely toxic substances in the ergot. However, some ergot compounds are now used clinically in small quantities as drugs to induce labor, to stop uterine bleeding, to treat high blood pressure, and to relieve one type of migraine headache.

James W. Richardson/CBR Images

Figure 29-22 Poisonous mushrooms

The destroying angel (*Amanita virosa*) is an extremely poisonous mushroom that is distinguished, as are other amanitas, by the ring of tissue around its stalk and by the underground cup from which the stalk protrudes. About 50 g (2 oz) of this mushroom can kill an adult man. The destroying angel, which is 7.5 to 20 cm (3 to 8 in.) tall, is found in grass or near trees throughout North America.

Fungi are used in bioremediation and to biologically control pests

Some fungi can biodegrade pesticides, herbicides, coal tars, and petroleum. Fungi convert these products into carbon dioxide and the basic elements of which they are composed. These fungi can be used along with certain bacteria to decontaminate farm land and to clean up oil spills.

Researchers are investigating fungi—for example, certain species of microsporidia—for the biological control of pathogens and insect pests. Some of these species are already being used to parasitize insect pests. In some cases, they interfere with reproduction in their insect host. It should be noted that some microsporidia may pose a threat to beneficial insects. For example, a microsporidian has been implicated as one factor in the die-off of honeybee colonies.

Some fungi cause diseases in humans and other animals

Certain ascomycetes cause superficial infections in which only the skin, hair, or nails are infected. Ringworm, athlete's foot, and jock itch are examples of superficial fungal infections. Because these fungi infect dead layers of skin that are not fed by capillaries, the immune system cannot launch an effective response.

Many pathogenic fungi are opportunists that cause infections only when the body's immune system is compromised, such as in patients infected with HIV. Cancer patients and organ transplant recipients who are given medication to suppress their immune systems are also at risk. *Candida* is an ascomycete that inhabits the human mouth and vagina. The immune system and the normal bacteria of these regions normally prevent this yeast from causing infection. However, when the immune system is compromised, *Candida* multiplies, causing thrush, a painful yeast infection of the mouth, throat, and vagina.

The ascomycete *Aspergillus fumigatus* is usually harmless but causes aspergillosis in people with lowered immune function. During the course of aspergillosis, the fungus can invade the lungs, heart, brain, kidneys, and other vital organs and cause death.

Other fungi also infect internal tissues and organs and may spread through many regions of the body. Histoplasmosis, for example, is a lung infection caused by inhaling spores of a fungus common in soil contaminated with bird feces. Most people in the eastern and midwestern parts of the United States have been exposed to this fungus at some time, and an estimated 40 million Americans have had mild infections. Fortunately, the infection is usually confined to the lungs and is of short duration, but if the infection spreads through the blood to the heart, brain, or other parts of the body, it can be serious and sometimes fatal.

Some fungi produce poisonous compounds collectively called **mycotoxins**. A few species of *Aspergillus*, for example, produce potent mycotoxins called *aflatoxins* that harm the liver and are known carcinogens. Foods on which aflatoxin-producing fungi commonly grow include peanuts, pecans, corn, and other grains. Other foods that may contain traces of aflatoxins include animal products such as milk, eggs, and meat (from animals that consumed feed contaminated by aflatoxin). Avoiding aflatoxin in the diet is impossible, but exposure should be minimized as much as possible. Any human food or animal forage product that has become moldy should be suspected of aflatoxin contamination and should be discarded.

Fungi contribute to sick-building syndrome, a situation in which occupants of a building experience acute adverse health effects linked to the time they spend in a given building. Mold-related insurance claims amount to hundreds of millions of dollars each year. When conditions are moist, molds can grow on carpets, leather, cloth, wood, insulation, and food. Mold spores, fragments, and aerosol mold products make their way into the air, and people are exposed through inhalation as well as by skin contact.

Exposure to molds and their toxins has been linked to depressed immune function, irritation of the throat and respiratory passageways, infection, and toxicity. The most common responses to mold exposure are reactions that range from mild to severe illnesses, including hay fever, sinusitis, asthma, and dermatitis.

Fungi cause many important plant diseases

Fungi are more destructive to plants than any other disease-causing organism. They are responsible for about 70% of all major crop diseases. Fungi cause serious epidemic diseases that spread rapidly and often result in complete crop failure. Fungal plant diseases costs billions of dollars in agricultural damage yearly.

All plants are apparently susceptible to some fungal infection. Damage may be localized in certain tissues or structures of the plant, or the disease may be systemic and spread throughout the entire plant. Fungal infections may cause stunting of plant parts or of the plant and may cause wartlike growths or kill the plant.

A plant often becomes infected after hyphae enter through stomata (pores) in the leaf or stem or through wounds in the plant body (FIG. 29-23). Alternatively, the fungus may produce *cutinase*, an enzyme that dissolves the waxy cuticle that covers the surface of leaves and stems. After dissolving the cuticle, the fungus easily invades the plant tissues. As the mycelium grows, it may stay mainly between the plant cells, or it may penetrate the cells. Parasitic fungi often produce special hyphal branches called **haustoria** (sing., *haustorium*) that penetrate the host cells and obtain nourishment from the cytoplasm.

Ascomycetes cause serious plant diseases, including powdery mildew, chestnut blight, Dutch elm disease, apple scab, wilt on potatoes, and brown rot, which attacks cherries, peaches, plums, and apricots (FIG. 29-24a).

Basidiomycetes cause smuts and rusts that attack corn, wheat, oats, and other grains (FIGS. 29-24b and c). Some fungal parasites, such as the basidiomycete *Puccinia graminis*, which causes black stem rust of wheat, have complex life cycles that involve two or more different host plants and the production of several kinds of spores. Before the late 1950s, black stem rust outbreaks occurred every few years somewhere in the world, destroying entire wheat crops. By the early 1960s, Norman Borlaug, winner of the Nobel Peace Prize in 1970, and other researchers had developed rust-resistant varieties of wheat, heralding in the green revolution. However, new mutations have put *Puccinia* and wheat rust back in the news. The new strain has spread through parts of Africa and into the Middle East. Each fungus releases billions of spores, which the wind can blow for hundreds of miles, spreading the fungus to new regions of the world. Its spread may lead to widespread food shortages. The genomes of several *Puccinia* species have been sequenced, and researchers are developing methods to quickly diagnose the diseases they cause. They are also working to develop new varieties of disease-resistant wheat.

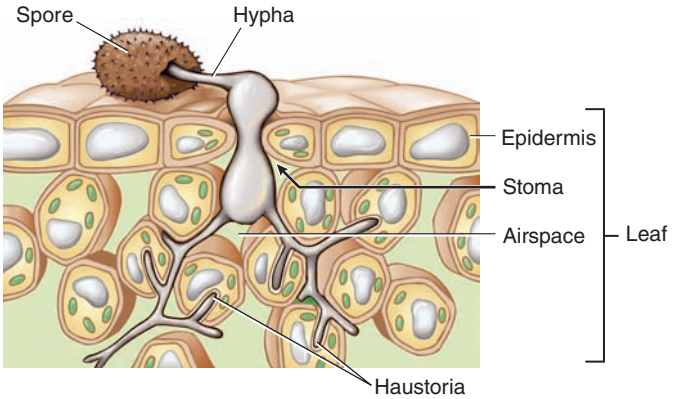

Figure 29-23 How a fungus parasitizes a plant

In this example, the hypha enters the leaf through a stoma. The hypha grows, branching extensively through the internal air spaces, and penetrates plant cells with specialized hyphal extensions called haustoria.

CHECKPOINT 29.5

- **CONNECT** In what ways (both positive and negative) are fungi important in modern biology and medicine?
- **CONNECT** Can fungi be beneficial to plants? In what ways are they harmful?

Summary: Focus on Learning Objectives

29.1 Characteristics of Fungi *(page 604)*

1 Describe the distinguishing characteristics of fungi.

- **Fungi** are eukaryotic heterotrophs that secrete digestive enzymes onto their food source and then absorb the predigested food. Fungi are characterized by cell walls that contain **chitin**.

2 Describe the body plan of a fungus.

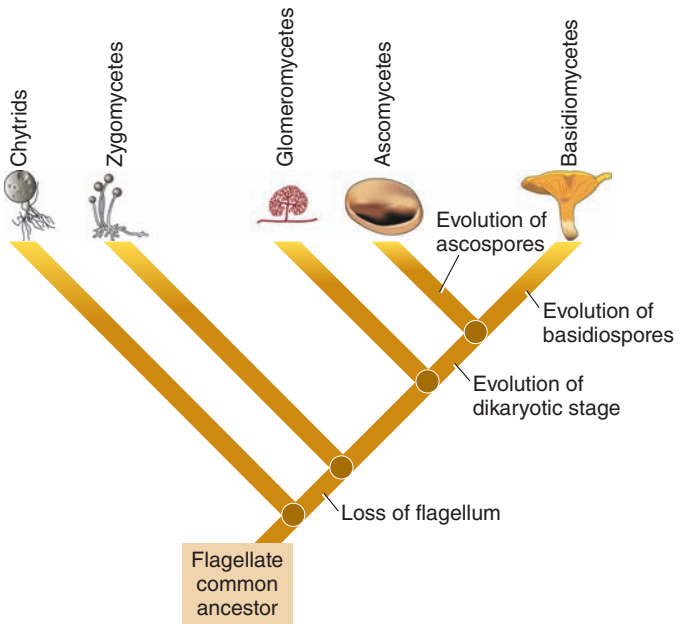
- A fungus may be a unicellular **yeast** or a filamentous, multicellular *mold*. The body of most multicellular fungi consists of long, threadlike filaments called **hyphae** that branch and form a tangled mass called a **mycelium**.
- In most fungi, perforated **septa**, or cross walls, divide the hyphae into individual cells. In some fungi, the hyphae are **coenocytes** that form an elongated, multinuclear cell.

29.2 Fungal Reproduction *(page 605)*

3 Describe the life cycle of a typical fungus, including sexual and asexual reproduction.

- Most fungi reproduce both sexually and asexually by means of **spores**. Spores are produced on aerial hyphae. When fungal spores land in a suitable spot, they germinate.
- When fungi of two different mating types meet, their hyphae fuse, a process called **plasmogamy**. The cytoplasm fuses, but the nuclei remain separate. The fungi enter a **dikaryotic** ($n + n$) stage in which each new cell formed has one nucleus of each type.
- **Karyogamy**, fusion of the nuclei, takes place in the hyphal tip and results in a diploid ($2n$) *zygote nucleus*.
- Meiosis produces four genetically different haploid (n) nuclei. Each nucleus becomes part of a spore. When the spores germinate, they form new mycelia by mitosis.
- Genetically similar asexual spores are produced by mitosis. When these spores germinate, they also develop into mycelia.

29.3 Fungal Diversity *(page 607)*



4 Give arguments to support the hypothesis that fungi are opisthokonts, more closely related to animals than to plants.

- Like animals, some fungi have flagellate cells—for example, chytrid gametes and spores—and the flagellate cells propel themselves with a single posterior flagellum. Also like animal cells, fungal mitochondria have platelike cristae.
- Based on chemical and structural characters, fungi are classified, along with animals and choanoflagellates, as **opisthokonts**.

5 Give arguments to support the hypothesis that chytrids may have been the earliest fungal group to evolve from the most recent common ancestor of fungi.

- **Chytrids**, or **chytridiomycetes**, produce flagellate spores at some stage in their life cycle. No other fungi have flagella. Thus, chytrids probably were the earliest fungi to evolve; the most recent common ancestor of all fungi was a flagellate protist.

6 List distinguishing characteristics, describe a typical life cycle, and give examples of each of the following fungal groups: chytridiomycetes, zygomycetes, glomeromycetes, ascomycetes, and basidiomycetes.

- Chytrids reproduce both asexually and sexually. Their gametes and zoospores are flagellate. *Allomyces*, a common chytrid, spends part of its life as a multicellular haploid thallus and part as a multicellular diploid thallus. The haploid **thallus** produces two types of flagellate gametes that fuse. Both plasmogamy and karyogamy occur, producing a flagellate zygote. The diploid thallus bears zoosporangia that produce diploid **zoospores** and resting sporangia in which haploid zoospores form by meiosis. The haploid zoospores form new haploid thalli.
- **Zygomycetes**, such as the black bread mold, *Rhizopus*, form a haploid thallus that produces both asexual spores and sexual spores. Asexual spores germinate and form new thalli. In sexual reproduction hyphae of two different haploid mating types form gametangia. Plasmogamy occurs as the gametangia fuse. Karyogamy occurs, and a diploid zygote is formed; the zygote develops into a **zygospore**. Meiosis produces recombinant haploid zygospores. When zygospores germinate, each hypha develops a sporangium at its tip. Spores are released and develop into new hyphae.
- **Microsporidia**, currently classified as zygomycetes, are opportunistic pathogens that penetrate and infect animal cells with their long, threadlike *polar tubes*.
- **Glomeromycetes** have coenocytic hyphae. They reproduce asexually with large, multinucleate spores called

Copyright 2019 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

blastospores. Glomeromycetes are symbionts that form intracellular associations called **mycorrhizae** with the roots of plants. Because they extend their hyphae into root cells, glomeromycetes are **endomycorrhizal fungi**. The most common endomycorrhizae are called *arbuscular mycorrhizae* because the hyphae inside the root cells form branched, tree-shaped structures known as **arbuscules**.

- **Ascomycetes** include yeasts, cup fungi, morels, truffles, and blue-green, pink, and brown molds. Some ascomycetes form mycorrhizae; others form lichens. Ascomycetes produce asexual spores called **conidia**; they produce sexual spores called **ascospores** in saclike **asci**. The asci line a fruiting body called an **ascocarp**.
- In ascomycetes haploid mycelia of opposite mating types produce septate hyphae. Plasmogamy occurs, and nuclei are exchanged. A dikaryotic ($n + n$) stage occurs in which hyphae form and produce asci and an ascocarp. Karyogamy occurs, followed by meiosis. The recombinant nuclei divide by mitosis, producing eight haploid nuclei that develop into ascospores. When the ascospores germinate, they can form new mycelia.
- **Basidiomycetes** include mushrooms, puffballs, bracket fungi, rusts, and smuts.
- These fungi produce sexual spores called **basidiospores** on the outside of a **basidium**. Basidia develop on the surface of **gills** in mushrooms; mushrooms are a type of **basidiocarp** (a fruiting body).
- Hyphae in the basidiomycetes have septa. Plasmogamy occurs with the fusion of two hyphae of different mating types. A dikaryotic **secondary mycelium** forms. Then a basidiocarp develops, and basidia form. Karyogamy occurs, producing a diploid zygote nucleus. Meiosis produces four haploid nuclei that become basidiospores. When basidiospores germinate, they form haploid **primary mycelia**.

29.4 Ecological Importance of Fungi *(page 618)*

7 Summarize the ecological significance of fungi as decomposers.

- Most fungi are decomposers that break down organic compounds in dead organisms, leaves, garbage, and wastes into simpler nutrients that can be recycled.

8 Describe the important ecological role of mycorrhizae.

- Mycorrhizae are mutualistic associations between fungi and the roots of plants. The fungus supplies water and nutrient minerals to the plant, and the fungus obtains organic compounds from the plant. Glomeromycetes form endomycorrhizae with roots. Some ascomycetes and basidiomycetes are **ectomycorrhizal fungi** that form mycorrhizae when their hyphae coat tree roots, but do not penetrate the root cells.

9 Characterize the unique nature of a lichen.

- A **lichen** is a combination of one or more fungi and a photoautotroph (an alga or cyanobacterium). In this symbiotic relationship, the photoautotroph provides the fungus with organic compounds. The fungus may provide the photoautotroph with shelter, water, and minerals. Lichens have three main forms: crustose, foliose, and fruticose.

29.5 Economic, Biological, and Medical Impact of Fungi *(page 621)*

10 Summarize some specific ways that fungi affect humans economically.

- Fungi cause huge economic losses by damaging food and crops. On the other hand, some fungi, like mushrooms, are foods; others, like yeasts, are used to produce beer, wine, and bread; and still others are used to produce cheeses or industrial chemicals.

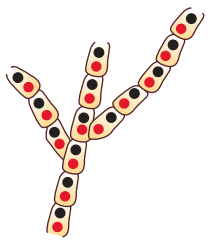
11 Summarize the importance of fungi to biology and medicine; describe how fungi infect plants and humans, describing at least one fungal animal disease and one fungal plant disease.

- Biologists use the yeast *Saccharomyces cerevisiae* and other fungi as model organisms for research in molecular biology and genetics. Fungi are also being investigated for the biological control of insects.
- Fungi are used to make many medications, including penicillin and other antibiotics; they are used in bioremediation and to control pests biologically.
- Fungi are opportunistic pathogens in humans. They cause human diseases, such as histoplasmosis; some fungi produce **mycotoxins**, such as *aflatoxins*, which can cause liver damage and cancer.
- Fungal hyphae infect plants through stomata. Hyphal branches called **haustoria** penetrate plant cells and obtain nourishment from the cytoplasm. Fungi cause many important plant diseases, including brown rot, corn smut, and wheat rust.

Test Your Understanding

Know and Comprehend

1. Fungi are (a) eukaryotes and opisthokonts (b) prokaryotes and opisthokonts (c) flagellate and dikaryotic (d) autotrophic eukaryotes (e) heterotrophs with cellulose cell walls
2. Which of the following fungi does *not* have a mycelium? (a) black bread mold (b) yeast (c) decomposer cup fungus (d) cultivated mushroom (e) *Penicillium*
3. A cell described as $n + n$ is (a) monokaryotic (b) diploid (c) haploid (d) coenocytic (e) dikaryotic
4. With the exception of chytridiomycetes, fungi are generally disseminated by (a) water currents (b) fragmentation of hyphae (c) soredia (d) airborne spores (e) flagellate zoospores
5. Which statement is *not* true of the chytrids? (a) they are simple aquatic fungi (b) they produce motile cells with single, posterior flagella (c) they undergo both sexual and asexual reproduction (d) their cells are dikaryotic (e) they were the earliest fungi to evolve



Copyright 2019 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in

Copyright 2019 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

6. Which statement is *not* true of the zygomycetes? (a) many members of this group form endomycorrhizae with tree roots (b) their sexual spores are called zygospores (c) they undergo both sexual and asexual reproduction (d) plasmogamy and karyogamy occur (e) they have coenocytic hyphae
7. Glomeromycetes (a) reproduce mainly by sexual spores called glomerospores (b) are characterized by unique structures called polar tubes (c) associate with cyanobacteria to form lichens (d) include many opportunistic pathogens that cause human disease (e) form arbuscular endomycorrhizae with tree roots
8. The ascomycete life cycle typically includes (a) mainly diploid thalli (b) the formation of a thick zygosporangium (c) the production of eight haploid ascospores within an ascus (d) the production of microsporidia (e) the production of ascospores, zoospores, and conidia at different stages
9. Which statement is *not* true of the basidiomycetes? (a) they produce a secondary mycelium with $n + n$ hyphae (b) their sexual spores are called basidiospores (c) they have a diploid thallus that produces zoospores (d) reproduction is mainly sexual (e) they have microscopic basidia
10. A compound organism consisting of a photoautotroph and a fungus is called (a) an arbuscular endomycorrhiza (b) an ectomycorrhiza (c) a lichen (d) a pathogenic agent (e) an aflatoxin
11. Mutualistic associations between fungi and the roots of plants are called (a) lichens (b) mycorrhizae (c) pathogenic associations (d) parasitic haustoria (e) mycotoxic symbioses
12. When a fungus infects a plant, it (a) infiltrates leaves with lichens (b) forms relationships by attaching mycorrhizae to stems (c) secretes powerful digestive juices onto the leaves (d) uses haustoria to dissolve roots (e) enters leaves or stems through stomata

Apply and Analyze

13. **VISUALIZE** The secondary mycelium of a basidiomycete is shown here. (a) How would you describe its cells? (b) What stage of its life cycle is it in? (c) Draw the next steps in this stage of its life cycle.

14. Explain the statement "Mushrooms are like the tips of icebergs." If you do not see mushrooms in your lawn, can you conclude that no fungi live there? Why or why not?

Evaluate and Synthesize

15. **EVOLUTION LINK** Justify (a) classifying fungi as opisthokonts, (b) classifying microsporidia as fungi, and (c) grouping ascomycetes and basidiomycetes as sister clades.
16. **CONNECT** The development of safe and effective antifungal agents presents a daunting challenge to researchers. Explain. (*Hint:* Drugs that combat bacterial diseases typically target differences between bacterial cells and those of the host.)
17. **SCIENCE, TECHNOLOGY, AND SOCIETY** Develop an argument for or against the use of scientific resources, including the latest technology, to sequence the genomes of fungi.

30 An Introduction to Animal Diversity

KEY CONCEPTS

30.1 Animals are multicellular, eukaryotic heterotrophs composed of cells specialized to perform specific functions. Most animals are diploid organisms that reproduce sexually, and most have a nervous system and a muscular system.

30.2 Animals evolved in marine environments, and most animal phyla still have members that inhabit marine environments. However, many animals are adapted to life in fresh water and others to terrestrial habitats.

30.3 The common ancestors of animals are choanoflagellates; choanoflagellates, fungi, and animals are a monophyletic group known as opisthokonts.

30.4 Biologists classify animals based on many characteristics, including their morphology (structure), features of their early development, and molecular data; biologists agree that bilateral animals split into at least three major clades.

PHOTO: Coral reef ecosystems, the most diverse of all marine environments. Below the swimming green sea turtle (*Chelonia mydas*), identify purple tube sponges (*Aplysina archeri*) and coral. Also find a pair of queen angelfish (*Holocanthus cikiaris*), as well as orange elephant ear sponges (*Agelas clathrodes*) and an azure vase sponge (*Callyspongia plicifera*). Which of these animals might be mistaken for a plant or rock? (Photographed in Bonaire, Caribbean Netherlands, Atlantic Ocean.) Georgette Douwma/Getty Images

Although members of most animal species are readily recognizable as animals, the identity of some others is less obvious. Early naturalists thought sponges were plants because they were anchored in one place. Many people still mistake certain marine animals, such as sponges and corals, for plants (see photograph). Locomotion is not a requirement for being classified as an animal.

Animal phylogeny is an exciting and rapidly changing field of study. Biologists have described and named more than 1.5 million species of animals, and 15,000 to 20,000 new species are named each year. Millions more probably remain to be discovered and classified. Interestingly, an estimated 99% of all animal species that ever inhabited our planet are extinct. Taxonomists have assigned the extant (living) animals to about 35 major groups (phyla). Molecular studies have confirmed that many of these groups are **monophyletic**; that is, they consist of *all* the descendants and *only* the descendants of a common ancestor. (Recall from Chapter 23 that a monophyletic group is called a **clade**.)

Animal groups that are not monophyletic have been split or reorganized, with some members of the groups being reassigned to other taxa. It is important to remember that the classification of animals and the relative positions of animal groups are a work in progress. As they consider new data, systematists redraw the tree of animal life.

In this chapter we discuss the characteristics of animals and their habitats. We then explore animal origins and some of the criteria biologists use to determine evolutionary relationships and to classify animals. Finally, we introduce the major animal groups, including the three major clades of bilateral animals.

30.1 Animal Characteristics

LEARNING OBJECTIVE

1 Describe several characteristics common to most animals.

Animals are so diverse that for almost any definition we can find exceptions. We can best describe animals by the characteristics they share:

1. Animals are multicellular eukaryotes. In contrast to plants, algae, and fungi, animal cells lack cell walls. Instead, structural support depends on an **extracellular matrix**, which the cells secrete (see Chapter 4). Collagen, the main structural protein in the extracellular matrix, forms very tough fibers. Collagen is an important *shared derived character* in animals (see Chapter 23).
2. Animals are **heterotrophs**. As consumers, they depend on producers for their raw materials and energy. In contrast to the fungi, most animals ingest their food first and then digest it inside the body, usually within a digestive system.
3. Cells that make up the animal body are specialized to perform specific functions. In all but the simplest animals, cells are organized to form tissues, and tissues are organized to form organs. In small animals with simple body plans, life processes such as gas exchange, circulation of materials, and waste disposal can take place by diffusion of gases and other substances directly to and from the environment. In larger animals, specialized organ systems perform these functions.
4. Animals have diverse body plans. The term *body plan* refers to the basic structure and functional design of the body. An animal's body plan and lifestyle are adapted to its methods of obtaining food and reproducing.
5. Most animals are capable of locomotion at some time during their life cycle. Some animals (such as sponges and corals) move about as larvae (immature forms) but are **sessile** (firmly attached to the ground or some other surface) as adults (see chapter-opening photograph).
6. Most animals have nervous systems and muscle systems that enable them to respond rapidly to stimuli in their environment.
7. Most animals are diploid organisms that reproduce sexually, with large, nonmotile eggs and small, flagellate sperm. A haploid sperm unites with a haploid egg, forming a diploid **zygote** (fertilized egg).
8. Animals go through a period of embryonic development. The zygote undergoes **cleavage**, a series of mitotic cell divisions. During cleavage the zygote develops into a hollow ball of cells called a **blastula**. Although some animals develop directly into adults, the majority first develop into a **larva**, a sexually immature form that may look very different from the adult (FIG. 30-1). The larva differs from the adult in many ways, including where it lives (its habitat), how it moves, and what it eats. Larvae typically go through **metamorphosis**, a developmental process that converts the immature animal into a juvenile form that can then grow into an adult.

CHECKPOINT 30.1

- **CONNECT** For centuries, scientists classified sponges as plants, but now they are classified as animals. What characteristics do sponges share with other animals?

Sonke Johnsen/Visuals Unlimited, Inc.

(a) Spiny lobster larva. Over a period of months, the larva passes through several stages before becoming an adult.

Dr. Magnus Kjaergaard

(b) Adult spiny lobster. The adult has two long antennae used to sense movement. Spiny lobsters lack large claws. The spines on their back help protect them. In this image you can see the two large spines above the animal's eyes. Spiny lobsters leave their hiding places at night to hunt.

Figure 30-1 Larva and adult spiny lobster

Most animals go through a larva stage before developing into an adult. The larva usually differs from the adult in size, appearance, and lifestyle.

30.2 Adaptations to Ocean, Freshwater, and Terrestrial Habitats

LEARNING OBJECTIVE

2 Compare the advantages and disadvantages of life in the ocean, in fresh water, and on land.

Fossil evidence suggests that animals first evolved in shallow, marine environments during the Proterozoic eon, at least 600 million years ago (mya; see Chapter 21). Although animals are now distributed in virtually every environment, at least some members of most animal phyla still inhabit marine environments.

Marine habitats offer many advantages

The buoyancy of sea water provides support, and its large volume keeps the water temperature relatively stable. The body fluids of most invertebrates have about the same osmotic concentration as sea water, so fluid and salt balance are more easily maintained there than in fresh water. **Plankton**, which mainly consists of the microscopic animals and protists that are suspended in the water, provides a ready source of food for many aquatic animals.

Life in the ocean also presents some challenges. Although the continuous motion of water brings nutrients to animals and washes their wastes away, animals must be able to cope with the water's movements and the currents that could sweep them away. Squids, fishes, and marine mammals have evolved as strong swimmers, usually able to direct their movements and maintain their location. However, most invertebrates and young vertebrates cannot swim strongly, and they have adapted in various ways to the tides and currents.

Some sessile animals attach permanently to a stable structure such as a rock. Others burrow in the sand and silt that cover the sea bottom. Many invertebrates have adapted by maintaining a small body size and becoming part of the plankton. As they are tossed about, their food supply continues to surround them.

Some animals are adapted to freshwater habitats

Fewer types of animals make their homes in fresh water than in the ocean because living in this habitat is more difficult. Fresh water is hypotonic to the tissue fluids of animals, so water tends to move into the animal by osmosis. To survive in this habitat, freshwater species must have mechanisms for removing excess water while retaining salts. This process, called *osmoregulation*, requires an expenditure of energy.

Fresh water offers a much less constant environment than sea water. Animals that inhabit fresh water must have adaptations for surviving variations in oxygen content, temperature, turbidity (due to sediments suspended in the water), and even water volume. In addition, fresh water generally contains less food than the sea.

Terrestrial living requires major adaptations

Living on land is even more difficult than living in fresh water, and the evolution of terrestrial animals involved major adaptations. Analyzing the fossil record, many biologists hypothesize that the first air-breathing terrestrial animals were scorpion-like arthropods that came ashore in the Silurian period about 444 mya. The first vertebrates to inhabit terrestrial environments, the amphibians, did not appear until the Devonian period, about 30 million years later.

The chief problem facing all terrestrial organisms is desiccation (drying out). Water is constantly lost by evaporation and is often difficult to replace. A body covering adapted to minimize fluid loss helps solve this problem in many terrestrial animals (FIG. 30-2). Location of the respiratory surface deep within the animal also helps prevent fluid loss. Thus, the gills of aquatic animals are typically located externally or near the body surface, but lungs and tracheal tubes of terrestrial animals are typically found deep inside the body.

Reproduction on land also poses challenges to protecting gametes and the developing offspring from desiccation. Aquatic animals typically shed their gametes in the water, where fertilization occurs. Some land animals, including most amphibians, return to the water for reproduction, and their larval forms develop in the water.

The evolution of internal fertilization has permitted many terrestrial animals, including land planarians, earthworms, land snails, insects, reptiles (including birds), and mammals, to meet the desiccation challenge. Because these terrestrial animals transfer sperm from the body of the male directly into the body of the female by copulation, a watery medium continuously surrounds the sperm. Another important adaptation to reproduction on land is the tough, protective shell that surrounds the eggs of many species (see Fig. 30-2). Secreted by the female, this shell protects the developing embryo from drying out. An alternative

E.R. Degginger/Science Source

Figure 30-2 Adaptations to terrestrial life

The tough, horny skin of the green iguana (*Iguana iguana*) has scales and is water resistant. Leathery eggs protect the embryos from drying out.

adaptation for terrestrial reproduction is development of the embryo within the moist body of the mother.

Water has buoyancy that helps support animals that inhabit aquatic environments. Air is less dense than water, and to inhabit the land, animals must have structures, such as a skeletal system and muscles, that support the body. The temperature extremes of terrestrial habitats also present challenges. In later chapters we discuss behavioral and physiological adaptations for maintaining body temperature.

CHECKPOINT 30.2

- What are some advantages of marine environments over freshwater and terrestrial habitats?
- **CONNECT** What are some animal adaptations to the terrestrial environment?

30.3 Animal Evolution

LEARNING OBJECTIVE

3 Use current hypotheses to trace the early evolution of animals.

Most biologists agree that animals share a common ancestor with a group of protists known as *choanoflagellates* (see Fig. 26-21). The cells of these colonial flagellates became specialized to perform specific functions, such as movement, feeding, or reproduction. As this division of labor evolved, a colony of flagellates reached the level of cooperation and coordination that qualified it to be considered a single organism, the first animal. The choanoflagellates, fungi, and animals are a monophyletic group known as **opisthokonts**. Recall from Chapter 26 that opisthokonts are characterized by a posterior flagellum on motile cells.

Historically, biologists depended on fossils, similarities in body plan (i.e., structure), and patterns of development to determine evolutionary relationships among various groups of animals. As discussed in Chapter 23, **molecular systematics**, the science that focuses on molecular structure to clarify evolutionary relationships, has provided additional data that are critical in answering questions about phylogeny. Molecular data often confirm hypotheses that were based on morphology (structure).

Complex genomes were apparently present early during animal evolution. Molecular studies suggest that the ancestor of animals had more than 1500 genes not found in other eukaryotes. Some of these genes may be traced to *horizontal gene transfer* from other domains, followed by modification of the genes. Complex genomes have been described in the sea anemone and in other animals that are relatively simple morphologically.

Molecular analyses indicate that the structure of genes that control development, RNA molecules, and many other molecules are very similar among all animal groups that have been studied. According to the *principle of parsimony*, such complex molecules are unlikely to have evolved multiple times (see Chapter 23). Thus, these data support the hypothesis that animals evolved only once. Animals are a monophyletic group.

Molecular systematics helps biologists interpret the fossil record

Because early animals were soft-bodied forms that left few fossils, the evolutionary history of animals has been vigorously debated. The scarcity of fossils has made it difficult to determine the age, rate of divergence, and number of branches of animal groups. In 2009, a research team found fossil traces in an oil field on the Arabian Peninsula that are thought to date back more than 635 million years. The fossil traces are steroids found only in the skeletal structures of certain sponges (demosponges). Before this discovery, the earliest known animal fossils were the *Ediacaran biota* from the **Ediacaran period** (635 mya to 541 mya). These fossils of small, simple animals suggest that sponges, jellyfish, and comb jellies were present during this period (see Fig. 21-9).

Paleontologists have discovered many large, complex animal fossils in Chengjiang, an Early Cambrian (542 mya to 520 mya) fossil site in China, and in the Burgess Shale in British Columbia, a Middle Cambrian fossil site (520 mya to 515 mya). Fossils of most extant phyla (and also many extinct animals) have been found at these sites. The rapid evolution of an amazing variety of body plans during this time is known as the **Cambrian radiation**, or less formally as the **Cambrian explosion** (see Fig. 21-10). The many new body plans that evolved during this time account for many branches of the animal tree.

Studies of large molecular data sets suggest that most animal clades actually diverged over a very long period during the Proterozoic eon (2.5 bya to 541 mya). Thus, the animal phyla that first left fossils during the Cambrian radiation may have evolved several hundred million years *before* they appear in the fossil record. Biologists estimate that certain groups are about twice as old as the oldest fossils found to date. According to this view, the Cambrian radiation was a rapid evolution of new animal body plans among clades that already existed. Perhaps fossils of these early animals remain to be discovered in Proterozoic rocks. Another hypothesis holds that a change in environmental conditions that occurred prior to the Cambrian radiation allowed fossils to form.

Biologists develop hypotheses about the evolution of development

Changes in animal body plans are linked to changes in patterns of embryonic development. Biologists have long used similarities and differences in embryonic development to hypothesize how animal groups are related. Traditionally, biologists depended mainly on structural changes to compare the process of development in various groups.

Researchers focusing on the molecular basis of developmental processes have identified genes that direct the early development of the body plan. They have discovered that many of these genes have been conserved during animal evolution. The same basic set of genes controls early development in all animal groups. Furthermore, the same genes are used in the same ways to regulate development.

Evolutionary developmental biology, sometimes referred to as **Evo Devo**, has become an important approach to studying

animal relationships. Biologists compare molecular events, such as gene regulation during development, in various animal groups.

Recall from Chapter 17 that ***Hox* genes** are a group of regulatory genes that specify the anterior–posterior axis during development (see Fig. 17-13). The presence and number of *Hox* genes provide insights about evolutionary relationships. These genes have been identified in all the bilateral animal groups that have been studied, suggesting that the last common ancestor of all bilateral animals had similar *Hox* genes. These genes have been identified in a sea anemone (*Nematostella vectensis*), which is a cnidarian. Cnidarians are marine animals, for example, jellyfish, with radial symmetry. This finding suggests that the cnidarians share a common ancestor with the bilateral animals.

Investigators think that the *Hox* gene groups had evolved by the beginning of the Cambrian period. Mutations in *Hox* genes could have resulted in rapid changes in animal body plans. For example, regulation by *Hox* gene groups has been linked with the development of wings or legs. Similarities in molecular development among different animal groups suggest that they had a common ancestor.

CHECKPOINT 30.3

- What was the Cambrian radiation?
- According to the current hypothesis, when did most major groups of animals evolve?
- **CONNECT** How has the discovery of *Hox* genes helped biologists understand animal evolution?

30.4 Reconstructing Animal Phylogeny

LEARNING OBJECTIVES

4 Describe how biologists use morphology (including variations in body symmetry, number of tissue layers, and type of body cavity) and patterns of early development to infer relationships among animal phyla.

5 Cite specific examples of how data from molecular systematics have confirmed or modified traditional animal phylogeny and identify the three major clades of bilateral animals.

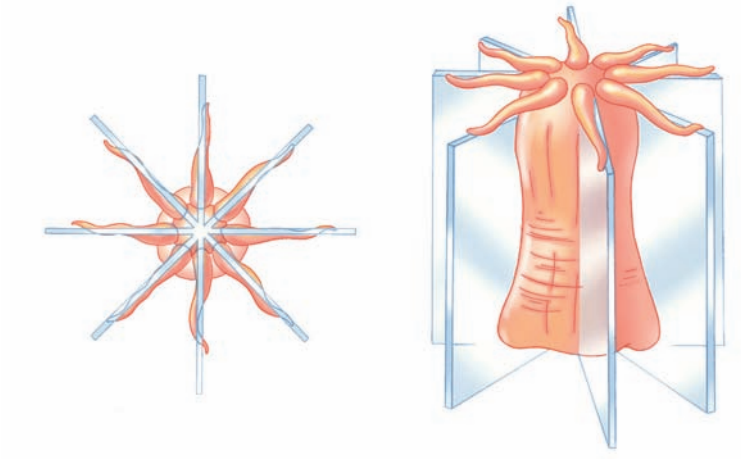
Because some animal body plans have been highly conserved throughout evolutionary history, variations in body plans can provide clues to animal relationships. For example, biologists compare variations in body symmetry, number of tissue layers, types of body cavity, and pattern of development. Biologists also use similarities and differences in embryonic development to infer evolutionary relationships among animal groups. In addition to these traditional methods, researchers now have molecular tools to enhance our understanding of animal phylogeny. Because of technological improvements over the last few decades, comparisons of nucleic acid (DNA and RNA) and protein structure provide critical data for biologists seeking to interpret and reconstruct animal phylogeny.

Animals exhibit two main types of body symmetry

Symmetry refers to the arrangement of body structures in relation to the body axis. Most sponges are not symmetrical, so when a sponge is cut in half, the two halves are not similar to each other. Most other animals exhibit either radial or bilateral body symmetry.

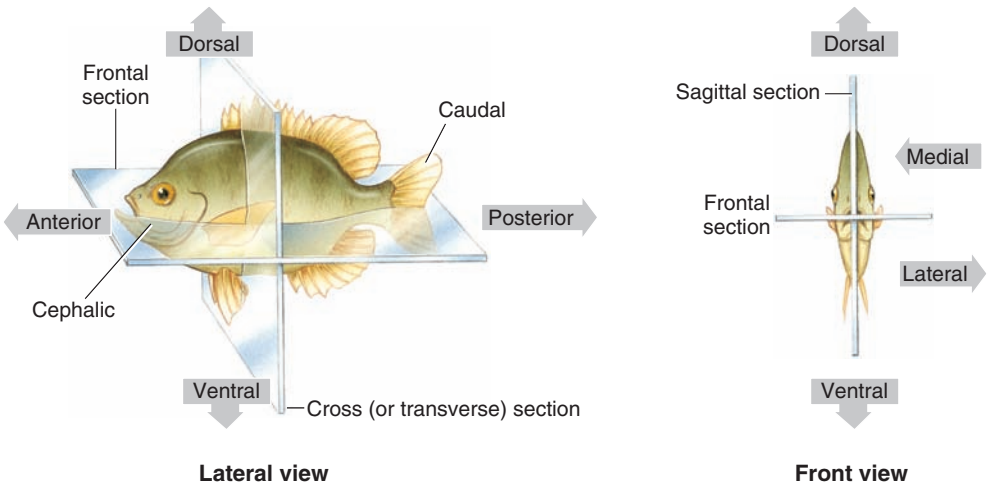
Cnidarians (jellyfish, sea anemones, and their relatives) and adult echinoderms (sea stars and their relatives) have **radial symmetry**. The body has the general form of a wheel or cylinder, and similar structures are regularly arranged as spokes from a central axis (FIG. 30-3a). Multiple planes can be drawn through the central axis, each dividing the organism into two mirror images. An animal with radial symmetry receives stimuli equally from all directions in the environment. Some animals have modified radial symmetry. For example, sea anemones and ctenophores (comb jellies) have *biradial symmetry*, in which parts of the body have become specialized so that only two planes can divide the body into similar halves.

Most animals exhibit **bilateral symmetry**, at least in their larval stages. A bilaterally symmetrical animal can be divided through only one plane (which passes through the midline of the body) to produce roughly equivalent right and left halves that are mirror images (FIG. 30-3b).



As bilateral symmetry evolved, natural selection led to **cephalization**, the development of a head where sensory structures are concentrated. In these groups, concentrations of nerve cells in the head form a brain, and one or two nerve cords extend from the brain toward the rear end of the animal. Bilateral symmetry and cephalization are adaptations for locomotion. The head end of the animal meets its environment first and is best equipped to capture food or respond to danger.

Some definitions of basic terms and directions will help in locating body structures in bilaterally symmetrical animals. The back surface of an animal is its **dorsal** surface; the underside (belly) is its **ventral** surface. **Anterior** (or *cephalic*) means toward the head end of the animal; **posterior**, or *caudal*, means toward the tail end. A structure is said to be *medial* if it is located toward the midline of the body, and it is *lateral* if it is toward one side of the body. For example, the human ear is lateral to the nose. In human anatomy the term *superior* refers to a structure located above some point of reference, or toward the head end of the body. The term *inferior* is used in human anatomy to mean located below some point of reference, or toward the feet.



A bilaterally symmetrical animal has three axes, each at right angles to the other two. Its anterior–posterior axis extends from head to tail. Its dorsal–ventral axis extends from back to belly, and a left–right axis extends from side to side. We can distinguish three planes or sections that divide the body into specific parts. A *sagittal plane* divides the body into right and left parts. A sagittal plane passes from anterior to posterior and from dorsal to ventral. A *frontal plane* divides a bilateral body into dorsal and ventral parts. A *transverse section*, also called a *cross section*, cuts at right angles to the body axis and separates anterior and posterior parts.

(a) Radial symmetry. Multiple planes can be drawn through the central axis; each divides the animal into two mirror images.

(b) Bilateral symmetry. The head of the animal is its anterior end, and the opposite end is its posterior end. The back of the animal is its dorsal surface, and the belly is its ventral surface. The diagrams illustrate various ways the body can be sectioned (cut) to study its internal structure. A cross (transverse) section divides the body into anterior and posterior parts. A frontal, or longitudinal, cut (lengthwise horizontal) divides the body into dorsal and ventral parts. A sagittal section (lengthwise vertical cut) divides the animal into right and left parts.

Figure 30-3 Radial and bilateral symmetry

Throughout this book, sections of animals are shown to illustrate the structure and arrangement of tissues and organs.

Animal body plans are linked to the level of tissue development

Sponges have several types of cells, but their cells are not organized into **tissues**, which are groups of closely associated, similar cells that work together to carry out specific functions. In the early development of all animals except sponges, cells form layers, called **germ layers**. The outer germ layer, or **ectoderm**, gives rise to the tissues that form the outer covering of the body as well as to nervous tissue. The inner layer, or **endoderm**, forms the lining of the digestive tube and other digestive structures. These layers develop into specific types of tissues.

Biologists describe cnidarians and ctenophores as **diploblastic** because they have only two germ layers. Other animals are **triploblastic**. They have a third germ layer, the **mesoderm**, which gives rise to most other body structures, including muscles, skeletal structures, and circulatory system (when present).

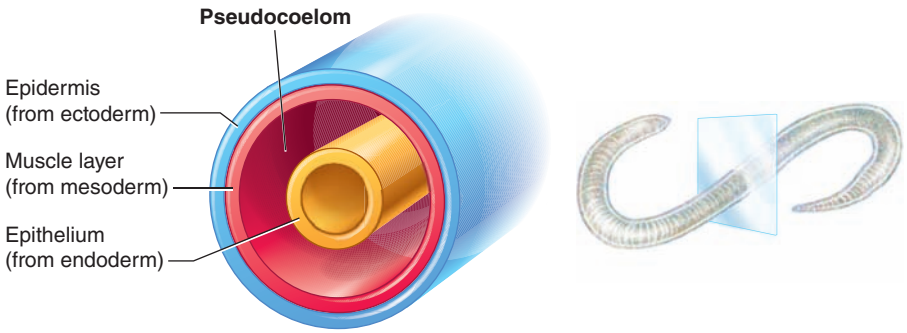
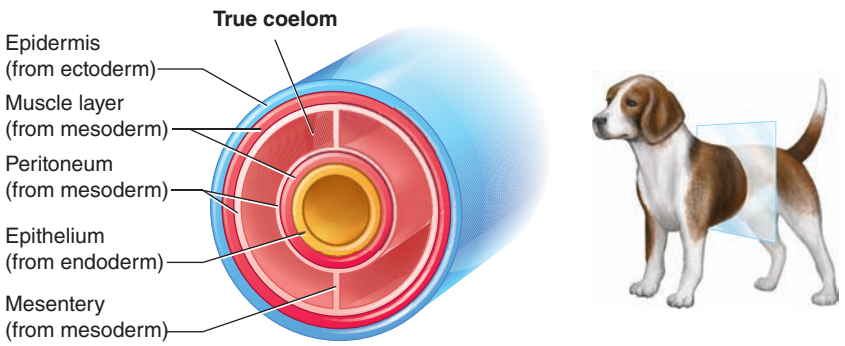
Most bilateral animals have a body cavity lined with mesoderm

The vast majority of bilateral animals have a fluid-filled body cavity, or **coelom** (pronounced "see´-lum"), between the outer wall of the body and the digestive tube (FIG. 30-4). The flatworms and ribbon worms are exceptions. They are bilateral and triploblastic but have a solid body; that is, they have no body cavity. They are referred to as **acoelomates** (*a-*, "without"; and *coelom*, "cavity").



Most animals have a body cavity that is completely lined with mesoderm. Such a body cavity is a *true* coelom. An animal with a true coelom is referred to as a **coelomate**. The coelom was one of the most important early animal adaptations. Evolution of the coelom was a critical step in the evolution of larger, more complex animals.

With the evolution of the coelom came a new body design, the *tube-within-a-tube* body plan. The coelom is a space that separates the body wall, the outer tube, from the digestive tube (gut), which is the inner tube. The digestive tube is attached to the body wall at its ends. Typically, the digestive tube has a mouth at one end for taking in food and an anus at the other end for eliminating wastes. Because the coelom separates the muscles of the body wall from those in the wall of the digestive tract, the digestive tube can move food along independently of body movements.



Because it is an enclosed compartment (or series of compartments) of fluid under pressure, the coelom can serve as a **hydrostatic skeleton** in which contracting muscles push against a tube of fluid. The hydrostatic skeleton also shapes the body of soft animals. The evolution of various shapes and divisions of the coelom provided the opportunity for animals to become specialized in swimming, crawling, or walking. Animals that can move quickly to capture food or avoid predators are more likely than slower-moving animals to survive.

(a) Acoelomate: flatworm (planarian worm). Acoelomate animals have no body cavity.

(b) Pseudocoelomate: nematode. Pseudocoelomate animals have a body cavity that is not completely lined with mesoderm.

(c) True coelomate: vertebrate. Coelomate animals have a coelom, a body cavity completely lined with tissue that develops from mesoderm. Many internal organs are located in the coelom.

Figure 30-4 Three basic body plans in triploblastic animals

The germ layer from which each tissue was derived is indicated in parentheses. Ectoderm is shown in *blue*, mesoderm in *red*, and endoderm in *yellow*.

Evolution of the coelom provided a space where internal organs could develop and function. For example, the pumping action of the heart is possible because of the surrounding space the coelom provides. The fluid-filled coelom also protects internal organs by cushioning them. (Other functions of the coelom will be discussed in Chapter 31.)

Some (typically, small) animals have a body cavity that is not completely lined with mesoderm. This type of body cavity is called a **pseudocoelom** ("false coelom"). Animals with a pseudocoelom, such as nematodes (roundworms) and rotifers, are called **pseudocoelomates**. Because the pseudocoelom appears to have evolved independently in different animal taxa, the presence of a pseudocoelom is not considered a useful characteristic for determining phylogeny. Instead, it is an example of homoplasy. (Recall from Chapters 18 and 23 that the term *homoplasy* refers to similarities that are independently acquired by convergent evolution.)

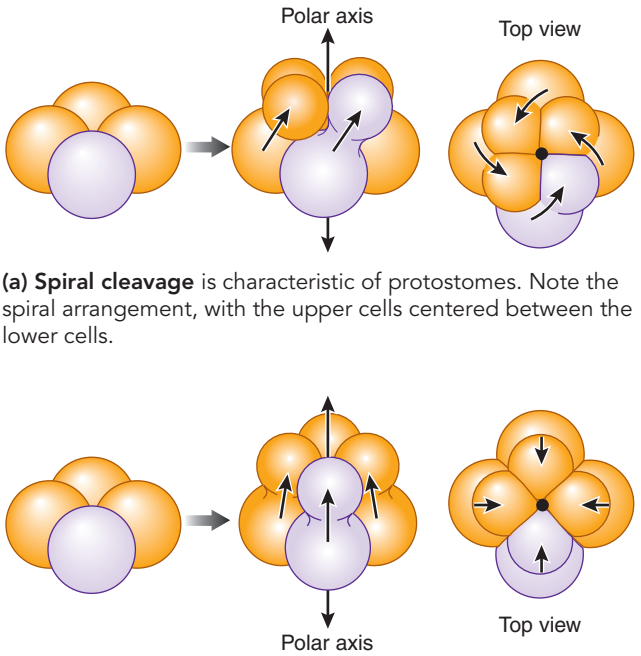
Bilateral animals form two main clades based on differences in development

Embryonic development begins as the zygote undergoes cleavage, the first several cell divisions of the embryo. During cleavage, the embryo develops into a hollow ball of cells, the blastula. Cells of the blastula undergo **gastrulation**, a process that forms and segregates the three germ layers.



Basic differences in the pattern of early development distinguish two main evolutionary lines of bilateral animals: **protostomes** (pro´-tuh-stomes), assigned to the clade *Protostomia*, and **deuterostomes** (doo´-ter-uh-stomes), assigned to the clade *Deuterostomia*. The protostomes include mollusks (e.g., snails, clams, squids), annelids (e.g., earthworms), arthropods (e.g., crabs, insects), and several other groups. Deuterostomes include the echinoderms (such as sea stars and sea urchins) and chordates (which include the vertebrates).

One important difference in the development of protostomes and deuterostomes is the pattern of cleavage. In many protostomes the early cell divisions are diagonal to the polar axis (the long axis of the embryo), resulting in a somewhat spiral arrangement of cells; any one cell lies between the two cells above or below it (FIG. 30-5a). This pattern of division is known as **spiral cleavage**. In **radial cleavage**, characteristic of the deuterostomes, the early divisions are either parallel or at right angles to the polar axis. The resulting cells lie directly above or below one another (FIG. 30-5b).

In the protostomes the developmental fate of each embryonic cell is typically fixed very early. For example, if the first four cells of an annelid embryo are separated, each cell develops into only a fixed quarter of the larva; this pattern of cleavage is called **determinate cleavage**. In contrast, deuterostomes typically undergo **indeterminate cleavage**. During early cleavage, each cell has the potential of developing into a complete embryo.

For example, if the first four cells of a sea star embryo are separated, each cell can form a complete, although small, larva. If a few cells are removed from a blastula undergoing indeterminate cleavage, other cells compensate, and the embryo develops normally. In contrast, if a few cells are removed from the blastula of an embryo undergoing determinate cleavage, some structure, such as a limb, does not develop.

During gastrulation, a group of cells moves inward, forming a sac that becomes the embryonic gut. The opening to the outside is called the **blastopore**. In most protostomes the blastopore develops into the mouth. The word *protostome* comes from Greek words meaning "first" and "the mouth." In deuterostomes the blastopore does not give rise to the mouth but generally develops into the anus. A second opening that forms later in development gives rise to the mouth. The word *deuterostome* derives from words meaning "second" and "the mouth."

(a) Spiral cleavage is characteristic of protostomes. Note the spiral arrangement, with the upper cells centered between the lower cells.

(b) Radial cleavage is characteristic of deuterostomes. The early divisions are either parallel to the polar axis or at right angles to it. The cells are stacked, with the upper cells centered directly above the lower cells.

Figure 30-5 Spiral and radial cleavage

The pattern of cleavage can be appreciated by comparing the positions of the *purple cells* in **(a)** and **(b)**.

Biologists have identified major animal clades based on structure, development, and molecular data

As we have discussed, biologists have long inferred evolutionary relationships among animals based on their structural variations and patterns of development. More recently, new technology, such as advances in microscopy, cell labeling, and genetics, has helped systematists clarify evolutionary relationships among animal groups. Molecular data have also challenged some traditional conclusions, such as *when* various animal groups diverged in relation to other groups. Such questions continue to be the topic of much debate.

Animals are referred to as *metazoa*. Animals with two or three germ layers (diploblastic or triploblastic) make up the *eumetazoa*. As we have described, some animals exhibit asymmetry (sponges), radial symmetry (cnidarians), or biradial symmetry (ctenophores). The *Bilateria*, the lineage of animals with bilateral symmetry, are triploblastic. (They have three germ layers: ectoderm, endoderm, and mesoderm.) As explained in the last section, biologists classify bilateral animals into protostome and deuterostome clades.

Molecular data show that the protostomes split into two major clades: **Lophotrochozoa** (pronounced "lo-fah-tro-kah-zo´-ah") and **Ecdysozoa** (pronounced "ek-dah-so-zo´-ah") (TABLE 30-1 and FIG. 30-6 on page 638). Animals assigned to the *Lophotrochozoa* are characterized by (1) a lophophore, a ciliated ring of tentacles surrounding the mouth that serves as a feeding organ; or (2) a type of larva called a *trochophore larva*. The Lophotrochozoa include the flatworms, ribbon worms, mollusks, annelids, and three groups sometimes referred to as the lophophorate phyla.

The name *Ecdysozoa* is derived from the animals in this group molting, a process called *ecdysis*. The Ecdysozoa include the nematodes and arthropods. Note that the phylogeny we have described assigns bilateral animals to three major clades: Lophotrochozoa, Ecdysozoa, and Deuterostomia.

Table 30-1 Overview of the Animal Kingdom

Major Groups and Subgroups	Some Key Characters/Comments
 **Poriferans** (sponges)	Collar cells, flagellated cells that trap food; cells loosely associated and do not form true tissues; sponge larvae have flagella and can swim about; poriferans are probably not a monophyletic group
 **Cnidarians** Medusozoans: hydras, jellyfish Anthozoans: corals, sea anemones	Radial symmetry; cnidocytes (stinging cells); polyp and medusa body forms; tentacles surround mouth; mainly marine
 **Ctenophores** (comb jellies)	Biradial symmetry; eight rows of cilia that resemble combs; tentacles with adhesive glue cells; marine predators
PROTOSTOMES: LOPHOTROCHOZOAN CLADE	Bilateral symmetry; triploblastic
 **Flatworms** (platyhelminths) Free-living planarians Parasitic flukes and tapeworms	Gastrovascular cavity with one opening; no coelom; cephalization
 **Nemerteans** (ribbon worms)	Proboscis (long, muscular tube that can be everted to capture prey); complete digestive tube; mainly marine carnivores
 **Mollusks** Chitons Gastropods: snails, slugs, nudibranchs Bivalves: clams, oysters Cephalopods: squids, octopods	Soft body typically covered by dorsal shell; muscular foot; mantle covers visceral mass; most have a radula (belt of teeth)
 **Annelids** Errantians: marine worms (sandworms, tubeworms) Sedentarians: earthworms, leeches	Segmented body; most have bristles, called setae, that provide traction during crawling
 **Lophophorates** Brachiopods Phoronids Bryozoans (ectoprocts)	Lophophore (ring of ciliated tentacles around mouth); mainly sessile, marine
 **Rotifers** (wheel animals)	Crown of cilia at anterior end; microscopic; freshwater and marine

Continued

Segmentation apparently evolved three times

Over millions of years, evolutionary forces acting on the basic animal body plan have produced changes resulting in a remarkable diversity of body forms. One very important innovation has been *segmentation*, a body plan in which certain structures are repeated, producing a series of body structures and compartments. In some cases, each compartment can be regulated somewhat independently of the others, which allows various parts of the body to become specialized to perform specific functions.

Perhaps the most obvious example of segmentation can be found in earthworms. However, as will be discussed in

Table 30-1 Overview of the Animal Kingdom (*continued*)

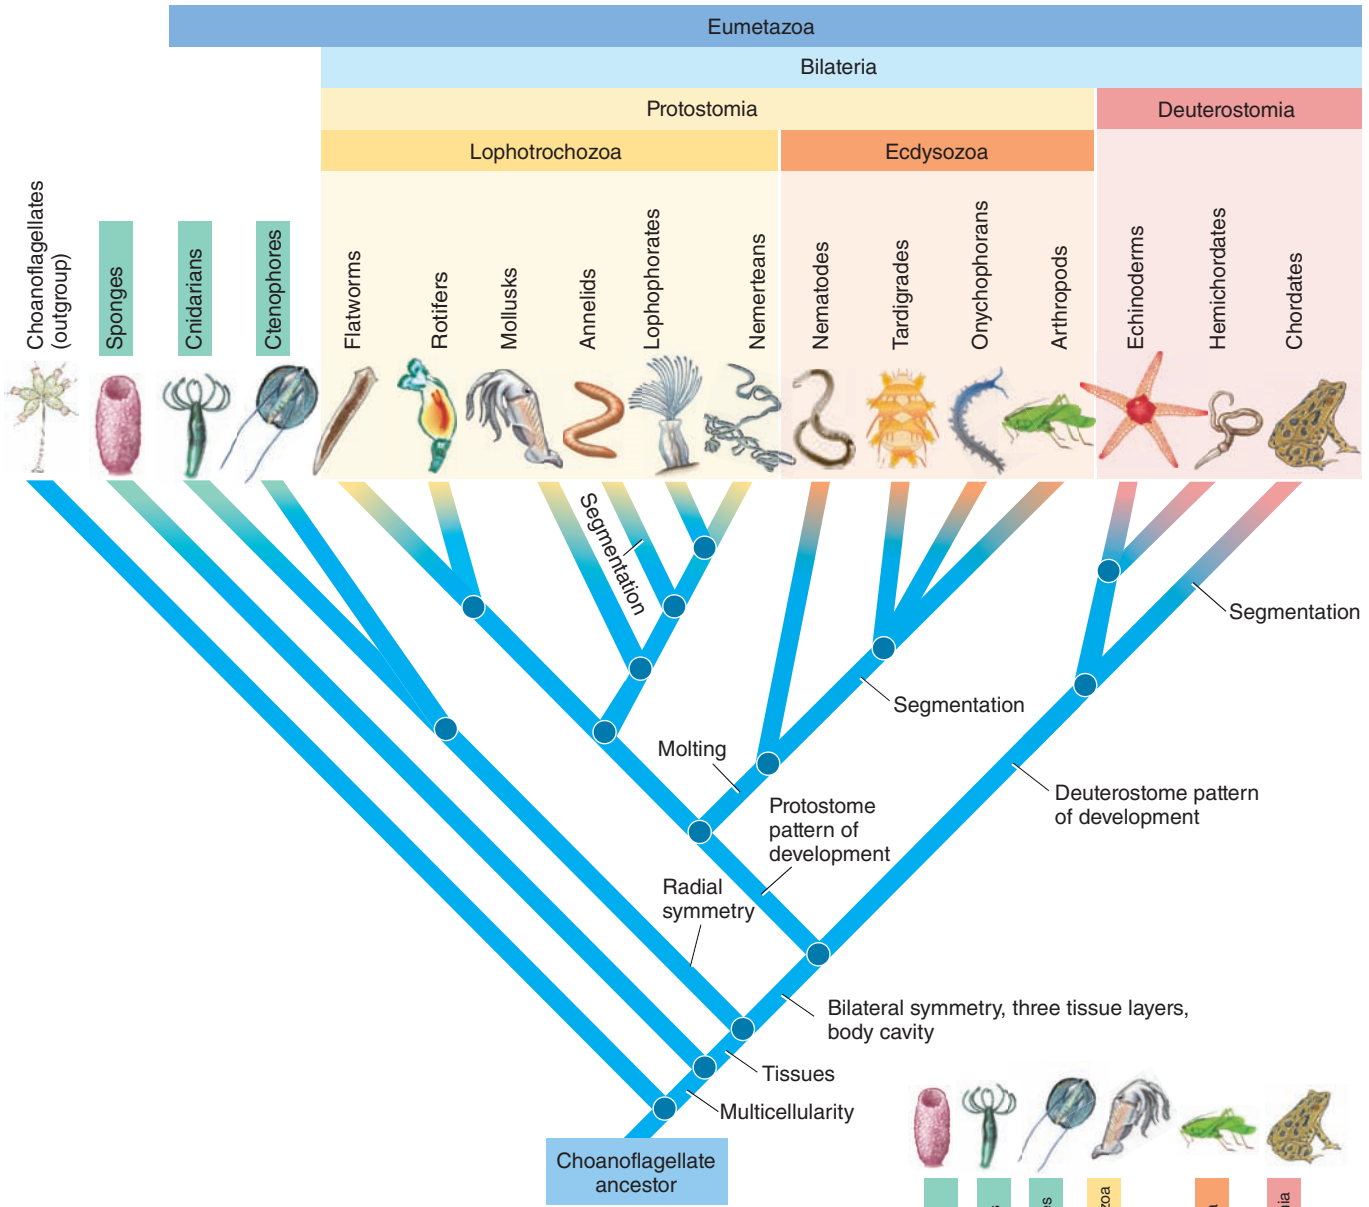
Major Groups and Subgroups	Some Key Characters/Comments
PROTOSTOMES: ECDYSOZOAN CLADE	Protostomes with cuticle that is molted and replaced as animal grows
 **Nematodes** (roundworms)	Fluid-filled pseudocoelom serves as hydrostatic skeleton; important decomposers; many are predators; some are parasites
Hookworms, trichina worms	
 **Arthropods**	Segmented; exoskeleton of chitin; paired, jointed appendages; insects and many crustaceans have compound eyes
Myriapods: centipedes and millipedes	
Chelicerates: horseshoe crabs and spiders	
Pancrustaceans: crustaceans (lobsters, crabs, barnacles, copepods) and hexapods (insects)	
DEUTEROSTOMES	Radial, indeterminate cleavage; pharyngeal slits
 **Echinoderms**	Water vascular system; tube feet; endoskeleton with spines; larvae bilateral, ciliated; adult, pentaradial symmetry; marine
Crinoids: sea lilies, feather stars	
Asteroids: sea stars	
Ophiuroids: basket stars, brittle stars	
Echinoids: sea urchins, sand dollars	
Holothuroids: sea cucumbers	
 **Hemichordates** (acorn worms)	Proboscis, collar, and trunk
 **Chordates**	Notochord; dorsal, tubular nerve cord; postanal tail; endostyle; segmented body
Cephalochordates (lancelets)	Notochord extends from anterior to posterior tip
Urochordates (tunicates)	Larvae have chordate characters
Vertebrates: hagfishes, lampreys, cartilaginous fishes, ray-finned fishes, coelacanths, lungfishes, amphibians, reptiles (including birds), mammals	Vertebral column; cranium; neural crest cells; endoskeleton

the following chapters, arthropods and vertebrates also have segmented body plans. Thus, segmented animals are found within each of the three major clades of bilateral animals. Molecular data suggest that segmentation evolved independently three times and is therefore another example of homoplasy. This view is reflected in the cladogram in Figure 30-6. In each independent origin of segmentation, natural selection apparently acted on many of the same genes (e.g., *Hox* genes).

In this chapter we have briefly discussed characteristics common to animals and the early evolution of animals. We described animal body plans and examined some of the criteria that biologists use to reconstruct phylogenetic relationships. The cladogram shown in Figure 30-6 depicts some of the current hypotheses regarding the relationships among major animals groups, and Table 30-1 summarizes these relationships. In the next two chapters, we survey these animal groups.

In Chapter 31 we describe three groups—sponges, cnidarians, and ctenophores—traditionally viewed as diverging early in the evolutionary history of animals. We then discuss one of the major clades of animals: the protostomes. Then, in Chapter 32, we discuss the deuterostomes, which include the echinoderms and chordates, the clade to which we humans belong. Many hypotheses are presented in these chapters, and we will discuss many examples of how systematists revise the relationships of the branches of the animal phylogenetic tree in response to new data.

CHECKPOINT 30.4



- How are animals classified based on type of symmetry?
- What are some differences between protostomes and deuterostomes?
- **VISUALIZE** Draw a cladogram illustrating the evolutionary relationships among the three main clades of bilateral animals. How do they differ from one another?

Key Point

Biologists recognize three major clades of bilateral animals: Lophotrochozoa, Ecdysozoa, and Deuterostomia.

(a) Some key characters are indicated on the branches. Note that segmentation evolved independently in each of the three major clades of bilateral animals.

(b) A simplified cladogram showing six major groups of animals.

Figure 30-6 Evolutionary relationships of animal clades

This cladogram is based on many forms of data, including comparisons of DNA sequences of several genes. Remember that any cladogram of animal relationships is a work in progress. As new data are considered, our understanding of relationships among animal groups changes. Characters labeled on the cladogram indicate when these key traits originated.

Note that the simplified cladogram shown in **(b)** is used as an icon for many figures in Chapters 31 and 32. The animal group being discussed is highlighted in the icon.

CONNECT Using the information indicated by the colored bars above the cladogram in **(a)**, identify which animal groups are assigned to the Ecdysozoa. What shared derived character present in the Ecdysozoa clade is indicated on the cladogram?

Summary: Focus on Learning Objectives

30.1 Animal Characteristics *(page 629)*

1 Describe several characteristics common to most animals.

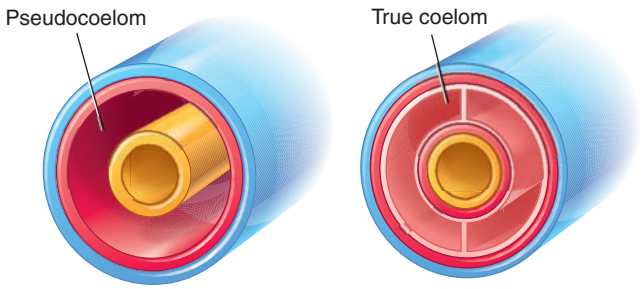
- Animals are eukaryotic, multicellular, heterotrophic organisms with cells specialized to perform specific functions. Animals have diverse body plans. The *body plan* is the basic structure and functional design of the body.
- Most animals are capable of locomotion at some time during their life cycle, can respond adaptively to external stimuli, and can reproduce sexually.
- In sexual reproduction sperm and egg unite to form a **zygote**. The zygote undergoes **cleavage**, a series of cell divisions that produce a hollow ball of cells called a **blastula**. Most animals develop into a **larva**, a sexually immature form that may appear and behave differently from the adult. Larvae typically go through **metamorphosis**, a developmental process that converts the immature animal into a juvenile form that grows into an adult.

30.2 Adaptations to Ocean, Freshwater, and Terrestrial Habitats *(page 630)*

2 Compare the advantages and disadvantages of life in the ocean, in fresh water, and on land.

- Marine environments have relatively stable temperatures, provide buoyancy, and provide readily available food. Fluid and salt balance are more easily maintained in sea water than in fresh water. Currents and other water movements can be a disadvantage.
- Fresh water offers a less constant environment and less food than sea water. Because fresh water is hypotonic to tissue fluid, animals must osmoregulate.
- Terrestrial animals have adaptations that protect them from drying out and from temperature changes, and that protect their gametes and embryos.

30.3 Animal Evolution *(page 631)*



3 Use current hypotheses to trace the early evolution of animals.

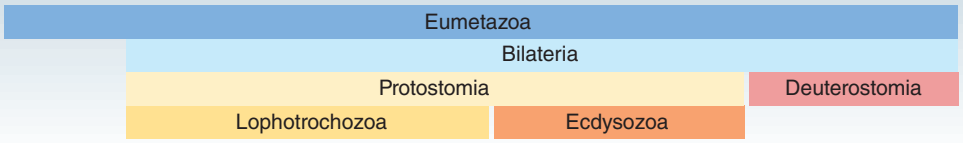
- Based on molecular data, biologists hypothesize that most animal clades actually diverged over a long period during the Proterozoic eon. During the **Cambrian radiation**, new animal body plans rapidly evolved among clades that already existed.
- ***Hox* genes** control early development in animal groups. These genes had evolved by the beginning of the Cambrian period, and mutations in these genes could have resulted in rapid changes in animal body plans.

30.4 Reconstructing Animal Phylogeny *(page 632)*

4 Describe how biologists use morphology (including variations in body symmetry, number of tissue layers, and type of body cavity) and patterns of early development to infer relationships among animal phyla.

- Biologists hypothesize that cnidarians (which have **radial symmetry**) and ctenophores (which have *biradial symmetry*) are more closely related to each other than to animals that exhibit **bilateral symmetry**. **Cephalization**, the development of a head, evolved along with bilateral symmetry.
- Biologists have also inferred relationships based on level of tissue development and type of body cavity. Embryonic tissues, called **germ layers**, include the outer layer, **ectoderm**, which gives rise to the body covering and the nervous system; the inner layer, **endoderm**, which lines the gut and other digestive organs; and a middle layer, **mesoderm**, which gives rise to muscle, skeletal structures, and most other body structures.
- In bilateral animals the type of body cavity has been used to classify animals. **Acoelomate** animals have no body cavity, and **coelomate** animals have a *true* coelom, a body cavity completely lined with mesoderm. Some animals have a **pseudocoelom** (literally, a "false cavity"), a body cavity that is not completely lined with mesoderm.

- Two major evolutionary branches of bilateral animals are **protostomes** (mollusks, annelids, and arthropods) and **deuterostomes** (echinoderms and chordates).
- Protostomes undergo **spiral cleavage**, in which early cell divisions are diagonal to the polar axis. Deuterostomes undergo **radial cleavage**, in which the early cell divisions are either parallel or at right angles to the polar axis, so the cells lie directly above or below one another.
- Protostomes undergo **determinate cleavage**, in which the fate of each embryonic cell is fixed very early. Deuterostomes undergo **indeterminate cleavage**: early in development each cell has the potential to develop into a complete organism.
- In protostomes the **blastopore**, the opening from the embryonic gut to the outside, develops into the mouth; in deuterostomes the blastopore typically becomes the anus.



5 Cite specific examples of how data from molecular systematics have confirmed or modified traditional animal phylogeny and identify the three major clades of bilateral animals.

- Molecular systematics has confirmed much of animal phylogeny that was originally based on structural characters, including the axiom that animal body plans usually evolved from simple to complex. However, molecular systematics has also provided evidence for exceptions.
- Based on molecular data, biologists now subdivide the protostomes into two clades: **Lophotrochozoa** and **Ecdysozoa**. The Lophotrochozoa include the flatworms, ribbon worms, mollusks, annelids, rotifers, and animals that have a lophophore, a ciliated ring of tentacles

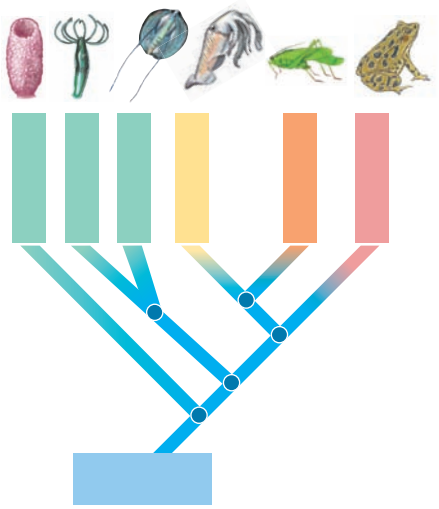
surrounding the mouth. The Ecdysozoa, animals that molt, include the nematodes and arthropods. The third clade of animals, Deuterostomia, includes the echinoderms, hemichordates, and chordates. These animals have radial, indeterminate cleavage and pharyngeal slits.



Test Your Understanding

Know and Comprehend

1. Which of the following is *not* a characteristic of all animals? (a) heterotrophic (b) multicellular (c) eukaryotic (d) presence of a coelom (e) formation of a zygote that undergoes cleavage
2. Which of the following is *not* an adaptation to terrestrial living? (a) internal fertilization (b) shell surrounding egg (c) adaptations for maintaining body temperature (d) surface for gas exchange deep in body (e) ability to maintain location
3. The Cambrian radiation (a) occurred during the late Cambrian period (b) was a rapid evolution of new animal body plans during the middle Cambrian (c) was a result of prokaryotic and eukaryotic migration to many new regions (d) is supported by the great variety of Ediacaran fossils (e) b and c
4. The germ layer that gives rise to the outer covering of the body and the nervous system is the (a) blastula (b) ectoderm (c) gastrula (d) endoderm (e) mesoderm
5. Radial symmetry is characteristic of (a) protostomes (b) chordates (c) mollusks (d) cnidarians (e) sponges
6. A coelom is a body cavity completely lined with (a) epithelium (b) ectoderm (c) mesoderm (d) endoderm (e) epidermis
7. Protostomes are characterized by (a) spiral cleavage (b) indeterminate cleavage (c) an acoelomate body plan (d) radial symmetry (e) a and c
8. The evolution of animals (a) followed an orderly progression from simple to complex (b) will be better understood as biologists continue to collect molecular and other types of data (c) has been determined by studying classification (d) began with the cnidarians (e) began with their common ancestor, a protostome
9. Which of the following is an example of a deuterostome? (a) lophotrochozoan (b) coral (c) chordate (d) planarian flatworm (e) insect

Apply and Analyze

10. **VISUALIZE** Label the branches of the diagram.

11. Imagine that you discover a new organism in a lake. How would you decide whether it is an animal? What are some characteristics that might contribute to your decision?
12. **EVOLUTION LINK** Examine the cladogram in Figure 30-6a. Based on the discussion in this chapter, what were some of the types of data that biologists used to determine these phylogenetic relationships?

Evaluate and Synthesize

13. **EVOLUTION LINK** Suggest and support a hypothesis for the view that segmentation evolved in three different animal clades.
14. **INTERPRET DATA** Imagine that a biologist discovers evidence that a newly discovered animal evolved from a very early protostome. Where would you place the branch (clade) for that animal on Figure 30-6a?

31 Sponges, Cnidarians, Ctenophores, and Protostomes

In Chapter 30 we introduced the animal kingdom and explored animal phylogeny. We examined how systematists use fossils, morphology, developmental patterns, and molecular data to determine animal relationships. In this chapter we begin with an introduction to the sponges, cnidarians, and ctenophores, groups characterized by asymmetry, radial symmetry, and biradial symmetry, respectively. The phylogeny of these animals is the focus of much current research. Although sponges, cnidarians, and ctenophores are mainly small animals with simple body structures, they are of great ecological importance. They have complex relationships with many other organisms. For example, they are important members of marine food webs and some form symbiotic relationships with other animals. Many provide shelter for other organisms. Corals that produce reefs are among the most ecologically important animals in the world.

Following our discussion of the sponges, cnidarians, and ctenophores, we begin our survey of the bilateral animals, the most familiar and by far the most numerous animals on Earth. More than 99% of animal species belong to the Bilateria. These diverse forms have adapted to life in almost every imaginable habitat in the ocean and in freshwater and terrestrial environments. The Sally Lightfoot crab shown in the photograph is an example of the diverse animals found among the Bilateria.

The remarkable success of the bilateral animals can be attributed to the evolution of adaptations that facilitated food capture, escape from predators, and reproduction. Among their key adaptations are cephalization (formation of a head), a central nervous system, muscles, a coelom, and compartmentalization of the body. Large animals developed body systems for gas exchange,

KEY CONCEPTS

31.1 Animals with asymmetry, radial symmetry, or biradial symmetry include sponges, cnidarians (hydras, jellyfish, sea anemones, corals), and ctenophores (comb jellies). Sponges are characterized by collar cells and by loosely associated cells that do not form true tissues; cnidarians are characterized by radial symmetry, two tissue layers, and cells that contain stinging organelles; and ctenophores have biradial symmetry, two tissue layers, eight rows of cilia, and tentacles with adhesive glue cells.

31.2 Protostomes are a large monophyletic group that includes two major clades: Lophotrochozoa and Ecdysozoa. The lophotrochozoans include the annelids (segmented worms), mollusks, and several smaller groups.

31.3 The ecdysozoans include the nematodes (roundworms) and arthropods (centipedes and millipedes; horseshoe crabs and spiders; crustaceans and insects). The remarkable biological success of the arthropods can be attributed to the evolution of complex body plans and life cycles, including their exoskeleton, segmentation, specialized jointed appendages, ability to fly (among insects), and metamorphosis.

waste disposal, and internal transport of nutrients, respiratory gases, wastes, and other materials.

Recall that based on molecular data, pattern of early development, and other data, biologists divide the bilateral animals into two main groups: protostomes and deuterostomes. The protostomes form two clades: Lophotrochozoa and Ecdysozoa. In this chapter we focus on the innovations in body plans, phylogenetic relationships, and life histories of several phyla of these two clades.

31.1 Sponges, Cnidarians, and Ctenophores

LEARNING OBJECTIVES

1. Identify important characteristics of poriferans.
2. Identify distinguishing characteristics of cnidarians, describe their two main clades, and list animals that belong to each clade.
3. Identify characteristics of ctenophores.

Recall from Chapter 30 that based on available evidence, animals and choanoflagellates (a group of unicellular and colonial protists) share a common choanoflagellate ancestor. Many biologists assign sponges to a basal group, **Parazoa** (*para*, "alongside"; and *zoa*, "animals"). This classification is based on the asymmetry and simple body plan of sponges. The cells of sponges are loosely associated and do not form true tissues. Other animals have true tissues and are classified as **Eumetazoa** (*eu*, "true"; *meta*, "later"; and *zoa*, "animals"). Thus, these biologists divide the animal kingdom into two major animal groups: Parazoa and Eumetazoa. Despite some controversy, most systematists consider sponges to be the oldest group of animals.

Based on molecular data, biologists hypothesize that sponges are a polyphyletic group. There is some evidence that at least one group of sponges (calcareous sponges) became simplified as they evolved from animals with more complex body plans.

Sponges have collar cells and other specialized cells

Sponges, or **poriferans**, are aquatic, mainly marine animals that are most abundant in warm waters. Their name, *Porifera* (paw-rif′-er-ah), means "to have pores." This name aptly describes these animals, whose bodies are perforated by tiny holes. Biologists have identified more than 8800 species of sponges. They range in size from a few millimeters to more than a meter in height and diameter (loggerhead sponges). Many sponges are asymmetrical, but they vary in shape from flat, encrusting growths to balls, cups, fans, or vases. Living sponges may be brightly colored—green, orange, red, yellow, blue, or purple—or they may be white or drab (FIG. 31-1). Some species are inhabited by symbiotic bacteria or algae that give them color.

Although they are multicellular and can be large, sponges function much like choanoflagellates. These protists are characterized by a single flagellum surrounded by a collar of microvilli (see Fig. 26-21). Sponges have flagellate cells called **collar cells**, or **choanocytes** (ko-an′-uh-sites), which are strikingly similar to choanoflagellates.

Sponge larvae have flagella and can swim about. Adult sponges attach to some solid object and have long been described as sessile. However, biologists have observed adults of several species moving slowly (about 4 mm per day), perhaps by the cumulative movement of cells along the sponge's lower surface.

Although sponges are multicellular, their cells are loosely associated and do not form true tissues. However, a division of labor exists among the several types of cells that make up the sponge, with certain cells specializing in nutrition, support, contraction, or reproduction. Many sponge cells are extremely versatile and can change form and function.

Collar cells make up the inner layer of certain sponges. Each cell is equipped with a tiny collar surrounding the base of the flagellum. The collar is an extension of the plasma membrane and consists of microvilli. Collar cells create the water current that brings food and oxygen to the cells and carries away carbon dioxide and other wastes. Collar cells also trap and phagocytize food particles. Together, the collar cells of some sponges can pump a volume of water equal to the volume of the sponge each minute!

Sponges have three types of canal systems through which water circulates. In the simple *asconoid* canal system, the beating flagella of collar cells create a current that pulls water through hundreds of tiny pores, called *ostia*. Specialized tubelike cells, called *porocytes*, form the pores. These cells regulate the diameter of the pores by contracting. Water passes into the central cavity, or **spongocoel** (spon′-jo-seel) (not a digestive cavity), and then flows out through the sponge's open end, the **osculum** (os′ kyuh-lum). The asconoid system is illustrated in Figure 31-1.

In the *syconoid* system, water enters through canals lined by collar cells. Most types of sponges have a *leuconoid* system. The body wall is extensively folded, and complex systems of canals provide increased surface area for food capture. *Epidermal cells* form the outer layer of the sponge and line the canals. The canals lead into small chambers that are lined with collar cells.

The skeletal framework of a sponge can be both rigid and fibrous. Between the outer and inner cell layers, the sponge body has a gelatin-like layer, the *mesohyl*, which is supported by slender skeletal spikes, or **spicules** (spik′-yuls). *Amoeboid cells*, which wander about in the mesohyl, secrete the spicules. The spicules are made of calcium carbonate or of silica. The fibrous part of the sponge skeleton consists of *spongin*, a form of collagen.

Most sponges are *suspension feeders*, adapted for trapping and eating whatever food is suspended in the water. As water circulates through the body, bacteria, algae, and other organic particles are trapped along the sticky collars of the collar cells. Thus, the collars *filter* the suspended food particles out of the water. Suspension feeders that filter the suspended food are known as *filter feeders*. Food particles are either digested within the collar cell or transferred to an amoeboid cell for digestion. The amoeboid cell transports nutrients to epidermal cells. Undigested food passes out through the osculum and is simply eliminated into the water. Researchers have discovered several species of carnivorous sponges that trap prey on very small hooks on their bodies. These sponges lack collar cells.

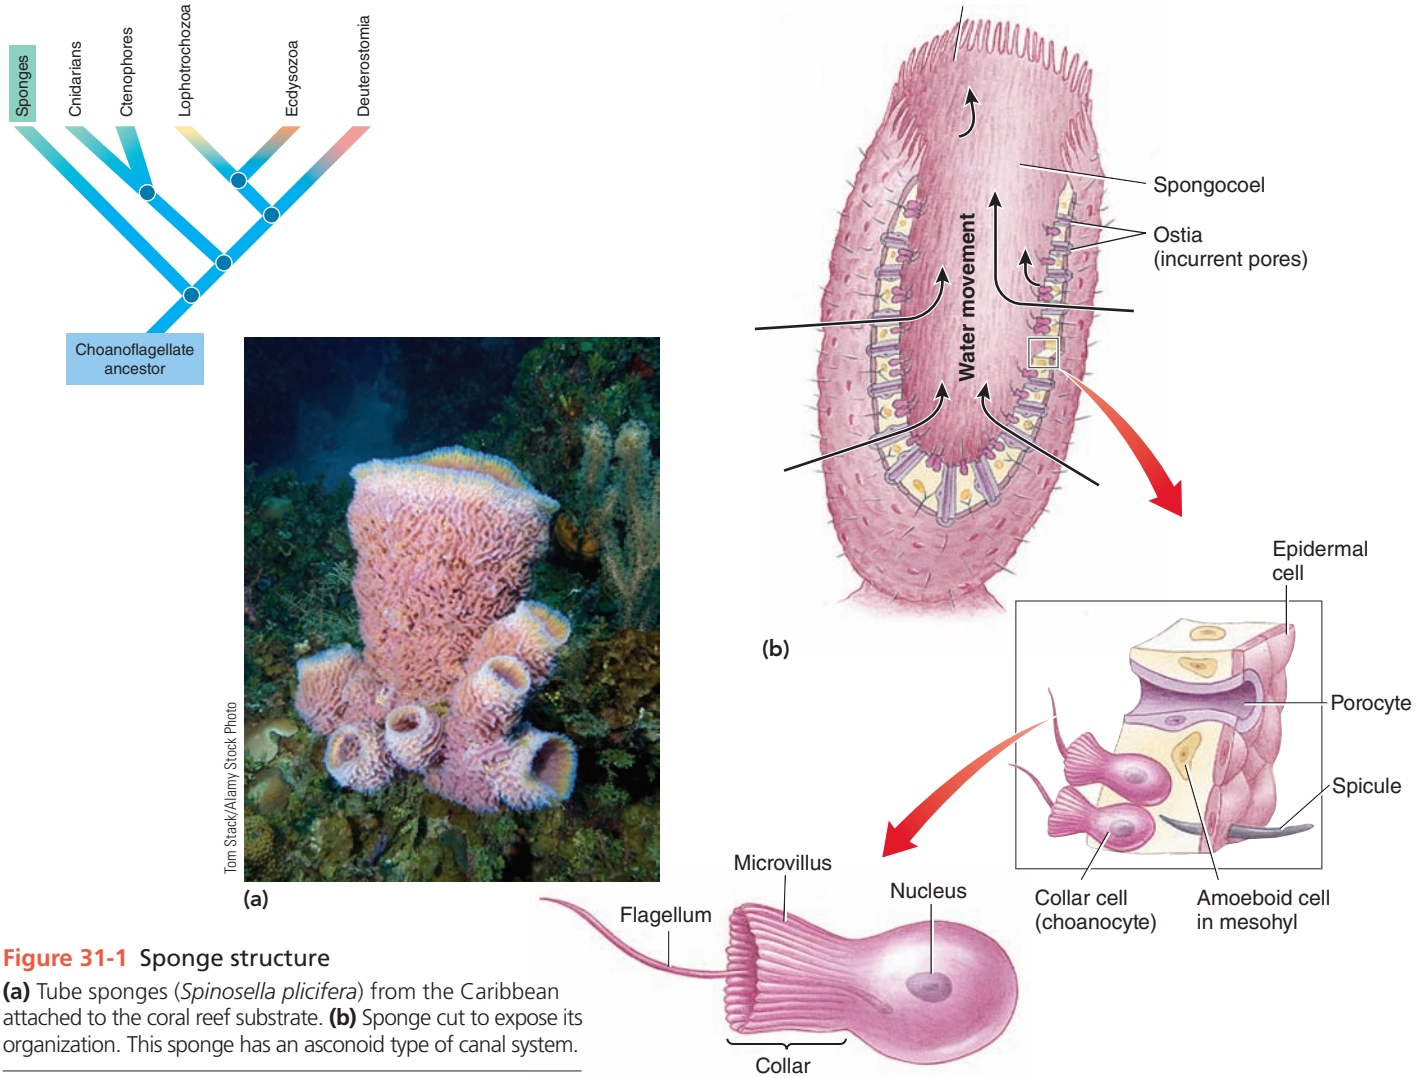

Figure 31-1 Sponge structure

(a) Tube sponges (*Spinosella plicifera*) from the Caribbean attached to the coral reef substrate. **(b)** Sponge cut to expose its organization. This sponge has an asconoid type of canal system.

Gas exchange and excretion of wastes depend on diffusion into and out of individual cells. Although cells of the sponge can react to stimuli, sponges do not have specialized nerve cells and so cannot react as a whole. However, electrical signals have been identified in certain glass sponges. Behavior appears limited to basic metabolic necessities such as capturing food and regulating the flow of water through the body.

Sponges reproduce both asexually and sexually. In asexual reproduction, a small fragment or bud may break free from the parent sponge and give rise to a new sponge. Such fragments may attach to the parent sponge, forming, or becoming part of, a colony. Most sponges are **hermaphrodites**, meaning that the same individual can produce both eggs and sperm. Some of the amoeboid cells develop into sperm cells and others into egg cells. However, hermaphroditic sponges usually produce eggs and sperm at different times, and they cross-fertilize with other sponges. They release mature sperm into the water, which are taken in by other sponges of the same species.

Fertilization and early development take place within the jellylike mesohyl. Zygotes develop into flagellate larvae that leave the parent along with the stream of outflowing water. After swimming for a while, a larva finds a solid object, attaches to it, and settles down to a sessile life.

Sponges have a remarkable ability to repair themselves when injured and to regenerate lost parts. When the cells of a sponge are separated experimentally, they recognize one another and their place in the whole and aggregate to re-form a complete sponge. Researchers have discovered that some sponges produce antibacterial and other compounds that may be effective against MRSA (see Chapter 25) and cancer cells.

There are three main groups of sponges: the *calcareous sponges* have spicules composed of calcium carbonate, whereas the *glass sponges* and the *demosponges* have spicules of silicon. About 95% of living sponges are demosponges. In some of the demosponges, spicules are bound together by spongin. Some demosponges do not have spicules. These soft sponges have been used for thousands of years as bath sponges and for cleaning. Unfortunately, as a result of overharvesting, bath sponges are now in short supply.

Sponges play significant roles in marine habitats. Larger species are important structural components in both shallow and deep water, providing homes to many species of annelids, crustaceans, and echinoderms. Sponges also serve as food for some invertebrates, fish, and sea turtles.

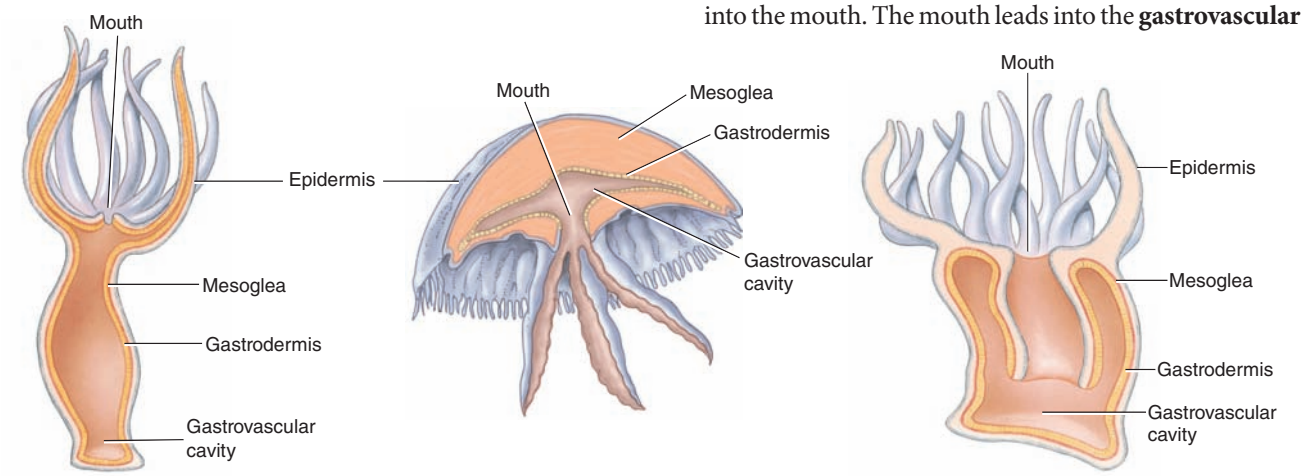
Cnidarians have unique stinging cells



More than 10,000 species of **cnidarians** (ni-dah′-ree-ans) have been described. Most are marine. The radially symmetrical cnidarian body is organized as a hollow sac with the mouth and surrounding tentacles located at one end. Some cnidarians live a solitary existence, whereas many others, such as corals, form colonies.

Cnidarians have two body shapes: polyp and medusa (FIG. 31-2). The **polyp** form, represented by *Hydra*, typically has a dorsal mouth surrounded by tentacles. In the **medusa** (pl., *medusae*), or jellyfish form, the mouth is located in the lower concave, or oral, surface; the convex upper surface is the *aboral* surface. Some cnidarians have the polyp shape during one stage of their life cycle and the medusa form during another stage. The Portuguese man-of-war and some other cnidarians consist of colonies of many individuals, some of which are polyps and others medusae.

Cnidarians get their name from specialized cells, called **cnidocytes** (from a Greek word meaning "nettle cells"), that contain stinging organelles. Cnidocytes are located mainly in the epidermis, especially on the tentacles. The cnidocytes contain stinging "thread capsules," called **nematocysts** (FIG. 31-3). Each cnidocyte has a small, projecting trigger (*cnidocil*) on its outer surface and a coiled, hollow thread inside. We can compare the cnidocyte to a loaded gun, ready to fire. When stimulated by touch or certain chemicals dissolved in the water, the nematocyst fires its thread. Some types of nematocyst threads are sticky. Others are long and coil around prey. A third type bears barbs or spines that can inject a protein toxin. This toxin paralyzes prey animals, such as small crustaceans.

Cnidarians use their tentacles to capture prey and push it into the mouth. The mouth leads into the **gastrovascular cavity**,

Dr. John D. Cunningham/Visuals Unlimited, Inc.

(a) Portuguese man-of-war (*Physalia physalis*) with fish prey trapped in its mass of tentacles. Many discharged nematocysts are visible as small *white dots* throughout the tentacles.

(b) Undischarged and discharged nematocyst. The cnidocil, or trigger, is a mechanoreceptor that discharges the nematocyst when it senses contact with an object.

Figure 31-3 Nematocysts

When cnidarian stinging cells (cnidocytes) are stimulated, the nematocyst discharges, ejecting a thread that may entangle or penetrate the prey. Some nematocysts secrete a toxic substance that immobilizes the prey.

where digestion takes place. The mouth is the only opening into the gastrovascular cavity and so must serve for both ingestion of food and expulsion of undigested material. Gas exchange and excretion occur by diffusion. The body wall is thin enough that no cell is far from the surface.

More highly organized than sponges, cnidarians are diploblastic; that is, they have two definite tissue layers. The ectoderm gives rise to the outer epidermis, a protective layer covering the body. The endoderm gives rise to the inner *gastrodermis*, which lines the gastrovascular cavity and functions in digestion. These thin layers are separated by a thick, jellylike **mesoglea**, which is mainly acellular.

The nerve cells of a cnidarian form a **nerve net** that connects sensory cells in the body wall to contractile cells and gland cells. An impulse set up by one sensory cell passes in all directions more or less equally. Nerve cells are not organized to form a brain or nerve cord. In some types of medusae, sense organs are positioned around the edge of the body. The sense organs include simple "eyes," called eyespots; organs of balance (statocysts); and chemoreceptors (cells that sense certain chemicals).

Both the epidermis and gastrodermis have cells specialized to contract. (However, they are not true muscle cells). Contractile fibers in the epidermal cells are arranged lengthwise, and those in the gastrodermis are arranged in a circular pattern. These two sets of contractile cells act on the water-filled gastrovascular cavity, forming a **hydrostatic skeleton**. This skeleton supports the body and allows movement. By contracting one set of contractile cells or the other, the hydra can shorten, lengthen, or bend its body (see Fig. 40-2).

Based on fossil and molecular evidence, systematists divide the cnidarians into two major clades that split during their early evolution. Clade Medusozoa consists of the hydrozoans, scyphozoans, and cubozoans. Clade Anthozoa includes the sea anemones, corals, and sea fans (TABLE 31-1).

Most medusozoans develop a medusa form during their lifetime *Hydrozoans* include hydras and *hydroids*, such as *Obelia* and the Portuguese man-of-war. Although not really typical, the solitary *Hydra* is the cnidarian that beginning biology students most often study (FIG. 31-4). To the naked eye, *Hydra* looks like a bit of frayed string. This tiny hydrozoan is found in freshwater ponds. Because it has a remarkable ability to regenerate, biologists named *Hydra* after the multiheaded monster of Greek mythology that could grow two new heads for each head cut off. When *Hydra* is cut into several pieces, each piece can regenerate all the missing parts and become a whole animal.

Hydra lives in fresh water and typically attaches to a rock, aquatic plant, or detritus by a disc of cells at its base. Hydras reproduce asexually by budding during periods when

Table 31-1 Major Clades of Cnidaria

Clade and Representative Animals	Characteristics
MEDUSOZOANS	
Hydrozoans *Hydra*, *Obelia*, Portuguese man-of-war	Mainly marine, but some freshwater species; alternation of polyp and medusa stages in most species (*Hydra* has only polyp form); some form colonies
Scyphozoans Jellyfish, cubozoans ("box jellyfish")	Mainly marine; typically inhabit coastal waters; free-swimming medusa most prominent form; polyp stage often reduced
ANTHOZOANS Sea anemones, corals, sea fans	Marine; solitary or colonial polyps; no medusa stage in most; gastrovascular cavity divided by partitions into chambers, increasing area for digestion

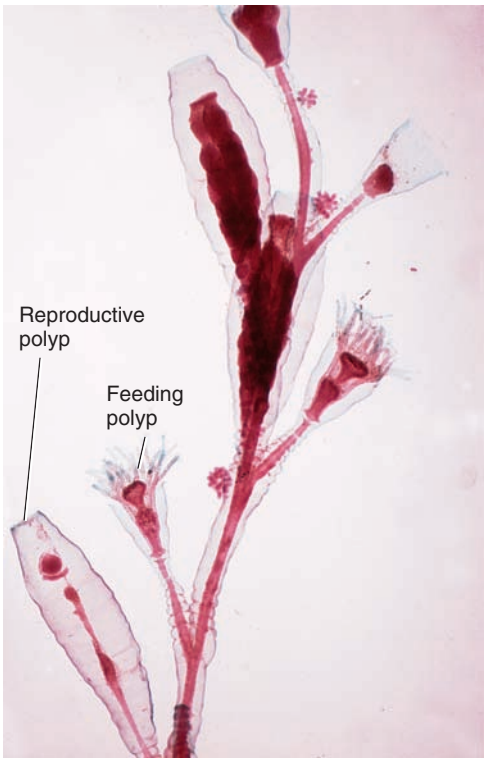
environmental conditions are optimal. However, they differentiate as males and females and reproduce sexually in the fall or when pond water becomes stagnant. The zygote may become covered with a shell that protects it through the winter or until conditions become more favorable.

Many hydrozoans form colonies consisting of hundreds or thousands of individuals. A colony begins with a single polyp that reproduces asexually by budding. However, instead of separating from the parent, the bud remains attached and eventually forms additional buds. Several types of individuals may develop in the same colony, some specialized for feeding, some for reproduction, and others for defense.

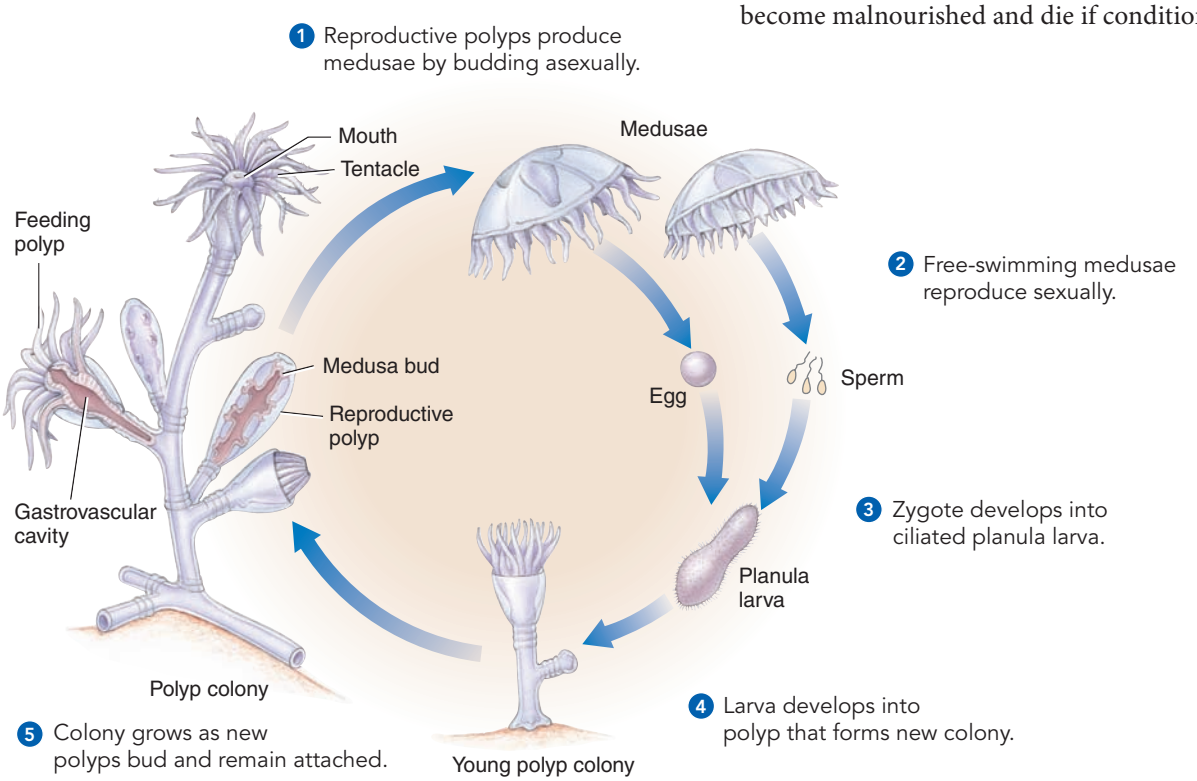
Some marine hydrozoans are remarkable for their alternation of sessile polyp and motile medusa stages. The life cycle of the colonial marine hydrozoan *Obelia* illustrates alternation of polyp and medusa stages (FIG. 31-5). In *Obelia*, polyps reproduce asexually by budding, whereas the medusae reproduce sexually, using meiosis to produce gametes. Both polyp and medusa are diploid; only sperm and eggs are haploid.

In both *scyphozoans* and *cubozoans*, the medusa is the dominant body form. Jellyfish medusae are generally larger than hydrozoan medusae. They have a thick, viscous mesoglea that gives firmness to the body. In scyphozoans the polyp stage is small and inconspicuous or may even be absent. The largest jellyfish, *Cyanea*, may be more than 2 m (6.5 ft) in diameter and have tentacles 30 m (98 ft) long. These orange and blue "monsters," among the largest invertebrates, can cause painful stings to swimmers in the North Atlantic and Pacific Oceans.



When viewed from above, cubozoans have a square shape. Known as "box jellyfish," they have four tentacles, or groups of tentacles. These fast-swimming jellyfish have complex eyes that form blurred images, and they actively hunt for prey. Some cubozoan species, referred to as *sea wasps*, produce extremely toxic venom. Found in waters off the northern Australian coast, the sea wasp *Chironex fleckeri* has long tentacles that can extend more than 3 m (10 ft). This sea wasp produces one of the deadliest venoms in the animal kingdom. Its venom contains toxins that can stun or kill fish and other prey. These toxins can also cause respiratory failure and cardiac arrest in humans. Fatalities are mainly associated with severe stings caused by contact with tentacles over a large area of the body. Interestingly, sea turtles feed on box jellyfish, apparently unaffected by their venom.

Anthozoans are polyps *Anthozoans*, which include the sea anemones and corals, are either individual or colonial polyps. There is no free-swimming medusa stage. The polyp produces eggs and sperm, and the fertilized egg develops into a small, ciliated **planula larva**. This larval form may swim to a new location before attaching to develop into a polyp.



Anthozoans differ from hydrozoans in that a series of vertical partitions partially divides the gastrovascular cavity into connected chambers. The partitions increase the surface area for digestion, enabling an anemone to digest an animal as large as a crab. Although corals can capture prey,

many tropical species depend for nutrition on photosynthetic dinoflagellates (*zooxanthellae*). These golden brown dinoflagellates live within cells lining the coral's digestive cavity (see Chapter 26 and Fig. 54-12). The relationship between coral and zooxanthellae is symbiotic and mutually beneficial. The coral supplies the dinoflagellates with a place to live and with waste products such as ammonia. The dinoflagellates use the ammonia to make nitrogen compounds for both partners and provide the coral with carbon compounds and oxygen.

In warm, shallow seas, much of the bottom is covered with coral or anemones, many of them brightly colored. Coral reefs consist of colonies of millions of corals and of algae (mainly coralline red algae). Living colonies occur only in the uppermost regions of such reefs, adding their own skeletons to the forming rock. Coral reefs are among the most productive of all ecosystems, rivaling tropical rain forests in species diversity (see Fig. 56-21). A single reef can serve as home for more than 3000 species of fishes and other marine organisms, and an estimated one-fourth of all marine species depend on coral reefs.

Many species of reef-building corals are endangered and are at increased risk for extinction. Human activities are responsible for much of the damage. Global climate change, which results from production of carbon dioxide and other greenhouse gases, causes ocean temperatures to rise (see Chapter 57). When stressed by the hot water, coral cells expel the symbiotic dinoflagellates that inhabit their cells. The coral then appears white, or "bleached." This process is known as **coral bleaching** (FIG. 31-6). Without their dinoflagellates, coral become malnourished and die if conditions do not improve.

Figure 31-6 Bleached staghorn coral

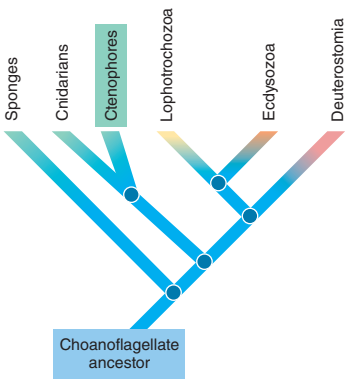
Global climate change (caused by human activities) is a major cause of coral bleaching. This staghorn coral (*Acropora*) was photographed off Heron Island on the Great Barrier Reef off the coast of Australia.

Other factors leading to the decline of coral reefs include acidification of the ocean caused by increase in carbon dioxide in the atmosphere, pollution, disease, smothering coral with the silt washed downstream from clear-cut forests, and overharvesting. At the time of this writing, damaging, widespread coral bleaching was continuing for the third year in a row. In 2016, 90% of the coral of Australia's Great Barrier Reef was affected by bleaching, killing more than 20% of the reef's coral.

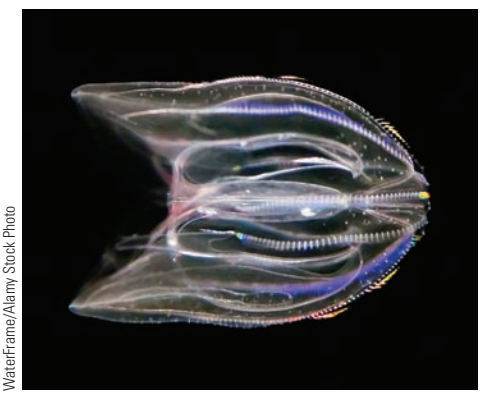
Comb jellies have adhesive glue cells that trap prey

The fragile, luminescent *comb jellies* are marine animals known as **ctenophores** (ten′-oh-forz). Approximately 150 species of ctenophores have been described. Some are as small as a pea; others are larger than a tomato. Ctenophores are an important part of the plankton.

The outer surface of a ctenophore bears eight rows of cilia that resemble combs (FIG. 31-7). Ctenophores are biradially symmetrical, meaning you could obtain equal halves by cutting through the body axis in two different ways. The ctenophore body plan is somewhat similar to that of a cnidarian medusa in that ctenophores have a type of radial symmetry, feeding tentacles, and two cell layers separated by a thick, jellylike mesoglea.



Some ctenophores have two tentacles. Their tentacles are equipped with adhesive glue cells. When prey comes in contact with the tentacle, the glue cells burst open, releasing sticky threads that trap the prey. Ctenophores do not have the stinging nematocysts characteristic of the cnidarians. Also unlike cnidarians, the ctenophore digestive system has a mouth for food intake at one end and two anal pores for the egestion of water and particles that are indigestible at the other end.



Ctenophores have a nervous system that includes a network of nerve cells and a sensory organ called a "statocyst" that coordinates beating of the cilia in the combs. The coordinated beating of the cilia moves the animal through the water. The statocyst also functions in balance and helps the animal orient itself.

Because of their similarities, biologists classify ctenophores near the cnidarians. However, their development is different, and their digestive cavity has openings at both ends. The similarities between ctenophores and cnidarians may be a result of convergent evolution from living in a similar environment, the ocean. Where, then, do the ctenophores belong on our cladogram? As systematists gather new data, the position of the ctenophores on the animal tree will become clearer.

31.2 The Lophotrochozoa

LEARNING OBJECTIVES

4 Summarize what is known about the phylogeny of the lophotrochozoans and cite the adaptive advantages of having a coelom and of cephalization.
5 Identify distinguishing characteristics of flatworms and nemerteans, and describe the main groups of flatworms, giving examples of animals that belong to each.
6 Describe the main characteristics of mollusks and of the four clades of mollusks discussed, giving examples of each group.
7 Describe the principal characteristics of annelids and of the two clades of annelids discussed, giving examples of each group.
8 Describe the distinguishing characteristics of the lophophorates and of the rotifers.

We begin our discussion of the bilateral animals with the **Lophotrochozoa**, one of the two major clades of protostomes. The Lophotrochozoa includes the flatworms (platyhelminths), rotifers (wheel animals), nemerteans (ribbon worms), mollusks, annelids (segmented worms), and the lophophorate phyla (see Fig. 30-6). Recall from Chapter 30 that the name *Lophotrochozoa* comes from two important characters of some animals in this clade: (1) the *lophophore*, a ciliated ring of tentacles surrounding the mouth in three small groups of animals; and (2) the *trochophore larva*, a type of larva that characterizes two major groups: the mollusks and annelids.

Most lophotrochozoans have **bilateral symmetry**, at least in their larval stages. They are **triploblastic**; that is, they have three definite tissue layers. In addition to the outer epidermis derived from ectoderm and an inner endodermis derived from endoderm, lophotrochozoans have a middle tissue layer that develops from mesoderm.

Most lophotrochozoans have a true **coelom** and a *tube-within-a-tube body plan* (see Chapter 30). Most coelomate animals have well-developed circulatory, excretory, and nervous systems. Many internal organs are suspended within folds of the tissue lining the coelom and can move independently of the outer body wall. In addition, the coelom provides space for the gonads to develop. During the breeding season of many animals, such as birds, the gonads enlarge within the coelom as they fill with ripe gametes.

In some animals, fluid within the coelom helps transport materials such as food, oxygen, and wastes. Cells bathed by the coelomic fluid can exchange materials with it. The cells receive nutrients and oxygen from the coelomic fluid and excrete wastes into it. Some coelomates have excretory structures that remove wastes directly from the coelomic fluid.

Animals that move about typically have an elongated body with definite anterior and posterior ends. They exhibit **cephalization**, the evolution of a head with a concentration of sense organs at the anterior end. A simple brain and paired sense organs are concentrated in the "head" region. An animal with a front end generally moves forward. With a concentration of sense organs in the part of the body that first meets its environment, the animal can actively search for food, shelter, and mates or can detect enemies quickly.

Flatworms are bilateral acoelomates

Platyhelminths (plat-ee-hel′-minths), or *flatworms*, are soft-bodied animals that left few fossils to provide clues to their evolutionary history. Their flat, elongated bodies are solid; that is, they are **acoelomate** (have no body cavity). Historically, biologists considered flatworms to be the simplest bilaterally symmetrical, triploblastic animals. However, it is unclear whether the Platyhelminthes evolved from ancestors that possessed a body cavity.

Most of the 20,000 or so species of flatworms belong to a clade called Rhabditophora. We can assign the rhabditophorans to four groups: Turbellarians are free-living flatworms that include planarians and their relatives. They are considered a paraphyletic group. Trematodes and monogeneans include the flukes, which are either internal or external parasites. Cestodes are tapeworms, which as adults are intestinal parasites of vertebrates (TABLE 31-2). These parasitic groups are considered a monophyletic group of rhabditophorans.

Flatworms typically have a simple **nervous system**. The brain consists of two masses of nervous tissue, called **ganglia**, in the head region. In many species the ganglia connect to two nerve cords that extend the length of the body. This nervous system is sometimes referred to as a "ladder-type nervous system" because a series of nerves connects the cords like the rungs of a ladder (see Fig. 42-2). Sense organs include simple "eyes," called eyespots, organs of balance (statocysts), and numerous chemoreceptors over their bodies for locating food and mates.

Table 31-2 Major Groups of Platyhelminths (Largest Clade: Rhabditophorans)

Group and Representative Animals	Characteristics
FREE-LIVING	
Turbellarians Planarians	Mainly free-living; marine, freshwater, and terrestrial; body covered by ciliated epidermis; typically predatory on other invertebrates
PARASITIC	
Trematodes, monogeneans Flukes	Parasites with a wide range of vertebrate and invertebrate hosts; may require intermediate hosts; adults have suckers for attachment to host
Cestodes Tapeworms	Parasites of vertebrates; complex life cycle; usually with one or two intermediate hosts; larval host may be invertebrate; typically have suckers and sometimes hooks for attachment to host; eggs produced within proglottids, which are shed; no digestive or nervous systems

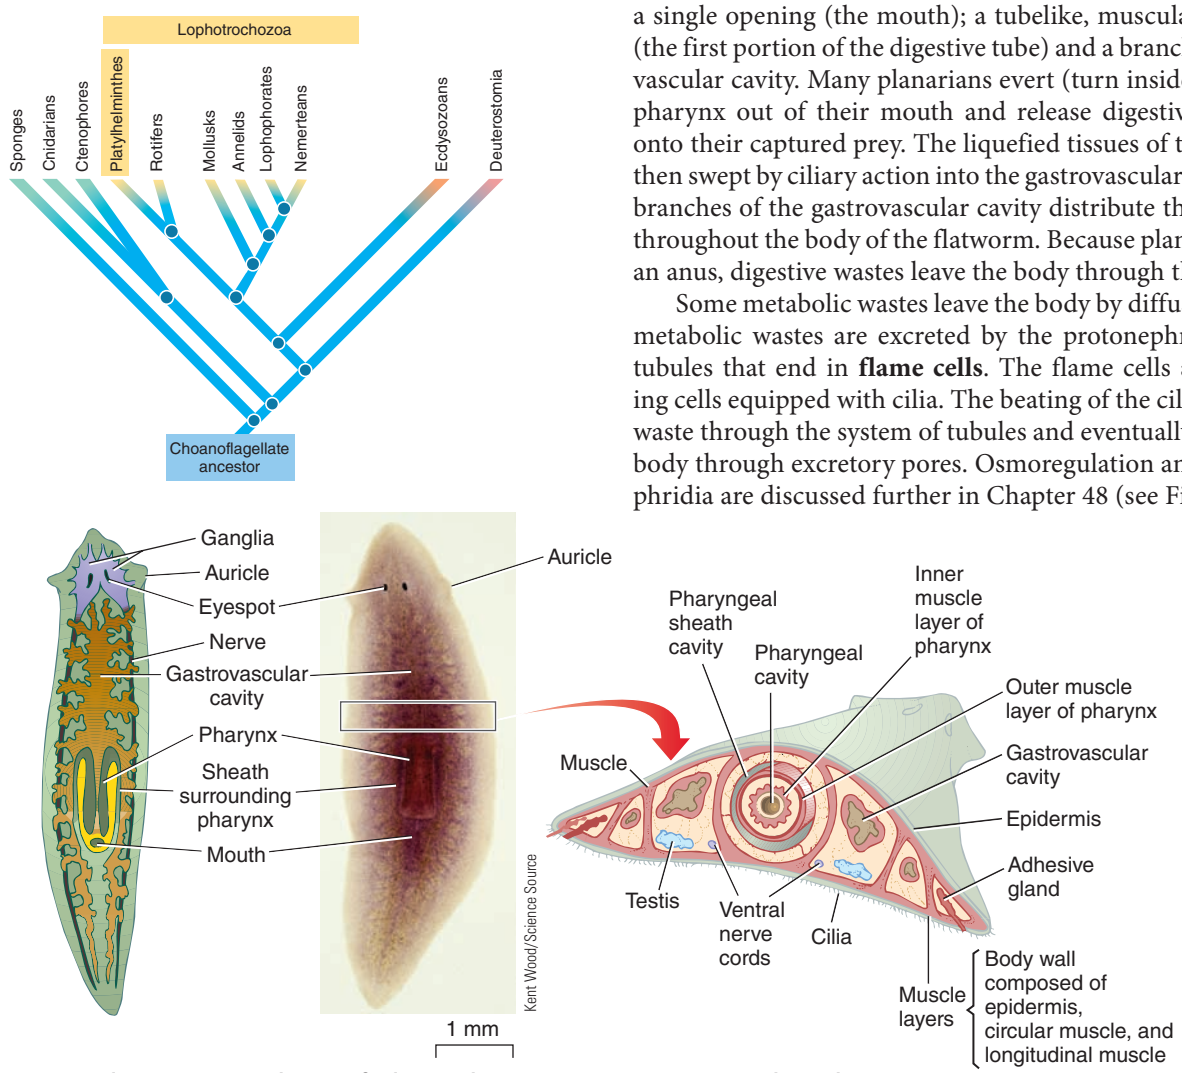
Flatworms have no organs for circulation or gas exchange. Gas exchange depends largely on diffusion through the body wall. The activities of some organs are coordinated and form simple organ systems, such as the digestive and nervous systems. As in the cnidarians, the digestive system is a gastrovascular cavity with only one opening, a mouth. The gastrovascular cavity is often extensively branched.



Parasitic flatworms—flukes and tapeworms—are highly adapted to and modified for their parasitic lifestyle. They have suckers or hooks for holding on to their hosts. The bodies of those that live in digestive tracts resist the digestive enzymes secreted by their hosts. Many have complicated life cycles and produce large numbers of eggs. Other adaptations include the loss of certain structures such as sense organs. Tapeworms have also lost the digestive system.

Turbellarians are free-living flatworms Most turbellarians are free-living flatworms. They inhabit marine, freshwater, and terrestrial habitats. Turbellarian flatworms typically have a muscular pharynx that takes in food and is connected with a branching gastrovascular cavity. They have a simple brain, multiple eyespots, and other sensory organs in the head; **protonephridia**, structures that function in osmoregulation (fluid balance) and metabolic waste disposal (excretion); and reproductive organs.

Planarians are turbellarian flatworms found in ponds, quiet streams, and moist terrestrial habitats throughout the world. One common genus of American planarians, *Dugesia*, contains aquatic worms that reach about 15 mm (0.6 in.) in length. They have what appear to be crossed "eyes" and flapping lateral projections called *auricles* (FIG. 31-8). The auricles actually serve as organs of chemoreception, which is important in locating food.

Most planarians are predators, capable of capturing and killing very small animals. Their digestive system consists of a single opening (the mouth); a tubelike, muscular **pharynx** (the first portion of the digestive tube) and a branched gastrovascular cavity. Many planarians evert (turn inside out) their pharynx out of their mouth and release digestive enzymes onto their captured prey. The liquefied tissues of the prey are then swept by ciliary action into the gastrovascular cavity. The branches of the gastrovascular cavity distribute the nutrients throughout the body of the flatworm. Because planarians lack an anus, digestive wastes leave the body through the mouth.

Some metabolic wastes leave the body by diffusion. Other metabolic wastes are excreted by the protonephridia, blind tubules that end in **flame cells**. The flame cells are collecting cells equipped with cilia. The beating of the cilia channels waste through the system of tubules and eventually out of the body through excretory pores. Osmoregulation and protonephridia are discussed further in Chapter 48 (see Fig. 48-2).

(a) Internal structure.

Planarians reproduce either asexually or sexually. In asexual reproduction an individual constricts its body and divides into two planarians. Each regenerates its missing parts. Sexually, these animals are hermaphrodites. During the warm months of the year, each is equipped with a complete set of male organs and female organs. Two planarians come together in copulation and exchange sperm cells so that their eggs are cross-fertilized.

Flukes parasitize other animals Although their body plan generally resembles that of the free-living flatworms, the *flukes*, trematodes and monogeneans, have structures, such as hooks and suckers, for attachment to their host. Flukes also have extremely prolific reproductive organs.

Flukes that are parasitic in humans include blood flukes, which are widespread in tropical areas of the world, and liver flukes, which are common in Asia, particularly in areas where humans use their own feces for fertilizing crops. Blood flukes of the genus *Schistosoma* cause the human disease schistosomiasis, the second most debilitating parasitic disease in the world. (Malaria is the first.) An estimated 250 million people are infected, most of them children. The worms live in blood vessels for many years and can damage the liver and kidneys.

Both blood flukes and liver flukes go through complicated life cycles involving several different forms. There is an alternation of sexual and asexual stages as well as parasitism on one or more intermediate hosts, such as snails and fishes (FIG. 31-9). The aquatic snails that serve as intermediate hosts thrive in ponds, rice paddies, and the marshy areas that develop when dams are built.

Tapeworms inhabit the intestine of vertebrates Adult members of the more than 5000 species of cestodes live as parasites in the intestine of probably every kind of vertebrate, including humans. Tapeworms are long, flat, ribbonlike animals strikingly specialized for their parasitic mode of life. The body consists of a *scolex* for attachment to a host and a long chain of segments called *proglottids*. The scolex is equipped

SPL/Science Library/Science Source

Figure 31-10 Scolex of a tapeworm

The small tapeworm (*Acanthrocirrus retrisrostris*) reaches maturity in the intestine of wading birds that eat barnacles. The color-enhanced SEM shows the pistonlike cluster of hooks that can be withdrawn into the head or thrust out and buried in the host's tissue. You can see two of the four powerful suckers beneath the hooks.

with suckers, and sometimes hooks, that enable the parasite to attach to the host's intestine (FIG. 31-10).

The reproductive adaptations and abilities of tapeworms are extraordinary. Each proglottid is an entire reproductive machine equipped with both male and female reproductive organs. A single proglottid contains up to 100,000 eggs. Because an adult tapeworm may have as many as 2000 segments, its reproductive potential is staggering. A single tapeworm can produce 600 million eggs per year! Proglottids farthest from the scolex contain the ripest eggs; these segments are shed from the host's body along with the feces.

A tapeworm has no mouth or digestive system. Digested food from the host is absorbed across the worm's body wall. Tapeworms also lack well-developed sense organs. Some tapeworms have complex life cycles, spending their larval stage within the body of an intermediate host and their adult life within the body of a different, final host. FIGURE 31-11 illustrates the life cycle of the beef tapeworm, which can infect humans when they eat undercooked beef containing the larvae.

Nemerteans are characterized by their proboscis

The **nemerteans** (neh-mur′-tee-uns) include the ribbon worms, a relatively small group of about 1200 species of free-living animals (FIG. 31-12). Most burrow in marine sediments, but a few species inhabit deep sea water, fresh water, or damp soil. Many nemerteans are predators, feeding on crustaceans and annelids. Nemerteans have long, narrow bodies, either cylindrical or flattened, ranging in length from 1 mm to more than 30 m (100 ft). Some are a vivid orange, red, or green, with black or colored stripes.

Their most remarkable organ, the *proboscis*, is a long, hollow, muscular tube that can be rapidly everted from the anterior end of the body. Used to capture prey, the sticky proboscis can be wrapped around a small animal. In some species the proboscis is sharp, and in various species it secretes toxic fluid that immobilizes prey. The proboscis is a *derived character* that distinguishes nemerteans from all other invertebrate groups. Because of this character, these animals are sometimes called *proboscis worms*.

Nemerteans have no heart; blood is circulated by contractions of muscular blood vessels and by movements of the body. The chamber surrounding the proboscis is a

coelomic space known as a *rhynchocoel*. It develops in the embryo as the coelom does in coelomate protostomes (see Chapter 30). However, it differs in position and function from the coelom of other animals. Biologists view the rhynchocoel as a remnant of the coelom of a coelomate ancestor. Because of its presence and recent molecular evidence, biologists classify nemerteans with the lophotrochozoans. Nemerteans evolved from a coelomate animal and became simpler over time.

Mollusks have a muscular foot, visceral mass, and mantle

The **mollusks** include clams, oysters, snails, slugs, octopuses, and the largest of all the invertebrates, the giant squid, which averages 9 to 16 m (about 30 to 53 ft) in length, including its tentacles. More than 100,000 living species and 35,000 fossil species (second only to the arthropods in number) have been described. Here we discuss chitons, gastropods, bivalves, and cephalopods—four of the eight recognized clades. We illustrate representatives of these clades in FIGURE 31-13 and describe them in TABLE 31-3.

Although most mollusks are marine, many snails and clams live in fresh water, and some species of snails and slugs inhabit the land. Mollusks probably evolved early in the history of the protostome clade, soon after the evolution of the coelom but before the origin of the segmented body that is characteristic of annelids. Although mollusks vary widely in outward appearance, most share six basic characteristics:

1. A soft body, usually covered by a dorsal shell composed mainly of calcium carbonate.
2. A broad, flat, muscular foot, located ventrally, which is used for locomotion.
3. The body organs (*viscera*) are concentrated as a **visceral mass** located above the foot.
4. The dorsal body wall forms a pair of folds called the **mantle**. The mantle is a thin sheet of tissue that generally overhangs the visceral mass, forming a mantle cavity. The mantle may contain glands that secrete a shell. The mantle cavity contains gills or a lung.
5. A rasplike (rough) structure called a **radula**, which is a belt of teeth in the mouth region. (The radula is not present in clams or their relatives, which are filter feeders.)
6. A coelom, generally reduced to small compartments around certain organs, including the heart and excretory organs (*metanephridia*). The main body cavity is typically a **hemocoel**, a space containing blood (see the following discussion of open circulatory systems). The hemocoel is not a coelom.

Mollusks have all the organ systems typical of complex animals. The digestive system is a tube, often coiled, consisting of a

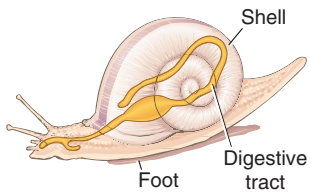
mouth, buccal cavity (mouth cavity), esophagus, stomach, intestine, and anus. The mollusk radula, located within the buccal cavity, projects out of the mouth and shows variation in structure among species related to feeding behaviors. In herbivorous species the radula is used to scrape algae from the surface of rocks or to remove tissue from live plants. The radulas of predatory mollusks may be used to inject toxins into prey, drill holes in the shells of prey animals, or rip apart flesh held in the beaks of cephalopods.

Most mollusks have an **open circulatory system** in which the blood, called **hemolymph**, bathes the tissues directly. The heart pumps blood into a single blood vessel, the aorta, which may branch into other vessels. Eventually, blood flows into a network of large spaces called *sinuses*, bringing the blood into direct contact with the tissues. This network makes up the hemocoel, or blood cavity. From the sinuses, blood drains into vessels that conduct it to the gills, where it is recharged with oxygen. After passing through the gills, the blood returns to the heart. Thus, blood flow in a mollusk follows this pattern:

heart → aorta → smaller blood vessels → blood sinuses (hemocoel) → blood vessels to gills → heart

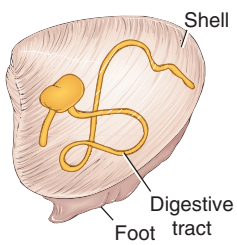
In open circulatory systems, blood pressure tends to be low, and tissues are not very efficiently oxygenated. Because most mollusks are slow-moving animals with low metabolic rates, this type of circulatory system is adequate. The active cephalopods (the class that includes the squids and octopuses) have a **closed circulatory system** in which blood flows through a complete circuit of blood vessels.



(a) Chiton.

Derek Holzapfel/Dreamstime.com

Chitons are sluggish marine animals with shells composed of eight overlapping plates. The blue lined chiton (*Tonicella undocaerulea*) inhabits rocks along the North American Pacific coast. It grazes on algae.



(b) Gastropod.

Table 31-3 Four Clades of Mollusks

Clade and Representative Animals	Characteristics
CHITONS	Marine; dorsal shell consisting of eight separate transverse plates; head reduced; broad foot used for locomotion; uses radula to scrape algae and other small organisms off rocks
GASTROPODS Snails, slugs, nudibranchs	Marine, freshwater, or terrestrial; coiled shell in many species; torsion of visceral mass; well-developed head with tentacles and eyes; predators, herbivores, and detritus feeders
BIVALVES Clams, oysters, mussels	Marine or freshwater; body laterally compressed; two-part shell hinged dorsally; hatchet-shaped foot; filter feeders
CEPHALOPODS Squids, octopuses	Marine; foot modified into tentacles, usually bearing suckers; well-developed eyes; closed circulatory system; predatory

Most marine mollusks pass through one or more larval stages. The first stage is typically a **trochophore larva**, a free-swimming, top-shaped larva with two bands of cilia around its middle (FIG. 31-14). In many mollusks (gastropods such as snails and bivalves such as clams) the trochophore larva develops into a **veliger larva**, which has a shell, foot, and mantle. The veliger larva is unique to the mollusks.

Chitons appear to be similar to ancestral mollusks

Polyplacophorans (pol-ee-plah-kof'-o-rans; meaning "many plates") are *chitons*, marine animals with flattened bodies (see Fig. 31-13a). Their most distinctive feature is a shell composed of eight separate but overlapping dorsal plates. The head is reduced, and there are no eyes or tentacles.

Chitons inhabit rocky intertidal zones, using a broad, flat foot to move and to hold on firmly to rocks. By pressing its mantle against the substratum and lifting the inner edge of the mantle, a chiton can produce a partial vacuum. The resulting suction lets the animal adhere powerfully to its perch. Using the radula for grazing, chitons scrape algae and other small organisms off rocks and shells.

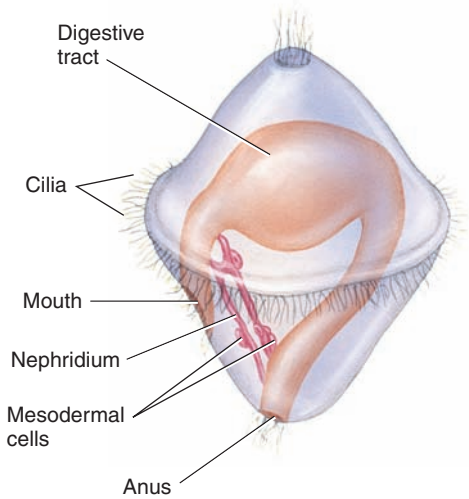

Figure 31-14 A trochophore larva

The first larval stage of a marine mollusk, the trochophore larva, is also characteristic of annelids. Just above the mouth, a band of ciliated cells functions as a swimming organ and, in some species, collects suspended food particles.

Gastropods are the largest group of mollusks

The *gastropods*—the snails, slugs, conchs, sea slugs, and their relatives—are the largest and most diverse group of mollusks (see Fig. 31-13b). In fact, with more than 70,000 extant species, gastropods constitute the second-largest class in the animal kingdom, second only to insects. Most gastropods inhabit marine waters, but others make their homes in brackish or fresh water or on land. We think of snails as having a single, spirally coiled shell into which they can withdraw the body, and many do. However, other gastropods, such as limpets, have shells like flattened dunce caps. Still others, such as garden slugs and the beautiful marine slugs known as *nudibranchs*, have no shell at all (FIG. 31-15).

Many gastropods have a well-developed head with tentacles. Two simple eyes may be located on stalks that extend from the head. The gastropod uses its broad, flat foot for creeping. Most land snails do not have gills. Instead, the mantle is highly vascularized and functions as a lung. Biologists describe these garden snails and slugs as pulmonate ("having a lung").

Torsion, a twisting of the visceral mass, is a unique feature of gastropods. This twisting is unrelated to the coiling of the shell. As the bilateral larva develops, one side of the visceral mass grows more rapidly than the other side. This uneven growth rotates the

Joao Pedro Silva/Getty Images

Figure 31-15 Nudibranch (*Felimare tricolor*)

Nudibranchs (known as sea slugs) are a group of gastropods that have no shell. They feed on sponges and other small marine animals. The species shown here is small, about 25 mm, but other nudibranchs grow to about 600 mm (24 in.).

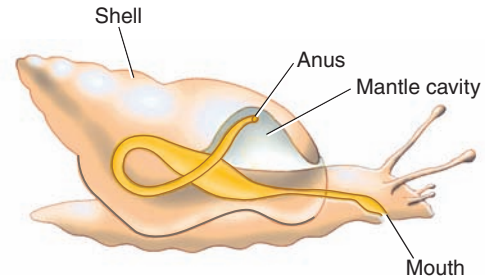

Figure 31-16 Torsion in a gastropod

As the bilateral larva develops, the visceral mass twists 180 degrees relative to the head. The digestive tube coils, and the anus becomes relocated near the mouth.

visceral mass. The visceral mass and mantle twist permanently up to 180 degrees relative to the head. As a result, the digestive tract becomes somewhat U-shaped, and the anus comes to lie above the head and gill (FIG. 31-16). Subsequent growth is dorsal and usually in a spiral coil. Torsion limits space in the body, and typically the gill, excretory organ (metanephridium), and gonads are absent on one side. Some biologists hypothesize that torsion is an adaptation that protects the head by allowing it to enter the shell first during withdrawal from potential predators. Without torsion, the foot would be withdrawn first.

Most bivalves are filter feeders The *bivalves* include clams, oysters, mussels, scallops, and their relatives (see Fig. 31-13c). Typically, the soft body is laterally compressed and completely enclosed by a two-part shell that hinges dorsally and opens ventrally (FIG. 31-17). This arrangement allows the hatchet-shaped foot to protrude ventrally for locomotion and for burrowing in mud. The two parts, or *valves*, of the shell are connected by an elastic ligament. Stretching of the ligament opens the shell. Large, strong adductor muscles attached to the shell permit the animal to close its shell.

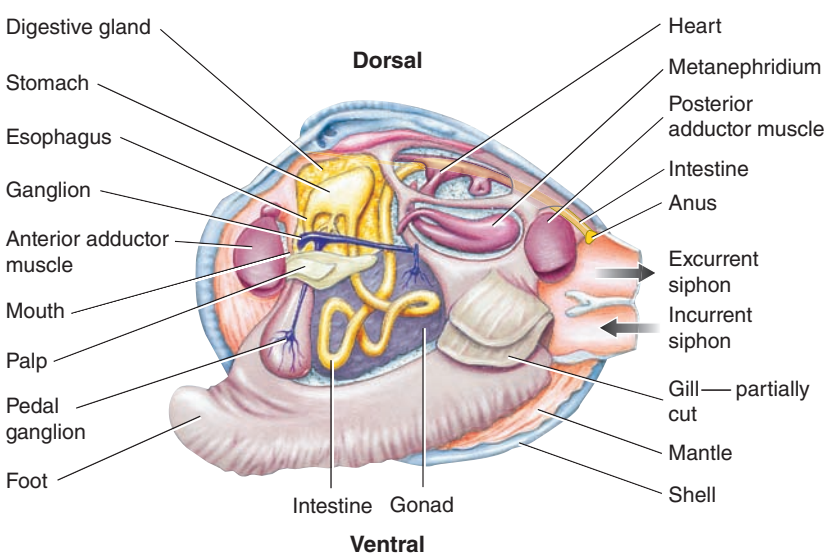

Figure 31-17 Internal anatomy of a clam

The two shells of a bivalve hinge dorsally and open ventrally.

The inner, pearly layer of the bivalve shell is made of calcium carbonate secreted in thin sheets by the epithelial cells of the mantle. Known as *mother-of-pearl*, this material is valued for making jewelry and buttons. Should a bit of foreign matter lodge between the shell and the mantle, the epithelial cells covering the mantle secrete concentric layers of calcium carbonate around the intruding particle. Many species of oysters and clams form pearls in this way.

Some bivalves, such as oysters, attach permanently to the substrate. Others burrow slowly through rock or wood, seeking protected dwellings. The shipworm, *Teredo*, a clam that damages dock pilings and other marine installations, is just looking for a home. A few bivalves, such as scallops, swim rapidly by clapping their two shells together with the contraction of a large adductor muscle (the part of the scallop that humans eat).

Clams and oysters are filter feeders that trap food particles suspended in sea water. They take water in through an extension of the mantle called the *incurrent siphon*. As the water passes over the gills, mucus secreted by the gills traps food particles in the stream of water. Cilia move the food to the mouth. Water and digestive wastes leave by way of an *excurrent siphon*. An oyster can filter more than 30 L (about 32 qt) of water per hour! As filter feeders, bivalves have no need for a radula, and indeed they are the only group of mollusks that lack this structure.

Cephalopods are active predators In contrast with most other mollusks, members of class *Cephalopoda* (meaning "head-foot") are fast-swimming predators (see Fig. 31-13d). The mouth of cephalopods is surrounded by tentacles, or arms: 8 in octopuses, 10 in squids, and as many as 90 in the chambered nautilus. The large cephalopod head has well-developed eyes that form images. Although they develop differently, their complex eyes are structurally similar to vertebrate eyes and function in much the same way. Octopuses have no shell, and the shells of squid, located inside the body, are greatly reduced.

The *nautilus* is a cephalopod with a coiled shell consisting of many chambers built up over time. Each year, the animal lives in the newest and largest chamber of the series. *Nautilus* secretes a mixture of gases similar to air into the other chambers. By regulating the amount of gas in the chambers, the animal controls its buoyancy in the ocean.

The tentacles of squids, octopuses, and cuttlefish are covered with suckers for seizing and holding prey. In addition to a radula, the mouth has two strong, horny beaks used to kill prey and tear it to bits. The thick, muscular mantle is fitted with a funnel-like *siphon*. By filling the cavity with water and ejecting it through the siphon, cephalopods achieve forceful jet propulsion. Squids and cuttlefish have streamlined bodies adapted for efficient swimming.

In addition to speed, a cephalopod has two other adaptations that facilitate escape from its predators, which include certain whales, seals, large fish, and other cephalopods. It can confuse the enemy by rapidly changing colors. By expanding and contracting *chromatophores*, cells in the skin

that contain pigment granules, a cephalopod can display an impressive variety of mottled colors. Another defense mechanism is its *ink sac*, which produces a thick, black liquid the animal releases in a dark cloud when alarmed. While its enemy pauses, temporarily blinded and confused, the cephalopod escapes. The ink inactivates the chemical receptors of some predators, making them incapable of detecting their prey.

Octopuses feed on crabs and other arthropods, catching and killing them with a poisonous secretion of their salivary glands. During the day, an octopus usually hides among the rocks; in the evening, it emerges to hunt for food. Its motion is incredibly fluid, giving little hint of the considerable strength in its eight arms.

Small octopuses survive well in aquariums and have been studied extensively. Because octopuses are relatively intelligent and can make associations among stimuli, researchers have used them as models for studying learning and memory. Their highly adaptable behavior more closely resembles that of the vertebrates than the more stereotypic patterns of behavior observed in other invertebrates (see Chapter 52).

Annelids are segmented worms

Annelids (an′-eh-lids) are segmented worms with bilateral symmetry and a tubular body that may be partitioned into more than 100 ringlike segments. More than 17,000 species of annelids have been identified. They inhabit terrestrial, marine, and freshwater environments.

The term *Annelida* (from a Latin word meaning "little rings") refers to the series of rings, or segments, that make up the annelid body. Both the body wall and many of the internal organs are segmented. Some structures, such as the digestive tract and certain nerves, extend the length of the body, passing through successive segments. Other structures, such as excretory organs, are repeated in each segment. In polychaetes and earthworms, segments are separated from one another internally by transverse partitions called **septa** (sing., *septum*).

An important advantage of **segmentation** is that it facilitates locomotion. The coelom is divided into segments, and each segment has its own muscles. This arrangement allows the animal to elongate one part of its body while shortening another part. The annelid's hydrostatic skeleton is important in movement. Polychaetes and earthworms have bristlelike structures called **setae** (sing., *seta*) located on each segment. Setae provide traction as the worm moves along by alternating contraction of its longitudinal and circular muscles. In earthworms, setae consist mainly of chitin.

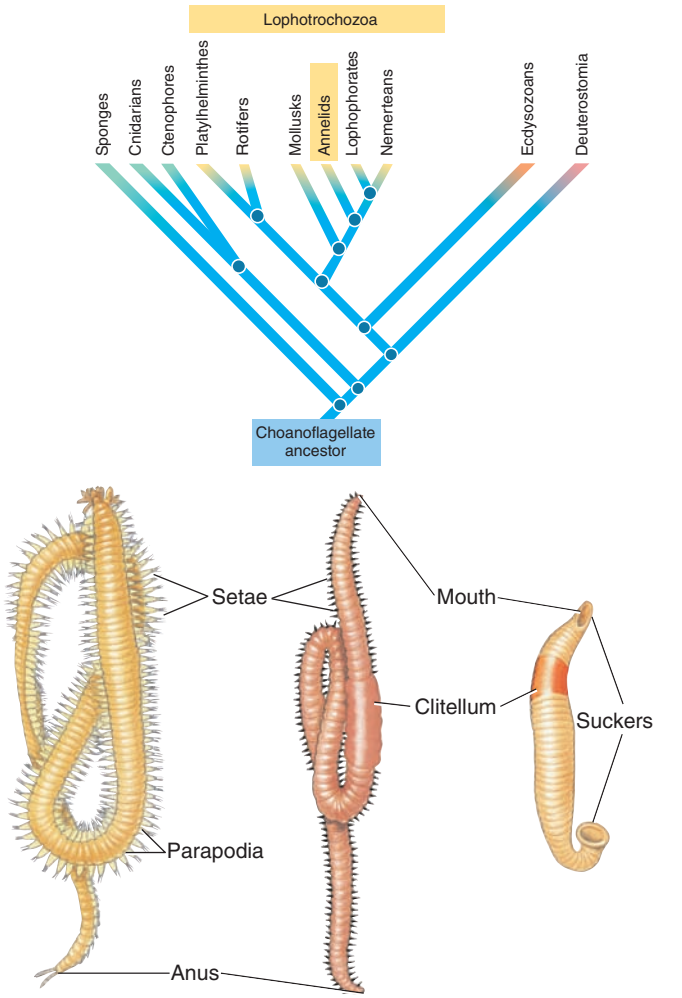
The annelid nervous system typically consists of a ventral nerve cord and a simple brain consisting of a pair of ganglia. Each segment has a pair of ganglia and lateral nerves. Annelids have a large, well-developed coelom; a closed circulatory system; and a complete digestive tract extending from mouth to anus. Respiration is *cutaneous*—that is, through the skin—or by gills. Typically, a pair of excretory tubules called **metanephridia** is located in each segment (described in Chapter 48).

Behavioral patterns that ensure fertilization have evolved in many annelid species. By responding to certain rhythmic variations, or cycles, in the environment, nearly all the females and males of a given species release their gametes into the water at the same time. For example, more than 90% of reef-dwelling *Palolo* worms of the South Pacific shed their eggs and sperm within a 2-hour period on the same night of the year. The posterior portion of the *Palolo* worm, loaded with eggs or sperm, breaks off from the rest of the body. It comes to the surface and bursts, releasing its gametes. This mass reproductive event occurs in October or November at the beginning of the last lunar quarter. Local islanders gather great numbers of the swarming polychaetes, which they bake or eat raw.

Traditionally, annelids were assigned to three main groups: the polychaetes, a group of mainly marine worms; the earthworms and their relatives; and the leeches (TABLE 31-4 and FIG. 31-18). Recent phylogenetic analyses indicate, however, that the annelids form two large clades: Errantia and Sedentaria.

Errantians include polychaete worms Many **errantians** are mobile marine worms that swim freely in the sea. Others crawl or burrow in the mud near the shore or in crevices of rocks or coral reefs. Still other errantians are part of the plankton and are important in marine food chains. Some errantians live in tubes they secrete or make by cementing bits of shell and sand together with mucus. Giant tube worms have been found in deep vents in the floor of the Pacific Ocean (see *Inquiring About: Life without the Sun* in Chapter 55).

Each body segment typically bears a pair of paddle-shaped appendages called **parapodia** (sing., *parapodium*) that function in locomotion and in gas exchange. Each of these fleshy structures bears many stiff setae. Most errantians have a well-developed head with eyes and antennae. The head may also be equipped with sensory tentacles and palps (feelers). Errantians develop from free-swimming trochophore larvae similar to those of mollusks.



Sedentarians include earthworms and leeches Compared to the errantian species, most **sedentarians** are less mobile. Some live in tubes and use their gills or tentacles to filter food from the water.

Table 31-4 Clades of Annelids

Clade and Representative Animals	Characteristics
ERRANTIANS	
Sandworms, tubeworms	Mainly marine; each segment bears a pair of parapodia with many setae; well-developed head; separate sexes; trochophore larva
SEDENTARIANS	
Earthworms	Terrestrial and freshwater worms; few setae per segment; lack well-developed head; hermaphroditic
Leeches	Most are blood-sucking parasites that inhabit fresh water; appendages and setae absent; prominent muscular suckers

(a) An errantian: polychaete. Polychaetes are marine worms with paddle-shaped parapodia.

(b) A sedentarian: earthworm. Earthworms inhabit fresh water and moist terrestrial areas.

(c) A sedentarian: leech. Many leeches are parasites that feed on blood.

Figure 31-18 Three types of annelids

Earthworms help maintain fertile soil More formally known as *oligochaetes*, earthworms live almost exclusively in fresh water and in moist terrestrial habitats. More than 5000 species have been identified. Earthworms lack parapodia, have only a few bristles per segment (the term *oligochaete* means "few bristles"), and lack a well-developed head. All oligochaetes are hermaphroditic.

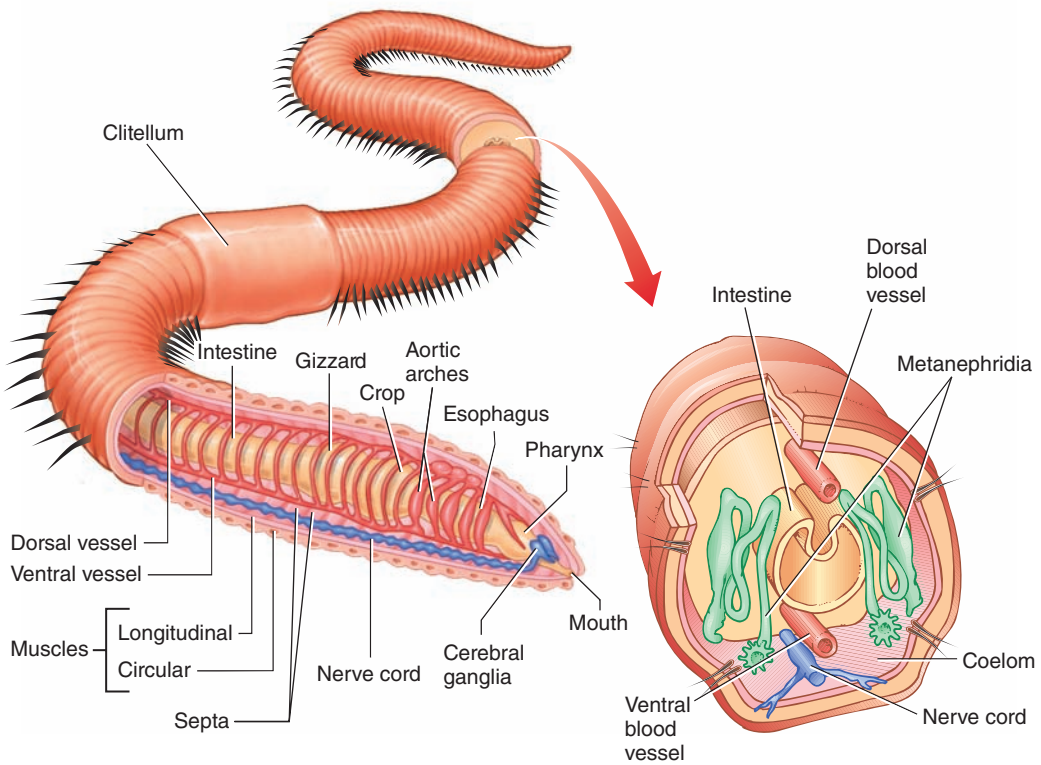
Lumbricus terrestris, a common earthworm, can reach 20 cm (8 in.) or more in length. Its body has more than 100 segments, separated externally by grooves that indicate the internal position of the septa (FIG. 31-19). The earthworm's body is somewhat protected from drying by a thin, transparent **cuticle** secreted by the cells of the epidermis. Mucus secreted by gland cells of the epidermis forms an additional protective layer over the body surface. The body wall has an outer layer of circular muscles and an inner layer of longitudinal muscles.

Earthworms eat living and dead plant material. Some species feed mainly above the soil surface and other species feed within the ground, consuming mineral soil particles and organic matter. As earthworms burrow and feed, they move nutrients through the soil. Their activity creates pathways for oxygen and water movement, which greatly increases suitability of the soil for plant growth.

Earthworms process their meals in complex digestive systems. Food is swallowed through the muscular **pharynx** and passes through the **esophagus**, modified to form a thin-walled *crop* where food is stored. Food then passes through a thick-walled, muscular *gizzard*, where food is ground to bits by sand grains consumed along with the meal. The rest of the digestive system is a long, straight *intestine* that chemically digests food and absorbs nutrients. Wastes pass out of the intestine to the exterior through the **anus**.

The efficient closed circulatory system consists of two main blood vessels that extend longitudinally. The dorsal blood vessel, just above the digestive tract, collects blood from vessels in the segments. The dorsal vessel functions as a heart: it contracts to pump blood anteriorly. Five pairs of blood vessels surrounding the esophagus, referred to as *aortic arches*, conduct blood from the dorsal to the ventral blood vessel. Small vessels branch from it and deliver blood to the various structures in each segment and to the body wall. Within these structures, blood flows through tiny capillaries before returning to the dorsal blood vessel.

Gas exchange takes place through the moist skin. Oxygen is transported by *hemoglobin*, a respiratory pigment in the blood. The excretory system consists of paired metanephridia, repeated in almost every segment of the body, that remove nitrogenous wastes from the coelomic fluid.



The nervous system consists of a pair of *cerebral ganglia* (a simple brain) just above the pharynx and a subpharyngeal ganglion just below the pharynx. A ring of nerve fibers connects these ganglia. From the lower ganglion, a ventral nerve cord extends beneath the digestive tract to the posterior end of the body. A pair of fused ganglia is present in each segment along the nerve cord. Nerves extend laterally from the ganglia to the muscles and other structures of that segment. The ganglia coordinate muscle contractions of the body wall, allowing the worm to creep along.

Like most annelids, earthworms are hermaphroditic. During copulation, two worms, headed in opposite directions, press their ventral surfaces together. These surfaces become glued together by the thick mucous secretions of each worm's *clitellum*, a thickened ring of epidermis. Sperm are then exchanged and stored in the *seminal receptacles* (small sacs) of the other worm. A few days later, each clitellum secretes a membranous cocoon containing a sticky fluid. As the cocoon is slipped forward, eggs are laid in it. Sperm are added as the cocoon passes over the openings of the seminal receptacles. As the cocoon slips free over the worm's head, its openings constrict so that a spindle-shaped capsule is formed. The fertilized eggs develop into tiny worms within this capsule. This reproductive pattern is an adaptation to terrestrial life; the cocoon protects the delicate gametes and young worms from drying out.

Many leeches are blood-sucking parasites Leeches are members of a group called *Hirudinida*. Most leeches inhabit fresh water, but some live in the sea or in moist areas on land.

(a) The internal structure has been exposed at the anterior end of the earthworm.

(b) Cross section of an earthworm.

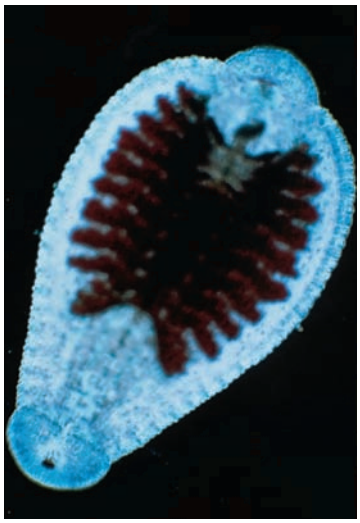
Figure 31-19 Body plan of an earthworm
(Reproductive structures are not shown.)

Some leeches are nonparasitic predators that capture small invertebrates such as earthworms and snails. However, about 75% of the known species of leeches are blood-sucking parasites. Leeches differ from other annelids in having neither setae nor parapodia.

Leeches have muscular suckers at both the anterior and posterior ends of their body. Most parasitic leeches attach themselves to a vertebrate host and bite through the skin (FIG. 31-20). They suck out a quantity of blood, which is stored in pouches in the digestive tract. *Hirudin*, an anticoagulant secreted by glands in the crop, ensures leeches a full meal of blood. In 31 minutes, a leech can suck out as much as 10 times its own weight in blood! Some leeches feed only about twice each year because they digest their food slowly over several months.

Leeches have been used since ancient times for drawing blood from areas swollen by poisonous stings and bites. During the 19th century, they were widely used to remove "bad blood," thought to be the cause of many diseases. Leeches are sometimes used in modern medicine to remove excess fluid and blood that accumulate within body tissues as a result of injury, disease, or surgery (see Fig. 31-20b). The leech attaches its sucker near the site of injury, makes an incision, and secretes hirudin. The hirudin prevents the blood from clotting and dissolves clots that already exist.

The lophophorates are distinguished by a ciliated ring of tentacles



With a few exceptions, **lophophorates** are marine animals adapted for life on the ocean floor. These coelomates are distinguished by their *lophophore*, a ring of ciliated tentacles that surrounds the mouth. The *lophophore* is an adaptation for capturing suspended particles in the water. Lophophorates do not have a distinct head.

The three lophophorate groups are Brachiopoda, Phoronida, and Bryozoa (also known as Ectoprocta). *Brachiopods*, or lampshells, are solitary marine animals that inhabit cold water. Until the mid-19th century, they were thought to be mollusks because they are suspension feeders that superficially resemble clams and other bivalve mollusks. Their body is enclosed between two shells and has a mantle and mantle cavity (FIG. 31-21a). However, brachiopods differ from bivalve mollusks in that the shells are dorsal and ventral rather than lateral; each shell is symmetrical about the midline, and the two shell valves are typically of unequal size.

Brachiopods attach to the substrate by a long stalk. The action of cilia on the lophophore brings water with suspended food into the slightly opened shell. Although there are now only about 325 living species, brachiopods were abundant and diversified during the Paleozoic era. Paleobiologists have described about 12,000 fossil species.

(b) Medicinal leeches (*Hirudo medicinalis*) are used here to treat hematoma, an accumulation of blood within tissues that results from injury or disease.

Figure 31-20 Leeches

Only about 20 extant species of *phoronids* are known. They are wormlike, sessile animals found in coastal marine sediments. Adult phoronids secrete chitinous tubes in which they live (FIG. 31-21b). They extend their lophophores from their tubes for feeding. Phoronids vary in length from 2 cm to more than 20 cm (less than 1 in. to about 8 in.), but they are only 1 to 3 mm in diameter.

Bryozoans, also known as *ectoprocts* or "moss animals," are microscopic aquatic animals that form sessile colonies by asexual budding (FIG. 31-21c). Each colony can consist of millions of individuals and can extend in length up to about 31 cm (about 1 ft). The colonies typically appear plantlike, but some have the appearance of coral. Approximately 4500 living species are known.

Biologists continue to debate the evolutionary position of the lophophorates. They were traditionally considered a monophyletic group and, based on certain structural similarities, a sister group to the deuterostomes. However, the lophophorate groups also have several morphological characters that

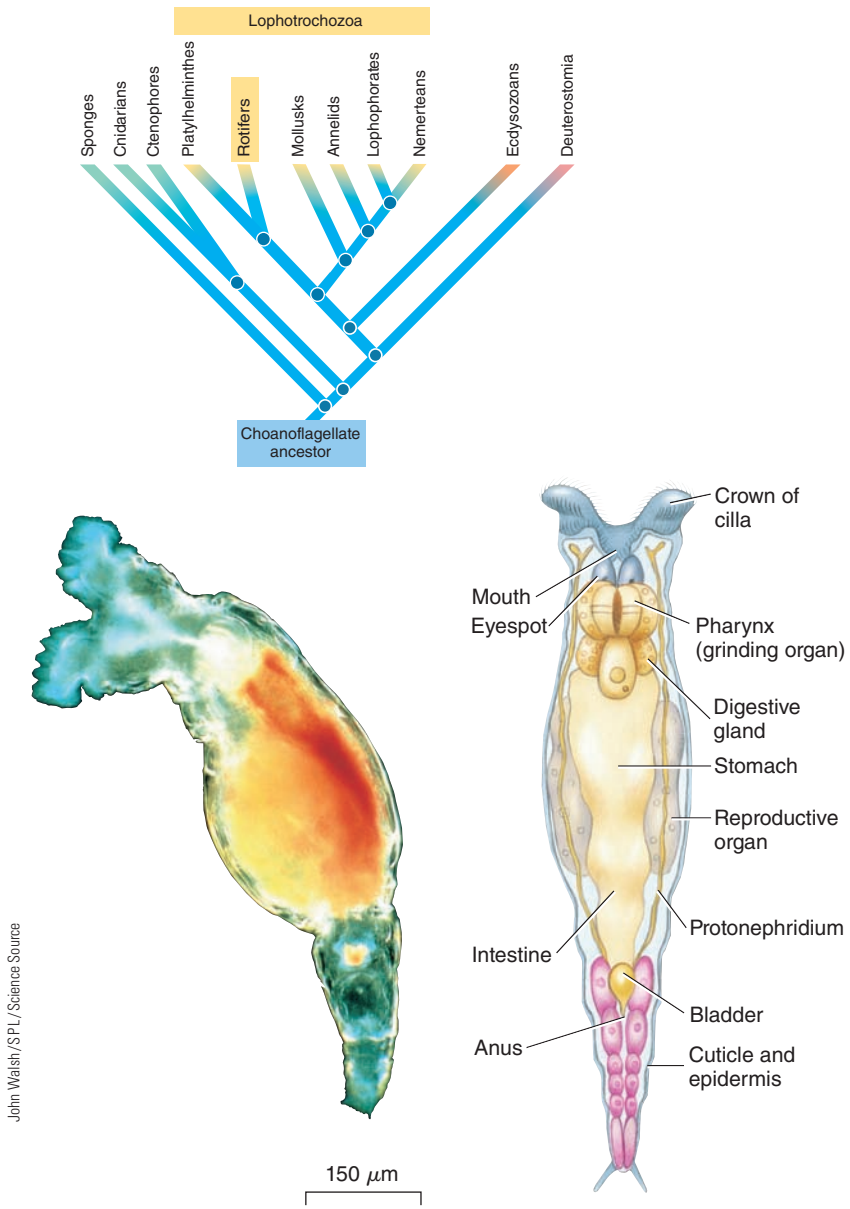
suggest a relationship with the lophotrochozoans. Although their phylogeny is still uncertain, based on molecular data (18S rDNA nucleotide sequences), the lophophorate phyla are currently classified as Lophotrochozoa.

Rotifers have a crown of cilia



Rotifers, or "wheel animals," are among the less familiar invertebrates. Although no larger than many protozoa, these aquatic, microscopic animals are multicellular with complex organ systems. Most of the 2000 described species inhabit fresh water, but some live in marine environments or damp soil. Rotifers are important in cycling nutrients in aquatic ecosystems. These animals do not have a true coelom and were formerly classified as pseudocoelomates. Current evidence suggests that rotifers evolved from animals with a true coelom, and we classify them as lophotrochozoans.

Rotifers have a characteristic crown of cilia on their anterior end. The cilia beat rapidly during swimming and feeding, giving the appearance of a spinning wheel (FIG. 31-22; also see Fig. 20-1). Rotifers feed on tiny organisms suspended in the stream of water drawn into the mouth by the cilia. A muscular organ posterior to the mouth grinds the food. The complete digestive tract ends in an anus through which wastes are eliminated.

Rotifers have a nervous system with a "brain" and sense organs, including eyespots. Protonephridia with flame cells remove excess water from the body and may also excrete metabolic wastes.

Biologists have discovered that rotifers, like some other animals with a pseudocoelom, are "cell constant," meaning that each member of a given species has exactly the same number of cells. Indeed, each part of the body has a precisely fixed number of cells arranged in a characteristic pattern. Cell division does not take place after embryonic development, and mitosis cannot be induced. Growth results from an increase in cell size. Do you think that rotifers could develop cancer? One of the challenging research problems of our time is to discover the difference between such nondividing cells and the dividing cells of other animals.

Another interesting characteristic of rotifers is their ability to survive very dry conditions and temperature extremes. These animals can remain in a dormant state for months or years. When conditions become favorable, they recover and become active once again.

31.3 The Ecdysozoa

LEARNING OBJECTIVES

9 Summarize what is known about the phylogeny of the ecdysozoans.

10 Describe characteristics of nematodes and identify four parasitic nematodes.

11 Describe six key characteristics of arthropods, summarize proposed phylogeny of arthropods, and distinguish among arthropod clades; give examples of animals that belong to each group.

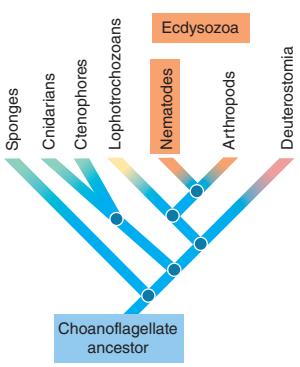
12 Identify adaptations that have contributed to the biological success of insects.

The **Ecdysozoa** include the nematodes (roundworms) and arthropods, animals characterized by a **cuticle**, a noncellular body covering secreted by the epidermis. The name *Ecdysozoa* refers to the process of **ecdysis**, or **molting**, which is characteristic of animals in this group. During ecdysis, an animal sheds its outer covering (e.g., cuticle, exoskeleton, or skin), which is then replaced by the growth of a new one. The taxonomic validity of the Ecdysozoa has been supported by many types of data, including molecular data.

Roundworms are of great ecological importance

Nematodes (nem′-uh-todes), or *roundworms*, play key ecological roles as decomposers, parasites, and predators of smaller organisms. Many soil nematodes eat bacteria. Nematodes are numerous and are widely distributed in soil and in marine and freshwater sediments. More than 25,000 species have been described, and many more remain to be discovered. The nematodes rival the insects in number of individuals. A spadeful of soil may contain thousands of these mainly microscopic worms, which thrash around, coiling and uncoiling. Greater understanding of soil nematode diversity and ecology will contribute to solving some important agricultural problems. *Caenorhabditis elegans*, a free-living soil nematode, is an important model research organism for biologists studying the genetic control of development (see Chapter 17).

The elongated, cylindrical, threadlike nematode body is pointed at both ends and covered with a tough, flexible cuticle (FIG. 31-23). Secreted by the underlying epidermis, the thick cuticle gives the nematode body shape and offers some protection. The epidermis is unusual in that it does not consist of distinct cells.



Nematodes have a fluid-filled pseudocoelom that serves as a hydrostatic skeleton. It transmits the force of muscle contraction to the enclosed fluid. Movement of fluid in the pseudocoelom is also important in transporting nutrients and wastes. Like ribbon worms, nematodes exhibit bilateral symmetry, a complete digestive tract, three definite tissue layers, and definite organ systems. However, they lack specific circulatory structures. The sexes are usually separate, and the male is generally smaller than the female.

Although most nematodes are free-living, others are important parasites in plants and animals. More than 50 species of roundworms are human parasites, including *Ascaris*, hookworms, pinworms, and the trichina worm. The common intestinal parasite *Ascaris* spends its adult life in the human intestine, where it ingests partly digested food (FIG. 31-24). *Ascaris* is a white worm up to 25 cm (10 in.) long. Like most parasites, it has remarkable reproductive adaptations that ensure survival within hosts. A mature female may produce as many as 200,000 eggs per day!

Hookworms attach to the lining of the intestine and suck blood, potentially causing serious tissue damage and blood loss. *Pinworms* are the most common worms found in children. The tiny pinworm eggs are often ingested by eating with hands contaminated with them. The *trichina worm* lives inside a variety of animals, including pigs, rats, and bears. Humans typically become infected by eating undercooked, infected meat. Larvae encyst in skeletal muscle and nervous tissue. Filiarial nematodes are small, threadlike parasitic worms that are spread among hosts by the bites of insects. Members of this group cause elephantiasis in humans. The dog heartworm infects cats, dogs, and their relatives.

Arthropods are characterized by jointed appendages and an exoskeleton of chitin

Arthropods (ar′-thro-pods) are the most biologically successful group of animals. More than 80% of all known animals are arthropods! They are more diverse and live in a greater range of habitats than the members of any other animal group. More than one million species have been described, and biologists

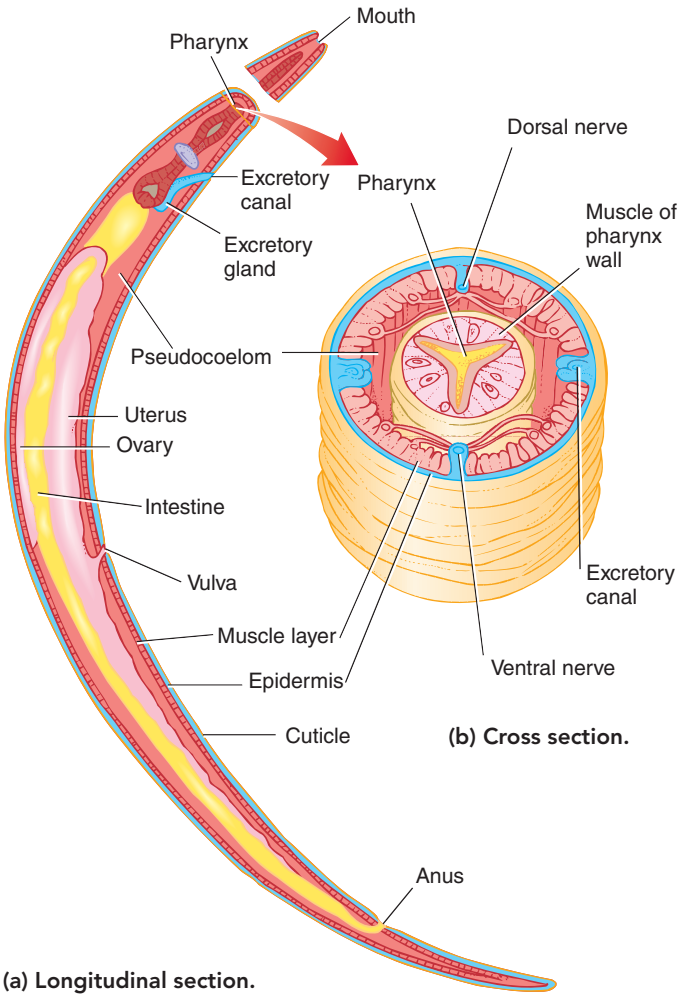

Figure 31-24 The roundworm *Ascaris*

(a) Note the complete digestive tract that extends from mouth to anus. **(b)** This cross section through *Ascaris* shows the tube-within-a-tube body plan. The protective cuticle that covers the body helps this parasite resist host defenses.

predict millions more will be identified. The following adaptations have greatly contributed to their success:

1. The arthropod body, like that of the annelid, is segmented. *Segmentation* is important from an evolutionary perspective because it provides the opportunity for specialization of body regions. In arthropods, groups of segments are specialized to perform particular functions. Segments differ in shape, muscles, or the appendages they bear.
2. A hard **exoskeleton**, composed of chitin and protein, covers the entire body and appendages. The exoskeleton serves as a coat of armor that protects against predators and helps prevent excessive loss of moisture. It also supports the underlying soft tissues. Arthropods move effectively because distinct muscles attach to the inner surface of the exoskeleton and operate the joints of the body and appendages.

   A disadvantage of the exoskeleton is that it is nonliving, and the arthropod periodically outgrows it. Recall that *molting* is the process of shedding an old exoskeleton, which is then replaced by a larger one. The shed exoskeleton represents a net metabolic loss, and molting also leaves the arthropod temporarily vulnerable to predators.
3. *Paired, jointed appendages*, from which this group gets its name (*arthropod* means "jointed foot"), are modified for many functions. They serve as swimming paddles, walking legs, mouthparts for capturing and manipulating food, sensory structures, or organs for transferring sperm.
4. The nervous system, which resembles that of the annelids, consists of a "brain" (cerebral ganglia) and a ventral nerve cord with ganglia. In some arthropods successive ganglia may fuse. Arthropods have a variety of very effective sense organs. Many have organs of hearing and **antennae** that sense taste and touch. Most insects and many crustaceans have **compound eyes** composed of many light-sensitive units called **ommatidia** (see Fig. 43-17). The compound eye can form an image and is especially adapted for detecting movement.

Arthropods have an *open circulatory system*. A dorsal, tubular heart pumps **hemolymph** into a dorsal artery, which may branch into smaller arteries. From the arteries, hemolymph flows into large spaces that collectively make up the hemocoel. Eventually, hemolymph re-enters the heart through openings, called *ostia*, in its walls.

The exoskeleton presents a barrier to diffusion of oxygen and carbon dioxide through the body wall. Specialized respiratory systems have evolved for gas exchange. Most aquatic arthropods have gills that function in gas exchange. In contrast, many terrestrial forms have a system of internal branching air tubes called **tracheae**, or **tracheal tubes** (see Fig. 46-1b). Other terrestrial arthropods have platelike *book lungs* (see Fig. 46-1d).

The arthropod digestive system is a tube similar to that of earthworms. Excretory structures vary somewhat among groups. The coelom is small and filled chiefly by the organs of the reproductive system.

Arthropod evolution and classification are controversial Two groups of animals once thought to be closely related to arthropods are the onychophorans and the tardigrades (FIG. 31-25). Like arthropods, onychophorans and tardigrades have a thick cuticle and must molt to grow. The body is segmented in all three groups, and all have legs, claws, and a ventral nervous system. These animals all have an open circulatory system, and their coelom is reduced to a hemocoel.

The caterpillar-like *onychophorans*, known as velvet worms, have paired appendages, but these are not jointed. As in arthropods, their jaws are derived from appendages. *Tardigrades*, known as "water bears," were thought to be the sister taxon of the arthropods. These tiny animals (typically less than 1 mm in length) have short, unjointed, clawed legs (see Fig. 2-11). At this time, the relationships of the onychophorans and tardigrades to the arthropods remain unclear.

Arthropod fossils have been identified dating back to the Proterozoic eon. Early in their evolutionary history, more than 540 million years ago (mya), arthropods diverged into several groups. Arthropods evolved rapidly during the Cambrian radiation, as evidenced by many diverse fossils in the Burgess Shale and other ancient sites.

Dr. Morley Read/Science Source

(a) Onychophoran. Note the soft segmented body and series of non-jointed legs. Extant onychophorans live in humid forests, but many extinct species inhabited the ocean.

Andrew Syred/Science Source

(b) Tardigrades. Commonly known as water bears, tardigrades normally live in moist habitats, such as thin films of water on mosses. Most are less than 1 mm long.

Figure 31-25 Onychophorans and tardigrades

In this edition, based on molecular and other data, we classify the arthropods as belonging to three clades: myriapods, chelicerates, and pancrustaceans (TABLE 31-5). However, as you study the following sections, bear in mind that arthropod systematics is a work in progress. Both the relationship of arthropods to other protostomes and the relationships among arthropods continue to be topics of lively debate.

Trilobites were early arthropods Among the earliest arthropods to evolve, *trilobites* inhabited shallow Paleozoic seas more than 500 mya. These arthropods, which have been extinct for about 250 million years, lived on the sea bottom and filtered mud to obtain food. Most ranged from 3 to 10 cm (about 1 to 4 in.), but a few reached almost 1 m (39 in.) in length.

Covered by a hard, segmented exoskeleton, the trilobite body was a flattened oval divided into three parts: an anterior head bearing a pair of antennae and a pair of compound eyes, a thorax, and a posterior abdomen (FIG. 31-26). At right angles to these divisions, two dorsal grooves extended the length of the animal, dividing the body into a median lobe and two lateral lobes. (The name *trilobite* derives from this division of the body into three longitudinal parts.) Each segment had a pair of segmented **biramous appendages**, that had two jointed branches extending from their base. In trilobites each appendage consisted of an inner walking leg and an outer branch with gills.

The clade Myriapoda includes the centipedes and millipedes **Myriapods** are a monophyletic group characterized by unbranched appendages called **uniramous appendages**, jawlike mandibles, and a single pair of antennae. Centipedes (*Chilopoda*) and millipedes (*Diplopoda*) are terrestrial and are typically found beneath stones or wood in the soil in both temperate and tropical regions. Both centipedes and millipedes have a head and an elongated trunk with many segments, each bearing uniramous legs (FIG. 31-27).

Centipedes ("hundred-legged") have one pair of legs on each segment behind the head. Most centipedes do not have

Table 31-5 Major Arthropod Clades

Clade and Selected Groups	Body Divisions	Appendages: Antennae, Mouthparts	Appendages: Legs	Gas Exchange	Development	Main Habitat
MYRIAPODS **Chilopods** (centipedes) **Diplopods** (millipedes)	Head with segmented body	Uniramous Antennae: one pair Mouthparts: mandibles, maxillae	Chilopods: one pair/segment Diplopods: usually two pairs/segment	Tracheae	Direct	Terrestrial
CHELICERATES **Merostomes** Horseshoe crabs **Arachnids** Spiders, scorpions, ticks, mites	Cephalothorax and abdomen	Uniramous Antennae: none Mouthparts: chelicerae, pedipalps	Merostomes: four pairs of walking legs Arachnids: four pairs on cephalothorax	Merostomes: gills Arachnids: book lungs or tracheae	Direct, except mites and ticks	Merostomes: marine Arachnids: mainly terrestrial
PANCRUSTACEANS **Crustaceans** Lobsters, crabs, shrimp, isopods (Malacostraca) Barnacles (Cirripedia) Copepods (Copepoda)	Head, thorax, and segmented abdomen	Biramous Antennae: two pairs Mouthparts: mandibles, two pairs of maxillae (for handling food)	Typically one pair/segment	Gills	Usually larval stages (nauplius larva)	Marine or freshwater; a few are terrestrial
Hexapods (insects) Bees, ants, grasshoppers, roaches, flies, beetles	Head, thorax, and abdomen (some multi-segmented)	Uniramous Antennae: one pair Mouthparts: mandibles, maxillae	Three pairs on thorax	Tracheae; gills in aquatic species	Typically, larval stages; most with complete metamorphosis	Mainly terrestrial

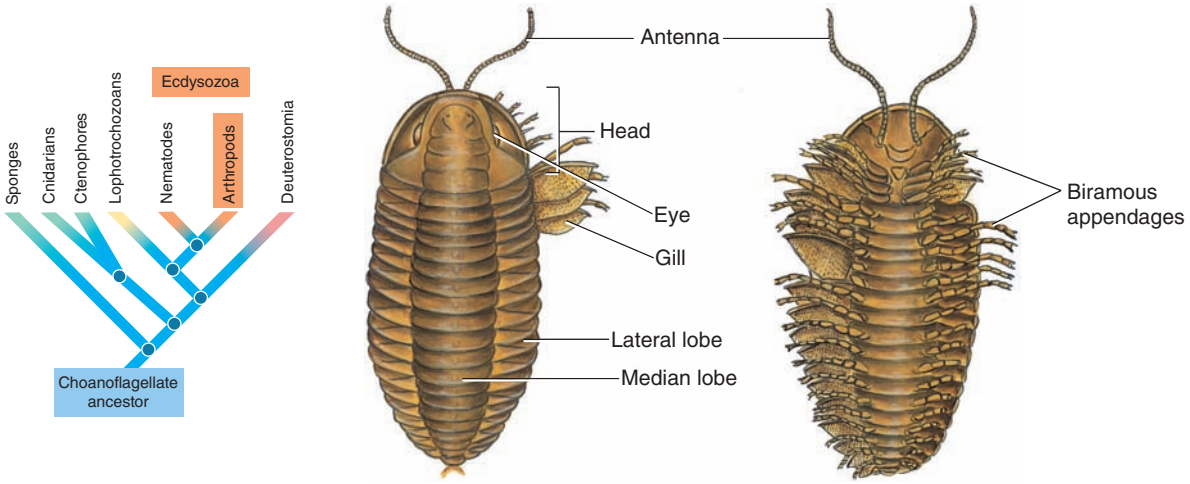

Figure 31-26 Fossil trilobites

These extinct arthropods (*Phacops rana*) were about 3 cm (1.2 in.) long. Note the large, well-developed eyes visible on either side of the head region. Biologists consider these extinct marine arthropods among the most primitive members of the arthropods. Trilobites flourished in the ocean during the Paleozoic era.

enough legs to merit their name; typically, they have approximately 30, although a few species have 100 or more. Because centipedes have long legs, they are able to run rapidly. They are predators that feed on other animals, mostly insects. Larger centipedes eat snakes, mice, and frogs. Using their poison claws located just behind the head on the first trunk segment, centipedes capture and kill their prey.

Millipedes ("thousand-legged") have two pairs of legs on most body segments. They are not as agile as chilopods, and most species can crawl only slowly over the ground. However, they can powerfully force their way through earth and rotting wood. Millipedes are generally herbivorous and feed on both living and dead vegetation.

Chelicerates are the only arthropods without antennae

Chelicerates are a monophyletic group that includes the merostomes (horseshoe crabs) and the arachnids. Chelicerates are now considered the sister group to all of the other arthropods. The chelicerate body consists of a *cephalothorax* (fused head and thorax) and an abdomen. Chelicerates have no chewing mandibles. Instead, the first appendages, located immediately anterior to the mouth, are a pair of **chelicerae** (sing., *chelicera*), fanglike feeding appendages. Most chelicerates suck fluid food from their prey. The second appendages are the *pedipalps*. The chelicerae and pedipalps are modified to perform different functions in various groups, including manipulation of food, locomotion, defense, and copulation. The four pairs of legs on the cephalothorax are specialized for walking.

Almost all the *merostomes* are extinct. Only the horseshoe crabs have survived, essentially unchanged for more than 350 million years. *Limulus polyphemus*, the species common along the Atlantic shore of North America, is horseshoe-shaped (FIG. 31-28a). Its long, spikelike tail is used in locomotion, not for defense or offense. Horseshoe crabs feed at night, capturing mollusks, worms, and other invertebrates that they find on the sandy ocean floor.

Arachnids include spiders, scorpions, ticks, harvestmen (daddy longlegs), and mites (FIGS. 31-28b and c). Most of the approximately 80,000 named species are predators that feed on insects and other small arthropods. Most arachnids have six pairs of jointed appendages. In spiders the first appendages, the chelicerae, are used to penetrate prey; some species use the chelicerae to inject venom into their prey. Spiders use the second pair of appendages, the pedipalps, to manipulate food.

Many arachnid species have pedipalps modified as sense organs for tasting food or for reproduction (for sperm transfer and courtship displays). Scorpions use their very large pedipalps as pincers for capturing prey. Chelicerates use the remaining four pairs of appendages for walking.

Typically, spiders have eight eyes arranged in two rows of four each along the anterior dorsal edge of the cephalothorax. The eyes detect movement, locate objects, and in some species form a relatively sharp image.

Gas exchange in arachnids takes place by tracheal tubes, book lungs, or both. A *book lung* consists of 15 to 20 parallel plates (like pages of a book) that contain tiny blood vessels. Air enters the body through abdominal slits and circulates between the plates. As air passes over the blood vessels in the plates, oxygen diffuses into the blood and carbon dioxide diffuses out of the blood into the air. As many as four pairs of book lungs provide an extensive surface area for gas exchange.

Spiders have unique glands in the abdomen that secrete silk, an elastic protein that is spun into fibers by organs called *spinnerets*. The silk is liquid as it emerges from the spinnerets but hardens after it leaves the body. Spiders use silk to build nests, to encase their eggs in a cocoon, and in some species to trap prey in a web. Many spiders lay down a silken dragline that serves both as a safety line and a means of communication between members of a species. From the type of dragline, another spider can determine the sex and maturity level of the spinner.

Although all spiders (and scorpions) have poison glands useful in capturing prey, only a few produce poison toxic to humans. The most widely distributed venomous spider in the United States is the black widow (see Fig. 31-28b). Its venom is a neurotoxin that interferes with transmission of messages from nerves to muscles. The shiny black female is about 3.8 cm (1.5 in.) long with a red or orange hourglass-shaped marking on the underside of its abdomen. Adult male black widow spiders are smaller and are harmless. After mating, the female sometimes kills and eats the male.

The brown recluse spider (*Loxosceles reclusa*) is more slender than the black widow and has a violin-shaped stripe on its dorsal cephalothorax. Its venom destroys the tissues surrounding the bite. Although painful, spider bites cause fewer than three fatalities per year in the United States.

Mites are incredibly abundant, but are rarely noticed because of their small size. Some mites contribute to soil fertility by breaking down organic matter. However, many mites are serious nuisances. They eat crops and are external parasites that infest livestock and pets. Some species have modified body shapes and reduced appendages, adaptations for their parasitic lifestyles. Chiggers (red bugs), the larval form of some red mite species, attach themselves to the skin and secrete an irritating

digestive fluid that may cause itchy red welts. Certain mites cause mange in dogs and other domestic animals.

Larger than mites, ticks are parasites on dogs, deer, and many other animals. They transmit the bacteria that cause diseases such as Rocky Mountain spotted fever and Lyme disease (see Fig. 54-2).

Clade Pancrustacea includes the crustaceans and insects Researchers have provided a variety of molecular evidence, including genome analyses, to support this clade. Morphological data, including eye structure, also supports Pancrustacea. Many systematists now think that insects (hexapods) evolved from early crustaceans and refer to insects as "terrestrial crustaceans."

Crustaceans are vital members of marine food webs **Crustaceans** include lobsters, crabs, shrimp, and barnacles plus tens of thousands of smaller species with great diversity (FIG. 31-29). Many crustaceans are primary consumers of algae and detritus. Countless billions of microscopic crustaceans are part of marine zooplankton, the free-floating, mainly microscopic organisms in the upper layers of the oceans. These crustaceans are food for many fishes and other marine animals, such as certain baleen whales. Paleobiologists have dated crustacean fossils to the Cambrian period (more than 505 mya).

A distinctive feature of many crustaceans is the *nauplius larva*, which is often the first stage after hatching. This larva has only the most anterior three pairs of appendages. Crustaceans are also characterized by mandibles, biramous appendages, and two pairs of **antennae**. Their antennae, which are the first and second pairs of appendages, serve as sensory organs for touch and taste. Most adult crustaceans have compound eyes, and many crustaceans have **statocysts**, sense organs that detect gravity (see Fig. 43-6).

The hard **mandibles**, used for biting and grinding food, are the third pair of appendages; they lie on each side of the ventral mouth. Crustaceans show great diversity in the number of appendages posterior to the mandibles. Some species have several pairs of appendages near the mouth, called **maxillae** and maxillipeds, that manipulate and hold food. More posteriorly along the thorax and along the segmented abdomen, other appendages are modified for swimming, walking, defense, sensation, mating, or carrying eggs or young.

Crustaceans are primarily aquatic; not surprisingly, they typically have gills for gas exchange. Two large glands located in the head excrete metabolic wastes and regulate salt balance. Most crustaceans have separate sexes. During copulation, the male uses specialized appendages to transfer sperm into the female. Many crustaceans hatch into a nauplius larva and then molt through a series of larval stages before developing the adult body form. However, some species resemble small adults immediately upon hatching. Newly hatched animals may resemble adults, or they may undergo successive molts as they pass through a series of larval stages before developing an adult body.

Barnacles, the only sessile crustaceans, differ markedly in external anatomy from other members of their clade. They are marine suspension feeders that secrete limestone cups within which they live (see Fig. 31-29a). The larvae of barnacles are free-swimming forms that go through several molts. They eventually become sessile and develop into the adult form. Louis Agassiz, a 19th-century naturalist, described the barnacle as "nothing more than a little shrimplike animal standing on its head in a limestone house and kicking food into its mouth."

The bane of marine boaters, barnacles can proliferate on ship bottoms in great numbers. Barnacles can reduce the speed

Colin Milkins/Getty Images

(a) Goose barnacles (*Lepas* sp.) filter feeding. These stalked barnacles are found in large numbers on intertidal rocks.

Wolfgang Polzer/Alamy Stock Photo

(b) Sponge crab (*Criptodromia octodenta*) wearing a sponge on its back. The sponge provides camouflage and shelter. The sponge crab uses its claws to cut out a fragment from a sponge and then trims the sponge to conform to its own shape. The last two pairs of the crab's legs bend upward over the crab's body and hold the sponge in place. The sponge grows along with the crab.

of a ship by up to 10% and increase fuel consumption by as much as 40%. The U.S. Office of Naval Research has been testing an underwater grooming robot (the HULL BUG) that cleans barnacles, oysters, and other marine life from the hulls of ships when they are in port. They project that HULL BUGS will save about $500 million annually in extra fuel costs and maintenance.

Isopods are mainly tiny (5 to 15 mm in length) marine crustaceans that inhabit the ocean floor. However, this group also includes some terrestrial animals: pill bugs and sow bugs. The most abundant crustaceans are the *copepods*, which are typically microscopic. Marine copepods are the most numerous component of zooplankton.

The largest and most familiar order of crustaceans, Decapoda, contains more than 10,000 species of lobsters, crayfish, crabs, and shrimp. Most **decapods** are marine, but a few, such as crayfish, certain shrimp, and a few crabs, live in fresh water. The crustaceans in general and the decapods in particular show striking specialization and differentiation of parts in the various regions of the animal. For example, the appendages in the different parts of the body differ markedly in form and function (FIG. 31-30).

In the lobster the five segments of the head and the eight segments of its thorax are fused into a cephalothorax, which is covered on the top and sides by a shield, the *carapace*, composed of chitin impregnated with calcium salts. The two pairs of antennae serve as chemoreceptors and tactile sense organs. The mandibles are short and heavy, with opposing surfaces used in grinding and biting food. Behind the mandibles are two pairs of accessory feeding appendages: the first and second maxillae.

The appendages of the first three segments of the thorax are the maxillipeds, which aid in chopping up food and passing it to the mouth. The fourth segment of the thorax has a pair of large *chelipeds*, or pinching claws. The last four thoracic segments bear walking legs. Gills for respiration branch dorsally from each of the thoracic appendages.

The appendages of the first abdominal segment are part of the reproductive system and are used by the male to transfer sperm. The following four abdominal segments bear paired *swimmerets*, small paddlelike structures used by some decapods for swimming and by the females of all species for holding eggs. Each branch of the sixth abdominal appendages consists of a large flattened structure. Together with the flattened posterior end of the abdomen, they form a tail fan used for swimming backward.

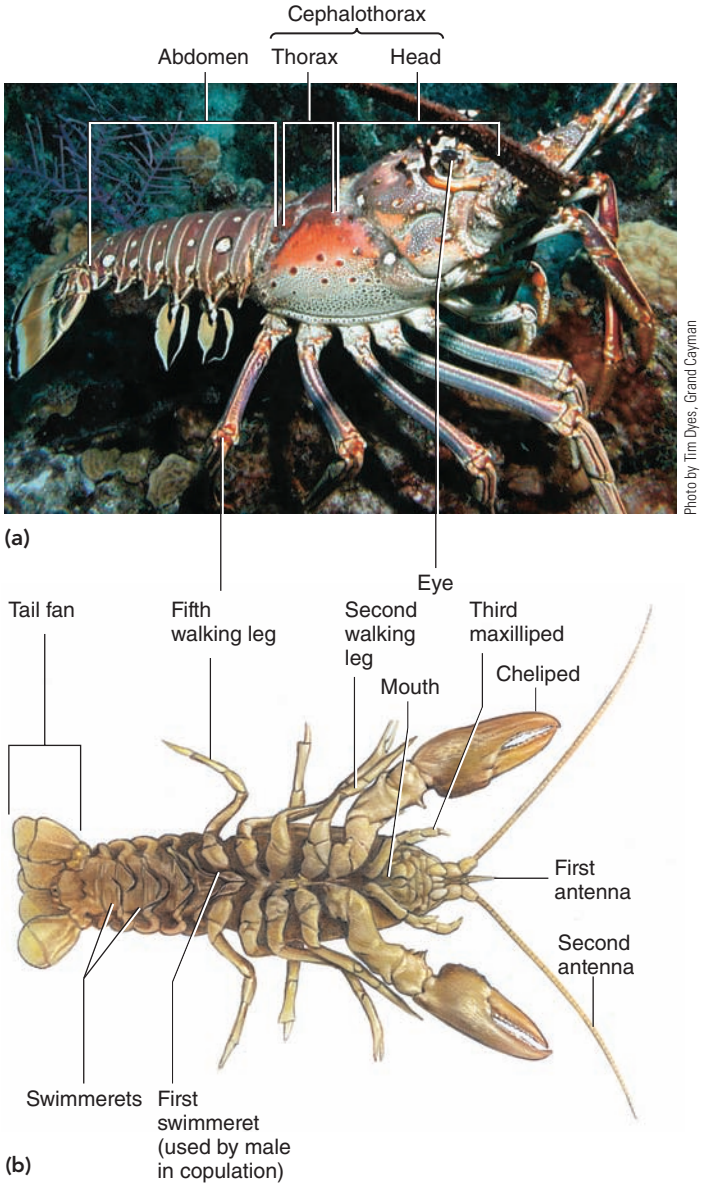

Figure 31-30 Anatomy of the lobster

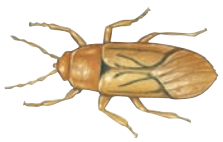
(a) Like other decapods, the spiny lobster (*Panulirus argus*) has five pairs of walking legs. The first pair of walking legs is modified as chelipeds (*large claws*). Photographed in Grand Cayman. **(b)** Ventral view of a lobster. Note the variety of specialized appendages.

Insects are articulated, tracheated hexapods With more than one million described species (and perhaps millions more not yet identified), insects are the most successful group of animals on our planet in terms of number of individuals, number of species, diversity, and geographic distribution (TABLE 31-6). What they lack in size, insects make up in sheer numbers. If we could weigh all the insects in the world, their weight would exceed that of all the remaining terrestrial animals. Although primarily terrestrial, some insect species live in fresh water, a few are truly marine, and others inhabit the shore between the tides.



The earliest fossil insects—primitive, wingless species—date to the Devonian period more than 360 mya. Insect fossils from the Carboniferous period more than 310 mya include both wingless and primitive winged species. Cockroaches, mayflies, and cicadas are among the insects that have survived relatively unchanged from the Carboniferous period to the present day. Hexapods form a very large monophyletic group, the clade **Hexapoda**. We describe insects as *articulated* (jointed), *tracheated* (having tracheal tubes for gas exchange) *hexapods* (having six feet).

The insect body consists of three distinct parts: head, thorax, and abdomen (FIG. 31-31). An insect's uniramous (unbranched) appendages include three pairs of legs that extend from the adult thorax and, in many orders, one or two pairs of wings. One pair of antennae protrudes from the head, and the sense organs include both simple and compound eyes. The complex mouthparts, which include mandibles and maxillae, are adapted for piercing, chewing, sucking, or lapping.

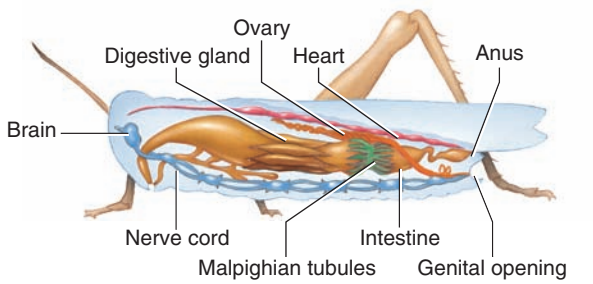
Table 31-6 Some Orders of Insects

Order, Number of Species, Some Characteristics	Representative Adult
HOMOPTERA (43,000)* Leafhoppers, scale insects. Typically, two pairs of membranous wings; piercing-sucking mouthparts form beak; parasites of plants; vectors of plant diseases; incomplete metamorphosis	 Buffalo treehopper *Stictocephala bubalus*
ODONATA (6000) Dragonflies, damselflies. Two pairs of long membranous wings; chewing mouthparts; large, compound eyes; active predators; larvae very different from adult; incomplete metamorphosis	 Damselfly *Ischnura elegans*
ORTHOPTERA (27,000) Grasshoppers, crickets. Forewings leathery, hindwings membranous; chewing mouthparts; most herbivorous, some cause crop damage; some predatory; incomplete metamorphosis	 Fork-tailed bush katydid *Scudderia furcata*
BLATTODEA (4000) Cockroaches. When wings present, forewings leathery, hindwings membranous; chewing mouthparts; legs adapted for running; incomplete metamorphosis	 American cockroach *Periplaneta americana*
ISOPTERA (2500) Termites. Two pairs of wings, or none; wings shed by sexual forms after mating; chewing mouthparts; social insects, form large colonies; eat wood; incomplete metamorphosis	 Eastern subterranean termite *Reticulitermes flavipes*
PHTHIRAPTERA (3000) Lice, sucking lice. No wings; piercing-sucking mouthparts; ectoparasites of mammals; head and body louse and crab louse are human parasites; vectors of typhus fever; incomplete metamorphosis	 Human head and body louse *Pediculus humanus*
HEMIPTERA (85,000) Chinch bugs, bedbugs, water striders; cicadas and aphids. Hindwings membranous; forewings smaller; piercing–sucking mouthparts form beak; most herbivorous; some parasitic; incomplete metamorphosis	 Chinch bug *Blissus leucopterus*
LEPIDOPTERA (160,000) Moths, butterflies. Usually two pairs of membranous, colorful, scaled wings; larvae are wormlike caterpillars with chewing mouthparts for eating plants; adult mouthparts adapted for sucking nectar; complete metamorphosis	 Luna moth *Aetias luna*
DIPTERA (151,000) Houseflies, mosquitoes, fruit flies. Only forewings functional in flying; hindwings reduced to small, knob-like balancing organs (halteres); mouthparts usually adapted for sucking (and piercing in some); larvae are maggots that damage domestic animals or food; adults transmit diseases such as sleeping sickness, yellow fever, and malaria; complete metamorphosis	 Deerfly *Chrysops vittatus*
SIPHONAPTERA (2000) Fleas. No wings; piercing–sucking mouthparts; legs adapted for clinging and jumping; parasites on birds and mammals; vectors of bubonic plague and typhus; complete metamorphosis	 Dog flea *Ctenocephalides canis*
COLEOPTERA (360,000) Beetles, weevil. Forewings modified as protective coverings for membranous hindwings (which are sometimes absent); chewing mouthparts; largest order of insects; most herbivorous; some aquatic; many larvae are grubs; complete metamorphosis	 Colorado potato beetle *Leptinotarsa decemlineata*
HYMENOPTERA (more than 125,000) Ants, bees, wasps. Usually two pairs of membranous wings; mouthparts may be modified for sucking or lapping nectar; many are social insects; some sting; important pollinators; complete metamorphosis	 Bald-faced hornet *Vespula maculata*
ZYGENTOMA (600) Silverfish. No wings; biting–chewing mouthparts; two to three "tails" extend from posterior tip of abdomen; inhabit dead leaves; eat starch in books; direct development	 Silverfish *Lepisma saccharina*



* The number of species listed for each order is approximate. Estimates vary widely.

(a) External structure. Note the three pairs of segmented legs.

(b) Internal anatomy.

Figure 31-31 Anatomy of the grasshopper

Insects, the most successful of all animals, are articulated, tracheated hexapods.

The unique **tracheal system** of insects has made an important contribution to their diversity. Air enters the **tracheal tubes**, or tracheae, through **spiracles**, tiny openings in the body wall. Oxygen passes directly to the internal organs via the tubes branching throughout the body. This effective oxygen delivery system permits insects to have the high metabolic rate necessary for activities such as flight, even though they have an open circulatory system.

Insects excrete metabolic wastes through two or more **Malpighian tubules**. These tubules receive metabolic wastes from the blood, concentrate the wastes, and discharge them into the intestine. Unique to terrestrial arthropods, Malpighian tubules also perform the extremely important function of conserving water (see Fig. 48-4).

The sexes are separate, and fertilization takes place internally. Several molts occur during development. The immature stages between molts are called *instars*. Primitive insects with no wings, such as silverfish, have direct, or simple, development: the young hatch as juveniles that resemble the adult form. Other insects, such as grasshoppers and cockroaches, undergo **incomplete metamorphosis** in which the egg gives rise to a larva that resembles the adult in many ways but lacks functional wings and reproductive structures. The larva goes through a series of molts during which it becomes more and more like the adult.

Most insects, including bees, butterflies, and fleas, undergo **complete metamorphosis** with four distinct stages in the life cycle: *egg, larva, pupa*, and *adult* (FIG. 31-32). The wormlike larva does not look at all like the adult. For example, caterpillars have a body form entirely different from that of butterflies. Typically, an insect spends most of its life as a larva, which has chewing mouthparts. Eventually, the larva stops feeding, molts, and enters a pupal stage, usually within a protective cocoon or underground burrow. The **pupa** does not feed and typically cannot defend itself. Energy reserves stored during the larval stage are spent remodeling its body. When it emerges as an adult, it is equipped with functional wings and reproductive organs.

Certain species of bees, ants, and termites live as colonies or societies made up of several different types of individuals, each adapted for some particular function. Insects communicate by tactile, auditory, visual, or chemical signals. The members of some insect societies communicate with one another by "dances." Insects also communicate by means of **pheromones**, hormonelike molecules secreted to the external environment that influence the behavior (or development) of members of the same species. For example, certain ant species use pheromones to mark trails and to warn of danger. Many insects use pheromones to attract mates. Social insects and their communication are discussed in Chapter 52.

Adaptations that contribute to the biological success of insects What are the secrets of insect success? The tough exoskeleton protects insects from predators and helps reduce water loss. Segmentation allows mobility and flexibility and permits regional specialization of the body. For example, cephalization and highly developed sense organs are important in both offense and defense.

The insect body plan has been modified and specialized in so many ways that insects are adapted to a remarkable number of lifestyles. The jointed appendages are specialized for various types of feeding, sensory functions, and different types of locomotion (walking, jumping, swimming). For example, grasshopper mouthparts are adapted for biting and chewing leaves. Moth and butterfly mouthparts are adapted for sucking nectar from flowers, and mosquito mouthparts are adapted for sucking blood. Aphids and leafhoppers have mouthparts specialized to pierce plants and feed on plant juices.

Another adaptation that contributes to insect success is the ability to fly. Unlike other terrestrial invertebrates, which creep slowly along on or under the ground, many insects fly rapidly through the air. Their wings and small size facilitate their wide distribution and, in many instances, their immediate survival. For example, when a pond dries up, adult aquatic insects can fly to another habitat.

The reproductive capacity of insects is remarkable. Under ideal conditions, the fruit fly *Drosophila* can produce 25 generations in a single year! Insect eggs are protected by a thick membrane. In addition, several eggs may be enclosed in a protective egg case. By dividing the insect life cycle into different stages, complete metamorphosis reduces competition among members of the same species (intraspecific competition). For example, larval forms have different lifestyles, so they do not compete with adults for food or habitats.

Insects have many interesting adaptations for offense and defense (see Fig. 7-8). We all are familiar with the stingers of bees and wasps, which are specialized egg-laying structures (ovipositors). Many insects have **cryptic coloration**, which makes them appear as dead twigs or leaves. They blend into the background of their habitat, avoiding predators. Others mimic poisonous insects, deriving protection from this resemblance. Still others "play dead" by remaining motionless.

Key Point

Complete metamorphosis reduces competition among insects within the same species; larval forms do not compete with adults for food or habitats.

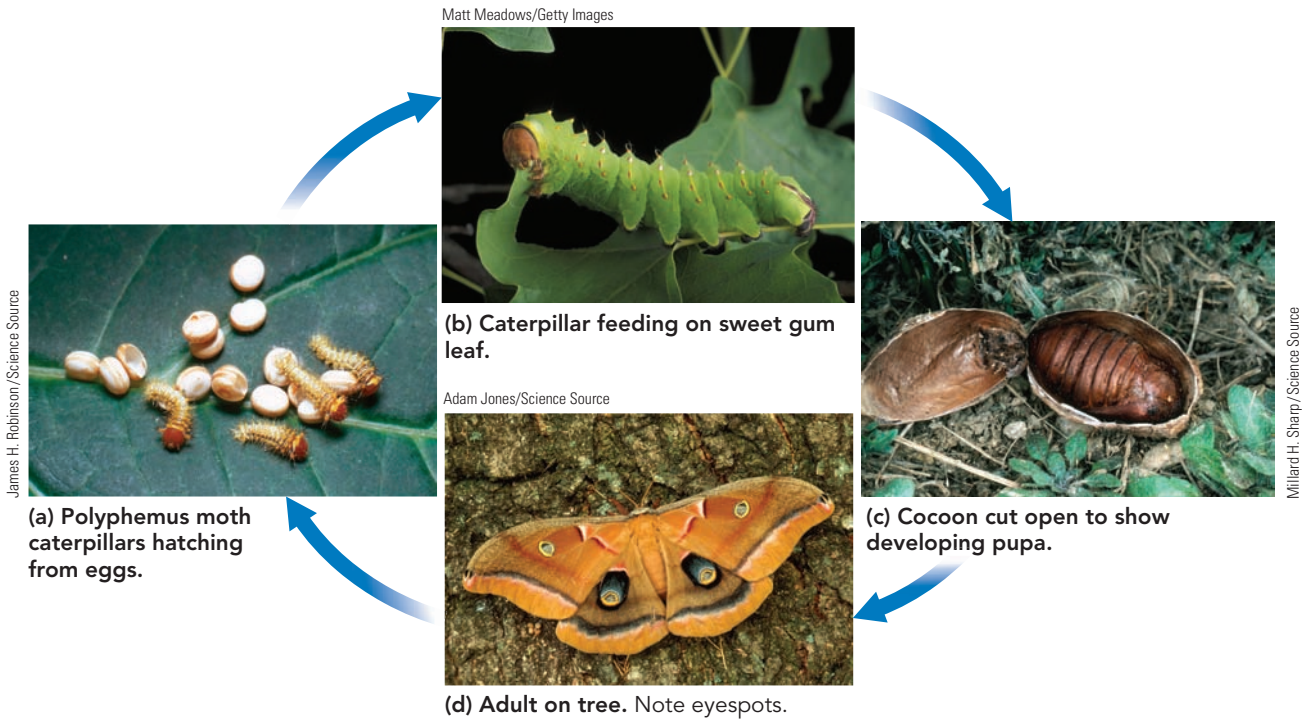

Figure 31-32 Complete metamorphosis in a Polyphemus moth
Insects, the most successful of all animals, are articulated, tracheated hexapods. This moth (*Antheraea polyphemus*) belongs to the family of giant silk moths.

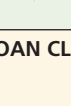
CONNECT Which of the following stages is haploid? diploid? (1) embryo developing in egg, (2) larva, (3) pupa, (4) adult

Impact of insects on humans Not all insects compete with humans for food or cause us to scratch, swell up, or recoil from their presence. Bees, wasps, beetles, and many other insects pollinate the flowers of crops and fruit trees. Some insects destroy other insects that are harmful to humans. For example, dragonflies eat mosquitoes. And many organic farmers and home gardeners buy ladybird beetles, which are adept at ridding plants of aphids and other insect pests. Insects are important members of many food webs. Many species of birds, mammals, amphibians, reptiles, and fishes depend on insects for food. Some beetles and the larvae (maggots) of flies are detritus feeders: they break down dead plants and animals and their wastes, permitting nutrients to be recycled.

Various insect products are useful to humans. Bees produce honey as well as beeswax, which we use to make candles, lubricants, and other products. Shellac is made from lac, a substance given off by certain scale insects that feed on the sap of trees. And the labor of silkworms provides us with beautiful fabric.

On the negative side, each year insects destroy crops worth billions of dollars. Fire ants not only inflict painful stings but cause farmers serious economic loss because of their large mounds, which damage mowers and other farm equipment. Moths damage clothing, and termites destroy buildings. Blood-sucking flies, screwworms, lice, fleas, and other insects annoy and transmit disease to humans and domestic animals. Mosquitoes are vectors of yellow fever and malaria (see Fig. 26-7). Fleas and lice transmit the rickettsia that cause typhus, and houseflies sometimes transmit typhoid fever and dysentery. Tsetse flies transmit African sleeping sickness, and fleas may be vectors of bubonic plague.

In this chapter we have surveyed the major groups of protostomes. TABLE 31-7 summarizes these groups. Chapter 32 focuses on the deuterostomes, which include the echinoderms and chordates.



CHECKPOINT 31.3

- **CONNECT** What characteristics distinguish nematodes from flatworms?
- **CONNECT** Describe four key arthropod characteristics, and explain how each contributes to arthropod success.
- How do crustaceans differ from chelicerates?
- **CONNECT** Describe four adaptations that have contributed to insect success.

Table 31-7 Overview of Sponges, Cnidarians, Ctenophores, and Protostomes

Major Groups		Body Plan	Some Key Characteristics
Poriferans (sponges)		Asymmetrical; cells loosely arranged and do not form true tissues; body is sac with pores, central cavity, and osculum	Collar cells (choanocytes); aquatic, mainly marine
Cnidarians **Medusozoans** Hydras, jellyfish **Anthozoans** Sea anemones, corals	 	Radial symmetry; diploblastic; gastrovascular cavity with one opening	Tentacles with cnidocytes (stinging cells) that discharge nematocysts; two body forms: polyp and medusa; some form colonies; mainly marine
Ctenophores (comb jellies)		Biradial symmetry; diploblastic; digestive system with mouth and anal pores	Eight rows of cilia that resemble combs; tentacles with adhesive glue cells; marine predators
PROTOSTOMES: LOPHOTROCHOZOAN CLADE			
Flatworms **Free-living** Planarians **Parasitic** Flukes, tapeworms		Bilateral symmetry; triploblastic; simple organ systems; gastrovascular cavity with one opening	No body cavity; some cephalization; some are free-living predators; many are parasites
Nemerteans (ribbon worms)		Bilateral symmetry; triploblastic; organ systems; complete digestive tube*	Proboscis (long, muscular tube that can be everted to capture prey); true coelom reduced; mainly marine predators
Mollusks **Chitons** **Gastropods** Snails, slugs **Bivalves** Clams, oysters **Cephalopods** Squids, octopuses		Bilateral symmetry; triploblastic; organ systems; complete digestive tube; true coelom	Soft body typically covered by dorsal shell; flat, muscular foot; mantle covers visceral mass; most have a radula (belt of teeth); most are marine
Annelids **Errantians** Marine worms **Sendentarians** Earthworms, leeches		Bilateral symmetry; triploblastic; organ systems; complete digestive tube; true coelom	Segmented body; most have setae, bristles that provide traction during crawling
Lophophorates Brachiopods, phoronids, bryozoans		Bilateral symmetry; triploblastic; organ systems; complete digestive tube; true coelom	Lophophore (ring of ciliated tentacles) surrounds mouth, captures suspended particles in water; mainly sessile, marine animals
Rotifers (wheel animals)		Bilateral symmetry; triploblastic; organ systems; complete digestive tube; pseudocoelom	Crown of cilia at anterior end; cell number constant; microscopic, aquatic animals
PROTOSTOMES: ECDYSOZOAN CLADE			
Nematodes (roundworms) *Ascaris*, hookworms, trichina worms		Bilateral symmetry; triploblastic; organ systems; complete digestive tube; pseudocoelom	Cylindrical, threadlike body; widely distributed in soil and aquatic sediments; important as decomposers; many are predators; some are parasites
Arthropods **Myriapods** Centipedes, millipedes **Chelicerates** Horseshoe crabs, spiders **Pancrustaceans** Crustaceans, hexapods (insects)		Bilateral symmetry; triploblastic; organ systems; complete digestive tube; true coelom	Segmented body; exoskeleton; paired, jointed appendages; insects and many crustaceans have compound eyes; insects have tracheal tubes for gas exchange; wings

* A complete digestive tube has a mouth for food intake and an opening (anus) for elimination of wastes.

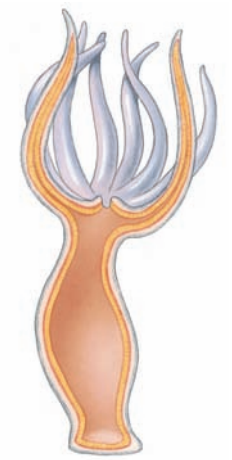
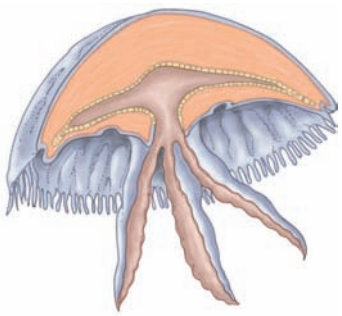
Summary: Focus on Learning Objectives



31.1 Sponges, Cnidarians, and Ctenophores *(page 642)*

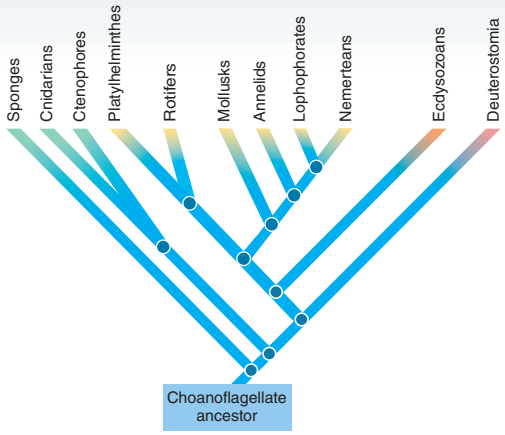


1 Identify important characteristics of poriferans.

- The **poriferans**, or sponges, are characterized by flagellate **collar cells (choanocytes)**, which generate a water current that brings food and oxygen to the cells. Collar cells also trap and phagocytize food particles. The sponge body is a sac with tiny openings through which water enters; a central cavity, or **spongocoel**; and an open end, or **osculum**, through which water exits. The cells of sponges are loosely associated; they do not form true tissues.

2 Identify distinguishing characteristics of cnidarians, describe their two main clades, and list animals that belong to each clade.

- **Cnidarians** are characterized by radial symmetry, two tissue layers, and **cnidocytes**, cells containing stinging organelles called **nematocysts**. The **gastrovascular cavity** has a single opening that serves as both mouth and anus. Nerve cells form irregular, nondirectional **nerve nets** that connect sensory cells with contractile and gland cells.
- The life cycle of many cnidarians includes a sessile **polyp** stage (a form with a dorsal mouth surrounded by tentacles) and a free-swimming **medusa** (jellyfish) stage.
- The cnidarians form two major clades: medusozoans and anthozoans. Medusozoans include *hydrozoans* (hydras and jellyfish). Jellyfish are generally medusae. *Anthozoans* (sea anemones and corals) are polyps and may be solitary or colonial; anthozoans differ from hydrozoans in the organization of the gastrovascular cavity.



3 Identify characteristics of ctenophores.

- **Ctenophores**, or *comb jellies*, are fragile, luminescent marine predators with biradial symmetry. Ctenophores have eight rows of cilia that resemble combs. They are diploblastic and have tentacles with adhesive glue cells.

31.2 The Lophotrochozoa *(page 649)*

4 Summarize what is known about the phylogeny of the lophotrochozoans and cite the adaptive advantages of having a coelom and of cephalization.

- The **Lophotrochozoa** make up a clade that includes flatworms, nemerteans, mollusks, annelids, the lophophorate phyla, and rotifers.

- The true **coelom** is a fluid-filled body cavity completely lined by mesoderm that lies between the digestive tube and the outer body wall. The coelom brings about the *tube-within-a-tube body plan*. The body wall is the outer tube. The inner tube is the digestive tube. The coelom can serve as a **hydrostatic skeleton** in which contracting muscles push against a tube of fluid. The coelom is a space in which internal organs, including gonads, can develop; it helps transport materials and protects internal organs.
- **Cephalization**, the evolution of a head with the concentration of sense organs and nerve cells at the anterior end, increases the effectiveness of a bilateral animal to actively find food, shelter, and mates and to detect enemies.

5 Identify distinguishing characteristics of flatworms and nemerteans, and describe the main groups of flatworms, giving examples of animals that belong to each.

- The *flatworms* are **acoelomate** (have no coelom) animals with bilateral symmetry, cephalization, three definite tissue layers, and well-developed organs. Many flatworms are **hermaphrodites**: a single animal produces both sperm and eggs. Flatworms have a ladder-type nervous system, typically consisting of sense organs and a simple brain composed of two **ganglia**. The ganglia are connected to two nerve cords that extend the length of the body. **Protonephridia** function in osmoregulation and disposal of metabolic wastes.
- Two main flatworm clades are recognized: A free-living clade, the turbellarians, includes planarians. The parasitic clade includes the trematodes and monogeneans (*flukes*) and *cestodes*, the tapeworms.
- The parasitic flukes and tapeworms typically have suckers or hooks for holding on to their hosts; they have complicated life cycles with intermediate hosts and produce large numbers of eggs.
- **Nemerteans** (ribbon worms) are characterized by the *proboscis*, a muscular tube used in capturing food and in defense. Nemerteans have a complete digestive tract with mouth and anus, and a circulatory system. The coelom is reduced.

6 Describe the main characteristics of mollusks and of the four clades of mollusks discussed, giving examples of each group.

- **Mollusks** are soft-bodied animals typically covered by a shell. They have a ventral *foot* for locomotion and a pair of folds called the **mantle** that covers the **visceral mass**, a concentration of body organs.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

- Mollusks have an **open circulatory system**, except for cephalopods, which have a **closed circulatory system**. A rasplike **radula** functions as a scraper in feeding in all groups except the bivalves, which are filter feeders. Typically, marine mollusks have free-swimming, ciliated **trochophore larvae**.
- Four mollusk clades are chitons, gastropods, bivalves, and cephalopods. **Chitons** have a dorsal shell consisting of eight overlapping dorsal plates. **Gastropods** include the snails, slugs, and their relatives. They have a well-developed head with tentacles and eyes. The body undergoes **torsion**, a twisting of the visceral mass.
- **Bivalves** are aquatic clams, scallops, and oysters. A two-part shell, hinged dorsally, encloses the bodies of these filter feeders. **Cephalopods** include the squids, octopuses, and *Nautilus*. These active, predatory swimmers have tentacles surrounding the mouth, which is located in the large head.

7 Describe the principal characteristics of annelids and of the two clades of annelids discussed, giving examples of each group.

- The **annelids**, the segmented worms, include many aquatic worms, earthworms, and leeches. Annelids have long bodies with **segmentation** both internally and externally; their large, compartmentalized coelom serves as a hydrostatic skeleton.
- **Errantians** and **sedentarians** make up the two annelid clades. Sandworms and tubeworms make up the errantian clade. These *polychaetes* are marine annelids characterized by **parapodia**, appendages used for locomotion and gas exchange. The parapodia bear many bristlelike structures called **setae**. Polychaetes also differ from other annelids in having a well-defined head with sense organs.
- Earthworms and leeches are sedentarians. *Oligochaetes*, the group that includes the earthworms, are characterized by a few short setae per segment. The body is divided into more than one hundred segments separated internally by **septa**. Earthworms are hermaphroditic.
- Leeches do not have setae or appendages. Parasitic leeches are equipped with suckers for holding on to their host.

8 Describe the distinguishing characteristics of the lophophorates and of the rotifers.

- The **lophophorates**, marine animals that have a lophophore, include the *brachiopods, phoronids*, and *bryozoans*. The *lophophore*, a ciliated ring of tentacles surrounding the mouth, is specialized for capturing suspended particles in the water.
- *Rotifers* are pseudocoelomates that are thought to have evolved from animals with a true coelom. They have a crown of cilia at their anterior end.

31.3 The Ecdysozoa *(page 662)*

9 Summarize what is known about the phylogeny of the ecdysozoans.

- **Ecdysozoa** is one of the three major animal clades; its validity is based on many types of evidence, including molecular data. Members of this group go through the process of **ecdysis**, or **molting**, during which an animal sheds its outer covering; the covering is replaced by the growth of a new one.

10 Describe characteristics of nematodes and identify four parasitic nematodes.

- **Nematodes**, or *roundworms*, have a pseudocoelom. The body is covered by a tough **cuticle** that helps prevent desiccation. Parasitic nematodes that infect humans include *Ascaris, hookworms, trichina worms,* and *pinworms*.

11 Describe six key characteristics of arthropods, summarize proposed phylogeny of arthropods, and distinguish among arthropod clades; give examples of animals that belong to each group.

- **Arthropods** are segmented protostomes with *paired, jointed appendages* and an armorlike **exoskeleton** of chitin. Molting is necessary for the arthropod to grow. Arthropods have an open circulatory system with a dorsal heart that pumps **hemolymph**. Aquatic forms have gills for gas exchange; terrestrial forms have either **tracheae** or *book lungs*.
- Based on molecular and other data, arthropods are currently assigned to three clades: **myriapods**, **chelicerates**, and **pancrustaceans**.
- The *trilobites* are extinct marine arthropods covered by a hard, segmented shell. Each segment had a pair of **biramous appendages**, appendages with two jointed branches: an inner walking leg and an outer gill branch.
- The myriapods include centipedes and millipedes. Members of this clade have **uniramous appendages**, that is unbranched appendages, and a single pair of antennae.
- The *merostomes* (horseshoe crabs) and the **arachnids** (spiders, mites, and their relatives) are chelicerates. The chelicerate body consists of a cephalothorax and abdomen; there are six pairs of uniramous, jointed appendages, of which four pairs serve as legs. The first appendages are **chelicerae**, and the second are *pedipalps*. These appendages are adapted for manipulation of food, locomotion, defense, or copulation. Chelicerates have no antennae and no mandibles.
- **Pancrustaceans** are a very large clade that includes crustaceans and insects (hexapods). Lobsters, crabs, shrimp, pill bugs, and barnacles, and their many relatives are familiar crustaceans. The crustacean body typically consists of a cephalothorax and abdomen. Crustaceans vary greatly in the appearance and in the number of biramous appendages. Crustaceans have two pairs of **antennae** that sense taste and touch, and a pair of **mandibles** used for chewing. Two pairs of **maxillae**, posterior to the mandibles, manipulate and hold food. The decapod crustaceans typically have five pairs of walking legs.
- An insect is an *articulated, tracheated hexapod*; its body consists of head, thorax, and abdomen. Insects have uniramous appendages, a single pair of antennae, **tracheae** for gas exchange, and **Malpighian tubules** for excretion.

12 Identify adaptations that have contributed to the biological success of insects.

- The biological success of the insects can be attributed to their many adaptations, including a versatile exoskeleton, segmentation, specialized jointed appendages, highly

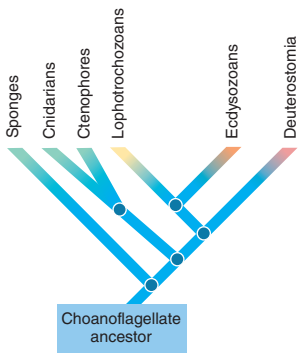
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

developed sense organs, and ability to fly. **Complete metamorphosis**, transition during the life cycle from one developmental stage to another, includes egg, larva, pupa, and adult stages. Complete metamorphosis reduces competition within the same species. Effective reproductive strategies, effective mechanisms for defense and offense, and the ability to communicate have evolved in insects.

Test Your Understanding

Know and Comprehend



1. Collar cells (choanocytes) are characteristic of (a) poriferans (b) cnidarians (c) most coelomates (d) lophotrochozoans (e) ecdysozoans
2. Cnidocytes (a) are characteristic of sponges (b) are found among cells lining the gastrovascular cavity (c) contain stinging organelles (d) are lined with mesoderm (e) have two main shapes
3. Which of the following is associated with the evolution of the coelom? (a) radial symmetry (b) tube-within-a-tube body plan (c) incomplete metamorphosis (d) bilateral symmetry (e) development of ganglia
4. Trochophore larvae are characteristic of (a) arthropods (b) cnidarians (c) flatworms (d) mollusks (e) crustaceans
5. Which of the following is *not* an adaptation to parasitic life? (a) production of a few well-protected eggs (b) hooks (c) suckers (d) reduced digestive system (e) intermediate host
6. An open circulatory system (a) is characteristic of squids and other active mollusks (b) permits contracting muscles to recover quickly (c) has no blood vessels (d) is a unique characteristic of annelids (e) has hemolymph, which bathes tissues directly
7. Which of the following characteristics is associated with mollusks? (a) mandibles (b) mantle (c) pedipalps (d) chelipeds (e) setae
8. Trilobites (a) were early mollusks (b) are onychophorans (c) are characterized by parapodia and setae (d) were early arthropods (e) are an evolutionary link between annelids and arthropods
9. Which of the following is *not* characteristic of arthropods? (a) exoskeleton (b) pseudocoelom (c) paired, jointed appendages (d) chitin (e) segmentation
10. Which of the following is characteristic of insects? (a) biramous appendages (b) two pairs of antennae (c) chelicerae (d) eight legs (e) mandibles

Apply and Analyze

11. The correct sequence of complete metamorphosis of an insect is (a) egg → immature form → adult (b) egg → trochophore larva → adult (c) egg → pupa → larva → adult (d) egg → larva → pupa → adult (e) adult → larva → egg → pupa
12. **VISUALIZE** Draw a cross section through a hydra. Label the epidermis, gastrodermis, gastrovascular cavity, and mesoglea.
13. **EVOLUTION LINK** Discuss important adaptations made possible by the development of the coelom.
14. **EVOLUTION LINK** Discuss the idea that every evolutionary adaptation has both advantages and disadvantages, using each of the following as an example: (a) cephalization, (b) the arthropod exoskeleton, and (c) segmentation with specialization.

Evaluate and Synthesize

15. **INTERPRET DATA** Imagine that you discover a new animal in a rain forest. It has an elongated, segmented body with bristles, and it has no obvious head. Where would you place this animal in the accompanying cladogram? Support your decision. Look at the more detailed cladogram in Figure 30-6a (in Chapter 30). What additional characteristics would help you place your animal in this cladogram? Explain your decision-making process.

16. **EVOLUTION LINK** Why have biologists stopped using type of body cavity as a major criterion for inferring relationships among animal groups?
17. **EVOLUTION LINK** Animal body plans have generally evolved from simple to more complex. How can we explain the exceptions?
18. **EVOLUTION LINK** Insects that undergo complete metamorphosis outnumber those that do not by more than 10 to 1. Hypothesize an explanation.
19. **SCIENCE, TECHNOLOGY, AND SOCIETY** Several international monitoring projects are gathering data to help us understand coral reef destruction. In your opinion, why is it important to take action to protect coral reefs? What role might technology play?

32 The Deuterostomes

KEY CONCEPTS

32.1 Echinoderms and chordates are the two most successful deuterostome lineages in terms of diversity, number of species, and number of individuals.

32.2 Echinoderms are characterized by radial symmetry in adults, a water vascular system, tube feet, and spiny skin.

32.3 At some time in its life, a chordate has a notochord; a dorsal, tubular nerve cord; a muscular postanal tail; and an endostyle (or thyroid gland).

32.4 Invertebrate chordates include tunicates and lancelets.

32.5 Shared derived characters of vertebrates include a vertebral column, a cranium, neural crest cells, and an endoskeleton of cartilage or bone.

32.6 Among the earliest vertebrates, ostracoderms were armored, jawless fishes. The extant hagfishes and lampreys have neither jaws nor paired fins.

32.7 Jaws and fins were key adaptations that contributed to the success of jawed fishes; the evolution of limbs was important in the transition to terrestrial life.

32.8 The evolution of the amniotic egg allowed animals to become fully terrestrial; the amniotic egg was the key adaptation leading to the evolution of reptiles and, later, to birds and mammals.

What does a sea star have in common with a fish, frog, hawk, or human? You may think it strange to group the echinoderms—the sea stars, sea urchins, and sand dollars—with the chordates, the clade (phylum) that includes humans and other animals with a vertebral column. However, even though these animals look and behave very differently from one another, fossil evidence and morphological, developmental, and molecular data suggest that chordates and echinoderms share a common ancestor and are closely related.

In Chapter 31 we discussed the two major protostome branches of the animal kingdom: the lophotrochozoans and the ecdysozoans. In this chapter we focus on the third major branch of the animal kingdom, the **deuterostomes**. Some biologists speculate that the last common ancestor of the deuterostomes was an animal that obtained food by filtering ocean water. The two major groups (phyla) of living animals assigned to the deuterostomes are the echinoderms (a group that includes sea stars and sea urchins) and the chordates. The largest chordate clade (subphylum) is Vertebrata, which includes the animals with which we are most familiar: fishes, amphibians, reptiles (including birds), and mammals. The Galápagos marine iguana is a reptile, a member of the vertebrate clade, that has many interesting adaptations (see photograph).

We begin this chapter with an introduction to the deuterostomes and a survey of the echinoderms. We then turn our attention to the chordates. We describe the key chordate characteristics

PHOTO: The Galápagos marine iguana (*Amblyrhynchus cristatus*), the only known marine lizard. This iguana lives on land and feeds along the shore and in the ocean. It is adapted to ingesting salt in its diet of red and green algae. It shoots out salty water through its nostrils. You can see encrusted salt as a white cap on its head. Charles Martin

and discuss the invertebrate chordates. After an introduction to the vertebrates, we discuss jawless fishes and the evolution of jaws, and later the origin of vertebrates with limbs. We discuss the evolution of the adaptations that made the transition to life on land possible. We then describe the evolution of amniotes, which encompasses reptiles (including birds) and mammals.

32.1 What Are Deuterostomes?

LEARNING OBJECTIVE

1 Identify shared derived characters of deuterostomes and briefly describe the hemichordates.

The deuterostomes (clade Deuterostomia) make up the third major branch of the animal kingdom. Deuterostomes include the *echinoderms*—the sea stars, sea urchins, and sand dollars—and the *chordates*, the phylum that includes humans and other *vertebrates* (animals with a vertebral column and bony cranium). Biologists also classify the **hemichordates**, a small group of wormlike marine animals, as deuterostomes. Hemichordates have a three-part body made up of a proboscis, collar, and trunk. These animals also have a characteristic ring of cilia surrounding the mouth. The most familiar of the hemichordates are the *acorn worms*, animals that live buried in mud or sand.

Deuterostomes evolved from a common ancestor during the Proterozoic eon more than 550 million years ago (mya). The major groups were present during the Early Cambrian period. Deuterostomes are characterized by several **shared derived characters** (synapomorphic characters), evolutionary novelties present in their most recent common ancestor (see Chapter 23). Evidence for the relatedness of the chordates, hemichordates, and echinoderms comes from molecular data and patterns of embryonic development. For example, deuterostomes are characterized by radial, rather than spiral, cleavage (see Chapter 30). Their cleavage is indeterminate, which means that the fate of their cells is fixed later in development than is the case in protostomes. In deuterostomes the mouth does not develop from the blastopore as in protostomes. The blastopore of deuterostomes becomes the anus (or is located near the future site of the anus), and the mouth develops from a second opening at the anterior end of the embryo, thus the name *deuterostome*, which is derived from the Greek words for "second mouth."

At some time in their life cycle, most deuterostomes develop *pharyngeal slits*, openings that connect the pharynx with the outside environment. Although there is evidence that some early echinoderms had pharyngeal slits, the extant (living) echinoderms have lost this character. *Basal deuterostomes* (members of the earliest deuterostome group to evolve) have a type of larva with a loop-shaped band of cilia used for locomotion. Deuterostomes have a true coelom.

CHECKPOINT 32.1

- What are three shared derived characters of deuterostomes?

32.2 Echinoderms

LEARNING OBJECTIVE

2 Identify three shared derived characters of echinoderms and describe the main clades (classes) of echinoderms.

The **echinoderms** (clade [phylum] *Echinodermata*) have one of the most highly derived body plans in the animal kingdom. With their unusual symmetry, spiny skins, water vascular system, and tube feet, echinoderms are one of the most unique animal groups. Echinoderm larvae are bilaterally symmetrical, ciliated, and free-swimming. However, during development the body reorganizes, and the adult exhibits *pentaradial symmetry*, in which the body is arranged in five parts around a central axis. Biologists have hypothesized that early echinoderms were sessile and that radial symmetry evolved as an adaptation to that lifestyle. Their radial symmetry allows these animals to respond effectively in every direction of their surrounding environment.

The most unique derived character of echinoderms is the **water vascular system**, a network of fluid-filled canals and chambers. In the sea star, for example, sea water enters through small pores in the *madreporite*, a sievelike structure on the body surface. Cilia lining the canals of the system move the water along. Branches of the water vascular system lead to numerous tiny **tube feet** that extend when filled with fluid. Each tube foot receives fluid from the main system of canals. A rounded muscular sac, or **ampulla**, at the base of the foot stores fluid and is used to operate the tube foot. A valve separates each tube foot from other parts of the system. When the valve shuts, the ampulla contracts, forcing fluid into the tube foot. The fluid causes the tube foot to extend. At the bottom of the foot, a suction-type structure presses against and adheres to whatever surface the tube foot is on. The water vascular system functions in feeding and gas exchange, and it serves as a hydrostatic skeleton important in locomotion.

Another unique echinoderm character is the **endoskeleton**, an internal skeleton, covered by a thin, ciliated epidermis. The endoskeleton consists of calcium carbonate ($CaCO_3$) plates and spines. The name *Echinodermata*, derived from words meaning "spiny skinned," was inspired by the spines that project outward from the endoskeleton. Some groups have pincer-like, modified spines called *pedicellariae* on the body surface. These structures, found only among the echinoderms, keep the surface of the animal free of debris.

Echinoderms have a well-developed coelom, containing coelomic fluid that transports materials. Although its structure varies in different groups, the complete digestive system is the most prominent body system. A variety of respiratory structures are found in the various clades. No excretory organs are present. Echinoderms have no brain. The nervous system is simple, generally consisting of a nerve ring with nerves that extend out from it. The sexes are usually separate, and eggs and sperm are generally released into the water, where fertilization takes place.

The fossil evidence suggests that echinoderms evolved from bilaterally symmetrical ancestors, probably during the Early Cambrian period. They achieved maximum diversity by the middle of the Paleozoic era, about 400 mya. By the beginning of

the Mesozoic era 252 mya, they had declined, leaving five main groups that have survived to the present day. Biologists have identified about 7000 living and more than 13,000 extinct species.

All echinoderms inhabit marine environments. They are found in the ocean at all depths. We consider the five extant clades: clade (class) Crinoidea, sea lilies and feather stars; clade (class) Asteroidea, sea stars; clade (class) Ophiuroidea, basket stars and brittle stars; clade (class) Echinoidea, sea urchins and sand dollars; and clade (class) Holothuroidea, sea cucumbers (TABLE 32-1 and FIG. 32-1).

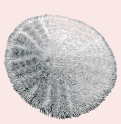
Feather stars and sea lilies are suspension feeders

Feather stars and sea lilies (clade *Crinoidea*) are the oldest living echinoderms (see Fig. 32-1a). Although many extinct crinoids are known, relatively few living species have been identified. The feather stars are motile, although they often remain in the same location for long periods. Sea lilies are sessile and remain attached to the ocean floor by a stalk.

Crinoids are suspension feeders. The movement of the surrounding water brings food to them. Several branched, feathery arms extend upward. Numerous tube feet shaped like small tentacles are located along the feathery arms. These tube feet are coated with mucus that traps microscopic organisms. The *oral surface* (location of the mouth) is on the upper side of the disc. In all other echinoderms, the mouth is located on the underside of the disc, facing the ocean floor.

Many sea stars capture prey

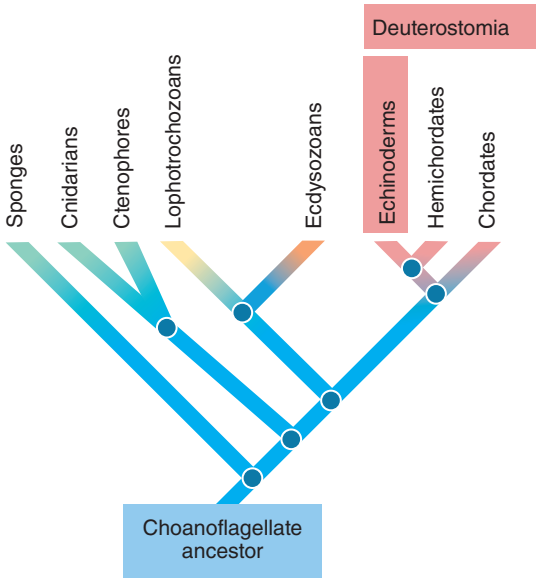
Sea stars (commonly called starfish) are asteroids (clade *Asteroidea*; see Fig. 32-1b). Their bodies consist of a central disc from which extend 5 to more than 20 arms, or rays (FIG. 32-2). The undersurface of each arm has hundreds of pairs of tube feet. The endoskeleton consists of a series of calcareous plates that permit some movement of the arms. Delicate dermal gills, small extensions of the body wall, carry on gas exchange. The mouth lies in the center of the underside of the disc.



Most sea stars are predators and scavengers that feed on cnidarians, crustaceans, mollusks, annelids, and even other echinoderms. A few species may catch small fish. The sea star's water vascular system does not permit rapid movement, so its prey usually consists of stationary or slow-moving animals, such as clams.

To attack a clam or other bivalve mollusk, the sea star mounts it and assumes a humped position as it straddles the edge opposite the hinge. Then, holding itself in position with its tube feet, the sea star slides its thin, flexible stomach out through its mouth and between the closed, or slightly gaping, valves (shell parts) of the clam. While the clam is still in its own shell, the sea star secretes enzymes that digest the soft parts of the clam to the consistency of a thick soup. When the partly digested meal is taken into the sea star body, it is further digested by enzymes secreted by digestive glands located in each arm.

The circulatory system in sea stars is poorly developed and probably of little help in transporting materials. Instead, the coelomic fluid, which fills the large coelom and bathes the internal tissues, assumes this function. Metabolic wastes pass to the outside by diffusion across the tube feet and dermal gills. The nervous system consists of a ring of nervous tissue encircling the mouth and a nerve extending from this ring into each arm.



Sea daisies are a curious group of asteroids characterized by small, disc-shaped, flat bodies (less than 1 cm in diameter) with no arms or mouth. They inhabit bacteria-rich wood sunk in deep water and apparently absorb bacteria through their body surface.

Table 32-1 Echinoderms Clades

Clade and Representative Animals		Characteristics
CRINOIDEA Feather stars, sea lilies		Feather stars motile; sea lilies, sessile, attach to ocean floor by stalk; oral surface on upper side of disc; tube feet along feathery arms trap microscopic organisms
ASTEROIDEA Sea stars		Arms (rays) extend from central disc; tube feet on undersurface of each arm; mouth in center of underside of disc; carnivorous predators and scavengers
OPHIUROIDEA Basket stars, brittle stars		Resemble sea stars, but arms long, slender, and more set off from central disc; tube feet used to collect and handle food
ECHINOIDEA Sea urchins, sand dollars		Skeletal plates flattened and fused to form a shell-like test; sand dollars burrow in sand and feed on organic particles; sea urchins graze on algae
HOLOTHUROIDEA Sea cucumbers		Body is elongated, muscular sac; mouth surrounded by tentacles that are modified tube feet; sluggish animals that live on sea bottom; many species eject organs when conditions are poor; for defense, can eject tubules out of anus

(a) A sea star viewed from above, with its arms in various stages of dissection. Similar structures are present in each arm, but some organs are not shown so as to highlight certain other structures. The two-part stomach is in the central disc with the anus on the aboral (*upper*) surface and the mouth beneath on the oral surface. **(b)** Cross section through arm and tube feet. **(c)** LM of underside of a sea star, showing its tube feet.

Basket stars and brittle stars make up the largest group of echinoderms

Basket stars and brittle stars (serpent stars) make up the largest clade of echinoderms (clade *Ophiuroidea*) both in number of species and individuals (see Fig. 32-1c). These animals resemble sea stars in that their bodies consist of a central disc with arms. However, the arms are long and slender and more sharply set off from the central disc than those of sea stars. Some brittle stars use their arms for locomotion, making rowing movements. Their tube feet lack suckers; they may be used to collect and handle food and may also serve a sensory function, perhaps that of taste.

Sea urchins and sand dollars have movable spines

Sea urchins and sand dollars (clade *Echinoidea*) have no arms (see Fig. 32-1d). Their skeletal plates are flattened and fused to form a solid shell called a test. The flattened body of the sand dollar is adapted for burrowing in the sand, where it feeds on tiny organic particles. Sand dollars have smaller spines than sea urchins.

Many sea urchins graze on algae, scraping the sea floor with their calcareous teeth. Sea urchins use their tube feet for locomotion. They also push themselves along with their movable spines. In some species the spines covering the body can penetrate flesh and are difficult to remove. So threatening are these spines that swimmers on tropical beaches are often cautioned to wear shoes when venturing offshore, where these living pincushions may dwell in abundance.

Sea cucumbers are elongated, sluggish animals

Sea cucumbers (clade *Holothuroidea*) are appropriately named, since some species are about the size and shape of a cucumber. The elongated body is a flexible, muscular sac (see Fig. 32-1e). The mouth is usually surrounded by a circle of tentacles that are modified tube feet. The endoskeleton consists of microscopic plates embedded in the body wall. The circulatory system, which is more highly developed than in other echinoderms, functions to transport oxygen and perhaps nutrients.

Sea cucumbers are sluggish animals that usually live on the bottom of the sea, sometimes burrowing in the mud. Some graze with their tentacles, whereas others stretch their branched tentacles out in the water and wait for dinner to float by. Algae and other morsels are trapped in mucus along the tentacles.

An interesting habit of some sea cucumbers is evisceration, in which the digestive tract, respiratory structures, and gonads

are ejected from the body, usually when environmental conditions are unfavorable. When conditions improve, the lost parts are regenerated. Even more curious, when certain sea cucumbers are irritated or attacked, they direct their rear end toward the enemy and shoot red tubules out of their anus! These unusual weapons become sticky in sea water, and the attacking animal may become hopelessly entangled in the spaghetti-like tangle of tubules. Some of the tubules release a toxic substance.

CHECKPOINT 32.2

- What are three derived characters of echinoderms? Describe each.
- **CONNECT** How do sea stars differ from crinoids? from sea urchins?

32.3 The Chordates: Major Characteristics

LEARNING OBJECTIVE

3 Describe characteristics of chordates, including four shared derived characters.

Biologists currently assign the chordates (phylum Chordata) to three clades, or subphyla: urochordates, marine animals called *tunicates*; cephalochordates, marine animals called *lancelets*; and vertebrates, animals with backbones. Although the structures of living species may suggest otherwise, molecular data support that urochordates (not cephalochordates) are the sister group to the vertebrates (FIG. 32-3).

Chordates are deuterostomes. They are coelomates with bilateral symmetry, a tube-within-a-tube body plan, and three well-developed germ layers. Four shared derived characters distinguish the chordates from all other groups of animals. These characters, which evolved in connection with their evolving methods of locomotion and obtaining food, are the notochord; the dorsal, tubular nerve cord; a postanal tail; and an endostyle or thyroid gland (FIG. 32-4).

1. All chordates have a **notochord** during some time in their life cycle. The notochord is a dorsal, longitudinal rod composed of spongy connective tissue cells surrounded by a tough fibrous sheath. The notochord is firm but flexible, and it supports the body. It also plays an important role in embryonic development of the vertebrates.
2. At some time in their life cycle, chordates have a **dorsal, tubular nerve cord**. The chordate nerve cord differs from the nerve cord of most other animals in that it is located dorsally rather than ventrally, is hollow rather than solid, and is single rather than double.
3. Chordates have a larva or embryo with a muscular **postanal tail**, an appendage that extends posterior to the anus.
4. The **endostyle** is a groove in the floor of the pharynx that secretes mucus and traps food particles in the sea water passing through the pharynx. The endostyle is present in the urochordates, cephalochordates, and lamprey larvae. The thyroid gland evolved from the endostyle and is present in all other chordates.

Pharyngeal slits are another important characteristic of chordates. During chordate embryonic development, a series of grooves develop in the body wall in the region of the pharynx (the part of the digestive tract just posterior to the mouth). A series of outpocketings from the lateral sides of the pharynx (pharyngeal pouches) extend to the grooves. In aquatic chordates the tissue between the grooves and pharyngeal pouches breaks through and forms **pharyngeal slits**, passageways that connect the inside of the pharynx with the surrounding environment.

The perforated pharynx first evolved as an adaptation for filtering food. As water flowed through the mouth and passed out of the pharynx through the pharyngeal slits, suspended food particles were trapped in mucus. Later, modifications evolved, including highly vascularized gills in the passageways. These additions adapted the pharyngeal slits for gas exchange in fishes and some other aquatic vertebrates. Early in vertebrate evolution, anterior pharyngeal arches (supporting tissue between the pharyngeal pouches) evolved into jaws. Although pharyngeal slits are found in all chordates, they are not considered a derived character of chordates because they are also present in hemichordates.

Typically, chordates have an endoskeleton and a closed circulatory system with a ventral heart. Chordates have

Key Point

The shared derived characters of chordates include a notochord; dorsal, tubular nerve cord; postanal tail; and endostyle, a groove in the floor of the pharynx that traps food particles in sea water.

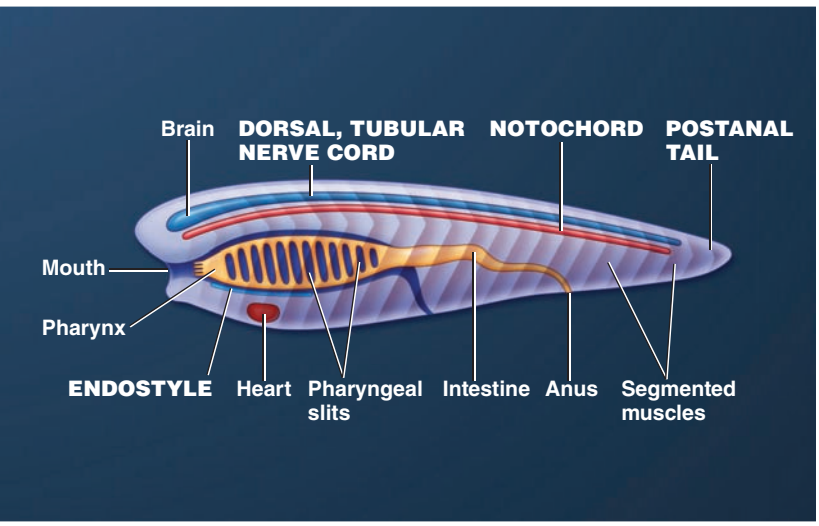

Figure 32-4 Generalized chordate body plan

Identify the shared derived characters: notochord; dorsal, tubular nerve cord; postanal tail; and endostyle. Other key characteristics include pharyngeal slits and segmented muscles.

PREDICT What structures do you think the dorsal, tubular nerve cord gives rise to during the development of vertebrate chordates?

segmented bodies, but specialization is so pronounced that the basic segmentation of the body plan may not be apparent. The segmentation is most obvious in the serially repeated body muscles and skeletal structures (like vertebrae), and in the nerves, which supply these tissues.

CHECKPOINT 32.3

- What are four shared derived characters of chordates?
- **CONNECT** How is the chordate nerve cord different from the nerve cord of most other animals?
- **CONNECT** What is the relationship between your jaws and the pharyngeal slits of early chordates?

32.4 Invertebrate Chordates

LEARNING OBJECTIVE

4 Compare tunicates and lancelets, and summarize the phylogeny of chordates.

Some chordates are not vertebrates. The invertebrate chordates include tunicates (urochordates) and lancelets (cephalochordates).

Tunicates are common marine animals

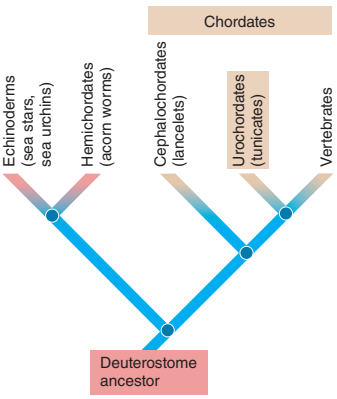
The **tunicates**, or **urochordates** (subphylum Urochordata), include the sea squirts and their relatives (FIG. 32-5). Larval tunicates have typical chordate characteristics and superficially resemble tadpoles. The expanded body has a pharynx with slits, and the long muscular tail contains a notochord and a dorsal, tubular nerve cord. Some tunicates (*appendicularians*) retain their chordate features and ability to swim. These animals are common members of the zooplankton.

Most tunicates are *ascidians*, commonly known as sea squirts (clade Ascidiacea). A sea squirt larva swims for a time and then attaches itself to a rock, a piling, or the sea bottom. It loses its tail, notochord, and much of its nervous system. Adult sea squirts are barrel-shaped, sessile marine animals unlike other chordates. Indeed, they are often mistaken for sponges or cnidarians. Only the pharyngeal slits, endostyle, and the structure of its larva indicate that the sea squirt is a chordate.

Adult tunicates develop a protective covering, or **tunic**, that may be soft and transparent or quite leathery. Curiously, the tunic consists of a carbohydrate much like cellulose. The tunic has two openings: the incurrent siphon, through which water and food enter; and the excurrent siphon, through which water, waste products, and gametes pass to the outside. Sea squirts get their name from their practice of forcefully expelling a stream of water from the excurrent siphon when irritated.

Tunicates are filter feeders that remove plankton suspended in the stream of water passing through the pharynx. Food particles are trapped in mucus secreted by cells of the endostyle, a groove that extends the length of the pharynx. Ciliated cells of the pharynx move the stream of food-laden mucus into the esophagus. Much of the water entering the pharynx passes out through the pharyngeal slits into an *atrium* (a chamber) and is discharged through the excurrent siphon.

Some species of tunicates form large colonies in which members share a common tunic and excurrent siphon. Colonial forms often reproduce asexually by budding. Sexual forms are typically hermaphroditic; that is, a single individual produces both eggs and sperm.



Lancelets clearly exhibit chordate characteristics

Most **cephalochordates** (subphylum **Cephalochordata**) belong to the genus *Branchiostoma*, which consists of animals commonly known as *lancelets*, or *amphioxus*. Lancelets are translucent, fish-shaped animals, 3 to 8 cm (1.3 to 3.2 in.) long and pointed at both ends. They are widely distributed in shallow seas. Although larvae and adults can swim freely, adults typically burrow in the sand in shallow water near the shore. In some parts of the world, lancelets are an important source of food. One Chinese fishery reports an annual catch of 35 tons (about one billion lancelets).

Chordate characteristics are highly developed in lancelets. The notochord extends from the anterior tip ("head"; hence the name *Cephalochordata*) to the posterior tip. A dorsal, tubular nerve cord also extends the entire length of the animal, and many pairs of pharyngeal slits are evident in the large pharyngeal

Figure 32-5 Tunicate body plan

region (FIG. 32-6). Although superficially similar to fishes, lancelets have a far simpler body plan. They do not have paired fins, jaws, sense organs, a heart, or a well-defined head or brain.

Like tunicates, lancelets are filter feeders. Cilia in the mouth and pharynx draw a current of water into the mouth. Microscopic organisms in the water are trapped in mucus secreted by the endostyle and are then moved back to the intestine by beating cilia.

Water passes through the pharyngeal slits into the atrium, a chamber with a ventral opening (the *atriopore*) located anterior to the anus. Metabolic wastes are excreted by segmentally arranged, ciliated *protonephridia* that open into the atrium. Unlike circulation in other invertebrates, the blood flows anteriorly in the ventral vessel and posteriorly in the dorsal vessel in lancelets. This circulatory pattern is similar to that of fishes.

Systematists debate chordate phylogeny

Fossils of early chordates contribute to our understanding of chordate phylogeny. Invertebrate chordates are soft-bodied and did not leave many fossils. However, some well-preserved, key fossils that date back to the Middle Cambrian have been found in the Burgess Shale of British Columbia, Canada. Early Cambrian fossil sites have been discovered in Chengjiang and Haikou, China. At Chengjiang, fine-grained rocks about 530 million years old have preserved soft-bodied animals, including *Haikouella*, in some detail. *Haikouella* was about 2 to 3 cm (approximately 1 in.) long and had a nerve cord, a notochord, pharyngeal slits, muscle segments, and a brain. Many biologists view *Haikouella* as an early chordate. Some investigators hypothesize that this fossil represents a transitional form between the earliest chordates and the first vertebrates.

Pikaia, a lancelet-like fossil discovered in the Burgess Shale, had a primitive notochord with muscles attached to it that allowed for locomotion. About 4 cm (1.5 in.) in length, *Pikaia* had a tail fin and probably filtered food from the water. *Pikaia* is also considered an early chordate, possibly sharing many similarities with modern cephalochordates.

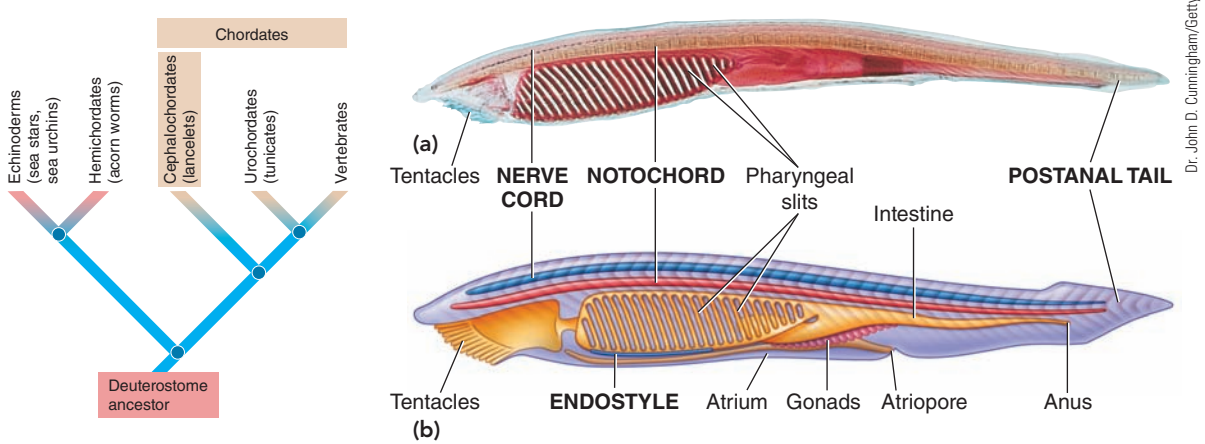

Figure 32-6 Cephalochordate body plan

(a) Photograph of a lancelet, *Branchiostoma* (amphioxus). Note the prominent pharyngeal slits. **(b)** Longitudinal section showing derived characters and other internal structures.

Are cephalochordates or urochordates the sister group of the vertebrates? Although structural similarities implicated cephalochordates, rather than urochordates, as the sister group to the vertebrates, the predominance of recent molecular data supports that urochordates are the closest relatives of the vertebrates. The molecular data combined with information gathered from available fossils suggest that cephalochordates, urochordates, and vertebrates all evolved from early chordates that had elongated bodies. Some of these very early chordates retained the same general body form and gave rise to the cephalochordates. In others, an adult that was sessile, rather than swimming, gave rise to the urochordates. A third lineage added a number of specialized features while giving rise to the vertebrates.

The tunicate *Ciona intestinalis* is an excellent model organism for studying chordate genetics and development because its genome consists of only about 16,000 protein-coding genes, the basic set of genes found in chordates. Interestingly, about 80% of *Ciona*'s genes are found in vertebrates. In fact, *Ciona* has most vertebrate gene families, but in simplified form. For example, *Ciona* has only a single copy of each gene family involved in cell signaling and regulation of development, whereas vertebrates have two or more copies of these gene families. (A gene family is a group of genes that evolved over time from a single ancestral gene through duplication and divergence.) Some of the "extra" copies probably evolved to code for new structures or functions. *Ciona* also has genes for some vertebrate structures and processes, even though it does not express these genes.

CHECKPOINT 32.4

- **CONNECT** How are the main derived chordate characters evident in a tunicate larva and in an adult tunicate?
- **CONNECT** If you found a small fishlike animal along the shoreline, how would you determine whether or not it was a lancelet?

32.5 Introducing the Vertebrates

LEARNING OBJECTIVES

5 Describe four shared derived characters of vertebrates.
6 Describe the major taxa of extant vertebrates.

Numbering about 50,000 described species, the **vertebrates** (subphylum Vertebrata) are less diverse and much less numerous than the insects. However, vertebrates rival the insects in their adaptations to an enormous variety of lifestyles (FIG. 32-7). In addition to the basic chordate characteristics, vertebrates have a number of shared derived characters not found in other groups.

The vertebral column is a derived vertebrate character

The vertebrates are distinguished from other chordates in having a **vertebral column** that forms the skeletal axis of the body. Although sometimes called the "backbone," the vertebral column actually consists of a series of separate skeletal elements, the *vertebrae*, which are made of cartilage or bone. This flexible support develops around the notochord, and in most species it largely replaces the notochord during embryonic development. Dorsal projections of the vertebrae enclose the nerve cord along its length. Anterior to the vertebral column, a cartilaginous or bony **cranium**, or braincase, encloses and protects the brain, the enlarged anterior end of the nerve cord.

The cranium and vertebral column are part of the *endoskeleton*. In contrast with the nonliving exoskeleton of many invertebrates, the vertebrate endoskeleton is a living tissue that grows with the animal. Some vertebrates (jawless and cartilaginous fishes) have skeletons made of cartilage. However, in most vertebrates the skeleton is mainly bone, a tissue that contains fibers made of the protein collagen. The hard matrix of bone consists of the compound hydroxyapatite,

Key Point

This cladogram provides a framework for understanding the evolution of vertebrate diversity and adaptations to aquatic and terrestrial environments.

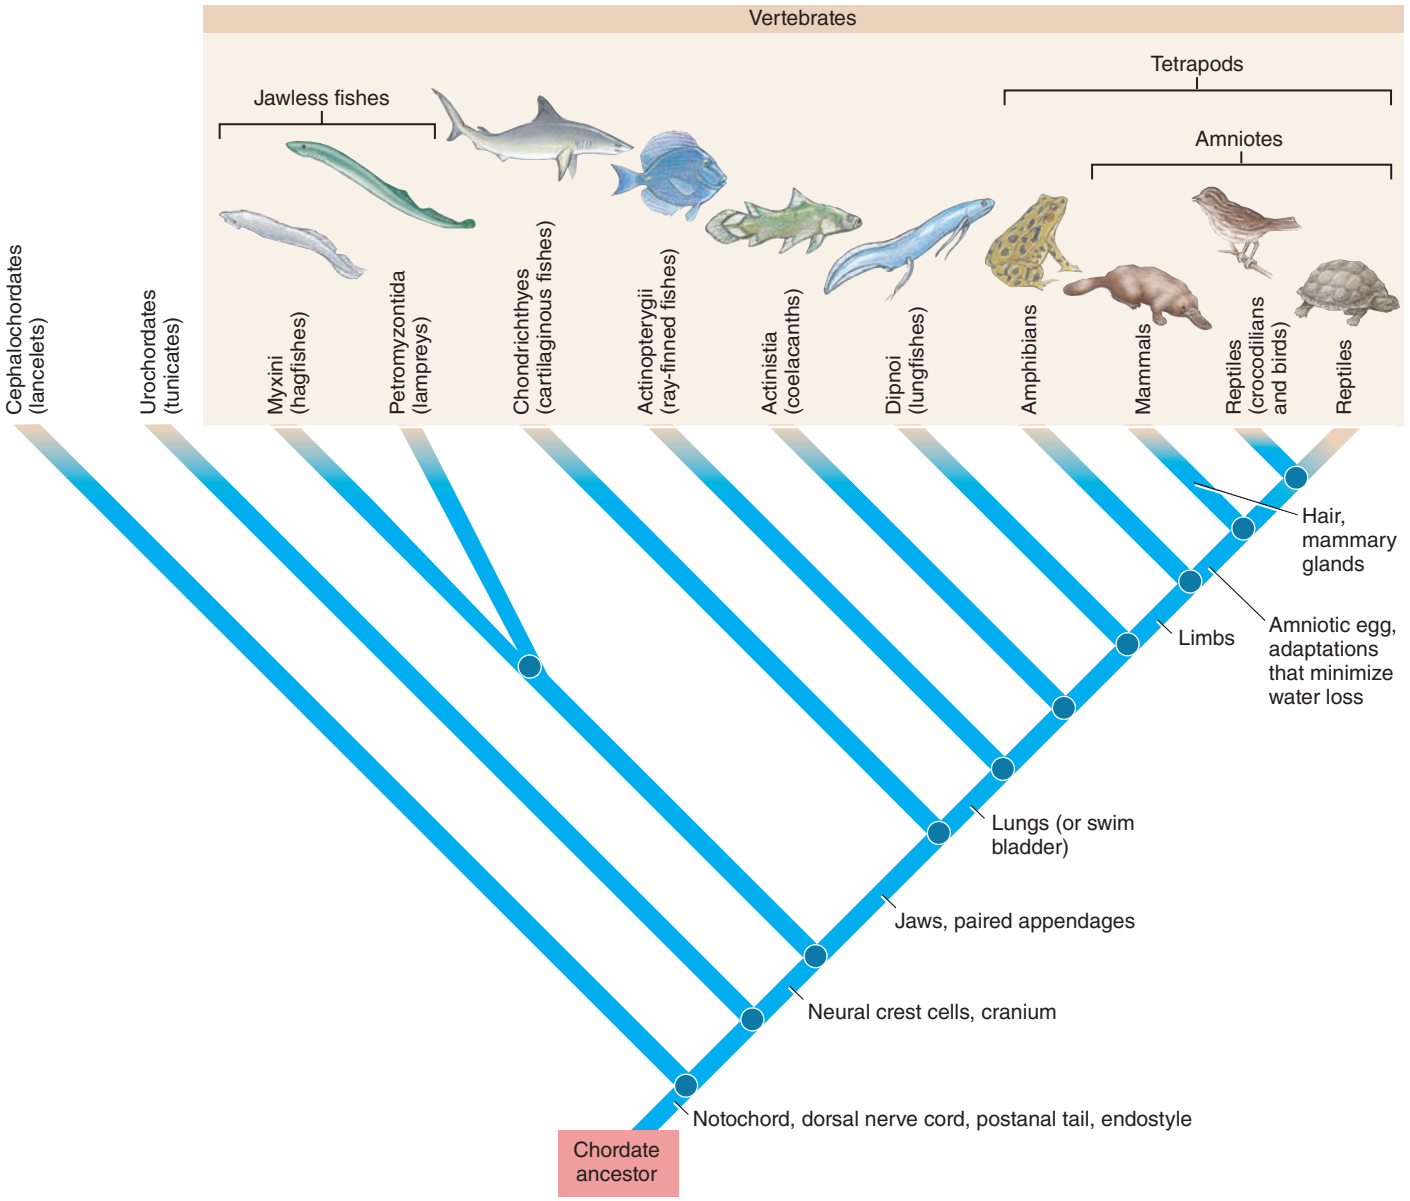

Figure 32-7 Evolutionary relationships of extant vertebrates

This cladogram represents one phylogenetic interpretation of vertebrate phylogeny. The evolution of certain key characters is indicated. As new data are collected and considered, details of the cladogram will likely change. Amniote relationships are shown in more detail in Figure 32-20.

CONNECT What are some advantages of the pronounced cephalization that occurred as vertebrates evolved from jawless fish to tetrapods?

composed mainly of calcium phosphate. Muscles are attached to the endoskeleton.

Many characters common to vertebrates have been derived from a group of embryonic cells called **neural crest cells**. These cells, found only in vertebrates, appear early in development and migrate to various parts of the embryo. Neural crest cells give rise to or influence the development of many structures, including nerves, head muscles, cranium, and jaws.

Recall that *Hox* genes are important in determining pattern development in embryos (see Chapter 17). Specifically, *Hox* genes determine the fate of cells in the anterior–posterior axis. These genes occur in clusters on specific chromosomes. Invertebrates and nonvertebrate chordates that have been studied have one *Hox* gene cluster. As a result of gene duplication, vertebrates have several duplicated clusters. Some species of fish have up to eight duplicated clusters of *Hox* genes. Mammals have four sets of *Hox* genes.

Other gene clusters, including some encoding transcription factors and others coding globin proteins for transporting oxygen, were also duplicated during the evolution of the early vertebrates. The significance of these genetic changes is the focus of investigation. It is reasonable, however, to hypothesize that the increase in genetic complexity contributed to the evolution of more complex and varied bodies.

Recall that some invertebrate groups show an evolutionary trend toward **cephalization**, the concentration of nerve cells and sense organs in a definite head. The vertebrates are characterized by *pronounced* cephalization. The brain has become larger and more elaborate, and its various regions have specialized to perform different functions. Either 10 or 12 pairs of **cranial nerves** emerge from the brain and extend to various organs of the body. Vertebrates have well-developed sense organs concentrated in the head: eyes; ears that serve as organs of balance and, in some vertebrates, for hearing as well; and organs of smell and taste.

Most vertebrates have two pairs of appendages. The fins of fishes are appendages that stabilize and/or help propel the fish in the water. Paired pectoral and pelvic fins are also used in steering. Based on structural, molecular, and fossil data, biologists hypothesize that jointed appendages that facilitated locomotion on land (i.e., legs) evolved from the lobed fins of lungfishes.

Vertebrates have a closed circulatory system with a ventral heart and blood containing hemoglobin. The complete digestive tract has specialized regions and large digestive glands (the liver and pancreas). Several *endocrine glands*, which are ductless glands, secrete hormones. Paired kidneys regulate fluid balance. The sexes are typically separate.

Early vertebrates were probably marine animals. In contrast to the tunicates and lancelets, which use cilia to beat a stream of water into the mouth and filter particles of food from the water, vertebrates use muscles for feeding. Some vertebrates use muscles to draw in a current of water from which both food and oxygen can be extracted. Muscles in the wall of the digestive tube are more powerful than cilia and probably contributed to an increase in both size and activity of early vertebrates. A muscular pharynx with firm skeletal elements for support may have permitted animals to crush small prey after capture. The evolution of more effective sensory systems, a more complex brain, and organs that could support increased activity was important in the shift from filter-feeding to a more active lifestyle.

Vertebrate taxonomy is a work in progress

The evolutionary relationships of vertebrates are an important focus of research. The earliest vertebrate fossils include *Haikouichthys*, conodonts, and a group known as *ostracoderms* (discussed in the next section). *Haikouichthys* was a fishlike animal about 2.5 cm (1 in.) long. It had several characters found in vertebrates, and some researchers think it was an early jawless fish.

Conodonts were simple fishlike chordates with gill arches (tissues that support the gills), muscular segments, and fins. They had large eyes and complex toothlike hooks that were probably used in capturing prey. Conodonts were abundant from the Precambrian to the Late Triassic period; they have been identified in several fossil beds around the world. Cladistic analyses suggest that conodonts were early vertebrates.

By the Late Cambrian, the chordates included a number of different taxa with skeletal elements (a rudimentary braincase, or cranium) protecting the brain. Some of these animals also showed evidence of vertebrae. These earliest vertebrates lacked jaws and are sometimes referred to as **agnathans** (*a*, "without"; and *gnathos*, "jaw").

The extant vertebrates can be assigned to nine clades (classes): six clades (classes) of fishes and three of **tetrapods** (four-limbed vertebrates) (TABLE 32-2; see also Fig. 32-7). Most modern biologists classify the tetrapods as *Tetrapoda* (including amphibians and amniotes) and *Amniota* (including the animals traditionally called reptiles, birds, and mammals). The extant amphibian clade includes frogs, toads, salamanders, newts, and caecilians; the extant reptilian clade includes lizards, snakes, turtles, alligators, and birds.

CHECKPOINT 32.5

- **CONNECT** What shared derived characters distinguish the vertebrates from the rest of the chordates?
- What are the main clades (classes) of fishes? the main groups of tetrapods?

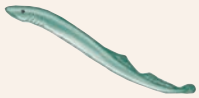
32.6 Jawless Fishes

LEARNING OBJECTIVE

7 Distinguish among the major groups of jawless fishes.

Some of the earliest known vertebrates, collectively referred to as **ostracoderms**, consisted of several groups of small, armored, jawless fishes that lived on the bottom and strained their food from the water (see Fig. 21-11). Thick bony plates protected their heads from predators, and thick scales covered their trunks and tails. Most ostracoderms lacked paired fins. Fragments of ostracoderm scales have been found in rocks from the Cambrian period, but most ostracoderm fossils are from the Ordovician and Silurian periods. They became extinct by the end of the Devonian period.

Like ostracoderms, present-day hagfishes and lampreys have neither jaws nor paired fins. They are eel-shaped animals, up to 1 m (about 3 ft) long. Their smooth skin lacks scales, and they are supported by a cartilaginous skeleton and well-developed notochord.



Hagfishes, clade *Myxini* (mik-sin′y), are marine scavengers (FIG. 32-8). They burrow for worms and other invertebrates or prey on dead and disabled fishes. Hagfishes use toothlike projections from their tongue to pull off flesh from prey. For leverage, a hagfish can tie itself into a knot. As a defense mechanism, hagfishes secrete large amounts of fluid that forms sticky slime in sea water. The hagfish becomes so slippery that predators cannot grasp it.

In the past, some systematists argued that the hagfishes did not quite qualify as vertebrates. Although they have many vertebrate characteristics, including a cranium, they were thought

Table 32-2 Extant Vertebrate Clades (Classes)

Clade		Examples	Characteristics
MYXINI		Hagfishes	Jawless, marine fishes that lack paired appendages; the notochord is their only axial support
PETROMYZONTIDA		Lampreys	Jawless, freshwater and marine fishes with skeleton of cartilage; complete cranium and rudimentary vertebrae; gills; specialized sense organs
CHONDRICHTHYES		Sharks, rays, skates, chimaeras	Jawed marine and freshwater fishes with skeleton of cartilage; vertebrae present; gills; placoid scales; two pairs of fins; oviparous, ovoviviparous, or viviparous (a few species); well-developed sense organs
ACTINOPTERYGII (ray-finned fishes)		Perch, salmon, tuna, trout	Bony, marine and freshwater fishes; gills; swim bladder; generally oviparous
ACTINISTIA (fleshy-finned fishes)		Coelacanths	Bony fishes; marine, nocturnal predators on fish; lobed fins
DIPNOI (fleshy-finned fishes)		Lungfishes	Bony freshwater fishes; have both functional gills and lungs
AMPHIBIA		Salamanders, frogs and toads, caecilians	Aquatic larva typically undergoes metamorphosis into terrestrial adult; gas exchange through lungs and/or moist skin; two atria and single ventricle; systemic and pulmonary circulation
REPTILIA		Turtles, lizards, snakes	Amniotes with horny scales; adapted for reproduction on land (internal fertilization, leathery shell, amnion); lungs; ventricles of heart partly divided
		Crocodilians and birds	Amniotes with two complete ventricles; care for their young. Birds have feathers; anterior limbs modified as wings; compact, endothermic; vocal calls and complex songs
MAMMALIA		Monotremes (Protheria), marsupials (Metatheria), mammals with well-developed placentas (Eutheria)	Amniotes with hair; females nourish young with mammary glands; differentiation of teeth; three middle-ear bones; diaphragm; heart with two separate atria and two separate ventricles; endothermic; highly developed nervous system

to lack any trace of vertebrae. However, more recently they have been shown to have rudimentary vertebrae. Hagfishes and lampreys are now classified as vertebrates and viewed as sister groups.

Lampreys, clade Petromyzontida (pet-tro-my-zon′-tih-da; from the Greek *petros*, "stone," and *myzon*, "sucking"), are jawless vertebrates. Lampreys hold onto stones by their mouths to prevent being washed away by the currents. Some lampreys spend their adult lives in the ocean and return to fresh water to reproduce. Many species of adult lampreys are parasites on other fishes (FIG. 32-9). Adult parasitic lampreys have a circular sucking disc around the mouth, which lies on the ventral side of the anterior end of the body. Using this disc to attach to a fish, the lamprey bores through the skin of its host with horny teeth (made of keratin) on the disc and tongue. Then the lamprey injects an anticoagulant into its host and sucks out blood and soft tissues.

As in hagfish, the notochord persists throughout life and is not replaced by a vertebral column. Lampreys have rudiments of vertebrae, cartilaginous segments that extend dorsally around the spinal cord.

CHECKPOINT 32.6

Figure 32-8 Pacific hagfish (*Eptatretus stoutii*)
The hagfish has a flexible body, which it can tie into knots. It knots its tail and then slides the knot toward its head. Being knotted gives it leverage when tearing flesh from its prey. Knotting itself also helps the hagfish remove excess slime from its body.

32.7 Evolution of Jaws and Limbs: Jawed Fishes and Tetrapods

LEARNING OBJECTIVE

8 Trace the evolution of jawed fishes and early tetrapods, and describe modern amphibians.

Imagine trying to hunt for food and then eat without jaws or limbs. Such was the challenge for early vertebrates, which helps explain why the jawless fishes are mainly scavengers and parasites. The evolution of jaws from a portion of the gill arch skeleton and the development of fins allowed fishes to become active predators. With jaws an animal can grasp and hold on to live prey while eating it. The evolution of fins allowed fishes to swim faster and with more control. Fishes with jaws and fins had many new opportunities for capturing food.

Fossil evidence suggests that jaws and paired fins evolved during the Late Silurian and Devonian periods. Two early groups of jawed fishes, now extinct, were the **acanthodians**, armored fishes with paired spines and pectoral and pelvic fins, and **placoderms**, armored fishes with paired fins (FIG. 32-10). Vertebrates with jaws are referred to as **gnathostomes** (nath′-o-stomes). The success of the jawed vertebrates probably contributed to the extinction of the ostracoderms.

When the fins of certain fishes evolved into limbs about 370 mya, a different type of locomotion was possible. These limbed vertebrates (early tetrapods) were able to move about in shallow waters and wetlands in search of food. Some of these early tetrapods were able to move on land and gained access to new food and habitats.

Most cartilaginous fishes inhabit marine environments

The cartilaginous fishes, members of clade **Chondrichthyes** (kon-drik′-thee-eez), appeared as successful marine forms in the Devonian period. Chondrichthyes are a monophyletic group that includes the sharks, rays, skates, and ratfishes (FIG. 32-11). Most species are ocean dwellers, but a few have invaded fresh water. With the exception of whales, the sharks are the largest living vertebrates. Some whale sharks (*Rhincodon*) exceed 15 m (49 ft) in length.

Alastair Pollock Photography/Getty Images

(b) Great white shark (*Carcharodon carcharias*). Photographed at Neptune Islands, Spencer Gulf, South Australia, this shark is considered the most dangerous shark to humans. It is actually white only on its ventral aspect; the rest of the body is brownish gray or bluish gray.

Figure 32-11 Cartilaginous fishes

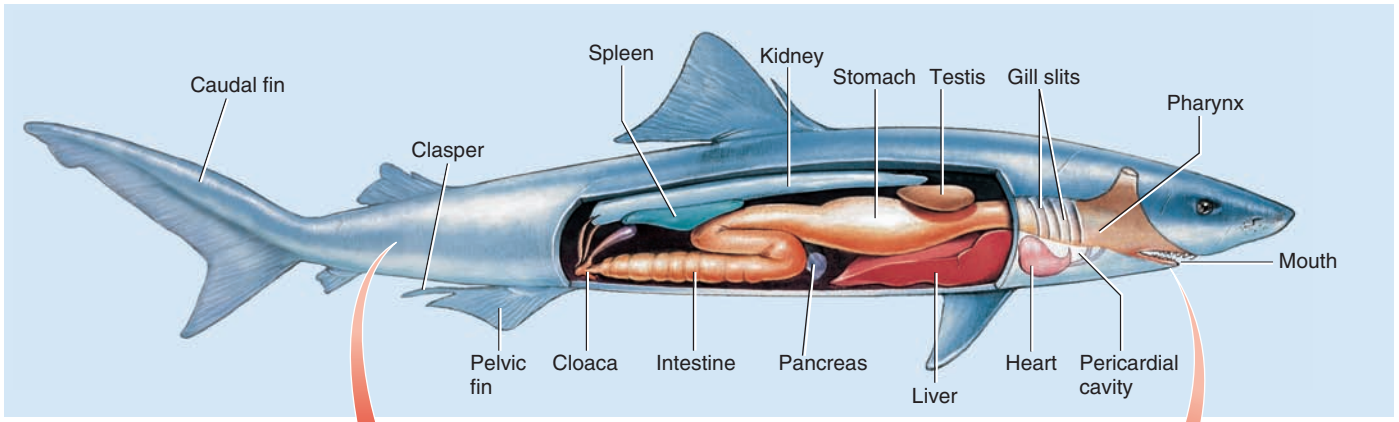
Most rays and skates are flattened creatures that live partly buried in the sand. Their enormous pectoral fins propel them along the bottom, where they feed on mussels and clams. The stingray has a whiplike tail with a barbed spine at its base that can inflict a painful wound. The electric ray has electric organs on either side of the head. These modified muscles can discharge enough electric current (up to 200 volts) to stun fairly large fishes as well as human swimmers.

Chondrichthyes retain their cartilaginous embryonic skeleton. Although this skeleton is not replaced by bone, in many species calcium salts are added to the cartilage for strength. All chondrichthyes have jaws and two pairs of fins (FIG. 32-12). The skin contains **placoid scales**, which are tooth-like structures. The lining of the mouth contains larger, but essentially similar, scales that serve as teeth. The teeth of other vertebrates are homologous with these scales. Shark teeth are embedded in the flesh and not attached to the jawbones; new teeth develop continuously in rows behind the functional teeth and migrate forward to replace any that are lost.

The streamlined shark body is adapted for rapid swimming. Lift is provided by body shape and fins. The shark stores a great deal of oil in its large liver (which may account for up to 30% of its body weight). Fats and oils decrease the overall density of fishes and contribute to buoyancy. Even so, the shark body is denser than water, so sharks tend to sink unless they are actively swimming.

Most sharks are predators that swim actively and prey on other fishes as well as on crustaceans and mollusks. The largest sharks and rays, like the largest whales, are filter feeders that strain plankton from the water. They gulp water through the mouth. As the water passes through the pharynx and out the gill slits, food particles are trapped in a sievelike structure.

Predatory sharks are attracted to blood, so a wounded swimmer or a skin diver towing speared fish is a target. However, despite the common portrayal of sharks in books and films as monstrous enemies, most do not go out of their way to attack humans. In fact, of the approximately 350 known shark species, fewer than 30 are known to attack humans.



Sharks have a complex brain and a spinal cord that is protected by vertebrae. Their well-developed sense organs effectively locate prey in the water. Sharks may detect other animals electrically in addition to sensing them by sight or smell.

Electroreceptors on the shark's head sense weak electric currents generated by the muscle activity of animals. The **lateral line organ**, found in all fishes and many amphibians, is a groove along each side of the body with many tiny openings to the outside. Sensory cells in the lateral line organ detect vibrations caused by waves and other movement in the water, including movements by predators or prey (see Fig. 43-7).

Cartilaginous fishes have no lungs. Gas exchange takes place through their five to seven pairs of gills. A current of water enters the mouth and passes over the gills and out the pharyngeal slits, constantly providing the fish with a fresh supply of dissolved oxygen. Sharks that actively swim depend on their motion to enhance gas exchange. Rays, skates, and sharks that spend time on the ocean floor use muscles of the jaw and pharynx to pump water over their gills.

(a) Internal structure of a shark.

(b) Placoid scales. These tough scales protect the shark against predators. The base of each placoid scale is embedded in the skin. Placoid scales are toothlike structures. They are covered with hard enamel.

(c) Teeth. Placoid scales are embedded in the flesh along the inner surface of the jaw cartilage where they function as teeth. Sharks have several rows of teeth. Old teeth are shed and quickly replaced.

Figure 32-12 Anatomy of a shark

The digestive tract of sharks consists of the mouth cavity; a long pharynx leading to the stomach; a short, straight intestine; and a **cloaca** (klow-a´-kuh), which opens on the underside of the body. (The cloaca is characteristic of many vertebrates; see Fig. 32-12.) The liver and pancreas discharge digestive juices into the intestine. The cloaca receives digestive wastes as well as metabolic wastes from the urinary system. In females the cloaca also serves as a reproductive organ.

The sexes are separate, and fertilization is internal. In the mature male, each pelvic fin has a slender, grooved section, known as a *clasper*, used to transfer sperm into the female's cloaca. The eggs are fertilized in the upper part of the female's oviducts. Part of the oviduct is modified as a shell gland, which secretes a protective coat around each egg.

Skates and about 30% to 40% of sharks, including zebra sharks, are **oviparous**. They lay eggs. After fertilization, the eggs are laid, typically within a leathery pouch. Other species of sharks, including nurse sharks and great white sharks, are **ovoviviparous**. Their young are enclosed in eggs and incubated within the mother's body. During development, the young depend on stored yolk for their nourishment rather than on transfer of materials from the mother. The young are born after hatching from the eggs.

Some species of sharks, including hammerhead sharks and blue sharks, are **viviparous**. Not only do the embryos develop within the uterus, but nutrients and oxygen from blood vessels in the uterus are delivered to them by the mother's blood. After a gestation period of up to 3 years, the young sharks are born alive.

Ray-finned fishes gave rise to modern bony fishes

Although bony fishes appear earlier in the fossil record than cartilaginous fishes, both groups may have evolved about the same time, during the Late Silurian or Early Devonian period. The two groups share many characteristics (such as continuous tooth replacement), but they also differ in important ways.

Most bony fishes are characterized by a bony skeleton with many vertebrae. Bone has advantages over cartilage because it provides excellent support and effectively stores calcium. Most species have flexible median and paired fins supported by long rays made of cartilage or bone. Overlapping, bony dermal scales cover the body. A lateral bony flap, the **operculum**, extends posteriorly from the head and protects the gills.

Most bony fishes are oviparous. Most species lay an impressive number of eggs and fertilize them externally. The

ocean sunfish, for example, lays more than 300 million eggs! Of course, most of the eggs and young become food for other animals. The probability of survival is increased by certain behavioral adaptations. For example, many species of fishes build nests for their eggs and protect them. Other species have internal fertilization and give birth to live young.

During the Devonian period, the bony fishes diverged into two major groups: the fleshy-finned fishes, *Sarcopterygii*; and the **ray-finned fishes** (clade *Actinopterygii*). Fossils of the earliest sarcopterygians date back to the Devonian period, about 400 mya. Lungs and fleshy, *lobed fins* characterized these fishes. The flexible fins were supported by thin, bony rays radiating out from a thick base of multiple bones and muscles. Lobed fins may have evolved as an adaptation for pushing along the bottom of any body of water.

Early sarcopterygians evolved along three separate lines: the *lungfishes* (clade *Dipnoi*), the *coelacanths* (clade *Actinistia*), and the *Tetrapodomorpha*, a clade consisting of tetrapods and their most recent ancestors. All three lineages had fins with fleshy bases of muscle and bone. Surviving from these groups today are three genera of lungfishes, two species of *coelacanths*, and the many thousands of species of tetrapods (amphibians and amniotes) in habitats worldwide.

Although the earliest ray-finned fishes also had both lungs and gills, they differed from the sarcopterygians in having more flexible fins with less bone and muscle at the base. The ray-finned fishes (actinopterygians) underwent two important adaptive radiations. The first gave rise during the Late Paleozoic era to a group of fishes that are now mostly extinct. The second radiation began during the Early Mesozoic era and gave rise to the very successful modern bony fishes.

In addition to gills, the common ancestor of the bony fishes had primitive lungs that could exchange gases in air. Lungs for gas exchange were retained by the tetrapods and lungfishes. In the modern ray-finned fishes, the lungs became modified as a **swim bladder**, an air sac that helps regulate buoyancy (FIG. 32-13). Bones and muscles are heavier than water, and without the swim bladder, the fish would sink. By regulating gas exchange between its blood and swim bladder, a fish can control the amount of gas in the swim bladder and thus change the overall density of its body. This ability allows a bony fish, in contrast to a shark, to hover at a given depth of water without much muscular effort.

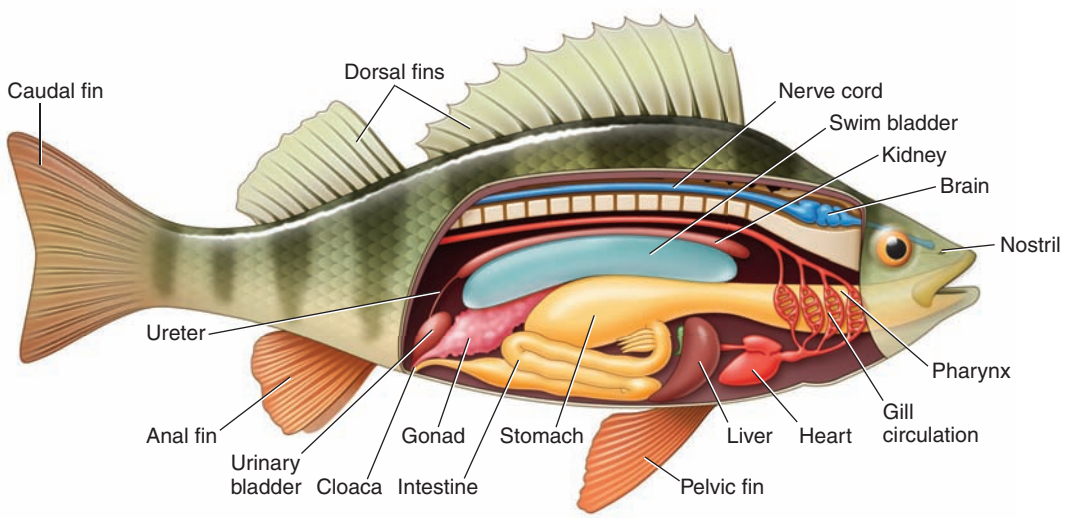
There are more species of bony fishes than of any other vertebrate group. Biologists have identified tens of thousands of living species of freshwater and saltwater bony fishes, of many shapes and colors (FIG. 32-14). Bony fishes range in size from that of *Paedocypris progenetica*, which has been measured at less than 8 mm (about 0.3 in) long, to that of the ocean sunfish (*Mola mola*; see Fig. 20-16c), which may reach 4 m (13 ft) and weigh about 1500 kg (about 3300 lb). *Paedocypris progenetica*, native to Indonesia, is the smallest known vertebrate.

The diversity of bony fishes may have resulted from the action of *Hox* genes. During the radiation of ray-finned fishes, entire chromosomes duplicated, resulting in one or more additional clusters of *Hox* genes. The zebrafish (see Fig. 17-6d) has seven *Hox* clusters. These additional genes could have provided the genetic material for the evolution of the diverse species of ray-finned fishes.

Tetrapods evolved from sarcopterygian ancestors

Biologists thought that the **coelacanths** were extinct by the end of the Paleozoic era, so in 1938 the scientific community was very excited when a commercial fisherman caught one off the coast of South Africa. Since that time, more than 200 specimens of these giant "living fossils" have been found in the deep waters off the southeastern coast of Africa, near the Comores Islands in the Indian Ocean, and off the coasts of Madagascar and Indonesia (FIG. 32-15). These coelacanths, which measure nearly 2 m (about 6 ft) in length, are nocturnal predators on other fishes.

The relationships among the three living groups of sarcopterygians (coelocanths, lungfishes, and tetrapods) have been investigated for many years. Although it was known that the tetrapods evolved from the fleshy-finned fishes, it was not known whether the lungfishes or the coelacanths were the nearest relatives of this group. Fossil evidence and DNA analyses support the lungfishes as the sister group to the tetrapods (FIG. 32-16).



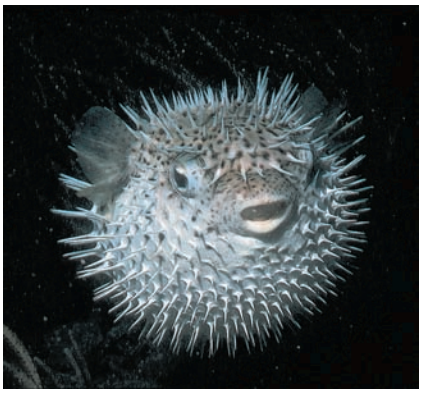


Figure 32-13 Perch, a representative bony fish
The swim bladder is a hydrostatic organ that enables the fish to change the density of its body and remain stationary at a given depth. Pectoral fins (*not shown*) and pelvic fins are paired.

Figure 32-14 Modern bony fishes

Peter Scoones/Taxi/Getty Images

Figure 32-15 Coelacanth

Although they were more diverse and widespread during their early history, the coelacanths, like this *Latimeria chalumnae*, are restricted today to certain deep sea environments.

Molecular data support the structural evidence that the limbs of tetrapods evolved from the lobed fins of fishes. Proteins encoded by certain regulatory genes, including *Hox* genes, have been found at the same developmental times and in the same locations in both limbs and fins. These findings indicate that limb and fin development are governed by the same genes.

What drove the evolution of tetrapod limbs? One hypothesis suggests that during the frequent seasonal droughts of the Devonian period, swamps became stagnant or dried up completely. Fishes with lobed fins had a tremendous advantage for survival under those conditions. They were strikingly preadapted for moving onto the land. They had lungs for breathing air, and their sturdy, fleshy fins allowed them to "walk" along in shallow water. These fins could support the fish's weight, so it could emerge onto dry land and make its way to another pond or stream.

A more recent hypothesis holds that limbs evolved in a fully aquatic environment. Animals with more-developed limbs could move along in shallow water or creep through dense aquatic vegetation more efficiently than their lobe-finned ancestors. ***Tiktaalik*** was a transitional form between fishes and tetrapods (FIG. 32-17).

Perennou Nuridsany/Science Source

Figure 32-16 South American lungfish (*Lepidosiren paradoxus*)
Lungfishes were common in Devonian and Carboniferous times (400 mya to 300 mya). South American lungfish have paired lungs on either side of the throat and can survive for long periods if the river they inhabit dries up.

Biologists consider *Tiktaalik*, which lived about 375 mya (during the Devonian period), a fish because it had scales, fins, gills, and lungs. However, *Tiktaalik* also had tetrapod features such as a movable neck and ribs that supported lungs.

Acanthostega was one of the earliest known tetrapods. Fossils from the Devonian period show that this animal had four legs with well-formed digits. However, because its limbs were not properly positioned for walking effectively on land and because it possessed gills and a tail fin, *Acanthostega* was a fully aquatic tetrapod. The ichthyostegids, tetrapods known from somewhat later in the Devonian, had more robust limbs and girdles, suggesting that they could move more easily on land. However, the evidence suggests that these early tetrapods were also very aquatic.

Those early tetrapods that could explore shallow wetlands and make their way onto dry land had access to new food sources. Terrestrial plants were already established, and terrestrial insects and arachnids were rapidly evolving. A vertebrate that could survive on land had less competition for food than one that was solely aquatic. However, success on land required the evolution of several major adaptations in addition to legs.

Zina Deretsky/National Science Foundation

Figure 32-17 *Tiktaalik*
This extinct fish, which grew to 2.75 m (9 ft), had limblike fins and other tetrapod features.

As discussed, the early sarcopterygians had lungs for gas exchange in addition to gills. Lungs were important because gills cannot function in air. Life on land also required changes in the muscles and skeleton to support the body's weight in air. Body coverings and other mechanisms were needed to protect animals against the drying effect of air.

Evolution of ears that could hear sound transmitted through air and olfactory mechanisms for detecting airborne odors contributed to the ability to find food and mates, and to avoid predators. It is likely that early tetrapods needed to return to the water for reproduction, but eventually adaptations evolved that allowed some animals to reproduce in terrestrial environments. The early tetrapods were very successful and eventually gave rise to the amphibians and the amniotes (including reptiles, birds, and mammals).

Amphibians were the first successful land vertebrates

Biologists classify modern **amphibians** (*Amphibia*) in three clades. *Caudata* ("with tail") includes salamanders, mud puppies, and newts, all animals with long tails. *Anura* ("no tail") is made up of frogs and toads, most with legs adapted for hopping. *Gymnophiona* contains the limbless caecilians (FIG. 32-18). Although some adult amphibians are quite successful as land animals and live in dry environments, most must return to the water to reproduce. Eggs and sperm are typically released in the water.

Many amphibians undergo **metamorphosis**, a transition from larva to adult. The embryos of most frogs and toads develop into larvae called *tadpoles*. These larvae have tails and gills, and most feed on aquatic plants. After a time, the tadpole undergoes metamorphosis, which is regulated by hormones secreted by the *thyroid gland*. During metamorphosis, gills and gill slits disappear, the tail is resorbed, and limbs emerge. The digestive tract shortens, and food preference shifts from plant material to a carnivorous diet; the mouth widens; a tongue develops; the tympanic membrane (eardrum) and eyelids appear; and the eye lens changes shape. Many biochemical changes accompany the transformation from a completely aquatic life to a semiterrestrial one.

Several salamanders, such as the mudpuppy *Necturus*, do not undergo complete metamorphosis; they retain many larval characteristics even when sexually mature adults. Recall from Chapter 20 that this retention of juvenile features is called **paedomorphosis** (see Fig. 20-17). This type of development permits these salamanders to remain aquatic rather than having to compete on land.

The coloration of amphibians may conceal them in their habitat or may be very bright and striking. Many of the brightly colored species are poisonous (see Fig. 32-18). Their distinctive colors warn predators that they are not encountering an ordinary amphibian. Some frogs camouflage themselves by changing color.

Adult amphibians do not depend solely on their primitive lungs for the exchange of respiratory gases. Their moist, glandular skin, which lacks scales and is plentifully supplied

Figure 32-18 Modern amphibians

with blood vessels, also serves as a respiratory surface. The numerous mucous glands within the skin help keep the body surface moist, which is important in gas exchange. The mucus also makes the animal slippery, facilitating its escape from predators. Most amphibians have glands in their skin that secrete toxic and/or foul-tasting substances that repel predators.

The amphibian heart contains two **atria** (sing. *atrium*), receiving blood, and a single **ventricle**, pumping blood into the arteries. A double circuit of blood vessels keeps oxygen-rich and oxygen-poor blood partially separate. Blood passes through the **systemic circulation** to the various tissues and organs of the body. Then, after returning to the heart, it is directed through the **pulmonary circulation** to the lungs and skin, where it is recharged with oxygen. The oxygen-rich blood returns to the heart to be pumped out into the systemic circulation again. We discuss the comparative anatomy of the heart and circulation of various vertebrate clades in Chapter 44.

CHECKPOINT 32.7

- **CONNECT** From an evolutionary perspective, what is the significance of each of the following: (1) placoderms, (2) lungfishes, (3) ray-finned fishes, and (4) *Tiktaalik*?
- What changes allow amphibians to move from aquatic life as a tadpole to terrestrial life as an adult?

32.8 Amniotes: Terrestrial Vertebrates

LEARNING OBJECTIVES

9 Describe three vertebrate adaptations to terrestrial life.

10 Describe the reptiles (including the birds) and argue for including the birds in the reptile clade.

11 Describe five key characters of mammals and contrast protherian (monotremes), metatherian (marsupials), and eutherian mammals, giving examples of animals that belong to each group.

The evolution of **reptiles** from ancestral amphibians required many adaptations that allowed them to become completely terrestrial. Evolution of the **amniotic egg** was an extremely important event because it allowed terrestrial vertebrates to complete their life cycles on land. The amniotic egg contains an **amnion**, a membrane that forms a fluid-filled sac around the embryo. The amnion provides the embryo with its own private "pond," permitting independence from a watery external environment. In addition to keeping the embryo moist, the amniotic fluid serves as a shock absorber that cushions the developing embryo.

The evolution of the amniotic egg is so important to the success of terrestrial vertebrates—reptiles (including birds) and mammals—that biologists refer to these animals as **amniotes**. Amniotes are a monophyletic group because they have a recent common ancestor that was itself an amniote.

In addition to the amnion, the amniotic egg has three other extraembryonic (not part of the developing body itself) membranes: *yolk sac*, *chorion*, and *allantois* (FIG. 32-19). These membranes protect the developing embryo, store nutrients (yolk sac), carry on gas exchange (chorion, allantois, and yolk sac), and store wastes (allantois). We discuss development of the extraembryonic membranes in Chapter 51. Although most extant mammals do not lay eggs, their embryos have an amnion and other extraembryonic membranes.

Another important adaptation to terrestrial life is a body covering that minimizes water loss. The amniote body covering is typically thick and contains **keratin**, a water-insoluble protein that helps protect the animal from injury. Keratin is found in the epidermis and in derivatives of the epidermis, such as scales, nails, feathers, hair, and horns. A body covering containing keratin presents another challenge: it severely decreases gas exchange across the body surface. This challenge has been met by the evolution of efficient lungs and circulatory systems for exchange of oxygen and

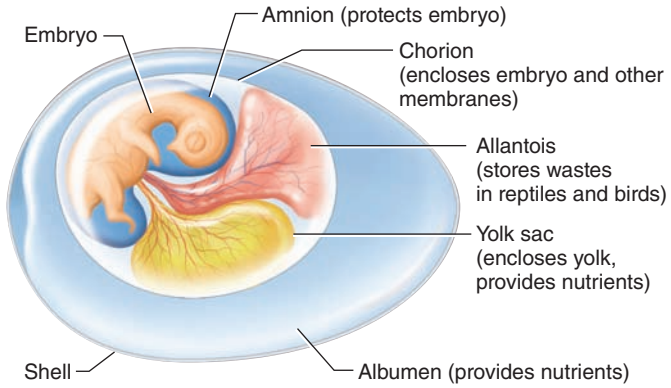

Figure 32-19 An amniotic egg

The amnion, a fluid-filled sac surrounding the embryo, keeps the embryo moist and protects it from mechanical shock. Other extraembryonic membranes include the yolk sac, which functions in nutrition; the allantois, which stores metabolic wastes; and the chorion, which along with the allantois, functions in gas exchange.

carbon dioxide. Amniotes also have physiological mechanisms for conserving water. For example, much of the water filtered from the blood by the kidneys is reabsorbed in the kidney tubules to decrease fluid loss during excretion of metabolic wastes.

Our understanding of amniote phylogeny is changing

Biology instructors once taught that the three main groups (classes) of amniotes were Reptilia, Aves (birds), and Mammalia. However, cladistic analysis determined that class Reptilia was not a monophyletic group without the birds. Because it included some, but not all, of its descendants, it was paraphyletic (see Fig. 23-7). For this reason, biologists now classify the birds as a group of reptiles.

Biologists hypothesize that the earliest amniotes resembled lizards. By the Late Carboniferous period, about 290 mya, amniotes had undergone an impressive adaptive radiation and had diverged into two main branches: **diapsids** and **synapsids** (FIG. 32-20 and TABLE 32-3). The term *diapsid* refers to the two pairs of openings in the temporal bones that characterize the skulls of these animals. Synapsid skulls have one pair of temporal openings. The diapsids comprise all extant reptilian groups, including the birds and most extinct reptiles. The synapsids include the extinct **therapsids** and the mammals.

A second great adaptive radiation of amniotes occurred during the Mesozoic era, which ended about 66 mya. During that time reptiles were the dominant terrestrial vertebrates (see Chapter 21). In fact, the Mesozoic era is known as the "Age of Reptiles." Reptiles had radiated into an impressive variety of ecological lifestyles (see Figs. 21-13, 21-14, and 21-15). Some could fly, others became marine, and many filled terrestrial habitats. Among the major groups were the *pterosaurs* (ter′-uh-sawr), the flying reptiles; the *saurischian dinosaurs* (saw-ris′-kee-un), a group that included *Tyrannosaurus* and *Diplodocus*; and the *ornithischian dinosaurs* (awr-nuh-this′-kee-un), including *Triceratops*.

Some of the dinosaurs were among the largest land animals to ever walk on Earth. Some dinosaurs apparently traveled in social groups and took care of their young. Fossil evidence supports the hypothesis that at least some dinosaurs may have been **endotherms**, meaning that they used metabolic energy to maintain a constant body temperature despite changes in the temperature of the environment. An advantage of endothermy is that it allows animals to be more active. The natural history and evolution of dinosaurs and other early reptiles are discussed in more detail in Chapter 21.

The reptiles were the dominant land vertebrates for almost 200 million years. Then, toward the end of the Mesozoic era, many reptiles, including all the dinosaurs and pterosaurs, disappeared from the fossil record. In fact, more than half of all animal species became extinct at that time (see Chapter 21).

Reptiles have many terrestrial adaptations

Many reptilian characters are adaptations to terrestrial life. The female reptile secretes a protective leathery shell around the egg, which helps prevent the developing embryo from drying out. The shell presents a challenge for reproduction because sperm cannot penetrate it. Fertilization must take place within the body of the female before the shell is added. In this process, the male uses a copulatory organ (penis) to transfer sperm into the female reproductive tract. An amnion surrounds the embryo as it develops within the protective shell.

The hard, dry, keratin scales that are part of the reptile's skin retard drying in yet another adaptation to life on land. This scaly protective armor, which also protects the reptile from predators, is shed periodically. The dry reptilian skin does not allow effective gas exchange. Reptilian lungs are better developed than the saclike lungs of amphibians. Divided into many chambers, the reptilian lung provides an increased surface area for gas exchange.

The hearts of amniotes contain two atria. The ventricle of reptiles is either partially or completely divided. The division into right and left ventricles enhances the separation of oxygen-rich and oxygen-poor blood. The more efficient circulatory and respiratory systems of reptiles are critical for animals with a keratinized epidermis.

Like fishes and amphibians, many extant reptiles lack metabolic mechanisms for regulating body temperature. They are **ectotherms**, meaning that their body temperature fluctuates with the temperature of the surrounding environment. Some reptiles have behavioral adaptations that help them maintain a body temperature higher than that of their environment (see Fig. 39-8a). For example, you may have observed a lizard basking in the sun, which raises its body temperature and so increases its metabolic rate. This increased rate permits the lizard to hunt actively for food. When the body of a reptile is cold, its metabolic rate is low and the animal tends to be sluggish. Ectothermy helps explain why lizards, snakes, and turtles are more successful in warm than in cold climates.

Many reptiles are predators. Their paired limbs, usually with five toes, are well adapted for running and climbing in search of prey. In addition, their well-developed sense organs enable them to locate prey.

Key Point

The diapsid reptiles gave rise to the birds, and the synapsids gave rise to the mammals. Note the five main branches of extant diapsids.

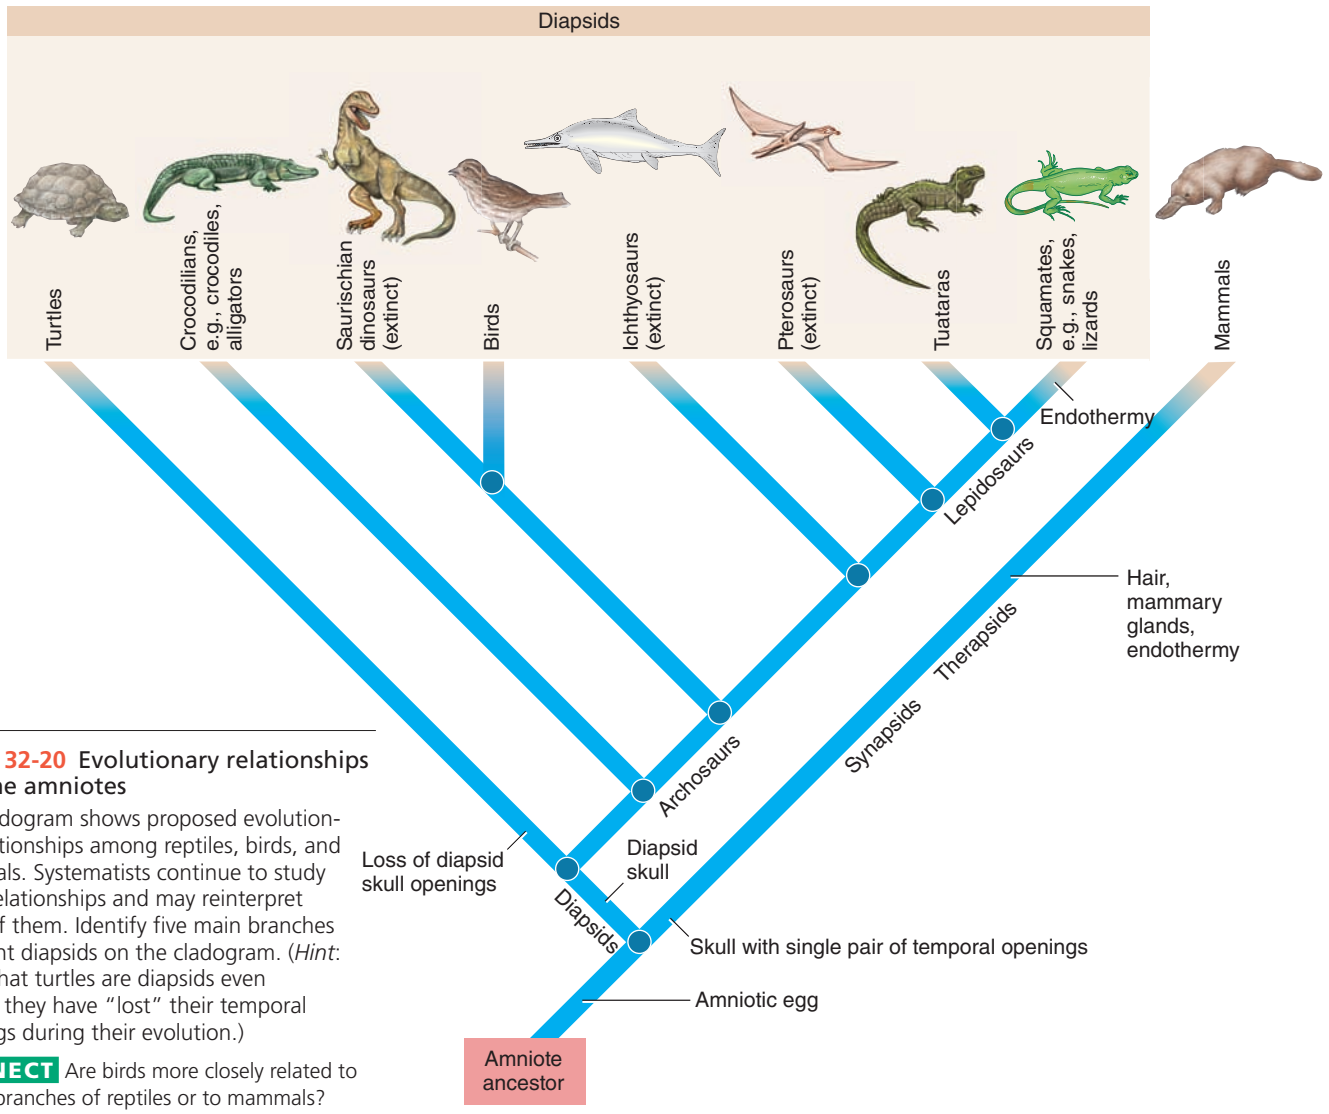

Figure 32-20 Evolutionary relationships of some amniotes

This cladogram shows proposed evolutionary relationships among reptiles, birds, and mammals. Systematists continue to study these relationships and may reinterpret some of them. Identify five main branches of extant diapsids on the cladogram. (*Hint*: Recall that turtles are diapsids even though they have "lost" their temporal openings during their evolution.)

CONNECT Are birds more closely related to extinct branches of reptiles or to mammals?

Biologists assign reptiles to two major lineages

The first major lineage, the **lepidosaurs**, includes squamates—snakes, lizards, worm lizards—and sphenodonts—tuataras, lizardlike animals that live in burrows (see Table 32-3). The second major lineage, **archosaurs**, includes the extant turtles, terrapins, and tortoises (testudines) and the crocodilians—crocodiles, alligators, caimans, and gavials. These animals, along with the birds, are the surviving reptiles of the archosaur lineage (FIG. 32-21).

The archosaur lineage also gave rise to three groups of animals that became extinct: (1) **pterosaurs**, flying reptiles of the Mesozoic era; (2) saurichians, a group of dinosaurs, including (*Tyrannosaurus*) that dominated the Mesozoic era; and (3) ornithischians, another group of Mesozoic dinosaurs that included *Triceratops*). Birds (Aves) descended from the saurichian lineage.

Lizards and snakes are common modern reptiles

Lizards and snakes are assigned to the squamate (squa-mate′) clade. These animals have rows of scales that overlap like shingles on a roof, forming a continuous, flexible armor that is shed periodically. Lizards range in size from certain geckos, which weigh as little as 1 g (less than 0.1 oz), to the Komodo dragon of Indonesia, which may weigh 100 kg (220 lb). Their body sizes and shapes vary greatly. Some lizards—for example, the "worm lizards" and the glass lizards—are legless. Iguanas make up a genus of herbivorous lizards, ranging in size from 1.5 to 1.8 m (5 to 6 ft).

Table 32-3 Some Major Groups of Amniotes

Clades	Important Characters
DIAPSIDS	**Skull with two pairs of temporal openings**
LEPIDOSAURS	Overlapping scales; a very successful group of modern reptiles
Squamates Snakes, lizards, worm lizards 	Flexible armor of overlapping, horny scales, which are shed
	Snakes: elongated body with no limbs; flexible, loosely jointed jaw; protrusible forked tongue
	Lizards: slender body, typically with four legs; some with no legs
Sphenodonts Tuataras 	Vertebrae concave at both ends; only two extant species
ICHTHYOSAURS (extinct) Marine reptiles of Mesozoic era 	Body shaped like that of modern dolphins; large eyes; vertical tail
ARCHOSAURS	Mainly terrestrial; some specialized for flight; ventricle completely divided in extant forms
Testudines Turtles, terrapins, tortoises 	Enclosed in bony shell; beak of keratin instead of teeth; some can withdraw head and legs into shell; temporal openings "lost" during their evolution ("anapsids")
Crocodilians Crocodiles, alligators, caimans, gavials 	Heart with two atria and two ventricles; closest extant relative to birds
Pterosaurs (extinct) Flying reptiles of Mesozoic era 	Membranous wings
Saurischians (extinct) Mesozoic dinosaurs (*Tyrannosaurus, Diplodocus*) **Birds descended from this lineage.** 	Some were two-legged carnivores; others were four-legged herbivores; some had feathers
Ornithischians (extinct) Mesozoic dinosaurs (*Triceratops*) 	Bipedal and quadrupedal herbivores; social behavior and parental care in many
SYNAPSIDS	**Skull with one pair of temporal openings**
Therapsids (extinct) **Mammals descended from this lineage.** 	Many mammal-like characters; became dominant land animals during Middle Permian period

Snakes are characterized by a flexible, loosely jointed jaw structure that allows them to swallow animals larger than the diameter of their own jaws. These reptiles have elongated bodies with no legs, although pythons have vestigial hind-limb bones (see Fig. 18-17). Remember that although not all the tetrapods have four limbs, all evolved from four-limbed ancestors. Snake eyes are covered by a transparent scale. They do not have movable eyelids. Also absent are an external ear opening, a tympanic membrane (eardrum), and a middle-ear cavity.

Snakes use their forked tongues as accessory sensory organs for touch and smell. Chemicals from the ground or air adhere to the tongue. Snakes rub the tips of their tongues across the opening of a sense organ in the roof of the mouth that detects odors. Pit vipers and some boas also have *pit organs* that detect heat from endothermic prey (see Fig. 43-3). These snakes use their *pit organs* to locate and capture birds and small nocturnal mammals.

Some snakes, such as king snakes, pythons, and boa constrictors, kill their prey by rapidly wrapping themselves around the animal and squeezing so it cannot breathe. Others have fangs, which are hollow teeth connected to venom glands. When the snake bites, it pumps venom through the fangs into the prey. Some snake venoms cause the breakdown of red blood cells; others, such as that of the coral snake, are neurotoxins, which interfere with nerve function. Venomous snakes of the United States include rattlesnakes, copperheads, cottonmouths, and coral snakes. Except for the coral snakes, all are pit vipers.

(e) Roseate spoonbill (*Ajaja ajaja*). The roseate spoonbill is a long-legged wading bird nearly three feet tall with a wingspan of more than four feet. This bird was photographed in John Prince Park, Lake Worth, Florida. The future of roseate spoonbills depends on protection of their habitats—coastal marshes, estuaries, and mangrove areas.

Figure 32-21 Representative extant reptiles

Worm lizards are considered modified lizards. They are well adapted for their burrowing lifestyle. They have elongated bodies with either no legs or a single pair of legs. In many species the eyes are hidden under the skin. Most are less than 15 cm (6 in.) long. Most species of worm lizards inhabit South America and southern Africa. Only one species (known as the Florida worm lizard) is found in the United States.

Tuataras superficially resemble lizards

Tuataras look somewhat like iguanas but have certain distinct characters. For example, they are the only amniotes with vertebrae that are concave at both ends; such vertebrae are characteristic of fish and some amphibians. The two extant species of tuataras inhabit New Zealand and several small islands off its coast. Tuataras have long been considered endangered species. When humans brought rats, cats, and dogs to New Zealand, these nonnative animals decimated the population of tuataras by eating their eggs. Tuataras became extinct on the New Zealand mainland. In 2005, these animals were reintroduced into a sanctuary in New Zealand, and they are now protected.

Turtles have protective shells

Turtles, terrapins, and tortoises are testudines (te-stood′-n-eez). They are enclosed in a protective shell made of bony plates overlaid by keratin scales. Some terrestrial turtles can

withdraw their heads and legs completely into their shells. Their keratin beak covers the jaws. They do not have teeth. Turtles are diapsid reptiles. During the course of evolution, members of this group have "lost" the temporal openings.

The size of adult turtles ranges in length from about 8 cm (3 in.) to more than 2 m (6.5 ft) in leatherback turtles, which are the largest marine species. The weight of a leatherback turtle can exceed 500 kg (more than 1000 lb). The forelimbs of marine turtles are modified into flippers. Sea turtles migrate hundreds of miles from the beaches where they hatch to feeding grounds. Females return to the same beaches where they hatched to mate and nest. Most species of sea turtles are endangered as a result of human activities.

Crocodilians have an elongated skull

Modern crocodilians include three groups: (1) the crocodiles of Africa, Asia, and the Americas; (2) the alligators of the southern United States and China, plus the caimans of Central America; and (3) the gavials of South Asia. Most species live in swamps, in rivers, or along seacoasts, feeding on various kinds of animals.

Crocodiles are the largest living reptiles; some exceed 7 m (23 ft) in length. The cranial skeleton is adapted for aquatic life. In the Americas, crocodiles can be distinguished from alligators or caimans by their more tapered snouts and by the large fourth tooth on the lower jaw that is visible when the mouth is closed.

How do we know that birds are really dinosaurs?

Cladistic analyses indicate that birds evolved from the lineage of saurischian dinosaurs, specifically from the **theropods** (theer′-uh-pods), a group of bipedal, saurischian dinosaurs that included *Tyrannosaurus* and *Deinonychus* (see Fig. 21-15). This view is supported by the remarkable array of Cretaceous and late Jurassic fossils discovered in the Yixian Formation and in other parts of China as well as in Europe.

Some dinosaurs had feathers Paleontologists have identified many theropod dinosaur fossils that demonstrate the evolution of feathers from very simple, tubular structures to complex modern forms. *Caudipteryx*, a feathered dinosaur discovered in the Yixian Formation, was about the size of a turkey. Fossils of *Caudipteryx* exhibit both dinosaur and bird characteristics. The bones in the foot and the shape and orientation of the pelvis were similar to those of dinosaurs. However, the fossils have well-preserved impressions of complex feathers on the tail and forelimbs. *Caudipteryx* had only a few teeth in the front of its upper jaw, and its bones show many birdlike characteristics. Although some investigators have argued that *Caudipteryx* was a flightless bird, the most recent consensus view is that this animal was a feathered dinosaur. Analyzing fossil evidence and molecular data, many paleontologists have hypothesized that feather evolution took place in terrestrial, bipedal dinosaurs *before* the evolution of birds or flight.

Asymmetrical feathers were important in the evolution of flight. Modern birds have asymmetrical feathers. In 2003, paleontologists reported finding a new species of feathered dinosaur, *Microraptor gui*. *Microraptor* had asymmetrical feathers on both its forelimbs and hind limbs, and also on its tail. (See the figure in *Inquiring About: The Origin of Flight in Birds* in Chapter 21.) However, their small size and body structure support the hypothesis that flying evolved from gliding; that is, *Microraptor* climbed trees and used its feathered limbs for gliding. These small dinosaurs, which lived about 126 mya, coexisted with early birds.

Biologists have debated why feathers may have evolved in dinosaurs. Were feathers important in courtship rituals or in camouflage? Were feathers an adaptation that conserved body heat? Insulating feathers could have contributed to the evolution of endothermy (the ability to maintain a constant body temperature), permitting animals to be more active.

Scientists have discovered fossils of more than 30 species of feathered dinosaurs. In 2010, paleontologists described a nearly complete skeleton of a basal theropod discovered in northwestern China. This fossil, named *Haplocheirus sollers*, had organelles containing pigment that colored its feathers, suggesting that feathers may have first evolved for color displays in courtship rituals. The presence of feathers and the bone structure of *Haplocheirus* indicate that striking evolutionary convergence occurred between feathered dinosaurs and birds. In 2016, scientists discovered the fossil of a birdlike dinosaur in Lioaning, China. Named *Jianianhualong tengi*, this dinosaur lived about 125 mya. It looked somewhat like a chicken with asymmetrical feathers that were longer on one side. The feathers had stiff quills with barbs.

Early birds were transitional forms

Many extinct theropods were long-tailed animals that moved about on two feet and had forelimbs with three clawed fingers. Although the bones of birds are fragile and disintegrate quickly, paleobiologists have found a few fossils of early birds. The first birds looked very much like dinosaurs. They had teeth (which modern birds lack), a long tail, and bones with thick walls. Like certain extinct theropods, modern birds have feet with three digits and thin-walled, hollow bones. Both have a *furcula*, or wishbone, which is formed by the two clavicles (collarbones) fusing in the midline. Many biologists classify modern birds as theropods.

Archaeopteryx (meaning "ancient wing") was an early bird that was about the size of a pigeon. More than ten specimens of this genus have been found in Bavaria in Jurassic limestone, which was laid down about 150 mya. Unlike those of extant birds, the jawbones of *Archaeopteryx* were armed with teeth, and its long, reptilian tail was covered with feathers (FIG. 32-22a). Each of its short, broad wings had three claw-bearing, functional digits.

(a) Reconstruction of *Archaeopteryx*, an early bird. This reconstruction illustrates a feathered *Archaeopteryx* preying on a dragonfly. *Archaeopteryx* was a climbing animal that had at least some ability to use its wings and feathers for gliding.

Thierry Hubin/Royal Belgian Institute of Natural Sciences

(b) Fossil of *Aurornis xui*, a very early bird. *Aurornis xui*, about the size of a pheasant, lived during the Middle–Late Jurassic period about 160 million years ago.

Figure 32-22 Fossil evidence supports the evolution of birds from the dinosaur lineage

Like modern birds, *Archaeopteryx* had wings, feathers, and a furcula. Its feathers were very similar to those of modern birds.

Using computer tomography and computerized 3-D reconstruction, researchers examined the inside of the *Archaeopteryx* skull. They found that *Archaeopteryx* had a birdlike brain with comparatively larger cerebral lobes than those of other reptiles. It had enlarged visual centers and highly developed inner ear canals similar to those of modern birds. These structures would support the coordination and agility needed for flight.

A complete fossil of an early bird from China was described in 2013. This fossil, named *Aurornis xui*, predates *Archaeopteryx* by about 10 million years. Like *Archaeopteryx, Aurornis xui* has a furcula, feathers, and teeth (FIG. 32-22b). The *Aurornis* fossil preserved traces of downy feathers. However, it shows no evidence of larger feathers, suggesting that this early bird was not able to fly.

Cretaceous rocks have yielded fossils of other early birds. *Hesperornis*, which lived in North America, was a toothed, aquatic diving bird with small wings and broad, lobed feet for swimming. *Ichthyornis* was a toothed, flying bird about the size of a small tern. Based on fossils, structural similarities, and molecular data, most biologists now view birds as living dinosaurs.

Modern birds are adapted for flight

By the end of the Cretaceous period, the major clades of present-day birds—palaeognaths and neognaths—had evolved. (Some biologists assign birds to class Aves and consider palaeognathae and neognathae as superorders.) *Palaeognaths* (from Greek *palaios*, "ancient," and *gnathos*, "jaw") include flightless birds such as the ostrich, kiwi, cassowary, and emu. These birds are called **ratites**. Their sternum (breastbone) is flat and does not have a ridge for attachment of wing muscles. They have only vestigial wings, but they have well-developed legs used for running.

Most modern birds are *neognaths* (from Greek *neos*, "new," and *gnathos*, "jaw"). These birds have powerful flight muscles attached to their keeled (ridged) sternum, and most neognaths fly. The penguins are an exception. They use their strong pectoral muscles and small, flipperlike wings to swim.

Biologists have described more than 10,000 species of extant birds and classified them into about 23 monophyletic taxa. Birds are a diverse group (FIG. 32-23). They have become adapted to a variety of environments, and various species have different types of beaks, feet, wings, tails, and behavioral patterns. They can be found on all continents, most islands, and even the open sea. The largest living birds are the ostriches of Africa, which may be up to 2 m (6.5 ft) tall and weigh 136 kg (300 lb). The great condors of the Americas have wingspans of up to 3 m (10 ft). The smallest known bird is the bee hummingbird of Cuba, with a length of less than 6 cm (about 2 in.) and a weight of less than 2 g (about 0.06 oz).

Like their reptilian ancestors, modern birds lay eggs and have reptilian-type scales on their legs. Birds have evolved remarkable specializations for flight. They are the only extant animals with feathers. Their feathers are an amazing example of biological engineering. They are very light, yet flexible and strong, and present a flat surface to the air. Feathers also protect the body and decrease water and heat loss. The anterior limbs of birds are wings, usually adapted for flight. The posterior limbs are modified for walking, swimming, or perching.

Other adaptations for flight include the compact, streamlined body and the fusion of many bones, which provides the rigidity needed for flying. The bones are strong but very light. Many are hollow, containing large air spaces. The avian jaw is light, and instead of teeth, birds have a lightweight beak of bone and keratin. The breastbone is broad and keeled for the attachment of the large flight muscles.

Birds have lungs with *air sacs*, thin-walled extensions that occupy spaces between the internal organs and within certain bones. The unique "one-way" flow of air through their respiratory system is metabolically efficient because their lungs

(c) Atlantic puffin (*Fratercula arctica*). This puffin has caught several fish. The puffin's beak becomes brightly colored during the breeding season.

Figure 32-23 Modern birds

Although they are diverse, most birds are highly adapted for flight, and their basic structure is similar.

can extract great amounts of oxygen from the air. (This respiratory system is described in more detail in Chapter 46.)

Birds have a four-chambered heart and a double circuit of blood flow. One circuit delivers oxygen-rich blood to the body tissues and returns low-oxygen blood to the heart; the other circuit takes blood to and from the lungs where it is oxygenated. The very effective respiratory and circulatory systems provide the cells with enough oxygen to permit a high metabolic rate, which is necessary for the strenuous muscular activity that flying requires. Some of the heat a bird generates by metabolic activities helps it maintain a constant body temperature. Because they are endotherms, birds can remain active in cold climates.

Birds excrete nitrogenous wastes mainly as semisolid uric acid. Because birds typically do not have a urinary bladder, these solid wastes are delivered into the cloaca. They leave the body with the feces, which are dropped frequently. This adaptive mechanism helps maintain a light body weight.

Bills are specifically adapted for the type of food the bird eats (see Fig. 1-13). Birds must eat frequently because they have a high metabolic rate and typically do not store much fat. Although the choice of food varies widely among species, most birds eat energy-rich foods such as seeds, fruits, worms, mollusks, or arthropods. Warblers and some other species eat mainly insects. Owls and hawks eat small mammals and other birds. Some hawks catch snakes and lizards. Vultures feed on dead animals. Pelicans, gulls, terns, and kingfishers catch fish.

An interesting feature of the bird digestive system is the *crop*, an expanded, saclike portion of the digestive tract below the esophagus in which food is temporarily stored. The stomach is divided into a *proventriculus*, which secretes gastric juices; and a thick, muscular *gizzard*, which grinds food. The bird swallows small bits of gravel that act as "teeth" in the gizzard to mechanically break down food.

Birds have a well-developed nervous system, with a brain that is proportionately larger than that of other reptiles. Birds rely heavily on vision, and their eyes are relatively larger than those of other vertebrates. Hearing is also well developed.

In striking contrast with the relatively silent non-avian reptiles, birds are very vocal. Most have short, simple *calls* that signal danger or influence feeding, flocking, or interaction between parent and young. *Songs* are usually more complex than calls and are performed mainly by males. Birds sing songs to attract and keep a mate and to claim and defend a territory.

One of the most fascinating aspects of bird behavior is the annual migration made by many species. Some birds, such as the golden plover and Arctic tern, fly from Alaska to Patagonia, South America, and back each year, covering perhaps 40,250 km (25,000 mi) en route. Migration and navigation are discussed in Chapter 52.

Many birds have beautiful, striking colors. The colors are due partly to pigments deposited during the development of the feathers and partly to reflection and refraction of light of certain wavelengths. Many birds, especially females, are protectively colored by their plumage. During the breeding season, the male often assumes brighter colors, which help attract a mate.

Mammals (class Mammalia) have many unique characters

Derived characters include **mammary glands** that produce milk for the young; hair (all **mammals** have at least a few hairs at some time in their life, and no other organism has true hair); one pair of temporal openings in the skull; differentiated *teeth* (incisors, canines, premolars, and molars); lungs with alveoli; completely divided ventricles; *kidneys*, which help conserve water; and three *middle-ear bones* (other tetrapods have only a single bone, the stapes, in the middle ear). The evolution of the *cochlea*, the organ of hearing in the inner ear, gives mammals an excellent sense of hearing.

Contributing significantly to the success of the mammals, *the nervous system is more highly developed than in any other group of animals*. The cerebrum is especially large and complex, with an outer gray region, the **cerebral cortex**. In mammals the highly specialized cerebral cortex, called the *neocortex*, has six layers of neurons. Specific regions in the neocortex are specialized for functions such as vision, hearing, touch, movement, emotional response, and higher cognitive functions.

Fertilization in mammals is internal, and with the exception of the monotremes that lay eggs, mammals are viviparous. Most mammals develop a **placenta**, an organ of exchange between developing embryo and mother. As the mother's blood passes through blood vessels in the placenta, it delivers nourishment and oxygen to the embryo and carries off wastes. By carrying their developing young internally, mammals avoid the hazards of having their eggs consumed by predators. By nourishing the young and caring for them, the parents offer both protection and an "education" on how to obtain food and avoid being eaten.

A muscular **diaphragm** helps move air into and out of the lungs. Like birds, mammals are endotherms, but mammals appear to have evolved endothermy independently of birds. Some of the adaptations that allow mammals to maintain a constant body temperature include the covering of insulating hair, very efficient lungs with alveoli (air sacs through which gas exchange with the blood takes place), a fully divided ventricle, and complete separation of pulmonary and systemic circulations. Red blood cells without nuclei serve as efficient oxygen transporters.

The limbs of mammals are variously adapted for walking, running, climbing, swimming, burrowing, or flying. In most terrestrial mammals, the limbs are more directly under the body than they are in extant reptiles, which contributes to speed and agility.

New fossil discoveries are changing our understanding of the early evolution of mammals

Mammals descended from **therapsids**, a group of synapsid amniotes, during the Triassic period more than 200 mya. The therapsids were somewhat doglike carnivores with differentiated teeth and legs adapted for running (FIG. 32-24). Until recently, early mammals were thought to be small, about the size of a mouse or shrew. However, fossil evidence indicates that mammals diversified earlier than previously thought. Some early mammals were fairly large, with limbs adapted for swimming or burrowing. Some had fur, and some were probably endothermic.

How did mammals manage to coexist with the abundant archosaurs during the approximately 160 million years that reptiles ruled Earth? Many adaptations permitted early mammals to compete for a place on this planet. Perhaps one of the most important was their skill at being inconspicuous. Many were **arboreal** (tree dwelling) and nocturnal (active at night), searching for food (mainly insects and plant material, and perhaps reptile eggs) at night while the reptiles were inactive. Although their eyes may have been small, early mammals had well-developed sense organs for hearing and smell.

As many reptiles became extinct, mammals adapted to the niches (lifestyles) that reptiles abandoned. During this time, the flowering plants, including many trees, underwent an adaptive radiation, providing new habitats, sources of food, and protection from predators. Numerous new varieties of mammals evolved. During the Early Cenozoic era (more than 55 mya), the mammals underwent an adaptive radiation; they became widely distributed and adapted to an impressive variety of ecological lifestyles.

Tom McHugh/Science Source

Figure 32-26 Short-beaked echidna (*Tachyglossus aculeatus*)
Female protherians lay eggs. They have mammary glands, but do not have nipples.

Modern mammals are assigned to three subclasses

By the end of the Cretaceous period, three main lineages of mammals had evolved (FIG. 32-25). Mammals now inhabit virtually every corner of Earth; they live on land, in fresh water and salt water, and in the air. They range in size from the tiny pygmy shrew, weighing about 2.5 g (less than 0.1 oz), to the blue whale, which may weigh up to 136,000 kg (150 tons) and which is probably one of the largest animals that has ever lived.

Modern mammals are classified in two main clades: **protheria**, which includes the **monotremes**, egg-laying mammals; and **theria**, which includes the mammals that bear their young alive. The therian clade is further divided into two groups: Metatheria, the **marsupials** (pouched mammals); and Eutheria, mammals that are more developed at birth than the marsupials. **Eutherians** are often referred to as placental mammals because they have well-developed placentas. However, some marsupials do have simple placentas.

One group of protherians includes the duck-billed platypus and a second, the spiny echidnas (FIG. 32-26). These animals live in Australia and Tasmania; two species of spiny echidnas inhabit New Guinea. Female protherians lay eggs that they carry in a pouch on the abdomen or keep warm in a nest. When the young hatch, they lap up milk secreted by their mother's mammary glands. Unlike other mammals, monotremes do not have nipples. With their long beaks and long, sticky tongues, spiny echidnas capture ants and termites. The duck-billed platypus, which lives in burrows along river banks, preys on freshwater invertebrates. It has webbed feet and a flat, beaverlike tail, which help it swim.

Marsupials include pouched mammals such as kangaroos and opossums (FIG. 32-27a). Embryos begin their development in the mother's uterus, where they are nourished by fluid and yolk. After a brief gestation, the young are born in an undeveloped stage. The young make their way to the *marsupium* (pouch), where they attach to a nipple. Nourished by the mother's milk, they complete their development (FIG. 32-27b).

At one time, marsupials probably inhabited much of the world, but placental mammals largely outcompeted them. Now marsupials live mainly in Australia, Central America, and South America. The only marsupial species that ranges into the United States is the Virginia opossum. Australia became geographically isolated from the rest of the world before placental mammals migrated there, and the marsupials remained the dominant mammals (see the discussion of continental drift in Chapter 18). Australian marsupials underwent adaptive radiation, paralleling the evolution of placental mammals elsewhere. Thus, marsupials that live in Australia and adjacent islands independently evolved body forms and natural histories similar to North American placental wolves, bears, rats, moles, flying squirrels, and even cats (FIG. 32-28).

Most familiar to us are the eutherian mammals, which are born at a more mature stage than marsupials (FIG. 32-29). Indeed, among some species the young can walk and begin to interact with other members of the group within a few minutes after birth. Eutherians have a well-developed placenta. The placenta

(b) A kangaroo soon after birth. Marsupials are born in an embryonic state and continue to develop in the safety of the mother's marsupium (pouch).

Figure 32-27 Marsupials

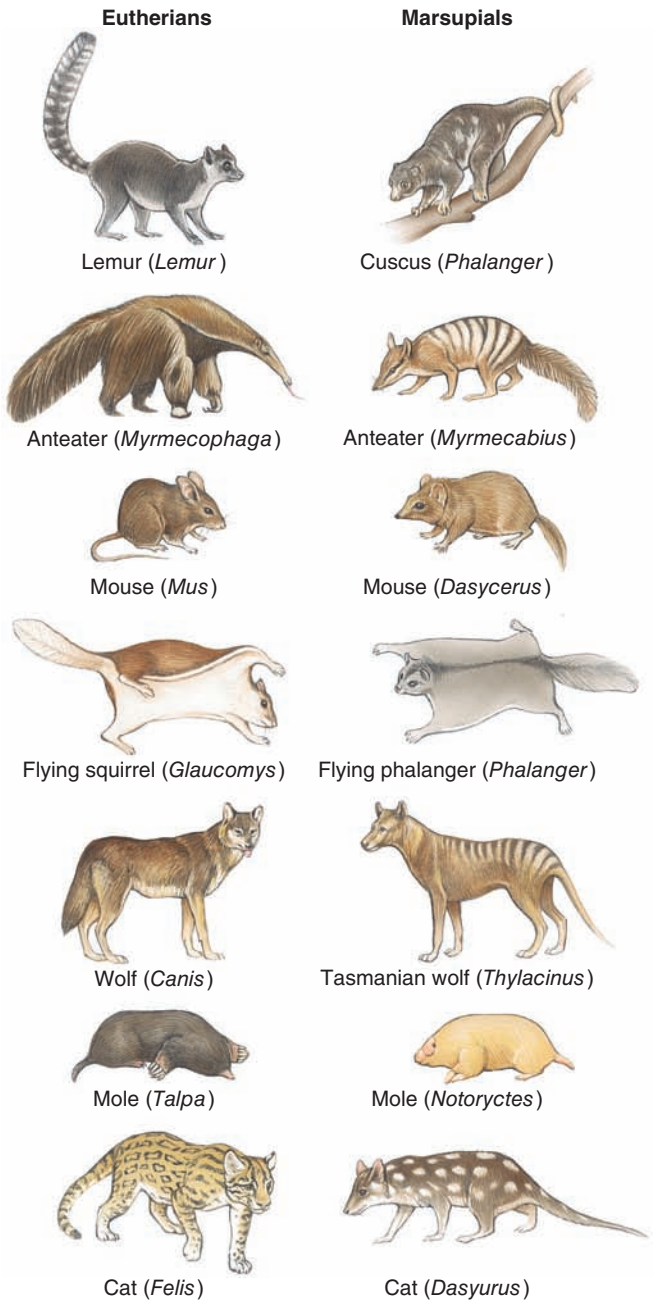

Figure 32-28 Convergent evolution in eutherian and marsupial mammals

For each mammal in one group, a counterpart has evolved in the other group. Their similarities include both lifestyles and structural features.

develops from both embryonic membranes and the maternal uterine wall. In the placenta, blood vessels of the embryo come very close to the blood vessels of the mother, so materials can be exchanged by diffusion. (The two circulations do not normally mix.) The placenta allows the young to remain within the mother's body until embryonic development is complete.

Extant placental mammals can be assigned to about 19 groups (orders). TABLE 32-4 gives a brief summary of some of these groups. Remember that aquatic mammals, such as dolphins, whales, and seals, evolved from terrestrial ancestors (see Fig. 18-9). Also refer to TABLE 32-5, which reviews the three main deuterostome groups.

CHECKPOINT 32.8

- **CONNECT** Describe three adaptations that have allowed amniotes to become completely terrestrial.
- **CONNECT** Which amniotes are endothermic? What are some advantages of endothermy?
- Argue for classifying birds and reptiles in a single clade.
- Contrast the three main clades of mammals.

(d) Egyptian fruit bat (*Rousettus aegyptiacus*). Often called "flying foxes," these small bats cluster in large colonies. They often hang by one foot from the cave ceiling.

Figure 32-29 Eutherian mammals

Table 32-4 Some Groups (Orders) of Extant Eutherian Mammals

Order, Representative Members, and Some Characteristics			
INSECTIVORA (moles, hedgehogs, shrews) Nocturnal; eat insects. Shrew is smallest living mammal; some weigh less than 5 g (about 0.2 ounces).	 African hedgehog *Atelerix albiventris*	**ARTIODACTYLA** (cattle, sheep, pigs, deer, giraffes) Hoofed with even numbers of digits per foot; most have two toes, some have four. Most have antlers or horns. Herbivores; most are ruminants, chew a cud, and have a series of stomachs inhabited by bacteria that digest cellulose.	 American elk *Cervus elaphus*
CHIROPTERA (bats) Adapted for flying; fold of skin extends from elongated fingers to body and legs, forming wing. Guided in flight by type of biological sonar; emit high-frequency squeaks and are guided by echoes from obstructions. Eat insects and fruit or suck blood of other animals.	 Bat *Eptesicus fuscus*	**XENARTHRA** (sloths, anteaters, armadillos) Teeth reduced or no teeth. Sloths are sluggish animals that hang upside down from branches; often protectively colored by green algae that grow on their hair. Armadillos are protected by bony plates; eat insects and small invertebrates.	 Nine-banded armadillo *Dasypus bellus*

Table 32-4 Some Groups (Orders) of Extant Eutherian Mammals (*continued*)

Order, Representative Members, and Some Characteristics			
CARNIVORA (cats, dogs, wolves, foxes, bears, otters, mink, weasels, skunks, seals, sea lions, walruses) Predators with sharp, pointed canine teeth and molars for shearing; keen sense of smell; complex social interactions; among fastest, strongest, and smartest animals. Seals, sea lions, and walruses are large marine predators with limbs adapted as flippers for swimming.	 Wolf *Canis lupus*	**RODENTIA** (squirrels, beavers, rats, mice, hamsters, porcupines, guinea pigs) Gnawing animals with chisel-like incisors. As they gnaw, teeth are worn down and so must grow continually. Most numerous mammals both in numbers and species.	 Flying squirrel *Glaucomys volans*
PERISSODACTYLA (horses, zebras, tapirs, rhinoceroses) Herbivores; hoofed with odd number of digits per foot; one or three toes; teeth adapted for chewing; usually large animals with long legs.	 Tapir *Tapirus* sp.	**PROBOSCIDEA** (elephants) Largest land animals; weigh up to 7 tons; large head; broad ears; long, muscular, flexible trunk (proboscis); thick loose skin is characteristic; two upper incisors are elongated as tusks. Includes extinct mastodons and woolly mammoths.	 African elephant *Loxodonta africana*
LAGOMORPHA (rabbits, hares, pikas) Like rodents, have chisel-like incisors; typically have long hind legs adapted for jumping; many have long ears.	 Pika *Ochontona* sp.	**SIRENIA** (sea cows, manatees) Herbivorous, aquatic mammals with finlike forelimbs and no hind limbs. They are probably the basis for most tales about mermaids. Evolved from Proboscidean ancestors.	 Manatee *Trichechus manatus*
PRIMATES (lemurs, monkeys, apes, humans) Highly developed brain and eyes; nails instead of claws; opposable thumb; eyes directed forward; omnivores; most species arboreal. (Primate evolution is discussed in Chapter 22.)	 Ring-tailed lemur *Lemur catta*	**CETACEA** (whales, dolphins, porpoises) Adapted for aquatic life with fish-shaped body and broad, paddlelike forelimbs (flippers); posterior limbs absent; many have thick layer of blubber under skin; some are filter feeders; mate and bear young in the water; very intelligent. Evolved from Artiodactylian ancestors.	 Humpback whale *Megaptera noveangliae*

Table 32-5 Overview of the Deuterostomes

Major Groups		Body Plan	Key Characteristics
Echinoderms (sea stars, sea urchins, sand dollars)		Larva bilateral, ciliated; adult pentaradial; triploblastic; organ systems; complete digestive tube	Endoskeleton with spines; water vascular system functions in locomotion, feeding, and gas exchange; tube feet; marine
Hemichordates (acorn worms)		Bilateral symmetry; triploblastic; organ systems; complete digestive tube	Ring of cilia surrounds mouth; three-part body: proboscis, collar, and trunk; pharyngeal slits; wormlike marine animals
Chordates (tunicates, lancelets, vertebrates)		Bilateral symmetry; triploblastic; organ systems; complete digestive tube	Notochord; dorsal, tubular nerve cord; endostyle; postanal tail; pharyngeal slits during some time in life cycle; segmented muscles

Summary: Focus on Learning Objectives

32.1 What Are Deuterostomes? *(page 677)*

1 Identify shared derived characters of deuterostomes and briefly describe the hemichordates.

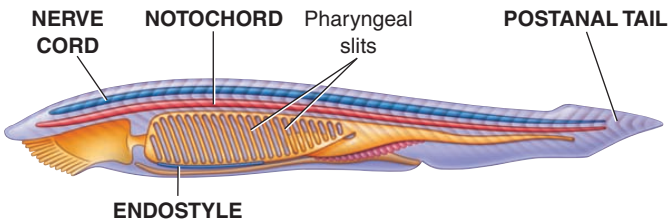
- The **deuterostomes** include echinoderms, hemichordates, and chordates. Shared derived characters include: radial, indeterminate cleavage; the blastopore becomes (or is near the future site of) the anus; and pharyngeal slits at some time in the life cycle. Basal deuterostomes have a larva with a loop-shaped ciliated band used for locomotion.
- **Hemichordates** (acorn worms) are marine deuterostomes with a three-part body, including proboscis, collar, and trunk.

32.2 Echinoderms *(page 677)*

2 Identify three shared derived characters of echinoderms and describe the main clades (classes) of echinoderms.

- **Echinoderms** (*Echinodermata*) are marine animals with a spiny "skin," **water vascular system**, **tube feet**, and **endoskeleton**. The larvae exhibit bilateral symmetry; most of the adults exhibit *pentaradial symmetry*.
- Clade Crinoidea includes sea lilies and feather stars. The *oral surface* of crinoids is turned upward; some crinoids are sessile.
- Clade Asteroidea consists of the sea stars. They have a central disc with five or more arms, and they use tube feet for locomotion.
- Clade Ophiuroidea includes the brittle stars, which resemble sea stars but have longer, more slender arms that are set off more distinctly from the central disc. They use their arms for locomotion. Their tube feet lack suckers and are not used in locomotion.
- Clade Echinoidea includes the sea urchins and sand dollars. Echinoids lack arms; they have a solid shell and are covered with spines.
- Clade Holothuroidea consists of sea cucumbers, animals with elongated flexible bodies. The mouth is surrounded by a circle of modified tube feet that serve as tentacles.

32.3 The Chordates: Major Characteristics *(page 681)*



3 Describe characteristics of chordates, including four shared derived characters.

- The **chordates** include three groups: tunicates (Urochordata), lancelets (Cephalochordata), and vertebrates (Vertebrata). At some time in its life cycle, a chordate has a flexible, supporting **notochord**; a **dorsal, tubular nerve cord**; a muscular **postanal tail**; and an **endostyle**, or thyroid gland; they are also characterized by **pharyngeal slits**, but that is a derived character of deuterostomes.

32.4 Invertebrate Chordates *(page 682)*

4 Compare tunicates and lancelets, and summarize the phylogeny of chordates.

- The **tunicates** are **urochordates**, suspension-feeding marine animals with tunics. Larvae have typical chordate characteristics and are free-swimming. Adults of most groups are sessile suspension feeders.
- The *lancelets* are **cephalochordates**, small, segmented, fishlike animals; their chordate characteristics are highly developed.
- The available evidence suggests that urochordates are the sister group of the vertebrates.

32.5 Introducing the Vertebrates *(page 684)*

5 Describe four shared derived characters of vertebrates.

- The vertebrates have a *vertebral column* composed of *vertebrae* that forms the chief skeletal axis of the body and a braincase, or **cranium**. **Neural crest cells** are embryonic cells important in the development of many structures, including the cranium and jaws. Vertebrates have pronounced cephalization and 10 or 12 pairs of cranial nerves. They have a complex brain, a muscular pharynx, and muscles attached to the endoskeleton.

6 Describe the major taxa of extant vertebrates.

- Vertebrates can be assigned to 10 clades (formerly referred to as classes). The hagfishes, which make up the *Myxini*, and the lampreys, which make up the *Petromyzontida*, have neither jaws nor paired fins. The *Chondrichthyes* comprise the sharks, rays, and skates; they are jawed fishes with skeletons of cartilage. The extant (living) bony fishes can be assigned to three clades (classes): *Actinopterygii*, ray-finned fishes; *Actinistia*, coelacanths; and *Dipnoi*, lungfishes.
- The **tetrapods** (Tetrapoda) include the amphibian clades (salamanders, frogs, and caecilians), many of which have aquatic larvae that undergo metamorphosis, and the amniote lineage (Amniota), which includes reptiles and mammals. **Reptiles** (clade Reptilia) include lizards, snakes, turtles, alligators, and birds.
- Reptiles are amniotes with keratin scales or feathers and reproduction adapted for terrestrial life; mammals (clade Mammalia) include monotremes, marsupials, and placental mammals. Mammals are amniotes with hair and mammary glands. (See Table 32-2 for a more detailed review.)

32.6 Jawless Fishes *(page 686)*

7 Distinguish among the major groups of jawless fishes.

- The extant jawless fishes are the hagfishes (Myxini) and the lampreys (Petromyzontida). Jaws and paired fins are absent in both hagfishes and lampreys. Hagfishes are marine scavengers that secrete slime as a defense mechanism. Many lampreys are parasites on other fishes.

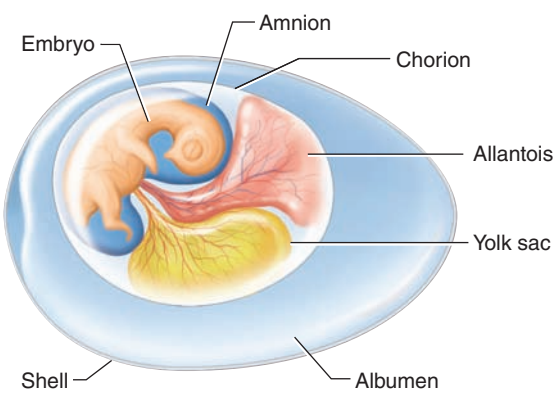
32.7 Evolution of Jaws and Limbs: Jawed Fishes and Tetrapods *(page 688)*



8 Trace the evolution of jawed fishes and early tetrapods, and describe modern amphibians.

- Chondrichthyes, the cartilaginous fishes (sharks, rays, and skates), evolved during the Devonian period. They have jaws, two pairs of fins, and **placoid scales**.
- During the Devonian period, bony fishes gave rise to two evolutionary lines: the Actinopterygii, or **ray-finned fishes**, and the Sarcopterygii, or *lobe-finned fishes*. The ray-finned fishes gave rise to the modern bony fishes. Their lungs have been modified as a **swim bladder**, an air sac for regulating buoyancy.
- The Sarcopterygii includes the Tetrapodomorpha, the *lungfishes* (Dipnoi), and the **coelacanths** (Actinistia). Evidence suggests that the Tetropodomorpha gave rise to the **tetrapods**, the land vertebrates. *Tiktaalik* was a transitional form between fishes and tetrapods.
- Early tetrapods were mainly aquatic animals that ventured onto the land to find food or escape predators. These early tetrapods had limbs strong enough to support the weight of their bodies on land.
- Modern **amphibians** (Amphibia) include salamanders and newts, frogs and toads, and caecilians. Most amphibians return to the water to reproduce. Frog embryos develop into tadpoles, which undergo **metamorphosis** to become adults. Amphibians use their moist skin as well as lungs for gas exchange. They have systemic and pulmonary circulations as well as hearts with two atria and one ventricle.

32.8 Amniotes: Terrestrial Vertebrates *(page 694)*

9 Describe three vertebrate adaptations to terrestrial life.

- Terrestrial vertebrates, or **amniotes**, include reptiles (including birds) and mammals. Adaptations for life on land include (1) the evolution of the **amniotic egg** with its shell and **amnion**, a membrane that forms a fluid-filled sac around the embryo; (2) internal fertilization; and (3) a body covering that retards water loss and physiological mechanisms that conserve water.

10 Describe the reptiles (including the birds) and argue for including the birds in the reptile clade.

- Biologists classify amniotes in two main groups: diapsids and synapsids. **Diapsids** include the turtles, squamates (snakes and lizards), tuataras, extinct ichthyosaurs, crocodiles, the extinct pterosaurs, the extinct ornisthischian dinosaurs, the extinct saurischian dinosaurs, and birds. The **synapsids** include the **therapsids**, which gave rise to the mammals. (See Table 32-3.)
- Extant **reptiles** (including birds) can be classified in five clades: (1) turtles, terrapins, and tortoises; (2) lizards, snakes, and worm lizards; (3) tuataras; (4) crocodiles, alligators, caimans, and gavials; and (5) birds (avian reptiles).
- Most non-avian reptiles have dry skin with horny scales, lungs with many chambers, and a heart with two completely separated atria and two ventricles that are incompletely separated. (In the crocodiles the two ventricles are completely partitioned.) Birds have many adaptations for powered flight, including feathers; wings; and light, hollow bones containing air spaces. They have completely divided ventricles and very efficient lungs, and they excrete solid metabolic wastes (uric acid). They are **endotherms**; that is, they maintain a constant body temperature. Birds have a well-developed nervous system with excellent vision and hearing.
- Based on fossil evidence and molecular data, feather evolution took place in terrestrial, bipedal dinosaurs before the evolution of birds or flight. Birds are considered feathered reptiles that evolved from the lineage of saurischian dinosaurs, specifically from the **theropods**, a group of bipedal, saurischian dinosaurs. Like theropods, modern birds have feet with three digits; thin-walled, hollow bones; and a *furcula*, or wishbone.

11 Describe five key characters of mammals and contrast protherian (monotremes), metatherian (marsupials), and eutherian mammals, giving examples of animals that belong to each group.

- **Mammals** have several derived characters, including **mammary glands**, hair, one pair of temporal openings in the skull, differentiated teeth, lungs with alveoli, completely divided ventricles, three middle-ear bones, and a highly developed nervous system, including a neocortex.
- Mammals can be assigned to two clades: **protherians** and **therians**. The protherians are the **monotremes**, mammals that lay eggs. This clade includes the duck-billed platypus and spiny anteaters.
- Therians bear their young alive. This clade includes metatheria (marsupials) and **eutherians**, mammals with a well-developed placenta. The **marsupials** are pouched mammals, such as kangaroos and opossums. The young, born at an immature stage, complete their development in their mother's marsupium, where they are nourished with milk from mammary glands.
- Eutherians are more developed at birth than marsupials; they are characterized by a well-developed **placenta**, an organ of exchange that develops between the embryo and the mother.

Test Your Understanding

Know and Comprehend

1. Which of the following is *not* a shared derived character of echinoderms? (a) water vascular system (b) notochord (c) tube feet (d) pentaradial symmetry in adult (e) endoskeleton of calcium carbonate plates and spines
2. Which of the following is/are found in tunicates? (a) dorsal, tubular nerve cord (b) tube feet (c) anal gill slits (d) two pairs of appendages (e) vertebral column
3. A shark is characterized by (a) amnion (b) bony skeleton (c) water vascular system (d) placoid scales (e) endothermy *and* amnion
4. Which of the following characteristics is/are associated with amphibians? (a) amnion (b) placoid scales (c) heart with two complete ventricles (d) swim bladder (e) metamorphosis
5. Reptiles (a) are all endotherms (b) are amniotes (c) have a great deal of keratin in their epidermis (d) have external fertilization (e) b and c are both correct
6. Which of the following is *not* characteristic of birds? (a) hollow bones (b) amnion (c) ectothermy (d) high metabolic rate (e) reptilian-like scales on legs
7. Which of the following is true of mammals? (a) they evolved from saurischian dinosaurs (b) they are exotherms (c) they have hair and three middle ear bones (d) mammalian embryos do not have an amnion (e) they all bear their young alive (do not lay eggs).

Apply and Analyze

8. **VISUALIZE** Draw a simple cladogram illustrating the evolutionary relationships among extant mammals (marsupials, eutherians, and monotremes). Include the following characters in your cladogram: well-developed placenta, vivipary, endothermy, marsupium, hair.
9. **EVOLUTION LINK** Sea urchins have radial symmetry. Explain why they are not classified as cnidarians.
10. **EVOLUTION LINK** Most biologists consider birds as living dinosaurs. Justify this position.
11. **EVOLUTION LINK** Discuss the relationships among the echinoderms and chordates, describing shared derived characters that support grouping these animals as deuterostomes.

Evaluate and Synthesize

12. **INTERPRET DATA** Imagine that you discover an interesting new animal. You examine it and gather the following data. It has a dorsal, tubular nerve cord; a cranium; skin with scales; and a heart with two atria and two ventricles. How would you classify the animal? Explain each step in your decision. Where would you place this animal on the cladogram shown in Figure 32-20?
13. **SCIENCE, TECHNOLOGY, AND SOCIETY** Every year hundreds of sea turtles are injured and killed as a result of human activities. All seven species of marine turtles are listed under the Endangered Species Act. What measures would you propose to protect sea turtles?

33 Plant Structure, Growth, and Development

KEY CONCEPTS

33.1 The structure of plant cells, tissues, and organs matches their functions. The vascular plant body is differentiated into three tissue systems: the ground tissue system, the vascular tissue system, and the dermal tissue system.

33.2 Primary meristems lengthen roots and shoots throughout the lifespan of most plants. Woody plants have both primary meristems and secondary meristems, which increase roots and shoots in thickness.

33.3 Plant development requires not only cell division and expansion but also cell determination and cell differentiation, and pattern formation and morphogenesis.

PHOTO: Foxgloves, herbaceous biennials, and oxeye daisies, herbaceous perennials. Foxgloves (*Digitalis purpurea*) and oxeye daisies (*Leucanthemum vulgare*) grow wild in this mountain meadow in Idaho. These non-native species are also popular garden plants. Foxglove is the source of digitalis, which is used to treat heart disease. Lee O'Dell/Shutterstock.com

The more than 300,000 species of flowering plants that live in and are adapted to the many environments on Earth represent remarkable variety. From desert cacti with enormously swollen stems, to cattails partly submerged in marshes, to orchids growing in the uppermost tree branches of lush tropical rain forests, they are all recognizable as plants. Almost all plants have the same basic body plan, which consists of roots, stems, and leaves.

Plants are either herbaceous or woody. *Herbaceous* plants are nonwoody. In temperate climates, the aerial parts (stems and leaves) of herbaceous plants die back to the ground at the end of the growing season. In contrast, the aerial parts of *woody* plants (trees and shrubs) persist. Botanically speaking, woody plants produce hard, lignified secondary tissues (the cell walls of secondary tissues contain *lignin*), and herbaceous plants do not. Lignin and the production of secondary tissues are discussed later in this chapter and in Chapters 35 and 36.

Annual plants are herbaceous plants (such as corn, geraniums, and marigolds) that grow, reproduce, and die in one year or less. Other herbaceous plants (such as carrots, Queen Anne's lace, cabbages, and foxgloves) are **biennial plants**; they take two years to complete their life cycles before dying (see photograph). During their first season, biennials produce extra carbohydrates, which they store and use during their second year, when they typically form flowers and reproduce.

Perennial plants are herbaceous or woody plants that have the potential to live for more than two years. In temperate climates the aerial (aboveground) stems of herbaceous perennials such as irises, rhubarb, onions, asparagus, and oxeye daisies (see photograph) die back each winter. Their underground parts (roots and underground stems) become dormant during the winter and send out new growth each spring. (In **dormancy** an organism reduces its metabolic state to a minimum level to survive unfavorable conditions.) Similarly, in certain

tropical climates with pronounced wet and dry seasons, the aerial parts of herbaceous perennials die back, and the underground parts become dormant during the unfavorable dry season. Other tropical plants, such as orchids, are herbaceous perennials that grow year-round.

All woody plants are perennials, and some of them live for hundreds or even thousands of years. In temperate climates, the aerial stems of woody plants become dormant during the winter. Many temperate woody perennials are **deciduous**; that is, they shed their leaves before winter and produce new stems with new leaves the following spring. Other woody perennials are **evergreen** and shed their leaves over a long period, so some leaves are always present. Because they have permanent woody stems that are the starting points for new growth the following season, many trees attain massive sizes.

In this chapter we focus on the structure, growth, and development of flowering plants, which are vascular plants characterized by flowers, double fertilization, endosperm, and seeds enclosed within fruits (see Chapter 28). We then examine other aspects of flowering plants in Chapters 34 to 38.

33.1 The Plant Body

LEARNING OBJECTIVES

1. Discuss the functions of various parts of the vascular plant body, including the nutrient- and water-absorbing root system and the photosynthesizing shoot system.
2. Describe the structure and functions of the ground tissue system (parenchyma tissue, collenchyma tissue, and sclerenchyma tissue).
3. Describe the structure and functions of the vascular tissue system (xylem and phloem).
4. Describe the structure and functions of the dermal tissue system (epidermis and periderm).

The plant body of flowering plants (and other vascular plants) is usually organized into a root system and a shoot system (FIG. 33-1). The **root system** is generally underground. The aerial portion, the **shoot system**, usually consists of a vertical stem that bears leaves and, in flowering plants, flowers and fruits that contain seeds.

Each plant typically grows in two different environments: the dark, moist soil and the illuminated, relatively dry air. Plants usually have both roots and shoots because they require resources from both environments. Thus, roots branch extensively through the soil, forming a network that anchors the plant firmly in place and absorbs water and dissolved minerals (inorganic nutrients). Leaves, the flattened organs of photosynthesis, are attached more or less regularly on the stem, where they absorb the sun's light and atmospheric carbon dioxide (CO_2) used in photosynthesis.

The plant body consists of cells and tissues

As in other organisms, the basic structural and functional unit of plants is the cell. Plants have evolved a variety of cell types, each specialized for particular functions. Plant cells are organized into tissues. A **tissue** is a group of cells that forms a structural and functional unit. *Simple tissues* are composed of only one kind of cell, whereas *complex tissues* have two or more kinds of cells.

In vascular plants, tissues are organized into three tissue systems, each of which extends throughout the plant body (FIG. 33-2). Each tissue system contains two or more kinds of tissues (TABLE 33-1 on page 714). Most of the plant body is composed of the **ground tissue system**, which has a variety of functions, including photosynthesis, storage, and support. The **vascular tissue system**, an intricate conducting system that extends throughout the plant body, is responsible for conduction of various substances, including water, dissolved minerals, and food (dissolved sugar). The vascular tissue system also functions in strengthening and supporting the plant. The **dermal tissue system** provides a covering for the plant body.

Roots, stems, leaves, flower parts, and fruits are **organs** because each is composed of all three tissue systems. The tissue systems of different plant organs form an interconnected network throughout the plant. For example, the vascular tissue system of a leaf is continuous with the vascular tissue system of the stem to which it is attached, and the vascular tissue system of the stem is continuous with the vascular tissue system of the root.

The ground tissue system is composed of three simple tissues

The bulk of a herbaceous plant is its ground tissue system, which is composed of three tissues: parenchyma, collenchyma, and sclerenchyma (TABLE 33-2 on pages 714 and 715). These tissues can be distinguished by their cell wall structures. Recall that plant cells are surrounded by a cell wall that provides structural support (see Chapter 4). A growing plant cell secretes a thin *primary cell wall*, which stretches and expands as the cell increases in size. After the cell stops growing, it sometimes secretes a thick, strong *secondary cell wall*, which is deposited *inside* the primary cell wall—that is, between the primary cell wall and the plasma membrane (see Fig. 4-30).

Plant cell walls have several important roles. As discussed later in this chapter, cell walls are involved in growth; the ability of primary cell walls to expand allows cells to increase in size. Scientists are increasingly aware that **signal transduction** takes place in plant cell walls because many carbohydrate and protein molecules in plant cell walls communicate with other molecules both inside and outside the cell. The cell wall is also the first line of defense against disease-causing organisms.

Parenchyma cells have thin primary walls

Parenchyma tissue, a simple tissue composed of parenchyma cells, is found throughout the plant body and is the most common type of cell and tissue (FIG. 33-3a on page 716). The soft parts of a plant, such as the edible part of an apple or a potato, consist largely of parenchyma.

Parenchyma cells perform several important functions, such as photosynthesis, storage, and secretion. Parenchyma cells that function in photosynthesis contain green chloroplasts, whereas nonphotosynthetic parenchyma cells lack chloroplasts and are often colorless. Materials stored in parenchyma cells include starch grains, oil droplets, water, and salts, which are sometimes visible as crystals. Resins, tannins, hormones, enzymes, and sugary nectar are examples of substances that may be secreted

Key Point

During the evolution of plants, the root and shoot systems specialized to obtain resources from the soil and air, respectively.

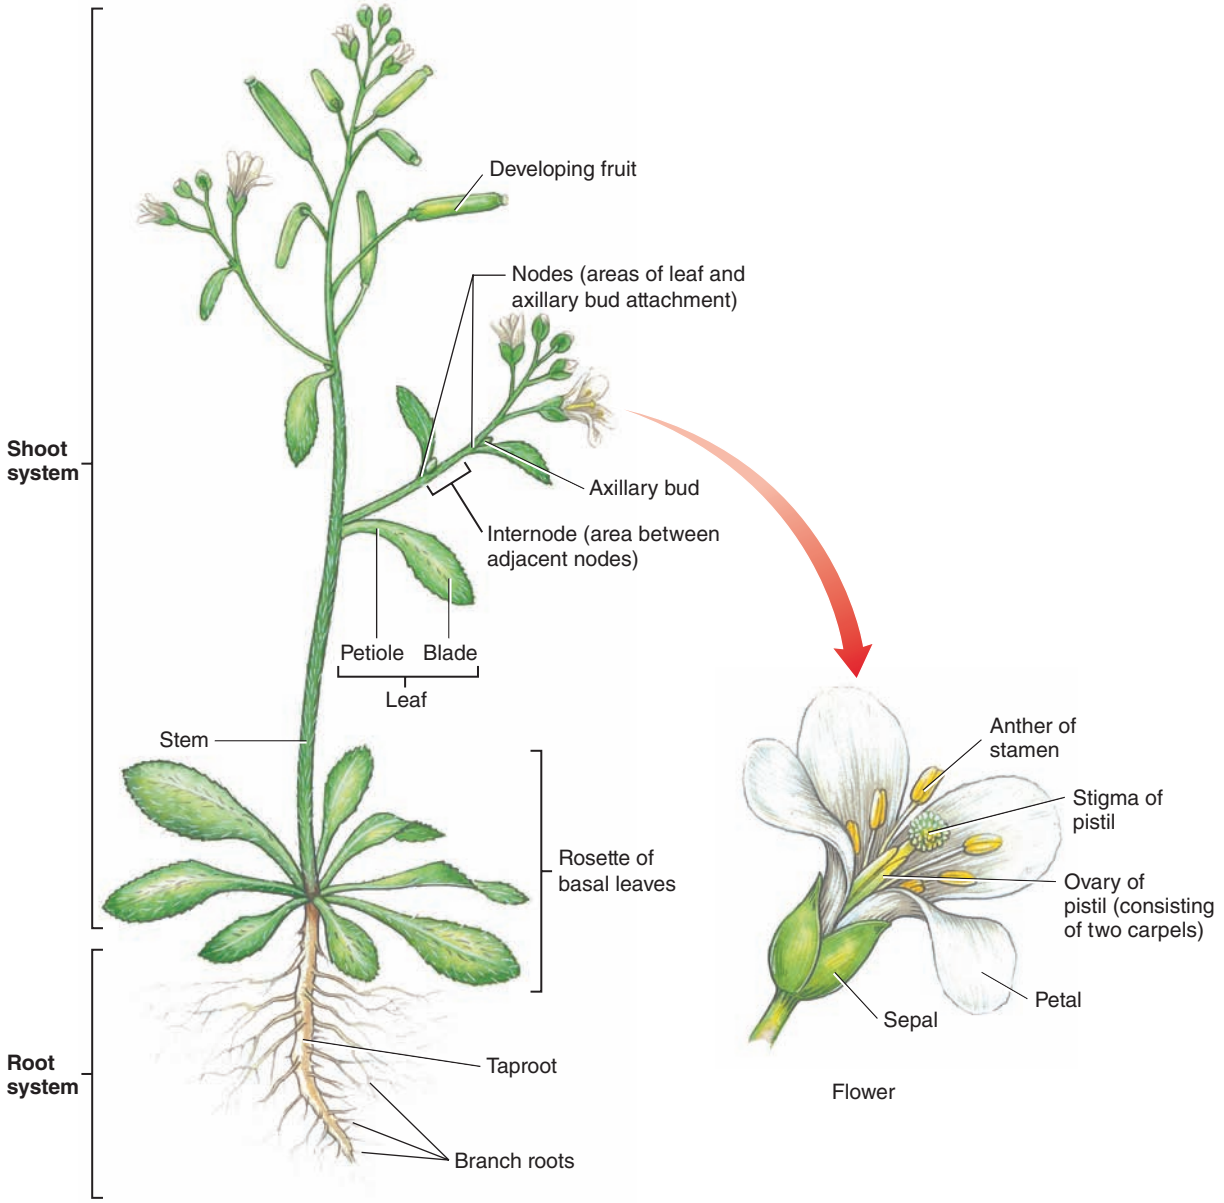

Figure 33-1 The plant body

A plant body consists of a root system, usually underground, and a shoot system, usually aerial. Shown is mouse-ear cress (*Arabidopsis thaliana*), a small plant in the mustard family that is a model plant for biological research. *Arabidopsis* is native to North Africa and Eurasia and has been naturalized (was introduced and is now growing in the wild) in California and the eastern half of the United States.

CONNECT What resources required for photosynthesis do plants obtain from the air? from the soil?

by parenchyma cells. The various functions of parenchyma require that parenchyma cells be alive and metabolically active.

Parenchyma cells have the ability to *differentiate* into other kinds of cells, particularly when a plant has been injured. If xylem (water-conducting) cells are severed, for example, adjacent parenchyma cells may divide and differentiate into new xylem cells within a few days. (Recall from Chapter 17 that it is possible to induce certain plant cells to become the equivalent of embryonic stem cells that can then differentiate into specialized cells.)

Collenchyma cells have unevenly thickened primary walls

Collenchyma tissue, a simple plant tissue composed of collenchyma cells, is an extremely flexible structural tissue that provides much of the support in soft, nonwoody plant organs

Key Point

The tissue systems are continuous throughout the plant. For example, the vascular tissue system in a leaf is continuous with the vascular tissue system in the stem to which it is attached.

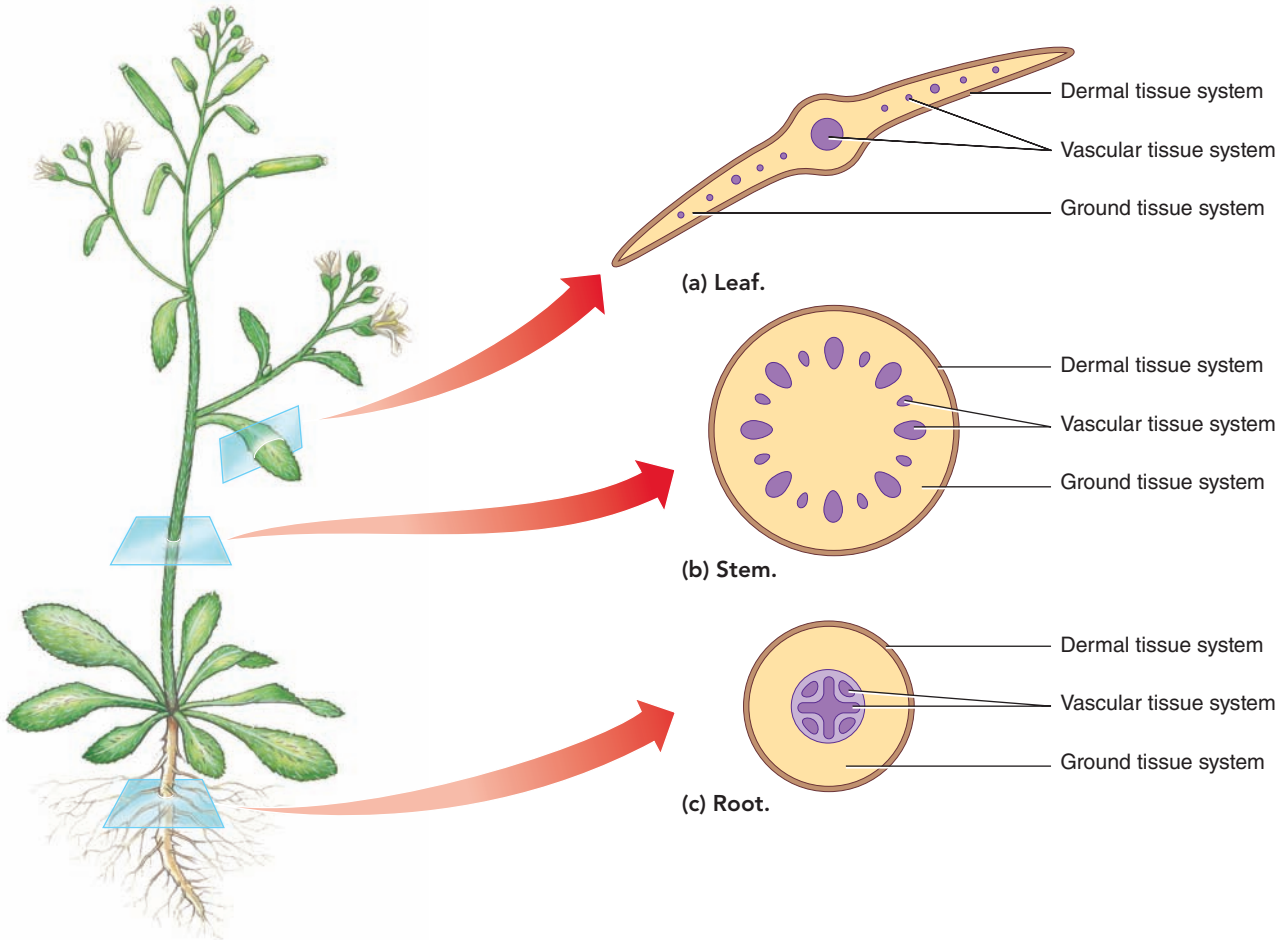

Figure 33-2 The three tissue systems in the plant body
This figure shows the distribution of the ground tissue system, vascular tissue system, and dermal tissue system in a herbaceous eudicot such as *Arabidopsis*.

PREDICT What do you think would happen if the vascular tissue system were to become discontinuous in the stem but the dermal and ground tissue systems were to remain intact?

(FIG. 33-3b on page 716). Support is crucial for plants, in part because it lets them grow upward to compete with other plants for available sunlight in a plant-crowded area. Plants lack the bony skeletal system typical of many animals; instead, individual cells, including collenchyma cells, support the plant body.

Collenchyma cells, which are usually elongated, are alive at maturity. Their primary cell walls are unevenly thickened and are especially thick in the corners. Collenchyma is not found uniformly throughout the plant and often occurs as long strands near stem surfaces and along leaf veins. The "strings" in a celery stalk, for example, consist of collenchyma tissue.

Sclerenchyma cells have both primary walls and thick secondary walls Another simple plant tissue specialized for structural support is **sclerenchyma** tissue, whose cells have both primary and secondary cell walls. The root of the word *sclerenchyma* is derived from the Greek word *sclero*, meaning "hard." The secondary cell walls of sclerenchyma cells become strong and hard because of extreme thickening. *Pits*, which are thin areas where secondary walls did not develop, allow an exchange of substances between adjacent living sclerenchyma cells. Mature sclerenchyma cells are unable to stretch or elongate. At functional maturity, when sclerenchyma tissue is providing support for the plant body, its cells are often dead.

Sclerenchyma tissue may be located in several areas of the plant body. Two types of sclerenchyma cells are sclereids and fibers. **Sclereids** are cells of variable shape common in the shells of nuts and in the stones of fruits such as cherries and peaches. The slightly gritty texture of pears results from the presence of clusters

Table 33-1 Tissue Systems, Tissues, and Cell Types of Flowering Plants

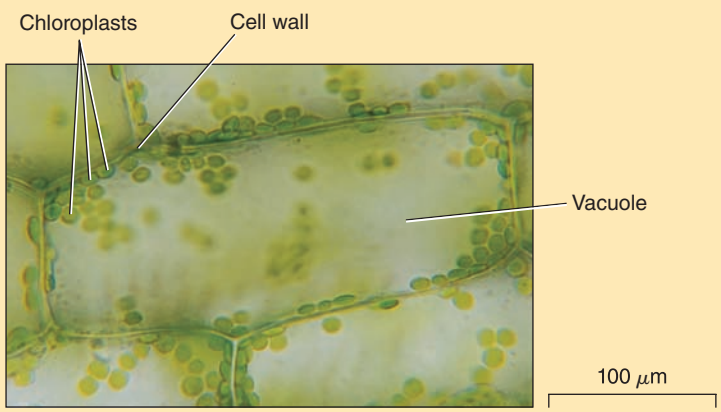
Tissue System	Tissue	Cell Types	Main Functions of Tissue
Ground tissue system	Parenchyma tissue	Parenchyma cells	Storage, secretion, photosynthesis
	Collenchyma tissue	Collenchyma cells	Support
	Sclerenchyma tissue	Sclerenchyma cells (sclereids or fibers)	Support, strength
Vascular tissue system	Xylem	Tracheids	Conduction of water and nutrient minerals, support
		Vessel elements	Conduction of water and nutrient minerals, support
		Xylem parenchyma cells	Storage
		Fibers (sclerenchyma cells)	Support, strength
	Phloem	Sieve tube elements	Conduction of sugar in solution, support
		Companion cells	May control functioning of sieve tube elements, loading sugar into sieve tube elements
		Phloem parenchyma cells	Storage
		Fibers (sclerenchyma cells)	Support, strength
Dermal tissue system	Epidermis	Epidermal cells	Protective covering over surface of plant body
		Guard cells	Regulate stomata
		Trichomes	Variable functions
	Periderm	Cork cells	Protective covering over surface of plant body
		Cork cambium cells	Meristematic (form new cells)
		Cork parenchyma cells	Storage

Table 33-2 Cell Types in the Ground Tissue System

Phil Gates/Biological Photo Service

Parenchyma cell

Description



Living, actively metabolizing; thin primary cell walls

Functions

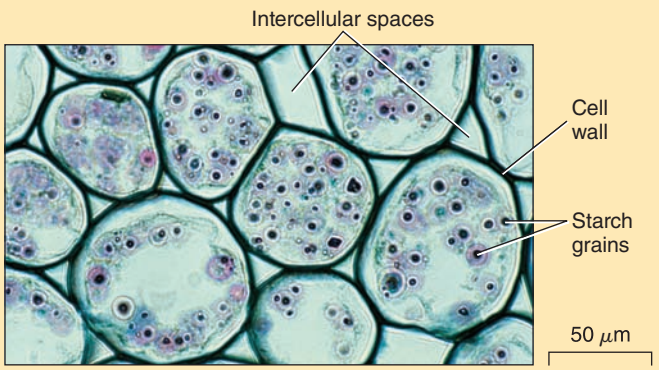
Storage; secretion, and/or photosynthesis

Location and comments

Throughout the plant body; shown is an LM of a stamen hair of a spiderwort (*Tradescantia virginiana*) flower; note the large pigmented vacuole; the nucleus is not inside the vacuole but is lying on *top* of the vacuole

Parenchyma cell

Description



Living, actively metabolizing; thin primary cell walls

Functions

Storage; secretion; photosynthesis

Location and comments

Throughout the plant body; shown is an LM of leaf cells from an aquatic plant (*Elodea*); note the many chloroplasts in the thin layer of cytoplasm surrounding the large, transparent vacuole

Parenchyma cell

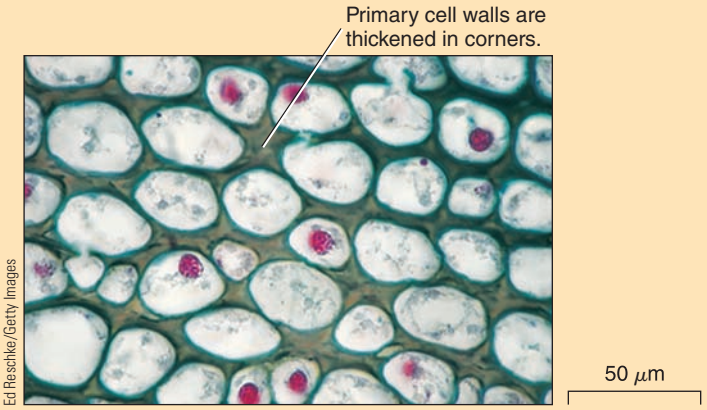
Description

Living, actively metabolizing; thin primary cell walls

Functions

Storage; secretion; photosynthesis

Location and comments



Throughout the plant body; shown is an LM of a cross section of part of a buttercup (*Ranunculus*) root; note the starch grains filling the cells

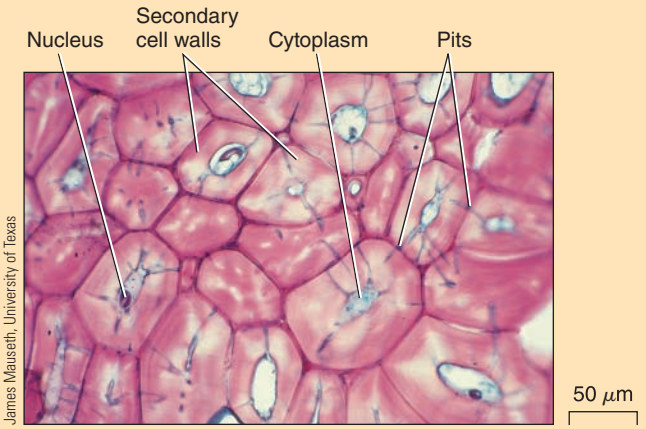
Table 33-2 Cell Types in the Ground Tissue System (*continued*)

Ed Reschke/Getty Images

Collenchyma cell

Description



Living; unevenly thickened primary cell walls

Function

Elastic support

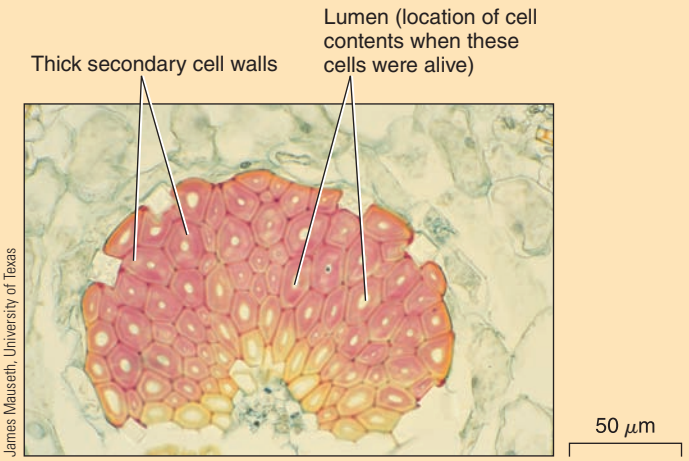
Location and comments

Just under stem epidermis; shown is an LM of a cross section of an elderberry (*Sambucus*) stem; note the unevenly thickened cell walls that are especially thick in the corners, making the cell contents assume a rounded shape in cross section

James Mauseth, University of Texas

Sclereid (sclerenchyma cell)

Description



May be living or dead at maturity; thick secondary cell walls; lacks secondary wall at pits

Functions

Strength; sclereid-rich tissue is hard and inflexible

Location and comments

Shells of walnuts and coconuts; pits of cherries and peaches; shown is an LM of living sclereids in a section through a cherry (*Prunus avium*) pit

James Mauseth, University of Texas

Fiber (sclerenchyma cell)

Description

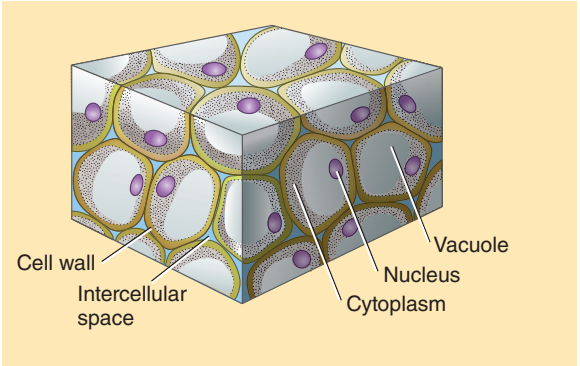
Often dead at maturity; thick secondary cell walls; fewer pits than in sclereids

Functions

Support; provides strength

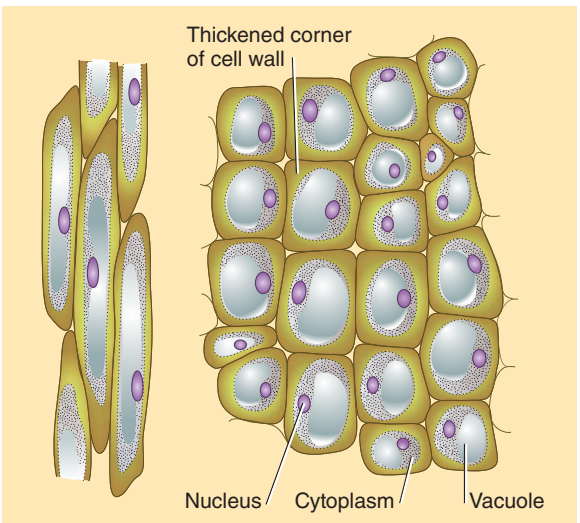
Location and comments

Throughout the plant body; common in stems and certain leaves; shown is an LM of a cross section through a clump of fibers from a century plant (*Agave*) leaf



of sclereids. **Fibers**, which are long, tapered cells that often occur in patches or clumps, are particularly abundant in the wood, inner bark, and leaf ribs (veins) of flowering plants (FIG. 33-3c).

Cells of the three simple tissues vary in their cell wall chemistry Parenchyma, collenchyma, and sclerenchyma cells can be distinguished by the chemistry of their cell walls. Cell walls may contain cellulose, hemicelluloses, pectin, and lignin. **Cellulose**, the most abundant polymer in the world, accounts for about 40% to 60% of the dry weight of plant cell walls. As discussed in Chapter 3, cellulose is a **polysaccharide** composed of glucose units joined by β-1,4 bonds. Each cellulose molecule consists of thousands of glucose subunits joined to form a flat, ribbonlike chain. From 40 to 70 of these chains lie parallel to one another and connect by hydrogen bonding to form a *cellulose microfibril*, a strong, tiny strand visible under the electron microscope (see Fig. 3-10a).



Cellulose microfibrils are cemented together by a matrix of hemicelluloses and pectins. *Hemicelluloses* are a group of polysaccharides that are more soluble than cellulose. Hemicelluloses

(a) Parenchyma cells have thin primary cell walls. They vary in size and structure, depending on their various functions within the plant body.

(b) Collenchyma cells in longitudinal section (*left*) and cross section (*right*). Note the elongated cells, evident in longitudinal section, and the unevenly thickened primary cell walls, evident in cross section.

(c) Sclerenchyma cells (fibers) in longitudinal section (*left*) and cross section (*right*). Mature fibers have thick secondary cell walls, are often dead at functional maturity, and therefore lack nuclei and cytoplasm; the lumen is the space formerly occupied by the living cell.

Figure 33-3 Cell types: parenchyma, collenchyma, and sclerenchyma

vary in their chemical composition from one species to another. Some hemicelluloses are composed of *xyloglucan*, which consists of a backbone of β-1,4-glucose molecules to which side chains of *xylose*, a 5-carbon sugar, are attached. Despite their name, the chemical structure of the hemicelluloses is significantly different from that of cellulose. *Pectin*, another cementing polysaccharide, is less variable in its monomer composition than are the hemicelluloses. Pectin monomer units are *α-galacturonic acid*, a 6-carbon molecule that is a derivative of glucose.

An important component of secondary plant cell walls, particularly those of wood, is **lignin**. Composing as much as 35% of the dry weight of the secondary cell wall, lignin is a strengthening polymer made up of monomers derived from certain amino acids. Scientists have not yet determined the exact chemical structure of lignin because it is hard to remove from cellulose and other cell wall materials to which it is covalently bound.

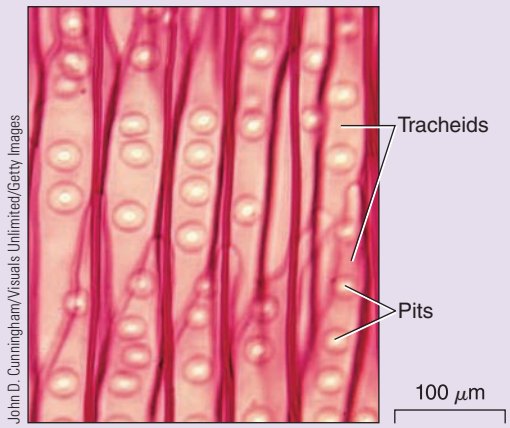
Having discussed the four main components in plant cell walls, we can now generalize about the cell chemistry of parenchyma, collenchyma, and sclerenchyma cells. The thin primary cell walls of parenchyma cells contain predominantly cellulose, although they also contain hemicelluloses and pectin. Both parenchyma and collenchyma cells have primary cell walls, but their walls are chemically distinct because the thickened areas of collenchyma walls contain large quantities of pectin in addition to cellulose and hemicelluloses. The thick secondary walls of sclerenchyma cells are chemically different because they are rich in lignin in addition to cellulose, hemicelluloses, and pectin.

The vascular tissue system consists of two complex tissues

The **vascular tissue system**, which is embedded in the ground tissue, transports needed materials throughout the plant via two complex tissues: xylem and phloem (TABLE 33-3). Both xylem and phloem are continuous throughout the plant body. (Chapter 35 discusses the mechanisms of transport in xylem and phloem.)

The conducting cells in xylem are tracheids and vessel elements

Xylem conducts water and dissolved minerals from the roots to the stems and leaves and provides structural support. In flowering plants, xylem is a complex tissue composed of four cell types: tracheids, vessel elements, parenchyma cells, and fibers. Two of the four cell types found in xylem, the **tracheids** and **vessel elements**, conduct water and dissolved minerals. Xylem also contains fibers that provide support, and parenchyma cells, known as *xylem parenchyma*, that perform storage functions.



Tracheids and vessel elements are highly specialized for conduction. As they develop, both types of cells undergo **apoptosis**, or programmed cell death. As a result, mature tracheids and vessel elements are dead and therefore hollow; only their cell walls remain. Tracheids, the chief water-conducting cells in gymnosperms (such as pines) and seedless vascular plants (such as ferns), are long, tapering cells located in patches or clumps (FIG. 33-4a). Water is conducted upward, from roots to shoots, passing from one tracheid into another through wide pits.

In addition to tracheids, flowering plants possess extremely efficient vessel elements (FIG. 33-4b). The cell diameters of vessel elements are usually greater than those of tracheids. Vessel elements are hollow, but unlike tracheids, the end walls have holes, known as *perforations*, or are absent. Vessel elements are stacked

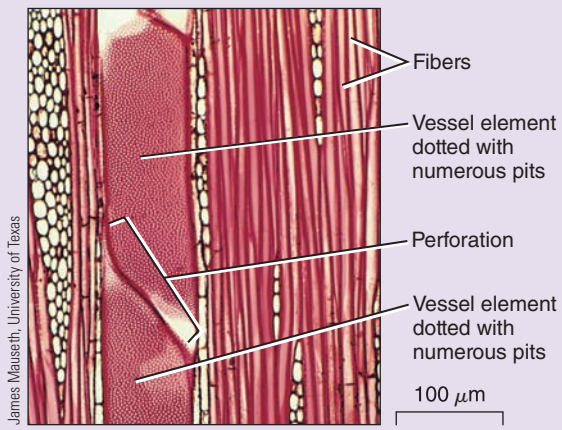
Tracheid

Description



Dead at maturity; lacks secondary wall at pits

Functions

Conduction of water and nutrient minerals; support

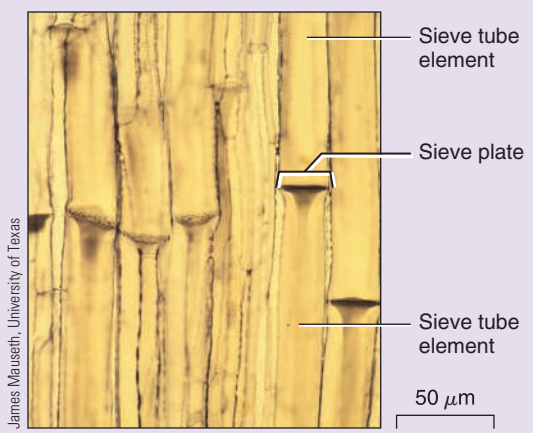
Location and comments

Occurs in clumps in xylem throughout plant body; shown is an LM of a longitudinal section of tracheids from white pine (*Pinus strobus*) wood

James Mauseth, University of Texas

Vessel element

Description



Dead at maturity; end walls have perforations; lacks secondary wall at pits

Functions

Conduction of water and nutrient minerals; support

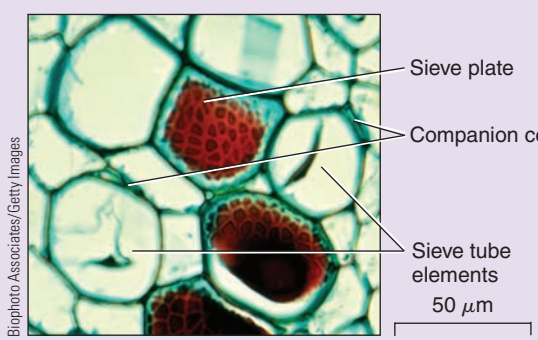
Location and comments

Xylem throughout plant body; vessel elements are more efficient than tracheids in conduction; shown is an LM of a longitudinal section of two vessel elements from an unidentified woody eudicot

James Mauseth, University of Texas

Sieve tube element

Description



Living but lacks nucleus and other organelles at maturity; end walls are sieve plates

Function

Conduction of sugar in solution

Location and comments

Phloem throughout plant body; shown is an LM of a longitudinal section through a clump of sieve tube elements in a squash (*Cucurbita*) petiole (leaf stalk)

Biophoto Associates/Getty Images

Companion cell

Description

Living; has cytoplasmic connections with sieve tube element

Function

Assists in moving sugars into and out of sieve tube element

Location and comments

Phloem throughout plant body; shown is an LM of phloem from a squash (*Cucurbita*) stem in cross section

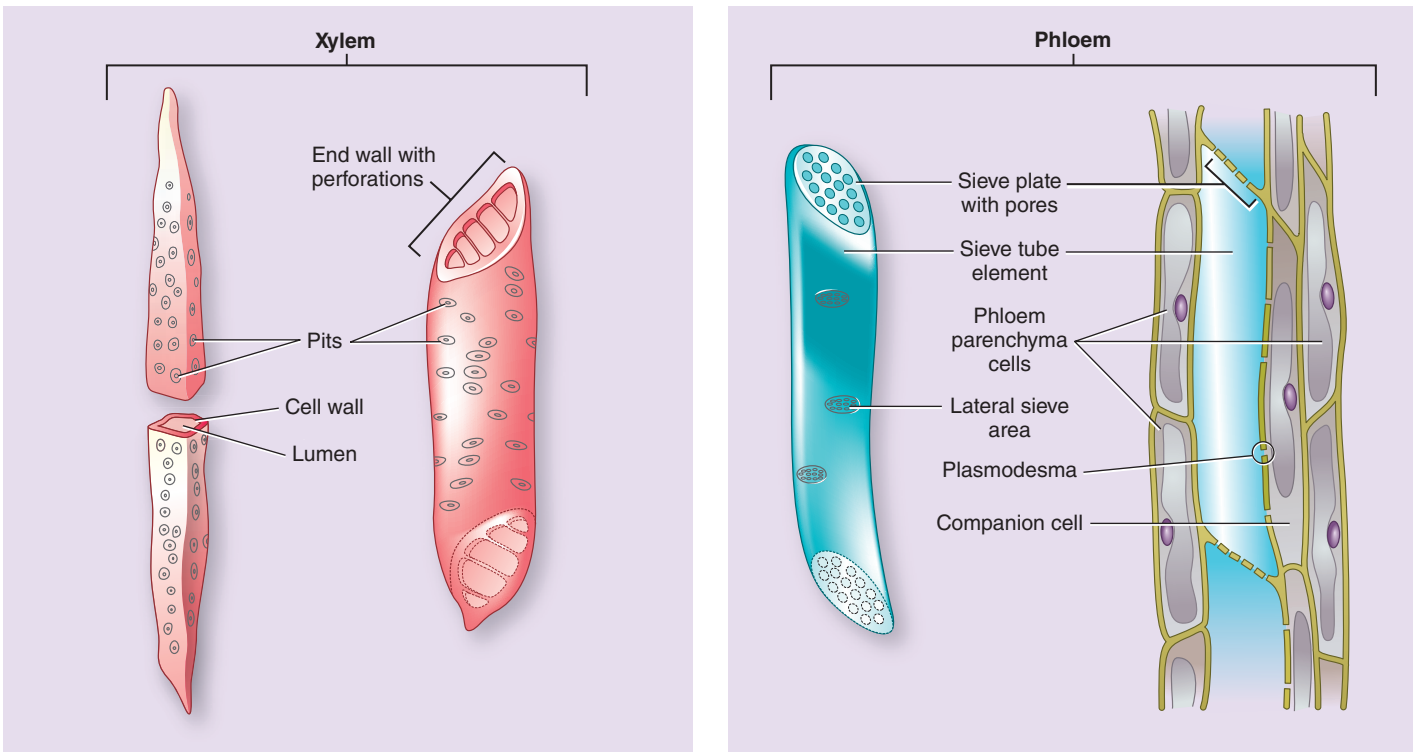
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

one on top of the other, and water is conducted readily from one vessel element into the next. A stack of vessel elements, called a **vessel**, resembles a miniature water pipe. Vessel elements also have pits in their side walls that permit the lateral transport (sideways movement) of water from one vessel to another.

Sieve tube elements are the conducting cells of phloem

Phloem conducts food materials—that is, carbohydrates formed in photosynthesis—throughout the plant and provides structural support. In flowering plants phloem is a complex tissue composed of four cell types: sieve tube elements, companion cells, fibers, and phloem parenchyma cells (FIGS. 33-4c and d). Fibers, which are usually extensive in the phloem of herbaceous plants, provide additional structural support for the plant body.



Food materials are conducted in solution—that is, dissolved in water—through the **sieve tube elements**, which are among the most specialized plant cells. Sieve tube elements are joined end to end to form long **sieve tubes**. The cells' end walls, called *sieve plates*, have a series of holes through which cytoplasm extends from one sieve tube element into the next. Sieve tube elements are living at maturity, but many of their organelles, including the nucleus, vacuole, mitochondria, and ribosomes, disintegrate or shrink as they mature.

Sieve tube elements are among the few eukaryotic cells that can function without nuclei. These cells typically live for less than a year. There are, however, notable exceptions. Certain palms have sieve tube elements that remain alive for approximately one hundred years.

Adjacent to each sieve tube element is a **companion cell** that assists in the functioning of the sieve tube element. The companion cell is a living cell, complete with a nucleus. This nucleus is thought to direct the activities of both the companion cell and sieve tube element. Numerous **plasmodesmata**—cytoplasmic connections through which cytoplasm extends from one cell to another (see Fig. 5-24)—link a companion cell with its adjoining sieve tube element. The companion cells play an essential role in moving sugar into the sieve tube elements for transport to other parts of the plant.

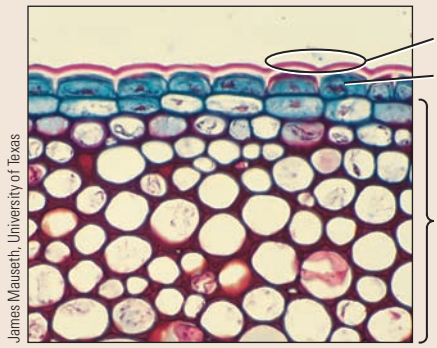
The dermal tissue system consists of two complex tissues

The **dermal tissue system**—the epidermis and periderm—provides a protective covering over plant parts (TABLE 33-4). In herbaceous plants the dermal tissue system is a single layer of cells called the epidermis. Woody plants initially produce

(a) Tracheid (xylem cell). The tracheid is opened to reveal the cell's appearance in cross section. At maturity, tracheids are usually dead.

(b) Vessel element (xylem cell). The end walls of vessel elements are perforated. Vessel elements are joined end to end, from roots to leaves and other shoot parts.

(c) Sieve tube element, showing the sieve plate. Sieve tube elements are joined end to end to form sieve tubes.



(d) Longitudinal section of phloem tissue. Sieve tube elements, companion cells, and phloem parenchyma cells. Fiber cells are not shown.

Table 33-4 Selected Cell Types in the Dermal Tissue System

James Mauseth, University of Texas

Epidermal cell

Description

Relatively unspecialized cell with thin primary wall; outer wall often thicker and covered by a noncellular waxy layer (cuticle)

Functions

Protective covering over surface of plant body; helps reduce water loss

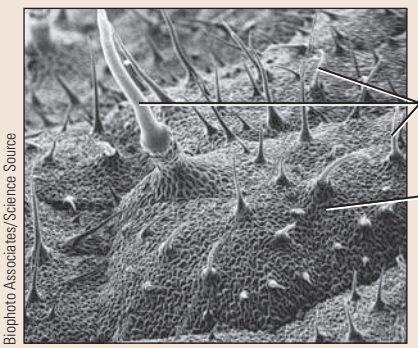
Location and comments

Epidermis is usually one cell thick; shown is an LM of a cross section through epidermis of an ivy (*Hedera helix*) stem

Ed Reschke/Getty Images

Guard cell

Description



Chloroplast-containing cell that occurs in pairs; pair changes shape to open and close stomatal pore

Function

Opens and closes stomatal pore

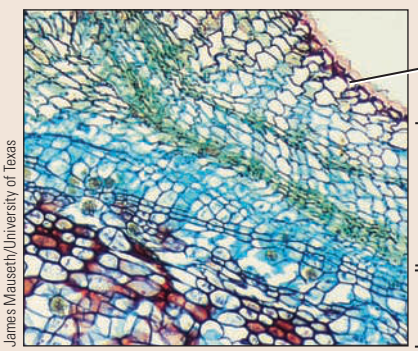
Location and comments

Epidermis of stems and leaves; shown is an LM of the epidermis of a spiderwort (*Tradescantia virginiana*) leaf

Biophoto Associates/Science Source

Trichome

Description



Hair or other epidermal outgrowth; may be unicellular or multicellular; occurs in variety of sizes and shapes

Functions

Varied; absorption; secretion; excretion; protection; reduction of water loss

Location and comments

Epidermis; shown is an SEM of a nettle (*Solanum carolinense*) leaf, which has trichomes that break off inside the skin of animals and inject irritating substances that cause a stinging sensation

James Mauseth/University of Texas

Cork cell

Description

Dead at maturity; cell walls impregnated with waterproof material (suberin)

Functions

Reduces water loss and prevents disease-causing organisms from penetrating

Location and comments

Produced in large numbers; cork often forms just under the epidermis; replaces epidermis in older stems and roots; shown is an LM of a cross section through the periderm of a calico flower (*Aristolochia elegans*) stem

an epidermis, but it splits apart as a result of the production of additional woody tissues inside the epidermis as the plant increases in girth. Periderm, which replaces the epidermis in the stems and roots of older woody plants, composes the outer bark.

Epidermis is the outermost layer of a herbaceous plant The **epidermis** is a complex tissue composed primarily of relatively unspecialized living cells. Dispersed among these cells are more specialized guard cells and outgrowths called trichomes (discussed later). In most plants the epidermis

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

consists of a single layer of flattened cells (FIG. 33-5). Epidermal cells generally contain no chloroplasts and are therefore transparent, so light can penetrate the interior tissues of stems and leaves. In both stems and leaves, photosynthetic tissues lie *beneath* the epidermis.

An important requirement of the aerial parts (stems, leaves, flowers, and fruits) of a plant is the ability to control water loss. Epidermal cells of aerial parts secrete a waxy **cuticle** over the surface of their exterior walls; this waxy layer greatly restricts water loss from plant surfaces.

Although the cuticle is extremely efficient at preventing most water loss through epidermal cells, it also slows the diffusion of CO_2, needed for photosynthesis, from the atmosphere into the leaf or stem. The diffusion of CO_2 is facilitated by **stomata** (sing., *stoma*). Stomata are minute pores in the epidermis that are surrounded by two cells called **guard cells** (see Fig. 34-5). Many gases, including CO_2, oxygen, and water vapor, pass through the stomata by diffusion. Stomata are generally open during the day when photosynthesis is occurring, and the water loss that also takes place when stomata are open provides some evaporative cooling. At night, stomata usually close. In drought conditions, the need to conserve water overrides the need to cool the leaves and exchange gases. Thus, during a drought, the stomata close in the daytime. Stomata are discussed in greater detail in Chapter 34.

The epidermis also contains special outgrowths, or hairs, called **trichomes**, which occur in many sizes and shapes and have a variety of functions. Plants that tolerate salty environments such as the seashore often have specialized trichomes on their leaves to remove excess salt that accumulates in the plant. The presence of trichomes on the aerial parts of desert plants may increase the reflection of light off the plants, thereby cooling the internal tissues and decreasing water loss. Other trichomes have a protective function. For example, the trichomes on stinging nettle leaves and stems contain irritating substances that may discourage herbivorous animals from eating the plant. **Root hairs** are simple, unbranched trichomes that increase the surface area of the root epidermis (which comes into contact with the soil) for more effective water and mineral absorption.

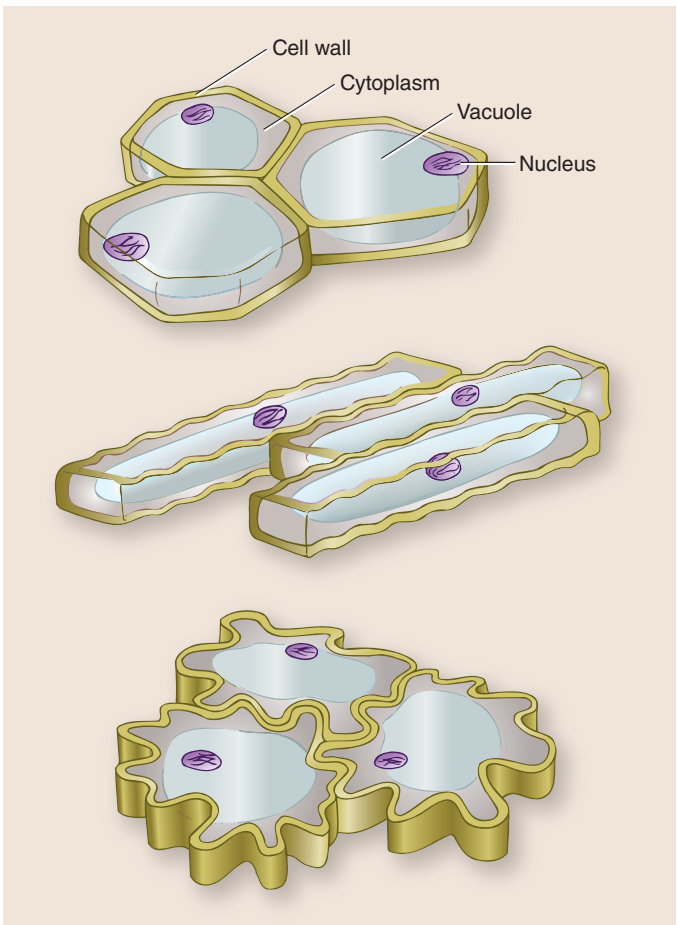

Figure 33-5 Cell types: epidermal cells
Epidermal cells from three different plants. Note that regardless of the cell shape, epidermal cells fit tightly together.

Periderm replaces epidermis in woody plants

Periderm, a tissue that can be anywhere from several to many cell layers thick, forms under the epidermis to provide a new protective covering as the epidermis is destroyed. As a woody plant continues to increase in girth, its epidermis is sloughed off, exposing the periderm. Periderm forms the outer bark of older stems and roots. It is a complex tissue composed mainly of cork cells and cork parenchyma cells. **Cork cells** are dead at maturity, and their walls are heavily coated with a waterproof substance called *suberin*, which helps reduce water loss. **Cork parenchyma** cells function primarily in storage. Periderm is discussed further in Chapters 35 and 36.

CHECKPOINT 33.1

- What are some of the functions of roots? of shoots?
- What are the three tissue systems in plants? Describe the functions of each.
- How do parenchyma, collenchyma, and sclerenchyma tissues differ in cell structure and function?
- What are the functions of xylem and phloem? Describe the conducting cells that occur in each of these complex tissues.
- **CONNECT** How are epidermis and periderm alike? How are they different?

33.2 Plant Meristems

LEARNING OBJECTIVES

5 State how growth in plants differs from growth in animals.
6 Distinguish between primary and secondary growth.
7 Distinguish between apical meristems and lateral meristems.

One difference between plants and animals is the *location* of growth. When plants grow, their cells divide only in specific areas, called **meristems**, which are composed of cells whose primary function is to form new cells by mitotic division. (In contrast, when a young animal is growing, all parts of its body grow, although not necessarily at the same rate.) Meristematic cells, also known as *stem cells*, do not differentiate. Instead, they retain the ability to divide by mitosis, a trait that many differentiated cells lose. The persistence of mitotically active meristems means that plants, unlike most animals, can grow throughout their entire lifespan.

This ability of roots and stems to grow throughout a plant's life is known as **indeterminate growth**. In contrast, many leaves and flowers have **determinate growth**; that is, they stop growing after reaching a certain size. The size of leaves and flowers with determinate growth varies from species to species and from individual to individual, depending on the plant's genetic programming and on environmental conditions such as availability of sunlight, water, and essential minerals.

Two kinds of meristematic growth may occur in plants. **Primary growth** is an increase in stem and root length. All plants have primary growth, which produces the entire plant body in herbaceous plants and the young, soft shoots and roots in woody trees and shrubs. **Secondary growth** is an increase in the girth of a plant. For the most part, only gymnosperms and woody eudicots have secondary growth. (Woody eudicots include such trees and shrubs as oak, sycamore, ash, cherry, apple, beech, and maple.)

Tissues produced by secondary growth compose the wood and bark, which make up most of the bulk of trees and shrubs. A few annuals—geraniums and sunflowers, for example—undergo limited secondary growth even though they lack obvious wood and bark tissues.

Primary growth takes place at apical meristems

Primary growth occurs as a result of the activity of **apical meristems**, areas located at the tips of roots and shoots, including within the buds of stems. **Buds** are dormant embryonic shoots that eventually develop into branches.

Primary growth is evident when a root tip is examined (FIG. 33-6). A protective layer of cells called a **root cap** covers the root tip. Directly behind the root cap is the root apical meristem, which consists of meristematic cells. Meristematic cells, which are cube shaped, remain small because they are continually dividing. (In meristems, as daughter cells begin to enlarge, one or both will divide again.)

Farther from the root tip, just behind the area of cell division, is an area of cell elongation where the cells have been displaced from the meristem. Here the cells are no longer dividing but instead are growing longer, pushing the root tip ahead of them, deeper into the soil. Some differentiation also begins to occur in the area of cell elongation, and immature tissues such as differentiating xylem and phloem become evident. The tissue systems continue to develop and differentiate into primary tissues (epidermis, xylem, phloem, and ground tissues) of the adult plant. Farther from the tip, behind the area of cell elongation, most cells have completely differentiated and are fully mature. Root hairs are evident in this area.

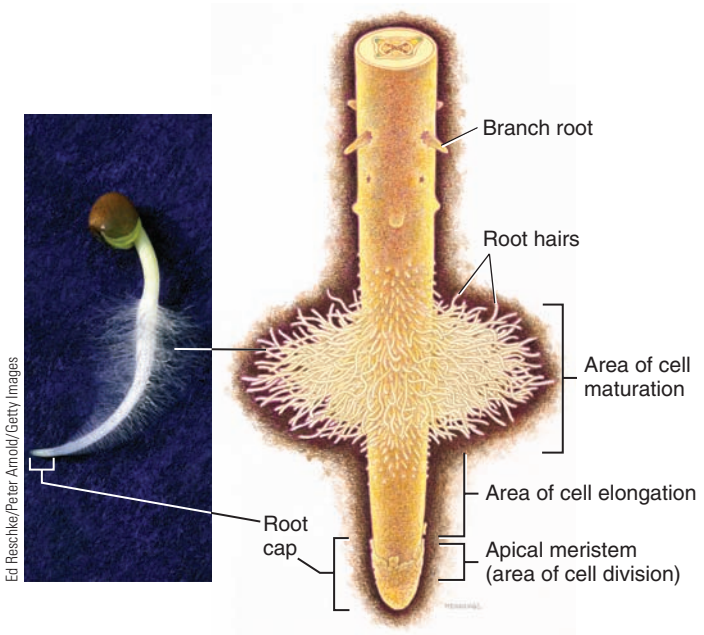

Figure 33-6 A root tip

The root apical meristem (where cells divide and thus increase in number) is protected by a root cap. Farther from the tip is an area of cell elongation where cells enlarge and begin to differentiate. Note the young root hairs in the area of cell maturation, which has fully mature, differentiated cells.

A shoot apex (such as the terminal bud) is quite different in appearance from a root tip (FIG. 33-7). A dome of minute, regularly arranged meristematic cells—the shoot apical meristem—is located in each shoot apex. *Leaf primordia* (developing leaves) and *bud primordia* (developing buds) arise from the shoot apical meristem. The tiny leaf primordia cover and protect the shoot apical meristem. As the cells formed by the shoot apical meristem elongate, the shoot apical meristem is pushed upward. Subsequent cell divisions produce additional stem tissue and cause new leaf and bud primordia to appear. Farther from the stem tip, the immature cells differentiate into the three tissue systems of the mature plant body.

Secondary growth takes place at lateral meristems

Trees and shrubs undergo both primary and secondary growth. These plants increase in length by primary growth and increase in girth by secondary growth. The increase in girth, which occurs in areas that are no longer elongating, is due to cell divisions that take place in **lateral meristems**, areas extending along the entire length of the stems and roots except at the tips. Two lateral meristems, the vascular cambium and the cork cambium, are responsible for secondary growth, which is the formation of secondary tissues: secondary xylem, secondary phloem, and periderm (FIG. 33-8).

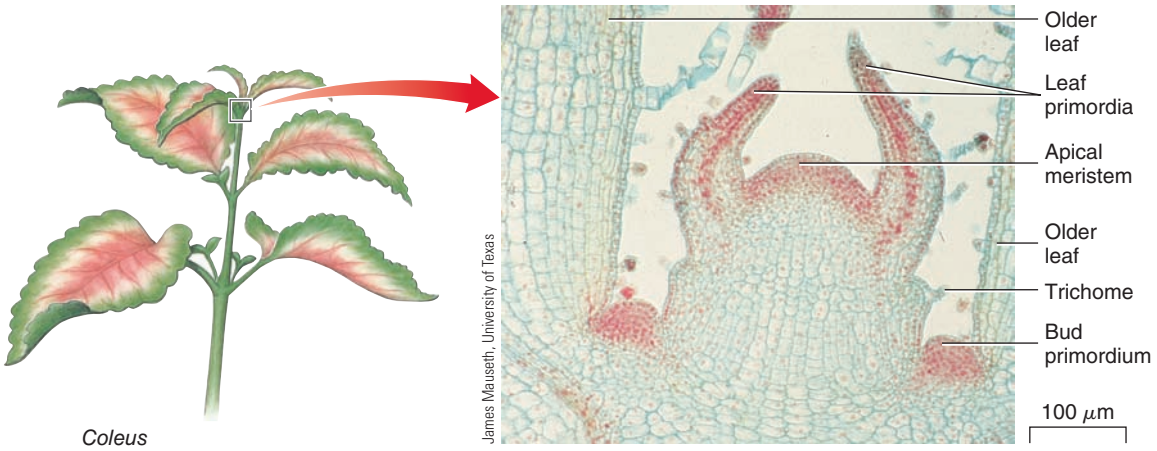

Figure 33-7 A shoot apex
LM of a longitudinal section through a shoot apex of *Coleus*, showing the shoot apical meristem, leaf primordia, and bud primordia.

The **vascular cambium** is a layer of meristematic cells that forms a long, thin, continuous cylinder within the stem and root. It is located between the wood and bark of a woody plant. Division of cells of the vascular cambium adds more cells to the wood (secondary xylem) and inner bark (secondary phloem).

The **cork cambium**, located in the outer bark, is composed of a thin cylinder or irregular arrangement of meristematic cells. Cells of the cork cambium divide and form **cork cells** toward the outside and one or more underlying layers of **cork parenchyma** cells that function in storage. Collectively, cork cells, cork cambium, and cork parenchyma make up the periderm.

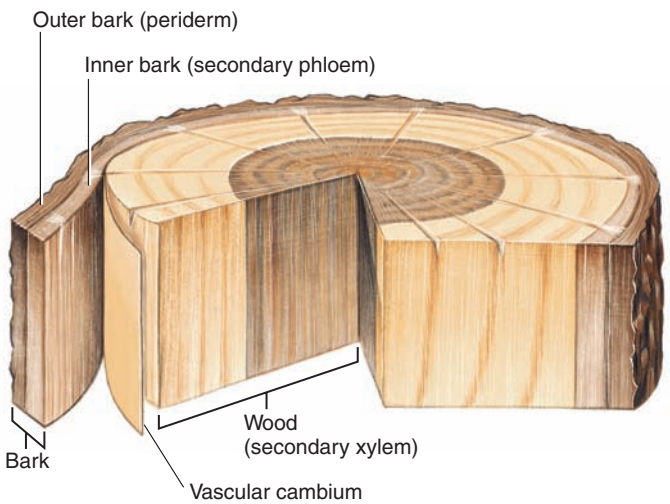

Figure 33-8 Secondary growth
The vascular cambium, a thin layer of cells sandwiched between the wood and bark, produces the secondary vascular tissues: the wood, which is secondary xylem, and the inner bark, which is secondary phloem. The cork cambium produces the periderm, the outer bark tissue that replaces the epidermis in a plant with secondary growth.

We are now ready to give a more precise definition of *bark*. **Bark**, the outermost covering over woody stems and roots, consists of all plant tissues located outside the vascular cambium. Bark has two regions, a living inner bark composed of secondary phloem and a mostly dead outer bark composed of periderm. Chapters 35 and 36 present a more comprehensive discussion of secondary growth.

CHECKPOINT 33.2

- **CONNECT** What is the role of plant meristems? Does animal growth involve meristems?
- How does secondary growth differ from primary growth?
- **CONNECT** How do the functions of apical and lateral meristems relate to primary and secondary growth?

33.3 Development of Form

LEARNING OBJECTIVES

8 Distinguish between cell division and cell expansion, and describe the roles of the preprophase band and cellulose microfibrils.
9 Describe the relationship between cell determination and cell differentiation and between pattern formation and morphogenesis.
10 Explain why the model organism *Arabidopsis* is so useful in the study of plant development.

Plants are growing, dynamic organisms. **Development** in plants encompasses all the changes that take place during the entire life of an individual. Of particular interest in developmental biology is the process by which cells specialize and

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

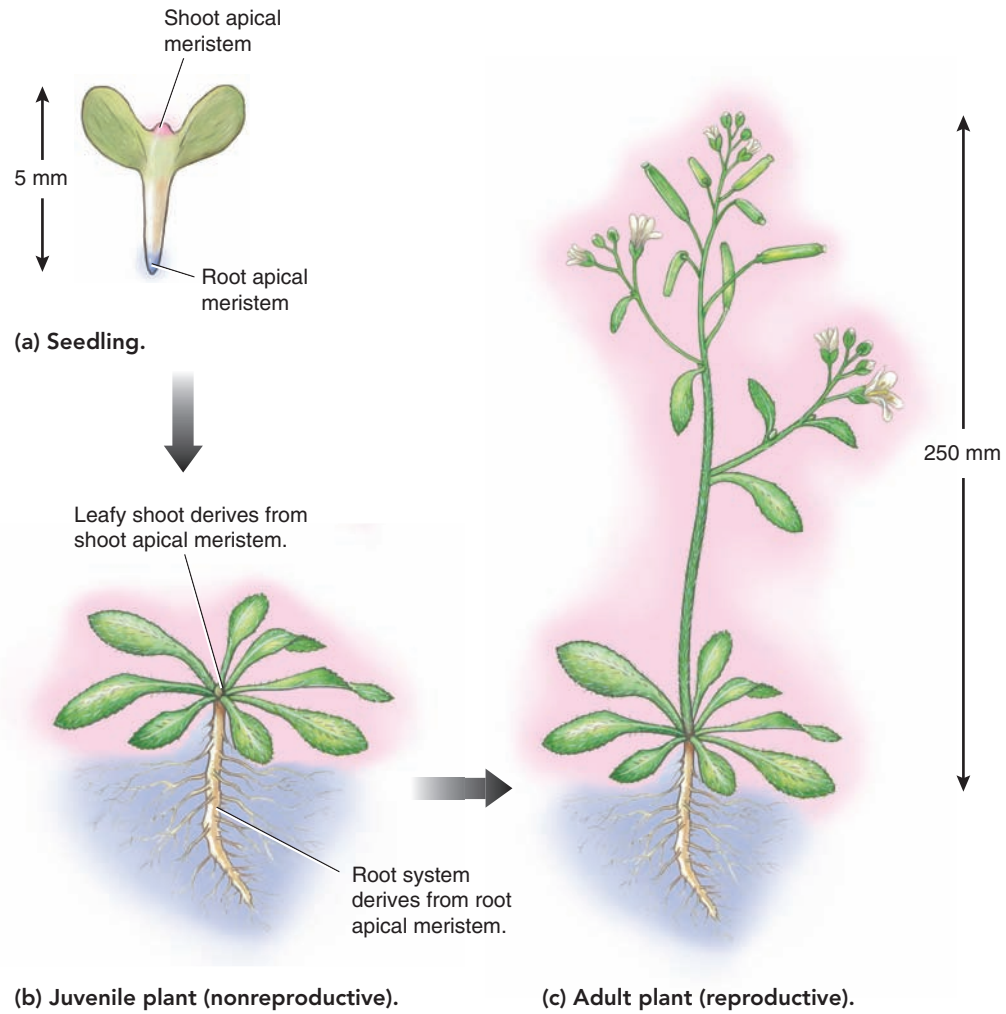

Figure 33-9 Growth of an *Arabidopsis* seedling into an adult plant

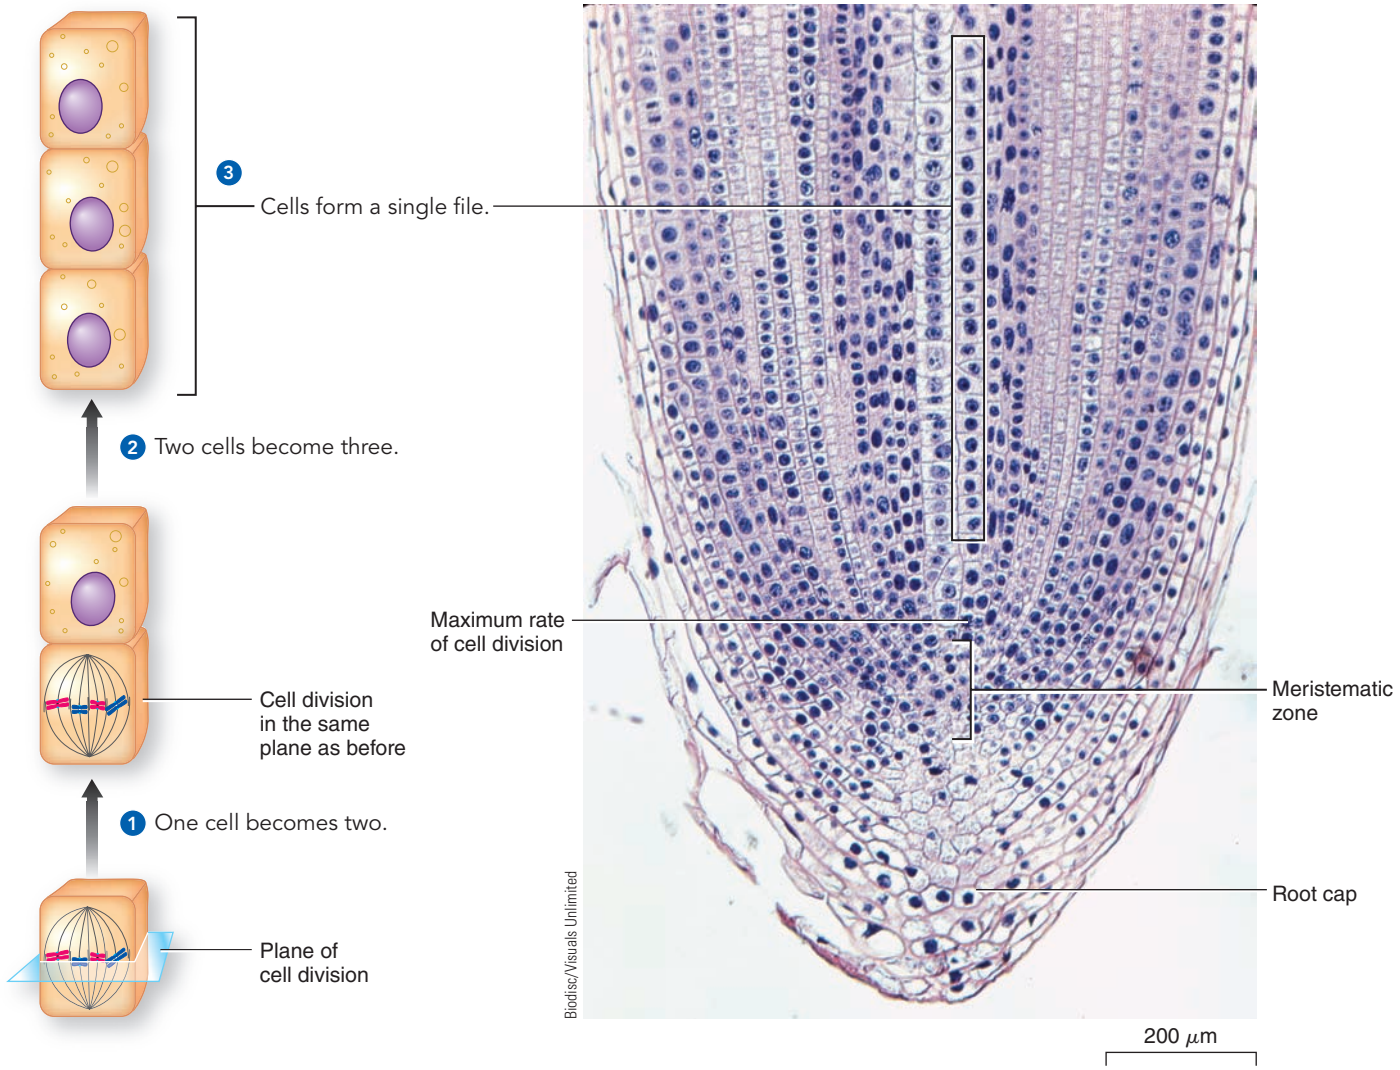
Almost all the differentiated tissues formed after a seed is germinated (often referred to as postembryonic growth) come from a small number of stem cells in the root and shoot apical meristems.

organize into a complex organism. For example, how does a microscopic, unicellular zygote give rise to a multicellular embryo in a seed? (See the stages of embryonic development in a typical eudicot in Figure 37-8.) How does the embryo in the seed give rise to the leaves, stems, and roots of a *juvenile* plant, and what mechanisms underlie the transition from a nonreproductive juvenile plant to an *adult plant* capable of flowering (FIG. 33-9)?

We now examine several aspects of plant development that affect form in plants. Flowering is discussed elsewhere in this book (see the ABC model in Chapter 17).



The plane and symmetry of cell division affect plant form

You have seen that plant growth is localized into meristems for cell division. At these sites, the cells undergo cell division in an orderly manner. In the onion root apical meristem, for example, files of cells can be traced back to the meristem region (FIG. 33-10). These cells divided in the same plane to produce each file of cells. Cell divisions in one plane, two planes, or more help establish the tissue patterns that will be produced during development.

How is the plane of cell division for a particular meristematic cell determined? In plant cells a dense array of microtubules forms a **preprophase band** just inside of the plasma membrane, encircling the nucleus much like a belt. (Chapter 4 contains a discussion of the dynamic nature of microtubules.) The preprophase band appears just prior to mitosis and determines the plane in which the cell will divide (FIG. 33-11). The preprophase band, which is located where the cell plate will form following mitosis and cytokinesis, also helps orient the mitotic spindle. The preprophase band is a plant characteristic; in animal cells, the orientation of the spindle determines the plane in which cells divide, and there is no preprophase band.

(a) Cells that divide in the same plane form a row, or file, of cells.

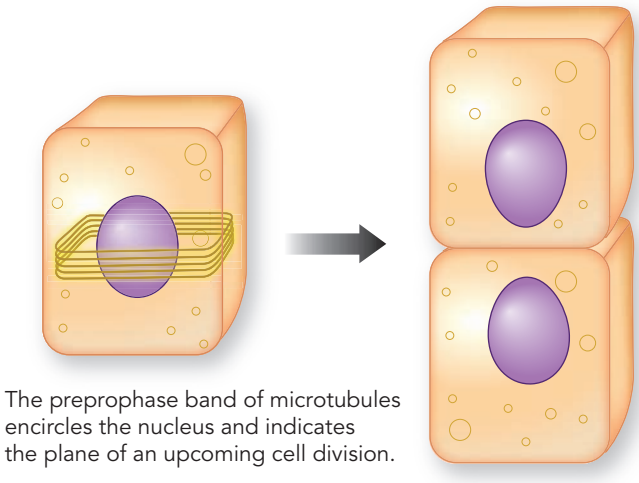
(b) A single file of cells in the onion root tip is labeled. If you look closely, you can see many other files.

Figure 33-10 The plane of cell division and the onion root tip
The root apical meristem maintains postembryonic root growth.

The orientation of cellulose microfibrils affects the direction of cell expansion

In plants, growth occurs by both an increase in the number of cells and an increase in cell size. Cell division and cell expansion (also called *elongation*) are governed by a genetic program that interacts with environmental signals from both the external and internal environments.

In growth, a newly formed plant cell absorbs water into its vacuole by osmosis. The water increases the cell's **turgor pressure**, hydrostatic pressure that develops within a walled cell and presses outward against the plasma membrane. Turgor pressure provides a force that exerts pressure on the cell wall and causes it to expand. In an onion root cell, the vacuole increases in size by some 30 to 150 times during elongation.



In growing tissue, the arrangement of cellulose microfibrils in the wall prevents the cell from expanding equally in all directions due to turgor pressure. When the microfibrils in the cell wall are oriented in the same direction, the wall expands perpendicularly to them (FIG. 33-12).

Cell differentiation depends in part on a cell's location

By themselves, cell division and cell expansion would produce only a formless heap of similar cells. The development of plant form is the result of a balanced combination of several fundamental processes that go beyond cell division and cell expansion: cell differentiation and cell determination, and pattern formation and morphogenesis.

The preprophase band of microtubules encircles the nucleus and indicates the plane of an upcoming cell division.

Figure 33-11 Preprophase band

As growth proceeds, cell division gives rise to increasing numbers of cells, which serve as the building blocks of development. At various times, certain cells become biochemically and structurally specialized to carry out specific functions through a process known as **cell differentiation**. Generally, a differentiated animal cell is irreversibly committed to its fate, but that is not the case with plants. As discussed earlier in this chapter, parenchyma cells can differentiate into other kinds of cells, for example, when the plant body is injured.

Cell differentiation occurs through **cell determination**, a series of molecular events in which the activities of certain genes are altered in ways that cause a cell to progressively commit to a particular differentiation pathway. As cell determination proceeds, a young cell's fate becomes more and more limited, restricting its development to a limited set of tissue types.

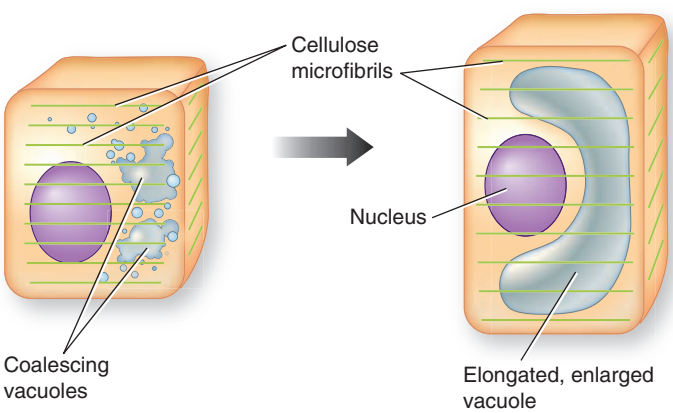

Figure 33-12 Direction of cell expansion

Following cell division, cellulose microfibrils are deposited into new cell walls in an orderly fashion that permits cell expansion. The orientation of the cellulose microfibrils determines the direction of cell expansion. Note that most of the cellulose microfilbrils are oriented transversely in this figure, which results in longitudinal cell expansion.

During cell differentiation, a cell's physical appearance may or may not change significantly. Nevertheless, when cell determination is complete, a cell becomes structurally and functionally recognizable—as an epidermal cell, for example—and its pattern of gene activity differs from that of other cell types. Thus, differentiated cells of the plant body have **differential gene expression**; that is, different genes are active in different cells at the same time. Differential gene expression is responsible for variations in chemistry, behavior, and structure among cells.

Tissue cultures involve differential gene expression

Cells can be isolated from certain plants and grown in a chemically defined, sterile nutrient medium. In initial experiments with such cultures, plant cells could be kept alive, but they did not divide. Researchers later discovered that adding certain natural materials, such as the liquid endosperm of coconut, also known as coconut milk, induced cells to divide in culture. By the late 1950s, plant cells from a variety of sources could be cultured successfully, dividing to produce a mass of disorganized, relatively undifferentiated cells, or **callus**.

In 1958, F.C. Steward, a plant physiologist at Cornell University, succeeded in generating an entire carrot plant from a single callus cell derived from a carrot root (see Fig. 17-2), thus demonstrating that each plant cell contains a genetic blueprint for all features of an entire organism. His work also showed that an entire plant can be grown from a single cell, provided differential gene expression occurs so that the proper genes are expressed at the appropriate times.

Since Steward's pioneering work, biologists have successfully cultured many plants by using a variety of cell sources. Plants have been regenerated from different tissues, organ explants (excised organs or parts such as root apical meristems), and single cells. Cell and tissue culture techniques help answer many fundamental questions involving growth and development in plants. These techniques also have great practical potential. Using tissue culture, researchers can regenerate many genetically identical plants from the cells of a single, genetically superior plant. Many kinds of plants—from orchids and African violets to coastal redwoods—have been cultured in this way.

Morphogenesis occurs through pattern formation

Cell differentiation by itself does not explain overall plant form. The differentiated cells must become progressively organized, shaping the intricate pattern of tissues and organs that characterizes a multicellular plant. This development of form, in which differentiated cells in specific locations become spatially organized into recognizable structures, is known as **morphogenesis**.

(a) Examples of leaf shapes.

(b) Examples of leaf margins.

Figure 33-13 Leaf variation and pattern formation

Leaves are quite variable in form; there are dozens of different leaf shapes and margins. Leaves on juvenile plants are often shaped differently than those on adult plants, and some adult plants have several leaf shapes on the same individual. Pattern formation, which is under genetic control, is largely responsible for leaf variation. (Also see Figure 34-2 for more examples of variation in leaves.)

Morphogenesis proceeds through the process of **pattern formation**, a series of steps requiring signaling between cells, changes in the shapes and metabolism of certain cells, and precise cell interactions. Pattern formation organizes cells into three-dimensional structures (FIG. 33-13). Depending on their location, cells are exposed to different concentrations of signaling molecules that specify **positional information**, that is, where the cell is located relative to the body's axes. This information affects cell differentiation and tissue formation. Thus, *where* a given cell is located often determines *what* it will become when it matures.

Arabidopsis mutants provide crucial insights into plant development Until the late 1970s, biologists knew little about how genes interact to control development. However, rapid progress in molecular biology led scientists to search for developmental mutants and to apply sophisticated techniques to study them. (A *mutant* is an individual with an abnormal phenotype caused by a gene mutation.) Biologists are now studying how genes are activated, inactivated, and modified to control development. Eventually, scientists expect to reach a major goal of systems biology: understanding how a single cell (a fertilized egg) develops into a multicellular plant.

You may recall from Chapter 17 that mouse-ear cress (*Arabidopsis thaliana*) is the organism most widely used to study the genetic control of development in plants. When biologists insert cloned foreign genes into *Arabidopsis* cells, the genes integrate into the chromosomes and are expressed. The researchers then induce these transformed cells to differentiate into transgenic plants.

Botanists use chemical mutagens to produce mutant strains and have isolated many developmental mutants of *Arabidopsis*. Consider the *monopteros (mp)* gene, which codes for a transcription factor affecting apical–basal pattern formation and the development of vascular tissues. Mutant *mp* seedlings lack basal structures, including a primary root. Such mutant phenotypes have helped scientists identify the genes essential for normal development.

CHECKPOINT 33.3

- Which process typically occurs first, cell differentiation or cell expansion?
- What are some kinds of events that contribute to pattern formation?
- **CONNECT** What is the relationship between pattern formation and morphogenesis?
- Why is *Arabidopsis* such a useful model organism for plant development?

Summary: Focus on Learning Objectives

33.1 The Plant Body *(page 711)*

1 Discuss the functions of various parts of the vascular plant body, including the nutrient- and water-absorbing root system and the photosynthesizing shoot system.

- The vascular plant body typically consists of a root system and a shoot system. The **root system** is generally underground and obtains water and dissolved minerals for the plant. Roots also anchor the plant firmly in place.
- The **shoot system** is generally aerial and obtains sunlight and exchanges gases such as CO_2, oxygen, and water vapor. The shoot system consists of a vertical stem that bears leaves and reproductive structures. **Buds**, undeveloped embryonic shoots, develop on stems.

2 Describe the structure and functions of the ground tissue system (parenchyma tissue, collenchyma tissue, and sclerenchyma tissue).

- The **ground tissue system** consists of three tissues with a variety of functions. **Parenchyma** tissue is composed of living parenchyma cells that have thin *primary cell walls*. Functions of parenchyma tissue include photosynthesis, storage, and secretion.
- **Collenchyma** tissue consists of collenchyma cells with unevenly thickened primary cell walls. This tissue provides flexible structural support.
- **Sclerenchyma** tissue is composed of sclerenchyma cells—**sclereids** or **fibers**—that have both *primary cell walls* and *secondary cell walls*. Sclerenchyma cells are often dead at maturity but provide structural support.

3 Describe the structure and functions of the vascular tissue system (xylem and phloem).

- The **vascular tissue system** conducts materials throughout the plant body and provides strength and support.
- **Xylem** is a complex tissue that conducts water and dissolved minerals. The actual conducting cells of xylem are **tracheids** and **vessel elements**.
- **Phloem** is a complex tissue that conducts sugar in solution. **Sieve tube elements** are the conducting cells of phloem; they are assisted by **companion cells**.

4 Describe the structure and functions of the dermal tissue system (epidermis and periderm).

- The **dermal tissue system** is the outer protective covering of the plant body.
- The **epidermis** is a complex tissue that covers the herbaceous plant body. The epidermis that covers aerial parts secretes a waxy **cuticle** that reduces water loss. **Stomata** permit gas exchange between the interior of the shoot system and the surrounding atmosphere. **Trichomes** are outgrowths, or hairs, that occur in many sizes and shapes and have a variety of functions.
- The **periderm** is a complex tissue that covers the plant body in woody plants.

33.2 Plant Meristems *(page 720)*

5 State how growth in plants differs from growth in animals.

- Growth in plants, unlike that in animals, is localized in specific regions called **meristems**. Meristems are composed of cells whose primary function is to form new cells by mitotic division.

6 Distinguish between primary and secondary growth.

- **Primary growth** is an increase in stem or root length. Primary growth occurs in all plants.
- **Secondary growth** is an increase in stem or root girth (thickness). Secondary growth typically occurs in long cylinders of meristematic cells throughout the length of older stems and roots.

7 Distinguish between apical meristems and lateral meristems.

- Primary growth results from the activity of **apical meristems** that are localized at the tips of roots and shoots and within the buds of stems.
- The two **lateral meristems** responsible for secondary growth are the **vascular cambium** and the **cork cambium**.

33.3 Development of Form *(page 722)*

8 Distinguish between cell division and cell expansion, and describe the roles of the preprophase band and cellulose microfibrils.

- Growth occurs by both cell division (an increase in the number of cells) and cell expansion (an increase in cell size).
- In plant cells, a dense array of microtubules forms a **preprophase band** just inside of the plasma membrane. The preprophase band appears just prior to mitosis and determines the plane in which the cell will divide.
- Absorption of water into a cell's vacuole increases the **turgor pressure**, which exerts pressure on the cell wall. The arrangement of cellulose microfibrils in the wall prevents the wall from expanding equally in all directions. When microfibrils are oriented the same way, the wall expands perpendicular to the microfibrillar orientation.

9 Describe the relationship between cell determination and cell differentiation and between pattern formation and morphogenesis.

- In **cell differentiation**, cells become biochemically and structurally specialized to carry out specific functions. Cell differentiation occurs through **cell determination**, a series of molecular events in which the activities of certain genes are altered in ways that cause a cell to progressively commit to a particular differentiation pathway.
- The development of form, in which differentiated cells in specific locations become spatially organized into recognizable structures, is known as **morphogenesis**. Morphogenesis proceeds through the process of **pattern formation**, a series of steps requiring signaling between cells, changes in the shapes and metabolism of certain cells, and precise cell interactions.

10 Explain why the model organism *Arabidopsis* is so useful in the study of plant development.

- Botanists have isolated many developmental mutants of *Arabidopsis*. Such mutant phenotypes have helped scientists identify genes essential for normal development.

Test Your Understanding

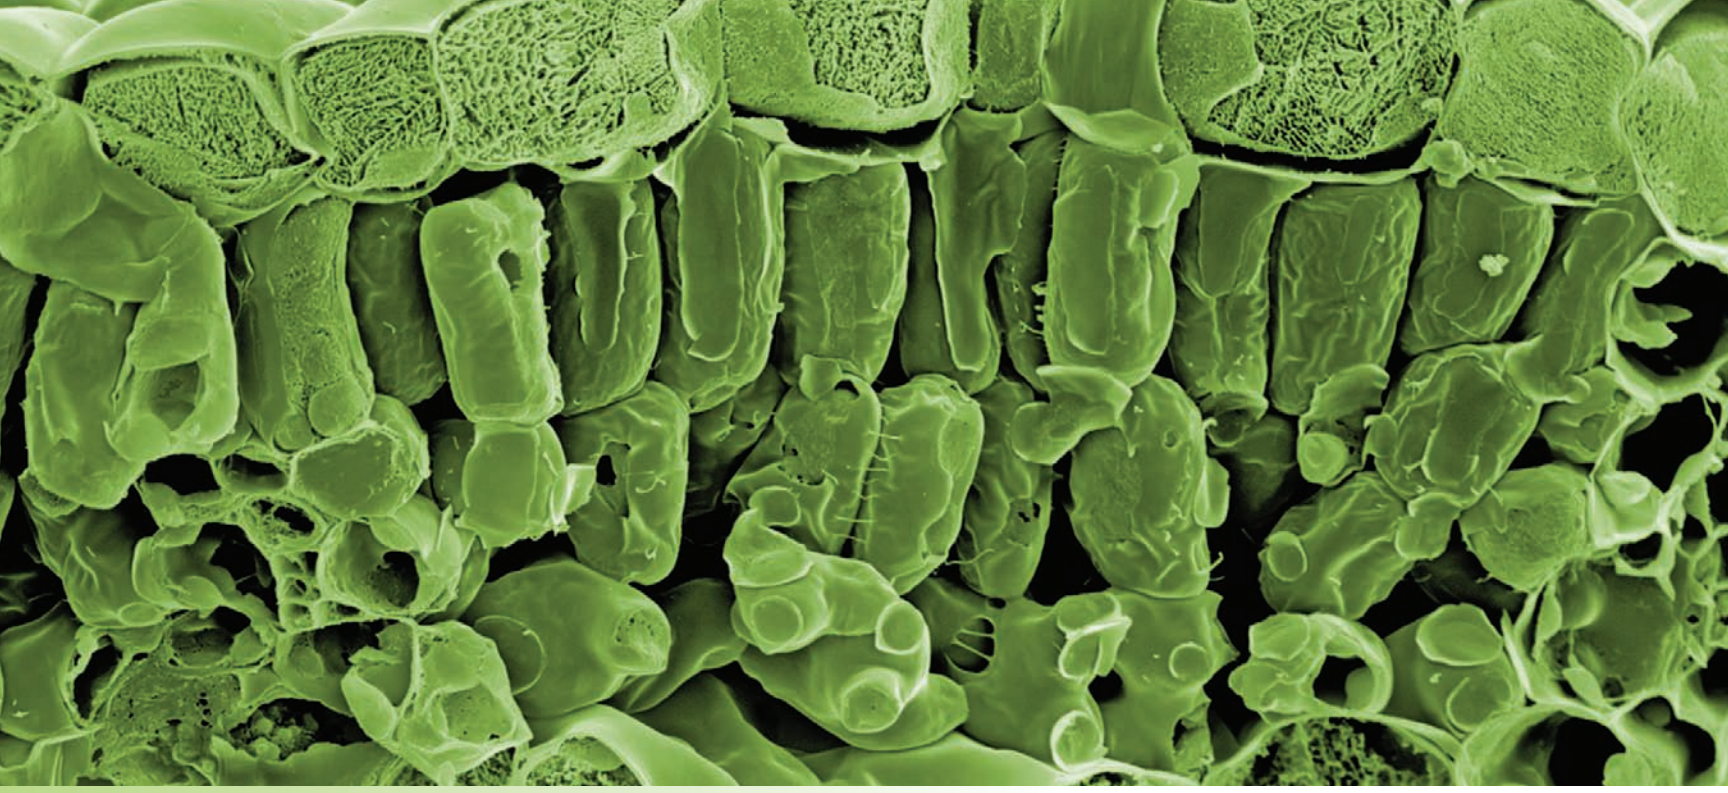
Know and Comprehend

1. Most of the plant body consists of the _____ tissue system. (a) ground (b) vascular (c) periderm (d) dermal (e) cortex
2. The cell walls of parenchyma cells (a) contain large quantities of pectin in the thickened corners (b) are rich in lignin but do not contain hemicelluloses and pectin (c) are predominantly cellulose, although they also contain hemicelluloses and pectin (d) contain cellulose, hemicelluloses, and lignin in approximately equal amounts (e) contain hemicelluloses, pectin, and lignin but no cellulose
3. Which tissue system provides a covering for the plant body? (a) ground (b) vascular (c) periderm (d) dermal (e) cortex
4. The two simple tissues that are specialized for support are (a) parenchyma and collenchyma (b) collenchyma and sclerenchyma (c) sclerenchyma and parenchyma (d) parenchyma and xylem (e) xylem and phloem
5. Sclereids and fibers are examples of which plant tissue? (a) parenchyma (b) collenchyma (c) sclerenchyma (d) xylem (e) epidermis
6. Which of the following statements about the vascular tissue system is *not* true? (a) xylem and phloem are continuous throughout the plant body (b) xylem not only conducts water and dissolved minerals but also provides support (c) four cell types occur in phloem: sieve tube elements, companion cells, tracheids, and vessel elements (d) sieve tube elements lack nuclei (e) vessel elements are hollow, and their end walls have perforations or are entirely dissolved away
7. Minute pores known as _____ dot the surface of the epidermis of leaves and stems; each pore is bordered by two _____. (a) stomata; guard cells (b) stomata; fibers (c) sieve tube elements; companion cells (d) sclereids; guard cells (e) cuticle; guard cells
8. Primary growth, an increase in the length of a plant, occurs at the (a) cork cambium (b) apical meristem (c) vascular cambium (d) lateral meristem (e) periderm
9. The preprophase band (a) appears just prior to mitosis in both plant and animal cells (b) determines the plane in which the cell will divide (c) attaches to cellulose microfibrils in the cell wall (d) is an essential part of pattern formation in plants (e) increases a cell's turgor pressure
10. Cell differentiation occurs through _____, whereas morphogenesis involves _____. (a) pattern formation; cell determination (b) cell division; cell expansion (c) cell expansion; pattern formation (d) cell determination; cell division (e) cell determination; pattern formation
11. The *monopteros* mutant (a) lacks a primary root (b) develops normally until the plant becomes reproductive (c) has abnormal leaf morphogenesis (d) was discovered in rice after its genome was sequenced (e) is one of only two developmental mutants known in *Arabidopsis*.

Apply and Analyze

12. Label the three tissue systems in this leaf cross section.

13. **VISUALIZE** Sketch a roughly cuboidal cell preparing to divide. Indicate the orientation of the preprophase band and the site where the new cell walls of the daughter cells will form.
14. **VISUALIZE** Sketch a cell preparing to expand. Indicate the orientation of the cellulose microfibrils and use a double-headed arrow to indicate the direction of subsequent cell elongation.



Evaluate and Synthesize

15. A couple carved a heart with their initials into a tree trunk 4 ft above ground level; the tree was 25 ft tall at the time. Twenty years later the tree was 50 ft tall. How far above the ground were the initials then? Explain your answer.
16. Sclerenchyma in plants is the functional equivalent of bone in humans (both sclerenchyma and bone provide support). However, sclerenchyma is dead, whereas bone is living tissue. What are some of the advantages of a plant having dead support cells? Can you think of any disadvantages? Explain your answer.
17. **EVOLUTION LINK** Flowering plants have both tracheids and vessel elements in their xylem. Conifers, which evolved earlier than flowering plants, have tracheids only. Do these differences in xylem structure help explain the difference in the success of these two plant groups? Explain your answer.
18. **SCIENCE, TECHNOLOGY, AND SOCIETY** Why is knowledge gained from sequencing the *Arabidopsis* genome important even though *Arabidopsis* has no commercial value?

34 Leaf Structure and Function

Plants allocate many resources into the production of leaves that are often short-lived. Each year, a large maple tree, for example, may produce 47 m^2 (500 ft^2) of leaves, which may weigh more than 113 kg (250 lb). The metabolic cost of producing so many leaves is high, but necessary. Simply put, leaves are essential to the tree's survival, so plants must invest in their production.

In most vascular plants, leaves are the primary organs to effectively collect solar energy and convert it into chemical energy. That is, leaves gather the sunlight necessary for **photosynthesis**, the biological process that converts radiant energy into the chemical energy of carbohydrate molecules. Plants use these molecules as starting materials to synthesize all other organic compounds and as fuel to provide energy for metabolism. During a single summer, the leaves of a maple tree will fix about 454 kg (1000 lb) of carbon dioxide (CO_2) into organic compounds.

The structure of a leaf is superbly adapted for its primary function of photosynthesis. Most leaves are thin and flat, a shape that allows optimal absorption of light energy and the efficient internal diffusion of gases such as CO_2 and O_2. As a result of their ordered arrangement on the stem, leaves efficiently catch the sun's rays with a minimum of "interference" from neighboring leaves. The leaves form an intricate green mosaic, bathed in sunlight and atmospheric gases.

To control water loss, a thin, transparent layer of wax covers the leaf surface. Such structural adaptations are compromises between competing needs, and some features that optimize photosynthesis promote water loss. For example, plants have minute pores that allow gas exchange for photosynthesis, but these openings also let water vapor escape into the atmosphere. Thus, leaf structure represents a trade-off between photosynthesis and water conservation.

In this chapter we examine leaf form and function. Leaf form is highly variable, and thousands of different leaf shapes have evolved over millions of years. Despite this diversity, most leaves "work" in the same way, and their internal structures (see photograph) support this similarity in function.

KEY CONCEPTS

34.1 Leaf structure reflects its primary function of photosynthesis.

34.2 Opening and closing of stomata affect carbon dioxide availability in the daily cycle of photosynthesis.

34.3 Transpiration, the loss of water vapor from leaf surfaces, keeps leaves from becoming overheated and promotes water transport in the plant. Guttation is the exudation of liquid water from leaf margins.

34.4 Leaf abscission is the seasonal removal of deciduous leaves.

34.5 Some leaves are modified for special functions in addition to photosynthesis and transpiration.

34.1 Leaf Form and Structure

LEARNING OBJECTIVES

1. Discuss variation in leaf form, including simple versus compound leaves, leaf arrangement on the stem, and venation patterns.
2. Describe the major tissues of the leaf (epidermis, photosynthetic ground tissue, xylem, and phloem) and sketch how they are arranged in a leaf cross section.
3. Compare leaf anatomy in eudicots and monocots.
4. Relate leaf structure to its function of photosynthesis.

Foliage leaves are the most variable of plant organs, so much so that plant biologists have developed specific terminology to describe their shapes, margins (edges), vein patterns, and the way they attach to stems. Because each leaf is characteristic of the species on which it grows, many plants can be identified by their leaves alone. Leaves may be round, needlelike, scalelike, cylindrical, heart-shaped, fan-shaped, or thin and narrow. They vary in size from those of the raffia palm (*Raphia ruffia*), whose leaves often grow more than 20 m (65 ft) long, to those of water-meal (*Wolffia*), whose leaves are so small that 16 of them laid end to end measure only 2.5 cm (1 in.).

The broad, flat portion of a leaf is the **blade**; the stalk that attaches the blade to the stem is the **petiole**. Some leaves also have **stipules**, which are leaflike outgrowths usually present in pairs at the base of the petiole (FIG. 34-1). Some leaves do not have petioles (i.e., the blades are attached directly to the stem) or stipules; leaves without a petiole are said to be *sessile*.

Leaves may be *simple* (having a single blade) or *compound* (having a blade divided into two or more leaflets) (FIG. 34-2a). Sometimes it is difficult to tell whether a plant has formed one compound leaf or a small stem bearing several simple leaves. One easy way to determine if a plant has simple or compound leaves is to look for axillary buds, so-called because each develops in a leaf *axil* (the angle between the stem and petiole). Axillary buds form at the base of a leaf, whether it is simple or compound. However, axillary buds never develop at the base of leaflets. Also, the leaflets of a compound leaf lie in a single plane (you can lay a compound leaf flat on a table), whereas simple leaves usually are not arranged in one plane on a stem.

Leaves are arranged on a stem in one of three possible ways (FIG. 34-2b). Plants such as beeches and walnuts have an *alternate leaf arrangement*, with one leaf at each **node**, the area of the stem where one or more leaves are attached. In an *opposite leaf arrangement*, as occurs in maples and ashes, two leaves grow at each node. In a *whorled leaf arrangement*, as in catalpa trees, three or more leaves grow at each node.

Leaf blades may possess *parallel venation*, in which the primary **veins**—strands of vascular tissue—run approximately parallel to one another (generally characteristic of monocots), or *netted venation*, in which veins are branched in such a way that they resemble a net (generally characteristic of eudicots; FIG. 34-2c).[1] Netted veins can be *pinnately netted*, with major veins branching off in succession along the entire length of the **midvein** (main or central vein of a leaf), or *palmately netted*, with several major veins radiating out from one point.

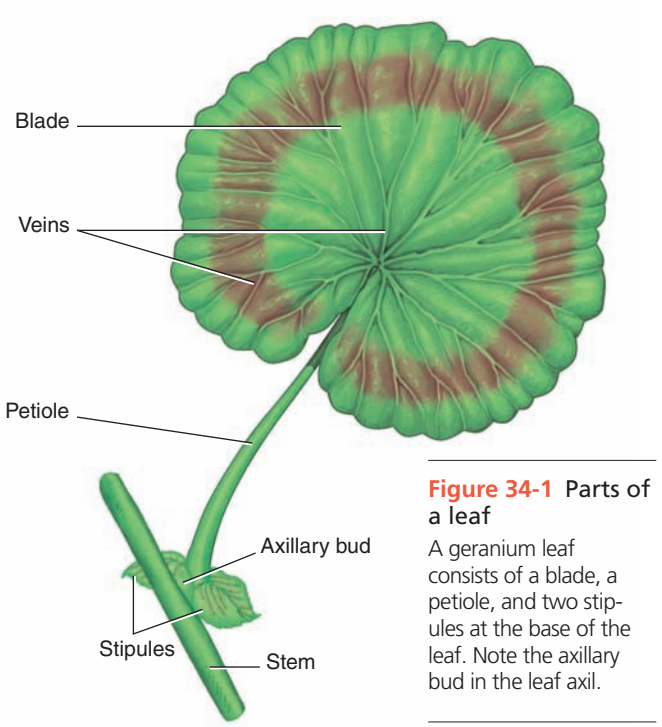

Figure 34-1 Parts of a leaf
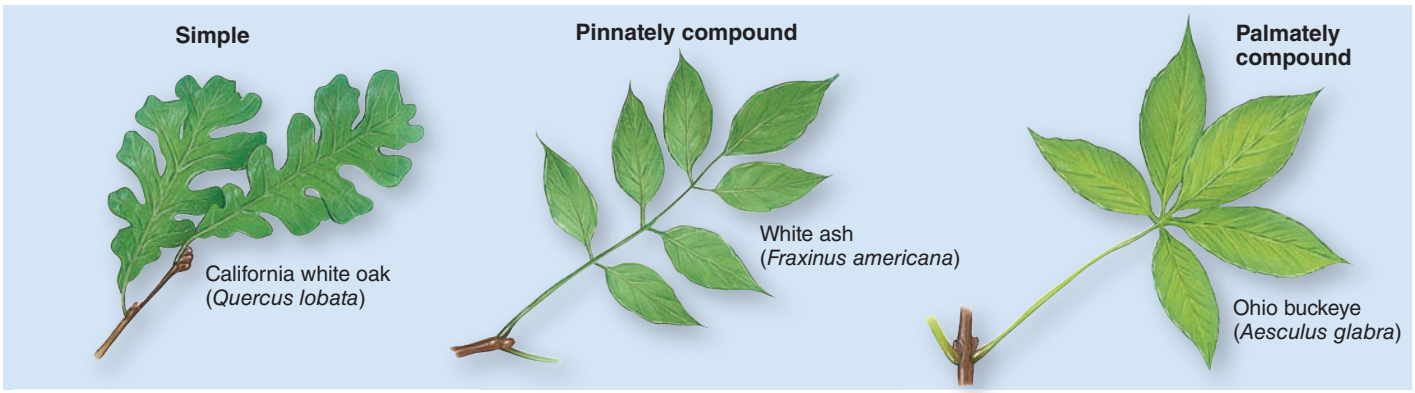
A geranium leaf consists of a blade, a petiole, and two stipules at the base of the leaf. Note the axillary bud in the leaf axil.

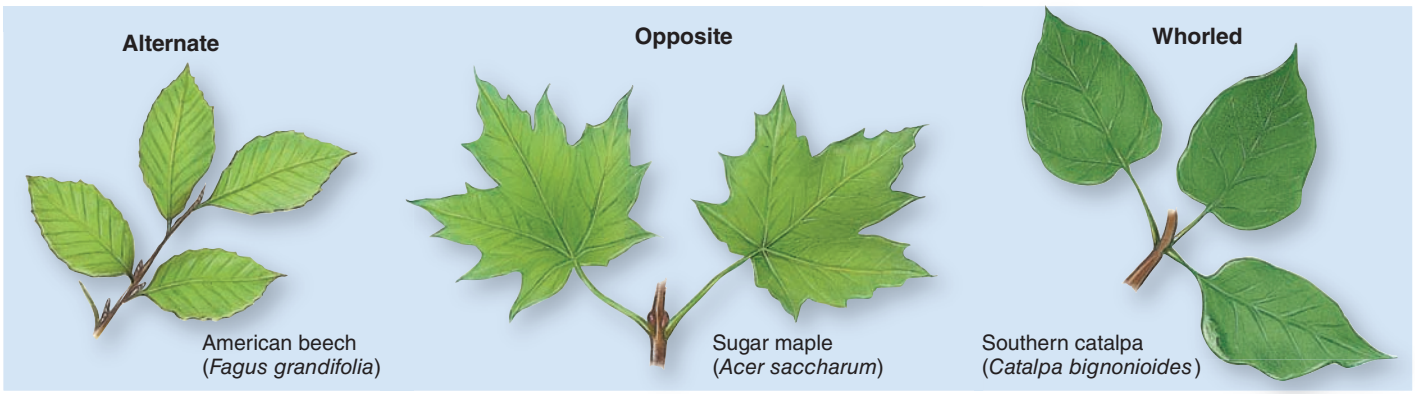
Plant scientists use sophisticated molecular techniques to study the genetic basis of various aspects of plant growth and development, including leaf form. Many of the genes under study code for transcription factors. As discussed in Chapter 14, *transcription factors* are DNA-binding proteins that regulate the synthesis of RNA from a DNA template. An exciting example of this type of research is described in FIGURE 34-3. Eventually, such research will help plant biologists to understand the roles of all genes involved in plant development, an important goal of systems biology.

Leaf structure is adapted for maximum light absorption



The leaf is a complex organ composed of several tissues organized to optimize photosynthesis (FIG. 34-4). The leaf blade has upper and lower surfaces, each consisting of a layer of **epidermis**. The *upper epidermis* covers the upper surface, and the *lower epidermis* covers the lower surface. Most cells in these layers lack chloroplasts and are relatively transparent. One interesting feature of leaf epidermal cells is that the cell wall facing toward the outside environment is somewhat thicker than the cell wall facing inward. This extra thickness may provide the plant with additional protection against injury or water loss.

Because leaves have such a large surface area exposed to the atmosphere, water loss by evaporation from the leaf's surface is unavoidable. However, epidermal cells secrete a waxy layer, the **cuticle**, that reduces water loss from their exterior walls (see Table 33-4). The cuticle, which consists primarily



[1] Recall that flowering plants, the focus of this chapter, are divided into two main groups, informally called *eudicots* and *monocots* (see Chapter 28). Examples of eudicots include beans, petunias, oaks, cherry trees, roses, and snapdragons; monocots include corn, lilies, grasses, palms, tulips, orchids, and bananas.

of the waxy substance *cutin*, varies in thickness in different plants, in part as a result of environmental conditions. As one might expect, the leaves of plants adapted to hot, dry climates have extremely thick cuticles. Furthermore, a leaf's exposed (and warmer) upper epidermis generally has a thicker cuticle than its shaded (and cooler) lower epidermis.

The epidermis of many leaves is covered with various hair-like structures called **trichomes**, which have several functions (see Table 33-4). Trichomes of some plants help reduce water loss from the leaf surface by retaining a layer of moist air next to the leaf and by reflecting sunlight, thereby protecting the plant from overheating. Some trichomes secrete stinging irritants for deterring *herbivores*, animals that feed on plants. In addition, a leaf covered with trichomes is difficult for an insect to walk over or eat. Other trichomes excrete excess salts absorbed from a salty soil.

The leaf epidermis contains minute openings, or **stomata** (sing., *stoma*), for gas exchange between leaf cells and the environment; the stomata are evenly spaced to optimize this gas exchange. Each stoma is flanked by two specialized epidermal **guard cells**, which are responsible for opening and closing the stoma (FIG. 34-5). Guard cells are usually the only epidermal cells with chloroplasts.

Stomata are especially numerous on the lower epidermis of horizontally oriented leaves (an average of about 100 stomata per square millimeter) and in many species are located *only* on the lower surface. The lower epidermis of apple (*Malus sylvestris*)

Key Experiment

What molecular controls determine if a developing leaf will become simple or compound?

EXPERIMENT: *NAM/CUC* (No Apical Meristem/Cup-Shaped Cotyledon) genes were cloned and genetically manipulated in four distantly related flowering plants that normally produce compound leaves: *Aquilegia caerulea* (columbine), *Solanum lycopersicum* (tomato), *Cardamine hirsuta* (hairy bittercress), and *Pisum sativum* (garden pea). *NAM/CUC* genes were already known to code for plant transcription factors involved in the establishment and function of the shoot apical meristem.

RESULTS AND CONCLUSION: European scientists Thomas Blein, Patrick Laufs, and colleagues reported that the *timing* of gene silencing of *NAM/CUC* genes had the potential to produce less elaborate, simpler leaf structures. If a young leaf at the shoot apical meristem of a columbine plant had already developed deeply lobed leaflets, silencing the *NAM/CUC* genes would not affect its further development (leaf 1). The leaf margins of leaves 2 and 3 developed with fewer lobes because the *NAM/CUC* genes had been silenced before much leaf development had taken place. In leaf 4, very early silencing resulted in a simple leaf with an entire margin. Similar leaf simplifications occurred due to the timing of silencing of the *NAM/CUC* genes in the developing leaves of tomato, hairy bittercress, and garden pea.

Figure 34-3 Molecular controls and the development of leaf form

CONNECT Studies by other researchers have provided evidence that genes other than the ones described here also influence leaf form. Based on what you have learned in Chapters 14 and 17, would you expect them all to code for transcription factors? Explain your answer.

leaves, for example, has almost 400 stomata per square millimeter, whereas the upper epidermis has none. This adaptation reduces water loss because stomata on the lower epidermis are shielded from direct sunlight and are therefore cooler than those on the upper epidermis. In contrast, floating leaves of aquatic plants, such as water lilies, have stomata only on the upper epidermis.

Guard cells are associated with special epidermal cells called **subsidiary cells** that are often structurally different from other epidermal cells. Subsidiary cells provide a reservoir

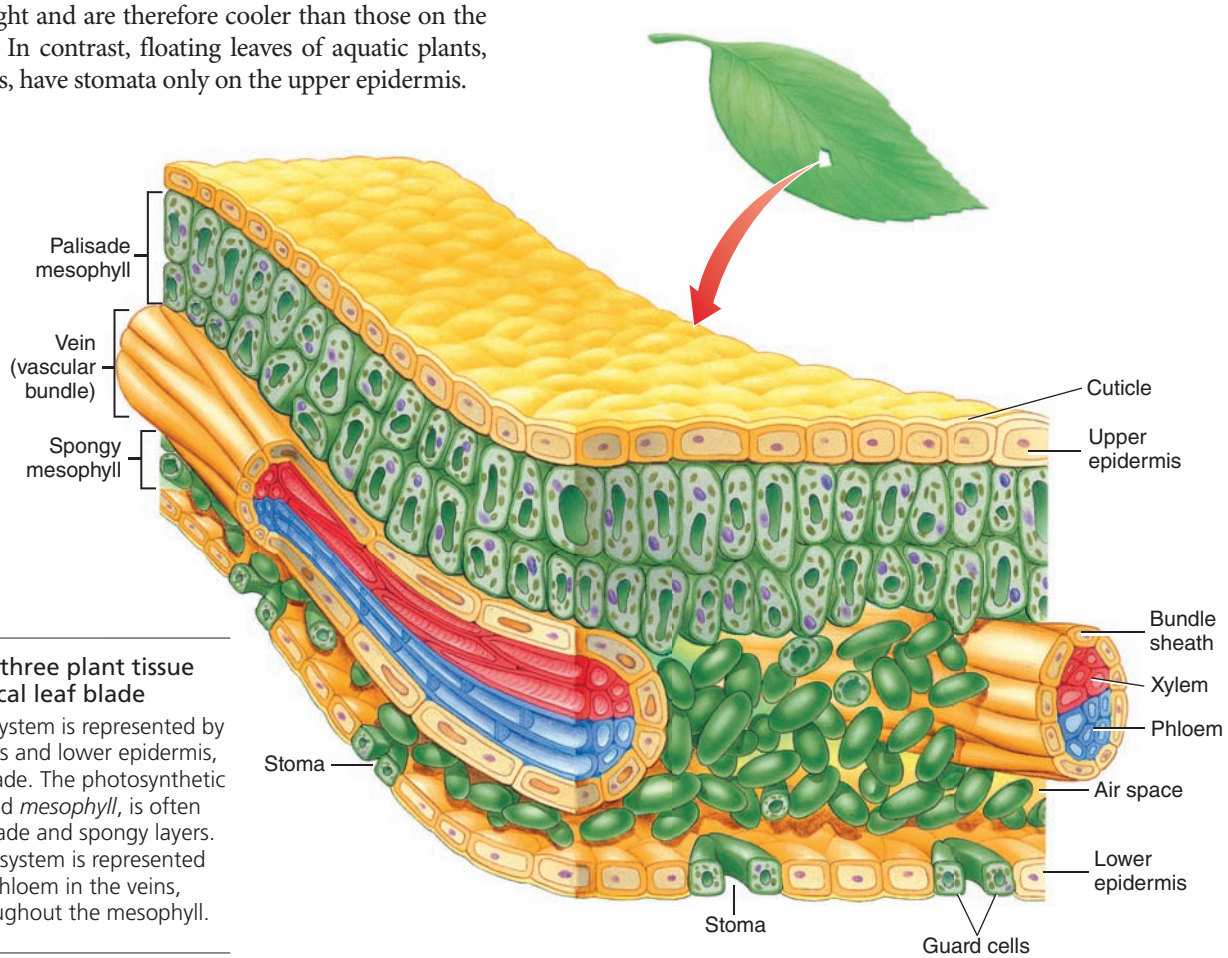

Figure 34-4 The three plant tissue systems in a typical leaf blade

The dermal tissue system is represented by the upper epidermis and lower epidermis, which cover the blade. The photosynthetic ground tissue, called *mesophyll*, is often arranged into palisade and spongy layers. The vascular tissue system is represented by the xylem and phloem in the veins, which branch throughout the mesophyll.

of water and ions that move into and out of the guard cells as they change shape during stomatal opening and closing (discussed later in this chapter).

The photosynthetic ground tissue of the leaf, called the **mesophyll** (from the Greek *meso*, "the middle of," and *phyll*, "leaf"), is sandwiched between the upper epidermis and the lower epidermis. Mesophyll cells, which are parenchyma cells (see Chapter 33) packed with chloroplasts, are loosely arranged, with many air spaces between them that facilitate gas exchange. These intercellular air spaces account for as much as 70% of the leaf's volume.

In many plants the mesophyll is divided into two sublayers. Toward the upper epidermis, the columnar cells are stacked closely together in a layer called **palisade mesophyll**. In the lower portion, the cells are more loosely and irregularly arranged in a layer called **spongy mesophyll**. The two layers have different functions. Palisade mesophyll is specialized for light capture and is the main site of photosynthesis in the leaf. Photosynthesis also occurs in the spongy mesophyll, but the primary function of the spongy mesophyll is to allow diffusion of gases, particularly CO_2, within the leaf.

Palisade mesophyll may be organized into one, two, three, or even more layers of cells. The presence of additional layers is at least partly an adaptation to environmental conditions. Leaves exposed to direct sunlight contain more layers of palisade mesophyll than do shaded leaves on the same plant. In direct sunlight the light is strong enough to effectively penetrate multiple layers of palisade mesophyll, allowing all layers to photosynthesize efficiently.

The veins, or *vascular bundles*, of a leaf extend through the mesophyll. Branching is extensive, and no mesophyll cell is more than two or three cells away from a vein. Therefore, the slow process of diffusion does not limit the movement of needed resources between mesophyll cells and veins. Each vein contains two types of vascular tissue: xylem and phloem. **Xylem**, which conducts water and dissolved minerals (inorganic nutrients), is usually located in the upper part of a vein, toward the upper epidermis. **Phloem**, which conducts dissolved sugars, is usually confined to the lower part of a vein.

One or more layers of nonvascular cells surround the larger veins and make up the **bundle sheath**. Bundle sheaths are composed of parenchyma or sclerenchyma cells (see Chapter 33). Frequently, the bundle sheath has support columns, called **bundle sheath extensions**, that extend through the mesophyll from the upper epidermis to the lower epidermis (FIG. 34-6). Bundle sheath extensions may be composed of parenchyma, collenchyma, or sclerenchyma cells.

(b) Monocot leaf. LM of part of a leaf cross section of corn (*Zea mays*). Corn leaves lack distinct regions of palisade and spongy mesophyll.

Figure 34-7 Eudicot and monocot leaf cross sections

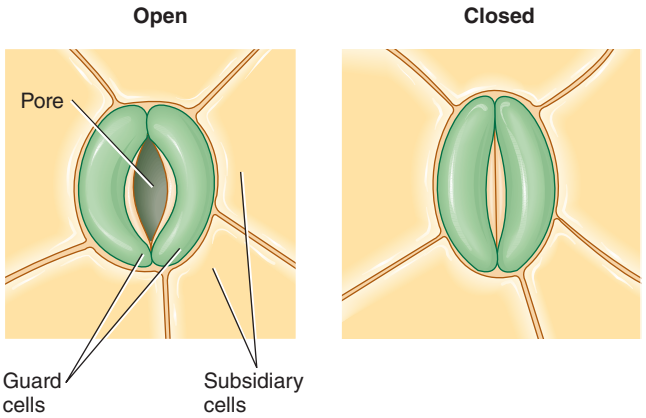
Leaf structure differs in eudicots and monocots Each eudicot leaf is usually composed of a broad, flattened blade and a petiole. As mentioned previously, eudicot leaves typically have netted venation. In contrast, many monocot leaves lack a petiole; they are narrow, and the base of the leaf often wraps around the stem to form a sheath. Parallel venation is characteristic of monocot leaves.

Eudicots and certain monocots also differ in internal leaf anatomy (FIG. 34-7). Although most eudicots and monocots have both palisade and spongy layers, some monocots (corn and other grasses) do not have mesophyll differentiated into distinct palisade and spongy layers. Because eudicots have netted veins, a cross section of a eudicot blade often shows veins in both cross-sectional and lengthwise views. In a cross section of a monocot leaf, in contrast, the parallel venation pattern produces evenly spaced veins, which all appear in cross section.

Differences between the guard cells in eudicot and certain monocot leaves also occur (FIG. 34-8). The guard cells of eudicots and many monocots are shaped like kidney beans. Other monocot leaves (those of grasses, reeds, and sedges) have guard cells shaped like dumbbells. These structural differences affect how the cells swell or shrink to open or close the stoma.

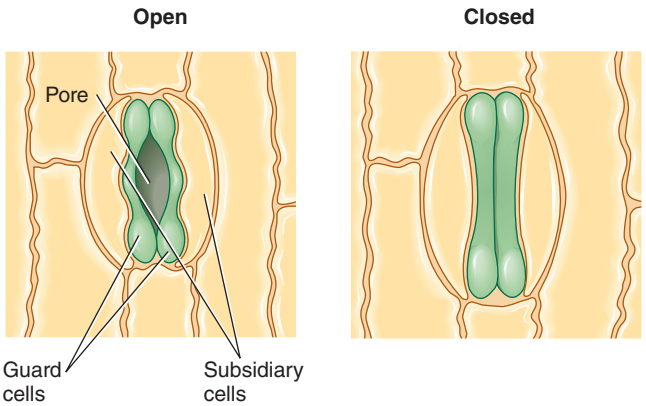
Leaf structure is related to function

How is leaf structure related to its primary function of photosynthesis? The epidermis of a leaf is relatively transparent and allows light to penetrate to the interior of the leaf where the photosynthetic ground tissue, the mesophyll, is located. Stomata, which dot the leaf surfaces, permit the exchange of gases between the atmosphere and the leaf's internal tissues. CO_2, a raw material of photosynthesis, diffuses into the leaf through stomata, and the oxygen produced during photosynthesis diffuses rapidly out of the leaf through stomata. Other gases, including air pollutants, also enter the leaf's interior via stomata.



Water required for photosynthesis is obtained from the soil and transported in the xylem to the leaf, where it diffuses into the mesophyll and moistens the surfaces of mesophyll cells. The loose arrangement of the mesophyll cells, with air spaces between cells, allows for rapid diffusion of CO_2 to the mesophyll cell surfaces; there it dissolves in a film of water before diffusing into the cells.

The veins not only supply the photosynthetic ground tissue with water and minerals (from the roots, by way of the xylem) but also carry (in the phloem) dissolved sugar produced during photosynthesis to all parts of the plant. Bundle sheaths and bundle sheath extensions associated with the veins provide additional support to prevent the leaf, which is structurally weak because of the large amount of air space in the mesophyll, from collapsing under its own weight.



Leaves are adapted to help a plant survive in its environment Leaf structure reflects the environment to which a particular plant is adapted. Although both aquatic plants and those adapted to dry conditions perform photosynthesis and have the same basic leaf anatomy, their leaves are modified to

Figure 34-8 Variation in guard cells

Guard cells are associated with epidermal cells called subsidiary cells.

enable them to survive different environmental conditions. The leaves of water lilies have petioles long enough to allow the blade to float on the water's surface. Large air spaces in the mesophyll make the floating blade buoyant. The petioles and other submerged parts have an internal system of air ducts; oxygen moves through these ducts from the floating leaves to the underwater roots and stems, which live in a poorly aerated environment.

Conifers are an important group of woody trees and shrubs that includes pine, spruce, fir, redwood, and cedar.[2] Most conifers are evergreen, which means that they lose leaves throughout the year rather than during certain seasons. Conifers dominate a large portion of Earth's land area, particularly in northern forests and mountains. The leaves of most conifers are waxy needles. Their needles have structural adaptations that help them survive winter, the driest part of the year. (Winter is arid even in areas of heavy snows because roots cannot absorb water from soil when the soil temperature is very low.) Indeed, many of the structural features of needles are also found in many desert plants.

FIGURE 34-9 shows a cross section of a pine needle. Note that the needle is somewhat thickened rather than thin and blade-like. The needle's relative thickness, which results in less surface area exposed to the air, reduces water loss. Other features that help conserve water include the thick, waxy cuticle and sunken stomata; these permit gas exchange while minimizing water loss. Thus, needles help conifers tolerate the dry winds that occur during winter (*dry* refers here to low relative humidity). With the warming of spring, soil water again becomes available, and the needles quickly resume photosynthesis.

[2] As discussed in Chapter 28, conifers are gymnosperms, one of the two groups of seed plants (the other group is the flowering plants, or angiosperms). Unlike flowering plants, whose seeds are enclosed in fruits, conifers bear "naked" seeds on the scales of female cones.

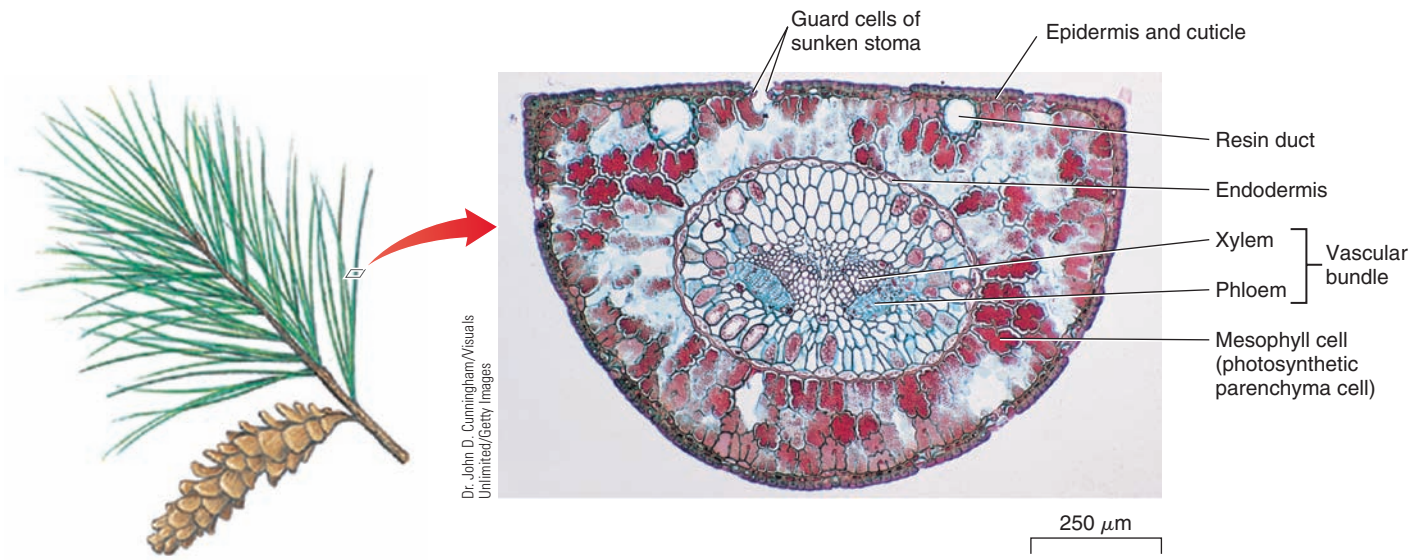

Figure 34-9 LM of a pine needle in cross section

The thick, waxy cuticle and sunken stomata are two structural adaptations that enable pine (*Pinus*) to retain its needles throughout the winter.

CHECKPOINT 34.1

- How are leaves adapted to conserve water?
- What is the photosynthetic ground tissue of a leaf called? What are its two sublayers?
- What are the two types of vascular tissue in a vascular bundle? Which vascular tissue is usually located in the upper part of the vascular bundle?
- How is the leaf organized to deliver the raw materials and remove the products of photosynthesis?

34.2 Stomatal Opening and Closing

LEARNING OBJECTIVES

5 Explain the role of blue light in the opening of stomata.
6 Outline the physiological changes that accompany stomatal opening and closing.

Stomata are adjustable pores that are usually open during the day when CO_2 is required for photosynthesis and closed at night when photosynthesis is shut down (see the section on CAM photosynthesis in Chapter 9 for an interesting exception). The opening and closing of stomata are controlled by changes in the shape of the two guard cells that surround each pore. The guard cells' shape is determined by their rigidity. When water moves into guard cells from surrounding non-guard cells, the guard cells become turgid (swollen) and bend, producing a pore. When water leaves the guard cells, they become flaccid (limp) and collapse against one another, closing the pore. What causes water to move into and out of guard cells?

Blue light triggers stomatal opening

Data from numerous experiments and observations are beginning to explain the complexities of stomatal movements. Let us begin with stomatal opening, which occurs when the plant detects light from the rising sun. You already know that light is a form of energy; plants absorb light and convert it to chemical energy in the process of photosynthesis. However, light is also an important *environmental signal* for plants; that is, light provides plants with information about their environment that they use to modify various activities at the molecular and cellular levels.

In stomatal opening and several other plant responses, *blue light*, which has wavelengths from 400 to 500 nm, is an environmental signal. Any plant response to light must involve a **pigment**, a molecule that absorbs the light, before the induction of a particular biological response. Data such as the responses of stomata to different colors of light suggest that the pigment involved in stomatal opening and closing is yellow (yellow pigments strongly absorb blue light). The yellow pigment is thought to be located in the guard cells, probably in their plasma membranes.

In FIGURE 34-10, blue light, which is a component of sunlight, triggers the activation of proton pumps, located in the guard cell plasma membrane. Blue light also triggers the synthesis of malic acid and the hydrolysis (splitting) of starch (discussed later).

The proton pumps use ATP energy to actively transport protons (H^+) out of the guard cells. The H^+ that are pumped are formed when malic acid produced in the guard cells ionizes to form H^+ and negatively charged malate ions. As the proton pumps in the plasma membranes of guard cells transport protons out of the guard cells, an **electrochemical gradient**—that is, a charge and concentration difference—forms across the guard cell plasma membrane.

The resulting electrochemical gradient of H^+ drives the facilitated diffusion of large numbers of potassium ions *into* guard cells. This movement occurs through **voltage-activated ion channels**, which are specific for potassium ions and open when a certain voltage (difference in charge between the two sides of the guard cell plasma membrane) is attained. This movement of potassium ions has been experimentally measured by the **patch clamp technique**, in which researchers seal the tip of a micropipette to a tiny patch of membrane that contains a single ion channel. As illustrated in Figure 41-5, these scientists then measure the flow of ions through that channel between the cytoplasm and the solution in the micropipette. (Interestingly, in animals, voltage-activated ion channels are found in the plasma membranes of nerve cells and are involved in transmitting neural impulses.)

Chloride ions are also taken into the guard cells through ion channels in the guard cell plasma membrane. The negatively charged chloride and malate ions help electrically balance the positively charged potassium ions.

The potassium, chloride, and malate ions accumulate in the vacuoles of the guard cells, thus increasing the solute concentration in the vacuoles. You may recall from the discussion of osmosis in Chapter 5 that when a cell has a solute concentration greater than that of surrounding cells, water flows *into* the cell. Thus, water enters the guard cells from surrounding epidermal cells by osmosis. The increased turgidity of the guard cells changes their shape because the thickened inner cell walls do not expand as much as the outer walls, and so the stoma opens.

> blue light activates proton pumps → proton pumps move H^+ out of guard cells → K^+ and Cl^- diffuse into guard cells through voltage-activated ion channels → water diffuses by osmosis into guard cells → guard cells change shape and stoma opens

Stomata close in the late afternoon or early evening, but not by an exact reversal of the opening process. Recent studies have demonstrated that the concentration of potassium ions in guard cells slowly decreases during the day.

Key Point

The accumulation of osmotically active ions (K^+ and Cl^-) in the guard cells is driven by a proton (H^+) gradient.

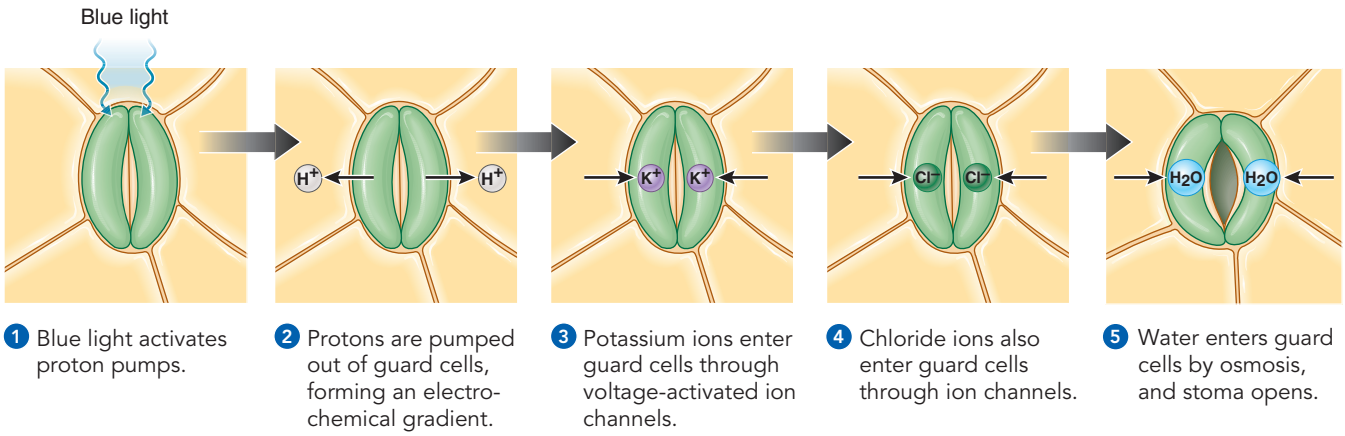

Figure 34-10 Mechanism of stomatal opening

CONNECT Guard cells are usually the only epidermal cells that are photosynthetic. How does that feature relate to the mechanisms of stomatal opening and closing?

However, the concentration of sucrose, another osmotically active substance, increases during the day—maintaining the open pore—and then slowly decreases as evening approaches. This sucrose comes from the hydrolysis of the polysaccharide starch, which is stored in the guard cell chloroplasts. As evening approaches, the sucrose concentration in the guard cells declines as sucrose is converted back to starch (which is osmotically inactive), water leaves by osmosis, the guard cells lose their turgidity, and the pore closes.

To summarize, different mechanisms appear to regulate the opening and closing of stomata. The uptake of potassium and chloride ions is mainly associated with stomatal opening, and the declining concentration of sucrose is mainly associated with stomatal closing. In Chapter 38 we discuss other blue-light responses in plants.

Additional factors affect stomatal opening and closing

Although light and darkness trigger the opening and closing of stomata, other environmental factors are also involved, including CO_2 concentration. A low concentration of CO_2 in the leaf induces stomata to open, even in the dark. The effects of light and CO_2 concentration on stomatal opening are interrelated. Photosynthesis, which occurs in the presence of light, reduces the internal concentration of CO_2 in the leaf, triggering stomatal opening. Another environmental factor that affects stomatal opening and closing is water stress. During a prolonged drought, stomata remain closed, even during the day. Stomatal opening and closing are under hormonal control, particularly by the plant hormone *abscisic acid* (see Table 38-1).

The opening and closing of stomata are also regulated by an internal biological clock that in some way measures time. For example, after plants are placed in continual darkness, their stomata continue to open and close at more or less the same time each day. Such biological rhythms that follow an approximate 24-hour cycle are known as **circadian rhythms**. Other examples of circadian rhythms are provided in Chapter 38.

CHECKPOINT 34.2

- How does blue light trigger stomatal opening?
- What physiological changes occur in guard cells during stomatal opening? during stomatal closing?

34.3 Transpiration and Guttation

LEARNING OBJECTIVES

7 Discuss transpiration and its effects on plants.
8 Distinguish between transpiration and guttation.

Despite leaf adaptations such as the cuticle, approximately 99% of the water that a plant absorbs from the soil is lost by evaporation from the leaves and, to a lesser extent, the stems. Loss of water vapor by evaporation from aerial plant parts is called **transpiration**.

Copyright 2019 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

The cuticle is extremely effective in reducing water loss by transpiration. It is estimated that only 1% to 3% of the water lost from a plant passes directly through the cuticle. Most transpiration occurs through open stomata. The numerous stomatal pores that are so effective in gas exchange for photosynthesis also provide openings through which water vapor escapes. In addition, the loose arrangement of the spongy mesophyll cells provides a large surface area within the leaf from which water can evaporate.

Several environmental factors influence the rate of transpiration. More water is lost from plant surfaces at higher temperatures than at lower temperatures. Light increases the transpiration rate, in part because it triggers stomatal opening and in part because it increases the leaf's temperature. Wind and dry air increase transpiration, but humid air *decreases* transpiration because the air is already saturated, or nearly so, with water vapor.

Although transpiration may seem wasteful, particularly to farmers in arid lands, it is an essential process that has adaptive value. Transpiration is responsible for water movement in plants, and without it water would not reach the leaves from the soil (see discussion of the tension–cohesion model in Chapter 35). The large amount of water that plants lose by transpiration may provide some additional benefits. Transpiration, like sweating in humans, cools the leaves and stems. When water passes from a liquid state to a vapor, it absorbs a great deal of heat. When the water molecules leave the plant as water vapor, they carry this heat with them. Thus, the cooling effect of transpiration may prevent leaves from overheating, particularly in direct sunlight.

Another benefit of transpiration is that it distributes essential minerals throughout the plant. The water that a plant transpires is initially absorbed from the soil, where it is present not as pure water but as a dilute solution of dissolved mineral salts. The water and dissolved minerals are then transported in the xylem throughout the plant, including its leaves. Water moves from the plant to the atmosphere during transpiration, but minerals remain in plant tissues. Many of these minerals are required for the plant's growth. It has been suggested that transpiration enables a plant to take in sufficient water to provide enough essential minerals; it has also been suggested that plants cannot satisfy their mineral requirements if the transpiration rate is not high enough.

There is no doubt, however, that under certain circumstances excessive transpiration can be harmful to a plant. On hot summer days, plants frequently lose more water by transpiration than they can take in from the soil. Their cells experience a loss of turgor, and the plants wilt (FIG. 34-11). If a plant is able to recover overnight because of the combination of negligible transpiration (recall that stomata are closed) and absorption of water from the soil, the plant is said to have experienced *temporary wilting*. Most plants recover from temporary wilting with no ill effects. In cases of prolonged drought, however, the soil may not contain sufficient moisture to permit recovery from wilting. A plant that cannot recover is said to be *permanently wilted* and will die.

(a) In the late afternoon of a hot day, the leaves have wilted because of water loss. Note that wilting helps reduce the surface area from which transpiration occurs.

(b) The next morning, water in the leaves has been replenished. Transpiration is negligible during the night, and the plants recover by absorbing water from the soil.

Figure 34-11 Temporary wilting in squash (*Cucurbita pepo*) leaves

Transpiration is an important part of the **hydrologic cycle**, in which water cycles from the ocean and land to the atmosphere and then back to the ocean and land (see Fig. 55-11). As a result of transpiration, water evaporates from leaves and stems to form clouds in the atmosphere. Thus, transpiration eventually results in precipitation. As you may expect, forest trees release substantial amounts of moisture into the air by transpiration. Researchers have determined that at least half the rain that falls in the Amazon rainforest basin is recycled again and again by transpiration and precipitation.

Some plants exude liquid water

Many leaves have special structures at vein endings through which liquid water is literally forced out. This loss of liquid water, known as **guttation**, occurs when transpiration is negligible and available soil moisture is high. Guttation typically occurs in low-growing plants at night because the stomata are closed, but water continues to move into the roots by osmosis. People sometimes mistake the early morning water droplets formed on leaf margins by guttation for dew (FIG. 34-12). Unlike dew, which condenses from cool night air, guttation droplets come from within the plant. (The mechanism for guttation is discussed in Chapter 35.)

CHECKPOINT 34.3

- **CONNECT** How is leaf structure related to transpiration?
- How do environmental factors (sunlight, temperature, humidity, and wind) influence the rate of transpiration?
- **CONNECT** In what ways is transpiration detrimental to plants? What are its benefits?
- How does guttation differ from transpiration?

34.4 Leaf Abscission

LEARNING OBJECTIVE

9 Define leaf *abscission*, explain why it occurs, and describe the physiological and anatomical changes that precede it.

All trees shed leaves, a process known as **abscission**. Many conifers shed their needles in small numbers year-round. The leaves of deciduous plants turn color and abscise, or fall off, once a year as winter approaches in temperate climates or at the beginning of the dry period in tropical climates with pronounced wet and dry seasons. In temperate forests, most woody plants with broad leaves shed their leaves to survive the low temperatures of winter. During winter, the plant's metabolism, including its photosynthetic machinery, slows down or halts temporarily.

Another reason for abscission is related to a plant's water requirements, which become critical during the physiological drought of winter. As mentioned previously, as the ground chills, absorption of water by the roots is inhibited. When the ground freezes, *no* absorption occurs. If the broad leaves were to stay on the plant during the winter, the plant would continue to lose water by transpiration but would be unable to replace it with water absorbed from the soil.

Leaf abscission is a complex process that involves many physiological changes, all initiated and orchestrated by changing levels of plant hormones, particularly *ethylene*. Briefly, the process is as follows. As autumn approaches, sugars, amino acids, and many essential minerals (such as nitrogen, phosphorus, and possibly potassium) are mobilized and transported from the leaves to other plant parts; these minerals will be reused during the following spring. Chlorophyll breaks down, allowing the **carotenoids** (orange carotenes and yellow xanthophylls), some of the accessory pigments in the chloroplasts of leaf cells, to become evident (see Fig. 3-14b). Accessory pigments are always present in the chloroplasts but are masked by the green of the chlorophyll. In addition, red water-soluble pigments called **anthocyanins** may accumulate in the vacuoles of epidermal leaf cells in some species; anthocyanins may protect leaves against damage by ultraviolet radiation. The various combinations of carotenoids and anthocyanins are responsible for the brilliant colors found in autumn landscapes in temperate climates.

In many leaves, abscission occurs at an abscission zone near the base of the petiole

The area where a petiole detaches from the stem is a structurally distinct area called the **abscission zone**. Composed primarily of thin-walled parenchyma cells, it is anatomically weak because it contains few fibers (FIG. 34-13). A protective layer of cork cells develops on the stem side of the abscission zone. These cells have a waxy, waterproof material impregnated in their walls. Enzymes then dissolve the **middle lamella** (the "cement" that holds the primary cell walls of adjacent cells together) in the abscission zone (see Fig. 4-30). Once this process is completed, nothing holds the leaf to the stem but a few xylem cells. A sudden breeze is enough to make the final break, and the leaf detaches. The protective layer of cork remains, sealing off the area and forming a leaf scar.

Although the structure of abscission zones and the physiological changes associated with abscission have been well known for many years, only recently have botanists investigated the genes responsible for the development of an abscission zone and the physiological changes of leaf abscission. Using **DNA microarrays**, for example, botanists have identified about 35 genes that are expressed in leaves only as winter approaches.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

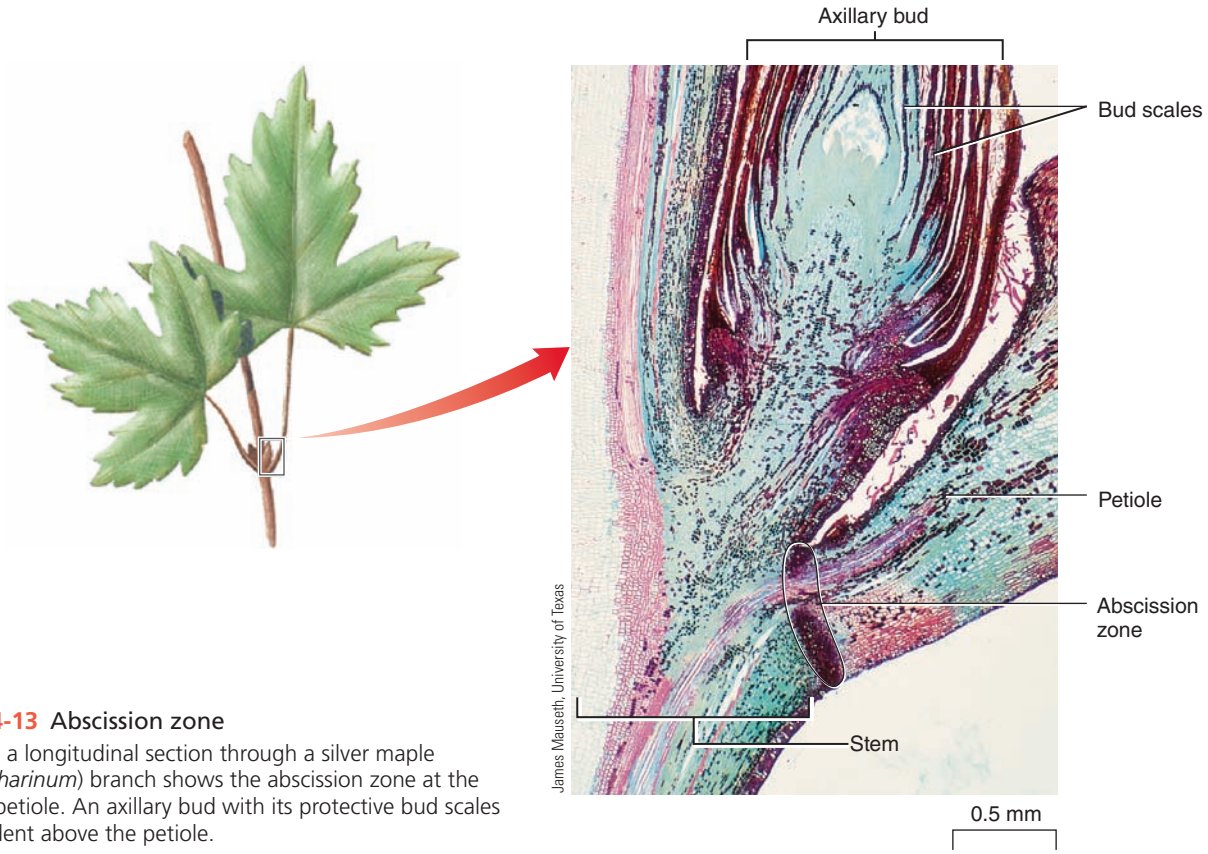

Figure 34-13 Abscission zone
This LM of a longitudinal section through a silver maple (*Acer saccharinum*) branch shows the abscission zone at the base of a petiole. An axillary bud with its protective bud scales is also evident above the petiole.

As discussed in Chapter 15, a DNA microarray contains hundreds of different DNA molecules placed on a glass slide or chip. Some of the genes identified in these studies code for degradative enzymes involved in breaking down proteins and other molecules; others have functions not yet identified.

CHECKPOINT 34.4

- Why do many woody plants living in temperate zones lose their leaves in autumn?
- What physiological changes occur during leaf abscission?
- What is the abscission zone?

34.5 Modified Leaves

LEARNING OBJECTIVE

10 List at least four examples of modified leaves and give the function of each.

Although photosynthesis is the main function of leaves, certain leaves have special modifications for other functions. Some plants have leaves specialized for deterring herbivores. **Spines**, modified leaves that are hard and pointed, are found on many desert plants, such as cacti (FIG. 34-14a). In the cactus, the main organ of photosynthesis is the stem rather than the leaf. Spines discourage animals from eating the succulent stem tissue.

Vines are climbing plants whose stems cannot support their own weight, so they often possess **tendrils** that help keep the vine attached to the structure on which it is growing. The tendrils of many vines, such as peas, cucumbers, squash, and sweet peas, are specialized leaves (FIG. 34-14b). However, some tendrils, such as those of ivy, Virginia creeper, and grape, are specialized stems.

The winter buds of a dormant woody plant are covered by **bud scales**. These modified leaves protect the delicate meristematic tissue of the bud from injury, freezing, or drying out (FIG. 34-14c).

Some leaves associated with flower clusters (inflorescences) are modified as **bracts**. In flowering dogwood, the inconspicuous flowers are clustered in the center of each inflorescence, and what appears to be four white or pink petals are actually bracts. Similarly, the red "petals" of poinsettia are not petals at all but bracts (FIG. 34-14d).

Leaves may also be modified for storage of water or food. For example, a **bulb** is a short, underground stem to which large, fleshy leaves are attached (FIG. 34-14e). Onions and tulips form bulbs. Many plants adapted to arid conditions, such as jade plants, medicinal aloes, and string-of-beads, have succulent leaves for water storage (FIG. 34-14f). These leaves are usually green and function in photosynthesis.

Some leaves are modified for either sexual reproduction (see discussion of flower evolution in Chapter 28, including Figure 28-15) or asexual reproduction (see Fig. 37-17).

Modified leaves of carnivorous plants capture insects

Carnivorous plants are plants that capture insects. Most carnivorous plants grow in poor soil that is deficient in certain essential minerals, particularly nitrogen. These plants meet some of their mineral requirements by digesting insects and other small animals. The leaves of carnivorous plants are adapted to attract, capture, and digest their animal prey.

Some carnivorous plants have passive traps. The leaves of a pitcher plant, for example, are shaped so that rainwater collects and forms a reservoir that also contains acid secreted by the plant (FIG. 34-15). Some pitchers are quite large; in the tropics, pitcher plants may be large enough to hold 1L (approximately 1 qt) or more of liquid. An insect attracted by the odor or nectar of the pitcher may lean over the edge and fall in. Although it may make repeated attempts to escape, the insect is prevented from crawling out by the slippery sides and the rows of stiff hairs that point downward around the lip of the pitcher. The insect eventually drowns, and part of its body disintegrates and is absorbed.

Most insects are killed in pitcher plants. However, the larvae of several insects (certain flies, midges, and mosquitoes) and a large community of microorganisms live inside the pitchers. These insect species obtain their food from the insect carcasses, and the pitcher plant digests what remains. It is not known how these insects survive the acidic environment inside the pitcher.

The Venus flytrap is a carnivorous plant with active traps. Its leaf blades resemble tiny bear traps (see Fig. 1-3). Each side of the leaf blade contains three small, stiff hairs. If an insect alights and brushes against two of the hairs or against the same hair twice in quick succession, the trap springs shut with amazing rapidity, about 100 milliseconds. The spines along the margins of the blades fit closely together to prevent the insect from escaping. After the leaf initially traps the insect, the leaf continues to slowly close for the next several hours. Digestive glands on the surface of the trap secrete enzymes in response to the insect pressing against them. Days later, after the insect has died and been digested, the trap reopens and the indigestible remains fall out.

Summary: Focus on Learning Objectives

34.1 Leaf Form and Structure *(page 730)*

1 Discuss variation in leaf form, including simple versus compound leaves, leaf arrangement on the stem, and venation patterns.

- Leaves may be simple (having a single **blade**) or compound (having a blade divided into two or more leaflets).
- Leaf arrangement on a stem may be alternate (one leaf at each **node**), opposite (two leaves at each node), or whorled (three or more leaves at each node).
- Leaves may have parallel or netted venation. Netted venation may be palmately netted, with several major **veins** radiating from one point, or pinnately netted, with veins branching along the entire length of the midvein.

2 Describe the major tissues of the leaf (epidermis, photosynthetic ground tissue, xylem, and phloem) and sketch how they are arranged in a leaf cross section.

- Upper and lower surfaces of the leaf blade are covered by an **epidermis**. A waxy **cuticle** coats the epidermis, enabling the plant to survive the dry conditions of a terrestrial existence.
- **Stomata** are small pores in the epidermis that permit gas exchange needed for photosynthesis. Each pore is surrounded by two **guard cells** that are often associated with special epidermal cells called **subsidiary cells**. Subsidiary cells provide a reservoir of water and ions that move into and out of the guard cells as they change shape during stomatal opening and closing.
- **Mesophyll** consists of photosynthetic parenchyma cells. Mesophyll is divided into **palisade mesophyll**, which functions primarily for photosynthesis, and **spongy mesophyll**, which functions primarily for gas exchange.
- Leaf veins have **xylem** to conduct water and essential minerals to the leaf and **phloem** to conduct sugar produced by photosynthesis to the rest of the plant.

3 Compare leaf anatomy in eudicots and monocots.

- Monocot leaves have parallel venation, whereas eudicot leaves have netted venation. Some monocots (corn and other grasses) do not have mesophyll differentiated into distinct palisade and spongy layers. Some monocots (grasses, reeds, and sedges) have guard cells shaped like dumbbells, unlike the more common bean-shaped guard cells.

4 Relate leaf structure to its function of photosynthesis.

- Leaf structure is adapted for its primary function of **photosynthesis**. Most leaves have a broad, flattened blade that efficiently collects the sun's radiant energy. The transparent epidermis allows light to penetrate into the middle of the leaf, where photosynthesis occurs.
- Stomata generally open during the day for gas exchange needed during photosynthesis and close at night to conserve water when photosynthesis is not occurring.
- Air spaces in mesophyll tissue permit the rapid diffusion of CO_2 and water into, and oxygen out of, mesophyll cells.

34.2 Stomatal Opening and Closing *(page 736)*

5 Explain the role of blue light in the opening of stomata.

- *Blue light*, which is a component of sunlight, triggers the activation of proton pumps located in the guard cell plasma membrane. Blue light also triggers the synthesis of malic acid and the hydrolysis of starch.

6 Outline the physiological changes that accompany stomatal opening and closing.

- Protons (H^+), produced when malic acid ionizes, are pumped out of the guard cells. As protons leave the guard cells, an **electrochemical gradient** (a charge and concentration difference) forms on the two sides of the guard cell plasma membrane.
- The electrochemical gradient drives the uptake of potassium ions (K^+) through specific **voltage-activated ion channels** into the guard cells. Chloride ions (Cl^-) are also taken into the guard cells through ion channels. These osmotically active ions increase the solute concentration in the guard cell vacuoles. The resulting osmotic movement of water into the guard cells causes them to become turgid, forming a pore.
- As the day progresses, potassium ions slowly leave the guard cells, and starch is hydrolyzed to sucrose, an osmotically active solute, which increases in concentration in the guard cells. Stomata close when water leaves the guard cells as a result of a decline in the concentration of sucrose, which occurs as evening approaches. The sucrose is converted to starch, which is osmotically inactive.

34.3 Transpiration and Guttation *(page 737)*

7 Discuss transpiration and its effects on plants.

- **Transpiration** is the loss of water vapor from aerial parts of plants. Transpiration, which occurs primarily through the stomata, is affected by environmental factors such as temperature, wind, and relative humidity.
- Transpiration appears to be both beneficial and harmful to the plant; that is, transpiration represents a trade-off between the CO_2 requirement for photosynthesis and the need for water conservation.

8 Distinguish between transpiration and guttation.

- **Guttation**, the release of liquid water from leaf margins of some plants, occurs through special structures when transpiration is negligible and available soil moisture is high. In contrast, transpiration is the loss of water vapor and occurs primarily through the stomata.

34.4 Leaf Abscission *(page 739)*

9 Define leaf *abscission*, explain why it occurs, and describe the physiological and anatomical changes that precede it.

- Leaf **abscission** is the loss of leaves that often occurs as winter approaches in temperate climates or at the beginning of the dry period in tropical climates with wet and dry seasons.
- Abscission involves physiological and anatomical changes that occur prior to leaf fall. An **abscission zone** develops where the petiole detaches from the

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

stem. Sugars, amino acids, and many essential minerals are transported from the leaves to other plant parts. Chlorophyll breaks down, and **carotenoids** and **anthocyanins** become evident.

34.5 Modified Leaves *(page 740)*

10 List at least four examples of modified leaves and give the function of each.

- **Spines** are leaves adapted to deter herbivores. Some **tendrils** are leaves modified for grasping and holding on to other structures (to support weak stems). **Bud scales** are leaves modified to protect delicate meristematic tissue or dormant buds. **Bracts** are modified leaves associated with some inflorescences. **Bulbs** are short, underground stems with fleshy leaves specialized for storage. Many plants adapted to arid conditions have succulent leaves for water storage. Carnivorous plants have leaves modified to trap insects.

Test Your Understanding

Know and Comprehend

1. Plants with an alternate leaf arrangement have (a) blades divided into two or more leaflets (b) major veins that radiate out from one point (c) one leaf at each node (d) major veins branching off along the entire length of the midvein (e) two leaves at each node
2. The primary function of the spongy mesophyll is (a) reducing water loss from the leaf surface (b) changing the shape of the guard cells (c) supporting the leaf to prevent it from collapsing under its own weight (d) diffusing gases within the leaf (e) deterring herbivores
3. Gas exchange occurs through microscopic pores formed by two (a) subsidiary cells (b) abscission cells (c) mesophyll cells (d) guard cells (e) stipules
4. The thin, noncellular layer of wax secreted by the epidermis of leaves is the (a) stoma (b) abscission zone (c) trichome (d) bundle sheath (e) cuticle
5. Which of the following is *not* an adaptation of pine needles to conserve water? (a) less surface area exposed to the air than thin-bladed leaves (b) a relatively thick cuticle (c) sunken stomata (d) netted veins instead of parallel veins (e) both c and d are not adaptations of pine needles
6. When transpiration is negligible, plants such as grasses exude excess water by (a) guttation (b) circadian rhythm (c) abscission (d) pumping H^+ out of and K^+ into guard cells (e) photosynthesis
7. At sunrise, the accumulation in the guard cells of the osmotically active substance _____ causes an inflow of water and the opening of the pore. (a) protons (b) starch (c) ATP synthase (d) sucrose (e) potassium ions
8. Stomatal opening is most pronounced in response to _____ light. (a) green (b) yellow (c) blue (d) ultraviolet (e) infrared
9. Anatomically, the abscission zone where a petiole detaches from a stem consists of (a) thin-walled parenchyma cells with few fibers (b) thick-walled cork parenchyma cells (c) clusters of fibers and collenchyma strands (d) hard, pointed stipules (e) epidermal cells with sunken stomata
10. Modified leaves that enable a stem to climb are called _____, whereas modified leaves that cover the winter buds of a dormant woody plant are called _____. (a) spines; bud scales (b) bud scales; tendrils (c) tendrils; bud scales (d) tendrils; spines (e) carnivorous leaves; spines
11. There is a trade-off between photosynthesis and transpiration in leaves because (a) numerous stomatal pores provide both gas exchange for photosynthesis and openings through which water vapor escapes (b) a waxy layer, the cuticle, reduces water loss (c) blue light triggers an influx of potassium ions (K^+) into the guard cells (d) leaves of deciduous plants abscise as winter approaches in temperate climates (e) stomata are closed at night, although water continues to move into the roots by osmosis

Apply and Analyze

12. Suppose that you are asked to observe a micrograph of a leaf cross section and distinguish between the upper and lower epidermis. How would you make this decision?
13. **CONNECT** Given that (a) xylem is located toward the upper epidermis in leaf veins and phloem is located toward the lower epidermis and (b) the vascular tissue of a leaf is continuous with that of the stem, suggest one possible arrangement of vascular tissues in the stem that might account for the arrangement of vascular tissue in the leaf.
14. **VISUALIZE** Draw a simple cross section of a leaf. Label the upper epidermis, lower epidermis, guard cells, spongy mesophyll, palisade mesophyll, and vascular tissue. Which cells contain chloroplasts?

Evaluate and Synthesize

15. What might be some of the advantages of a plant having a few large leaves? What might be some disadvantages? What might be some advantages of having many small leaves? What disadvantages might that entail? How would your answers differ for plants growing in a humid environment compared with those in a desert?
16. **EVOLUTION LINK** What is the selective advantage of seasonal leaf abscission in woody flowering plants living in colder climates? What adaptations enable conifers to survive these climates without leaf abscission?
17. **SCIENCE, TECHNOLOGY, AND SOCIETY** Briefly explain why research on the molecular mechanism of stomatal closure might be of future use in agriculture.

35 Stem Structure and Transport

A vegetative (not sexually reproductive) vascular plant has three parts: roots, leaves, and stems. As discussed in Chapter 33, roots serve to anchor the plant and absorb materials from the soil, whereas leaves are primarily for photosynthesis, converting radiant energy into the chemical energy of carbohydrate molecules. Stems, the focus of this chapter, link a plant's roots to its leaves and are usually located aboveground, although many plants have underground stems. Stems exhibit varied forms, ranging from ropelike vines to massive tree trunks (see photograph). They can be herbaceous, with soft, nonwoody tissues, or they can be woody, with extensive hard tissues of wood and bark.

Stems perform three main functions in plants. First, stems of most species support leaves and reproductive structures. The upright position of most stems and the arrangement of the leaves on them allow each leaf to absorb light for use in photosynthesis. Reproductive structures (such as flowers and fruits) are located on stems in areas accessible to insects, birds, and air currents, which transfer pollen from flower to flower and help disperse seeds and fruits.

Second, stems provide internal transport. They conduct water and dissolved minerals (inorganic nutrients) from the roots, where these materials are absorbed from the soil, to leaves and other plant parts. Stems also conduct the sugar produced in leaves by photosynthesis to roots and other parts of the plant. Remember, however, that stems are not the only plant organs that conduct materials. The vascular system is continuous throughout all parts of a plant, and conduction occurs in roots, stems, leaves, and reproductive structures.

KEY CONCEPTS

35.1 Primary tissues (epidermis, cortex, pith, xylem, and phloem) of stems develop from shoot apical meristems. Secondary tissues (wood and bark) of stems develop from two lateral meristems: vascular cambium and cork cambium.

35.2 The concept of water potential explains the direction of water transport into, through, and out of a plant. According to the tension–cohesion model, transpiration pulls water up through the stem as water evaporates from leaves by transpiration.

35.3 According to the pressure–flow model, sucrose is translocated in phloem sap from the source, where the sugar is loaded into phloem, to the sink, where the sugar is removed from phloem.

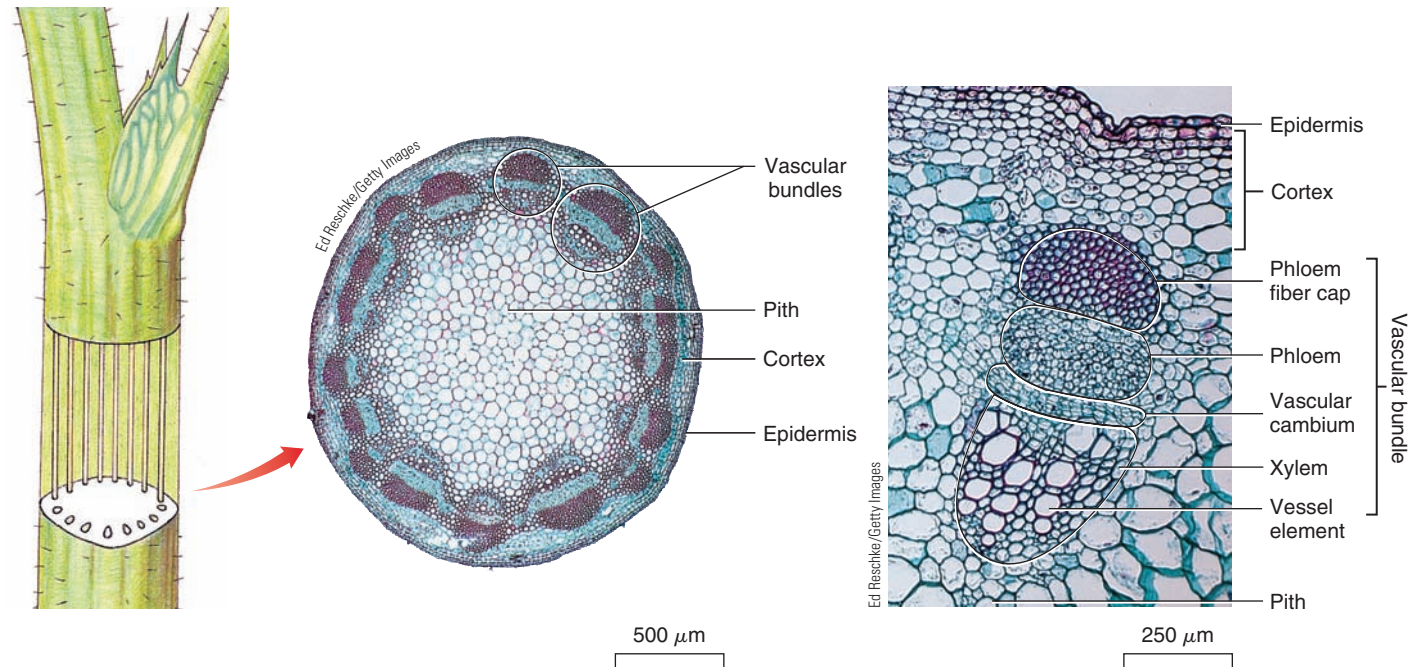
Third, stems produce new living tissue. They continue to grow throughout a plant's life, producing *buds* that develop into stems with new leaves and/or reproductive structures. In addition to the main functions of support, conduction, and production of new stem tissues, stems of some species are modified for asexual reproduction (see Chapter 37) or, if green, to manufacture sugar by photosynthesis.

35.1 Stem Growth and Structure

LEARNING OBJECTIVES

1. Sketch cross sections of herbaceous eudicot and monocot stems, and describe the functions of each tissue.
2. Name the two lateral meristems and describe the tissues that arise from each.
3. Outline the transition from primary growth to secondary growth in a woody stem.



You may recall from Chapter 33 that plants have two different types of growth. **Primary growth** is an increase in the length of a plant and occurs at **apical meristems** located at the tips of roots and shoots and also within the buds of stems. **Secondary growth** is an increase in the girth (thickness) of a plant as a result of the activity of **lateral meristems** located within stems and roots. The new tissues formed by the lateral meristems are called *secondary tissues* to distinguish them from *primary tissues* produced by apical meristems.

All plants have primary growth; some plants have both primary and secondary growth. Stems with only primary growth are herbaceous, whereas those with both primary and secondary growth are generally woody. (Certain herbaceous stems, such as geranium and sunflower, also have a limited amount of secondary growth.) A woody plant increases in length by primary growth at the tips of its stems and roots, whereas its older stems and roots farther back from the tips increase in girth by secondary growth. In other words, at the same time that primary growth is increasing the length of the stem, secondary growth is adding wood and bark, thereby causing the stem to thicken.

Herbaceous eudicot and monocot stems differ in internal structure

Although considerable structural variation exists in stems, they all possess an outer protective covering (epidermis or periderm), one or more types of ground tissue, and vascular tissues (xylem and phloem). Let us first consider the structure of herbaceous eudicot stems and then the structure of monocot stems.

Vascular bundles of herbaceous eudicot stems are arranged in a circle in cross section A young sunflower stem is a representative herbaceous eudicot stem that exhibits primary growth (FIG. 35-1). Its outer covering, the **epidermis**, provides protection in herbaceous stems, as it does in leaves and herbaceous roots (see Table 33-4 and Fig. 33-5). The **cuticle**, a waxy layer of *cutin*, covers the stem epidermis and reduces water loss from the stem surface. **Stomata** permit gas exchange. (Recall from Chapter 34 that a cuticle and stomata are also associated with the leaf epidermis.)

(a) Cross section of a sunflower (*Helianthus annuus*) stem. Note the vascular bundles arranged in a circle around a central core of pith.

(b) Close-up of a vascular bundle. In each bundle, xylem is located toward the stem's interior, and phloem toward the exterior. Each vascular bundle is "capped" by a batch of fibers for additional support.

Figure 35-1 LMs of a herbaceous eudicot stem

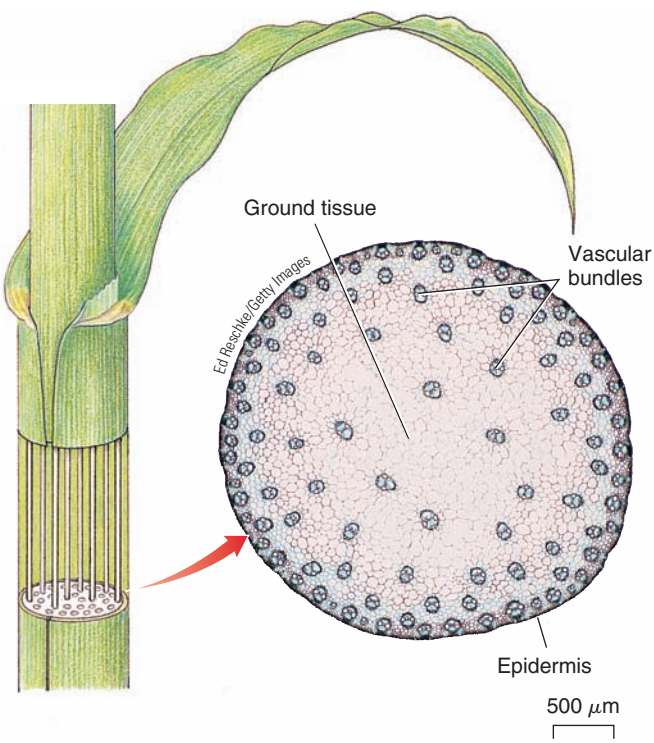
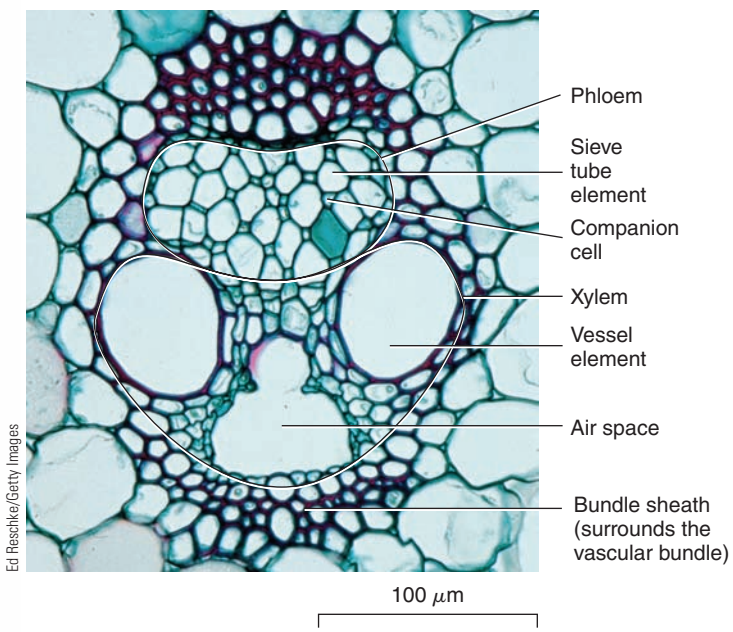
Inside the epidermis is the **cortex**, a cylinder of ground tissue that may contain parenchyma, collenchyma, and sclerenchyma cells (see Table 33-2 and Fig. 33-3). As might be expected from the various types of cells that it contains, the cortex in herbaceous eudicot stems can have several functions, such as photosynthesis, storage, and support. If a stem is green, photosynthesis occurs in chloroplasts of cortical parenchyma cells. Parenchyma in the cortex also stores starch (in amyloplasts) and crystals (in vacuoles). Collenchyma and sclerenchyma in the cortex confer strength and structural support for the stem.



The vascular tissues provide conduction and support. In herbaceous eudicot stems, the vascular tissues are located in bundles that, when viewed in cross section, are arranged in a circle. However, viewed lengthwise, these bundles extend as long strands throughout the length of a stem and are continuous with vascular tissues of both roots and leaves.

Each vascular bundle contains both **xylem**, which transports water and dissolved minerals from roots to leaves, and **phloem**, which transports dissolved sugar (see Table 33-3 and Fig. 33-4). Xylem is located on the inner side of the vascular bundle, and phloem is found toward the outside. Sandwiched between xylem and phloem in some herbaceous stems is a single layer of cells called the *vascular cambium*, a lateral meristem responsible for secondary growth (discussed later).



Because most stems support the aerial plant body, they are much stronger than roots. The thick walls of tracheids and vessel elements in xylem help support the plant. Fibers also occur in both xylem and phloem, although they are usually more extensive in phloem. These fibers add considerable strength to the herbaceous stem. In sunflowers and certain other herbaceous eudicot stems, phloem contains a cluster of fibers toward the outside of the vascular bundle, called a *phloem fiber cap*, that helps strengthen the stem. The phloem fiber cap is not present in all herbaceous eudicot stems.

The **pith** is a ground tissue at the center of the herbaceous eudicot stem that consists of large, thin-walled parenchyma cells that function primarily in storage. Because of the arrangement of the vascular tissues in bundles, there is no distinct separation of cortex and pith between the vascular bundles. The areas of parenchyma between the vascular bundles are often referred to as *pith rays*.

Vascular bundles are scattered throughout monocot stems An epidermis with its waxy cuticle covers monocot stems, such as the herbaceous stem of corn. As in herbaceous eudicot stems, the vascular tissues run in strands throughout the length of a stem. In cross section the vascular bundles contain xylem toward the inside and phloem toward the outside. In contrast with herbaceous eudicots, however, vascular bundles of monocots are not arranged in a circle but are scattered throughout the stem (FIG. 35-2). Each vascular bundle is enclosed in a bundle sheath of supporting sclerenchyma cells. The monocot stem does not have distinct areas of cortex

(a) Cross section of a corn (*Zea mays*) stem shows vascular bundles scattered throughout ground tissue.

(b) Close-up of a vascular bundle. The air space is the site where the first xylem elements were formed and later disintegrated. The entire bundle is enclosed in a bundle sheath of sclerenchyma for additional support.

and pith. The ground tissue in which the vascular tissues are embedded performs the same functions as cortex and pith in herbaceous eudicot stems.

Monocot stems do not possess lateral meristems (vascular cambium and cork cambium) that give rise to secondary growth. Monocots have primary growth only and do not produce wood and bark. Although some treelike monocots (such as palms) attain considerable size, they do so by a modified form of primary growth in which parenchyma cells divide and enlarge. Stems of some monocots (such as bamboo and palm) contain a great deal of sclerenchyma tissue, which makes them hard and woodlike in appearance.

Woody plants have stems with secondary growth

Woody plants undergo secondary growth, an increase in the girth of stems and roots. Secondary growth occurs as a result of the activity of two lateral meristems: vascular cambium and cork cambium. Among flowering plants, only woody eudicots (such as apple, hickory, and maple) have secondary growth. Cone-bearing gymnosperms (such as pine, juniper, and spruce) also have secondary growth.

Cells in the **vascular cambium** divide and produce two conducting and supporting tissues: secondary xylem (wood) to replace primary xylem and secondary phloem (inner bark) to replace primary phloem. Primary xylem and primary phloem are not able to transport materials indefinitely and so are replaced in plants that have extended lifespans.

Cells of the outer lateral meristem, called cork cambium, divide and produce cork cells and cork parenchyma. **Cork cambium** and the tissues it produces are collectively referred to as **periderm** (outer bark), which functions as a replacement for the epidermis (see the last LM in Table 33-4).

Vascular cambium gives rise to secondary xylem and secondary phloem Primary tissues in woody eudicot stems are organized like those in herbaceous eudicot stems, with the vascular cambium forming a thin layer of cells sandwiched between xylem and phloem in the vascular bundles. Once secondary growth begins, the internal structure of a stem changes considerably (FIG. 35-3). Although vascular cambium is not initially a continuous cylinder of cells (because the vascular bundles are separated by pith rays), it becomes continuous when production of secondary tissues begins. This continuity develops because certain parenchyma cells in each pith ray retain the ability to divide. These cells connect to vascular cambium cells in each vascular bundle, forming a complete ring of vascular cambium in cross section.

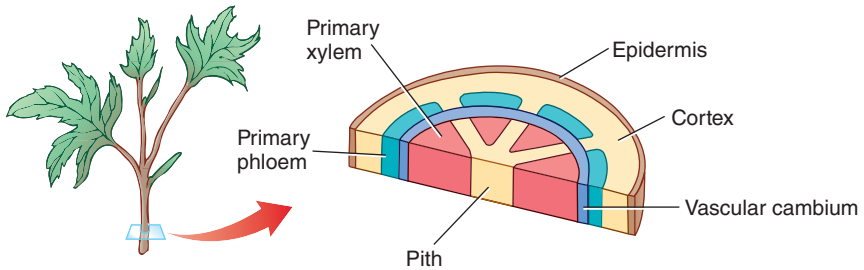
Cells in the vascular cambium divide and produce daughter cells in two directions. The cells formed from the dividing vascular cambium are located either *inside* the ring of vascular cambium (to become secondary xylem, or wood) or *outside* it (to become secondary phloem, or inner bark) (FIG. 35-4). When a cell in the vascular cambium divides tangentially (inward or outward), one daughter cell remains meristematic; that is, it remains part of the vascular cambium. The other cell may divide again several times, but eventually it stops dividing and develops into mature secondary tissue. Thus, vascular cambium is a thin layer of cells sandwiched between the wood and inner bark, the two tissues it produces (FIG. 35-5).

As the stem increases in circumference, the number of cells in the vascular cambium also increases. This increase in cells occurs by an occasional radial division of a vascular cambium cell, at right angles to its normal direction of division. In this case, both daughter cells remain meristematic.

What happens to the original primary tissues of a stem once secondary growth develops? As a stem increases in thickness, the orientation of the original primary tissues changes. For example, secondary xylem and secondary phloem are laid down between the primary xylem and primary phloem within each vascular bundle. Therefore, as vascular cambium forms secondary tissues, the primary xylem and primary phloem in each vascular bundle become separated from each other. The primary tissues located outside the cylinder of secondary growth (i.e., primary phloem, cortex, and epidermis) are subjected to the mechanical pressures produced by secondary growth and are gradually crushed or torn apart and sloughed off.

Secondary tissues replace the primary tissues in function. Secondary xylem conducts water and dissolved minerals from roots to leaves in the woody plant. It contains the same types of cells found in primary xylem: water-conducting tracheids and vessel elements in addition to xylem parenchyma cells and fibers. The arrangement of the different cell types in secondary xylem produces the distinctive wood characteristics of each species.

Secondary phloem conducts dissolved sugar from its place of manufacture or of breakdown of starch to a place of use and storage. The same types of cells found in primary phloem (sieve tube elements, companion cells, phloem parenchyma cells, and fibers) are also found in secondary phloem, although secondary phloem usually has more fibers than primary phloem.



Secondary xylem and secondary phloem transport water, minerals, and sugar vertically throughout the woody plant body. However, materials must also move horizontally (laterally). Lateral movement occurs through *rays*, which are chains of parenchyma cells that radiate from the center of the woody stem or root (see Fig. 35-5). The vascular cambium forms rays, which are often continuous from the secondary xylem to the secondary phloem. Water and dissolved minerals are transported laterally through rays, from the secondary xylem to the secondary phloem. Likewise, rays form pathways for the lateral transport of dissolved sugar, from the secondary phloem to the secondary xylem,

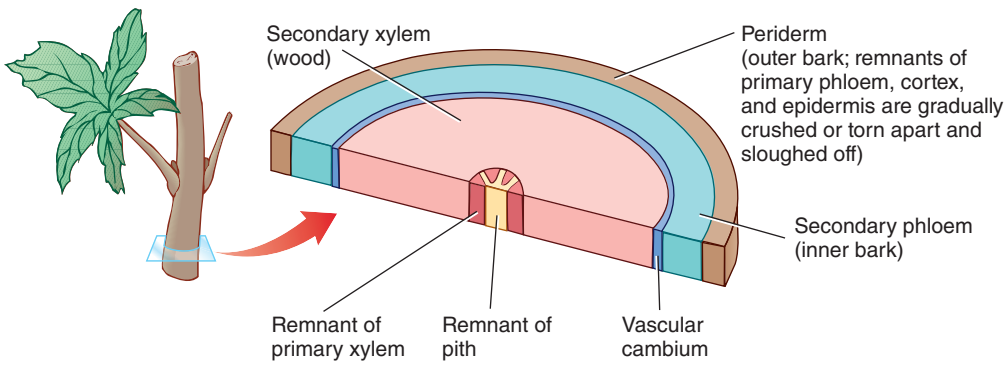
Key Point



The stems of many plants undergo secondary growth to increase in girth.

1 At the onset of secondary growth, vascular cambium arises in the parenchyma between the vascular bundles (i.e., in the pith rays), forming a cylinder of meristematic tissue (*blue circle in cross section*).

2 Vascular cambium begins to divide, forming secondary xylem on the inside and secondary phloem on the outside.

3 A young woody stem. Vascular cambium produces significantly more secondary xylem than secondary phloem.

Figure 35-3 Development of secondary growth

Vascular cambium and the tissues it produces are shown in cross section; cork cambium is not depicted. (The figures change in scale because of space limitations; pith and primary xylem are actually the same size in all three diagrams, but the change in scale makes those tissues appear to shrink in each succeeding diagram.)

CONNECT How is the arrangement of the vascular bundles in a monocot stem unsuited to the functioning of a vascular cambium?

and of waste products to the center, or heart, of the tree (discussed later).

Cork cambium produces periderm Cork cambium, which usually arises from parenchyma cells in the outer cortex, produces *periderm*, the functional replacement for the epidermis. Cork cambium is either a continuous cylinder of dividing cells (similar to vascular cambium) or a series of overlapping arcs of meristematic cells that form from parenchyma cells in successively deeper layers of the cortex and,

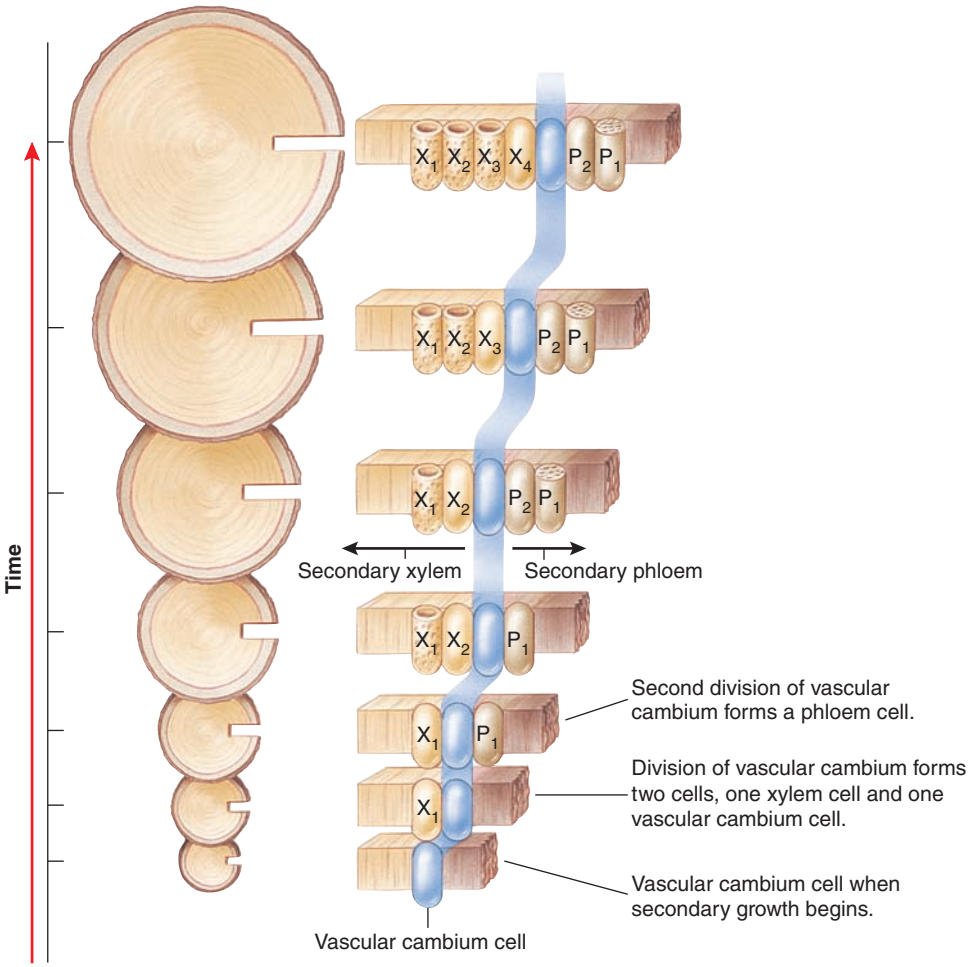

Figure 35-4 Divisions of a vascular cambium cell during a single growing season

To study the figure, start at the bottom and move up. Note that vascular cambium (*blue cell*) divides in two directions, forming secondary xylem (X) to the inside and secondary phloem (P) to the outside. These cells, which are numbered in the order in which they are produced, differentiate into the mature cell types associated with xylem and phloem. As secondary xylem accumulates, vascular cambium "moves" outward, and the woody stem increases in diameter.

eventually, secondary phloem. Variation in cork cambia and their rates of division explain why the outer bark of some tree species is fissured (as in bur oak), rough and shaggy (shagbark hickory), scaly (Norway pine), or smooth and peeling (paper birch).

As is true of vascular cambium, cork cambium divides to form new tissues in two directions: to its inside and its outside. Cork cells, formed to the outside of cork cambium, are dead at maturity and have walls that contain layers of *suberin* and waxes, making them waterproof. These cork cells protect the woody stem against mechanical injury, mild fires, attacks by insects and fungi, temperature extremes, and water loss. To its inside, cork cambium sometimes forms cork parenchyma cells that store water and starch granules. Cork parenchyma is only one to several cells thick, much thinner than the cork cell layer.

Cork cells are impermeable to water and gases, yet the living internal cells of the woody stem require oxygen and must be able to exchange gases with the surrounding atmosphere. As a stem thickens from secondary growth, the epidermis, including stomata that exchange gases for the herbaceous stem, dies. Stomata are replaced by **lenticels**, which permit gas exchange through the periderm (FIG. 35-6).

Woody twigs of deciduous trees bear characteristic features in winter A woody *twig* is that part of a branch produced during the current growing season. Twigs have **buds**, which are embryonic shoots. A **terminal bud** is the embryonic shoot located at the tip of a stem. The dormant (not actively growing) apical meristem of a terminal bud is covered and protected by an outer layer of **bud scales**, which are modified leaves (see Fig. 34-14c). **Axillary buds**, also called *lateral buds*, are located in the axils of a plant's leaves (see Fig. 34-1). An *axil* is the upper angle between a leaf and the stem to which it is attached. When terminal and axillary buds grow, they form branches that bear leaves and/or flowers. The area on a stem where each leaf is attached is called a **node**, and the region between two successive nodes is an **internode**.

To demonstrate certain structural features of the stem, we can use a woody branch of a deciduous tree that has shed its leaves, as shown in FIGURE 35-7. Bud scales cover the terminal bud and protect its delicate apical meristem during dormancy. When the bud resumes growth, the bud scales covering the terminal bud fall off, leaving **bud scale scars** on the stem where they were attached. Because temperate-zone woody plants form terminal buds at the end of each year's growing season, the number of sets of bud scale scars on a twig indicates its age. A **leaf scar** shows where each leaf was attached on the stem; the pattern of leaf scars can be used to determine leaf arrangement on a stem: alternate, opposite, or whorled (see Fig. 34-2b). The vascular (conducting) tissue that extends from the stem out into the leaf forms **bundle scars** within a leaf scar. Axillary buds may be found above the leaf scars. Also, the bark of a woody twig has lenticels, which look like tiny specks on the bark of a twig.

Common terms associated with wood are based on plant structure If you have ever examined different types of lumber, you may have noticed that some trees have wood with two different colors (FIG. 35-8). The functional secondary xylem—the part that conducts water and dissolved

flowering plants, although there is a substantial variation from one species to another. The balsa tree, for example, is a flowering plant whose extremely light, soft wood is used to fashion airplane models.

Woody plants that grow in temperate climates where there is a growing period (during spring and summer) and a dormant period (during winter) exhibit *annual rings*, concentric circles found in cross sections of wood. To determine the age of a woody stem in the temperate zone, simply count the annual rings. In the tropics environmental conditions, particularly seasonal or year-round precipitation patterns, determine the presence or absence of rings, so rings are not a reliable method of determining the ages of most tropical trees.

Examination of annual rings with a magnifying lens reveals no actual "ring," or line, separating one year's growth from the next. The appearance of a ring in cross section is due to differences in cell size and cell wall thickness between secondary xylem formed at the end of the preceding

minerals—is the *sapwood*, a thin layer of younger, lighter-colored wood that is closest to the bark. *Heartwood*, the older wood in the center of the tree, is typically a brownish red. A microscopic examination of heartwood reveals that its vessels and tracheids are plugged with pigments, tannins, gums, resins, and other materials. Therefore, heartwood no longer functions in conduction but instead functions as a storage site for waste products. Because it is denser than sapwood, heartwood provides structural support for trees. Some evidence suggests that heartwood is also more resistant to decay than sapwood.

Almost everyone has heard of hardwood and softwood. Botanically speaking, *hardwood* is the wood of flowering plants, and *softwood* is the wood of conifers (cone-bearing gymnosperms). The wood of pine and other conifers typically lacks fibers (with their thick secondary cell walls) and vessel elements; the conducting cells in gymnosperms are tracheids. These cell differences generally make conifer wood softer than the wood of

year's growth and that formed at the beginning of the following year's growth. In the spring, when water is plentiful, wood formed by vascular cambium has large-diameter conducting cells (tracheids and vessel elements) and few fibers and is appropriately called *springwood* or *early wood* (see Fig. 35-5). As summer progresses and water becomes less plentiful, the wood formed, known as *summerwood* or *late wood*, has narrower conducting cells and many fibers. It is this difference in cell size between the summerwood of one year and the springwood of the following year that gives the appearance of rings.

Tree-ring analysis provides useful scientific information In temperate climates the number of annual rings indicates the age of a tree. The size of each ring varies depending on local weather conditions. Sometimes the variation can be attributed to a single environmental factor, and similar patterns appear in the rings of different species over a large geographic area. For example, years with adequate

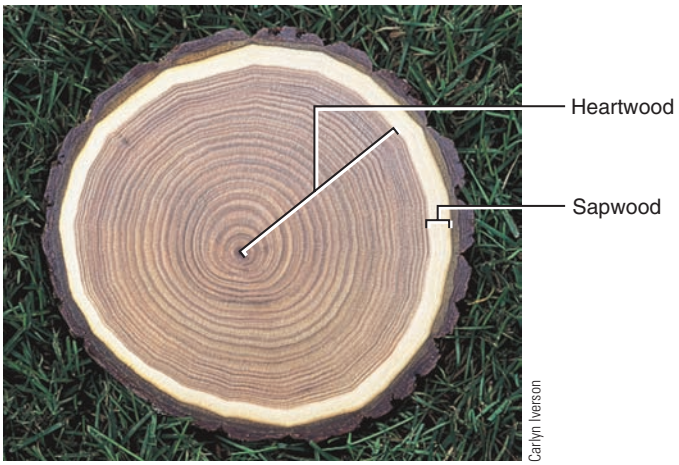

Figure 35-8 Heartwood and sapwood

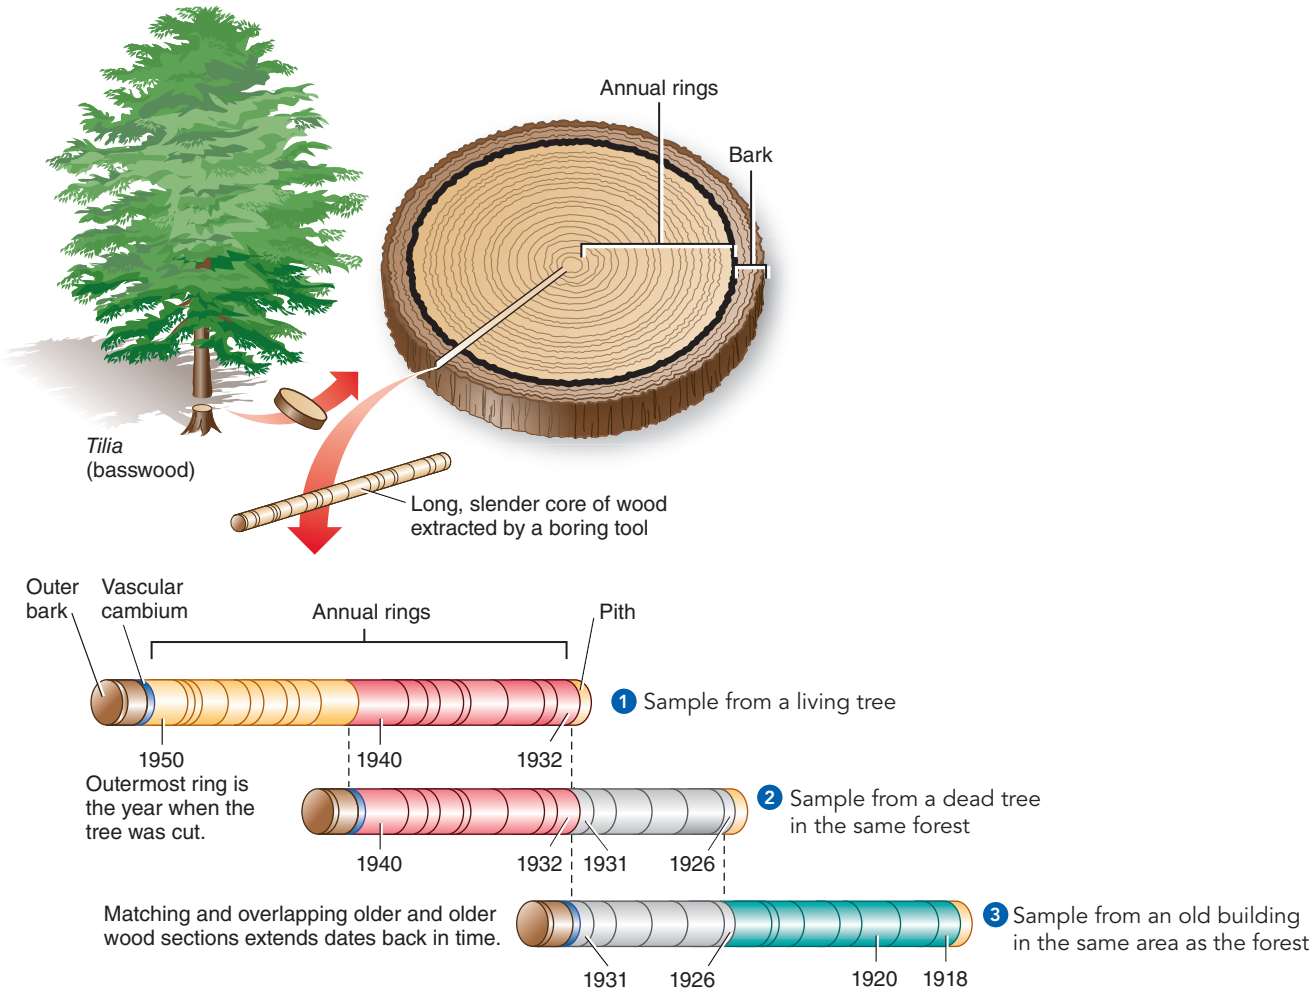
The wood of older trees consists of a dense central heartwood and an outer layer of sapwood. The sapwood is the functioning xylem that conducts water and dissolved minerals. The annual rings in the heartwood are very conspicuous.

precipitation produce wider growth rings, and years of drought produce narrower rings. It is possible to study ring sequences that are several thousand years old by constructing a *master chronology*, a complete sample of rings dating back as far as possible (FIG. 35-9).

Dendrochronology, the study of both visible and microscopic details of tree rings, has been used extensively in several fields. Tree-ring analysis has helped date Native American prehistoric sites in the Southwest. For example, using tree-ring analysis, scientists determined that the Cliff Palace in Mesa Verde National Park dates back to the year 1073. Tree-ring analysis is also useful in ecology (to study changes in a forest community over time), environmental science (to study the effects of air pollution on tree growth), and geology (to date earthquakes and volcanic eruptions).

Climatologists are increasingly using tree-ring data to study past climate patterns. Annual rings of certain tree species that grow at high elevations are sensitive to yearly temperature variations; the rings of these trees are wider in warm years and narrower in cool years. Studying tree rings over long periods helps researchers determine the natural pattern of global temperature fluctuations. This information is particularly important because of concerns about the human influence on global climate.



Although scientists generally agree that Earth has warmed in recent decades, they are not sure how much of the recent warming is the result of human influence rather than natural climate variability. To help answer this vital question, European scientists have been developing a 10,000-year master chronology that will help reconstruct annual temperatures across northern Europe and Asia since the end of the last Ice Age.

Research Method

WHY IS IT USED? By matching the rings of a wood sample of unknown age to the master chronology, investigators can accurately determine the age of the sample. Tree-ring analysis provides useful information in a variety of fields, such as to date prehistoric sites, study past climate patterns, and date major prehistoric earthquakes.

HOW IS IT DONE? A master chronology is developed using progressively older pieces of wood from the same geographic area. A small core of wood is bored out of the trunk of a living tree. The oldest rings (toward the center of the tree) are matched with the youngest rings (toward the outside) of an older tree, perhaps a dead one in the forest. The master chronology is extended back in time by overlapping matching ring sequences of successively older and older sections of wood, even those found in prehistoric dwellings. Currently, the longest master chronology—of bristlecone pines in the western United States—goes back almost 9000 years. Ring matching, once a tedious, painstaking job, is performed by computers today.

35.2 Water Transport

LEARNING OBJECTIVES

4 Describe the pathway of water movement in plants.
5 Define *water potential*.
6 Compare tension–cohesion and root pressure as mechanisms responsible for the rise of water and dissolved minerals in xylem.

Now that we have discussed stem structure and primary and secondary growth, we examine internal transport in the vascular system of the plant (FIG. 35-10). Roots obtain water and dissolved minerals from the soil. Once inside roots, these materials are transported upward to stems, leaves, flowers, fruits, and seeds. Furthermore, sugar molecules are transported from their place of manufacture or of breakdown of starch throughout the plant body, including into the subterranean roots. Water and dissolved minerals are transported from roots to other parts of the plant in xylem, whereas dissolved sugar is *translocated* in phloem.

Xylem transport and phloem translocation do not resemble the movement of materials in animals because in plants nothing *circulates* in a system of vessels. Water and minerals, transported in xylem, travel in one direction only (upward), whereas translocation of dissolved sugar may occur upward or downward in separate phloem cells. In addition, xylem transport and phloem translocation differ from internal circulation in animals because movement in both xylem and phloem is driven largely by natural physical processes rather than by a pumping organ, or heart.

How do materials travel in the continuous system of the plant's vascular tissues? We first examine water and its movement through the plant, and later we discuss the translocation of dissolved sugar.

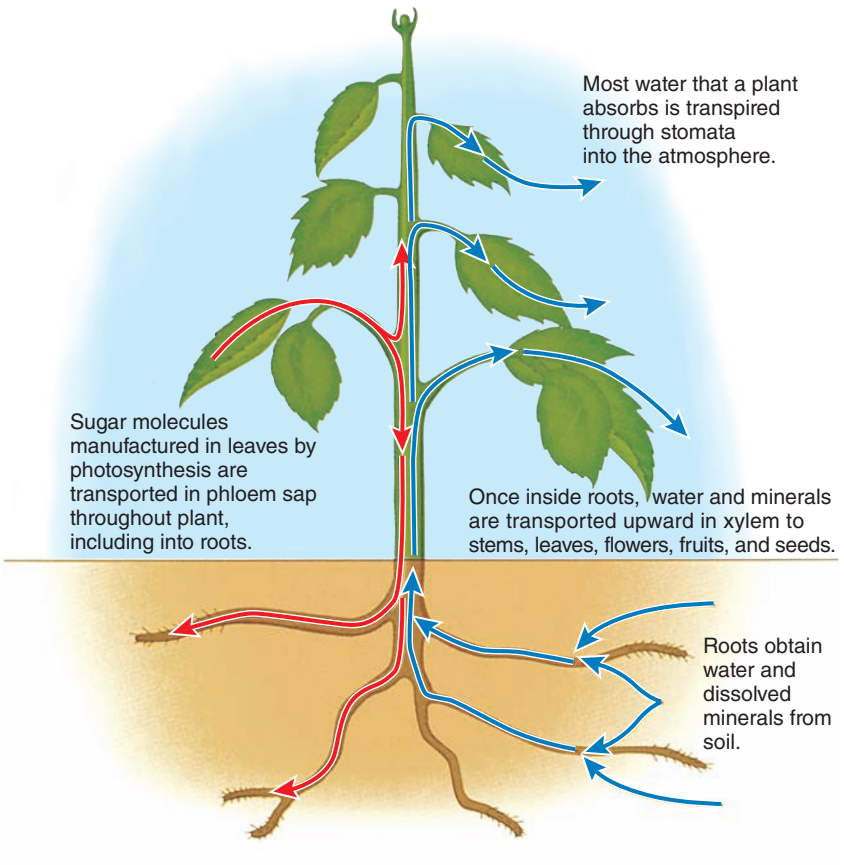

Figure 35-10 Overview of transport in vascular plants
Xylem transport is explained on the *right side* of the figure (start at the bottom and work upward), and phloem transport is on the *left side*.

Water and minerals are transported in xylem

Water initially moves horizontally into roots from the soil, passing through several tissues until it reaches xylem. Once the water moves into the tracheids and vessel elements of root xylem, it travels upward through a continuous network of these hollow, dead cells from root to stem to leaf. Dissolved minerals are carried along passively in the water. The plant does not expend any energy of its own to transport water, which moves as a result of natural physical processes. The transport of xylem sap is the most rapid of any movement of materials in plants (TABLE 35-1).

How does water move to the tops of plants? It is either pushed up from the bottom of the plant or pulled up by the top of the plant. Although plants use both mechanisms, current evidence indicates that most water is transported through xylem by being *pulled* to the top of the plant.

Table 35-1 Xylem and Phloem Transport Rates in Selected Plants

Plant	Maximum Rate in Xylem (cm/min)	Maximum Rate in Phloem (cm/min)
Conifer	2	0.8
Woody eudicot	73	2
Herbaceous eudicot or monocot	100	2.8–11
Herbaceous vine	250	1.2

Note: Xylem and phloem rates are from different plants within each general group and should be used for comparative purposes only.

Water movement can be explained by a difference in water potential

To understand how water moves, it is helpful to introduce **water potential**, which is defined as the **free energy** of water (see Chapter 7). Water potential (Ψ_w), represented by the Greek letter psi, is important in plant physiology because it is a measure of a cell's ability to absorb water by osmosis. (Recall from Chapter 5 and Figure 5-11 that **osmosis** is a special kind of diffusion that involves the net movement of water through a selectively permeable membrane from a region of higher effective concentration of water to a region of lower concentration.) Water potential also provides a measure of water's tendency to evaporate from cells.

The water potential of pure water is conventionally set at 0 megapascal (MPa) because it cannot be measured directly. (A megapascal is a unit of pressure equal to about 10.2 kg/cm^2, or 145.1 $1b/in^2$.) However, botanists can measure differences in the free energy of water molecules in different situations. When solutes dissolve in water, the free energy of water decreases. Solutes induce **hydration**, in which water molecules surround ions and polar molecules, keeping them in solution by preventing them from coming together (see Fig. 2-10). The association of water molecules with hydrated molecules and ions reduces the motion of water molecules, decreasing their free energy. Thus, dissolved solutes lower the water potential to a negative number. Water moves from a region of higher (less negative) water potential to a region of lower (more negative) water potential.

The water potential of the soil varies, depending on how much water it contains. When a soil is extremely dry, its water potential is very low (very negative). When a soil is moister, its water potential is higher, although it still has a negative value because dissolved minerals are present in dilute concentrations (TABLE 35-2).

The water potential in root cells is also negative because of the presence of dissolved solutes. Roots contain more dissolved materials than soil water does, unless the soil is extremely dry. This means that under normal conditions the water potential of the root is more negative than the water potential of the soil. Thus, water moves by osmosis from the soil into the root.

According to the tension–cohesion model, water is pulled up a stem

In 1896, Irish botanist Henry Dixon proposed the tension–cohesion model to explain the ascent of water against the force of gravity. Although initially met with widespread skepticism in the scientific community, this model has withstood the test of time. According to the **tension–cohesion model**, also known as the **transpiration–cohesion model**, water is pulled up the plant as a result of a *tension* produced at the top of the plant (FIG. 35-11). This tension is caused by the evaporative pull of transpiration. Recall from Chapter 34 that **transpiration** is the evaporation of water vapor from plants.

Table 35-2 Representative Water Potential (Ψ_w) Values

Plant Parts and the Nearby Environment	Water Potentials in Megapascals (MPa)
Atmosphere near leaves	−80.0
Leaf interior	−1.5
Stem xylem	−0.7
Root interior	−0.4
Soil water	−0.1

Note: Actual values vary widely, depending on environmental factors such as solute concentration, hydrostatic pressure, and gravity.

Most water loss from transpiration takes place through stomata, the numerous microscopic pores present on leaf and stem surfaces. Water vapor diffuses through the stomata into a boundary layer of quiet air adjacent to the leaf surface. The *boundary layer* is thicker when the wind is calm than when it is gusty; a thicker boundary layer results in a slower rate of transpiration.

The tension extends from leaves, where most transpiration occurs, down the stems and into the roots. It draws water up stem xylem to leaf cells that have lost water as a result of transpiration and pulls water from root xylem into stem xylem. As water is pulled upward, additional water from the soil is drawn into the roots. Thus, the pathway of water movement is as follows:

soil → root tissues (epidermis, cortex, etc.) → root xylem → stem xylem → leaf xylem → leaf mesophyll → atmosphere

This upward pulling of water is possible only as long as there is an unbroken column of water in xylem throughout the plant. Water forms an unbroken column in xylem because water molecules exhibit **cohesion**—that is, they are strongly attracted to one another—due to **hydrogen bonding**. In addition, the **adhesion** of water to the walls of xylem cells, also the result of hydrogen bonding, is an important factor in maintaining an unbroken column of water. Thus, the cohesive and adhesive properties of water enable it to form a continuous column that can be pulled up through the xylem.

The movement of water in xylem by the tension–cohesion mechanism can be explained in terms of water potential. The atmosphere has an extremely negative water potential. For example, air with a relative humidity of 50% has a water potential of −100 MPa; even moist air at a relative humidity of 90% has a negative water potential of −13 MPa. Thus, there is a water potential gradient from the least negative (the soil) up through the plant to the most negative (the atmosphere). This gradient literally pulls the water from the soil up through the plant.

Although the tension–cohesion model was first proposed toward the end of the 19th century, conclusive experimental evidence to support this mechanism was not obtained until the late 1990s and early 2000s. At that time, several research groups made direct measurements of the large negative pressure that exists in xylem, indicating that the water potential gradients in root, stem, and leaf xylem are adequate to explain the observed movement of water.

Is the tension–cohesion model powerful enough to explain the rise of water in the tallest plants? Plant biologists have studied this question for years. For example, a 2004 study of five of the eight tallest trees in the world (all redwoods, or *Sequoia sempervirens*) concluded that the tension produced

Key Point

Transpiration is the driving force of the tension–cohesion model.

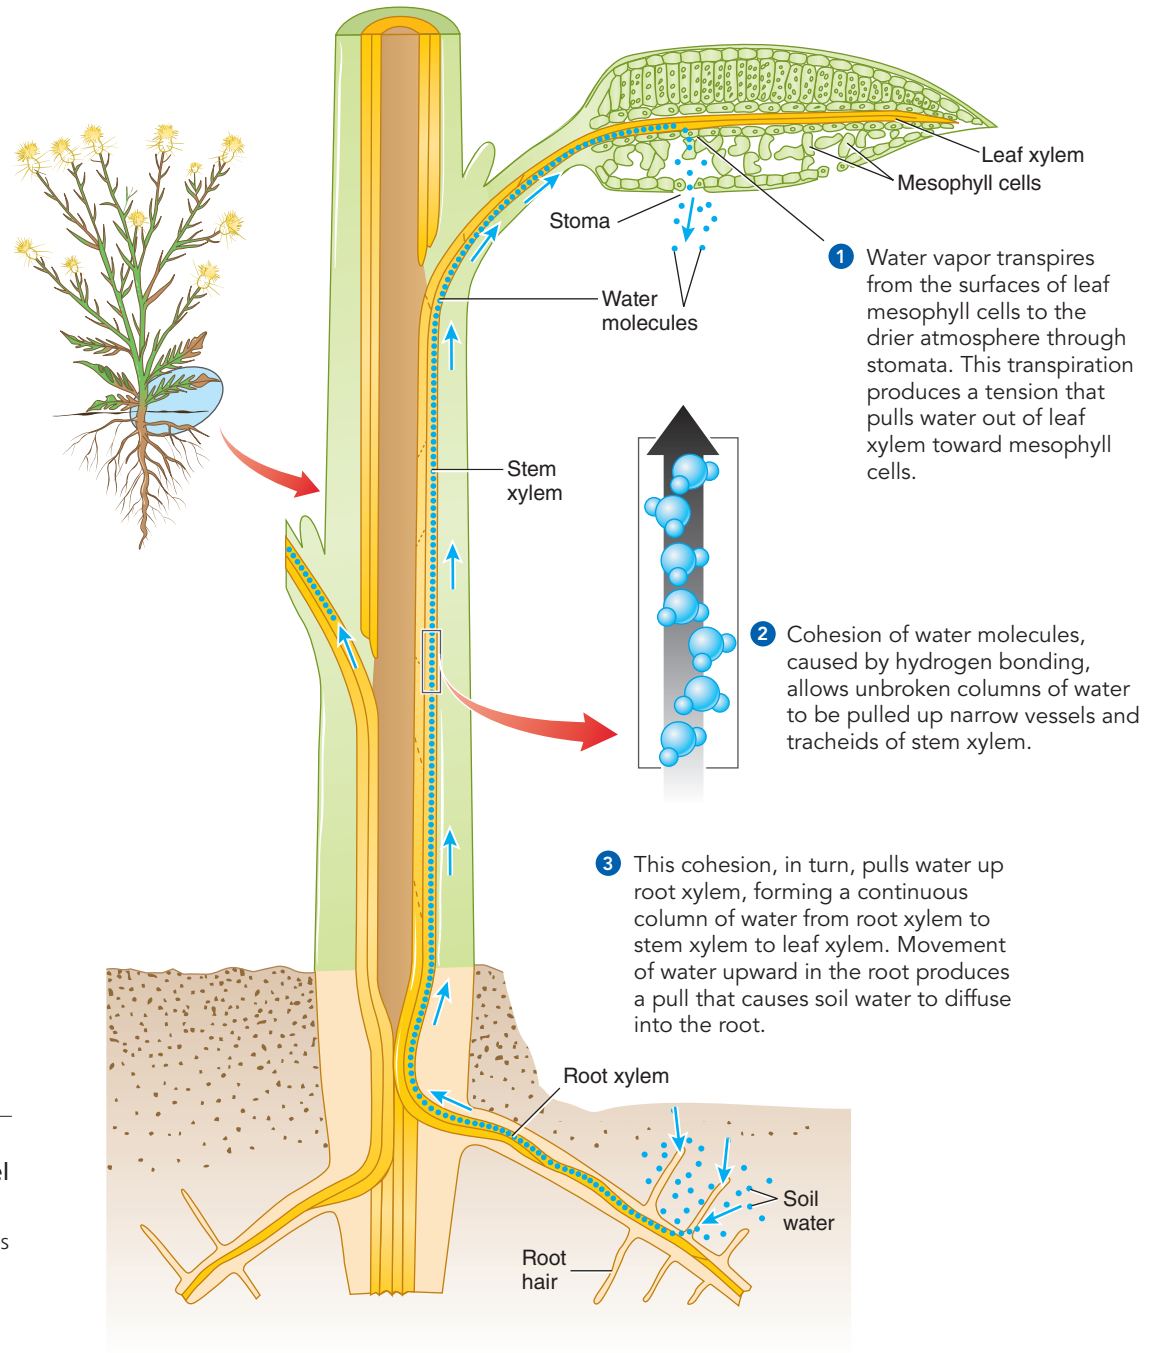

Figure 35-11 The tension–cohesion model

PREDICT What do you think would happen if solutes added to the soil water were to make its water potential more negative than that of the root tissue?

by transpiration is strong enough to pull water upward to a maximum height of 130 m (422 ft). Because the height of the tallest known living tree, a coast redwood in California, measured 115.7 m (379 ft) in 2007, the tension–cohesion model easily accounts for the transport of water. Botanists generally consider the tension–cohesion model to be the dominant mechanism of xylem transport in most plants.

Root pressure pushes water from the root up a stem

In the less important mechanism for water transport, known as **root pressure**, water that moves into roots from the soil is *pushed* up through xylem toward the top of the plant. Root pressure occurs because mineral ions that are actively

absorbed from the soil are pumped into the xylem, decreasing its water potential. This accumulation of ions has an osmotic effect, causing water to move into xylem cells from surrounding root cells. In turn, water moves into roots by osmosis because of the difference in water potential between the soil and root cells. The accumulation of water in root tissues produces a positive pressure (as high as +0.2 MPa) that forces the water up through the root xylem into the shoot.

Guttation, a phenomenon in which liquid water is forced out through special openings in the leaves (see Fig. 34-12), results from root pressure. However, root pressure is not strong enough to explain the rise of water to the tops of tall trees. Root pressure exerts an influence in much smaller plants, particularly in the spring when the soil is moist, but it clearly does not cause water to rise to the tops of the tallest plants. Furthermore, root pressure does not occur to any appreciable extent in summer (when water is often not plentiful in soil), yet water transport is greatest during hot summer days.

CHECKPOINT 35.2

- **CONNECT** How is the movement of water in a plant related to water potential?
- How does the tension–cohesion model explain the rise of water in the tallest trees?

35.3 Translocation of Sugar in Solution

LEARNING OBJECTIVES

7 Describe the pathway of sugar translocation in plants.
8 Discuss the pressure–flow model of sugar translocation in phloem.

The sugar produced during photosynthesis is converted into sucrose (common table sugar), a disaccharide composed of one molecule of glucose and one of fructose (see Fig. 3-8b), before being loaded into phloem and translocated to the rest of the plant. Sucrose is the predominant photosynthetic product carried in phloem. Phloem sap also contains much smaller amounts of other materials, such as amino acids, organic acids, proteins, hormones, and certain minerals (e.g., potassium, chloride, phosphate, and magnesium). Sometimes disease-causing plant viruses are transported throughout the plant in phloem. Translocation of phloem sap is not as rapid as xylem transport (see Table 35-1).

Fluid within phloem tissue moves both upward and downward. Sucrose is translocated in individual sieve tubes from a *source*, an area of excess sugar supply (usually a leaf), to a *sink*, an area of storage (as insoluble starch) or of sugar use, such as roots, apical meristems, fruits, and seeds.

The pressure–flow model explains translocation in phloem

Current experimental evidence supports the **translocation** of dissolved sugar in phloem by the **pressure–flow model**, which was first proposed in 1926 by German scientist Ernst Münch. The pressure–flow model states that solutes (such as dissolved sugars) move in phloem by means of a pressure gradient, that is, a difference in pressure. The pressure gradient exists between the source, where the sugar is loaded into phloem, and the sink, where the sugar is removed from phloem.

At the source, the dissolved sucrose is moved from a leaf's mesophyll cells, where it was manufactured, into the companion cells, which load sucrose into the sieve tube elements of phloem. Sucrose loading occurs by active transport, a process that requires adenosine triphosphate (ATP) (FIG. 35-12). The ATP supplies energy to pump protons (H^+) out of the sieve tube elements, producing a proton gradient that drives the uptake of sugar through specific channels by the **cotransport** of protons back into the sieve tube elements. (Recall the discussion of a cotransport system in Chapter 5.) In the cotransport system involved in phloem loading, sugar is moved from a region of low concentration to a region of high concentration by coupling its transport to the transport of protons down their concentration gradient.

The sugar therefore accumulates in the sieve tube element. The increase in dissolved sugars in the sieve tube element at the source—a concentration that is two to three times as great as in surrounding cells—decreases (makes more negative) the water potential of that cell. As a result, water moves by osmosis from nearby xylem cells into the sieve tubes, increasing the **turgor pressure** (hydrostatic pressure) inside them. Thus, phloem loading at the source occurs as follows:

proton pump moves H^+ out of sieve tube element → sugar is actively transported into sieve tube element → water diffuses from xylem into sieve tube element → turgor pressure increases within sieve tube

At its destination (the sink), sugar is unloaded by various mechanisms, both active and passive, from the sieve tube elements. With the loss of sugar, the water potential in the sieve tube elements at the sink increases (becomes less negative). Therefore, water moves out of the sieve tubes by osmosis and into surrounding cells where the water potential is more negative. Most of this water diffuses back to the xylem to be transported upward. This water movement decreases the turgor pressure inside the sieve tubes at the sink. Thus, phloem unloading at the sink proceeds as follows:

sugar is transported out of sieve tube element → water diffuses out of sieve tube element and into xylem → turgor pressure decreases within sieve tube

Key Point

In phloem, solutes move from sources to sinks. The pressure gradient within the sieve tube causes translocation from the area of higher turgor pressure (the source) to the area of lower turgor pressure (the sink).

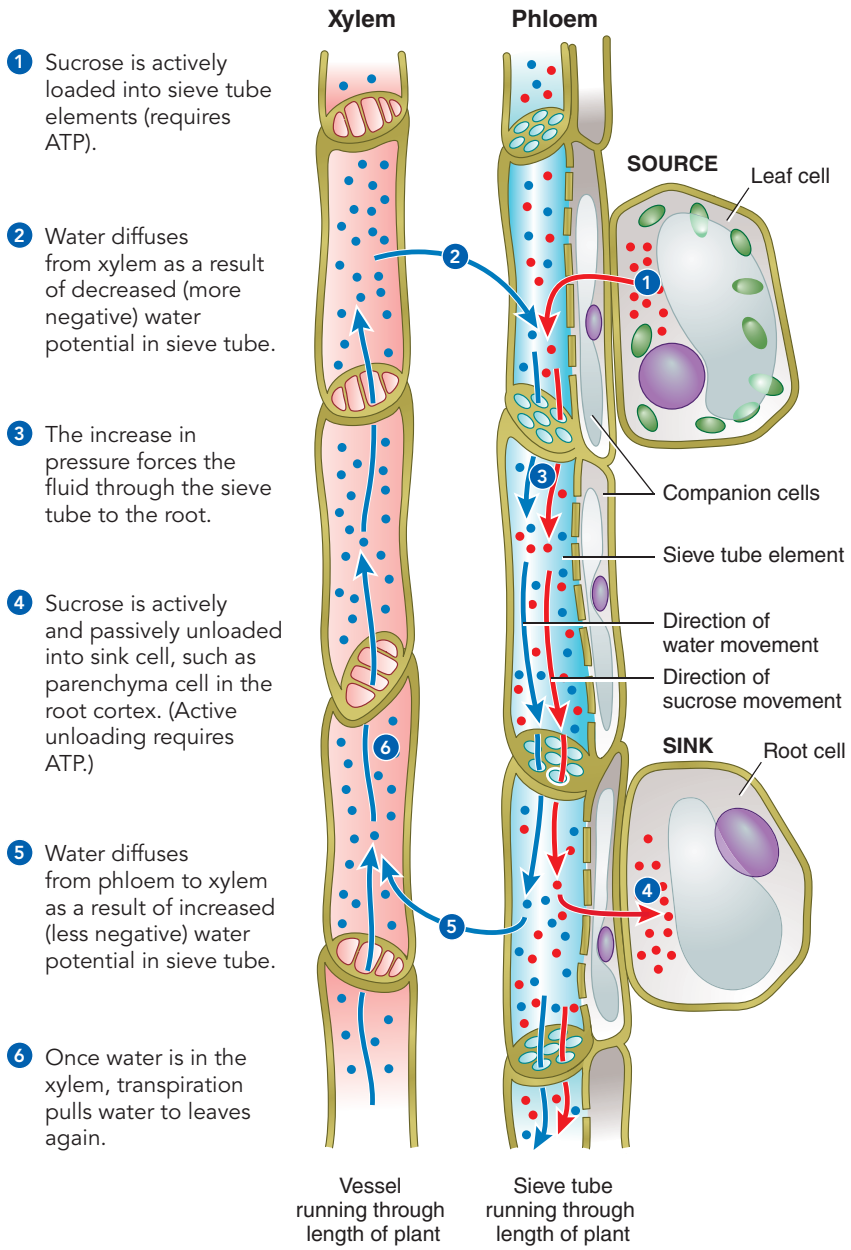

Figure 35-12 The pressure–flow model

PREDICT In what direction would transport occur in the phloem if the source were starch being broken down in a storage root in the spring and the sink were a developing leaf?

The pressure–flow model explains the movement of dissolved sugar in phloem by means of a pressure gradient. The difference in sugar concentrations between the source and the sink causes translocation in phloem as water and dissolved sugar flow along the pressure gradient. This pressure gradient pushes the sugar solution through phloem much as water is forced through a hose.

The actual translocation of dissolved sugar in phloem does not require metabolic energy. However, the loading of sugar at the source and the active unloading of sugar at the sink require energy derived from ATP to move the sugar across cell membranes by active transport.

Although the pressure–flow model adequately explains current data on phloem translocation, much remains to be learned about this complex process. Phloem translocation is difficult to study in plants. Because phloem cells are under pressure, cutting into phloem to observe it releases the pressure and causes the contents of the sieve tube elements (the phloem sap) to exude and mix with the contents of other severed cells that are also unavoidably cut. In the 1950s, scientists developed a unique research tool to avoid contaminating the phloem sap: aphids, which are small insects that insert their mouthparts into phloem sieve tubes for feeding (FIG. 35-13). The pressure in the punctured phloem drives the sugar solution through the aphid's mouthpart into its digestive system. When the aphid's mouthpart is severed from its body by a laser beam, the sugar solution continues to flow through the mouthpart at a rate proportional to the pressure in phloem. This rate can be measured, and the effects on phloem transport of different environmental conditions—varying light intensities, darkness, and mineral deficiencies, for example—can be ascertained.

The identity and proportions of translocated substances can also be determined using severed aphid mouthparts. This technique has verified that in most plant species the sugar sucrose is the primary carbohydrate transported in phloem; however, some species transport other sugars, such as raffinose, or sugar alcohols, such as sorbitol.

CHECKPOINT 35.3

- How does the direction of transport differ in xylem and phloem?
- How does the pressure–flow model explain sugar movement in phloem? Include in your answer the activities at source and sink.

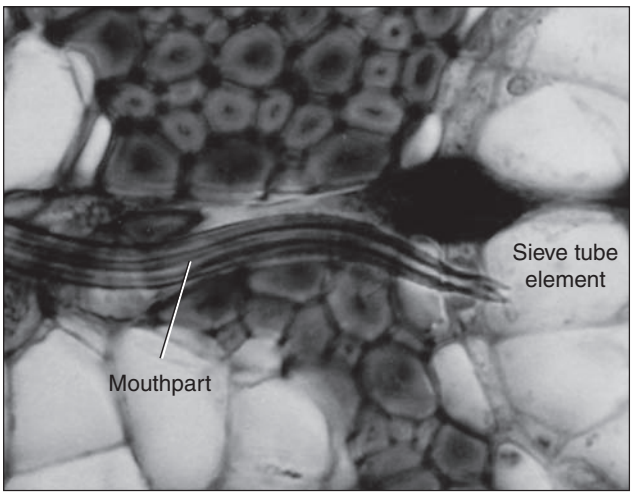
Key Experiment



How can phloem sap be studied without cutting non-phloem cells that would contaminate the sap?

HYPOTHESIS: An aphid mouthpart can be used to penetrate a single sieve tube.

EXPERIMENT: After allowing aphids to insert their mouthparts into phloem of a stem, researchers anesthetized the feeding aphids with CO_2 and used a laser to cut their bodies away from their mouthparts. The mouthparts remained in the phloem and functioned like miniature pipes.

Summary: Focus on Learning Objectives

35.1 Stem Growth and Structure *(page 746)*

1 Sketch cross sections of herbaceous eudicot and monocot stems, and describe the functions of each tissue.

- Herbaceous stems possess an epidermis, vascular tissue, and either ground tissue or cortex and pith. The **epidermis** is a protective layer covered by a water-conserving **cuticle**. **Stomata** permit gas exchange. **Xylem** conducts water and dissolved minerals, and **phloem** conducts dissolved sugar. The **cortex**, **pith**, and ground tissue function primarily for storage.
- All herbaceous stems have the same basic tissues, but their arrangement varies. Herbaceous eudicot stems have the vascular bundles arranged in a circle (in cross section) and have a distinct cortex and pith. Monocot stems have vascular bundles scattered in ground tissue.

2 Name the two lateral meristems and describe the tissues that arise from each.

- **Vascular cambium** is the lateral meristem that produces secondary xylem (wood) and secondary phloem (inner bark).
- **Cork cambium** produces **periderm**, which consists of cork parenchyma and cork cells. Cork cells are the functional replacement for epidermis in a woody stem. Cork parenchyma functions primarily for storage in a woody stem.

3 Outline the transition from primary growth to secondary growth in a woody stem.

- **Secondary growth** (the production of the secondary tissues, wood and bark) occurs in some flowering plants (woody eudicots) and in all cone-bearing gymnosperms. During secondary growth, the vascular cambium divides in two directions to form secondary xylem (to the inside) and secondary phloem (to the outside). The primary xylem and primary phloem in the original vascular bundles become separated as secondary growth proceeds.

35.2 Water Transport *(page 754)*

4 Describe the pathway of water movement in plants.

- Water and dissolved minerals move from the soil into root tissues (epidermis, cortex, etc.). Once in root xylem, water and minerals move upward, from root xylem to stem xylem to leaf xylem. Much of the water entering the leaf exits leaf veins and passes into the atmosphere.

5 Define *water potential*.

- **Water potential (Ψ_w)** is a measure of the **free energy** of water. Pure water has a water potential of 0 megapascal (MPa), whereas water with dissolved solutes has a negative water potential. Water moves from an area of higher (less negative) water potential to an area of lower (more negative) water potential.

6 Compare tension–cohesion and root pressure as mechanisms responsible for the rise of water and dissolved minerals in xylem.

- The **tension–cohesion model** explains the rise of water in even the tallest plants. The evaporative pull of **transpiration** causes tension at the top of the plant. This tension is the result of a water potential gradient that ranges from the slightly negative water potentials in the soil and roots to the very negative water potentials in the atmosphere. As a result of the **cohesion** of water molecules to each other and their **adhesion** to the xylem cell walls, the column of water pulled up through the plant remains unbroken.
- **Root pressure**, caused by the movement of water into roots from the soil as a result of the active absorption of mineral ions from the soil, helps explain the rise of water in smaller plants, particularly when the soil is wet. Root pressure pushes water up through xylem.

35.3 Translocation of Sugar in Solution *(page 757)*

7 Describe the pathway of sugar translocation in plants.

- **Translocation** of dissolved sugar occurs upward or downward in phloem, from a source (an area of excess sugar, usually a leaf) to a sink (an area of storage or of sugar use, such as roots, apical meristems, fruits, and seeds). Sucrose is the predominant sugar translocated in phloem.

8 Discuss the pressure–flow model of sugar translocation in phloem.

- Movement of materials in phloem is explained by the **pressure–flow model**. Companion cells actively load sugar into the sieve tubes at the source; ATP is required for this process. The ATP supplies energy to pump protons out of the sieve tube elements. The proton gradient drives the uptake of sugar by the cotransport of protons back into the sieve tube elements. Sugar therefore accumulates in the sieve tube element, causing the movement of water into the sieve tubes by **osmosis**.
- Companion cells actively (requiring ATP) and passively (not requiring ATP) unload sugar from the sieve tubes at the sink. As a result, water leaves the sieve tubes by osmosis, decreasing the **turgor pressure** (hydrostatic pressure) inside the sieve tubes.
- The flow of materials between source and sink is driven by the turgor pressure gradient produced by water entering phloem at the source and water leaving phloem at the sink.

Test Your Understanding

Know and Comprehend

1. Axillary buds are located (a) at the tips of stems (b) in unusual places, such as on roots (c) in the region between two successive nodes (d) in the upper angle between a leaf and the stem to which it is attached (e) within the loosely arranged cells of lenticels
2. Ground tissue in monocot stems performs the same functions as _____ and _____ in herbaceous eudicot stems. (a) phloem; xylem (b) cork cambium; vascular cambium (c) epidermis; periderm (d) primary xylem; secondary xylem (e) cortex; pith
3. Which of the following statements is *false*? (a) primary growth is an increase in the length of a plant (b) primary growth occurs at both apical and lateral meristems (c) all plants have primary growth (d) herbaceous stems have primary growth, whereas woody stems have both primary and secondary growth (e) buds are embryonic shoots that contain apical meristems
4. The two lateral meristems responsible for secondary growth are (a) phloem and xylem (b) cork cambium and vascular cambium (c) epidermis and periderm (d) primary xylem and secondary xylem (e) cortex and pith
5. Cork cambium and the tissues it produces are collectively called (a) periderm (b) lenticels (c) cortex (d) epidermis (e) wood
6. Each annual ring in a section of wood represents one year's growth of (a) primary xylem (b) secondary xylem (c) primary xylem or secondary xylem in alternate years (d) primary phloem (e) secondary phloem
7. Water potential is (a) the formation of a proton gradient across a cell membrane (b) the transport of a watery solution of sugar in phloem (c) the transport of water in both xylem and phloem (d) the removal of sucrose at the sink, causing water to move out of the sieve tubes (e) the free energy of water in a particular situation
8. Which of the following is a mechanism of water movement in xylem that is responsible for guttation? (a) pressure–flow (b) tension–cohesion (c) root pressure (d) active transport of potassium ions into guard cells (e) transpiration
9. Which of the following is a mechanism of water movement in xylem that combines the evaporative pull of transpiration with the cohesive and adhesive properties of water? (a) pressure–flow (b) tension–cohesion (c) root pressure (d) active transport of potassium ions into guard cells (e) guttation
10. Which of the following is a mechanism of phloem transport in which dissolved sugar is moved by means of a pressure gradient that exists between the source and the sink? (a) pressure–flow (b) tension–cohesion (c) root pressure (d) active transport of potassium ions into guard cells (e) guttation
11. How does increasing solute concentration affect water potential? (a) water potential becomes more positive (b) water potential becomes more negative (c) water potential becomes more positive under certain conditions and more negative under other conditions (d) water potential is not affected by solute concentration (e) water potential is always zero when solutes are dissolved in water

Apply and Analyze

12. **VISUALIZE** Sketch side by side two daughter cells formed after mitosis of a meristematic cell in the vascular cambium of a eudicot stem. Label the cell formed toward the interior of the stem a meristematic cell. Should the daughter cell formed toward the outside be labeled primary xylem, primary phloem, secondary xylem, or secondary phloem?

Evaluate and Synthesize

13. When a strip of bark is peeled off a tree branch, what tissues are usually removed?
14. Could a tree grow to a height of 150 m (488 ft)? Why or why not?
15. **EVOLUTION LINK** Like stems in general, some vines are herbaceous and others are woody. Tropical rain forests have a greater diversity of vines than in any other environment on Earth, and most of these vines are woody. Develop a hypothesis to explain why natural selection has favored the evolution of more species of woody vines (as opposed to herbaceous vines) in tropical rain forests.
16. **INTERPRET DATA** A plant cell with a water potential $\Psi_w = -1.5$ MPa is adjacent to a second cell with $\Psi_w = -1.8$ MPa. Will water flow by osmosis from one cell to the other? If so, in which direction?

36 Roots and Mineral Nutrition

KEY CONCEPTS

36.1 Root structure is related to function. Primary tissues (epidermis, cortex, endodermis, pericycle, xylem, and phloem) of roots develop from root apical meristems. Secondary tissues (wood and bark) of woody roots develop from lateral meristems.

36.2 Roots associate and interact with many organisms, including soil bacteria and fungi.

36.3 Soil, the layer of Earth's crust that has been modified by contact with weather, wind, water, and organisms, contains most of the essential elements required by plants.

PHOTO: Storage roots. Cassava (*Manihot esculenta*) plants have been dug up to show the growth habit of the storage roots. Cassava roots are an important staple crop in the tropics. Some cassava roots contain a poison (prussic acid), which is destroyed during cooking. Inga Spence/Alamy Stock Photo

Branching underground root systems are often more extensive than a plant's aerial parts. The roots of a corn plant, for example, may grow to a depth of 2.5 m (about 8 ft) and spread outward 1.2 m (4 ft) from the stem. Desert-dwelling tamarisk (*Tamarix*) trees reportedly have roots that grow to a depth of 50 m (163 ft) to tap underground water. The extent of a plant's root depth and spread varies considerably among different species and even among different individuals in the same species.

Because roots are usually underground and out of sight, people do not always appreciate the important functions they perform. First, as anyone who has ever pulled weeds can attest, roots anchor a plant securely in the soil. A plant needs a solid foundation from which to grow. Firm anchorage is essential to a plant's survival so that the stem remains upright, enabling leaves to absorb sunlight effectively. Second, roots absorb water and dissolved minerals (inorganic nutrients) such as nitrates, phosphates, and sulfates, which are necessary for synthesizing important organic molecules. These dissolved minerals are then transported throughout the plant in the xylem.

Many roots perform the function of storage. Carrots, sweet potatoes, cassava, and other root crops are important sources of human food (see photograph). Surplus sugars produced in the leaves by photosynthesis are transported in the phloem to the roots for food storage (usually as starch or sucrose) until needed. Other plants, particularly those living in arid regions, possess storage roots adapted to store water.

In certain species roots are modified for functions other than anchorage, absorption, conduction, and storage. Roots specialized to perform uncommon functions are discussed later in the chapter.

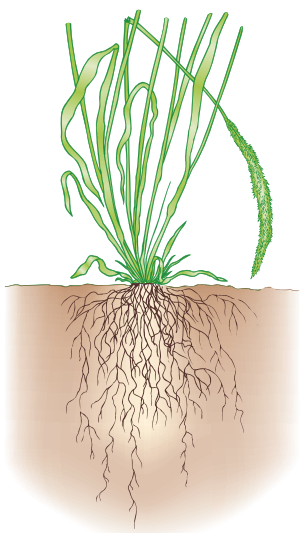
36.1 Root Structure and Function



LEARNING OBJECTIVES

1. Distinguish between taproot and fibrous root systems.
2. Compare cross sections of a primary eudicot root and a monocot root, and describe the functions of each tissue.
3. Trace the pathway of water and mineral ions from the soil through the various root tissues and distinguish between the symplast and apoplast.
4. Discuss the structure of roots with secondary growth.
5. Describe at least three roots that are modified to perform uncommon functions.

Two types of root systems, a taproot system and a fibrous root system, occur in plants (FIG. 36-1). A **taproot system** consists of one main root that formed from the seedling's enlarging **radicle**, or embryonic root. Many lateral roots of various sizes branch out of a taproot. Taproots are characteristic of many eudicots and gymnosperms. A dandelion is a good example of a common herbaceous plant with a taproot system. A few trees, such as hickory, retain their taproots, which become quite massive as the plants age. Most trees, however, have taproots when young and later develop large, shallow, lateral roots from which other roots branch off and grow downward.

(a) A taproot system develops from the embryonic root in the seed.

(b) The roots of a fibrous root system are adventitious and develop from stem tissue.

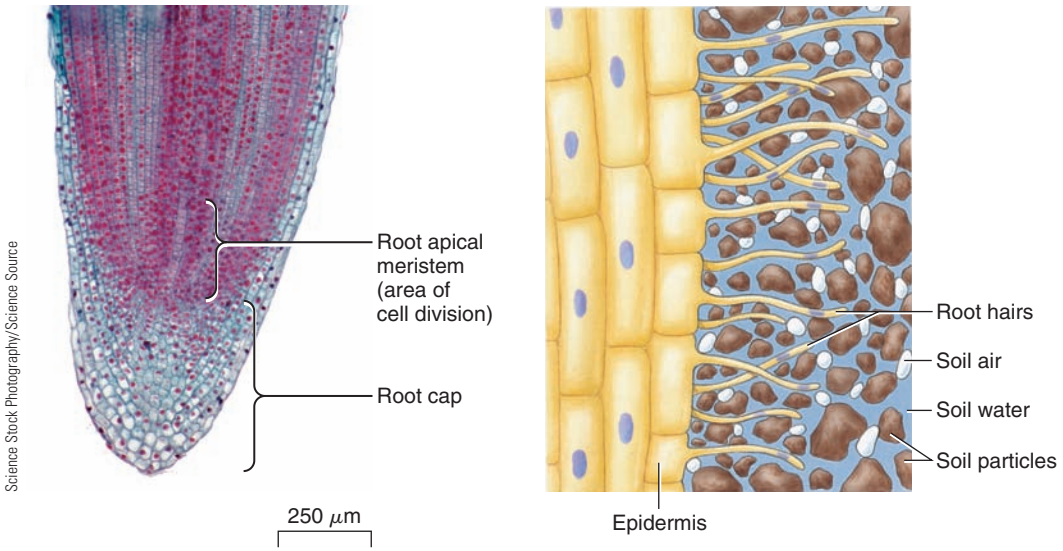
Figure 36-1 Root systems

A **fibrous root system** has several to many roots of similar size developing from the end of the stem, with lateral roots branching off these roots. Fibrous root systems form in plants that have a short-lived embryonic root. The roots originate first from the base of the embryonic root and later from stem tissue. The main roots of a fibrous root system do not arise from pre-existing roots but from the stem; such roots are called **adventitious** roots. Adventitious organs occur in an unusual location, such as roots that develop on a stem or buds that develop on roots. Onions, crabgrass, and other monocots have fibrous root systems.

Taproot and fibrous root systems are adapted to obtain water in different sections of the soil. Taproot systems often extend down into the soil to obtain water located deep underground, whereas fibrous root systems, which are located relatively close to the soil surface, are adapted to obtain rainwater from a larger area as it drains into the soil.

Roots have root caps and root hairs

Because of the need to adapt to the soil environment instead of the atmospheric environment, roots have several structures, such as root caps and root hairs, that shoots lack. Although stems and leaves have various types of hairs, they are distinct from root hairs in structure and function.



Each root tip is covered by a **root cap**, a protective, thimblelike layer many cells thick that covers the delicate root **apical meristem** (FIG. 36-2a; also see Fig. 33-6). As the root grows, pushing its way through the soil, cells of the root cap are sloughed off by the frictional resistance of the soil particles and replaced by new cells formed by the root apical meristem. The root cap cells secrete lubricating polysaccharides that reduce friction as the root passes through the soil. The root cap also appears to be involved in orienting the root so that it grows downward (see discussion of gravitropism in Chapter 38). When a root cap is removed, the root apical meristem grows a new cap. However, until the root cap has regenerated, the root grows randomly rather than in the direction of gravity.

Root hairs are short-lived tubular extensions of epidermal cells located just behind the growing root tip. Root hairs continually form in the area of cell maturation closest to the root tip to replace those that are dying off at the more mature end of the root-hair zone (FIG. 36-2b; also see Fig. 33-6). Each root hair is short (typically less than 1 cm, or 0.4 in., in length), but they are quite numerous. Root hairs greatly increase the absorptive capacity of roots by increasing their surface area in contact with moist soil. Soil particles are coated with a microscopically thin layer of water in which minerals are dissolved. The root hairs establish an intimate contact with soil particles, which allows efficient absorption of water and minerals. They also modify the composition of the soil by exuding a diverse array of organic molecules.

Scientists are actively studying the control of root hair development. Through investigations using the model angiosperm *Arabidopsis thaliana*, it has been learned that the spatial arrangement of root hairs in the root epidermis is a consequence of complex interactions between cells that form root hairs and adjacent cells that do not. Many of the genes involved

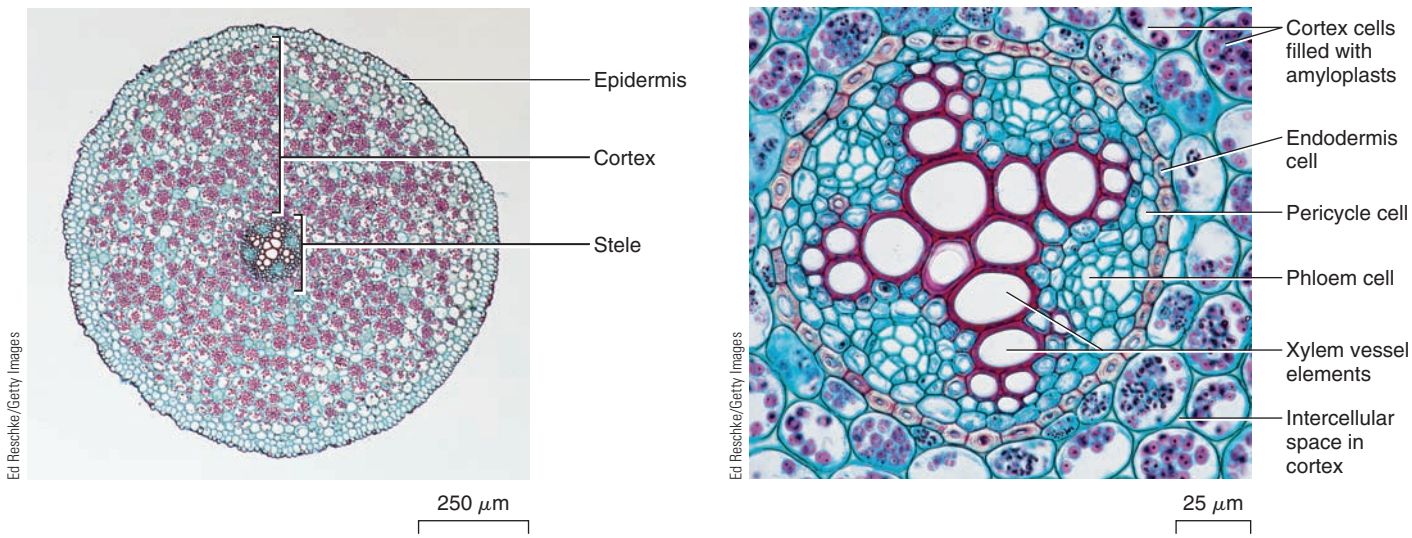

Figure 36-2 Structures unique to roots

code for **transcription factors**. (You may recall from Chapter 14 that transcription factors are DNA-binding proteins that regulate the synthesis of RNA from a DNA template.) Some of these genes have been shown to have an ancient origin with evolutionary significance. Researchers have demonstrated that two genes that code for transcription factors involved in the control of root hair formation in the sporophyte stage of *Arabidopsis* are essentially the same as two genes that control rhizoid formation in the gametophyte stage of *Physcomitrella patens*, the first moss to have its genome sequenced (see Fig. 27-11). Mosses such as *Physcomitrella* represent an ancient lineage of land plants thought to have diverged from the line leading to vascular plants about 420 million years ago. It therefore appears that these genes were conserved during the evolution from a dominant gametophyte in mosses to a dominant sporophyte in flowering plants.

The arrangement of vascular tissues distinguishes the roots of herbaceous eudicots and monocots

Although considerable variation exists in herbaceous eudicot and monocot roots, they all have an outer protective covering (epidermis), a cortex for storage of starch and other organic molecules, and vascular tissues for conduction. Let us first consider the structure of herbaceous eudicot roots.

In most herbaceous eudicot roots, the central core of vascular tissue lacks pith The buttercup root is a representative eudicot root with primary growth (FIG. 36-3). Like other parts of this herbaceous eudicot, a single layer of

Key Point

The symplast pathway (*blue*) consists of living cells interconnected by plasmodesmata. The apoplast pathway (*red*) uses cell walls and intercellular spaces.

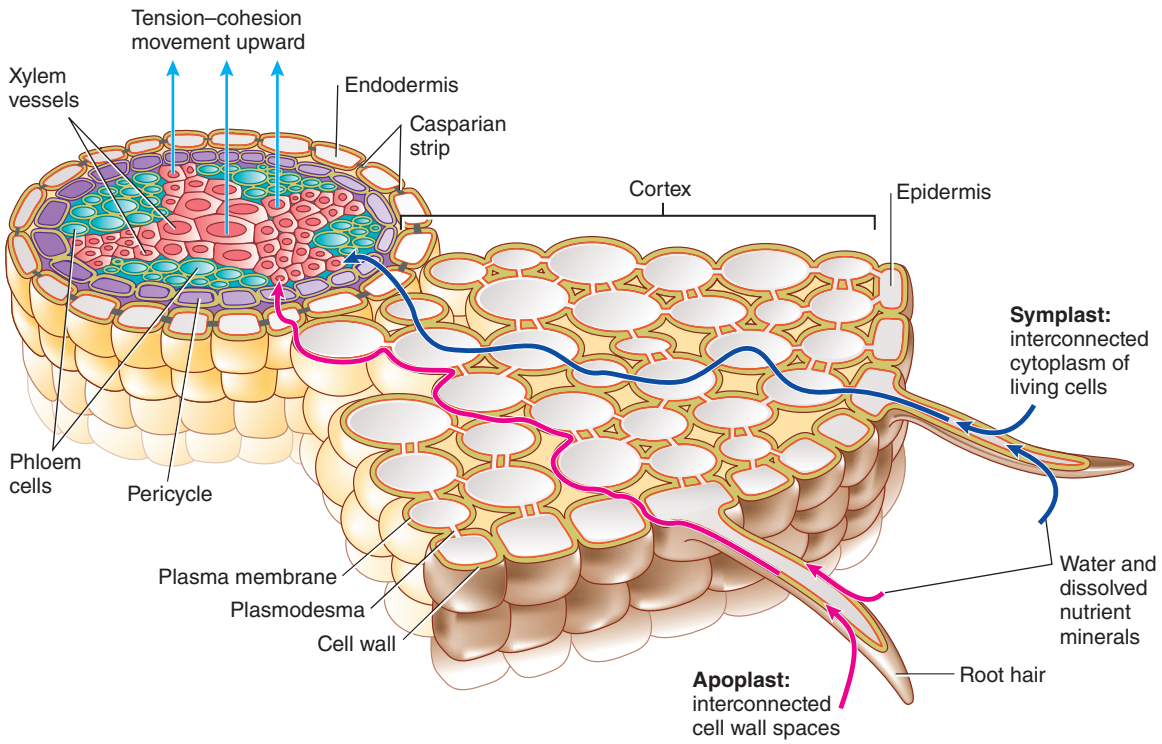

Figure 36-4 Pathways of water and dissolved minerals in the root

Water and dissolved minerals travel from cell to cell along the interconnected porous cell walls (the apoplast) or from one cell's cytoplasm to another through plasmodesmata (the symplast). On reaching the endodermis, water and minerals can move into the root's center only if they pass through a plasma membrane and enter the cytoplasm of an endodermal cell.

PREDICT Would you expect to find minerals not needed by the plant in the apoplast? in the symplast? Explain your answer.

protective tissue, the **epidermis**, covers its roots. The root hairs are a modification of the root epidermis that enables it to absorb more water from the soil. The root epidermis does not secrete a thick, waxy cuticle in the region of root hairs because this layer would impede the absorption of water from the soil. Both the lack of a cuticle and the presence of root hairs increase absorption.

Beginning with the root hairs, most of the water that enters the root moves along the cell walls rather than enters the cells. A major component of cell walls is cellulose, which absorbs water as a sponge does. An example of the absorptive properties of cellulose is found in cotton balls, which are almost pure cellulose.

The root **cortex**, which is made up primarily of loosely packed **parenchyma** cells, composes the bulk of a herbaceous eudicot root. Roots usually lack supporting **collenchyma** cells, probably because the soil supports the root, although roots as they age may develop some **sclerenchyma** (another supporting tissue; see Chapter 33). The primary function of the root cortex is storage. A microscopic examination of the parenchyma cells that form the cortex often reveals numerous amyloplasts (see Figs. 36-3b and 3-9a), which store starch. Starch, an insoluble carbohydrate composed of glucose subunits, is the most common form of stored energy in plants. When used at a later time, these reserves provide energy for such activities as growth and cell replacement following an injury.

The large intercellular (between-cell) spaces, a common feature of the root cortex, provide a pathway for water uptake and allow for aeration of the root. The oxygen that root cells need for aerobic respiration diffuses from air spaces in the soil into the intercellular spaces of the cortex and from there into the cells of the root.

The water and dissolved minerals that enter the root cortex from the epidermis move in solution along two pathways: the symplast and the apoplast (FIG. 36-4). The **symplast** is the continuum of living cytoplasm, which is connected from one cell to the next by cytoplasmic bridges called **plasmodesmata** (see Fig. 5-24). Some dissolved mineral ions move from the epidermis through the cortex via the symplast. The **apoplast** consists of the interconnected porous cell walls of a plant along which water and mineral ions move freely. The water and mineral ions can diffuse across the cortex without ever crossing a plasma membrane to enter a living cell. Together the symplast and apoplast make up the entire plant body.

Key Point

The endodermis regulates the kinds of minerals that are absorbed from the soil and conducted to the rest of the plant body.

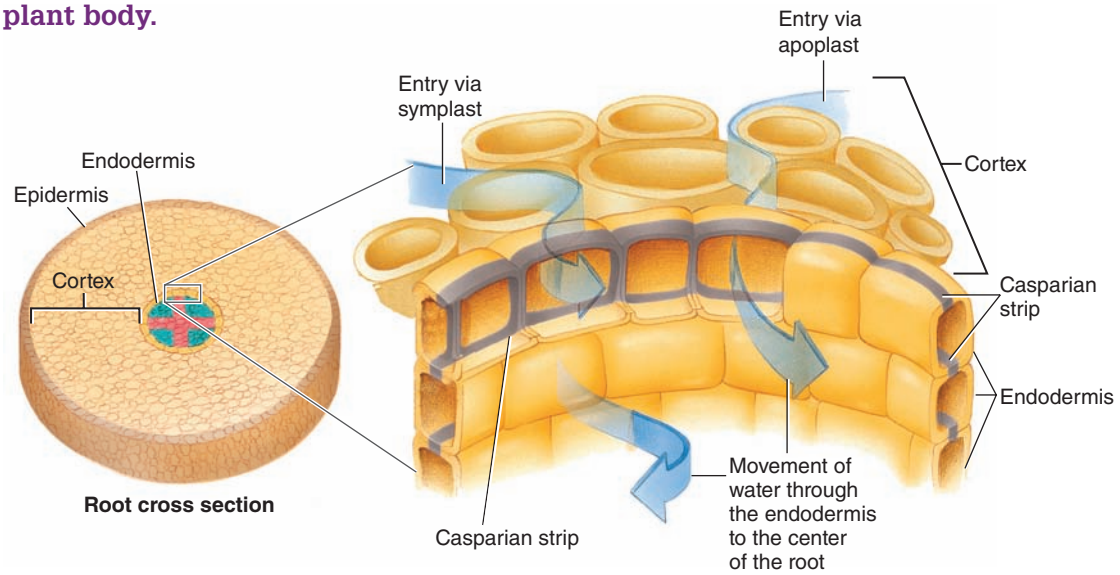

Figure 36-5 Endodermis and mineral uptake

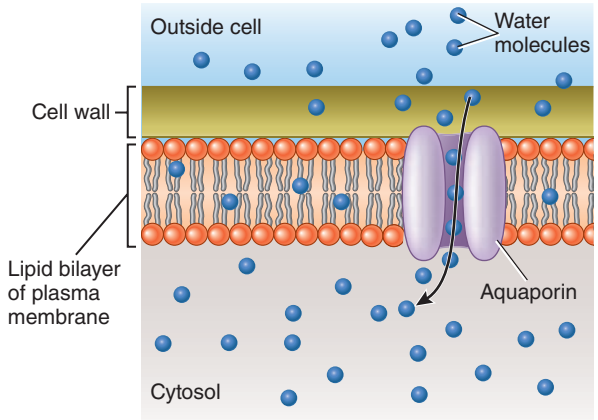
Note the Casparian strip around the radial and transverse walls that prevents water and dissolved minerals from passing into the stele along endodermal cell walls. To reach the vascular tissues, water and dissolved minerals must pass through the plasma membranes of endodermal cells.

CONNECT Does the entry of water from the apoplast into the endodermal cells require a direct or indirect input of metabolic energy? Explain your answer.

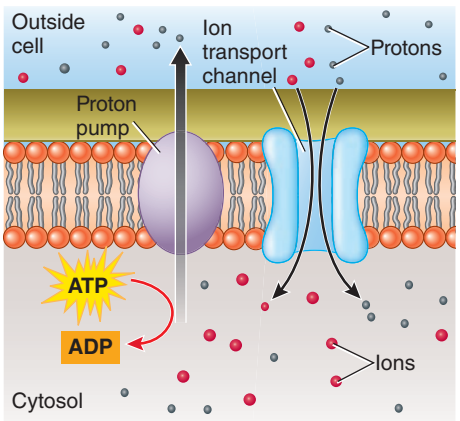
The inner layer of the cortex, the **endodermis**, regulates the movement of water and minerals that enter the xylem in the root's center. Structurally, the endodermis differs from the rest of the cortex. Endodermal cells fit snugly against one another, and each has a special bandlike region, called a **Casparian strip** (FIG. 36-5), on its radial (side) and transverse (upper and lower) walls. Casparian strips contain *suberin*, a fatty material that is waterproof. (Recall from Chapter 33 that suberin is also the waterproof material in cork cell walls.)

Until the endodermis is reached, most of the water and dissolved minerals have traveled along the apoplast and therefore have not passed through a plasma membrane or entered the cytoplasm of a root cell. However, the waterproof Casparian strip on the radial and transverse walls of the endodermal cells prevents water and minerals from continuing to move passively along the cell walls. For substances to pass farther into the root interior, they must move from the cell walls into the cytoplasm of the endodermal cells. Water enters by osmosis, both directly across the lipid bilayer of the endodermal plasma membrane and through **aquaporins**, integral membrane proteins that facilitate the rapid transport of water across the membrane (FIG. 36-6a). As in water movement across the lipid bilayer, water moves through aquaporins only along the osmotic gradient, from a region of higher effective water concentration to a region of lower water concentration. The key role of aquaporins in the uptake of water by root cells is currently under active study.



Minerals enter endodermal cells by passing through carrier proteins in their plasma membranes. In **carrier-mediated active transport**, the mineral ions are pumped *against* their concentration gradient—that is, from an area of *low* concentration of that mineral in the soil solution to an area of *high* concentration in the plant's cells (FIG. 36-6b). One of many reasons root cells require sugar and oxygen for aerobic respiration is that this active transport requires the expenditure of energy, usually in the form of ATP. From the endodermis, water and mineral ions enter the root xylem (botanists do not yet know precisely how this is done) and are conducted to the rest of the plant.

At the center of a eudicot primary root is the **stele**, or **vascular cylinder**, a central cylinder of vascular tissues. The outermost layer of the stele is the **pericycle**, which is just inside the endodermis. The pericycle consists of a single layer of parenchyma cells that give rise to multicellular *lateral roots*, also called branch roots (FIG. 36-7). Lateral roots originate when cells in a portion of the pericycle start dividing. As it grows, the lateral root pushes through several layers of root tissue (endodermis, cortex, and epidermis) before entering the soil. Each lateral root has all the structures and features—root cap, root hairs, epidermis, cortex, endodermis, pericycle, xylem, and phloem—of the larger root from which it emerges. In addition to producing lateral roots, the pericycle is involved in forming the lateral meristems that produce secondary growth in woody roots (discussed later in the chapter).



Xylem, the centermost tissue of the stele, often has two, three, four, or more extensions, or "xylem arms" (see Fig. 36-3b). **Phloem** is located in patches between the xylem arms. The xylem and phloem of the root have the same functions and kinds of cells as in the rest of the plant: water and dissolved minerals are conducted in **tracheids** and **vessel elements** of xylem, and dissolved sugar (sucrose) is conducted in **sieve tube elements** of phloem.

(a) Movement of water. Water crosses membranes by diffusion through the lipid layer (*left*) and, more rapidly, through aquaporins (*right*).

(b) Movement of mineral ions by carrier-mediated active transport. The lipid bilayer of plant membranes is impermeable to mineral ions, which can only pass through ion transport channels. The hydrolysis of ATP pumps protons outside the cell, forming an energy-charged proton gradient. Ion transport channels allow mineral ions to enter the cell with protons.

Figure 36-6 Transport of water and minerals across plant membranes

After passing through the endodermal cells, water enters the root xylem, often at one of the xylem arms. Up to this point, the pathway of water has been horizontal from the soil into the center of the root:

root hair/epidermis → cortex → endodermis → pericycle → root xylem

Once water enters the xylem, it is transported upward through root xylem into stem xylem and from there to the rest of the plant.

One direction of phloem conduction is from the leaves, where sugar is made by photosynthesis, to the root, where sugar is used for the growth and maintenance of root tissues or stored,

Figure 36-7 LM of a lateral root
Lateral roots originate at the pericycle.

usually as starch. Another direction of phloem conduction is from the root, where sugar is stored as starch, to other parts of the plant, where sugar is used for growth and maintenance of tissues.

The *vascular cambium*, which gives rise to secondary tissues in woody plants, is sandwiched between the xylem and phloem. Because it has an inner core of vascular tissue, the primary eudicot root lacks **pith**, a ground tissue found in the centers of many stems and roots.

Xylem does not form the central tissue in some monocot roots Monocot roots vary considerably in internal structure compared with eudicot roots. The layers found in some monocot roots, starting from the outside, are epidermis, cortex, endodermis, and pericycle (FIG. 36-8). Unlike the xylem in herbaceous eudicot roots, the xylem in many monocot roots does not form a solid cylinder in the center. Instead, the phloem and xylem are in separate, alternating bundles arranged around the central pith, which consists of parenchyma cells.

Because virtually no monocots have secondary growth, no vascular cambium exists in monocot roots. Despite their lack of secondary growth, long-lived monocots, such as palms, may have thickened roots produced by a modified form of primary growth in which parenchyma cells in the cortex divide and enlarge.

Woody plants have roots with secondary growth

Plants that produce stems with secondary growth also produce roots with secondary growth. These plants—gymnosperms and woody eudicots—have primary growth at

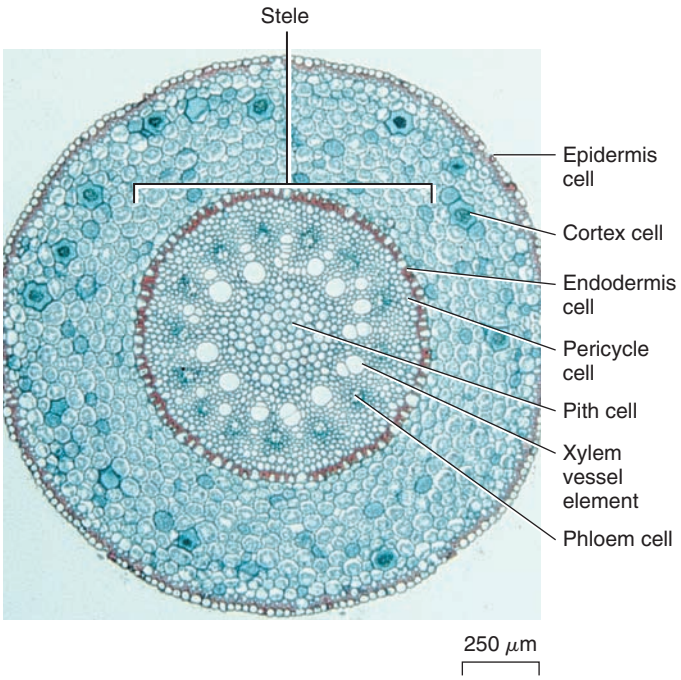

Figure 36-8 LM of a cross section of a monocot root
Shown is a greenbrier (*Smilax*) root. As in herbaceous eudicot roots, the cortex of a monocot root is extensive.

apical meristems and secondary growth at lateral meristems. The production of secondary tissues occurs some distance back from the root tips and results from the activity of the same two lateral meristems found in woody stems: the vascular cambium and the cork cambium. Major roots of trees are often massive and have both wood and bark. In temperate climates the wood of both roots and stems exhibits annual rings in cross section.

Before secondary growth starts in a root, the **vascular cambium** is sandwiched between the primary xylem and the primary phloem (FIG. 36-9). At the onset of secondary growth, the vascular cambium extends out to the pericycle, which develops into vascular cambium opposite the xylem arms. As a result, the pericycle links the separate sections of vascular cambium so that the vascular cambium becomes a continuous, noncircular loop of cells in cross section. As the vascular cambium divides to produce secondary tissues, it eventually forms a cylinder of vascular cambium that continues to divide, producing secondary xylem (wood) to the inside and secondary phloem (inner bark) to the outside. The root increases in girth (thickness), and the vascular cambium continues to move outward.

The epidermis, cortex, endodermis, and primary phloem are gradually torn apart as the root increases in girth. The root epidermis is replaced by **periderm**, composed of cork cells and cork parenchyma, both produced by the **cork cambium** (the last figure in Table 33-4 shows an LM of periderm). The cork cambium in the root initially arises from regions in the pericycle.

Some roots are specialized for unusual functions

Adventitious roots often arise from the nodes of stems. Many aerial adventitious roots are adapted for functions other than anchorage, absorption, conduction, or storage. **Prop roots** are adventitious roots that develop from branches or a vertical stem and grow downward into the soil to help support the plant in an upright position (FIG. 36-10a). Prop roots are more common in monocots than in eudicots. Corn and sorghum, both monocots, are herbaceous plants that produce prop roots. Many tropical and subtropical eudicot trees, such as red mangrove, also produce prop roots.

The roots of many tropical rainforest trees are shallow and concentrated near the surface in a mat only a few centimeters (an inch or so) thick. The root mat catches and absorbs almost all minerals released from leaves by decomposition. Swollen bases or braces called **buttress roots** hold the trees upright and aid in the extensive distribution of the shallow roots (FIG. 36-10b).

In swampy or tidal environments where the soil is flooded or waterlogged, some roots grow upward until they are above the high-tide level. Even though roots live in the soil, they still require oxygen for aerobic respiration. Flooded soils are depleted of oxygen, so these aerial "breathing" roots, known as **pneumatophores**, may assist in getting oxygen to the submerged roots (FIG. 36-10c). Pneumatophores, which also help anchor the plant, have a well-developed system of internal air spaces that is continuous with the submerged parts of the root, presumably allowing gas exchange. Black mangroves and white mangroves are examples of plants with pneumatophores.

Climbing plants and **epiphytes**, which are plants that grow attached to other plants, have aerial roots that anchor the plant to the bark, branch, or other surface on which they grow. Some epiphytes have aerial roots specialized for functions other than anchorage. Certain epiphytic orchids, for example, have photosynthetic roots (FIG. 36-10d). Epiphytic roots may absorb moisture as well.

Some parasitic epiphytes, such as mistletoe, have modified roots that penetrate the host-plant tissues and absorb water. Another plant that starts its life as an epiphyte is the strangler fig, which produces long roots that eventually reach the ground and anchor the plant (now a tree rather than an epiphyte) in the soil. The tree on which the strangler fig originally grew is often killed as the strangler fig grows around it, competing with it for light and other resources and crushing its secondary phloem.

CHECKPOINT 36.1

- What are the advantages of a taproot system? of a fibrous root system?
- If you were examining a cross section of a primary root of a flowering plant, how would you determine whether it was a eudicot or a monocot?

Key Point

The production of secondary tissues in roots, like that in stems, is the result of the activity of two lateral meristems: the vascular cambium and the cork cambium.

1. Tissues in primary root.
2. At onset of secondary growth, vascular cambium extends out to pericycle, forming continuous, noncircular loop.
3. Vascular cambium produces secondary xylem to its inside and secondary phloem to its outside.
4. Ring of vascular cambium gradually becomes circular. As vascular cambium continues to divide, epidermis, cortex, and primary phloem located in outer bark are torn apart.

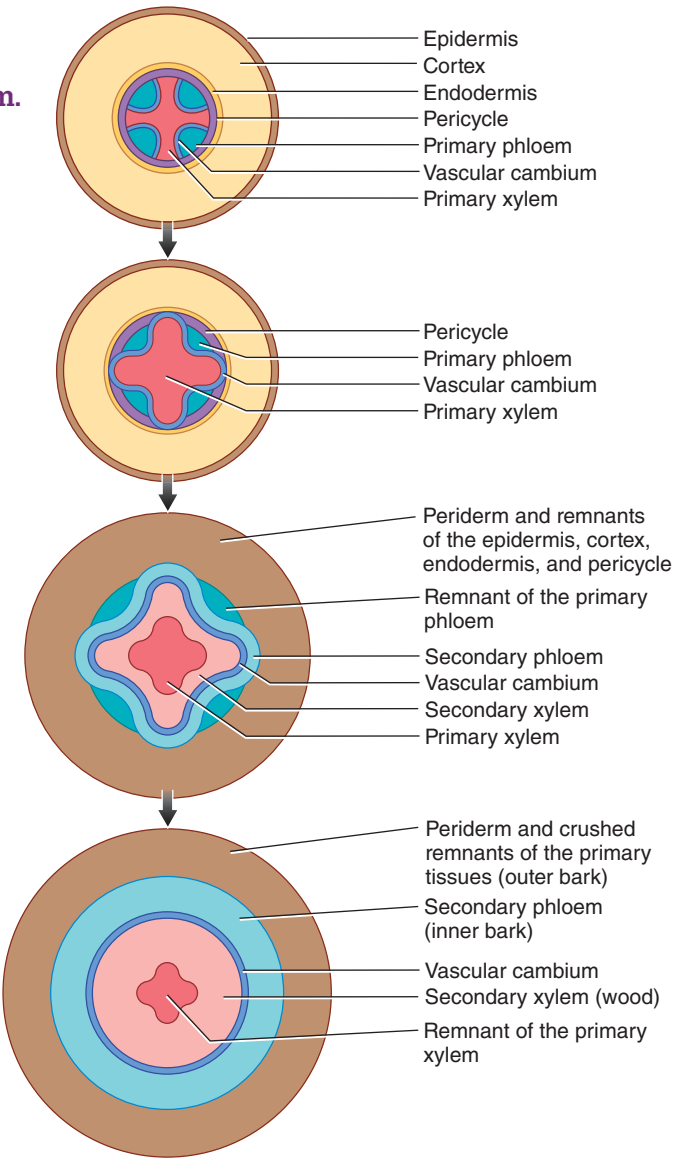

Figure 36-9 Development of secondary vascular tissues in a primary root

The figures are not drawn to scale because of space limitations; the primary xylem is actually the same size in all four diagrams, but differences in scale make the xylem appear different sizes.

CONNECT In what directions does the stem vascular cambium produce secondary xylem and secondary phloem?

- By what mechanism(s) do water and dissolved minerals move through the symplast? the apoplast?
- In what way does the possession of a Casparian strip enable endodermal cells to carry out their essential function?
- How do the vascular cambium and the cork cambium of a herbaceous eudicot root function in the production of secondary tissues?
- What are the functions of each of the following: prop roots, buttress roots, and pneumatophores?

36.2 Root Associations and Interactions

LEARNING OBJECTIVE

6 List and describe two mutualistic relationships between roots and other organisms.

As roots of an individual plant extend through the soil, they often encounter the roots of related or unrelated plants. The nature of these interactions is largely unknown, but several

studies suggest that roots are involved in complex ways, sometimes recognizing the identity of neighboring roots and modifying their growth accordingly. For example, wild strawberry roots have been demonstrated to grow more vigorously when they encounter ground ivy roots; in contrast, root growth of ground ivy is inhibited by strawberry roots.

(c) Fruiting body of the mycorrhizal fungus *Laccaria bicolor*, which is colonizing the roots of nearby Douglas fir seedlings.

Figure 36-11 Mycorrhizae

Mycorrhizae enhance plant growth by providing essential minerals to the roots.

Such root associations affect community dynamics in natural ecosystems and may affect the productivity of agricultural ecosystems.

The roots of terrestrial plant species may form *mutualistic*—that is, mutually beneficial—relationships with certain soil microorganisms: *mycorrhizal fungi* and *rhizobial bacteria*. These mutualistic relationships provide plants with access to essential minerals that are in limited supply in the soil.

Mycorrhizae facilitate the uptake of essential minerals by roots

Subterranean associations between roots and certain fungi, known as **mycorrhizae**, are found in virtually all terrestrial ecosystems. Mycorrhizae permit the transfer of materials (such as carbon compounds produced by photosynthesis) from roots to the fungus. At the same time, essential minerals, such as phosphorus, move from the fungus to the roots of the host plant. The threadlike body of the fungal partner extends into the soil, extracting minerals well beyond the reach of the plant's roots. In some mycorrhizae, the fungal mycelium encircles the root like a sheath; in others, the fungus penetrates cell walls of the root cortex and forms branching **arbuscules** (FIG. 36-11; also see Fig. 29-11).

The mycorrhizal relationship is an ancient one: some of the earliest known plant fossils (about 400 million years old) contain mycorrhizal fungi in the roots. The mycorrhizal relationship is mutually beneficial because when mycorrhizae are not present, neither the fungus nor the plant grows as well (see Fig. 29-19).

The hyphal network of mycorrhizae appears to interconnect the roots of different plant species in the community so that carbon compounds may flow from one plant to another through their mutual fungal partner.

The genome of an ectomycorrhizal fungus, *Laccaria bicolor*, has been sequenced, and scientists have identified many genes that code for *small secreted proteins* that may be involved in establishing the mutualistic relationship between the fungus and its plant partner (see Fig. 36-11c). For example, it has been learned that one such protein is secreted by the fungus in response to signals that diffuse from plant roots. The fungal

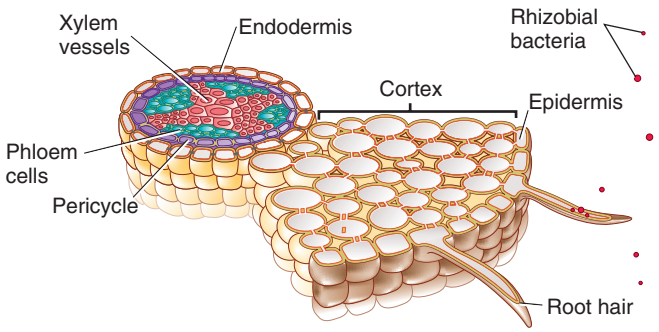
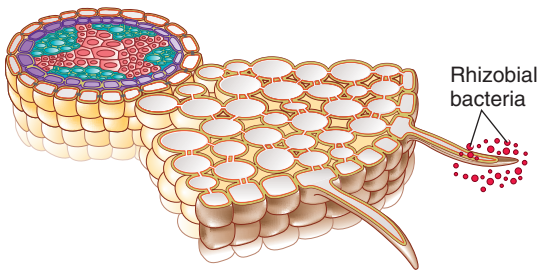
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.



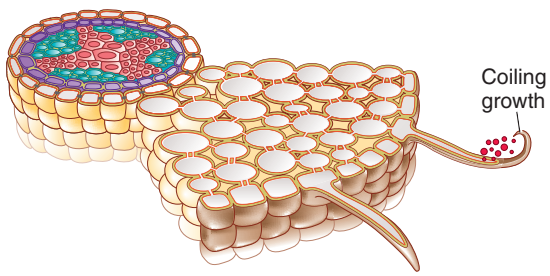
protein is then taken up by plant root cells by endocytosis and enters the nuclei where it affects the transcription of plant genes that promote the mutualistic mycorrhizal relationship.

Rhizobial bacteria fix nitrogen in the roots of leguminous plants

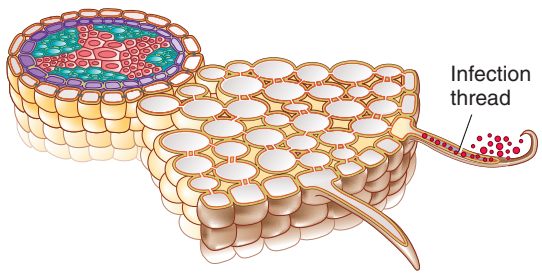


Certain nitrogen-fixing bacteria, collectively called **rhizobia**, form associations with the roots of leguminous plants such as clover, peas, and soybeans. **Nodules** (swellings) that house millions of the rhizobia develop on the roots (see Fig. 55-9). Evidence indicates that the rhizobial relationship evolved much later than the mycorrhizal relationship; unlike mycorrhizae, which infect most plant species, rhizobia almost exclusively infect plants of the legume family, which evolved about 70 million years ago. (A few other plant–bacteria associations that fix nitrogen have also evolved.)

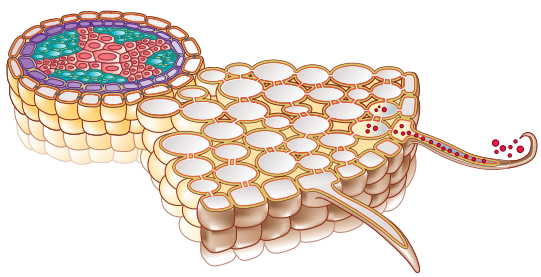
As with mycorrhizae, the association between nitrogen-fixing bacteria and the roots of legumes is mutually beneficial. Bacteria receive photosynthetic products from plants while helping plants meet their nitrogen requirements by producing ammonia (NH_3) from atmospheric nitrogen.



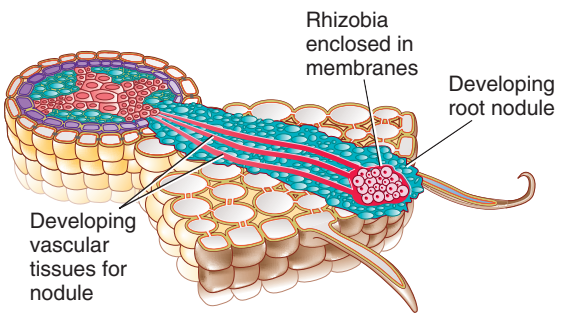
For several decades, biologists have been studying the molecular basis of associations between plants and nitrogen-fixing bacteria. The two partners in this association use **cell signaling**—that is, a molecular dialogue back and forth between them—to establish contact and develop nodules. When soil contains a low level of nitrogen, legume roots secrete chemical attractants (flavonoids) toward which the rhizobial bacteria swim (FIG. 36-12).



1 Legume root secretes chemical signal that attracts rhizobia.



2 Rhizobia congregate around root hair.



3 Rhizobia secrete chemicals (nodulation, or nod, factors) that cause root hair to coil around them.

4 Rhizobia enter root hair and move through infection thread (tube surrounded by plasma membrane) that extends down root-hair cell.

5 Rhizobia move from infection thread into cells in cortex; each bacterium is surrounded by a membrane.

6 Chemicals produced by rhizobia induce cell division and formation of root nodule. Some nodule cells are "infected."

Figure 36-12 Establishment of a relationship between rhizobial bacteria and leguminous plants
Much of the nitrogen produced by nitrogen-fixing bacteria in legume root nodules is transported in the vascular tissues throughout the plant body, including the seeds.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

The initial signal molecules produced by rhizobial bacteria are called *nodulation factors*, or *nod factors*. These nod factors help root-hair cells in the roots of leguminous plants recognize the presence of the bacteria; recognition is the first step in the infection by rhizobia and the development of root nodules. The nod factor apparently attaches to a plant receptor on the root-hair plasma membrane. This attachment triggers a calcium-dependent **signal transduction** cascade within root cells that alters gene expression and metabolism, resulting in nodule formation. The plant hormone **cytokinin**, which triggers cell division (see Chapter 38), is involved in root nodule formation.

Some genes are involved in the initiation of both mycorrhizal and rhizobial associations Because both mycorrhizae and rhizobia infect plant roots, some biologists have hypothesized that the genes and signal transduction components involved in mycorrhizal relationships may have been recruited for the rhizobial relationships that evolved much later. There is experimental evidence to support this hypothesis. Some of the same genes that trigger infection and changes in root development to form rhizobial nodules are also involved in establishing mycorrhizal infections. Evidence includes several legume mutants that biologists have identified; these mutants lack the ability to develop nodules for rhizobial bacteria and cannot form mycorrhizal associations.

CHECKPOINT 36.2

- How are mycorrhizae and root nodules similar? How are they different?

36.3 The Soil Environment

LEARNING OBJECTIVES

7 Describe the roles of weathering, organisms, climate, and topography in soil formation.
8 List the four components of soil and give the ecological significance of each.
9 Describe how roots absorb positively charged mineral ions by the process of cation exchange.
10 Distinguish between macronutrients and micronutrients.
11 Explain the effects of mineral depletion and soil erosion on plant growth.

We now examine the soil environment in which most roots live. *Soil* is a relatively thin layer of Earth's crust that has been modified by the natural actions of weather, wind, water, and organisms. It is easy to take soil for granted. We walk on and over it throughout our lives but rarely stop to think about how important it is to our survival. Vast numbers and kinds of organisms colonize soil and depend on it for shelter and food. Most plants anchor themselves in soil, and from it they receive water and minerals. Almost all the elements essential for plant growth are obtained directly from the soil. With few exceptions, plants cannot survive on their own without soil, and because we depend on plants for our food, neither could humans exist without soil.

Soils are generally formed from rock (called "parent material") that is gradually broken down, or fragmented, into smaller and smaller particles by biological, chemical, and physical **weathering processes** (FIG. 36-13). Two important factors that work together in the weathering of rock are climate and organisms. When plant roots and other organisms living in the soil respire, they produce carbon dioxide (CO_2), which diffuses into the soil and reacts with soil water to form carbonic acid (H_2CO_3). Soil organisms such as lichens produce other kinds of acids. Recall from Chapter 29 that a lichen is a compound organism composed of one or more fungi and a phototroph (photosynthetic organism). These acids etch tiny cracks, or fissures, in the rock surface, and water then seeps into these cracks. If the parent material is located in a temperate climate, the alternate freezing and thawing of the water during winter causes the cracks to enlarge, breaking off small pieces of rock. Small plants can then become established and send their roots into the larger cracks, fracturing the rock further.

Topography, a region's surface features such as the presence or absence of mountains and valleys, is also involved in soil formation. Steep slopes often have little or no soil on them because the soil and rock are continually transported down the slopes by gravity. Runoff from precipitation tends to amplify erosion on steep slopes. Moderate slopes, in contrast, may encourage the formation of deep soils.

The disintegration of solid rock into finer and finer mineral particles in the soil takes an extremely long time, sometimes thousands of years. Soil forms constantly as the weathering of parent material beneath soil that is already formed continues to add new soil.

Soil comprises inorganic minerals, organic matter, air, and water

Soil comprises four distinct components: inorganic mineral particles (which make up about 45% of a typical soil), organic matter (about 5%), water (about 25%), and air (about 25%). The plants, animals, fungi, and microorganisms that inhabit soil interact with it, and minerals are continually cycled from the soil to organisms, which use them in their biological processes. When the organisms die, bacteria and other soil organisms decompose the remains, returning the minerals to the soil.

The inorganic mineral particles, which come from weathered rock, provide anchorage and essential minerals for plants as well as pore space for water and air. Because different rocks consist of different minerals, soils vary in mineral composition and chemical properties. Rocks rich in aluminum form acidic soils, for example, whereas rocks that contain silicates of magnesium and iron form soils that may be deficient in calcium, nitrogen, and phosphorus. Also, soils formed from the same kind of parent material may not develop in the same way because other factors, such as weather, topography, and organisms, differ.

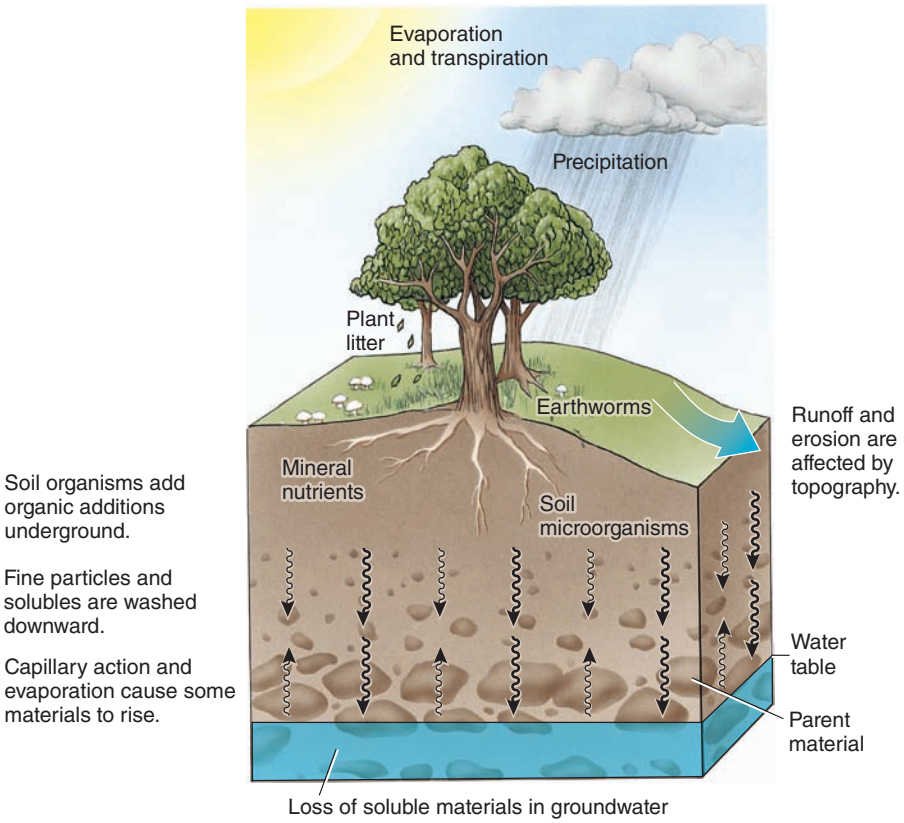

Figure 36-13 The dynamics of soil formation

Weather, climate, topography, and organisms interact with Earth's crust to form soil, the material that supports plants and many other organisms on land.

The *texture*, or structural characteristic, of a soil is determined by the percentages (by weight) of the different-sized inorganic mineral particles—sand, silt, and clay—in it. The size assignments for sand, silt, and clay give soil scientists a way to classify soil texture. Particles larger than 2 mm in diameter, called gravel or stones, are not considered soil particles because they do not have any direct value to plants. The largest soil particles are called "sand" (0.02 to 2 mm in diameter); the medium-sized particles, "silt" (0.002 to 0.02 mm in diameter); and the smallest particles, "clay" (less than 0.002 mm in diameter). Sand particles are large enough to be seen easily with the eye, and silt particles (about the size of flour particles) can be seen with an ordinary light microscope. Most individual clay particles can be seen only under an electron microscope.

A soil's texture affects many of that soil's properties, in turn influencing plant growth. The clay component of a soil is particularly important in determining many of its characteristics because clay particles have the greatest surface area of all soil particles. If the surface areas of about 450 g (1 lb) of clay particles were laid out side by side, they would occupy 1 hectare (2.5 acres).

Each clay particle has predominantly negative electric charges on its outer surface that attract and reversibly bind **cations**, which are positively charged mineral ions such as potassium (K^+) and magnesium (Mg^{2+}). Because many cations are essential for plant growth, cation adhesion to soil particles is an important aspect of soil fertility. Roots secrete protons (H^+), which are exchanged for other positively charged mineral ions adhering to the surface of soil particles, in a process known as **cation exchange**. These "freed" ions and the water that forms a film around the soil particles are absorbed by the plant's roots (FIG. 36-14).

In contrast, **anions**, which are negatively charged mineral ions, are repelled by the negative surface charges of clay particles and tend to remain in solution. Anions such as nitrate (NO_3^-) are often washed out of the root zone by water moving through the soil.

Soil always contains a mixture of different-sized particles, but the proportions vary from one soil to another. A *loam*, which is an ideal agricultural soil, has an optimum combination of different soil particle sizes: it contains approximately 40% each of sand and silt and about 20% of clay. Generally, the larger particles provide structural support, aeration, and permeability to the soil, whereas the smaller particles bind into aggregates, or clumps, and hold minerals and water. Soils with larger proportions of sand are not as desirable for most plants because they do not hold water and mineral ions well. Plants grown in such soils are more susceptible to drought and mineral deficiencies. Soils with larger proportions of clay are also not desirable for most plants because they provide poor

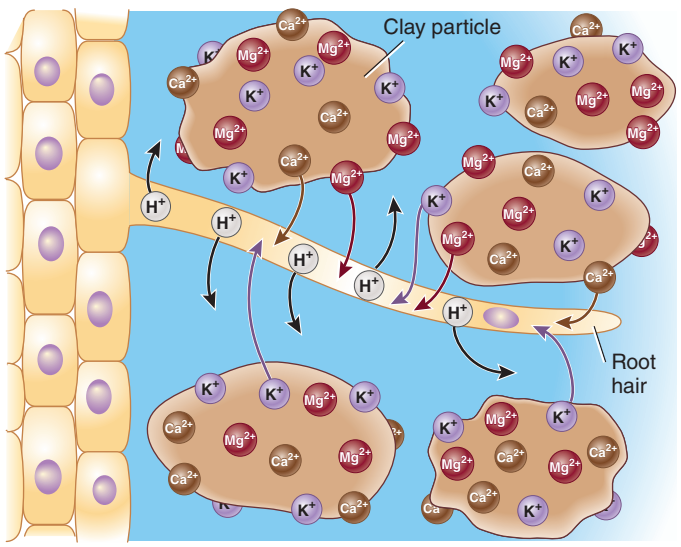

Figure 36-14 Cation exchange

Negatively charged clay particles bind to positively charged mineral cations, holding them in the soil. Roots pump out protons (H^+), which are exchanged for the cations, facilitating their absorption.

drainage and often do not provide enough oxygen. Clay soils used in agriculture tend to compact, which reduces the number of soil spaces that can be filled by water and air.

A soil's organic matter consists of the wastes and remains of soil organisms The organic matter in soil is composed of litter (dead leaves and branches on the soil's surface); droppings (animal dung); and the dead remains of plants, animals, and microorganisms in various stages of decomposition. Organic matter is decomposed by microorganisms, particularly bacteria and fungi, that inhabit the soil. During decomposition, essential mineral ions are released into the soil, where they may be bound by soil particles or absorbed by plant roots. Organic matter increases the soil's water-holding capacity by acting much like a sponge. For this reason, gardeners often add organic matter to soils, especially sandy soils, which are naturally low in organic matter.

The partly decayed organic portion of the soil is referred to as **humus**. Humus, which is not a single chemical compound but a mix of many organic compounds, binds mineral ions and holds water. On average, humus persists in agricultural soil for about 20 years. Certain components of humus may persist in the soil for hundreds of years. Although humus is somewhat resistant to decay, a succession of microorganisms gradually reduces it to carbon dioxide, water, and minerals.

About 50% of soil volume is composed of pore spaces

Soil has numerous pore spaces of different sizes around and among the soil particles. Pore spaces occupy roughly 50% of a soil's volume and are filled with varying proportions of air and water. Both soil air and soil water are necessary to produce a moist but aerated soil that sustains plants and other soil-dwelling organisms. Water is usually held in the smaller pores, whereas air is found in the larger pores. After a prolonged rain, almost all the pore spaces may be filled with water, but water drains rapidly from the larger pore spaces, drawing air from the atmosphere into those spaces.

Soil air contains the same gases as atmospheric air, although they are usually present in different proportions. As a result of respiration by soil organisms, there is less oxygen and more carbon dioxide in soil air than in atmospheric air. (Aerobic respiration uses oxygen and produces carbon dioxide.) Among the important gases in soil are oxygen (O_2), required by soil organisms for aerobic respiration; nitrogen (N_2), used by nitrogen-fixing bacteria; and carbon dioxide (CO_2), involved in soil weathering.

Soil water originates as precipitation, which drains downward, or as groundwater (water stored in porous underground rock), which rises upward from the water table (the uppermost level of groundwater). Soil water contains low concentrations of dissolved minerals that enter the roots of plants when they absorb water. Water not bound to soil particles or absorbed by roots percolates (moves down) through soil, carrying dissolved minerals with it. The removal of dissolved materials from soil by percolating water is called **leaching**. The deposition of leached material in the lower layers of soil is known as **illuviation**. Iron and aluminum compounds, humus, and clay are some illuvial materials that can gather in the subsurface portion of the soil. Some substances completely leach out of the soil because they are so soluble that they migrate down into the groundwater. It is also possible for water that is moving *upward* through the soil to carry dissolved materials with it.

Soil organisms form a complex ecosystem

A single teaspoon of fertile agricultural soil may contain millions of microorganisms, such as bacteria, fungi, algae, protozoa, as well as microscopic nematodes and other worms. Other organisms also colonize the soil ecosystem, including plant roots, earthworms, insects, moles, snakes, and groundhogs (FIG. 36-15). Most numerous in soil are bacteria, which number in the hundreds of millions per gram of soil. Scientists have identified about 170,000 species of soil organisms, but thousands remain to be identified. Little is known about the roles and interactions of soil organisms, in part because it is hard to study their activities under natural conditions.

Worms are some of the most important organisms living in soil. Earthworms, probably one of the most familiar soil inhabitants, ingest soil and obtain energy and raw materials by digesting humus. *Castings*, bits of soil that have passed through the gut of an earthworm, are deposited on or near the soil surface. In this way, minerals from deeper layers are brought to upper layers. Earthworm tunnels serve to aerate the soil, and the worms' waste products and corpses add organic material to the soil.

Ants live in the soil in enormous numbers, constructing tunnels and chambers that help aerate it. Members of soil-dwelling ant colonies forage on the surface for bits of food, which they carry back to their nests. Not all this food is eaten, however, and its eventual decomposition helps increase the organic matter in the soil. Many ants are also indispensable in plant reproduction because they bury seeds in the soil (discussed in Chapter 37).

Soil pH affects soil characteristics and plant growth

Acidity is measured using the pH scale, which extends from 0 (extremely acidic) through 7.0 (neutral) to 14.0 (extremely alkaline). The pH of most soils ranges from 4.0 to 8.0, but some soils are outside this range. The soil of the Pygmy Forest in Mendocino County, California, is extremely acidic (pH 2.8 to 3.9). At the other extreme, certain soils in Death Valley, California, have a pH of 10.5.

Plants are affected by soil pH, partly because the solubility of certain minerals varies with differences in pH. Soluble minerals can be absorbed by the plant, whereas insoluble forms cannot. At a low pH, for example, aluminum and manganese in soil water are more soluble than at higher pH and are sometimes absorbed by the roots in toxic concentrations. At

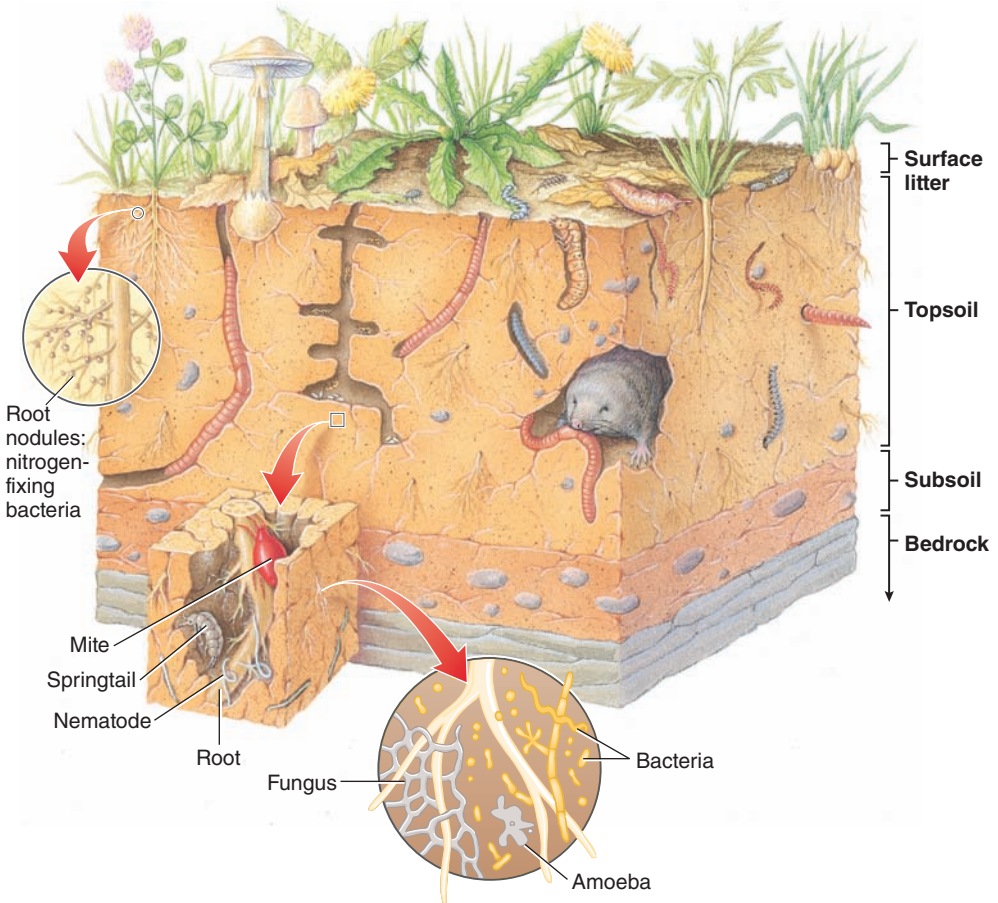

Figure 36-15 Diversity of life in fertile soil

Plants, algae, protozoa, fungi, bacteria, earthworms, flatworms, roundworms, insects, spiders and mites, and burrowing animals such as moles and groundhogs live in soil.

a higher pH, certain mineral salts essential for plant growth, such as calcium phosphate, become less soluble and thus less available to plants than at lower pH.

Soil pH also affects the leaching of minerals. An acidic soil has less ability than other soil to bind positively charged ions to it because the soil particles also bind the abundant protons (FIG. 36-16). As a result, certain mineral ions essential for plant growth, such as potassium (K^+), are leached more readily from acidic soil than other soil. The optimum soil pH for most plant growth is 6.0 to 7.0 because most essential minerals are available to plants in that pH range.

Acid precipitation, a type of air pollution in which sulfuric and nitric acids produced by human activities fall to the ground as acid rain, sleet, snow, or fog, can seriously decrease soil pH. Acid precipitation is one of several factors implicated in *forest decline*, the gradual deterioration, and often death, of trees that has been observed in many European and North American forests in recent decades. Forest decline may be partly the result of soil changes, such as leaching of essential cations, caused by acid precipitation. In central European forests that have experienced forest decline, for example, a strong correlation has been demonstrated between forest damage and soil chemistry altered by acid precipitation.

Soil provides most of the minerals found in plants

More than 90 naturally occurring elements exist on Earth, and more than 60 of them, including elements as common as carbon and as rare as gold, have been found in plant tissues. Not all these elements are essential for plant growth, however.

Nineteen elements have been found essential for most, if not all, plants (TABLE 36-1). Ten of them are required in fairly large quantities (greater than 0.05% dry weight) and are therefore known as **macronutrients**. Macronutrients are carbon, hydrogen, oxygen, nitrogen, potassium, calcium, magnesium, phosphorus, sulfur, and silicon. The remaining nine **micronutrients** are needed in trace amounts (less than 0.05% dry weight) for normal plant growth and development. Micronutrients are chlorine, iron, boron, manganese, sodium, zinc, copper, nickel, and molybdenum.

Four of the 19 elements—carbon, oxygen, hydrogen, and nitrogen—come directly or indirectly from soil water or from gases in the atmosphere. Carbon is obtained from carbon dioxide in the atmosphere during photosynthesis. Oxygen is obtained from atmospheric oxygen (O_2) and water (H_2O). Water also supplies hydrogen to the plant. Plants absorb their nitrogen from the soil as ions of nitrogen salts, but the nitrogen in nitrogen salts ultimately comes from atmospheric nitrogen (N_2). The remaining 15 essential elements are obtained from the soil as dissolved mineral ions. Their ultimate source is the parent material from which the soil was formed.

Let us examine the main functions of essential elements. Carbon, hydrogen, and oxygen are found as part of the structure of all biologically important molecules, including lipids, carbohydrates, nucleic acids, and proteins. Nitrogen is part of proteins, nucleic acids, and chlorophyll.

Potassium, which plants use in fairly substantial amounts, is not found in a specific organic compound in plant cells. Instead, it remains as free K^+ and plays a key physiological role in maintaining the turgidity of cells because it is osmotically active. The presence of K^+ in cytoplasm causes water to pass through the plasma membrane into the cell by osmosis. Potassium is also involved in the opening of stomata.

Calcium plays a key structural role as a component of the middle lamella (the cementing layer between cell walls of adjacent plant cells). Calcium ions (Ca^{2+}) are also important

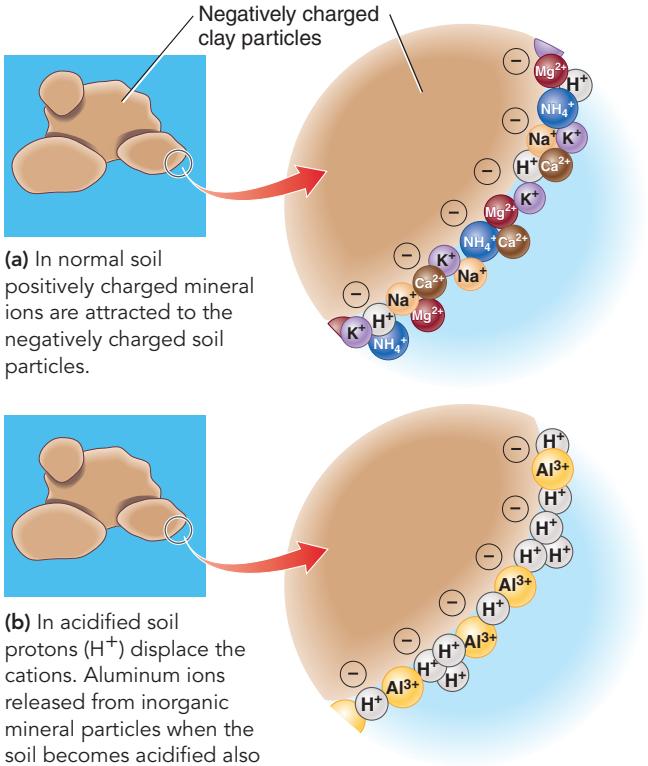

Figure 36-16 How acid alters soil chemistry

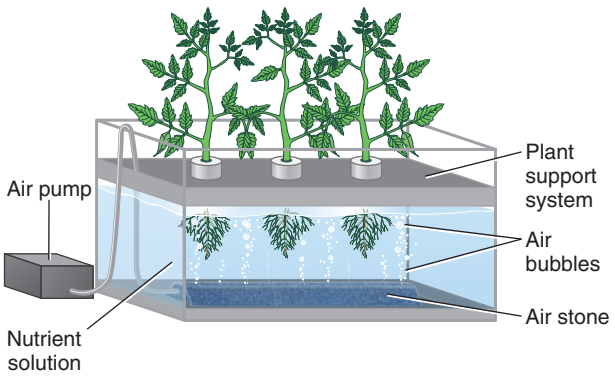
in physiological roles in plants, such as altering membrane permeability and as **second messengers** in various cell signaling responses (see Chapter 6).

Magnesium is critical for plants because it is part of the chlorophyll molecule. Phosphorus is a component of nucleic acids, phospholipids (part of cell membranes), and energy transfer molecules such as ATP. Sulfur is essential because it is found in certain amino acids and vitamins. Many plants accumulate silicon in their cell walls and intercellular spaces. Silicon enhances the growth and fertility of some species and may help reinforce cell walls.

Chlorine and sodium are micronutrients that help maintain cell turgor. In addition to this osmotic role, chloride (Cl^-) and sodium (Na^+) ions are essential for photosynthesis. Six of the micronutrients (iron, manganese, zinc, copper, nickel, and molybdenum) are associated with various plant enzymes, often as **cofactors**, and are involved in certain enzymatic reactions. Boron, present in cell walls, is also involved in nucleic acid metabolism and in cell growth.

How do biologists determine whether an element is essential? It is impossible to conduct mineral nutrition experiments by growing plants in soil because soil is too complex and contains too many elements. Therefore, nutritional studies require special methods. One of the most useful techniques to test whether an element is essential is **hydroponics**, which is the growing of plants in aerated water to which mineral salts have been added (FIG. 36-17). Hydroponics has commercial

Table 36-1 Functions of Elements Required by Most Plants



Element	Taken Up As	Major Functions
MACRONUTRIENTS		
Carbon	CO_2	Component of carbohydrate, lipid, protein, and nucleic acid molecules
Hydrogen	H_2O	Component of carbohydrate, lipid, protein, and nucleic acid molecules
Oxygen	O_2, H_2O	Component of carbohydrate, lipid, protein, and nucleic acid molecules
Nitrogen	NO_3^-, NH_4^+	Component of proteins, nucleic acids, chlorophyll, and certain coenzymes
Potassium	K^+	Osmotic and ionic balance; opening of stomata; enzyme activator (for 40 enzymes)
Calcium	Ca^{2+}	In cell walls; involved in membrane permeability; enzyme activator; second messenger in metabolism
Magnesium	Mg^{2+}	In chlorophyll; enzyme activator in carbohydrate metabolism (phosphate transfer)
Phosphorus	HPO_4^{2-}, $H_2PO_4^-$	In nucleic acids, phospholipids, ATP (energy transfer compound), and coenzymes
Sulfur	SO_4^{2-}	In certain amino acids and vitamins
Silicon	SiO_3^{2-}	In cell walls; increased resistance to pests and diseases; important primarily in grasses and sedges
MICRONUTRIENTS		
Chlorine	Cl^-	Ionic balance; involved in photosynthesis (production of oxygen)
Iron	Fe^{2+}, Fe^{3+}	In enzymes and electron transport molecules involved in photosynthesis, respiration, and nitrogen fixation
Boron	$H_2BO_3^-$	In cell walls; involved in nucleic acid metabolism and in cell elongation
Manganese	Mn^{2+}	In enzymes involved in respiration and nitrogen metabolism; required for photosynthesis (production of oxygen)
Sodium	Na^+	Involved in photosynthesis (in C_4 and CAM plants); substitutes for potassium in osmotic and ionic balance
Zinc	Zn^{2+}	In enzymes involved in respiration and nitrogen metabolism
Copper	Cu^+, Cu^{2+}	In enzymes involved in photosynthesis
Nickel	Ni^{2+}	In enzymes (urease) involved in nitrogen metabolism; required by nitrogen-fixing bacteria
Molybdenum	MoO_4^{2-}	In enzymes involved in nitrogen metabolism

Research Method

WHY IS IT USED? Using hydroponics, it is possible to grow plants in which only the mineral under investigation is absent from a nutrient solution. (It would be impossible to design such an experiment using soil.) Growing plants hydroponically in the absence of an essential mineral produces recognizable deficiency symptoms.

HOW IS IT DONE? The experimental and control plants are grown in two liquid solutions of mineral nutrients through which air is bubbled to allow the roots to respire. The liquid solution for the experimental plants contains all nutrient minerals known to be essential for plant growth except for one. The liquid solution for the control plants contains all known essential elements, including the one under study.

Figure 36-17 Plant nutritional studies in hydroponic growth systems

applications in addition to its scientific use. Lettuce is one of several crops that is grown hydroponically.

If biologists suspect that a particular element is essential for plant growth, they grow plants in a nutrient solution that contains all known essential elements *except* the one in question. If plants grown in the absence of that element cannot develop normally or complete their life cycle, the element may be essential. Additional criteria are used to confirm whether an element is essential. For example, it must be demonstrated that the element has a direct effect on the plant's metabolism and that the element is essential for a wide variety of plants.

Soil can be damaged by human mismanagement

Soil is a valuable natural resource on which humans depend for food. Many human activities generate or aggravate soil problems, including mineral depletion, soil erosion, and accumulation of salt.

Mineral depletion may occur in agricultural soils

In a natural ecosystem, the essential minerals removed from the soil by plants are returned when the plants or the animals that eat them die and are decomposed. An agricultural system disrupts this pattern of nutrient cycling when the crops are harvested. Plant material containing minerals is removed from the nutrient cycle, and the harvested crops fail to decay and release their nutrients back to the soil. Over time, farmed soil inevitably loses its fertility, that is, its ability to produce abundant crops. Homeowners often mow their lawns and remove the clippings, similarly preventing decomposition and cycling of minerals that were in the grass blades.

The essential material (water, sunlight, or some essential element) that is in shortest supply usually limits plant growth. This phenomenon is sometimes called the concept of **limiting resources**. The three elements that are most often limiting resources for plants are nitrogen, phosphorus, and potassium. To sustain the productivity of agricultural soils, farmers periodically add fertilizers to depleted soils to replace the minerals that limit plant growth.

Soil erosion is the loss of soil from the land

Water, wind, ice, and other agents cause **soil erosion**, the wearing away or removal of soil from the land. Water and wind are particularly effective in moving soil from one place to another. Rainfall loosens soil particles that can then be transported by moving water (FIG. 36-18). Wind loosens soil and blows it away, particularly if the soil is barren and dry. Soil erosion is a natural process that can be greatly accelerated by human activities.

Soil erosion is a national and international problem that does not make the headlines very often. The U.S. Department of Agriculture estimates that approximately 4.2 billion metric tons (4.6 billion tons) of topsoil are eroded each year from U.S. croplands and rangelands. Erosion causes a loss in soil fertility because essential minerals and organic matter that are a part of the soil are removed. As a result of these losses, the productivity of eroded agricultural soils declines, and more fertilizer must be used to replace the nutrients lost to erosion.

USDA/Natural Resources Conservation Service

Figure 36-18 Soil erosion in an open field
Removal of plant cover exposes bare soil to erosion in heavy rains. Precipitation can cause gullies to enlarge rapidly because they provide channels for the runoff of water.

Humans often accelerate soil erosion through poor soil management practices. Agriculture is not the only culprit; the removal of natural plant communities during surface mining, unsound logging practices (such as clear-cutting large areas of forest), and the construction of roads and buildings also accelerate erosion.

Soil erosion has an impact on other natural resources. Sediment that enters streams, rivers, and lakes degrades water quality and fish habitats. Pesticides and fertilizer residues in sediment may add pollutants to the water. Also, when forests are removed within the watershed of a hydroelectric power facility, accelerated soil erosion fills the reservoir behind the dam with sediment much faster than usual. This process reduces electricity production at that facility.

Sufficient plant cover reduces the amount of soil erosion: leaves and stems cushion the effect of rainfall, and roots help hold the soil in place. Although soil erosion is a natural process, abundant plant cover makes it negligible in many natural ecosystems.

Salt accumulates in soil that is improperly irrigated

Although irrigation improves the agricultural productivity of arid and semiarid lands, it sometimes causes salt to accumulate in the soil, a process called *salinization*. In a natural scenario, as a result of precipitation runoff, rivers carry dissolved salts away. Irrigation water, however, normally soaks into the soil and does not run off the land into rivers, so when water evaporates, the salt remains behind and accumulates in the soil. Salty soil results in a decline in productivity and, in extreme cases, renders the soil completely unfit for crop production.

Most plants cannot obtain all the water they need from salty soil because a water balance problem exists: water moves by osmosis *out* of plant roots and into the salty soil. Obviously, most plants cannot survive under these conditions (see Fig. 5-13). Plant species that thrive in saline soils have special adaptations that enable them to tolerate the high amount of salt. Black mangroves, for example, excrete excess salt through their leaves.

Unless they have been genetically selected to tolerate high salt, most crops are not productive in saline soil. Research on the molecular aspects of salt tolerance suggests that mutations in membrane transport proteins confer salt tolerance. Biologists genetically engineered a salt-tolerant variety of *Arabidopsis* to overexpress a single gene that codes for a sodium transport protein in the vacuolar membrane. These plants can store large quantities of sodium in their vacuoles, thereby tolerating saline soils.

CHECKPOINT 36.3

- What are the four components of soil, and how is each important to plants?
- How does cation exchange make mineral ions available for absorption by plant roots?
- In what ways do weathering processes convert rock into soil?
- What criteria are used to distinguish macronutrients from micronutrients?
- What are three ways in which human mismanagement can cause soil damage?

Summary: Focus on Learning Objectives

36.1 Root Structure and Function *(page 763)*

1 Distinguish between taproot and fibrous root systems.

- A **taproot system** has one main root (formed from the **radicle**) from which many lateral roots extend. A **fibrous root system** has several to many **adventitious** roots of the same size developing from the end of the stem. Lateral roots branch from these adventitious roots.

2 Compare cross sections of a primary eudicot root and a monocot root, and describe the functions of each tissue.

- Primary roots have an epidermis, ground tissues (cortex and, in certain roots, pith), and vascular tissues (xylem and phloem). Each root tip is covered by a **root cap**, a protective layer that covers the delicate root **apical meristem** and may orient the root so that it grows downward.
- **Epidermis** protects the root. **Root hairs**, short-lived extensions of epidermal cells, aid in absorption of water and dissolved minerals.
- **Cortex** consists of parenchyma cells that often store starch. **Endodermis**, the innermost layer of the cortex, regulates the movement of water and minerals into the root xylem. Cells of the endodermis have a **Casparian strip** around their radial and transverse walls that is impermeable to water and dissolved minerals.
- Pericycle, xylem, and phloem collectively make up the root's **stele**, or **vascular cylinder**. **Pericycle** gives rise to lateral roots and lateral meristems. **Xylem** conducts water and dissolved minerals; **phloem** conducts dissolved sugar.
- Xylem of a herbaceous eudicot root forms a solid core in the center of the root. The center of a monocot root often consists of pith surrounded by a ring of alternating bundles of xylem and phloem.

3 Trace the pathway of water and mineral ions from the soil through the various root tissues and distinguish between the symplast and apoplast.

- As water and dissolved mineral ions move from the soil into the root, they pass through the following tissues: root hair/epidermis → cortex → endodermis → pericycle → root xylem.
- Water and dissolved minerals move through the epidermis and cortex along one of two pathways: the **apoplast** (along the interconnected porous cell walls) or the **symplast** (from one cell's cytoplasm to the next through **plasmodesmata**).

4 Discuss the structure of roots with secondary growth.

- Roots of gymnosperms and woody eudicots develop secondary tissues (wood and bark). The production of secondary tissues is the result of the activity of two lateral meristems: the vascular cambium and cork cambium. The **vascular cambium** produces secondary xylem (wood) and secondary phloem (inner bark). The **cork cambium** produces **periderm** (outer bark).

5 Describe at least three roots that are modified to perform uncommon functions.

- **Prop roots** develop from branches or from a vertical stem and grow downward into the soil to help support certain plants in an upright position. **Buttress roots** are swollen bases or braces that support certain tropical rainforest trees that have shallow root systems. **Pneumatophores** are aerial "breathing" roots that may assist in getting oxygen to submerged roots.

36.2 Root Associations and Interactions *(page 769)*

6 List and describe two mutualistic relationships between roots and other organisms.

- **Mycorrhizae**, which are mutually beneficial associations between roots and soil fungi, enhance plant growth by providing essential minerals such as phosphorus to the roots.
- Root **nodules** are swellings that develop on roots of leguminous plants and house millions of **rhizobia** (nitrogen-fixing bacteria).

36.3 The Soil Environment *(page 773)*

7 Describe the roles of weathering, organisms, climate, and topography in soil formation.

- Factors influencing soil formation include parent material (type of rock), climate, organisms, the passage of time, and topography. Most soils are formed from parent material that is broken into smaller and smaller particles by **weathering processes**. Climate and organisms work together in weathering rock.
- Soil organisms such as plants, algae, fungi, worms, insects, spiders, and bacteria are important not only in forming soil but also in cycling minerals.
- Topography, a region's surface features, affects soil formation. Steep slopes have little or no soil on them, whereas moderate slopes often have deep soils.

8 List the four components of soil and give the ecological significance of each.

- Soil comprises inorganic minerals, organic matter, air, and water. Inorganic minerals provide anchorage and essential minerals for plants. Organic matter increases the soil's water-holding capacity and, as it decomposes, releases essential minerals into the soil. Soil air provides oxygen for soil organisms to use during aerobic respiration. Soil water provides water and dissolved minerals to plants and other organisms.

9 Describe how roots absorb positively charged mineral ions by the process of cation exchange.

- **Cations**, positively charged mineral ions, are attracted and reversibly bound to clay particles, which have predominantly negative charges on their outer surfaces. In **cation exchange**, roots secrete protons (H^+), which are exchanged for other positively charged mineral ions, freeing them into the soil water to be absorbed by roots.

10 Distinguish between macronutrients and micronutrients.

- Plants require 19 essential elements for normal growth. Ten elements are **macronutrients**: carbon, hydrogen, oxygen, nitrogen, potassium, calcium, magnesium, phosphorus, sulfur, and silicon. Macronutrients are required in fairly large quantities.
- Nine elements are **micronutrients**: chlorine, iron, boron, manganese, sodium, zinc, copper, nickel, and molybdenum. Micronutrients are needed in trace amounts.

11 Explain the effects of mineral depletion and soil erosion on plant growth.

- Mineral depletion may occur in soils that are farmed because the natural pattern of nutrient cycling is disrupted when crops are harvested (and not allowed to decompose into the soil).
- **Soil erosion** is the removal of soil from the land by agents such as water and wind. Erosion causes a loss in soil fertility because essential minerals and organic matter that are a part of the soil are removed.

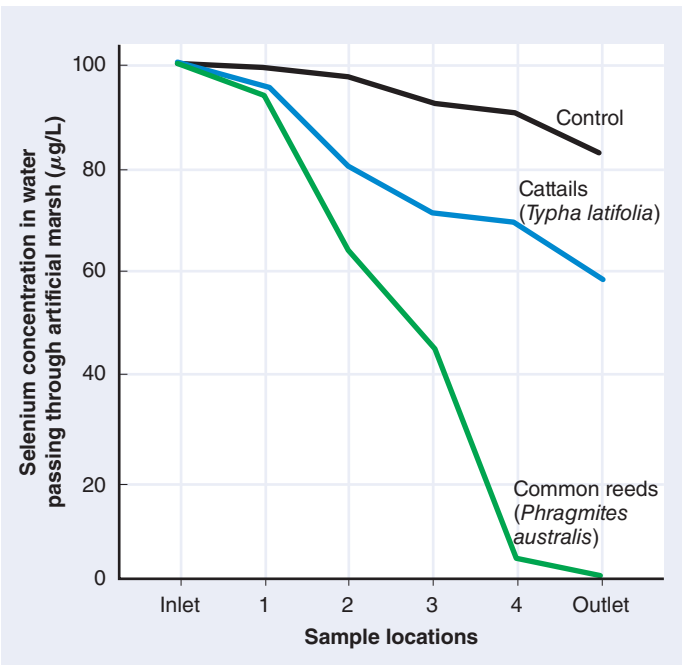
Test Your Understanding

Know and Comprehend



1. One main root, formed from the enlarging embryonic root, with many smaller lateral roots branching off it is (a) a fibrous root system (b) an adventitious root system (c) a taproot system (d) a storage root system (e) a prop root system
2. Root hairs (a) cover and protect the delicate root apical meristem (b) increase the absorptive capacity of roots (c) secrete a waxy cuticle (d) orient the root so that it grows downward (e) store excess sugars produced in the leaves
3. Certain plants adapted to flooded soil produce aerial "breathing" roots known as (a) fibrous roots (b) pneumatophores (c) mycorrhizae (d) nodules (e) prop roots
4. The waterproof region around the radial and transverse walls of endodermal cells is the (a) Casparian strip (b) pericycle (c) apoplast (d) symplast (e) pneumatophore
5. The apoplast is (a) a layer of cells that surround the vascular region in roots (b) the layer of cells just inside the endodermis (c) a system of interconnected plant cell walls through which water moves (d) the central cylinder of the root that comprises the vascular tissues (e) a continuum of cytoplasm of many cells, all connected by plasmodesmata
6. Plants obtain positively charged mineral ions from clay particles in the soil by cation exchange, in which (a) roots passively absorb the positively charged mineral ions (b) mineral ions flow freely along porous cell walls (c) roots secrete protons, which free other positively charged mineral ions to be absorbed by roots (d) the Casparian strip effectively blocks the passage of water and mineral ions along the endodermal cell wall (e) a well-developed system of internal air spaces in the root allows both gas exchange and cation exchange
7. The cell layer from which lateral roots originate is the (a) epidermis (b) cortex (c) endodermis (d) pericycle (e) vascular cambium
8. Mutually beneficial associations between certain soil fungi and the roots of most plant species are called (a) mycorrhizae (b) pneumatophores (c) nodules (d) rhizobia (e) humus
9. Which of the following statements about soil is *true*? (a) pore spaces are always filled with about 50% air and 50% water (b) a single teaspoon of fertile agricultural soil may contain up to several hundred living microorganisms (c) the texture of a soil is determined by the soil's pH (d) a soil's organic matter includes litter, droppings, and the dead remains of plants, animals, and microorganisms (e) soil formation is unaffected by a region's climate or topography
10. Carbon, hydrogen, oxygen, nitrogen, potassium, calcium, magnesium, phosphorus, sulfur, and silicon are collectively known as (a) micronutrients (b) microvilli (c) micronuclei (d) macronuclei (e) macronutrients

Apply and Analyze

11. **VISUALIZE** Draw a simple sketch illustrating the relationships of the following in a cross section of a primary root: remnant of primary xylem, vascular cambium, secondary phloem, secondary xylem, and periderm.

Evaluate and Synthesize

12. A mesquite root is found penetrating a mine shaft about 46 m (150 ft) below the surface of the soil. How could you determine *when* the root first grew into the shaft? (*Hint*: Mesquite is a woody plant.)
13. You are given a plant part that was found growing in the soil and are asked to determine whether it is a root or an underground stem. How would you identify the structure without a microscope? with a microscope?
14. Explain why, once secondary growth has occurred, that portion of the root is no longer involved in absorption. Where does absorption of water and dissolved minerals occur in plants that have roots with secondary growth?
15. **EVOLUTION LINK** A barrel cactus that is 60 cm tall and 30 cm in diameter has roots more than 3 m long. However, all the plant's roots are found in the soil at a depth of 5 to 15 cm. What possible adaptive value does such a shallow root system confer on a desert plant?
16. **SCIENCE, TECHNOLOGY, AND SOCIETY** What is the agricultural value of research to understand the control of root hair development? of the interactions leading to the development of mycorrhizal associations?
17. **INTERPRET DATA** When soil has become polluted with hazardous materials such as heavy metals, it is sometimes cost-effective to construct an artificial marsh around the site. Water is pumped through the contaminated soil, picking up the hazardous material, and then the water is passed through the artificial wetland. In one experiment, scientists compared the effectiveness of the roots of two different marsh plants (cattails and common reeds) in absorbing the heavy metal selenium. Which plant's roots removed the most selenium? What should be done to the plants after they have absorbed selenium?

37 Reproduction in Flowering Plants

KEY CONCEPTS

37.1 The flower is the site of sexual reproduction in angiosperms. A typical flower consists of four whorls: sepals, petals, stamens, and carpels.

37.2 Pollen grains are transported to stigmas by a variety of agents, such as animals and wind.

37.3 Double fertilization results in a plant embryo and endosperm. The seed is a mature ovule, and the fruit is a mature ovary.

37.4 Following a period of dormancy, a seed germinates, or sprouts. The young seedling becomes anchored in the ground and begins to photosynthesize.

37.5 Many vegetative organs (roots, stems, and leaves) are modified for asexual reproduction.

37.6 Sexual reproduction in flowers results in genetic variability in the offspring, whereas asexual reproduction in vegetative structures generally results in individuals that are genetically identical.

PHOTO: Longleaf starwort flower. This plant (*Stellaria longifolia*) is native to northern Europe and North America. Joel Sartore/Getty Images

Flowering plants, or **angiosperms**, include about 300,000 species and are the largest, most successful group of plants. You may have admired flowers for their fragrances as well as their appealing colors and varied shapes (see photograph). The biological function of flowers is sexual reproduction. Their colors, shapes, and fragrances increase the likelihood that pollen grains, which produce sperm cells, will be carried from one plant to another. Sexual reproduction in plants includes *meiosis* and the fusion of reproductive cells: egg and sperm cells, collectively called **gametes**. The union of gametes, called fertilization, occurs within the flower's ovary.

Sexual reproduction offers the advantage of new gene combinations, not found in either parent, that may make an individual plant better suited to its environment. These new combinations result from the crossing-over and independent assortment of chromosomes that occur during meiosis, before the production of egg and sperm cells (see Chapter 11).

Many flowering plants also reproduce asexually. Asexual reproduction often does not involve the formation of flowers, seeds, and fruits. Instead, offspring generally form when a vegetative organ (such as a stem, root, or leaf) expands, grows, and then becomes separated from the rest of the plant, often by the death of tissues. Because asexual reproduction requires only one parent and no meiosis or fusion of gametes occurs, the offspring of asexual reproduction are virtually genetically identical to one another and to the parent plant.[1]

This chapter examines both sexual and asexual reproduction in flowering plants, including floral adaptations that are important in

[1] Somatic mutations can result in some variability among asexually derived offspring.

pollination, seed and fruit structure and dispersal, germination and early growth, and several kinds of asexual reproduction. We conclude with a discussion of the evolutionary advantages and disadvantages of sexual and asexual reproduction.

37.1 The Flowering Plant Life Cycle

LEARNING OBJECTIVES

1. Describe the functions of each part of a flower.
2. Identify where eggs and pollen grains are formed within the flower.

In Chapters 27 and 28 you learned that angiosperms and other plants undergo a cyclic **alternation of generations** in which they spend a portion of their life cycle in a multicellular haploid stage and a portion in a multicellular diploid stage. The haploid portion, called the **gametophyte generation**, gives rise to gametes by mitosis. When two gametes fuse during **fertilization**, the diploid portion of the life cycle, called the **sporophyte generation**, begins. The sporophyte generation produces haploid spores by meiosis. Each spore has the potential to give rise to a gametophyte plant, and the cycle continues.

In flowering plants the diploid sporophyte generation is larger and nutritionally independent. The haploid gametophyte generation, which is located in the flower, is microscopic and nutritionally dependent on the sporophyte. We say more about alternation of generations in flowering plants after our discussion of the role of flowers as reproductive structures. (It may be helpful for you to review Figure 28-13, which shows the main stages in the flowering plant life cycle.)

Flowers develop at apical meristems

How does a plant "know" that it is time to start forming flowers? Correct timing in the switch from vegetative to reproductive development is crucial to ensure reproductive success. A variety of environmental cues, such as temperature and day length, ensure proper timing, and different species are adapted to respond to distinct environmental cues. These environmental signals interact with a variety of plant hormones and developmental pathways.

In recent years some biologists have focused on the molecular aspects of developmental pathways that initiate flowering in plants such as the model organism *Arabidopsis.* When environmental conditions induce flowering, many genes are activated or inactivated. For example, one gene, the *Flowering Locus C (FLC)* gene, codes for a *transcription factor* that represses flowering. (You may recall from Chapter 14 that transcription factors are DNA-binding proteins that regulate the synthesis of RNA from a DNA template.) Another gene, called *Flowering Locus D (FLD)*, codes for a protein that removes acetyl groups from histones in the chromatin where the *FLC* gene is located. When deacetylation occurs, the *FLC* gene is not transcribed (i.e., the repressive transcription factor is not produced), and the shoot apical meristem undergoes a transition from vegetative growth to reproductive growth. It is intriguing that the plant FLD protein is homologous to a mammalian protein that also removes acetyl groups from chromatin.

Other genes are also involved in the initiation of flowering, and this area remains a focus of active research interest. In Chapter 38 we discuss the initiation of flowering further.

Each part of a flower has a specific function

Flowers are reproductive shoots, usually consisting of four kinds of organs—sepals, petals, stamens, and carpels—arranged in whorls (circles) on the end of a flower stalk (FIG 37-1; also see Fig. 28-11). In flowers with all four organs, the normal order of whorls from the flower's periphery to the center (or from the flower's base upward) is as follows:

sepals → petals → stamens → carpels

The tip of the stalk enlarges to form a **receptacle** on which some or all of the flower parts are borne. All four floral parts are important in the reproductive process, but only the stamens (the "male" organs) and carpels (the "female" organs) participate directly in sexual reproduction; sepals and petals are sterile.

Sepals, which constitute the outermost and lowest whorl on a floral shoot, cover and protect the flower parts when the flower is a bud. Sepals are leaflike in shape and form and are often green. Some sepals, such as those in lily flowers, are colored and resemble petals (FIG. 37-2). The collective term for all the sepals of a flower is **calyx**.

The whorl just inside and above the sepals consists of **petals**, which are broad, flat, and thin (like sepals and leaves) but widely varied in shape and frequently brightly colored, which attracts pollinators. Petals play an important role in ensuring that sexual reproduction will occur. Sometimes petals fuse to form a tube or other floral shape. The collective term for all the petals of a flower is **corolla**.

Just inside and above the petals are the **stamens**, the male reproductive organs. Each stamen has a thin stalk, called a **filament**, at the top of which is an **anther**, a saclike structure in which **pollen grains** form. For sexual reproduction to occur, pollen grains must be transferred from the anther to the female reproductive structure (the carpel), usually of another flower of the same species. At first, each pollen grain consists of two cells surrounded by a tough outer wall. One cell, the *generative cell*, divides mitotically to form two nonflagellate male gametes, known as *sperm cells*. The other cell, the *tube cell*, produces a **pollen tube** through which the sperm cells travel to reach the ovule.

One or more **carpels**, the female reproductive organs, are located in the center or top of most flowers. Carpels bear **ovules**, which are structures with the potential to develop into seeds. The carpels of a flower may be separate or fused into a single structure. The female part of the flower, often called a **pistil**, may be a single carpel (a *simple pistil*) or a group of

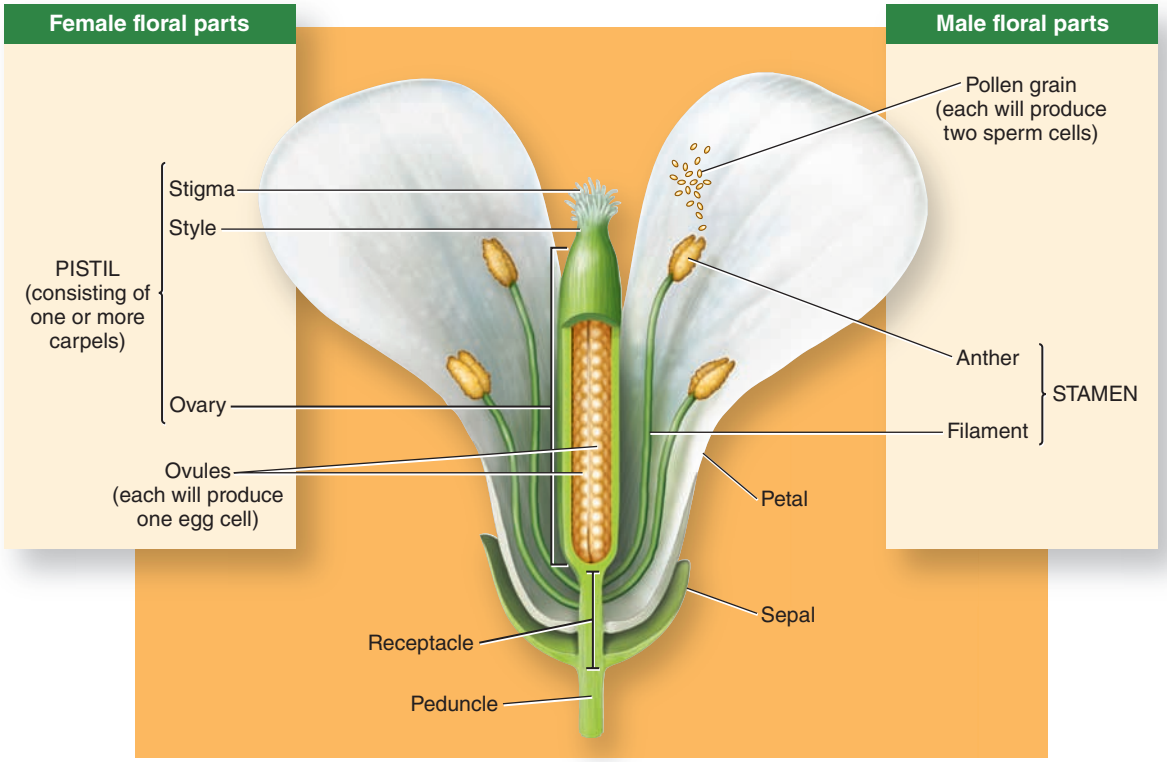

Figure 37-1 Floral structure

An *Arabidopsis* flower has four sepals (two are shown in this cutaway view), four petals (two are shown), six stamens, and one long pistil. Four of the stamens are long, and two are short (two long and two short are shown). Pollen grains develop within sacs in the anthers. In *Arabidopsis*, the compound pistil consists of two carpels, each containing numerous ovules.

fused carpels (a *compound pistil*) (see Fig. 28-12). Each pistil has three sections: a **stigma**, on which the pollen grains land; a **style**, a necklike structure through which the pollen tube grows; and an **ovary**, a juglike structure that contains one or more ovules and can develop into a fruit.

Holmes Garden Photos / Alamy Stock Photo

Figure 37-2 Lily flowers

In lily (*Lilium*), the three sepals and three petals are similar in size and color.

Considerable variation in flower structure occurs from one species to another, but flower structure is virtually constant within a given species. For that reason, flower structure is important in plant identification, and if flowers are present, flowering plant species are easy to evaluate in the field.

Female gametophytes (embryo sacs) are produced in the ovary, male gametophytes in the anther Before we proceed, it may be helpful to relate the stages in alternation of generations to floral structure. As discussed in Chapters 27 and 28, angiosperms and certain other plants are heterosporous and produce two kinds of spores: megaspores and microspores (FIG. 37-3).

Each young ovule within an ovary contains a diploid cell, the *megasporocyte*, which undergoes meiosis to produce four haploid **megaspores**. Three of them usually disintegrate, and the fourth, the functional megaspore, divides mitotically to produce a multicellular **embryo sac**, which is the *female gametophyte*. The embryo sac, which is embedded in the ovule, typically contains seven cells with eight haploid nuclei. Six of these cells, including the egg cell (the female gamete), contain a single nucleus each; a large central cell has two nuclei, called **polar nuclei**.

Key Point

In alternation of generations in flowering plants, the female and male gametophytes are microscopic and nutritionally dependent on the sporophyte plant.

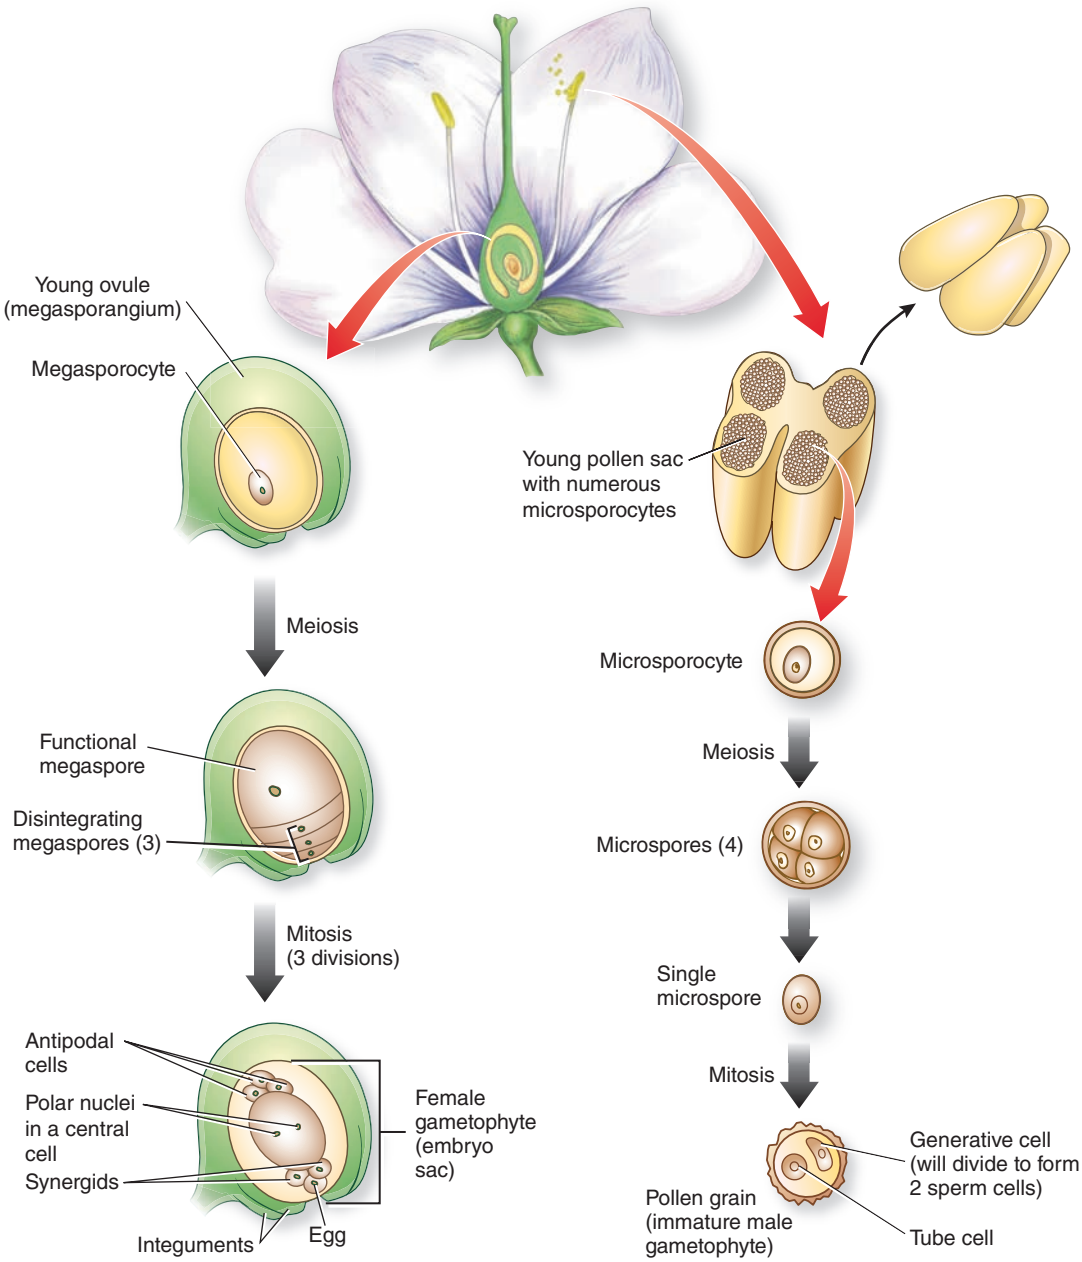

Figure 37-3 Development of female and male gametophytes

(*Left side*) The embryo sac (female gametophyte) develops within the ovule. (*Right side*) The immature male gametophytes, or pollen grains, develop within pollen sacs in the anthers.

CONNECT State if each of the following is haploid, diploid, or triploid: megasporocyte, megaspore, polar nucleus, egg, microsporocyte, microspore, generative cell, and sperm cell.

The egg and both polar nuclei participate directly in fertilization.

Pollen sacs within the anther contain numerous diploid cells called *microsporocytes*, each of which undergoes meiosis to produce four haploid cells called **microspores**. Each microspore divides mitotically to produce an immature male gametophyte, also called a pollen grain, that consists of two cells: the tube cell and the generative cell. The pollen grain becomes mature when its generative cell divides to form two nonmotile sperm cells.

CHECKPOINT 37.1

- How do petals differ from sepals? How are they similar?
- How do stamens differ from carpels? How are they similar?
- **CONNECT** What are the female gametophytes of flowering plants, and where are they formed?
- **CONNECT** What are the male gametophytes of flowering plants, and where are they formed?

37.2 Pollination

LEARNING OBJECTIVES

3 Compare the evolutionary adaptations that characterize flowers pollinated in different ways (by insects, birds, and bats).

4 Define *coevolution* and give examples of ways that plants and their animal pollinators have affected each other's evolution.

Before fertilization can occur, pollen grains must travel from the anther (where they form) to the stigma. The transfer of pollen grains from anther to stigma is known as **pollination**. Plants are *self-pollinated* if pollination occurs within the same flower or a different flower on the same individual plant. When pollen grains are transferred to a flower on another individual of the same species, the plant is *cross-pollinated*. Flowering plants accomplish pollination in a variety of ways. Beetles, bees, flies, butterflies, moths, wasps, and other insects pollinate many flowers. Animals such as birds, bats, snails, and small nonflying mammals (rodents, primates, and marsupials) also pollinate plants. Wind is an agent of pollination for certain flowers; and water, for a few aquatic flowers.

Many plants have mechanisms that prevent self-pollination

In plant sexual reproduction, the two gametes that unite to form a zygote may be from the same parent or from two different parents. The combination of gametes from two different parents increases the variation in offspring, and this variation may confer a selective advantage. Some offspring, for example, may be able to survive environmental changes better than either parent can.

Evolution has resulted in a variety of mechanisms that prevent self-pollination and thus prevent **inbreeding**, which is the mating of genetically similar individuals. Inbreeding can increase the concentration of harmful genes in the offspring. Some plants, such as asparagus and willow, have separate male and female individuals; the male plants have staminate flowers that lack carpels, and the female plants have pistillate flowers that lack stamens. Other species have flowers with both stamens and pistils, but the pollen is shed from a given flower either before or after the time when the stigma of that flower is receptive to pollen. These characteristics promote **outbreeding** (also called *outcrossing*), which is the mating of dissimilar individuals.

Many species have genes for **self-incompatibility**, a genetic condition in which the pollen is ineffective in fertilizing the same flower or other flowers on the same plant. In other words, an individual plant can identify and reject its own pollen. Genes for self-incompatibility usually inhibit the growth of the pollen tube in the stigma and style, thereby preventing delivery of sperm cells to the ovules. Self-incompatibility, which is more common in wild species than in cultivated plants, ensures that reproduction occurs only if the pollen comes from a genetically different individual.

In plants such as oilseed rape, self-incompatibility is based on a high degree of variation at a particular locus called the *S* locus; the many alleles at this locus are designated S_1, S_2, S_3, S_4, and so on. Here is an example of how the *S* locus blocks self-fertilization. A plant with the genotype S_1S_2 produces pollen grains that land on a stigma of another plant with the genotype S_1S_3 . In this case, the presence of the S_1 allele in both the pollen and stigma triggers a self-recognition signaling cascade in surface cells of the stigma. As a result, the stigma cells do not undergo changes that allow the pollen grain to grow a pollen tube. Therefore, fertilization does not occur.

The molecular basis of self-incompatibility in *Arabidopsis* and related plants is an area of active scientific interest. *Arabidopsis* can self-pollinate. Biologists have determined that the genes involved in self-incompatibility and outcrossing exist in *Arabidopsis* but have undergone mutations so that they are no longer functional. Thus, it appears that self-incompatibility in these plants is the ancestral condition.

Flowering plants and their animal pollinators have coevolved

Animal pollinators and the plants they pollinate have had such close, interdependent relationships over time that they have affected the evolution of certain physical and behavioral features in one another. **Coevolution** describes such reciprocal adaptation, in which two species interact so closely that they become increasingly adapted to each other as they each undergo evolutionary change by *natural selection*. We now examine some of the features of flowers and their pollinators that may be the products of coevolution.

Flowers pollinated by animals have various features to attract their pollinators, including showy petals (a visual attractant) and scent (an olfactory attractant) (FIG. 37-4 and TABLE 37-1). One reward for the animal pollinator is food. Pollen grains are a protein-rich food for many animals. As they move from flower to flower searching for food, pollinators inadvertently carry along pollen grains on their body parts, helping the plants reproduce sexually.

Some flowers produce nectar, a sugary solution in special floral glands called *nectaries*. Pollinators use nectar, which is also rich in amino acids, alkaloids, and other floral chemicals, as an energy-rich food. Some nectars contain alkaloids such as nicotine to prevent animal pollinators from drinking all the nectar in a single visit. (Nicotine is poisonous.) Thus, pollinators are encouraged to visit multiple flowers, and each flower has multiple pollinator visitors.

Biologists estimate that insects pollinate about 70% of all flowering plant species. Bees are particularly important as pollinators of crop plants. Crops pollinated by bees provide about 30% of human food. Plants pollinated by insects often have blue or yellow petals. The insect eye does not see color the same way the human eye does. Most insects see well in the violet, blue, and yellow range of visible light but do not perceive red as a distinct color. So, flowers pollinated by insects are not usually red. Insects also see in the ultraviolet range,

Table 37-1 Floral Characteristics Associated with Various Animal Pollinators

Animal Pollinator	Common Flower Color	Scent	Pollinator Reward	Time of Flowering
Bee	Yellow, blue, purple	Strong, floral	Nectar, pollen	Day
Butterfly	Red, pink	Weak, floral	Nectar	Day
Moth	White	Strong, sweet	Nectar	Dusk, night
Carrion fly	Reddish-brown, purple	Strong, rotten	No reward	Day, night
Beetle	Green, white	Strong, various scents	Nectar, pollen	Day, night
Bird	Red, pink	No scent	Nectar	Day
Bat	White	Strong, musklike or sweet	Nectar, pollen	Night

wavelengths that are invisible to the human eye. Insects see ultraviolet radiation as a color called *bee's purple*. Many flowers have dramatic UV markings that may or may not be visible to humans but that direct insects to the center of the flower where the pollen grains and nectar are.

Insects have a well-developed sense of smell, and many insect-pollinated flowers have a strong scent that may be pleasant or foul to humans. The carrion plant, for example, is pollinated by flies and smells like the rotting flesh in which flies lay their eggs. As flies move from one reeking flower to another looking for a place to lay their eggs, they transfer pollen grains.

Birds such as hummingbirds are important pollinators. Flowers pollinated by birds are usually red, orange, or yellow because birds see well in this range of visible light. Because most birds do not have a strong sense of smell, bird-pollinated flowers usually lack a scent.

Bats, which feed at night and do not see well, are important pollinators, particularly in the tropics. Bat-pollinated flowers bloom at night and have dull white petals and a strong nighttime output of scent that usually smells like fermented fruit. Nectar-feeding bats are attracted to the flowers by the scent; they lap up the nectar with their long, extendible tongues. As they move from flower to flower, they transfer pollen grains. An unusual adaptation that encourages pollination by bats has evolved in the tropical vine *Mucana holtonii*. When the pollen in a given flower is mature, a concave petal lifts up. The petal bounces the echo from the bat's echo-locating calls back to the bat, helping it find the flower.

Specialized features such as petals, scent, and nectar to attract pollinators have coevolved with adaptations of animal pollinators. Specialized body parts and behaviors adapted animals to aid pollination as they obtain nectar and pollen grains as a reward. For example, coevolution has selected for bumblebees' hairy bodies, which catch and hold the sticky pollen grains for transport from one flower to another.

Coevolution may have led to the long, curved beaks of the ʻi'iwi, one of the Hawaiian honeycreepers, that inserts its beak into tubular flowers to obtain nectar (see Figs. 1-13b and 20-18). The long, tubular corolla of the flowers that ʻi'iwis visit probably also came about through coevolution. During the 20th century, some of the tubular flower species (such as lobelias) became rare, largely as a result of grazing by nonnative cows and feral goats, and about 25% of lobelia species have become extinct. The ʻi'iwi now feeds largely on the flowers of the ʻohi'a tree, which lacks petals, and the ʻi'iwi bill appears to be adapting to this change in feeding preference. Comparison of the bills of ʻi'iwi museum specimens collected in 1902 with the bills of live birds captured in the 1990s showed that ʻi'iwi bills were about 3% shorter in the 1990s than in 1902.

Plants and the behavior of their animal pollinators have coevolved, sometimes in bizarre and complex ways. The flowers of certain orchids (*Ophrys*) resemble female bees in coloring and shape. The unpollinated flowers secrete a scent similar to that produced by female bees, and the males are irresistibly attracted to it. The resemblance between *Ophrys* flowers and female bees is so strong that male bees mount the flowers and try to copulate with them. During this *pseudocopulation*, a pollen sac usually attaches to the back of the bee. When the frustrated bee departs and tries to copulate with another orchid flower, pollen grains are transferred to that flower. Interestingly, once a flower has been pollinated, it emits a scent like that released by female bees that have already mated. Male bees have no interest in visiting flowers that have been pollinated (just as they lose interest in female bees that have already been inseminated).

Biologists think that hummingbird-pollinated flowers arose from insect-pollinated flowers many times during the course of flowering plant evolution. In one experiment researchers demonstrated that a single gene mutation affecting petal color could have been partly responsible for the pollinator shift that resulted in the evolution of two closely related species, *Mimulus lewisii* and *Mimulus cardinalis*, from their insect-pollinated common ancestor (FIG. 37-5).

Some flowering plants depend on wind to disperse pollen

Some flowering plants, such as grasses, ragweed, maples, and oaks, are pollinated by wind. Wind-pollinated plants produce many small, inconspicuous flowers (FIG. 37-6). They do not produce large, colorful petals, scent, or nectar. Some have large, feathery stigmas, presumably to trap wind-borne pollen grains. Because wind pollination is a hit-or-miss affair, the likelihood of a particular pollen grain landing on a stigma of the same species of flower is slim. Wind-pollinated plants produce large quantities of pollen grains, which increase the likelihood that some pollen grains will land on the appropriate stigma.

Key Experiment

Can a single gene mutation in flower color affect animal pollinators?

HYPOTHESIS: If flower color is changed by a mutation, pollinator preferences for the resulting flower may change.

EXPERIMENT: *Mimulus lewisii* has violet-pink flowers and is pollinated by bumblebees; the closely related *M. cardinalis* has orange-red flowers and is pollinated by hummingbirds. Alleles at the same locus in both species affect flower color.

Researchers transferred the allele for orange-red flowers from *M. cardinalis* to *M. lewisii*, which then produced yellow-orange petals. They also transferred the allele for pink flowers from *M. lewisii* to *M. cardinalis*, which then produced dark pink petals.

Wild-type *M. cardinalis*

Reprinted by permission from Macmillan Publishers Ltd: *Nature*, Vol. 426, November 13, 2003

Altered *M. cardinalis*

RESULTS AND CONCLUSION: The modified *M. lewisii* flowers were yellow-orange in color and had 68 times as many hummingbird visits as the unaltered *M. lewisii* flowers. The modified *M. cardinalis* flowers had dark pink petals and were visited by 74 times as many bumblebees as the unaltered *M. cardinalis* flowers. Thus, a single mutation in a gene for flower color resulted in a shift in animal pollinators.

CHECKPOINT 37.2

- **PREDICT** A flower has yellow petals, a pleasant scent, and sugary nectar. How is it probably pollinated?
- **PREDICT** A flower has small, inconspicuous flowers without petals, a scent, or nectar. How is it probably pollinated?
- Give three examples in which the relationship of a plant and its pollinators demonstrates coevolution.

37.3 Fertilization and Seed and Fruit Development

LEARNING OBJECTIVES

5 Distinguish between pollination and fertilization.
6 Trace the stages of embryo development in flowering plants and list and define the main parts of seeds.
7 Explain the relationships among ovules, ovaries, seeds, and fruits.
8 Distinguish among simple, aggregate, multiple, and accessory fruits.

After pollen grains have been transferred from anther to stigma, the tube cell—one of the two cells in the pollen grain—grows a thin pollen tube down through the style and into an ovule in the ovary. How does the pollen tube "know" where

to grow? Scientists have identified molecular signals from the synergid cells located adjacent to the egg that guide the growing pollen tube toward the ovule. Two attracting signals (called LUREs), both small polypeptides, have been studied in wishbone flowers (*Torenia fournieri*), and there are ongoing investigations to detect others and to understand their mechanisms of action.

Once a pollen tube penetrates the ovule, the attracting signals are no longer produced. As a result, only one pollen tube enters each embryo sac. The second cell within the pollen grain divides to form two male gametes (the sperm cells), which move down the pollen tube and enter the ovule (FIG. 37-7).

A unique double fertilization process occurs in flowering plants

The egg within the ovule unites with one of the sperm cells, forming a zygote (fertilized egg) that develops into an embryonic plant contained in the future seed. The two polar nuclei in the central cell of the ovule fuse with the second sperm cell to form the first cell of the triploid (*3n*) **endosperm**, the tissue with nutritive and hormonal functions that surrounds the developing embryonic plant in the seed. This process, in which two separate cell fusions occur, is called **double fertilization**. It is, with few exceptions, unique to flowering plants. (A type of double fertilization has been reported in two gymnosperm species, *Ephedra nevadensis* and *Gnetum gnemon*.)

After double fertilization, the ovule develops into a *seed*, and the surrounding ovary develops into a *fruit* (see discussion in Chapter 28).

Embryonic development in seeds is orderly and predictable

Flowering plants package a young plant embryo, complete with stored nutrients, in a compact **seed**, which develops from the ovule after fertilization. The nutrients in seeds are not only used by germinating plant embryos but also eaten by animals, including humans. Development of the embryo and endosperm following fertilization is possible because of the constant flow of nutrients into the developing seed from the parent plant.

Cell divisions of the fertilized egg to form a multicellular embryo proceed in several ways in flowering plants. We describe eudicot embryonic development; monocot embryonic development is similar in the early stages.

1 **Proembryo.** This stage is the earliest multicellular stage of the embryo.

2 **Globular stage embryo.** As cell division continues, the embryo becomes a ball of cells.

3 **Heart stage embryo.** As two cotyledons begin to emerge, the embryo is shaped like a heart.

4 **Torpedo stage embryo.** Cotyledons continue to elongate, forming the torpedo stage.

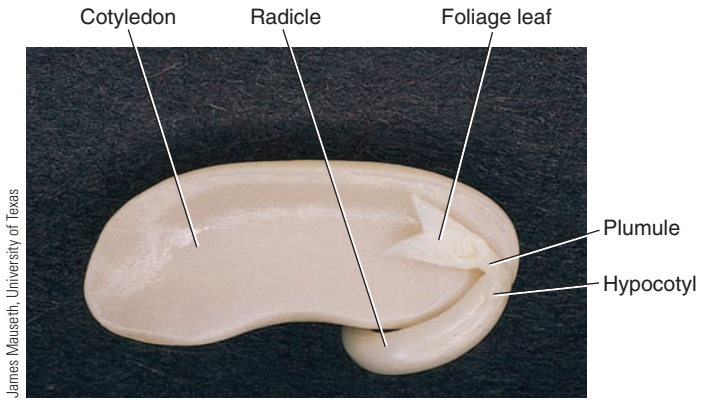
5 **Maturing embryo within seed.** Food originally stored in endosperm has been almost completely depleted during embryonic growth and development, and most of the food for the embryonic plant is now stored in the cotyledons.

6 **Fruit.** Longitudinal section through a fruit of shepherd's purse reveals numerous tiny seeds, each containing a mature embryo. Each seed developed from an ovule.

Figure 37-8 Embryonic development in shepherd's purse (*Capsella bursa-pastoris*)
The ovule is shown apart from the ovary in parts 1 through 5.

The two cells (basal cell and apical cell) that are formed as a result of the first division of the fertilized egg establish *polarity*, or direction, in the embryo. The large *basal cell* (located toward the outside of the ovule) typically develops into a **suspensor**, an embryonic tissue that anchors the developing embryo and aids in nutrient uptake from the endosperm. The *apical cell* (toward the inside of the ovule) develops into the plant embryo. Scientists are currently studying molecular differences between the apical cell and basal cell to determine the initial molecular signals that are involved in establishing polarity.

Initially, the apical cell divides to form a small cluster of cells, called a *proembryo* (FIG. 37-8). As cell division continues, a sphere of cells, often called a *globular embryo*, develops. Cells begin to develop into specialized tissues during this stage. When the eudicot embryo starts to develop its two cotyledons (seed leaves), it has two lobes and resembles a heart (the *heart stage*). During the *torpedo stage*, the embryo continues to grow as the cotyledons elongate. As the embryo enlarges, it often curves back on itself and crushes the suspensor.



The mature seed contains an embryonic plant and storage materials

A mature seed contains an embryonic plant and food (stored in the cotyledons or endosperm), surrounded by a tough, protective **seed coat** derived from the **integuments**, which are the outermost layers of an ovule. The seed, in turn, is enclosed within a fruit.

The mature embryo within the seed consists of a short embryonic root, or **radicle**; an embryonic shoot; and one or two seed leaves, or **cotyledons** (FIG. 37-9). Monocots have a

Figure 37-9 Seed structure

A bean seed has been dissected—its seed coat and one of its two cotyledons were removed—to show the radicle, hypocotyl, remaining cotyledon, and plumule with its foliage leaf at the shoot apex. This particular seed had begun germinating, so its radicle is larger than in an ungerminated seed.

single cotyledon, whereas eudicots have two. The short portion of the embryonic shoot connecting the radicle to one or two cotyledons is the **hypocotyl**. The shoot apex, or terminal bud, located above the point of attachment of the cotyledon(s) is the **plumule**. After the radicle, hypocotyl, cotyledon(s), and plumule have formed, the young plant's development is arrested, usually by desiccation (drying out) or **dormancy** (a temporary state of arrested physiological activity). When conditions are right for continuing the developmental program, the seed *germinates*, and the embryo resumes growth.

Many seeds are known to remain dormant for a decade or so. Only a few instances of germination after hundreds of years of dormancy have been scientifically documented. In 2008, a team of biologists from Israel and Switzerland successfully germinated a date seed (*Phoenix dactylifera*) that was radiocarbon dated at about 2000 years old. Before this report, the oldest documented instance of germination was a 1200-year-old lotus seed (*Nelumbo nucifera*).

Because the embryonic plant is nonphotosynthetic, it must be nourished during germination until it becomes photosynthetic and therefore self-sufficient. The cotyledons of many plants function as storage organs and become large, thick, and fleshy as they absorb the food reserves (starches, oils, and proteins) initially produced as endosperm. Seeds that store nutrients in cotyledons have little or no endosperm at maturity. Examples of such seeds are peas, beans, squashes, sunflowers, and peanuts. Other plants—wheat and corn, for example—have thin cotyledons that function primarily to help the young plant digest and absorb food stored in the endosperm.

Fruits are mature, ripened ovaries

After double fertilization takes place within the ovule, the ovule develops into a seed, and the ovary surrounding it develops into a **fruit**. For example, a pea pod is a fruit, and the peas within it are seeds. A fruit may contain one or more seeds; some orchid fruits contain several thousand to a few million seeds! Fruits provide protection for the enclosed seeds and sometimes aid in their dispersal.

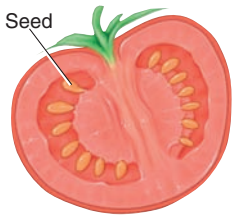
There are several types of fruits; their differences result from variations in the structure or arrangement of the flowers from which they were formed. The four basic types of fruits—simple fruits, aggregate fruits, multiple fruits, and accessory fruits—are summarized in FIGURE 37-10.

Most fruits are simple fruits. A **simple fruit** develops from a single ovary, which may consist of a single carpel or several fused carpels. At maturity, simple fruits may be fleshy or dry. Two examples of simple, fleshy fruits are berries and drupes. A **berry** is a fleshy fruit that has soft tissues throughout and contains few to many seeds; a blueberry is a berry, as are grapes, cranberries, bananas, and tomatoes. Many so-called berries do not fit the botanical definition. Strawberries, raspberries, and mulberries, for example, are not berries; these three fruits are discussed shortly.

A **drupe** is a simple, fleshy or fibrous fruit that contains a hard stone (pit) surrounding a single seed. Examples of drupes are peaches, plums, olives, and almonds. The almond shell is actually the stone, which remains after the rest of the fruit has been removed.

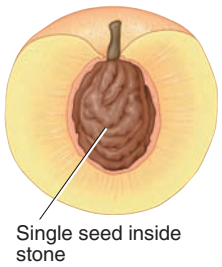
Many simple fruits are dry at maturity; some of them split open, usually along seams, called *sutures*, to release their seeds. A milkweed pod is an example of a **follicle**, a simple, dry fruit that develops from a single carpel and splits open along one suture to release its seeds. A **legume** is a simple, dry fruit that develops from a single carpel and splits open along two sutures. Pea pods are legumes, as are green beans, although both are generally harvested before the fruit has dried out and split open. Pea seeds are usually removed from the fruit and consumed, whereas in green beans the entire fruit and seeds are eaten. A **capsule** is a simple, dry fruit that develops from two or more fused carpels and splits open along two or more sutures or pores. Iris, poppy, and cotton fruits are capsules.

Other simple, dry fruits, such as **caryopses** (*sing., caryopsis*), or **grains**, do not split open at maturity. Each caryopsis contains a single seed. Because the seed coat is fused to the fruit wall, a caryopsis looks like a seed rather than a fruit. Kernels of corn and wheat are fruits of this type.



An **achene** is similar to a caryopsis in that it is simple and dry, does not split open at maturity, and contains a single seed. However, the seed coat of an achene is not fused to the fruit wall. Instead, the single seed is attached to the fruit wall at one point only, permitting an achene to be separated from its seed. The sunflower fruit is an example of an achene. One can peel off the fruit wall (the shell) to reveal the sunflower seed within.

Nuts are simple, dry fruits that have a stony wall and do not split open at maturity. Unlike achenes, nuts are usually large, single seeded, and often derived from a compound ovary. Examples of nuts are chestnuts, acorns, and hazelnuts. Many so-called nuts do not fit the botanical definition. Peanuts and Brazil nuts, for example, are seeds, not nuts.



Aggregate fruits are a second main type of fruit. An **aggregate fruit** is formed from a single flower that contains several to many separate (free) carpels (FIG. 37-11). After fertilization, each ovary from each individual carpel enlarges. As they enlarge, the

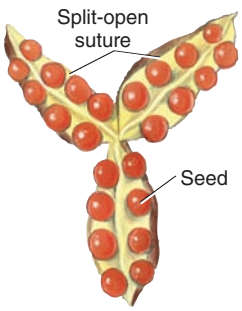
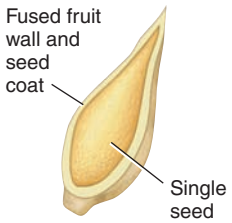
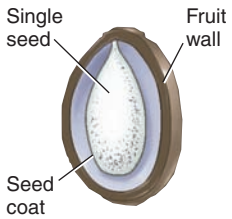
Berry (simple fruit)
A simple, fleshy fruit in which the fruit wall is soft throughout.
Tomato (*Lycopersicon lycopersicum*)



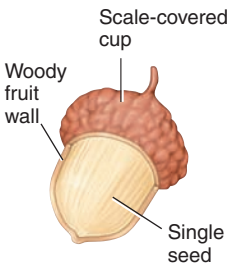
Drupe (simple fruit)
A simple, fleshy fruit in which the inner wall of the fruit is a hard stone.
Peach (*Prunus persica*)



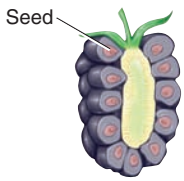
Follicle (simple fruit)
A simple, dry fruit that splits open along one suture to release its seeds; fruit is formed from ovary that consists of a single carpel.
Milkweed (*Asclepias syriaca*)



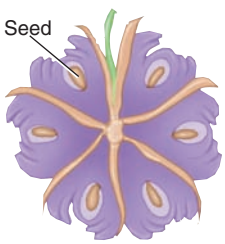
Legume (simple fruit)
A simple, dry fruit that splits open along two sutures to release its seeds; fruit is formed from ovary that consists of a single carpel.
Green bean (*Phaseolus vulgaris*)



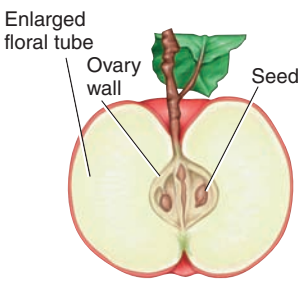
Capsule (simple fruit)
A simple, dry fruit that splits open along two or more sutures or pores to release its seeds; fruit is formed from ovary that consists of two or more carpels.
Iris (*Iris*)



Caryopsis (simple fruit)
A simple, dry fruit in which the fruit wall is fused to the seed coat.
Wheat (*Triticum*)



Achene (simple fruit)
A simple, dry fruit in which the fruit wall is separate from the seed coat.
Sunflower (*Helianthus annuus*)



Nut (simple fruit)
A simple, dry fruit that has a stony wall, is usually large, and does not split open at maturity.
Oak (*Quercus*)

Aggregate fruit
A fruit that develops from a single flower with several to many pistils (i.e., carpels are not fused into a single pistil).
Blackberry (*Rubus*)

Multiple fruit
A fruit that develops from the ovaries of a group of flowers.
Mulberry (*Morus*)

Accessory fruit
A fruit composed primarily of nonovarian tissue (such as the receptacle or floral tube).
Apple (*Malus sylvestris*)

Figure 37-10 Fruit types
Fruits are botanically classified into four groups—simple, aggregate, multiple, and accessory—based on their structure and mechanism of seed dispersal.

The little "hairs" on the blackberry are remnants of stigmas and styles. **(c)** Developing blackberry fruits at various stages of maturity.

ovaries may fuse to form a single fruit. Raspberries, blackberries, and magnolia fruits are examples of aggregate fruits.

A third type is the **multiple fruit**, formed from the ovaries of many flowers that grow in proximity on a common floral stalk. The ovary from each flower fuses with nearby ovaries as it develops and enlarges after fertilization. Pineapples, figs, and mulberries are multiple fruits.

Accessory fruits are the fourth type. They differ from other fruits in that plant tissues in addition to ovary tissue make up the fruit. For example, the edible portion of a strawberry is the red, fleshy receptacle. Apples and pears are also accessory fruits; the outer part of each of these fruits is an enlarged *floral tube*, consisting of receptacle tissue along with portions of the calyx, that surrounds the ovary (FIG. 37-12).

Seed dispersal is highly varied

Wind, animals, water, and explosive dehiscence disperse the various seeds and fruits of flowering plants (FIG. 37-13). Effective methods of seed dispersal have made it possible for certain plants to expand their geographic range. In some cases, the seed is the actual agent of dispersal; in others, the fruit performs this role. In

Figure 37-13 Seed (and fruit) dispersal

tumbleweeds, such as Russian thistle, the entire plant is the agent of dispersal because it detaches and blows across the ground, scattering seeds as it bumps along. Tumbleweeds are lightweight and are sometimes blown many kilometers by the wind.

Wind is responsible for seed dispersal in many plants. Plants such as maple trees have winged fruits adapted for wind dispersal. Light, feathery plumes enable other seeds or fruits to be transported by wind, often for considerable distances. Both dandelion fruits and milkweed seeds have this type of adaptation.

Some plants have special structures that aid in dispersal of their seeds and fruits by animals. The spines and barbs of burdock burs and similar fruits catch in animal fur and fall off as the animal moves about.

Fleshy, edible fruits are also adapted for animal dispersal. Birds, bats, primates, grazing ruminants, and ants are common dispersal agents. These animals are attracted to the fruit by its color, location, odor, and taste. As the animal eats these fruits, it either discards or swallows the seeds. Many seeds that are

swallowed have thick seed coats and are not digested; instead, they pass through the digestive tract and are deposited in the animal's feces some distance from the parent plant. In fact, some seeds do not germinate unless they have passed through an animal's digestive tract; the animal's digestive juices probably aid germination by helping break down the seed coat. Some edible fruits apparently contain chemicals that function as laxatives to speed seeds through an animal's digestive tract; the less time these seeds spend in the gut, the more likely they will germinate.

Animals such as squirrels and many bird species also help disperse acorns and other fruits and seeds by burying them for winter use. Many buried seeds are never used by the animal and germinate the following spring. Ants collect the seeds of many plants and take them underground to their nests. Ants disperse and bury seeds for hundreds of plant species in almost every terrestrial environment, from northern coniferous forests to tropical rain forests to deserts.

Both ants and flowering plants benefit from their association. The ants ensure the reproductive success of the plants whose seeds they bury, and the plants supply food to the ants. A seed that is collected and taken underground by ants often contains a special structure called an *elaiosome*, or *oil body*, that protrudes from the seed. Elaiosomes are a nutritious food for ants, which carry seeds underground before removing the elaiosome. Once an elaiosome is removed from a seed, the ants discard the undamaged seed in an underground refuse pile, which happens to be rich in organic material (such as ant droppings and dead ants) and minerals (inorganic nutrients) required by young seedlings. Thus, ants not only bury the seeds away from animals that might eat them but also place the seeds in rich soil that is ideal for germination and seedling growth.

The coconut is an example of a fruit adapted for dispersal by water. The coconut has air spaces that make it buoyant and capable of being carried by ocean currents for thousands of kilometers. When it washes ashore, the seed may germinate and grow into a coconut palm tree.

Some seeds are not dispersed by wind, animals, or water. Such seeds are found in fruits that use *explosive dehiscence*, in which the fruit bursts open suddenly and quite often violently, forcibly discharging its seeds. These fruits burst open due to pressure caused by differences in *turgor* (hydrostatic pressure) as the cells in the fruit dry out. The fruits of plants such as touch-me-not and bitter cress split open so explosively that seeds are scattered a meter or more.

CHECKPOINT 37.3

- What are the main stages of eudicot embryonic development?
- What is a fruit?
- How are the following fruits distinguished: simple, aggregate, multiple, and accessory?
- What are some characteristics of animal-dispersed seeds and fruits?

37.4 Germination and Early Growth

LEARNING OBJECTIVE

9 Summarize the influence of internal and environmental factors on the germination of seeds.

In flowering plants, pollination and fertilization are followed by seed and fruit development. Each seed develops from an ovule and contains an embryonic plant and food to provide nourishment for the embryo during germination. **Germination**—the process of a seed sprouting—and the growth of young seedlings into mature plants are aspects of growth and development. Within a given species, the precise requirements for seed germination represent evolutionary adaptations that protect the young seedlings from adverse environmental conditions. Environmental cues, such as the presence of water and oxygen, proper temperature, and sometimes the presence of light penetrating the soil surface, influence whether or not a seed germinates.

No seed germinates unless it has absorbed water. The embryo in a mature seed is dehydrated, and a watery environment is necessary for active metabolism. When a seed germinates, its metabolic machinery is turned on, and numerous materials are synthesized and others degraded. Therefore, water is an absolute requirement for germination. The absorption of water by a dry seed is **imbibition**. As a seed imbibes water, it often swells to several times its original, dry size (FIG. 37-14). Cells imbibe water by adhesion of water onto and into materials such as cellulose, pectin, and starches within the seed.

Germination and subsequent growth require a great deal of energy. Because young plants obtain this energy by converting the energy of food molecules stored in the seed's endosperm or cotyledons to ATP during aerobic respiration, much oxygen is usually needed during germination. (Some plants, such as rice, grow in flooded soil where oxygen is absent and

Marion Lobstein

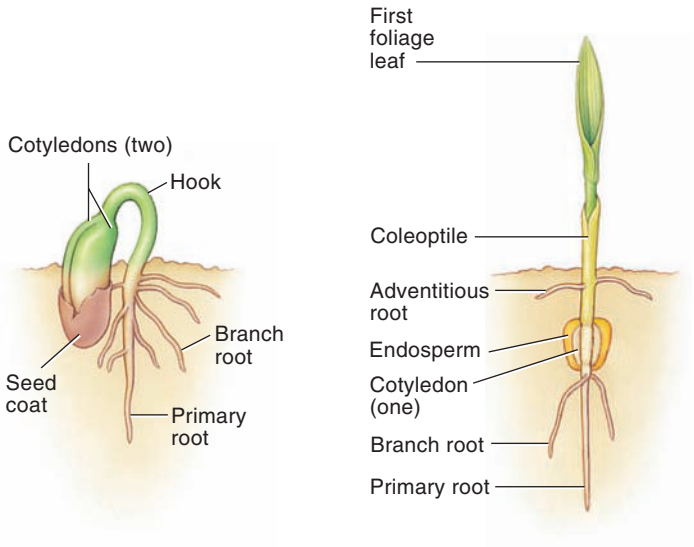
carry out *alcohol fermentation* during the early stages of germination and seedling growth.)

Temperature is another environmental factor that affects germination. Each species has an optimal, or ideal, temperature at which the germination percentage is highest. For most plants, the optimal germination temperature is between 25°C and 30°C (77°F and 86°F). Some seeds, such as those of apples, require prolonged exposure to low temperatures before their seeds break dormancy and germinate. Some of the environmental factors needed for germination help ensure the survival of the young plant. The requirement of a prolonged low-temperature period ensures that seeds adapted to temperate climates germinate in the spring rather than the fall.

Some plants, especially those with tiny seeds, such as lettuce, require light for germination. A light requirement ensures that a tiny seed germinates only if it is close to the soil surface. If such a seed were to germinate several centimeters below the soil surface, it might not have enough food reserves to grow to the surface. If this light-dependent seed remains dormant until the soil is disturbed and it is brought to the surface, however, it has a much greater likelihood of survival.

Some seeds do not germinate immediately



A mature seed is often dormant and may not germinate immediately even if growing conditions are ideal. In certain seeds, internal factors, which are under genetic control, prevent germination even when all external conditions are favorable. Many seeds are dormant because certain chemicals are present or absent or because the seed coat restricts germination. For example, the seeds of many desert plants contain high concentrations of *abscisic acid* (discussed in Chapter 38), which inhibits germination under unfavorable conditions. Abscisic acid is washed out only when rainfall is sufficient to support the plant's growth after the seed germinates.

Some seeds, such as certain legumes, have extremely hard, thick seed coats that prevent water and oxygen from entering, thereby inducing dormancy. *Scarification*, the process of scratching or scarring the seed coat (physically with a knife or chemically with an acid) before sowing it, induces germination in these plants. Scarification in nature occurs, for example, when these seeds pass through the digestive tracts of animals or when the seed coats are partially digested by soil bacteria.

Eudicots and monocots exhibit characteristic patterns of early growth

Once conditions are right for germination, the first part of the plant to emerge from the seed is the radicle, or embryonic root. As the root grows and forces its way through the soil, it encounters considerable friction from soil particles. A root cap protects the delicate apical meristem of the root tip.

The shoot (the stem with its leaves and reproductive structures) is next to emerge from the seed. Stem tips are not protected by a structure comparable to a root cap, but plants have ways to protect the delicate stem tip as it grows through the soil to the surface. The stem of a bean seedling (a eudicot), for instance, curves over to form a hook so that the stem tip and cotyledons are actually *pulled* up through the soil (FIG. 37-15a). Corn and other grasses (monocots) have a special sheath of cells called a **coleoptile** that surrounds and protects the young shoot (FIG. 37-15b). First, the coleoptile pushes up through the soil, and then the leaves and stem grow through the tip of the coleoptile.

(a) Common bean, a eudicot. The hook in the stem protects the delicate stem tip as it grows through the soil. Once the shoot emerges from the soil, the hook straightens.

(b) Corn, a monocot. The coleoptile, a sheath of cells, emerges first from the soil. The shoot and leaves grow through the middle of the coleoptile.

- **CONNECT** How does early seedling development differ in eudicots and monocots?

37.5 Asexual Reproduction in Flowering Plants

LEARNING OBJECTIVES

10 Explain how the following structures may be used to propagate plants asexually: rhizomes, tubers, bulbs, corms, stolons, plantlets, and suckers.

11 Define *apomixis*.

Flowering plants have many kinds of asexual reproduction, several of which involve modified stems: rhizomes, tubers,

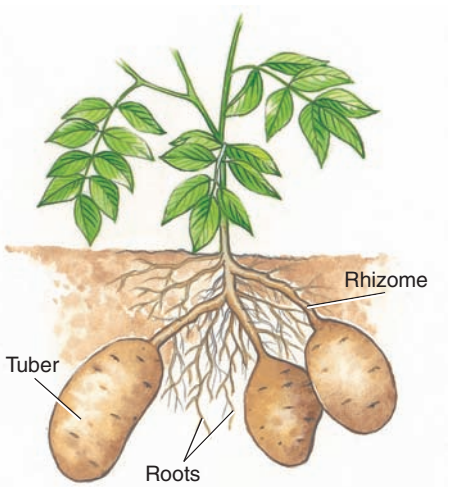
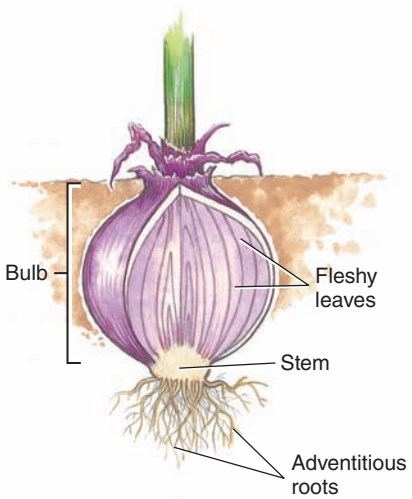
Copyright 2019 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

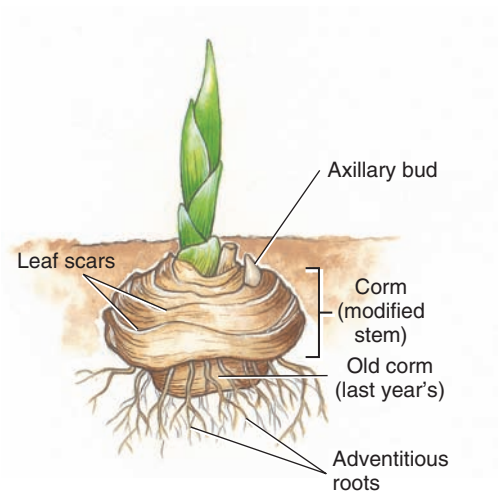


bulbs, corms, and stolons. A **rhizome** is a horizontal underground stem that may or may not be fleshy. Fleshiness indicates that the rhizome is used for storing food materials, such as starch (FIG. 37-16a). Although rhizomes resemble roots, they are actually stems, as indicated by the presence of scalelike leaves, buds, nodes, and internodes. (Roots have none of these features.) Rhizomes frequently branch in different directions. Over time, the old portion of the rhizome dies, and the two branches eventually separate to become distinct plants. Irises, bamboos, ginger, and many grasses are examples of plants that reproduce asexually by forming rhizomes.

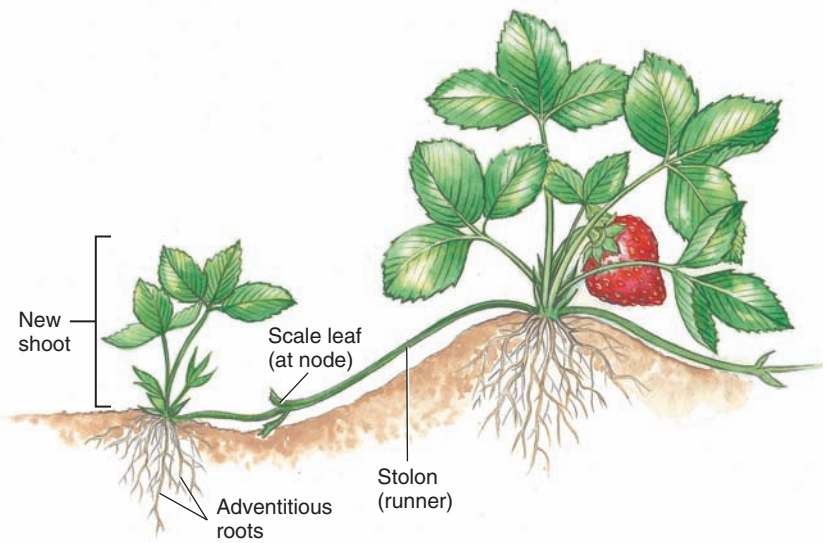
Some rhizomes produce greatly thickened ends called **tubers**, which are fleshy underground stems enlarged for food storage. When the attachment between a tuber and its parent plant breaks, often as a result of the death of the parent plant, the tuber grows into a separate plant. Potatoes and elephant's ear (*Caladium*) are examples of plants that produce tubers (FIG. 37-16b). The "eyes" of a potato are axillary buds, evidence that the tuber is an underground stem rather than a storage root such as a sweet potato or carrot.



A **bulb** is a modified underground bud in which fleshy storage leaves are attached to a short stem (FIG. 37-16c). A bulb



(a) Rhizome. Irises have horizontal underground stems called rhizomes. New aerial shoots arise from buds that develop on the rhizome.



(b) Tuber. Potato plants form rhizomes, which enlarge into tubers (the potatoes) at the ends.

(c) Bulb. A bulb is a short underground stem to which overlapping, fleshy leaves are attached; most of the bulb consists of leaves.

(d) Corm. A corm is an underground stem that is almost entirely stem tissue surrounded by a few papery scales.

(e) Stolon. Strawberries reproduce asexually by forming stolons, or runners. New plants (shoots and roots) are produced at every other node.

Figure 37-16 Modified stems

Copyright 2019 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in

Copyright 2019 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

is globose (round) and covered by paperlike bulb scales, which are modified leaves. It frequently forms axillary buds that develop into small daughter bulbs (bulblets). These new bulbs are initially attached to the parent bulb, but when the parent bulb dies and rots away, each daughter bulb can become established as a separate plant. Lilies, tulips, onions, and daffodils are some plants that form bulbs.

A **corm** is a short, erect underground stem that superficially resembles a bulb (FIG. 37-16d). Unlike the bulb, whose food is stored in underground leaves, the corm's storage organ is a thickened underground stem covered by papery scales (modified leaves). Axillary buds frequently give rise to new corms; the death of the parent corm separates these daughter corms, which then become established as separate plants. Familiar garden plants that produce corms include crocus, gladiolus, and cyclamen.

Stolons, or **runners**, are horizontal aboveground stems that grow along the surface and have long internodes (FIG. 37-16e). Buds develop along the stolon, and each bud gives rise to a new shoot that roots in the ground. When the stolon dies, the daughter plants live separately. The strawberry plant produces stolons.

Some plants form detachable *plantlets* (small plants) in notches along their leaf margins. *Kalanchoe*, whose common name is "mother of thousands," has meristematic tissue that gives rise to an individual plantlet at each notch in the leaf (FIG. 37-17). When these plantlets reach a certain size, they drop to the ground, root, and grow.

Some plants reproduce asexually by producing **suckers**, aboveground shoots that develop from adventitious buds on roots (FIG. 37-18). Each sucker grows additional roots and becomes an independent plant when the parent plant dies. Examples of plants that form suckers are black locust, pear, apple, cherry, blackberry, and aspen. A quaking aspen (*Populus tremuloides*) colony in the Wasatch Mountains of Utah contains at least 47,000 tree trunks formed from suckers that can be traced back to a single individual; this massive "organism" occupies almost 43 hectares (106 acres). Some weeds, such as field bindweed, produce many suckers. These plants are difficult to control because pulling the plant out of the soil seldom removes all the roots, which can grow as deep as 3 m (10 ft). In fact, in response to wounding, the roots produce additional suckers, which can be a considerable nuisance to humans.

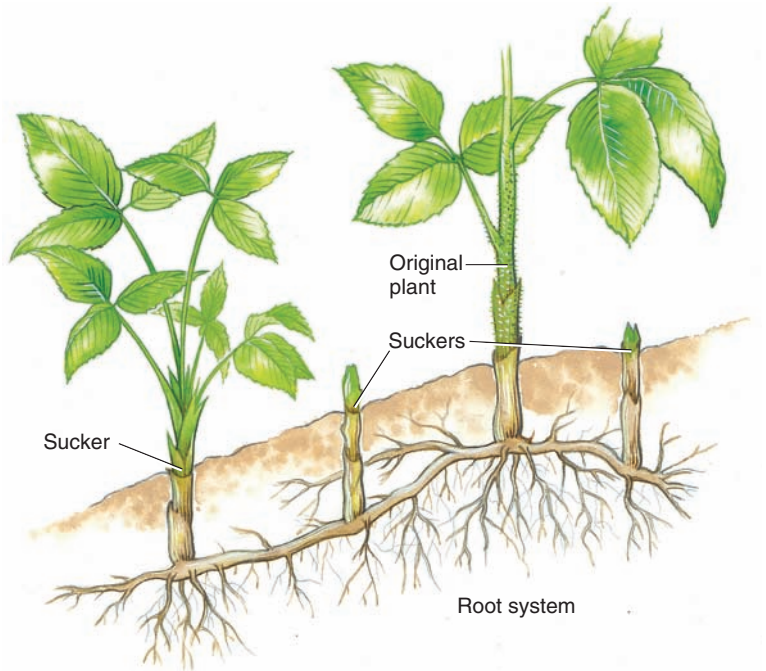


Figure 37-18 Suckers in various stages of development
All the suckers are connected to one another through the root system.

Jerome Wexler/Science Source

Figure 37-17 Plantlets
The "mother of thousands" (*Kalanchoe*) produces detachable plantlets along the margins of its leaves. The young plantlets drop off and root in the ground.

Apomixis is the production of seeds without the sexual process

Some flowering plants produce embryos in seeds without meiosis and the fusion of gametes. Seed production by **apomixis** is a form of asexual reproduction in which the offspring are maternal clones. For example, an embryo may develop from a diploid cell in the ovule rather than from a diploid zygote that forms from the union of two haploid gametes. Because there is no fusion of gametes, the embryo is virtually genetically identical to the maternal genotype. However, the advantage of apomixis over other methods of asexual reproduction is that the seeds and fruits produced by apomixis can be dispersed by methods associated with sexual reproduction.

Apomixis, which occurs in various species of more than 40 angiosperm families, is often found in plants that are polyploid with varying degrees of sterility. Apomixis allows these sterile plants to reproduce and therefore survive. Examples of

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

plants that can reproduce by apomixis are dandelions, citrus trees, mango, blackberries, garlic, and certain grasses.

Plant biologists are actively engaged in identifying the genes involved in asexual reproduction by apomixis. For example, it has been demonstrated that mutation of a single gene in *Arabidopsis* can result in production of diploid female gametes, a first step toward apomixis. If researchers can transfer this or similar genes to crop plants that possess superior traits such as high yield, they may be able to develop apomictic crop plants whose traits do not get lost or diluted during the genetic shuffling of sexual reproduction.

CHECKPOINT 37.5

- How are rhizomes and tubers involved in asexual reproduction?
- **CONNECT** How are corms and bulbs similar? How are they different?
- What is apomixis? How is the ability to reproduce by apomixis advantageous compared with other forms of asexual reproduction?

37.6 A Comparison of Sexual and Asexual Reproduction

LEARNING OBJECTIVE

12 State the differences between sexual reproduction and asexual reproduction, and discuss the evolutionary advantages and disadvantages of each.

Sexual reproduction and asexual reproduction are suited for different environmental circumstances. As you know, sexual reproduction results in offspring that are genetically different from the parents; that is, the parental genotypes are not preserved in the offspring. This genetic diversity of offspring may be selectively advantageous, particularly in an unstable, or changing, environment. (We define *environment* broadly to include all external conditions, both living and nonliving, that affect an organism.) If a plant species that reproduces sexually (and is therefore genetically diverse) is exposed to increasing annual temperatures as a result of climate change, for example, some of the individuals may be more fit than the parents or other offspring. The genetic diversity from sexual reproduction may also let the individuals of a species exploit new environments, thereby expanding their range.

You have seen that asexual reproduction results in offspring that are virtually genetically identical to the parent; that is, the parental genotype is preserved. Assuming that the parent is well adapted to its environment (i.e., the parent has a favorable combination of alleles), this genetic similarity may be selectively advantageous if the environment remains stable (unchanging) for several generations. None of the offspring of asexual reproduction is more fit than the parent, but neither is any less fit.

Despite the apparent advantages of asexual reproduction, most plant species whose reproduction is primarily asexual occasionally reproduce sexually. Even in what appears to be a stable environment, plants are exposed to changing selective pressures, such as changes in the number and kinds of herbivores and parasites, the availability of food, competition from other species, and climate. Sexual reproduction permits species whose reproduction is primarily asexual to increase their genetic variability so that at least some individuals are adapted to the changing selective pressures in a stable environment.

Sexual reproduction has some disadvantages

Although the genetic diversity produced by sexual reproduction is advantageous to a species' long-term survival, sexual reproduction is a costly form of reproduction. Sexual reproduction requires both male and female gametes, which must meet for reproduction to occur. The many adaptations of flowers for different modes of pollination represent one cost of sexual reproduction.

Sexual reproduction produces some individuals with genotypes that are well-adapted to the environment, but it also produces some individuals that are less well-adapted. Therefore, sexual reproduction is usually accompanied by high death rates among offspring, particularly when selective pressures are strong. (As discussed in Chapter 18, however, this aspect of sexual reproduction is an important part of evolution by natural selection.)

Every biological process involves trade-offs, and sexual reproduction is no exception. Although sexual reproduction has its costs, it also has adaptive advantages over asexual reproduction.

CHECKPOINT 37.6

- How does sexual reproduction in plants differ from asexual reproduction?
- **CONNECT** What is an adaptive advantage of sexual reproduction? Why is sexual reproduction considered costly?

Summary: Focus on Learning Objectives

37.1 The Flowering Plant Life Cycle *(page 783)*

1 Describe the functions of each part of a flower.

- **Sepals** cover and protect the flower parts when the flower is a bud. **Petals** play an important role in attracting animal pollinators to the flower.
- **Stamens** produce pollen grains. Each stamen consists of a thin stalk (the **filament**) attached to a saclike structure (the **anther**).
- The **carpel** is the female reproductive unit. A **pistil** may consist of a single carpel or a group of fused carpels. Each pistil has three sections: a **stigma**, on which the pollen grains land; a **style**, through which the pollen tube grows; and an **ovary** that contains one or more **ovules**.

2 Identify where eggs and pollen grains are formed within the flower.

- **Pollen grains** form within pollen sacs in the anther.
- An egg and two **polar nuclei**, along with several other nuclei, are formed in the ovule. Both egg and polar nuclei participate directly in fertilization.

37.2 Pollination *(page 786)*

3 Compare the evolutionary adaptations that characterize flowers pollinated in different ways (by insects, birds, and bats).

- Flowers pollinated by insects are often yellow or blue and have a scent. Bird-pollinated flowers are often yellow, orange, or red and do not have a strong scent. Bat-pollinated flowers often have white petals and are scented.

4 Define *coevolution* and give examples of ways that plants and their animal pollinators have affected each other's evolution.

- **Coevolution** is reciprocal adaptation caused by two different species (such as flowering plants and their animal pollinators) forming an interdependent relationship and affecting the course of each other's evolution. For example, flowers with large, showy petals and scent have evolved in some plants, whereas hairy bodies that catch and hold sticky pollen grains have evolved in bees.

37.3 Fertilization and Seed and Fruit Development *(page 789)*

5 Distinguish between pollination and fertilization.

- **Pollination** is the transfer of pollen grains from anther to stigma. After pollination, **fertilization**, the fusion of gametes, occurs.
- Flowering plants undergo **double fertilization**. The egg fuses with one sperm cell, forming a zygote (fertilized egg) that eventually develops into a multicellular embryo in the **seed**. The two polar nuclei fuse with the second sperm cell, forming a triploid nutritive tissue called **endosperm**.

6 Trace the stages of embryo development in flowering plants and list and define the main parts of seeds.

- A eudicot embryo develops in the seed in an orderly fashion, from proembryo to globular embryo to the heart stage to the torpedo stage.
- A mature seed contains both a young plant embryo and nutritive tissue—stored in the endosperm or in the **cotyledons** (seed leaves)—for use during germination. A tough, protective **seed coat** surrounds the seed.

7 Explain the relationships among ovules, ovaries, seeds, and fruits.

- Ovules are structures with the potential to develop into seeds, whereas ovaries are structures with the potential to develop into fruits. Seeds are enclosed within **fruits**, which are mature, ripened ovaries.

8 Distinguish among simple, aggregate, multiple, and accessory fruits.

- **Simple fruits** develop from a single ovary that consists of one carpel or several fused carpels. **Aggregate fruits** develop from a single flower with many separate ovaries. **Multiple fruits** develop from the ovaries of many flowers growing in close proximity on a common axis. In **accessory fruits**, the major part of the fruit consists of tissue other than ovary tissue.

37.4 Germination and Early Growth *(page 796)*

9 Summarize the influence of internal and environmental factors on the germination of seeds.

- **Germination** is the process of seed sprouting. Internal factors affecting whether a seed germinates include the maturity of the embryo; the presence or absence of chemical inhibitors; and the presence or absence of hard, thick seed coats.
- External environmental factors that may affect germination include requirements for oxygen, water, temperature, and light.

37.5 Asexual Reproduction in Flowering Plants *(page 797)*

10 Explain how the following structures may be used to propagate plants asexually: rhizomes, tubers, bulbs, corms, stolons, plantlets, and suckers.

- A **rhizome** is a horizontal underground stem. A **tuber** is a fleshy underground stem enlarged for food storage. A **bulb** is a modified underground bud with fleshy storage leaves attached to a short stem. A **corm** is a short, erect underground stem covered by papery scales. A **stolon** is a horizontal aboveground stem with long internodes.
- Some leaves have meristematic tissue along their margins and give rise to detachable *plantlets*.
- Roots may develop adventitious buds that develop into **suckers**. Suckers produce additional roots and may give rise to new plants.

11 Define *apomixis*.

- **Apomixis** is the production of seeds and fruits without sexual reproduction.

37.6 A Comparison of Sexual and Asexual Reproduction *(page 800)*

12 State the differences between sexual reproduction and asexual reproduction, and discuss the evolutionary advantages and disadvantages of each.

- Sexual reproduction involves the union of two gametes; the offspring produced by sexual reproduction are genetically variable. Asexual reproduction involves the formation of offspring without the fusion of gametes; the offspring are virtually genetically identical to the single parent.

Copyright 2019 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

- Genetic diversity among offspring produced by sexual reproduction may let certain individuals survive in a changing environment or exploit new environments. Sexual reproduction is costly because both male and female gametes must be produced and must meet.
- Genetic similarity among offspring produced by asexual reproduction may be advantageous if the environment is stable. Most plant species whose reproduction is primarily asexual occasionally reproduce sexually, thereby increasing their genetic variability.

Test Your Understanding

Know and Comprehend

1. The normal order of whorls from the flower's periphery to the center is (a) sepals, petals, carpels, stamens (b) stamens, carpels, sepals, petals (c) sepals, petals, stamens, carpels (d) petals, carpels, stamens, sepals (e) carpels, stamens, petals, sepals
2. A pistil consists of (a) stigma, style, and stamen (b) anther and filament (c) sepal and petal (d) stigma, style, and ovary (e) radicle, hypocotyl, and plumule
3. The transfer of pollen grains from anther to stigma is (a) fertilization (b) double fertilization (c) pollination (d) germination (e) apomixis
4. The observation that insects with long mouthparts pollinate long, tubular flowers and insects with short mouthparts pollinate flowers with short corollas is explained by (a) coevolution (b) germination (c) double fertilization (d) apomixis (e) explosive dehiscence
5. The process of _____ in flowering plants involves one sperm cell fusing with an egg cell and one sperm cell fusing with two polar nuclei. (a) coevolution (b) germination (c) double fertilization (d) apomixis (e) pollination
6. The nutritive tissue in the seeds of flowering plants that is formed from the union of a sperm cell and two polar nuclei is called the (a) plumule (b) endosperm (c) cotyledon (d) hypocotyl (e) radicle
7. After fertilization, the ovule develops into a _____, and the ovary develops into a _____ (a) fruit; seed (b) seed; fruit (c) calyx; corolla (d) corolla; calyx (e) follicle; legume
8. In plants that lack endosperm in their mature seeds, the cotyledons function to (a) enclose and protect the seed (b) aid in seed dispersal (c) serve as an absorptive embryonic root (d) store food reserves (e) attach the embryo within the ovule
9. _____ fruits develop from many ovaries of a single flower, whereas _____ fruits develop from the ovaries of many separate flowers. (a) multiple; accessory (b) simple; accessory (c) aggregate; multiple (d) accessory; aggregate (e) simple; multiple
10. A horizontal underground stem that may or may not be fleshy and that is often specialized for asexual reproduction is called a (a) stolon (b) bulb (c) corm (d) rhizome (e) tuber

Apply and Analyze

11. Place the following events in the correct order: 1. pollen tube grows into ovule 2. insect lands on flower to drink nectar 3. embryo develops within the seed 4. fertilization occurs 5. pollen carried by insect contacts stigma (a) 2, 5, 1, 4, 3 (b) 1, 4, 2, 5, 3 (c) 3, 2, 5, 1, 4 (d) 5, 1, 3, 4, 2 (e) 2, 5, 4, 3, 1
12. **VISUALIZE** Draw a simple sketch of a eudicot flower with a single pistil and label a petal, anther, ovule, stigma, ovary, filament, stamen, style, and sepal.
13. **VISUALIZE** Sketch the kinds of flowers that form simple, aggregate, multiple, and accessory fruits.

Evaluate and Synthesize

14. Using what you have learned in this chapter, speculate whether it is more likely that offspring of asexual reproduction develop in close proximity to or widely dispersed from the parent plant. Explain your reasoning. How could you test your hypothesis?
15. Which type of reproduction, sexual or asexual, might be more beneficial in the following circumstances and why? (a) a perennial (plant that lives more than two years) in a stable environment (b) an annual (plant that lives one year) in a rapidly changing environment (c) a plant adapted to an extremely narrow climate range
16. **EVOLUTION LINK** Is seed dispersal by ants an example of coevolution? Why or why not?
17. **SCIENCE, TECHNOLOGY, AND SOCIETY** What is the value to society of research on genes that control flowering? on those that control seed germination?

38 Plant Developmental Responses to External and Internal Signals

The ultimate control of plant growth and development, which includes all the changes that take place during the entire life of an individual, is genetic. If the genes required for development of a particular trait, such as the shape of a leaf, the color of a flower, or the type of root system, are not present, that characteristic does not develop. When a particular gene is present, its expression—that is, how it exhibits itself as an observable feature of an organism—is determined by several factors, including regulatory signals from other genes and from the environment. The location of a cell in the young plant body also has a profound effect on gene expression during development. Chemical signals from adjacent cells help a cell "perceive" its location within the plant body. Each cell's spatial environment helps determine what that cell ultimately becomes.

Growth and development, including a plant's responses to various changes in its environment, are controlled by plant *hormones*, organic molecules that are present in very low concentrations in plant tissues and that act as chemical signals between cells. Environmental cues, such as changing day length and variations in precipitation and temperature, exert an important influence on gene expression and hormone production, as they do on all aspects of plant growth and development.

For example, the initiation of sexual reproduction is often under environmental control, particularly in temperate latitudes, and plants switch from vegetative to reproductive growth after receiving appropriate signals from the environment. Many flowering plants are sensitive to changes in the relative amounts of daylight and darkness that accompany the changing seasons,

KEY CONCEPTS

38.1 A plant may respond to an external stimulus, such as light, gravity, or touch, by a tropism, a directional growth response. Study of tropisms has helped biologists elucidate links between the external environment and internal signals such as hormones.

38.2 Hormones are chemical signals responsible for coordinating and regulating many aspects of plant development. Although there are many plant hormones, six have been well characterized: auxins, gibberellins, cytokinins, ethylene, abscisic acid, and brassinosteroids.

38.3 Plants have different receptors that detect various colors of light. Phytochrome detects red light and far-red light, which affect several aspects of development, including the timing of flowering.

38.4 The exposure of a plant to a pathogen or herbivore causes a localized hypersensitive response that seals off the affected area. The plant also sends signals from the site of localized infection, leading to systemic acquired resistance and long-lasting, enhanced defenses throughout the plant.

and these plants flower in response to those changes (see photograph). In this chapter we will see that plants use light as an external signal to help regulate many aspects of growth and development, such as tropisms (directional growth), time of flowering, shade avoidance, and circadian rhythms.

Other plants have temperature requirements that induce sexual reproduction. Thus, plants continually perceive information from the environment and use this information to help regulate normal growth and development. We consider these various aspects of growth and development in this chapter.

38.1 Tropisms

LEARNING OBJECTIVE

1 Describe phototropism, gravitropism, and thigmotropism.

Plants exhibit movements in response to environmental stimuli such as light, gravity, and touch. A plant may respond to such an external stimulus by directional growth; that is, the direction of growth depends on the direction of the stimulus. Such a directional growth response, called a **tropism**, results in a change in the position of a plant part. Tropisms are irreversible and may be positive or negative, depending on whether the plant grows toward the stimulus (a positive tropism) or away from it (a negative tropism). Tropisms are under hormonal control, which is discussed later in the chapter.

Phototropism is the directional growth of a plant caused by light (FIG. 38-1). Most growing shoot tips exhibit positive phototropism by bending (growing) toward light, something you may have observed if you place houseplants near a sunny window. This growth response increases the likelihood that stems and leaves receive adequate light for photosynthesis. The bending response of phototropism is triggered by blue light with wavelengths less than 500 nm. (You may recall from Chapter 34 that blue light also induces stomata to open.)

For a plant or any organism to have a biological response to light, it must contain a light-sensitive substance, called a *photoreceptor*, to absorb the light. The photoreceptor that absorbs blue light and triggers the phototropic response and other blue-light responses (such as stomatal opening) is a family of yellow pigments called **phototropins**. Phototropins are light-activated **kinases**, enzymes that transfer phosphate groups. There is evidence that phototropins become phosphorylated—that is, a phosphate group is added—in response to blue light. Thus, phosphorylation is an early step in the blue-light-signaling pathway.

Martin Shields/Alamy Stock Photo

Figure 38-1 Phototropism
A bean seedling (*Phaseolus vulgaris*) grows in the direction of light and therefore exhibits positive phototropism. The bending is caused by greater elongation on the shaded side of the stem than on the lighted side.

Growth in response to the direction of gravity is called **gravitropism**. Most stem tips exhibit negative gravitropism by growing away from Earth's center, whereas most root tips exhibit positive gravitropism (FIG. 38-2). The root cap is the site of gravity perception in roots; when the root cap is removed, the root continues to grow, but it loses any ability to perceive gravity. Special cells in the root cap possess starch-containing **amyloplasts** (see Fig. 3-9a) that collect toward the bottom of the cells in response to gravity, and these amyloplasts may initiate at least some of the gravitropic response. If the root

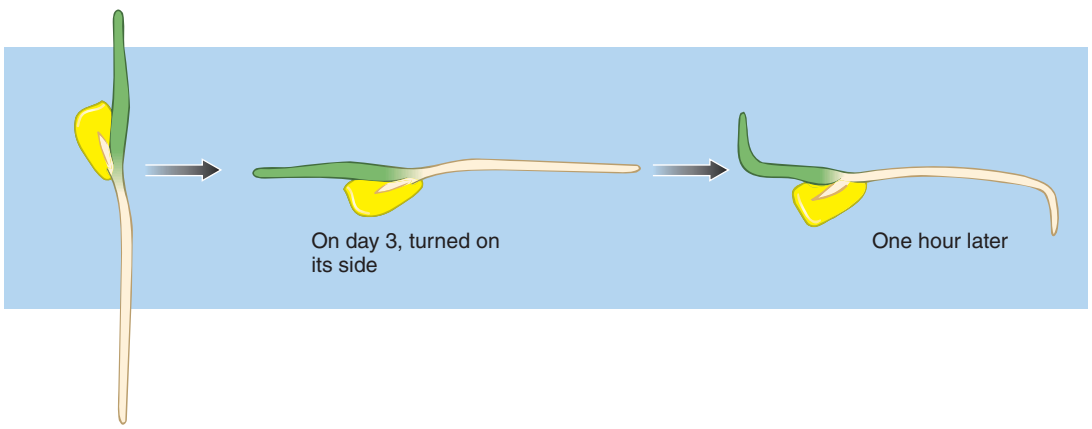

Figure 38-2 Gravitropism
A corn (*Zea mays*) seedling was turned on its side three days after germinating. In 1 hour the root and shoot tips had curved.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

is put in a different position, as when a potted plant is laid on its side, the amyloplasts tumble to a new position, always settling in the direction of gravity. The gravitropic response (bending) occurs shortly thereafter and involves the hormone *auxin* (discussed later in the chapter).

Despite the movement of amyloplasts in response to gravity, researchers question their role in gravitropism. A mutant *Arabidopsis thaliana* plant that lacks amyloplasts in its root cap cells still responds gravitropically when placed on its side, indicating that roots do not necessarily need amyloplasts to respond to gravity. Ongoing research may clarify how roots perceive gravity.

Thigmotropism is growth in response to a mechanical stimulus, such as contact with a solid object. The twining or curling growth of tendrils or stems, which helps attach a climbing plant such as a vine to some type of support, is an example of thigmotropism (see Fig. 34-14b).

CHECKPOINT 38.1

- **CONNECT** How does the yellow color of phototropins relate to the wavelengths of light to which they respond?
- How do phototropism, gravitropism, and thigmotropism differ?

38.2 Plant Hormones and Development

LEARNING OBJECTIVES

2 Describe a general mechanism of action for plant hormones, using auxin as your example.
3 Describe early auxin experiments involving phototropism.
4 List several ways that each of these hormones affects plant growth and development: auxins, gibberellins, cytokinins, ethylene, abscisic acid, and brassinosteroids.

A plant **hormone** is an organic compound that acts as a chemical signal eliciting a variety of responses that regulate growth and development. The study of plant hormones is challenging because hormones are effective in extremely small concentrations (less than 10^{-6} mol/L). In addition, the effects of different plant hormones overlap, and it is difficult to determine which hormone, if any, is the primary cause of a particular response. Plant hormones may also stimulate a response at one concentration and inhibit that same response at a different concentration.

For many years, biologists studied five major classes of plant hormones: auxins, gibberellins, cytokinins, ethylene, and abscisic acid. More recently, researchers have uncovered compelling evidence for brassinosteroids as a sixth plant hormone. Additional plant hormones will probably be characterized in the future. (TABLE 38-1 summarizes the six plant hormones.)

Plant hormones act by signal transduction

Researchers have used molecular genetic techniques to better understand the biology of plant hormones. *Arabidopsis* mutants are particularly useful. For example, different mutants have defects in hormone synthesis, hormone transport, signal reception, or signal transduction (FIG. 38-3). In **signal transduction** a receptor converts an extracellular signal into an intracellular signal that causes one or more cellular responses.

Such mutants enable plant biologists to identify and clone genes involved in these aspects of hormone biology. Studying the mutant phenotypes helps plant biologists establish connections between the mutant genes and specific physiological activities involved in growth and development. Using this research, biologists are elucidating the general mechanisms of plant hormone action, an important goal of systems biology.

As discussed in Chapter 6, it appears that many plant hormones bind to *enzyme-linked receptors*; the hormone binds to the receptor, where it triggers an enzymatic reaction of some sort. Let us consider a specific example that involves the plant

Table 38-1 Plant Hormones

Hormone	Site of Production	Principal Actions
Auxins (e.g., IAA)	Shoot apical meristem, young leaves, seeds	Stem elongation, apical dominance, root initiation, fruit development
Gibberellins	Young leaves and shoot apical meristems, embryo in seed	Seed germination, stem elongation, flowering, fruit development
Cytokinins (e.g., zeatin)	Various sites in plants	Cell division, delay of leaf senescence, inhibition of apical dominance, flower development, embryo development, seed germination
Ethylene	Stem nodes, ripening fruit, damaged or senescing tissue	Fruit ripening, responses to environmental stressors, seed germination, maintenance of apical hook on seedlings, root initiation, senescence and abscission in leaves and flowers
Abscisic acid	Almost all cells that contain plastids (leaves, stems, roots)	Seed dormancy, responses to water stress
Brassinosteroids (e.g., brassinolide)	Shoots (leaves and flower buds), seeds, fruits	Light-mediated gene expression, cell division, cell elongation, seed germination, vascular development

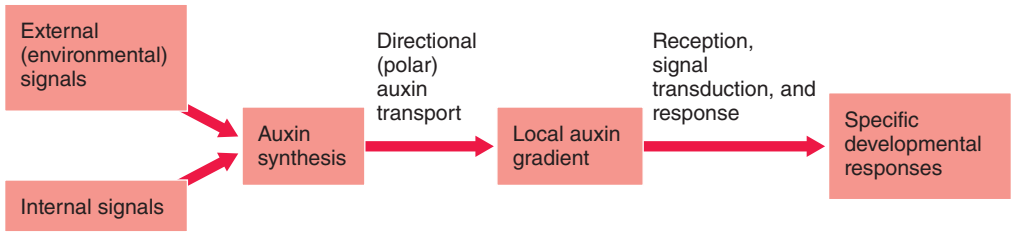

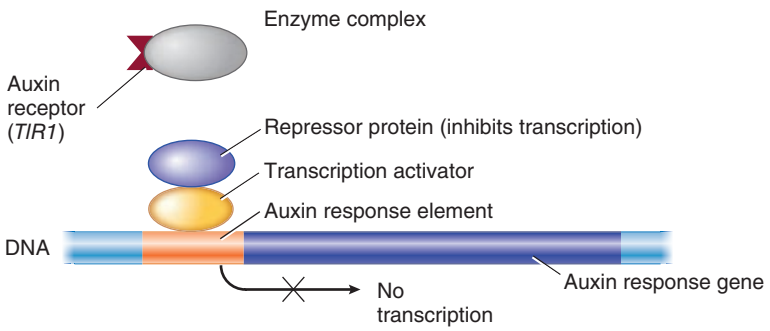

Figure 38-3 General mechanism of action for the hormone auxin

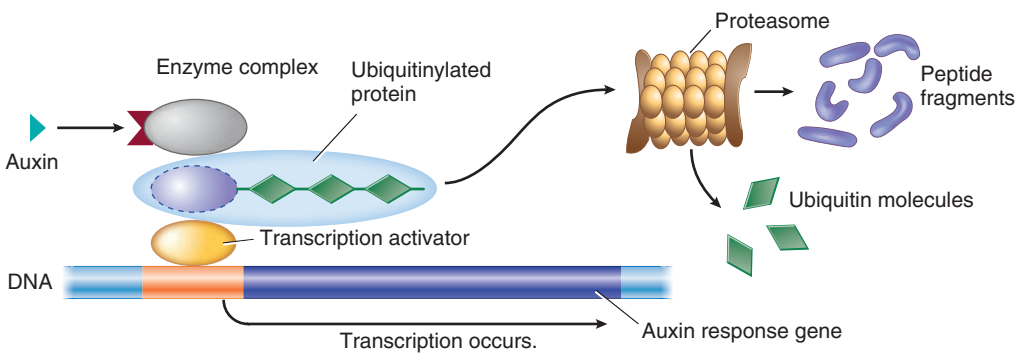
Various external and/or internal signals trigger the synthesis of auxin. Once synthesized, auxin is transported directionally, causing local auxin gradients to form in the plant. In turn, these gradients trigger specific developmental responses in certain cells by reception, signal transduction, and response (discussed shortly). *Arabidopsis* mutants have been identified with defects involving auxin synthesis, auxin transport, or other steps in the process.



hormone *auxin*, which is known to cause rapid changes in gene expression. One receptor for auxin is located in either the cytosol or the nucleus and has a three-dimensional shape that binds to the auxin molecule. The binding of auxin to its receptor (designated the *TIR1 receptor*) catalyzes the attachment of the molecule *ubiquitin* to repressor proteins that inhibit the transcription of certain genes, designated *auxin response genes* (FIG. 38-4).

The ubiquitinylated protein is therefore targeted for degradation into peptide fragments in a proteasome. (See Figure 14-17, which shows the ubiquitin–proteasome degradation of proteins.) As a result, transcription of the auxin response gene occurs, resulting in changes in cell growth and development.

The *TIR1* receptor for auxin is an *F-box protein*. The F-box is a short sequence of amino acids found in molecules that catalyze the addition of ubiquitin tags to proteins targeted for destruction. Interestingly, all animals, plants, and fungi examined to date use ubiquitin to target proteins for destruction, but bacteria do not, which suggests that the use of ubiquitin tags evolved early in

(a) Auxin absent. A repressor protein binds to a transcription activator, inhibiting transcription of the auxin response gene.

(b) Auxin present. Auxin binds to the *TIR1* receptor, which is part of an enzyme complex that attaches ubiquitin to the repressor protein. The ubiquitinylated repressor protein is then degraded into peptide fragments in a proteasome. With the repressor protein no longer bound to the transcription activator, transcription of the auxin response gene occurs.

Key Experiment

What part of the grass coleoptile depends on light for phototropic growth?

HYPOTHESIS: The coleoptile tip is required for the growth (bending) of the coleoptile shaft that accompanies exposure to light coming from one direction.

EXPERIMENT: Some canary grass coleoptiles were uncovered, some were covered only at the tip, some had the tip removed, and some were covered everywhere but at the tip (*left*). The covers were impervious to light.

RESULTS AND CONCLUSION: After exposure to light coming from one direction, the uncovered plants and the plants with uncovered tips grew toward the light (*right*). The plants with tips covered or removed did not bend toward light. The Darwins concluded that some substance was produced in the tip and transmitted to the lower part, causing it to bend.

SOURCES: C.R. Darwin, *The Power of Movement in Plants* (John Murray, London, 1880); P. Boysen-Jensen, "Concerning the Performance of Phototropic Stimuli on the *Avena* Coleoptile," *Berichte der Deutschen Botanischen Gesellschaft* (Reports of the German Botanical Society), Vol. 31 (1913): 559–566.

Figure 38-5 The Darwins' phototropism experiments

PREDICT Devise an experiment to test the hypothesis that a minimum period of light exposure is required to produce bending.

eukaryote evolution and was conserved as the various groups of eukaryotes diversified. Plants have more than 700 different F-box proteins. Although not much is known about most of them, it is significant that researchers have identified other plant hormones and signaling molecules that use F-box proteins as receptors, including gibberellin, ethylene, and abscisic acid.

Auxins promote cell elongation

Charles Darwin, the British naturalist best known for developing the scientific theory of natural selection to explain evolution, also provided the first evidence for the existence of auxins. The experiments that Darwin and his son Francis performed in the 1870s involved positive phototropism, the directional growth of plants toward light. The plants they used were newly germinated canary grass seedlings. As in all grasses, the first part of a canary grass seedling to emerge from the soil is the coleoptile, a protective sheath that encircles the stem. When coleoptiles are exposed to light from only one direction, they bend toward the light. The bending occurs below the tip of the coleoptile.

The Darwins tried to influence this bending in several ways (FIG. 38-5). For example, they covered the tip of the coleoptile as soon as it emerged from the soil. When they covered that part of the coleoptile above where the bend would be expected to occur, the plants did not bend. On other plants, they removed the coleoptile tip and found that bending did not occur. When the bottom of the coleoptile where the curvature would occur was shielded from the light, the coleoptile bent toward light. From these experiments, the Darwins concluded that "some influence is transmitted from the upper to the lower part, causing it to bend."

In the 1920s, Frits Went, a young Dutch scientist, isolated the phototropic hormone from oat coleoptiles. He removed the coleoptile tips and placed them on tiny blocks of agar for a period of time. When he put one of these agar blocks squarely on a decapitated coleoptile, normal growth resumed. When he placed one of these agar blocks to one side of the tip of a decapitated coleoptile in the dark, bending occurred (FIG. 38-6). The results indicated that the substance had diffused from the coleoptile tip into the agar and, later, from the agar into the decapitated coleoptile. Went named this substance **auxin** (from the Greek *aux*, "enlarge" or "increase").

Auxin is a group of several natural (and artificial) plant hormones; the most common and physiologically important auxin is **indoleacetic acid (IAA)**. The purification and elucidation of the primary auxin's chemical structure were accomplished in the mid-1930s by a research team led by Kenneth Thimann at the California Institute of Technology.

The movement of auxin in the plant is said to be *polar*, or unidirectional. Auxin moves downward along the shoot–root axis from its site of production, usually the shoot apical

Key Experiment

Is there a chemical substance responsible for elongation of coleoptiles, and can it be isolated?

HYPOTHESIS: The factor responsible for coleoptile growth is a diffusible chemical that can be isolated from coleoptile tips.

EXPERIMENT: Coleoptile tips were placed on agar blocks for a period of time **(a)**. The agar block was transferred to a decapitated coleoptile. It was placed off-center, and the coleoptile was left in darkness **(b)**.

RESULTS AND CONCLUSION: The coleoptile bent **(c)**, indicating that a chemical moved from the original coleoptile tip to the agar block and from there to the same side of the decapitated coleoptile, causing that side to elongate.

SOURCE: F. Went, "A Growth Substance and Growth," *Recueils Travaux Botaniques Néerlandais* (Collections of Dutch Botanical Works), Vol. 25 (1928: 1–116.

Figure 38-6 Isolating auxin from coleoptiles

PREDICT Devise an experiment to test the hypothesis that the auxin that has diffused into the agar blocks is sensitive to heat.

meristem. (Young leaves and seeds are also sites of auxin production.) This directional cell-to-cell transport results in an *auxin gradient* (a spatial difference in auxin concentration) that triggers specific responses. Special auxin transport proteins in the plasma membranes of plant cells control the movement of auxin out of cells; this process is responsible for the directional movement of auxin. Mutations in auxin transport proteins inhibit the transmission of auxin, which normally moves about 1 cm per hour.

Auxin's most characteristic action is promotion of cell elongation in stems and coleoptiles. This effect, apparently exerted by acidification of cell walls, increases their plasticity and thus enables them to expand under the force of the cell's internal turgor pressure. Auxin's effect on cell elongation also provides an explanation for phototropism. When a plant is exposed to a light from only one direction, some of the auxin migrates laterally to the shaded side of the stem before moving down the stem by polar transport. Because of the greater auxin concentration on the shaded side of the stem, the cells there elongate more than the cells on the light side, and the stem bends toward the light (FIG. 38-7). Auxin is also involved in gravitropism and thigmotropism.

Auxin exerts other effects on plants. For example, some plants tend to branch out very little when they grow. Growth in these plants occurs almost exclusively from the apical meristem rather than from axillary buds, which do not develop as long as the terminal bud is present. Such plants are said to exhibit **apical dominance**, the inhibition of axillary bud growth by the apical meristem. In plants with strong apical dominance, auxin produced in the apical meristem inhibits axillary buds near the apical meristem from developing into actively growing shoots. When the apical meristem is pinched off, the auxin source is removed, and axillary buds grow to form branches. Apical dominance is often quickly reestablished, however, as one branch begins to inhibit the growth of others. Other hormones (ethylene and cytokinin, both discussed later) are also involved in apical dominance. As with many physiological activities, the changing ratios of these hormones may be the factor responsible for apical dominance.

Auxin produced by developing seeds stimulates the development of the fruit. When auxin is applied to certain flowers

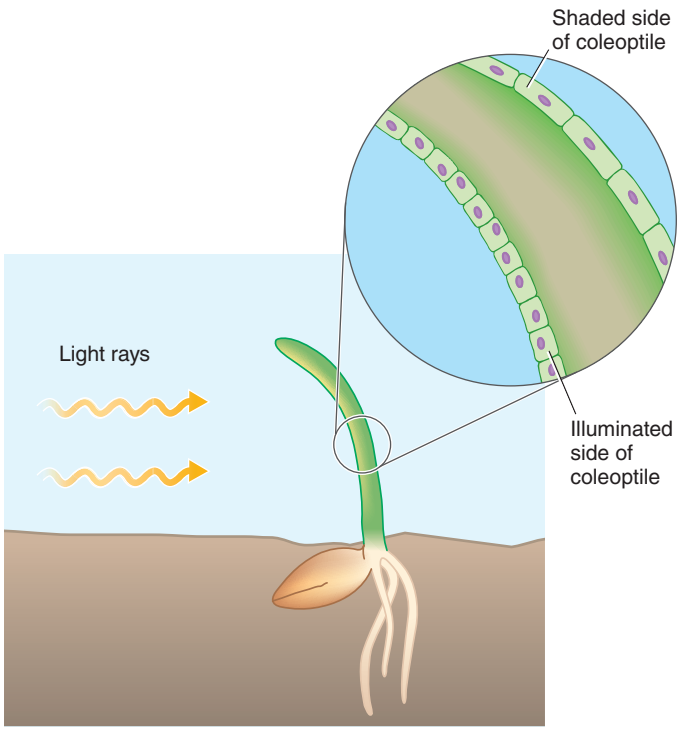

Figure 38-7 Phototropism and the unequal distribution of auxin

Auxin travels down the side of the stem or coleoptile *away* from the light, causing cells on the shaded side to elongate. Therefore, the stem or coleoptile bends toward light.

Joe Eakes, Color Advantage/Visuals Unlimited

Figure 38-8 Auxin and root development on stem cuttings
Many adventitious roots developed on a honeysuckle (*Lonicera fragrantissima*) cutting placed in a solution with a high concentration of synthetic auxin (*left*). Fewer roots developed in a lower auxin concentration (*middle*). The cutting placed in water (no auxin) served as a control and did not form roots in the same period (*right*).

in which fertilization has not occurred (and therefore in which seeds are not developing), the ovary enlarges and develops into a seedless fruit. Seedless tomatoes are produced in this manner.[1] Auxin is not the only hormone involved in fruit development, however.

Some manufactured, or synthetic, auxins have structures similar to that of IAA. The synthetic auxin naphthalene acetic acid stimulates root development on stem cuttings and is used for asexual propagation, particularly of woody plants with horticultural importance (FIG. 38-8). The synthetic auxins 2,4-D and 2,4,5-T have been used as selective herbicides (weed killers). These compounds kill plants with broad leaves but, for reasons not completely understood, do not kill grasses. Both herbicides are similar in structure to IAA and disrupt the plants' normal growth processes. Because many of the world's most important crops are grasses (such as wheat, corn, and rice), 2,4-D and 2,4,5-T can kill broadleaf weeds that compete with these crops. The use of 2,4,5-T is no longer allowed in the United States, however, because of its association with dioxins, a group of mildly to very toxic compounds formed as byproducts when 2,4,5-T is manufactured.

Gibberellins promote stem elongation

In the 1920s and 1930s, a Japanese biologist was studying a disease of rice in which the young rice seedlings grew extremely tall and spindly, fell over, and died. The cause of the disease was a fungus (*Gibberella fujikuroi*) that produces a chemical substance named **gibberellin (GA)**. Not until after World War II did scientists in Europe and North America learn of the work done by this Japanese scientist and others. During the 1950s and 1960s, studies in the United States and Great Britain showed that gibberellins are produced by healthy plants as well as by the fungus.

Gibberellins are hormones involved in many normal plant functions. The symptoms of the seedling disease are caused by an abnormally high GA concentration in the plant tissue (because both plant and fungus produce gibberellin). Currently, dozens of naturally occurring GAs are known, although only about four function as plant hormones; the rest are inactive precursors. There are no synthetic gibberellins.

Gibberellins promote stem elongation in many plants. When GA is applied to a plant, particularly certain dwarf varieties, this elongation may be spectacular. Some corn and pea plants that are dwarfs as a result of one or more mutations grow to a normal height when treated with GA. Short-stemmed, high-yielding varieties of wheat have short stems because they have a reduced response to GA. These varieties put less of their resources into stem height and more resources into grain production. Gibberellins are also involved in **bolting**, the rapid elongation of a floral stalk that occurs naturally in many plants when they initiate flowering (FIG. 38-9).

Gibberellins cause stem elongation by stimulating cells to divide as well as to elongate. The actual mechanism of cell elongation differs from that caused by auxin, however. Recall that IAA-induced cell elongation involves the acidification of the cell wall. In GA-induced cell elongation, cell wall acidification does not occur; biologists do not yet know how gibberellins modify cell wall properties to cause cell elongation.

Robert Lyons/Visuals Unlimited

Figure 38-9 Gibberellin and stem elongation
Like many biennials, Indian blanket (*Gaillardia pulchella*) grows as a rosette, which is a circular cluster of leaves close to the ground, during its first year (*left*). It then bolts when it initiates flowering in the second year (*right*). The plant in bloom grows to 0.6 m (2 ft).

[1] Not all seedless fruits are produced by treatment with auxin. In Thompson seedless grapes, fertilization occurs but the embryos abort; therefore, the seeds fail to develop. Thompson seedless grapes are sprayed with the hormone gibberellin to increase berry size.

Gibberellins affect several reproductive processes in plants. They stimulate flowering, particularly in long-day plants (discussed later in this chapter). In addition, GAs substitute for the low temperature that biennials require before they begin flowering. If GAs are applied to biennials during their first year of growth, flowering occurs without exposure to a period of low temperature. Gibberellins, like auxin, affect fruit development. Agriculturalists apply GAs to several varieties of grapes to produce larger fruits.

Gibberellins are also involved in seed germination in certain plants. In a classic experiment involving barley seed germination, researchers showed that the release of GA from the embryo triggers the synthesis of α-amylase, an enzyme that digests starch in the endosperm. As a result, glucose becomes available for absorption by the embryo. Although enzymes mobilize starch reserves in many types of seeds, GA control of seed enzymes appears restricted to cereals and other grasses. In addition to mobilizing food reserves in newly germinated grass seeds, application of gibberellins substitutes for low-temperature or light requirements for germination in seeds of plants such as lettuce, oats, and tobacco.

Scientists are actively conducting research in gibberellin signaling and have identified several GA receptors in the nucleus, repressor proteins designated *DELLA proteins*, as well as an F-box protein. When GA is not bound to the receptor, a DELLA protein inhibits transcription of *GA response genes*. When GA is present, it binds to the receptor, which triggers an enzyme that attaches ubiquitin to the DELLA protein. This protein is targeted for degradation into peptide fragments in a proteasome. With the DELLA protein no longer present, transcription of the GA response genes occurs. This signaling process may sound familiar: the GA signal transduction process shares similarities with the auxin signal transduction pathway described earlier in this chapter.

Cytokinins promote cell division

During the 1940s and 1950s, researchers were trying to find substances that might induce plant cells to divide in **tissue culture**, a technique in which cells are isolated from plants and grown in a nutrient medium. (Plant tissue culture is discussed in Chapter 33.) They discovered that cells would not divide without a substance found in coconut milk. Because coconut milk has a complex chemical composition, investigators did not chemically identify the division-inducing substance for some time. Finally, researchers isolated an active substance from a different source, aged DNA from herring sperm. They called it **cytokinin** because it induces cytokinesis, or cytoplasmic division. In 1963, researchers identified the first plant cytokinin, zeatin, in corn. Since then, similar molecules have been identified in other plants. Biologists have also synthesized several cytokinins.

Cytokinins are structurally similar to adenine, a purine base that is part of DNA and RNA molecules. Biologists are beginning to elucidate the cytokinin signal transduction pathway, which is more complex than those of auxin and gibberellin. The cytokinin pathway has multiple steps, each under the control of a number of genes. The presence of feedback loops and links to other signaling pathways adds another level of complexity to the regulation of cytokinin activity.

Cytokinins promote cell division and differentiation of young, relatively unspecialized cells into mature, more specialized cells in intact plants. They are a required ingredient in any plant tissue culture medium and must be present for cells to divide. In tissue culture, cytokinins interact with auxin during the formation of plant organs such as roots and stems (FIG. 38-10). For example, in tobacco tissue culture, a high ratio of auxin to cytokinin induces root formation, whereas a low ratio of auxin to cytokinin induces shoot formation.

Cytokinins and auxin also interact in the control of apical dominance. Here their relationship is antagonistic: auxin inhibits the growth of axillary buds, and cytokinin promotes their growth.

One effect of cytokinins on plant cells is to delay the aging process. Plant cells, like all living cells, go through a natural aging process known as **senescence**. Senescence is accelerated in cells of plant parts that are cut, such as flower stems. Botanists think that plants must have a continual supply of cytokinins from the roots. Cut stems, of course, lose their source of cytokinins and therefore age rapidly. When cytokinins are sprayed on leaves of a cut stem of many species, they remain green, whereas unsprayed leaves turn yellow and die.

Despite their involvement in regulating many aspects of plant growth and development, cytokinins currently have few

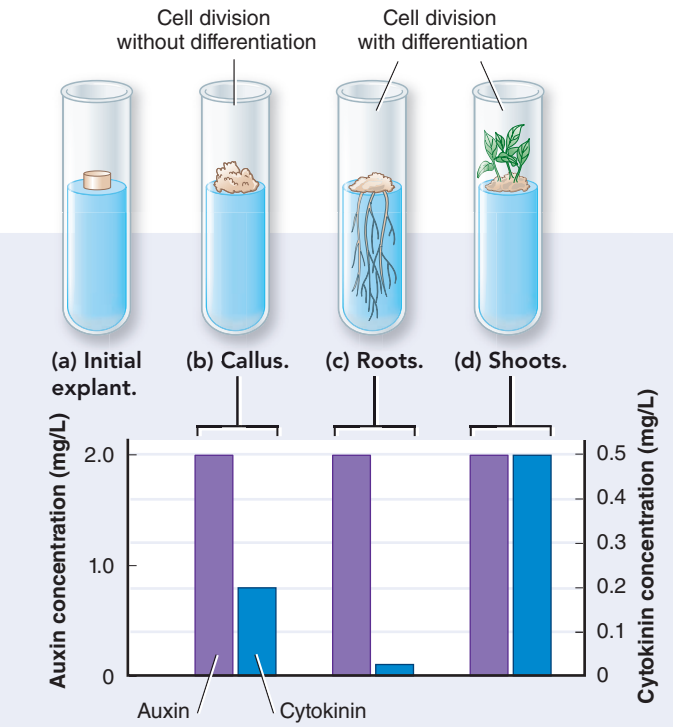

Figure 38-10 Auxin–cytokinin interactions in tissue culture
Varying amounts of auxin and cytokinin in the culture media produce different growth responses. **(a)** The initial explant is a small piece of sterile tissue from the pith of a tobacco stem, which is placed on nutrient agar. **(b)** Nutrient agar containing 2.0 mg/L of auxin and 0.2 mg/L of cytokinin causes cells to divide and form a clump of undifferentiated tissue called a callus. **(c)** Agar with 2.0 mg/L of auxin and 0.02 mg/L of cytokinin (high ratio of auxin to cytokinin) stimulates root growth. **(d)** Agar with 2.0 mg/L of auxin and 0.5 mg/L of cytokinin (low ratio of auxin to cytokinin) stimulates shoot growth.

commercial applications other than plant tissue culture. However, molecular biologists at the University of Wisconsin have combined a promoter from a gene activated during normal senescence with a gene that encodes an enzyme involved in cytokinin synthesis. (Recall from Chapter 13 that the **promoter** is the nucleotide sequence in DNA to which RNA polymerase attaches to begin transcription.) The leaves of transgenic tobacco plants that contained this recombinant DNA produced more cytokinin and therefore lived longer and continued to photosynthesize (FIG. 38-11). This type of application of molecular technology may have the potential to increase the longevity and productivity of certain crops.

Ethylene promotes abscission and fruit ripening

During the early 20th century, scientists observed that the gas **ethylene** (C_2H_4) has several effects on plant growth, but not until 1934 did they demonstrate that plants produce ethylene. This natural hormone influences many plant processes. Ethylene inhibits cell elongation, promotes seed germination, promotes apical dominance, and is involved in plant responses to wounding or invasion by disease-causing microorganisms.

Ethylene also has a major role in many aspects of senescence, including fruit ripening. As a fruit ripens, it produces ethylene, which triggers an acceleration of the ripening process and induces the fruit to produce more ethylene, which further accelerates ripening. The expression "one rotten apple spoils the barrel" is true. A rotten apple is one that is overripe and produces large amounts of ethylene, which diffuses and triggers the ripening process in nearby apples. Humans use ethylene commercially to uniformly ripen bananas and tomatoes. These fruits are picked while green and shipped to their destination, where they are exposed to ethylene before they are delivered to grocery stores (FIG. 38-12).

Plants growing in a natural environment encounter rain, hail, wind, and contact with passing animals. All these mechanical stressors alter their growth and development, making them shorter and stockier than plants grown in a greenhouse. Ethylene regulates such developmental responses to mechanical stimuli, known as **thigmomorphogenesis**. Plants that are mechanically disturbed produce additional ethylene, which in turn inhibits stem elongation and enhances cell wall thickening in supporting cells (collenchyma and sclerenchyma). These changes are adaptive because shorter, thicker stems are less likely than longer, thinner stems to be damaged by mechanical stressors.

Ethylene is involved in leaf abscission, which is actually influenced by two antagonistic hormones, ethylene and auxin. As a leaf ages (as autumn approaches, for deciduous trees in temperate climates), the level of auxin in the leaf decreases. Concurrently, cells in the abscission layer at the base of the petiole (where the leaf will break away from the stem) begin producing ethylene.

Researchers studying ethylene signaling have identified a similar mechanism to that already described for auxin and gibberellin. When ethylene is present, it binds to a receptor. This binding triggers an enzyme that attaches ubiquitin to a protein targeted for degradation into peptide fragments in

a proteasome. At least two F-box proteins are involved in the protein degradation that occurs in ethylene signal transduction.

Abscisic acid promotes seed dormancy

In 1963, two different research teams discovered **abscisic acid (ABA)**. Despite its name, abscisic acid does not induce abscission in most plants. Instead, ABA is involved in a plant's response to stress and in seed **dormancy**, a temporary state of arrested physiological activity. As an environmental stress hormone, ABA particularly promotes changes in plant tissues that are water-stressed. (Recall that ethylene also affects plant responses to certain stressors, such as mechanical stressors and wounding.)

Botanists best understand the effect of abscisic acid on plants suffering from water stress. The level of ABA increases dramatically in the leaves of plants exposed to severe drought conditions. The high level of ABA in the leaves activates a signal transduction process that leads to the closing of stomata. The closing of stomata saves the water that the plant would normally lose by transpiration, thereby increasing the plant's likelihood of survival. As knowledge of ABA signaling in guard cells increases, botanists hope to use this information to engineer crops and horticultural plants that are resistant to drought.

The onset of winter is also a type of stress on plants. A winter adaptation that involves abscisic acid is dormancy in seeds. Many seeds have high levels of ABA in their tissues and do not germinate until the ABA washes out. In a corn mutant unable to synthesize ABA, the seeds germinate as soon as the embryos are mature, even while attached to the ear (FIG. 38-13).

Abscisic acid is not the only hormone involved in seed dormancy. For example, addition of gibberellin reverses the effects of dormancy. In seeds the level of ABA decreases during the winter, and the level of GA increases. Cytokinins are also implicated in breaking dormancy. Once again, we see that a single physiological activity such as seed dormancy may be controlled in plants by the interaction of several hormones. The plant's actual response may result from changing ratios of hormones rather than the effect of each individual hormone.

Figure 38-13 The absence of abscisic acid causes precocious germination

In a corn (*Zea mays*) mutant that does not produce abscisic acid, some of the kernels have germinated while still on the ear, producing roots (*arrows*).

Brassinosteroids are plant steroid hormones

Although steroid hormones have long been known to have crucial roles in animals, the roles of steroid hormones in plants were not well characterized until the mid-1990s. The **brassinosteroids (BRs)** are a group of steroids that function as plant hormones. BRs are involved in several aspects of growth and development. *Arabidopsis* mutants that cannot synthesize BRs are dwarf plants with small curly leaves and reduced fertility; researchers can reverse this defect by applying BR to the plant. Studies of these mutants suggest that brassinosteroids are involved in multiple developmental processes, such as cell division, cell elongation, light-induced differentiation, vascular development, and seed germination (FIG. 38-14).

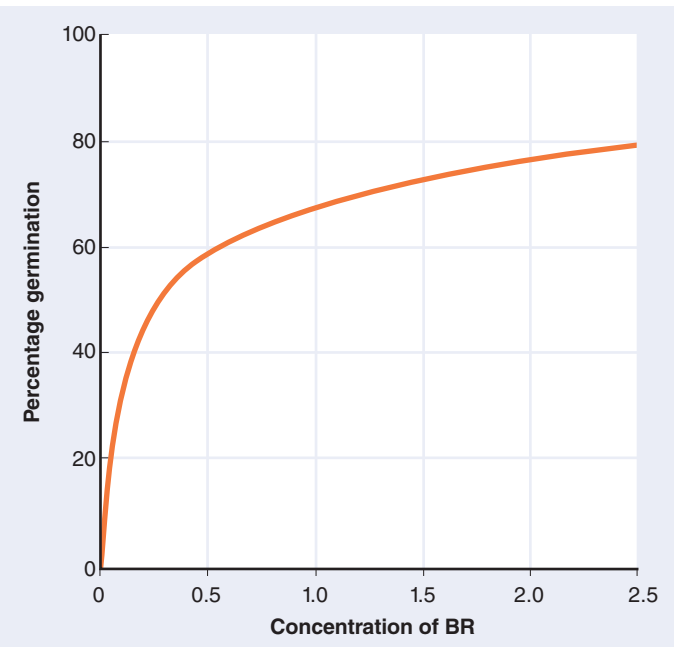

Figure 38-14 Brassinosteroids and seed germination in *Arabidopsis*

Researchers used a GA-insensitive *Arabidopsis* mutant that produced seeds that did not germinate. (Recall that GA promotes seed germination, so a plant that does not respond to endogenous GA is required.) The scientists overcame the inability of the mutant seeds to germinate by treating them with a brassinosteroid (BR). Note how the percentage of germination increases as the concentration of BR to which the seeds were exposed increases. Adapted from Steber, C.M., and P. McCourt, "A Role for Brassinosteroids in Germination in *Arabidopsis*," *Plant Physiology*, Vol. 125 (2001): 287–297.

Many steps of the BR signaling pathway have been characterized. BRs bind to a receptor kinase in the plant plasma membrane (unlike steroid hormones in animals, which enter the cell and bind to receptors in the cytoplasm or nucleus). When BR binds to its receptor, the receptor phosphorylates molecules in the cytosol, which in turn triggers a signaling cascade that ultimately alters gene expression in the cell. Part of the signal transduction process involves attaching ubiquitin to nuclear proteins targeted for degradation in a proteasome. As a result, the expression of BR target genes is adjusted.

Identification of a universal flower-promoting signal remains elusive

Experiments in which different tobacco species are grafted together indicate that unidentified flower-promoting and flower-inhibiting substances may exist. *Nicotiana silvestris* is a *long-day* tobacco plant (it requires a short night to flower); a variety of *N. tabacum* is a *day-neutral* tobacco plant (seasonal changes do not affect when it flowers). When a long-day tobacco is grafted to a day-neutral tobacco and exposed to short nights, both plants flower (FIG. 38-15). The day-neutral tobacco plant flowers sooner than it normally would.

Biologists hypothesize that a flower-promoting substance, *florigen*, may be induced in the long-day plant and transported to the day-neutral plant through the graft union, causing the day-neutral tobacco plant to flower sooner than expected. An intact plant may produce florigen in the leaves and transport it in the phloem to the shoot apical meristem. There, it induces a transition from vegetative to reproductive development, that is, to a meristem that produces flowers.

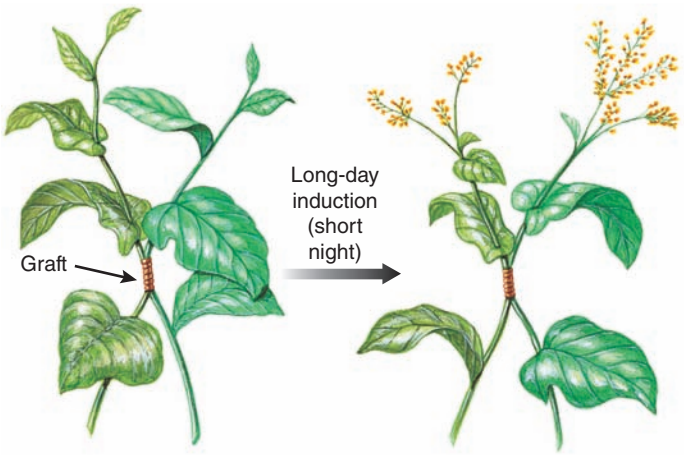

Figure 38-15 Evidence for the existence of a flower-promoting substance

When a long-day tobacco plant (*Nicotiana silvestris*) is grafted to a day-neutral tobacco plant (*N. tabacum*) and both plants are exposed to a long-day/short-night regimen, they both flower. The day-neutral plant flowers sooner than it normally would, presumably because a flower-promoting substance passes from the long-day plant to the day-neutral one through the graft.

When a botanist grafts a long-day tobacco to a day-neutral tobacco and exposes them to long nights, neither plant flowers. As long as these conditions continue, the day-neutral plants do not flower even when they would normally do so. In this case, the long-day tobacco may produce a flower-inhibiting substance that is transported to the day-neutral tobacco through the graft union. This substance prevents the day-neutral tobacco from flowering.

CHECKPOINT 38.2

- How are signal reception, signal transduction, and altered cell activity part of the general mechanism of action for auxin?
- How is auxin involved in phototropism?
- Which hormones are involved in each of the following physiological processes: (1) seed germination, (2) stem elongation, (3) fruit ripening, (4) leaf abscission, and (5) seed dormancy?

38.3 Light Signals and Plant Development

LEARNING OBJECTIVES

5 Explain how varying amounts of light and darkness induce flowering.
6 Describe the role of phytochrome in flowering, including a brief discussion of phytochrome signal transduction.
7 Define *circadian rhythm* and give an example.
8 Distinguish between phytochrome and cryptochrome.

Photoperiodism is any response of a plant to the relative lengths of daylight and darkness. Initiation of flowering at the shoot apical meristem is one of several physiological activities that are photoperiodic in many plants. Plants are classified into four main groups—short day, long day, intermediate day, and day neutral—on the basis of how photoperiodism affects their transition from vegetative growth to flowering.

Short-day plants (also called **long-night plants**) flower when the night length is equal to or greater than some critical period (FIG. 38-16a). Thus, short-day plants detect the lengthening nights of late summer or fall. There are two kinds of short-day plants: qualitative and quantitative. In *qualitative short-day plants*, flowering occurs only in short days; in *quantitative short-day plants*, flowering is accelerated by short days. The initiation of flowering in short-day plants is not due to the shorter period of daylight but to the long, uninterrupted period of darkness. The minimum critical night length varies considerably from one plant species to another but falls between 12 and 14 hours for many. Examples of short-day plants are florist's chrysanthemum, cocklebur, and poinsettia, which typically flower in late summer or fall. Poinsettias, for example, typically initiate flower buds in early October in the Northern Hemisphere and flower about 8 to 10 weeks later; hence, they are traditionally associated with Christmas.

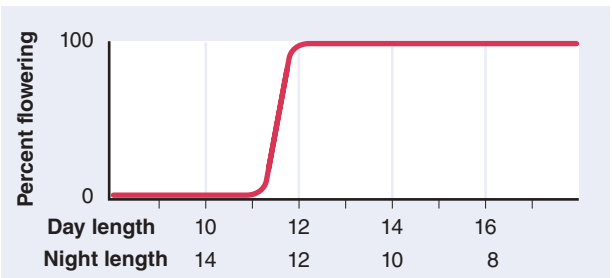
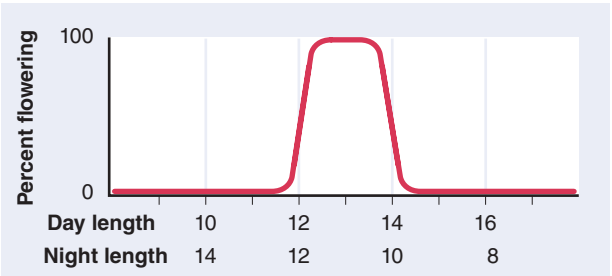
Long-day plants (also called **short-night plants**) flower when the night length is equal to or less than some critical period (FIG. 38-16b). In *qualitative long-day plants*, flowering occurs only in long days; in *quantitative long-day plants*, long days accelerate flowering. Long-day plants, such as spinach, black-eyed Susan (see chapter-opening photograph), and the model research plant *Arabidopsis*, flower when they detect the shortening nights of spring and early summer.



Intermediate-day plants do not flower when night length is either too long or too short (FIG. 38-16c). Sugarcane and coleus are intermediate-day plants. These plants flower when exposed to days and nights of intermediate length.

Some plants, called **day-neutral plants**, do not initiate flowering in response to seasonal changes in the period of daylight and darkness but instead respond to some other type of stimulus, external or internal. Cucumber, sunflower, corn, and onion are examples of day-neutral plants. Many of these plants originated in the tropics, where day length does not vary appreciably during the year. In contrast, short-day, long-day, and intermediate-day plants are temperate or subtropical (midlatitude species).



Plant biologists have experimented with the effects of various light regimens on flowering. FIGURE 38-17 shows how flowering in long-day and short-day plants is affected by different light treatments, including a short-day/long-night regimen with a *night break*, a short burst of light in the middle of the night.

(a) Short-day plants flower when the night length is equal to or exceeds a certain critical length in a 24-hour period.

(b) Long-day plants flower when the night length is equal to or less than a certain critical length in a 24-hour period. The critical length varies among different species; short-day plants may require a shorter night length than long-day plants, as shown.

(c) Intermediate-day plants have a narrow night-length requirement.

Figure 38-16 Generalized photoperiodic responses in short-day, long-day, and intermediate-day plants

Phytochrome detects day length

The main photoreceptor for photoperiodism and many other light-initiated plant responses (such as germination and seedling establishment) is **phytochrome**, a family of about five blue-green pigment proteins, each of which is coded for by a different gene. A mixture of phytochrome proteins is present in cells of all vascular plants examined so far. For example, five members of the phytochrome family—designated phyA, phyB, phyC, phyD, and phyE—occur in *Arabidopsis*. Phytochrome is also a photoreceptor in certain bacteria, fungi, and slime molds.

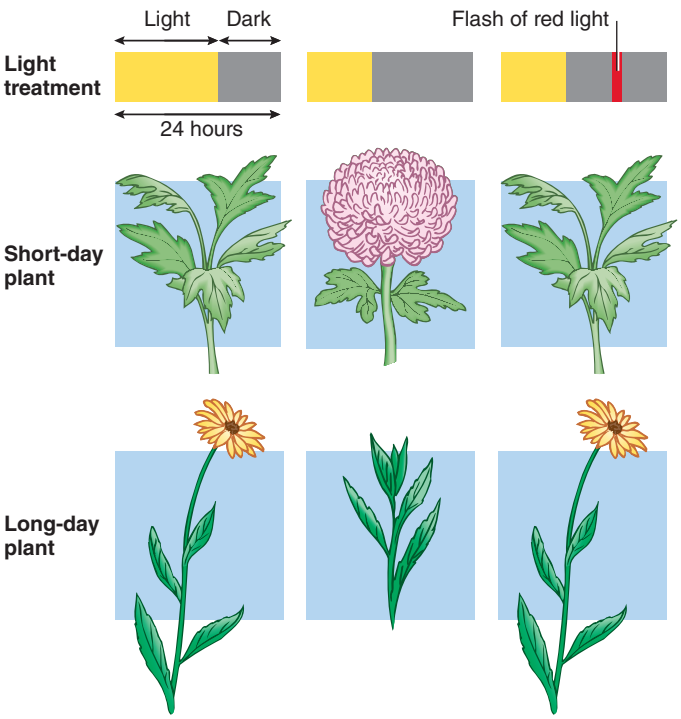


Figure 38-17 Photoperiodic responses of short-day and long-day plants

A short-day plant flowers when it is grown under long-night conditions (*top middle*), but it does not flower when exposed to a long night interrupted with a brief flash of red light (*top right*). A long-day plant does not flower when grown under long-night conditions (*bottom middle*) unless the long night is interrupted with a brief flash of red light (*bottom right*).

Much of the current knowledge of phytochrome in *Arabidopsis* is based on various mutant plants that do not express a specific phytochrome gene, such as the gene that codes for phyA. By studying the physiological response of plants that do not produce an individual phytochrome, biologists have concluded that the individual forms of phytochrome have both unique and overlapping functions. PhyB appears to exert its influence at all stages of the plant life cycle, whereas the other forms of phytochrome have narrower functions at specific stages in the life cycle.

PhyA and phyB may have antagonistic (opposite) effects on flowering. In long-day plants phyB may inhibit flowering, and phyA may induce flowering. Flowering occurs more rapidly in long-day plants with mutations in the gene that codes for phyB; such mutations reduce or eliminate the production of phyB. In contrast, flowering is delayed or prevented in long-day plants with mutations in the gene that codes for phyA.

Each member of the phytochrome family exists in two forms and readily converts from one form to the other after absorption of light of specific wavelengths. One form, designated **Pr** (for *r*ed-absorbing *p*hytochrome), strongly absorbs light with a relatively short red wavelength (660 nm). In the process, the shape of the molecule changes to the second form of phytochrome, **Pfr**, so designated because it absorbs *f*ar-*r*ed light, which is light with a relatively long red wavelength (730 nm; FIG. 38-18). When it absorbs far-red light, Pfr reverts to the original form, Pr. Pfr is the active form of phytochrome, triggering or inhibiting physiological responses such as flowering.

What does a pigment that absorbs red light and far-red light have to do with daylight and darkness? Sunlight consists of various amounts of the entire spectrum of visible light in addition to ultraviolet and infrared radiation. Sunlight contains more red than far-red light, however, so when a plant is exposed to sunlight, the level of Pfr increases. During the night, the level of Pfr slowly decreases as Pfr, which is less stable than Pr, is degraded.

The importance of phytochrome to plants cannot be overemphasized. Timing of day length and darkness is the most reliable way for plants to measure the change from one season to the next. This measurement, which synchronizes the stages of plant development, is crucial for survival, particularly in environments where the climate has an annual pattern of favorable and unfavorable seasons.

Competition for sunlight among shade-avoiding plants involves phytochrome

Plants sense the proximity of nearby plants, which are potential competitors, and react by changing the way they grow and develop. Many plants, from small herbs to large trees, compete for light, a response known as **shade avoidance**, in which plants tend to grow taller when closely surrounded by other plants. If successful, the shade-avoiding plant projects its new growth into direct sunlight and thereby increases its chances of survival.

Since the 1970s, botanists have recognized the environmental factor that triggers shade avoidance: plants perceive changes in the ratio of red to far-red light that result from the presence of nearby plants. The leaves of neighboring plants absorb much more red light than far-red light. (The green pigment chlorophyll strongly absorbs red light during photosynthesis.) In a densely plant-populated area, the ratio of red light to far-red light (r/fr) decreases, affecting the equilibrium between the Pr and Pfr forms, particularly of phyB. This signal triggers a series of responses that cause the shade-avoiding plant, which is adapted to full-light environments,

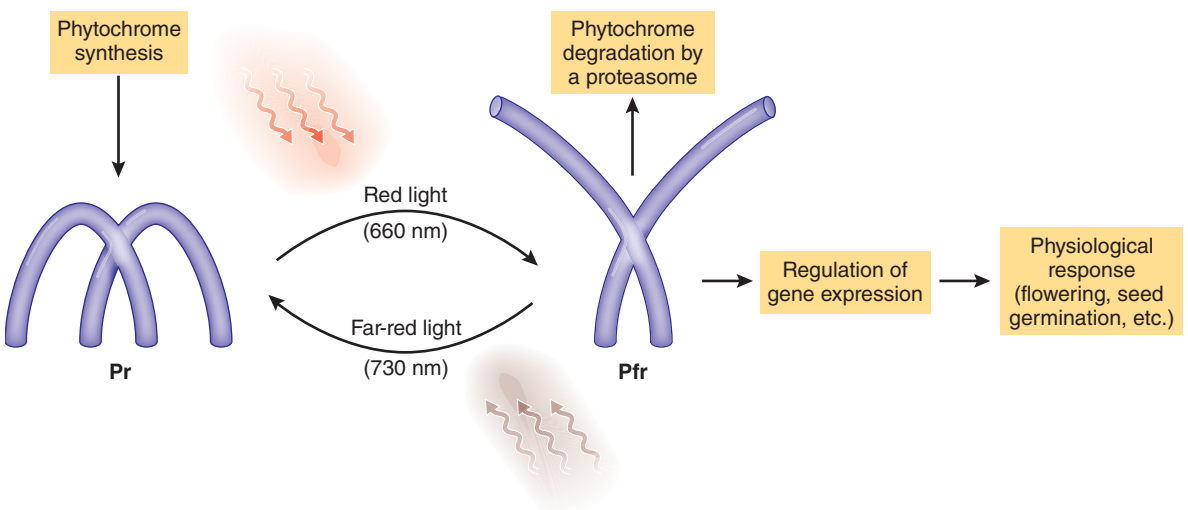

Figure 38-18 Phytochrome

Each member of the phytochrome family occurs in two forms, designated Pr and Pfr, and readily converts from one form to the other. Red light (660 nm) converts Pr to Pfr, and far-red light (730 nm) converts Pfr to Pr.

to grow taller or flower earlier than it would in a less densely populated area. FIGURE 38-19 shows an interesting application of additional (reflected) far-red light without the reduction in incoming sunlight that occurs in shade avoidance.

When a plant is using many of its resources for stem elongation, it has fewer resources for new leaves and branches, storage tissues, and reproductive tissues. However, for a shade-avoiding plant that is shaded by its neighbors, a rapid increase in stem length is advantageous because once this plant is taller than its neighbors, it obtains a larger share of unfiltered sunlight.

Phytochrome is involved in other responses to light, including germination

Phytochrome is involved in the light requirement that some seeds have for germination. Seeds with a light requirement must be exposed to light containing red wavelengths. Exposure to red light converts Pr to Pfr, and germination occurs. Many temperate forest species with small seeds require light for germination. (Larger seeds generally do not have a light requirement.) This adaptation enables the seeds to germinate at the optimal time. During early spring, sunlight, including red light, penetrates the bare branches of overlying deciduous trees and reaches the soil between the trees. As spring temperatures warm, the seeds on the soil absorb red light and germinate. During their early growth, the newly germinated seedlings do not have to compete with the taller trees for sunlight.

Other physiological functions under the influence of phytochrome include sleep movements in leaves (discussed later); shoot dormancy; leaf abscission; and pigment formation in flowers, fruits, and leaves.

Cary Wolinsky

Figure 38-19 Colored mulches and plant growth processes
The red mulch reflects far-red light from the ground to the tomato plants. The plants, absorbing the extra far-red light, react as if nearby plants are present. Their aboveground growth is greater, and their fruits ripen earlier. Manipulating mulch colors also modifies yield, flavor, and nutrient content.

Phytochrome acts by signal transduction

Some phytochrome-induced responses are very rapid and short term, whereas others are slower and long term. The rapid responses probably involve reversible changes in the properties of membranes, altering cell ionic balances. Red light, for example, causes potassium ion (K^+) channels to open in cell membranes involved in plant movements caused by changes in turgor. Exposure to far-red light causes the K^+ channels to close. Slower phytochrome-induced responses involve the selective regulation of transcription of numerous genes. For example, phytochrome activates transcription of the gene for the small subunit of *rubisco*, an enzyme involved in photosynthesis (see Chapter 9).

Each phytochrome molecule consists of a protein attached to a light-absorbing photoreceptor. Biologists hypothesize that the absorption of light by the photoreceptor portion of phytochrome elicits a change in the shape of the protein portion of the phytochrome molecule. This change, in turn, triggers one or more **signal transduction** pathways.

One important research tool in studying phytochrome signal transduction is mutant plants that respond as if they were exposed to a particular light stimulus even if they were not. Research indicates that the active form of phytochrome moves from the cytoplasm into the nucleus, where it affects gene expression by activating a **transcription factor**. When activated, the transcription factor, which binds to the promoter of a gene, either turns on or represses transcription that leads to protein synthesis.

In one such pathway, inactive phytochrome (Pr) in the cytoplasm absorbs red light and is converted into the active form, Pfr, which moves into the nucleus. There, phytochrome binds to PIF3 (phytochrome-interacting factor 3), a transcription factor that is already bound to the promoters of light-responsive genes, thereby activating (or repressing) their transcription.

The signal transduction pathway is shut down by far-red light, which is absorbed by the Pfr in the Pfr–PIF3 complex in the nucleus. When Pfr is converted to Pr, it dissociates from PIF3.

The signal transduction pathway just described is not the end of the story. Phytochrome does not regulate just one but numerous light-responsive signaling pathways that affect gene expression. Also, we do not understand the specifics of how the transition from Pr to Pfr participates in so many signaling cascades.

Light influences circadian rhythms

Almost all organisms, including plants, animals, fungi, eukaryotic microorganisms, and many bacteria, appear to have an internal timer, or biological clock, that approximates a 24-hour cycle, the time it takes Earth to rotate around

Frank Salisbury

(b) Leaf position at midnight.

Figure 38-20 Sleep movements

its own axis. These internal molecular cycles are known as **circadian rhythms** (from the Latin *circum*, "around," and *diurn*, "daily"). Circadian rhythms help an organism detect the time of day, whereas photoperiodism enables a plant to detect the time of year.

Why do plants and other organisms exhibit daily circadian rhythms? Predictable environmental changes, such as sunrise and sunset, occur during the course of each 24-hour period. These predictable changes may be important to an individual organism, causing it to change its physiological activities or its behavior (in the case of animals). Researchers think that circadian rhythms help an organism synchronize repeated daily activities so that they occur at the appropriate time each day. If, for example, an insect-pollinated flower does not open at the time of day that pollinating insects are foraging for food, reproduction will be unsuccessful.

Circadian rhythms in plants affect such biological events as gene expression, the timing of photoperiodism (i.e., of seasonal reproduction), the rate of photosynthesis, and the opening and closing of stomata. *Sleep movements* observed in the common bean and other plants are another example of a circadian rhythm (FIG. 38-20). During the day, bean leaves are horizontal, possibly for optimal light absorption, but at night the leaves fold down or up, a movement that orients them perpendicular to their daytime position. The biological significance of sleep movements is unknown at this time.

When constant environmental conditions are maintained, circadian rhythms such as sleep movements repeat every 20 to 30 hours, at least for several days. In nature the rising and setting of the sun reset the biological clock so that the cycle repeats every 24 hours. The functioning of the circadian clock is under genetic control.

Mutants of the model plant *Arabidopsis* in which the circadian clock is not synchronized to match the external day–night cycle have been found to contain less chlorophyll, fix less carbon by photosynthesis, grow more slowly, and have less of a competitive advantage than *Arabidopsis* plants with a normal circadian clock.

For *Arabidopsis* and many other plants, two photoreceptors—the red light–absorbing phytochrome and the blue/ultraviolet-A light–absorbing **cryptochrome**—are implicated in resetting the biological clock. Certain amino acid sequences of the protein portion of phytochrome are homologous with amino acid sequences of clock proteins in fruit flies, fungi, mammals, and bacteria; this molecular evidence strongly supports the circadian-clock role of phytochrome. The evidence for cryptochrome as a clock protein is also convincing. First discovered in plants, cryptochrome counterparts are found in the fruit fly and mouse biological-clock proteins. Possibly both photoreceptors are involved in resetting the biological clock in plants; researchers have evidence that phytochrome and cryptochrome sometimes interact to regulate similar responses.

CHECKPOINT 38.3

- What is phytochrome? What are two roles of phytochrome?
- What are the steps in phytochrome signal transduction?
- In what process is cryptochrome involved?

38.4 Responses to Herbivores and Pathogens

LEARNING OBJECTIVE

9 Distinguish between the hypersensitive response and systemic acquired resistance.

Plants lack an immune system such as is found in humans and other mammals, but plants can defend themselves from attack by pathogenic and herbivorous enemies. Each plant cell has an innate immune system to fight against local infections. When a molecule produced by a pathogen or herbivore binds to a receptor in a plant cell, it triggers a signal transduction pathway. As a result, a *hypersensitive response* occurs that seals off the infected area, causing it to die. These *necrotic lesions*, or dead areas, prevent or slow the spread of the initial infection (FIG. 38-21).

The plant also sends signals from the site of localized infection, leading to **systemic acquired resistance (SAR)**, a buildup of long-lasting, enhanced resistance throughout the plant. The signal travels in the phloem. Systemic acquired resistance is broad spectrum; that is, SAR is a heightened defense against many types of pathogens, not just the one that caused the initial infection.

Plant biologists continue to discover new hormone-like signaling molecules. Many of these signaling molecules are involved in the defensive responses of plants to disease organisms and insects. Here we briefly consider two groups: jasmonic acid and methyl salicylate.

Figure 38-21 Hypersensitive response
The necrotic lesions on these oak leaves were produced in response to invasion by a fungal pathogen.

Jasmonic acid activates several plant defenses

Jasmonic acid affects several plant processes, such as pollen development, root growth, fruit ripening, and senescence. This lipid-derived plant hormone, which is structurally similar to *prostaglandins* in animals (see Chapter 49), is also produced in response to the presence of insect pests and disease-causing organisms.

Jasmonic acid triggers the production of enzymes that confer an increased resistance against herbivorous (plant-eating) insects. For example, caterpillar-infested tomato plants release volatile jasmonic acid into the air that attracts natural caterpillar enemies, such as parasitic wasps; the wasps lay their eggs on the caterpillars' bodies. When the eggs hatch, the wasp larvae consume, and ultimately kill, the host insects. In one study, treating plants with jasmonic acid increased parasitism on caterpillar pests twofold over control fields in which the plants did not have jasmonic acid applications. Jasmonic acid may be of practical value in controlling certain insect pests without the use of chemical pesticides.

Biologists have made progress in identifying key aspects of the jasmonic acid signaling pathway. Interestingly, the jasmonic acid signaling pathway includes ubiquitin, which was discussed earlier in the chapter in relation to auxin (see Fig. 38-4). As in the auxin signaling pathway, the ubiquitin tags in the jasmonic acid signaling pathway cause degradation of transcription repressors, thereby altering gene expression.

Methyl salicylate may induce systemic acquired resistance

For centuries, people chewed willow (*Salix*) bark to treat headaches and other types of pain. **Salicylic acid** was first extracted from willow bark and is chemically related to aspirin (acetylsalicylic acid). More recently, biologists have shown that salicylic acid helps plants defend against insect pests and pathogens such as viruses. When a plant is under attack, the concentration of salicylic acid increases, and it spreads systemically throughout the plant.

Based on current research, biologists think that *methyl salicylate*, a derivative of salicylic acid also known as *oil of wintergreen*, binds to a cell receptor, triggering a signal transduction pathway that switches on genes. These genes code for proteins that establish systemic acquired resistance to fight infection and promote wound healing.

Plants also use methyl salicylate, which is volatile, to signal nearby plants. Tobacco plants infected with tobacco mosaic virus release methyl salicylate into the air. When nearby healthy plants receive the airborne chemical signal, they begin synthesizing antiviral proteins that enhance their resistance to the virus.

CHECKPOINT 38.4

- You observe necrotic lesions on the leaves of a plant in your garden. Are they more likely due to a hypersensitive response or to systemic acquired resistance (SAR)? Explain your answer.

Summary: Focus on Learning Objectives

38.1 Tropisms *(page 804)*

1 Describe phototropism, gravitropism, and thigmotropism.

- **Tropisms** are directional growth responses. **Phototropism** is growth in response to the direction of light. **Gravitropism** is growth in response to the influence of gravity. **Thigmotropism** is growth in response to contact with a solid object.

38.2 Plant Hormones and Development *(page 805)*

2 Describe a general mechanism of action for plant hormones, using auxin as your example.

- Plants produce and respond to **hormones**, organic molecules that act as highly specific chemical signals to elicit a variety of responses that regulate growth and development.
- Many plant hormones bind to *enzyme-linked receptors* located in the plasma membrane; the hormone binds to the receptor, triggering an enzymatic reaction of some sort. The receptor for auxin, which is located in the cytosol or nucleus, binds to auxin. This catalyzes the attachment of ubiquitin to a repressor protein, targeting it for destruction. When genes repressed by those proteins are then expressed, changes in cell growth and development result.

3 Describe early auxin experiments involving phototropism.

- Charles Darwin and his son Francis performed phototropism experiments in the 1870s on grass seedlings. When they covered the coleoptile tip, the plant did not bend. When they removed the coleoptile tip, bending did not occur. When the bottom of the coleoptile was shielded from the light, the coleoptile bent. The Darwins concluded that some substance is transmitted from the upper to the lower part that causes the plant to bend.
- In the 1920s, Frits Went isolated the phototropic hormone from oat coleoptiles by removing the coleoptile tips and placing them on agar blocks. Normal growth resumed when he put one of these agar blocks squarely on a decapitated coleoptile; the substance had diffused from the coleoptile tip into the agar and, later, from the agar into the decapitated coleoptile. Went named this substance auxin.

4 List several ways that each of these hormones affects plant growth and development: auxins, gibberellins, cytokinins, ethylene, abscisic acid, and brassinosteroids.

- **Auxin** is involved in cell elongation; tropisms; **apical dominance**, the inhibition of axillary buds by the apical meristem; and fruit development. Auxin also stimulates root development on stem cuttings.
- **Gibberellins (GA)** are involved in stem elongation, flowering, and germination.
- **Cytokinins** promote cell division and differentiation; delay **senescence**, the natural aging process; and interact with auxin and ethylene in apical dominance. Cytokinins induce cell division in **tissue culture**, a technique in which cells are isolated from plants and grown in a nutrient medium.
- **Ethylene** plays a role in ripening fruits; apical dominance; leaf abscission; wound response; **thigmomorphogenesis**, a developmental response to mechanical stressors such as wind; and senescence.
- **Abscisic acid (ABA)** is an environmental stress hormone involved in stomatal closure caused by water stress and in seed **dormancy**, a temporary state of reduced physiological activity.
- Plant steroids known as **brassinosteroids (BRs)** are involved in several aspects of plant growth and development, such as cell division, cell elongation, light-induced differentiation, seed germination, and vascular development.

38.3 Light Signals and Plant Development *(page 813)*

5 Explain how varying amounts of light and darkness induce flowering.

- **Photoperiodism** is any response of plants to the duration and timing of light and dark. Flowering is a photoperiodic response in many plants. **Short-day plants** detect the lengthening nights of late summer or fall and flower at that time. **Long-day plants** detect the shortening nights of spring and early summer and flower at that time. **Intermediate-day plants** flower when exposed to days and nights of intermediate length.

6 Describe the role of phytochrome in flowering, including a brief discussion of phytochrome signal transduction.

- The photoreceptor in photoperiodism is **phytochrome**, a family of about five blue-green pigments. Each type of phytochrome has two forms, **Pr** and **Pfr**, named by the wavelength of light they absorb. Pfr is the active form, triggering or inhibiting physiological responses such as flowering, **shade avoidance**, and a light requirement for germination.
- The pathway in phytochrome **signal transduction** begins when inactive phytochrome in the cytoplasm absorbs red light and is converted into the active form, Pfr, which moves into the nucleus. There, phytochrome binds to the transcription factor PIF3 (phytochrome-interacting factor) and activates or represses the transcription of light-responsive genes.

7 Define *circadian rhythm* and give an example.

- A **circadian rhythm** is a regular period in an organism's growth or activities that approximates the 24-hour day and is reset by the rising and setting of the sun. Two examples of circadian rhythms are the opening and closing of stomata and *sleep movements*.

8 Distinguish between phytochrome and cryptochrome.

- Both phytochrome and **cryptochrome** are photoreceptors that sometimes interact to regulate similar responses, such as resetting the biological clock. Phytochrome strongly absorbs red light, whereas cryptochrome absorbs blue and ultraviolet-A light.

38.4 Responses to Herbivores and Pathogens *(page 817)*

9 Distinguish between the hypersensitive response and systemic acquired resistance.

- Each plant cell has an innate immune system to fight against local infections. A *hypersensitive response* seals off the infected area, causing it to die. These dead areas prevent or slow the spread of the initial infection.
- **Systemic acquired resistance (SAR)** is a buildup of long-lasting, enhanced resistance throughout the plant. Systemic acquired resistance is broad spectrum (against many types of pathogens).

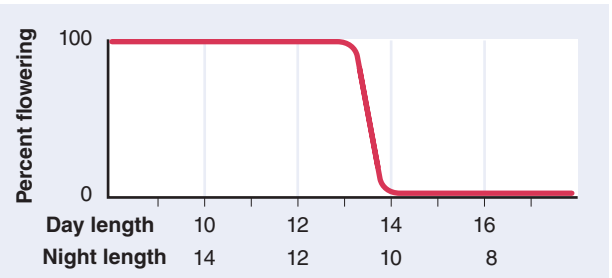
Test Your Understanding

Know and Comprehend



1. In the signal transduction process for the hormone auxin, the molecule ubiquitin (a) absorbs blue light (b) becomes phosphorylated (c) tags certain proteins for destruction (d) interacts antagonistically with gibberellins (e) binds to a receptor in the plant cell's plasma membrane
2. When you prune shrubs to make them "bushier"—that is, to prevent apical dominance—you are affecting the distribution and action of which plant hormone? (a) auxin (b) jasmonic acid (c) salicylic acid (d) ethylene (e) abscisic acid
3. Research on a fungal disease of rice provided the first clues about the plant hormone (a) auxin (b) gibberellin (c) cytokinin (d) ethylene (e) abscisic acid
4. This plant hormone interacts with auxin during the formation of plant organs in tissue culture. (a) florigen (b) gibberellin (c) cytokinin (d) ethylene (e) abscisic acid
5. The stress hormone that helps plants respond to drought is (a) auxin (b) gibberellin (c) cytokinin (d) ethylene (e) abscisic acid
6. This hormone promotes seed dormancy. (a) auxin (b) gibberellin (c) cytokinin (d) ethylene (e) abscisic acid
7. The three classes of photoreceptors that enable plants to sense the presence and duration of light are (a) phytochrome, cryptochrome, and circadian rhythms (b) chlorophyll, photosynthesis, and photoperiodism (c) phytochrome, photoperiodism, and chlorophyll (d) phytochrome, cryptochrome, and phototropin (e) phototropin, photosynthesis, and photoperiodism
8. Pfr, the active state of _____, forms when red light is absorbed. (a) photosystem I (b) phytochrome (c) far-red light (d) phototropin (e) cryptochrome
9. Which photoreceptor(s) is/are implicated in resetting the biological clock? (a) phytochrome only (b) cryptochrome only (c) phototropin only (d) cryptochrome and gibberellin (e) phytochrome and cryptochrome
10. Which signaling molecule triggers the release of volatile substances that attract parasitic wasps to plant-eating caterpillars? (a) phytochrome (b) jasmonic acid (c) auxin (d) methyl salicylate (e) gibberellin

Apply and Analyze

11. Arrange the following steps in the correct order in the phytochrome signal transduction pathway: 1. red light; 2. light-responsive gene is switched on (or off); 3. movement of Pfr to nucleus; 4. conversion of Pr to Pfr; 5. formation of Pfr–PIF3 complex that is bound to promoter region
12. **PREDICT** State whether flowering in a short-day plant with a minimum critical night length of 14 hours would be expected to occur in the following situations. Explain each answer.
    (a) The plant is exposed to 15 hours of daylight and 9 hours of uninterrupted darkness.
    (b) The plant is exposed to 9 hours of daylight and 15 hours of darkness.
    (c) The plant is exposed to 9 hours of daylight and 15 hours of darkness, with a 10-minute exposure to red light in the middle of the night.
13. **PREDICT** If you transplanted the short-day plant discussed in Question 12 to the Equator, would it flower? Explain your answer.

Evaluate and Synthesize

14. **EVOLUTION LINK** What adaptive advantages are conferred on a plant whose stems are positively phototropic and whose roots are positively gravitropic?
15. **EVOLUTION LINK** Explain why a plant with a mutation in one of its phytochrome genes that affects flowering time would be at an evolutionary disadvantage.
16. **INTERPRET DATA** Examine the figure. When the day length is 10 hours and the night length is 14 hours, what percentage of the plants flower? When the day length is 16 hours and the night length is 8 hours, what percentage of the plants flower? What is the critical night length for this plant?

17. **SCIENCE, TECHNOLOGY, AND SOCIETY** Do you think that our expanding knowledge of the molecular basis of plant signaling molecules could improve agricultural productivity in the future? Explain your answer.

39 Animal Structure and Function: An Introduction

Animal species are dramatically diverse, with radically different body structures. For example, consider how different the elephant and the bird are, not only in size but also in body form and lifestyle (see photograph). Despite their differences, animal groups share many characteristics, including their relatively large size.

Why are most animals larger than bacteria, archaea, protists, and fungi? The answer may be related to *ecological niches*—the functional roles of a species within a community. By the time animals evolved, other organisms already occupied most available ecological niches. For new species to succeed, they had to displace others from a niche or adapt to a new one. Success in a new niche required a new body plan, and new body plans often required larger size. Increased size also provided more opportunity for capturing food. Predators are typically larger than their prey.

To grow larger than their bacterial and protist competitors, animals had to be multicellular. Recall that the size of a single cell is limited by the ratio of its surface area (plasma membrane) to its volume (see Chapter 4). The plasma membrane needs to be large enough relative to the cell's volume to permit passage of materials into and out of the cell so that the conditions necessary for life can be maintained. In a multicellular animal, each cell has a large enough ratio of surface area to volume to effectively regulate its internal environment. Individual cells live and die, and they are replaced while the organism continues to maintain itself and thrive. The number of cells, not their individual sizes, is mainly responsible for the size of an animal.

In unicellular organisms such as bacteria and many protists, the single cell carries on all the activities necessary for life. Recall that unicellular and small, flat organisms depend on diffusion for many life processes, including gas exchange and disposal of metabolic wastes. One reason they can be small is that they do not require complex organ systems like multicellular organisms do.

KEY CONCEPTS

39.1 Cells make up tissues, various types of tissues make up organs, and tissues and organs working together make up organ systems. The main types of tissues found in animals are epithelial, connective, muscle, and nervous tissues.

39.2 Homeostatic mechanisms are mainly negative feedback systems that maintain a relatively stable internal environment.

39.3 Thermoregulation is the process of maintaining homeostasis of body temperature despite changes in surrounding (or internal) temperature.

PHOTO: Larger body size does not mean bigger cells. The cells of the elephant mother, her calf, and the bird on the young elephant's back are all about the same size. The elephants are larger than the bird because their genes specify that their bodies consist of a larger number of cells. The cells of the young elephant will continue to multiply until it reaches adult size (African elephant, *Loxodonta africana*). MaggyMeyer/Shutterstock.com

In this chapter we focus on the basic form and function of the animal body. **Anatomy** is the study of an organism's structure. **Physiology** is the study of how the body functions. Remember that in biological systems, structures are adapted to function at every level of organization. Notice the many examples of this basic principle as we describe the types and functions of tissues and the principal organ systems of animals. In this chapter we also discuss the important concept of *homeostasis*, using regulation of body temperature as an example. In the following chapters, we discuss how organ systems work together to maintain homeostasis as animals carry out their many life processes.

39.1 Tissues, Organs, and Organ Systems

LEARNING OBJECTIVES

1. Compare the structure and function of the four main kinds of animal tissues: epithelial, connective, muscle, and nervous tissues.
2. Compare the main types of epithelial tissue and describe their functions.
3. Compare the main types of connective tissue and describe their functions.
4. Contrast the three types of muscle tissue and describe their functions.
5. Relate the structure of the neuron to its function.
6. Briefly describe the organ systems of a mammal and summarize the functions of each organ system.

In a multicellular organism, cells specialize to perform specific tasks. Recall from Chapter 1 that cells organize to form *tissues*, and tissues associate to form *organs* such as the heart or stomach. Groups of tissues and organs make up the *organ systems* of a complex *organism*. Billions of cells organize to form the tissues, organs, and organ systems of a lobster, a crocodile, or an elephant.

A **tissue** consists of a group of closely associated, similar cells that carry out specific functions. Biologists classify animal tissues as epithelial, connective, muscle, or nervous tissue. Classification of tissues depends on their structure and origin. Each kind of tissue is composed of specialized cells with specific sizes, shapes, and arrangements. Some tissues are specialized to transport materials, whereas others contract, enabling the animal to move. Still others secrete hormones that regulate metabolic processes. Structure and function are closely linked at every level of organization. As we discuss each tissue type, notice the relationship between its form and its function. Notice also how biological systems continuously interact.

Epithelial tissues cover the body and line its cavities

Epithelial tissue (also called *epithelium*) consists of cells fitted tightly together to form a continuous layer, or sheet, of cells. One surface of the sheet is typically exposed because it covers the body (outer layer of the skin) or lines a cavity, such as the cavity (*lumen*) of the intestine. The other surface of an epithelial layer attaches to the underlying tissue by a noncellular **basement membrane** consisting of tiny *fibers* and nonliving polysaccharide material that the epithelial cells produce.

Epithelial tissue forms the outer layer of the skin and the linings of the digestive, respiratory, excretory, and reproductive tracts. As a result, everything that enters or leaves the body must cross at least one layer of epithelium. Food taken into the mouth and swallowed is not really "inside" the body until it is absorbed through the epithelium of the digestive tract and enters the blood. To a large extent, the permeabilities of the various epithelial tissues regulate the exchange of substances between the different parts of the body as well as between the animal and the external environment.

Epithelial tissues perform many functions, including protection, absorption, secretion, and sensation. The epithelial layer of the skin, the **epidermis**, covers the entire body and protects it from mechanical injury, chemicals, bacteria, and fluid loss. The epithelial tissue lining the digestive tract absorbs nutrients and water into the body. Some epithelial cells form **glands** that secrete cell products such as hormones, enzymes, or sweat. Other epithelial cells are sensory receptors that receive information from the environment. For example, epithelial cells in taste buds and in the nose specialize as chemical receptors.
