Dedication

This book is dedicated to a group of virologists who possess not only superior ingenuity, but also remarkable benevolence. Without their help, compilation of such an all-encompassing volume on major animal viral pathogens will be unimaginable.

Contents

Preface xv
Editor xvii
Contributors xix

Chapter 1 Introductory Remarks 1
Dongyou Liu

SECTION I Positive-Sense RNA Viruses

Chapter 2 *Betanodavirus* 9
Dongyou Liu

Chapter 3 Taura Syndrome Virus 17
Parin Chaivisuthangkura, Akapon Vaniksampanna, Phongthana Pasookhush, Siwaporn Longyant, and Paisarn Sithigorngul

Chapter 4 Bee Paralysis Virus 27
Panuwan Chantawannakul

Chapter 5 *Iflavirus* (Deformed Wing Virus) 37
Jessica M. Fannon and Eugene V. Ryabov

Chapter 6 Avian Encephalomyelitis Virus 47
Mazhar I. Khan, Zhixun Xie, Theodore Girshick, and Zhiqin Xie

Chapter 7 Duck Hepatitis Virus 53
Dabing Zhang and Ning Liu

Chapter 8 Foot-and-Mouth Disease Virus 61
Dongyou Liu

Chapter 9 Porcine Encephalomyocarditis Virus 67
Sandra Blaise-Boisseau, Aurore Romey, and Labib Bakkali Kassimi

Chapter 10 Porcine Teschovirus 79
Cristina Cano-Gómez and Miguel Ángel Jiménez-Clavero

Chapter 11 Swine Vesicular Disease Virus 89
Jovita Fernández-Pinero, Giulia Pezzoni, Cristina Cano-Gómez, Paloma Fernández-Pacheco, Emiliana Brocchi, and Miguel Ángel Jiménez-Clavero

Downloaded From Vet-eBooks.com

Chapter 12 Avian Astroviruses 101
Victoria Smyth

Chapter 13 Hepatitis E Virus 111
Ilaria Di Bartolo, Fabio Ostanello, and Franco Maria Ruggeri

Chapter 14 Feline Calicivirus 121
Rudi Weiblen, Luciane Teresinha Lovato, and Andréia Henzel

Chapter 15 Porcine Caliciviruses 129
Dongyou Liu

Chapter 16 Vesicular Exanthema of Swine Virus 135
Nick J. Knowles, Begoña Valdazo-González, Britta A. Wood, Katarzyna Bachanek-Bankowska, and Donald P. King

Chapter 17 Avian Leukosis Virus 145
Yongxiu Yao and Venugopal Nair

Chapter 18 Bovine Leukemia Virus 157
Silvina E. Gutiérrez and Agustina Forletti

Chapter 19 Caprine Arthritis–Encephalitis Virus and Visna–Maedi Virus 167
Nuria Barquero, Ana Domenech, and Esperanza Gomez-Lucia

Chapter 20 Equine Infectious Anemia Virus 177
Caroline Leroux and R. Frank Cook

Chapter 21 Feline Immunodeficiency Virus 191
Dongyou Liu

Chapter 22 Feline Leukemia Virus 197
Dongyou Liu

Chapter 23 Reticuloendotheliosis Viruses 205
Dongyou Liu

Chapter 24 Border Disease Virus 211
Jieyuan Jiang and Wenliang Li

Chapter 25 Bovine Viral Diarrhea Viruses 1 and 2 223
Benjamin W. Newcomer

Chapter 26 Classical Swine Fever Virus 233
Dongyou Liu

Downloaded From Vet-eBooks.com

Chapter 27 Louping Ill Virus 241
Nicholas Johnson

Chapter 28 West Nile Virus 247
Dongyou Liu

Chapter 29 Eastern and Western Equine Encephalitis Viruses 255
Norma P. Tavakoli and Laura D. Kramer

Chapter 30 Venezuelan Equine Encephalitis Virus 269
María Belén Pisano, Marta Contigiani, and Viviana Ré

Chapter 31 Equine Arteritis Virus 277
Udeni B.R. Balasuriya

Chapter 32 Porcine Reproductive and Respiratory Syndrome Virus 287
Dongyou Liu

Chapter 33 Yellow Head Complex Viruses, including Gill-Associated Virus 295
James Munro

Chapter 34 Avian Infectious Bronchitis Virus 307
Vagner Ricardo Lunge, Aline Padilha de Fraga, and Nilo Ikuta

Chapter 35 Bovine Coronavirus 317
Dongyou Liu

Chapter 36 Feline Enteric Coronavirus and Feline Infectious Peritonitis Virus 323
Niels C. Pedersen

Chapter 37 Porcine Epidemic Diarrhea Virus 331
Dongyou Liu

Chapter 38 Toroviruses 339
Dongyou Liu

SECTION II Negative-Sense RNA Viruses

Chapter 39 Avian Bornavirus 347
Francesca Sidoti, Maria Lucia Mandola, Francesca Rizzo, Rossana Cavallo, and Cristina Costa

Chapter 40 Bovine Ephemeral Fever Virus 355
Hakan Bulut and Ahmet Kursat Azkur

Downloaded From Vet-eBooks.com

Chapter 41 Rabies Virus 361
Dongyou Liu

Chapter 42 Vesicular Stomatitis Virus 369
Dongyou Liu and Sándor Belák

Chapter 43 Avian Influenza Virus 377
Erica Spackman

Chapter 44 Equine Influenza Virus 383
Thomas M. Chambers and Udeni B.R. Balasuriya

Chapter 45 Infectious Salmon Anemia Virus 393
Dongyou Liu

Chapter 46 Swine Influenza A Virus 399
Jianqiang Zhang, Phillip Gauger, and Karen Harmon

Chapter 47 Avian Metapneumovirus 407
José Francisco Rivera-Benitez, Jazmín De la Luz-Armendáriz, Alberto Bravo-Blas, Luis Gómez-Núñez, and Humberto Ramírez-Mendoza

Chapter 48 Bovine Respiratory Syncytial Virus 413
Sara Hägglund and Jean François Valarcher

Chapter 49 Canine Distemper Virus 421
Rebecca P. Wilkes

Chapter 50 Hendra Virus 431
Dongyou Liu

Chapter 51 Menangle Virus 437
Timothy R. Bowden

Chapter 52 Newcastle Disease Virus 447
Dongyou Liu

Chapter 53 Nipah Virus 455
Supaporn Wacharapluesadee, Akanitt Jittmittraphap, Sangchai Yingsakmongkon, and Thiravat Hemachudha

Chapter 54 Peste des Petits Ruminants Virus 467
Pam Dachung Luka

Downloaded From Vet-eBooks.com

Chapter 55 Porcine Rubulavirus (Blue Eye Disease Virus) 477
José Iván Sánchez Betancourt and María Elena Trujillo Ortega

Chapter 56 Rinderpest Virus 485
Anke Brüning-Richardson

Chapter 57 Ebola Virus 495
Baochuan Lin and Anthony P. Malanoski

Chapter 58 Marburg Virus 507
Junping Yu and Hongping Wei

SECTION III Negative- and Ambi-Sense RNA Viruses

Chapter 59 Akabane Virus 521
Akiko Uema, Yohsuke Ogawa, and Hiroomi Akashi

Chapter 60 Hantaviruses 533
Dongyou Liu

Chapter 61 Nairobi Sheep Disease Virus 543
Devendra T. Mourya and Pragya D. Yadav

Chapter 62 Rift Valley Fever Virus 553
William C. Wilson, Natasha N. Gaudreault, and Mohammad M. Hossain

Chapter 63 Schmallenberg Virus 563
Dongyou Liu

Chapter 64 Arenaviruses 569
Randal J. Schoepp and Aileen E. O'Hearn

Chapter 65 Picobirnaviruses 585
Yashpal S. Malik, Naveen Kumar, Kuldeep Dhama, Krisztián Banyai, Joana D'Arc Pereira Mascarenhas, and Raj Kumar Singh

Chapter 66 Infectious Myonecrosis Virus 593
Maria Erivalda Farias de Aragão, Maria Verônyca Coelho Mello, and Maria de Lourdes Oliveira Otoch

Chapter 67 Infectious Bursal Disease Virus 601
Maja Velhner, Dejan Vidanović, and Ivan Dobrosavljević

Chapter 68 African Horse Sickness Virus 609
Dongyou Liu and Frank W. Austin

Downloaded From Vet-eBooks.com

Chapter 69 Bluetongue Virus 619
Fan Lee

Chapter 70 Epizootic Hemorrhagic Disease Virus 629
Srivishnupriya Anbalagan

Chapter 71 Equine Encephalosis Virus 637
Dongyou Liu

Chapter 72 Rotavirus 643
Helen O'Shea, P.J. Collins, Lynda Gunn, Barbara A. Blacklaws, John McKillen, and Miren Iturriza Gomara

SECTION IV DNA Viruses

Chapter 73 Beak and Feather Disease Virus 659
Ana Margarida Henriques, Teresa Fagulha, and Miguel Fevereiro

Chapter 74 Porcine Circovirus 671
Yu-Liang Huang, Hui-Wen Chang, Victor Fei Pang, and Chian-Ren Jeng

Chapter 75 Aleutian Mink Disease Virus 679
Trine Hammer Jensen and Åse Uttenthal

Chapter 76 Canine Parvovirus 687
S. Parthiban

Chapter 77 Goose Parvovirus 693
Yakun Luo and Shangjin Cui

Chapter 78 *Penaeus monodon* Hepandensovirus 699
Dongyou Liu

Chapter 79 *Penaeus stylirostris* Penstyldensovirus 705
Norma A. Macías-Rodríguez, Erika Camacho-Beltrán, Edgar Rodríguez-Negrete, Norma E. Leyva-López, and Jesús Méndez-Lozano

Chapter 80 Porcine Parvovirus 713
Zhengyang Wang, Yu Zhu, Miaomiao Kong, and Shangjin Cui

Chapter 81 Polyomaviruses 719
Wojciech Kozdruń

Chapter 82 Bovine Papillomaviruses 727
M.A.R. Silva, R.C.P. Lima, M.N. Cordeiro, G. Borzacchiello, and A.C. Freitas

Downloaded From Vet-eBooks.com

Chapter 83 Poultry Adenoviruses 735
Győző L. Kaján

Chapter 84 *Betaherpesvirinae* (*Suid herpesvirus* 2) 747
Timothy J. Mahony

Chapter 85 Iltovirus (Infectious Laryngotracheitis Virus) 753
Joseph J. Giambrone and Shan-Chia Ou

Chapter 86 Macavirus 765
Richa Sood, Kh. Victoria Chanu, and Sandeep Bhatia

Chapter 87 Marek's Disease Virus (*Gallid herpesvirus* 2) and Herpesvirus of Turkey (*Melagrid herpesvirus* 1) 773
Grzegorz Woźniakowski and Jowita Samanta Niczyporuk

Chapter 88 Cyprinivirus 783
Kenneth A. McColl, Agus Sunarto, and Lijuan Li

Chapter 89 *Ictalurid Herpesvirus* 1 797
Larry Hanson

Chapter 90 Abalone Herpesvirus 807
Mark St. J. Crane, Kenneth A. McColl, Jeff A. Cowley, Kevin Ellard, Keith W. Savin, Serge Corbeil, Nicholas J.G. Moody, Mark Fegan, and Simone Warner

Chapter 91 African Swine Fever Virus 817
Dongyou Liu

Chapter 92 Megalocytivirus 825
Chun-Shun Wang and Chiu-Ming Wen

Chapter 93 Avipoxvirus 837
Bimalendu Mondal

Chapter 94 Capripoxviruses (Sheeppox, Goatpox and Lumpy Skin Disease Viruses) 845
E.H. Venter

Chapter 95 Myxoma Virus 855
June Liu and Peter Kerr

Chapter 96 Orthopoxvirus 869
Vinayagamurthy Balamurugan, Gnanavel Venkatesan, and Veerakyathappa Bhanuprakash

Downloaded From Vet-eBooks.com

Chapter 97 Parapoxvirus 881

Graziele Oliveira, Galileu Costa, Felipe Assis, Ana Paula Franco-Luiz, Giliane Trindade, Erna Kroon, Filippo Turrini, and Jonatas Abrahão

Chapter 98 White Spot Syndrome Virus 891

Dongyou Liu

SECTION V Prions

Chapter 99 Bovine Spongiform Encephalopathy 901

Akikazu Sakudo and Takashi Onodera

Chapter 100 Chronic Wasting Disease 913

Akikazu Sakudo and Takashi Onodera

Downloaded From Vet-eBooks.com

Preface

Being the smallest life form of all, viruses possess inadequate structural frameworks to lead an independent life of their own and rely on the living cells of other organisms (including bacteria, fungi, protozoa, helminths, insects, animals, humans, and plants) for replication and maintenance. The process of viruses settling inside their host organisms is commonly referred to as infection. As infectious agents, viruses are remarkably ingenious and highly efficient. While many viruses establish various symbiotic relationships with their hosts and play a beneficial role in augmenting genetic diversity, others may be extremely harmful and induce pathological changes in and even death to their hosts.

Animals constitute one of the largest and most diverse groups of living organisms on Earth. The significance of animals in the ecological balance of the environment and the well-being of human society is indisputable. Considering the devastating effects of pathogenic viruses on their animal hosts, it is crucial that animal-infecting viruses are rapidly and accurately detected and identified so that appropriate and timely control and prevention measures are implemented. In addition, as many viruses have the capacity to move from animals to humans, application of improved diagnostic techniques for animal-infecting viruses provides an effective early-warning system for any possible zoonotic infections that may exert a toll on human society.

With these issues in sight, this book aims to present an expert summary on the state-of-the-art diagnostic approaches for major animal viral pathogens. Each chapter contains a concise overview of the classification, morphology, epidemiology, clinical features, and diagnosis of one or a group of related viral pathogens; an outline of clinical sample collection and preparation procedures; a judicious selection of ready-to-use molecular detection protocols; and a discussion on further research requirements relating to improved diagnosis and control. With contributions from specialists in respective animal viral pathogen research, this book offers a trustworthy reference on molecular detection of major animal viral pathogens; an indispensable tool for medical, veterinary, and industrial laboratory scientists involved in virus determination; a convenient textbook for undergraduate and graduate students majoring in virology; and an essential guide for upcoming and experienced laboratory scientists wishing to acquire and polish their skills in molecular diagnosis of animal viral diseases.

Given the diverse nature of animal viral pathogens, a comprehensive book such as this is obviously beyond the capacity of an individual's undertaking. I was fortunate and honored to have a large group of virologists as the chapter contributors, whose detailed knowledge and technical insights on animal viral pathogen research have greatly enhanced its credibility. Additionally, the professionalism and dedication of CRC Press Executive Editor Chuck Crumly and Senior Project Coordinator Jill Jurgensen have increased its overall appeal. Finally, the understanding and support from my family—Liling Ma, Brenda, and Cathy—have helped maintain my focus during the compilation of this all-inclusive book.

Editor

Dongyou Liu, PhD, undertook veterinary science education at Hunan Agricultural University, China, and postgraduate training at the University of Melbourne, Victoria, Australia. Over the past two decades, he worked at several research and clinical laboratories in Australia and the United States of America, with focuses on molecular characterization and virulence determination of microbial pathogens, such as ovine footrot bacterium (*Dichelobacter nodosus*), dermatophyte fungi (*Trichophyton, Microsporum*, and *Epidermophyton*), and listeriae (*Listeria* spp.), and the development of nucleic acid–based quality assurance modules for security-sensitive and emerging viral pathogens. Dr. Liu is the primary author of more than 50 original research and review articles in various international journals, a contributor of 140 book chapters, and the editor of *Handbook of Listeria Monocytogenes* (2008), *Handbook of Nucleic Acid Purification* (2009), *Molecular Detection of Foodborne Pathogens* (2009), *Molecular Detection of Human Viral Pathogens* (2010), *Molecular Detection of Human Bacterial Pathogens* (2011), *Molecular Detection of Human Fungal Pathogens* (2011), Molecular Detection of Human Parasitic Pathogens (2012), and *Manual of Security Sensitive Microbes and Toxins* (2014), which were published by CRC Press. He is also a coeditor for *Molecular Medical Microbiology*, *Second Edition* (2014, Elsevier).

1.1 PREAMBLE

As noncellular, submicroscopic agents that do not possess organelles for independent living and have to rely on cellular machinery of another organism for replication and maintenance, viruses are notably small. In fact, with a dimension of 20–400 nm (or 10^{-8}–10^{-6} mm), viruses are 10–100 times smaller than prokaryotes (10^{-7}–10^{-4} mm) and 1000 times smaller than eukaryotes (10^{-5}–10^{-3} mm). Being able to pass through conventional sterilizing filters (0.2 μm), viruses were initially referred to as filterable agents.

When not inside an infected cell or in the process of infecting a cell, viruses assume the form of independent particles (i.e., viral particles or virions). Structurally, viral particles (virions) consist of the genetic material (long molecules of either DNA or RNA that carry genetic information), a protein coat (also called the capsid or nucleocapsid, which surrounds and protects the genetic material), and in some cases an envelope [which is made up of host-derived cell membranes (phospholipids and proteins) and viral proteins, and which surrounds the protein coat when they are outside a cell]. Morphologically, viral particles (virions) may appear spherical, fusiform, rodlike, brick shaped, or pleomorphic. The envelope, when present, may be decorated with spikes, giving it a distinct appearance. The capsid (or nucleocapsid) may be icosahedral (isometric), helical, and complex in shape. The genetic material (or viral genome) may consist of either single-stranded (ss) or double-stranded (ds) ribonucleic acid (RNA) or deoxyribonucleic acid (DNA), in association with viral proteins (enzymes) that facilitate viral replication inside host cytoplasm (all RNA viruses) or nucleus (all DNA viruses apart from those belonging to the families *Asfarviridae* and *Poxviridae*).

Viruses are renowned for their ubiquity, abundance, and diversity. To date, >6000 distinct viruses have been identified from various ecological niches on Earth, including ocean, soil, air (aerosols), and inside bacteria, fungi, parasites, insects, animals, and plants. Besides ordinary viruses, there exists a category of viruses that have protein-coding deficiency and depend on other viruses for virion assembly, release, and subsequent infection of other cells (so-called viroids or subviral satellite). This is exemplified by hepatitis D virus, which is negative-sense, ssRNA virus considered as a subviral satellite of hepatitis B virus due to its reliance on the latter for the completion of its lifecycle. In addition, there is another category of viruses called prions, which is abbreviated from *pr*oteinaceous and *i*nfectious viri*on*. Prion is noted for its ability to change the normal shape of a host protein into the prion shape, which converts even more proteins into prions. Finally, a large DNA virus called mimivirus (for microbe mimicking virus) was described in 1992 from amoeba cultures. Resembling gram-positive bacterium (with a diameter of about 750 nm), mimivirus shares some characteristics with iridovirus, asfarvirus, and phycodnavirus, all members of the nucelocytoplasmic large DNA virus (NCLDV) family.

1.2 VIRUS TAXONOMY

According to their nucleic acid compositions, viruses are divided into two major groups: (1) RNA viruses that include ribonucleic acids in their genomes and (2) DNA viruses that use deoxyribonucleic acids as genetic material. On the basis of the strandedness of their nucleic acids, viruses are separated into ss or ds RNA or DNA viruses. In view of the polarity of RNA strands, RNA viruses are differentiated into positive sense, negative sense, or ambisense. As the genomic RNA of positive-sense RNA viruses is identical to viral mRNA that can be directly translated into proteins by the host ribosomes, positive-sense RNA molecules can replicate without going through additional transcription. The resulting proteins then direct the replication of the genomic RNA. On the other hand, the genomic RNA of the negative-sense RNA viruses is complementary to viral mRNA and needs to be transcribed to positive-sense mRNA by a RNA-dependent RNA polymerase (RdRp) before replication. Therefore, purified RNA of a positive-sense virus may be infectious when transfected into cells, whereas purified RNA of a negative-sense virus is not immediately infectious [1].

The modern virus taxonomy reflects the morphological, physical, biological, and genetic (genome structure and sequence homology) properties of the viruses. The latest release

Downloaded From Vet-eBooks.com

of International Committee on Taxonomy of Viruses classifies viruses into seven orders:

1. *Caudovirales* (*Myoviridae, Podoviridae Siphoviridae*),
2. *Herpesvirales* (*Alloherpesviridae, Herpesviridae, Malacoherpesviridae*),
3. *Ligamenvirales* (*Lipothrixviridae, Rudiviridae*),
4. *Mononegavirales* (*Bornaviridae, Filoviridae, Nyamiviridae, Paramyxoviridae, Rhabdoviridae*),
5. *Nidovirales* (*Arteriviridae, Coronaviridae, Mesoniviridae, Roniviridae*),
6. *Picornavirales* (*Dicistroviridae, Iflaviridae, Marnaviridae, Picornaviridae, Secoviridae*), and
7. *Tymovirales* (*Alphaflexiviridae, Betaflexiviridae, Gammaflexiviridae, Tymoviridae*).

There also are 78 families that have yet been assigned to an order (*Adenoviridae*, *Alphatetraviridae*, *Alvernaviridae*, *Amalgaviridae*, *Ampullaviridae*, *Anelloviridae*, *Arenaviridae*, *Ascoviridae*, *Asfarviridae*, *Astroviridae*, *Avsunviroidae*, *Baculoviridae*, *Barnaviridae*, *Benyviridae*, *Bicaudaviridae*, *Bidnaviridae*, *Birnaviridae*, *Bromoviridae*, *Bunyaviridae*, *Caliciviridae*, *Carmotetraviridae*, *Caulimoviridae*, *Chrysoviridae*, *Circoviridae*, *Clavaviridae*, *Closteroviridae*, *Corticoviridae*, *Cystoviridae*, *Endornaviridae*, *Flaviviridae*, *Geminiviridae*, *Globuloviridae*, *Guttaviridae*, *Hepadnaviridae*, *Hepeviridae*, *Hypoviridae*, *Hytrosaviridae*, *Inoviridae*, *Iridoviridae*, *Leviviridae*, *Luteoviridae*, *Marseilleviridae*, *Megabirnaviridae*, *Metaviridae*, *Microviridae*, *Mimiviridae*, *Nanoviridae*, *Narnaviridae*, *Nimaviridae*, *Nodaviridae*, *Nudiviridae*, *Ophioviridae*, *Orthomyxoviridae*, *Papillomaviridae*, *Partitiviridae*, *Parvoviridae*, *Permutotetraviridae*, *Phycodnaviridae*, *Picobirnaviridae*, *Plasmaviridae*, *Polydnaviridae*, *Polyomaviridae*, *Pospiviroidae*, *Potyviridae*, *Poxviridae*, *Pseudoviridae*, *Quadriviridae*, *Reoviridae*, *Retroviridae*, *Sphaerolipoviridae*, *Spiraviridae*, *Tectiviridae*, *Togaviridae*, *Tombusviridae*, *Totiviridae*, *Turriviridae*, *Virgaviridae*, and unassigned family). In turn, each family may contain one or more genera, each genus may include one or more species, and some species may have one or more isolates [2–4].

1.3 VIRUS INFECTIONS AND DISEASES

In general, the infection of host cells by a typical virus is a multistepped process: (1) after uptake by the host, virus utilizes surface proteins (enveloped) or capsid proteins (nonenveloped) to specifically bind to receptors on the host cellular membrane; (2) virus then enters into the cytoplasm through receptor-mediated endocytosis or membrane fusion; (3) inside the cytoplasm, virus uncoats or removes capsid by viral or host enzymes to release the viral genome; (4) viral polymerase transcribes from viral genome into viral mRNA and then translates into viral proteins; (5) viral proteins interact with new viral genome to form new virion particles; (6) newly assembled viruses bud off or release after cell lysis [1].

While many viruses reside in bacteria, fungi, parasites, insects, and plants, some find their way into animal hosts and cause a range of clinical symptoms (e.g., fever, inflammation, encephalitis, diarrhea), which are generally nonspecific. Tables 1.1 and 1.2 summarize major RNA and DNA virus families that are associated with clinical diseases in animals, although prions are not included in these tables. It is notable that a number of viruses are responsible for serious, and sometimes fatal diseases in animals, leading to significant economic losses and endangering the reliability of food supply. For instance, foot-and-mouth disease virus (see Chapter 8) and bluetongue virus (see Chapter 6) are associated with debilitating illnesses in livestock; canine parvovirus (see Chapter 76) causes deadly infection in pups; and deformed wing virus (see Chapter 5) induces stunted wings in honey bee. In addition, three RNA viruses [viral encephalopathy and retinopathy (see Chapter 2), yellow head virus (see Chapter 33), and gill associated virus (see Chapter 33)] and four DNA viruses [abalone viral ganglioneuritis (see Chapter 90), megalocytivirus (see Chapter 92), ostreid herpesvirus-1 microvariant (see Chapter 92), and white spot syndrome virus (see Chapter 98)] are implicated in serious contagious diseases in aquatic animals. Moreover, influenza viruses (see Chapters 41 and 46), rabies virus (see Chapter 43), hantaviruses (see Chapter 60), and arenaviruses (see Chapter 64) are examples of animal viral pathogens that pose health risks to human populations.

1.4 VIRUS IDENTIFICATION AND TYPING

Given the diversity of viruses and nonspecific signs they induce in animal hosts, an accurate diagnosis of viral infections and diseases requires the use of laboratory tests.

Traditionally, virus identification and characterization have relied heavily on phenotypic procedures. These include observing the morphological features of virions under electron microscopy; determining the viral stability by treatment at different temperatures, with various pH solutions, lipid solvents, and detergents; assessing the cytopathic effects of viruses *in vitro* using a variety of mammalian and insect cell lines; evaluating the viral pathogenicity *in vivo* using various animal models; analyzing the antigenicity and cross-reactivity of related viruses with serological tests; and ascertaining the number and sizes of viral segments by gel electrophoresis [5].

Since many of the phenotypic procedures lack the desired sensitivity, specificity, accuracy, intra- and interassay precision, as well as speed and cost-effectiveness, nucleic acid–based technologies such as gene probes, polymerase chain reaction (PCR), and nucleotide sequencing are increasingly adopted in clinical microbiological laboratories. In particular, due to their high sensitivity, specificity, and rapid testing turnaround, PCR and its derivatives (nested, multiplex, real time) have emerged as the method of choice for identification and typing of viruses and diagnosis of viral disease [6].

Nevertheless, due to the possibility that false-positive and false-negative results may occur in the nucleic acid amplification techniques such as PCR, it is critical to properly validate and standardize these test before routine application.

TABLE 1.1
Classification and Property of Animal-Infecting RNA Virus Families

Family	Strand/Sense	Genome Size (kb)	Structure (Segment)	Envelope	Virion Shape/Size (nm)	Nucleocapsid	Transmission Route	Examples
Nodaviridae	Single/positive	4.5	Linear (2)	–	Spherical/25–34	Icosahedral	Exposure, feeding	Betanodavirus
Dicistroviridae	Single/positive	7–10	Linear (1)	–	Spherical/30–32	Icosahedral	Close contact, feeding	Taura syndrome virus
Iflaviridae	Single/positive	8–10	Linear (1)	–	Spherical/26–32	Icosahedral	Feeding, mite vector	Deformed wing virus
Picornaviridae	Single/positive	7	Linear (1)	–	Spherical/28–30	Icosahedral	Feeding, droplet contact	Avian encephalitis virus; foot-and-mouth disease virus
Astroviridae	Single/positive	6–7	Linear (1)	–	Spherical/27–31	Icosahedral	Feeding	Avian astrovirus
Hepeviridae	Single/positive	7.2	Linear (1)	–	Spherical/27–34	Icosahedral	Feeding	Hepatitis E virus
Caliciviridae	Single/positive	8	Linear (1)	–	Spherical/35–39	Icosahedral	Feeding	Feline calicivirus; vesicular exanthema of swine virus
Retroviridae	Single/positive	7–11	Linear (1)	+	Spherical/80–100	Icosahedral	Close contact, mother's milk	Avian leukosis virus; feline immunodeficiency virus
Flaviviridae	Single/positive	10–12	Linear (1)	+	Spherical/45–60	Icosahedral	Insect bites; close contact, inhalation	Bovine viral diarrhea viruses; classical swine fever virus
Togaviridae	Single/positive	10–12	Linear (1)	+	Spherical/70	Icosahedral	Insect bite, droplet contact	Venezuelan equine encephalitis virus
Arteriviridae	Single/positive	15	Linear (1)	+	Spherical/45–60	Icosahedral	Close contact, feeding	Equine arteritis virus; porcine reproductive and respiratory syndrome virus
Roniviridae	Single/positive	26	Linear (1)	+	Rod shaped/160–200 × 34–63	Helical	Close contact, feeding	Yellow head virus
Coronaviridae	Single/positive	20–33	Linear (1)	+	Spherical/80–220	Helical	Droplet contact, inhalation	Avian infectious bronchitis virus; porcine epidemic diarrhea virus
Bornaviridae	Single/negative	9	Linear (1)	+	Spherical/90–150	Helical	Feeding, droplet contact	Avian bornavirus
Rhabdoviridae	Single/negative	11–15	Linear (1)	+	Bullet shaped/180 × 75	Helical	Insect bites, close contact, droplet contact	Bovine ephemeral fever virus; rabies virus
Orthomyxoviridae	Single/negative	12–15	Linear (7–8)	+	Pleomorphic/100	Helical	Droplet contact	Avian influenza virus; infectious salmon anemia virus
Paramyxoviridae	Single/negative	15–16	Linear (1)	+	Pleomorphic/150–300	Helical	Droplet contact, feeding	Canine distemper virus; Newcastle disease virus
Filoviridae	Single/negative	19	Linear (1)	+	Filamentous, pleomorphic/790–970 × 80	Helical	Direct contact	Ebola virus; Marburg virus
Bunyaviridae	Single/negative or ambisense	10–23	Linear (3)	+	Spherical, pleomorphic/80–120	Helical	Insect bite, inhalation	Akabane virus; Nairobi sheep disease virus
Arenaviridae	Single/ambisense	5–11	Circular (2)	+	Spherical/110–130	Helical	Close contact	Arenavirus
Picobirnaviridae	Double/ambisense	4–4.5	Linear (2)	–	Spherical/35–40	Icosahedral	Feeding, droplet contact	Picobirnavirus
Totiviridae	Double/ambisense	7.5	Linear (1)	–	Spherical/40	Icosahedral	Close contact, feeding	Infectious myonecrosis virus
Birnaviridae	Double/ambisense	6.1	Linear (2)	–	Spherical/60	Icosahedral	Feeding	Infectious bursal disease virus
Reoviridae	Double/ambisense	18–30	Linear (10–12)	–	Spherical/60–80	Icosahedral	Feeding; insect bite	Bluetongue virus; epizootic hemorrhagic disease virus

In addition, participation in external quality assurance programs provides an opportunity to assess the technical preparedness of the diagnostic laboratories involved in the molecular identification and typing of viruses.

1.5 CONCLUSION

With amazing diversity, versatility, and adaptability, viruses have found their way into virtually all ecological niches on Earth. Continuing population growths accompanied by habitat alteration and destruction, and increasing international trades and travels have contributed to the spread of viruses to where they were once absent. As a consequence, emerging and remerging viral pathogens are responsible for an-ever climbing number of epidemics in animals and humans worldwide. Owing to their time-consuming and variable nature, traditional phenotypic procedures are incapable of dealing this emergency. With exceptional sensitivity, specificity, detection limit, repeatability, and reproducibility, new generation genotypic procedures, especially PCR-based techniques, have risen to the challenge and are now widely adopted in routine diagnostic laboratories for detection and tying of viral pathogens of veterinary and medical significance. Nevertheless, certain phenotypic procedures such as virus isolation remain indispensable for advanced studies of viruses, including virus genome sequencing and characterization, analysis of immune responses, determination of pathogenicity in animal model, assessment of phenotypic antiviral susceptibility and vaccine preparations.

2.1 INTRODUCTION

Betanodavirus is the etiological agent of viral nervous necrosis (VNN), also known as vacuolating encephalopathy and retinopathy (VER) or encephalomyelitis, which is a devastating viral disease affecting marine and freshwater fish species worldwide. First observed in 1986 on an aquaculture farm of Japanese parrotfish (*Calotomus japonicus*) in Nagasaki, Japan, VNN was linked to loss of balance, necrosis in the brain and retina, and death of fish fry (of 6–25 mm length) during the summer (June–July) [1]. Almost simultaneously, VNN was discovered in Australia, Norway, and France, involving barramundi (Asian sea bass, *Lates calcarifer*), turbot (*Scophthalmus maximus*), European sea bass (*Dicentrarchus labrax*), red-spotted grouper (*Epinephelus akaara*), striped jack (*Pseudocaranx dentex*) [2–5], and other cultured warm-water and cold-water marine fish species ($n = 30$) throughout the world [1]. Given its capacity to induce high mortality (80%–100%) in juvenile fish, VNN exerts huge economic and ecological burdens on aquaculture industry and wild marine species [6]. In this chapter, we focus on betanodavirus in relation to its taxonomy, morphology, genome structure, epidemiology, clinical features, pathogenesis, diagnosis, and control, together with stepwise molecular protocols for its identification and diagnosis.

2.1.1 Classification

The family *Nodaviridae* (noda, derived from Nodamura, a Japanese village where Nodamura virus [NoV] was isolated) encompasses small (<5 kb), nonenveloped, isometric viruses with bipartite, positive-sense, single-stranded (ss) RNA genomes that are infective to insects (genus *Alphanodavirus*) and fish (genus *Betanodavirus*). Currently, the genus *Alphanodavirus* contains five recognized insect-infecting species (black beetle virus, Boolarra virus, flock house virus, NoV, and Pariacoto virus), while the genus *Betanodavirus* consists of four established fish-infecting species (barfin flounder nervous necrosis virus [BFNNV], red-spotted grouper nervous necrosis virus [RGNNV], striped jack nervous necrosis virus [SJNNV, type species], and tiger puffer nervous necrosis virus [TPNNV]). In addition, a large number of viruses remain unassigned in the family *Nodaviridae*, with >30 viruses being tentatively placed in the genus *Betanodavirus* alone [7–9].

Classification of betanodaviruses has been largely based on similarities detected in the variable region of the viral coat protein (CP) gene (located on RNA2 segment) [8]. Through comparative analysis of 78 full-length CP gene sequences of betanodaviruses originated from various geographical locations, six major clusters (groups I, II, III, IV, V, VI) are noted. Of these, groups II, III, IV, and VI are similar to the classic species, while groups I and V are single-isolate clusters that may be considered as new species. More specifically, group II (TPNNV) consists of two isolates from tiger puffer in Japan; group III (SJNNV) includes 10 isolates from striped jack, gilt-head sea bream, sole fish, and greasy grouper; group IV (BFNNV) has nine isolates in three subgroups (IVa, IVb, and IVc), with group IVa containing four isolates from Atlantic cod, group IVb having three isolates from barfin flounder, and group IVc having one isolate each from Atlantic cod and Malabar grouper;

Downloaded From Vet-eBooks.com

and group VI (RGNNV) covers 55 isolates from 14 fish species with very different geographical locations in Asia, Europe, and Australia. Groups I and V are single-isolate clusters originated from European sea bass and turbot in colder regions (France and Norway, respectively) (Table 2.1) [10–13]. Indeed, despite its relatedness to group II (TPNNV) and group III (SJNNV) isolates based on comparative analysis of the partial RNA2 sequence, group I turbot nodavirus (AJ608266), originally isolated from turbot in Norway, was sufficiently different to represent possibly a fifth species in the genus *Betanodavirus* [14]. Similarly, placed in between the BFNNV and RGNNV clusters, *Dicentrarchus labrax* encephalitis virus (U39876) from sea bass in France may constitute another distinct species within the genus [8].

Due to the multiplicity of hosts, diversity of environments, and frequent movement of virus-infected fish through international trade, betanodaviruses with bipartite RNA genomes are constantly subjected to mutation (substitution) and reassortment pressures, which contribute to their genetic variability [15]. This is exemplified by the findings that group IV (BFNNV) can be subdivided into three subgroups (IVa, IVb, and IVc) on the basis of sequence differences in CP gene and that some RGNNV and SJNNV isolates from the Mediterranean possess RNA1 segment related to one particular species and RNA2 segment related to another species (i.e., RGNNV/SJNNV and SJNNV/RGNNV). Serologically, both BFNNV and RGNNV belong to serotype C, despite being present mainly in cold-water species and warm-water species, respectively, while SJNNV is of serotype A and TPNNV of serotype B. This highlights the value of analyzing sequences from both RNA1 and RNA2 segments for precise determination of a given *Betanodavirus* isolate [8].

Interestingly, recent experimental study on the effect of two coexistent *Betanodavirus* viruses through coinfection and superinfection indicated that SJNNV replication is partially inhibited by the coexistence with RGNNV, whereas RGNNV replication is favored in coinfection or superinfection with SJNNV [16].

TABLE 2.1
Phenotypic and Genotypic Characteristics of the Genus *Betanodavirus*

Species	Optimal Temperature for Replication	Serotype	Phylogroup
Striped jack nervous necrosis virus (SJNNV)	20°C–25°C	A	III
Tiger puffer nervous necrosis virus (TPNNV)	20°C	B	II
Barfin flounder nervous necrosis virus (BFNNV)	15°C–20°C	C	IV (IVa, IVb, IVc)
Red-spotted grouper nervous necrosis virus (RGNNV)	25°C–30°C	C	VI
Turbot nodavirus (TNV) (AJ608266/Norway)	No growth on SSN-1 cells	Unknown	I
Dicentrarchus labrax encephalitis virus (U39876/France)	25°C	Unknown	V

2.1.2 Morphology and Genome Structure

Members of the genus *Betanodavirus* are spherical, nonenveloped, and icosahedral viruses of about 25–34 nm in diameter. Being "nonenveloped," these viruses lack an outermost layer that is usually made up of lipids and proteins, and their genetic material is surrounded by icosahedral-shaped capsid (shell), which is constructed of 32 capsomers and shows a triangulation number = 3 ($T = 3$) icosahedral symmetry [17].

The genome of betanodaviruses is composed of two linear positive-sense, single-stranded RNA segments: RNA1 and RNA2 (both of which possess a 5′ terminal methylated cap and a non-polyadenylated 3′ terminal, i.e., without a poly(A) tail). The virion RNA is infectious and serves as both the genome and viral messenger RNA.

RNA1 (3103 nt in length with a G + C content of 49.6%) consists of an open reading frame (ORF) flanked by a 78 nt 5′-nontranslated regions (NTR) and a 77 nt 3′-NTR region. This ORF encodes a 982 aa protein with a calculated molecular mass of 110.74 kDa, which includes multiple functional domains: a mitochondrial targeting domain, a transmembrane domain, an RNA-dependent RNA polymerase (RdRp) domain, a self-interaction domain, and an RNA capping domain [6,8].

At the *N*-terminal region (the 3′ end) of RNA1 segment, a subgenomic RNA (sgRNA3 or RNA3, of 371 nt in length with a G + C content of 62%) exists. RNA3 contains an ORF that encodes a 75 aa peptide corresponding to a hypothetical B2 protein. This protein functions as an RNA silencing inhibitor of the host RNA interference system and facilitates intracellular viral RNA accumulation. RNA3 is present only in the nucleus of a virus-infected cell but not incorporated into the virion [6,18].

RNA2 (of 1433 nt in length with a G + C content of 53.24%) harbors an ORF flanked by 26 nt 5′-NTR and a 390 nt 3′-NTR. This ORF encodes a 338 aa viral capsid protein precursor α (of 42 kDa), which is autocleaved at a conserved Asn/Ala site during virus assembly into two mature proteins: a β-protein with a calculated molecular mass of 37.059 kDa and a γ-protein of 5 kDa [19]. The β-protein (CP) is the key component of the viral capsid and consists of a highly conserved region and a variable region [6].

2.1.3 Biology and Epidemiology

Replication of betanodavirus involves a number of steps. These include (1) penetration into the host cell, (2) uncoating and release of the viral genomic RNA into the cytoplasm, (3) translation of RNA1 into RdRp protein, (4) synthesis of dsRNA genome from the genomic ssRNA(+), (5) transcription of dsRNA genome into viral mRNAs/new ssRNA(+) genomes, (6) expression of subgenomic RNA3, (7) translation of RNA2 into capsid protein α, (8) assembly of virus around genomic RNA1 and RNA2 in the cytoplasm, (9) cleavage of assembled capsid protein alpha into capsid protein β and γ, and (10) release of infectious particles [8].

Betanodavirus often enters the host via fin epithelial cells or skin epithelial cells. After passage through the fin skin into the fin tissue, the virus multiplies and spreads to the circulatory system. Large quantities of virus particles are distributed in primary tissues (brain and retina). Surviving fish may copious amounts of virus remaining in fin tissue, resulting in a carrier state. The release of the virus from fin epithelial cells into the seawater facilitates horizontal transmission to other fish [8,20–22].

Although the causative agent of VNN was first purified from diseased striped jack larvae and named striped jack nervous necrosis virus (SJNNV) in the later 1980s in Japan, Australia, Norway, and France [1], the earliest evidence related to the virus dates back to 1984 in Queensland, Australia, when clinical signs and histopathological lesions similar to VNN were observed in diseased larval barramundi (*Lates calcarifer*) [2].

A broad range of fish species, including marine and freshwater fish produced through aquaculture or living in the wild, are susceptible to betanodavirus infection [23,24]. To date, 39 fish species belonging to 22 families in 8 orders have been found to be prone to VNN. These include marine food and game fish species (red drum [*Sciaenops ocellatus*], cobia [*Rachycentron canadum*], sea bass [*Dicentrarchus labrax*], barramundi [*Lates calcarifer*], gilt-head sea bream [*Sparus aurata*], Pacific bluefin tuna [*Thunnus orientalis*], grouper [family *Serranidae*], halibut [*Hippoglossus hippoglossus*], and Japanese flounder [*Paralichthys oliveatus*]), marine ornamental fish species (convict surgeonfish [*Acanthurus triostegus*], lined surgeonfish [*Acanthurus lineatus*], narrowstripe cardinalfish [*Apogon exostigma*], threespot dascyllus [*Dascyllus trimaculatus*], Scopas tang [*Zebrasoma scopas*], blueband goby [*Valenciennea strigata*], tiger puffer [*Takifugu rubripes*], lemonpeel angelfish [*Centropyge flavissimus*], and orbicular batfish [*Platax orbicularis*]), freshwater species (tilapia [*Oreochromis niloticus*] and Chinese catfish [*Parasilurus asotus*]), and ornamental fish (guppy [*Poecilia reticulata*)] [25–34]. In laboratory studies, medaka (*Oryzias latipes*) and zebrafish *(Danio rerio*) are susceptible [35–37].

While fish at larvae or juvenile stages are often affected, significant mortality may also occur in older fish. In striped jack, VNN may occur between 1 and 20 days posthatching (8 mm total length), leading to an almost complete loss of larvae [1,38]. In European sea bass, mortality due to VNN is not seen until about 30 days posthatching. In seven-band grouper (*Epinephelus septemfasciatus*), VNN causes those of up to 1.8 kg body weight to exhibit belly-up swimming and inflation of the swim bladder, with lowered mortality in juvenile or older fish [39].

VNN has been reported on all continents apart from South America, including Asia (Japan, Korea, China, Taiwan, Vietnam, Thailand, Malaysia, Singapore, Indonesia, Brunei, Philippines, India), Middle East (Israel), Oceania (Australia, Tahiti), Europe (Croatia, Bosnia, Greece, Malta, Italy, France, Spain, Portugal, Tunisia, United Kingdom, Norway), and North America (United States, Canada) [6,40–44].

It appears that various betanodaviruses have adapted to tropical, subtropical, or cold-temperate environments. This is indicated by the preferred temperature ranges of 25°C–30°C, 20°C–25°C, 20°C, and 15°C–20°C, for RGNNV, SJNNV, TPNNV, and BFNNV, respectively (Table 2.1). Use of an established cell line (SSN-1) pinpoints that the optimal temperature for betanodavirus growth is 25°C and that the upper temperature limits for RGNNV are ~32°C [45].

Betanodaviruses can be spread horizontally (from infected fish to uninfected, naïve fish in the same water body) or acquired through exposure to virus-contaminated water [46]. They may also be transmitted through feeding of contaminated live foods, fish and mollusks, including copepod (*Tigriopus japonicus*), brine shrimp (*Artemia*), shrimp (*Acetesinte medius*), Japanese jack mackerel (*Trachurus japonicus*), and Japanese common squid (*Todarodes pacificus*) [47]. Furthermore, betanodaviruses may be transmitted vertically from brood stock to offspring, both within and on fertilized eggs [48–50].

2.1.4 Clinical Features and Pathogenesis

Betanodaviruses are neuropathogenic with the ability to cause damages throughout the central nervous system. Therefore, clinical signs of VNN-affected larvae and juvenile stages are largely neurological, ranging from anorexia, lethargy (clustering near the side of a pool), abnormal schooling and swimming behavior (vertical positioning and spinning), flexing of the body, muscle tremors, hyperinflation of the swim bladder (causing fish to float belly up at the surface), traumatic lesions (due to uncontrolled swimming/spinning), changes in skin pigmentation (either darkening or lightening), and scoliosis to death (up to 100% within 1 week of symptom onset).

Histopathologically, VNN is characterized by severely extended necrosis, vacuolation, and degeneration of the central nervous system (brain, spinal cord) and retina, but some fish in early larval stages may lack tissue vacuolation [42].

Betanodaviruses manage to evade the host's protective systems by interrupting and inhibiting host nonspecific (innate) and specific immune responses through production of the interferon-induced antiviral protein Mx in the infected fish [51,52]. This enables the virus to replicate and transmit progeny to other cells or to remain undetected by host immune surveillance in a latent condition [53]. In addition,

Downloaded From Vet-eBooks.com

betanodaviruses are adept in exploiting various environmental and procedural stressors (e.g., high density and high temperatures) that weaken the immune systems of fish and render them vulnerable to microbial infections.

2.1.5 Diagnosis

Differential diagnosis of VNN includes various microbial infections (bacteria, virus, parasites), environmental factors (e.g., high ammonia levels in water), or toxins (e.g., pesticides), which may also contribute to changes in swimming behavior and pigmentation. A number of laboratory diagnostic tests can be used to confirm VNN, including histopathology, virus isolation, serology, and nucleic acid detection [34].

Histopathology involves preparation of thin, fixed-tissue sections on a glass slide, staining, and examination under microscope. Observation of vacuoles (holes) and necrosis (presence of dead tissue) in the brain, spinal cord, and retina of the eye by light microscopy provides presumptive diagnosis of VNN [34]. Electron microscopic examination reveals the virus in association with vacuolated cells and accumulating intracytoplasmically in paracrystalline arrays or as aggregates.

Virus isolation relies on cell culture to isolate and propagate the virus and to detect its cytopathic effects [34]. Several fish cell lines are now available for betanodavirus isolation: SSN-1 and E-11 derived from striped snakehead (*Ophicephalus striatus*) [54–56], GF-1 and other cell lines from groupers [57,58], and TV-1 and TF from turbot [59].

Serology checks for evidence of virus antigens or fish antibodies made against the virus. Commonly used serological tests include immunostaining methods, fluorescent antibody test, immunohistochemistry, and enzyme-linked immunoassay, as well as immunomagnetic reduction assay, which employs magnetic nanoparticles coated with dextran and antibodies [34,60].

Nucleic acid detection of betanodaviruses can be done by direct hybridization with a DNA probe or through amplification and detection by reverse transcription polymerase chain reaction (RT-PCR) or other techniques [61–64]. RT-PCR provides a rapid and convenient method for identification of betanodaviruses. Nested PCR involving second-round amplification is useful to diagnose asymptomatic fish (brood stock) [65–69]. In particular, the primer set R3 and F2 targeting the variable region (ca. 380 bases) of the SJNNV CP gene allows detection of most genotypic variants [65,66]. Recent development of real-time RT-PCR assay (rRT-PCR) enables highly sensitive detection and quantification of betanodaviruses [70–73]. Other nucleic acid detection approaches include loop-mediated isothermal amplification (LAMP), real-time LAMP, and microfluidic LAMP system [74–77]. Ideally, PCR detection is followed by another method, either histopathology with immunostaining or virus isolation in cell culture, for result validation [78].

2.1.6 Treatment and Prevention

Currently, no effective treatments are available for VNN. Depopulation followed by disinfection is recommended. Good husbandry, close monitoring of fish behavior, and prompt identification of betanodavirus infection by laboratory tests are critical to limit the damages due to this disease. It is vital to isolate sick fish and handle them separately. Quarantine of new fish in a separate building before adding to existing farm populations is important.

To prevent horizontal transmission of infection, betanodaviruses can be inactivated with 50 ppm of chlorine, 50 mg/L sodium hypochlorite, calcium hypochlorite, benzalkonium chloride, and iodine for 10 min, 60% ethanol, 50% methanol, high alkalinities (pH 12 for 10 min), heat treatment (60°C for 30 min), ultraviolet (UV) radiation ($1.5–2.5 \times 10^5$ μ Ws/cm^2 at a UV intensity of 440 μ W/cm^2), acid–peroxygen, and ozone (at 0.1 μg/mL for 2.5 min). However, they are resistant to chloroform, ether, and formalin [79,80].

To prevent vertical transmission of infection from brood stock to offspring, washing fertilized eggs in ozone-treated seawater and disinfection of rearing water by ozone (e.g., 1 mg O_3/L for 1 min for striped trumpeter) are effective in controlling VNN in larvae production of striped jack, barfin flounder, Atlantic halibut, seven-band grouper, and striped trumpeter [22,81].

Improvement in spawning induction methods including brood stock feed and water supply is beneficial [81]. As betanodavirus can be spread by contaminated water, it is necessary to keep separate equipment (nets, siphon hoses) for each system, to disinfect systems or tanks between uses, to place footbaths and hand disinfectants (alcohol spray or handwashing stations) judiciously, and to use water from a clean source (e.g., deep wells) or water that has been processed with adequate UV sterilization or chlorinated and dechlorinated.

Vaccination of larvae and older grow-out fish with inactivated betanodavirus or viruslike particles expressed by baculovirus or *Escherichia coli*, synthetic peptides based on the virus capsid, recombinant proteins, and DNA vaccine increases the production of neutralizing antibodies against the homologous virus, activates genes associated with cellular and innate immunity, suppresses viral replication in the brains and kidneys, and reduces disease incidence [82–84]. Vaccination of brood stock reduces the risk of vertical transmission of NNV to offspring [50].

2.2 METHODS

2.2.1 Sample Preparation

Samples are collected using aseptic technique from juvenile fish showing clinical signs of VNN. The preferred/primary samples for betanodavirus diagnosis are brain, eye (retina), and fin. Other samples (gill, head, kidney, heart, intestine, liver, spleen, muscle, and blood) may be used as alternatives.

The tissues are frozen in liquid nitrogen and homogenized in 10 volumes of L15 medium, centrifuged at 10,000 rpm for 20 min, and the supernatant is passed through a 0.22 μm filter and stored at −80°C until use.

Total RNA may be extracted from fish eyes/brain or cell culture supernatant using RNeasy Mini kit (Qiagen), NucleoSpin RNA virus kit (Macherey-Nagel), or TRIzol

Downloaded From Vet-eBooks.com

reagent (Invitrogen). For NucleoSpin RNA virus kit, 150 µL of cell culture supernatant or 150 µL of supernatant of organ pool (brain and eyes) ground up in cold phosphate buffered saline (PBS) (10%, w/v) is used. For TRIzol reagent (Invitrogen), 100 mg tissue is mixed with 1 mL TRIzol reagent and 200 µL of ice-cold chloroform. After isopropanol precipitation, the RNA pellet is resuspended in diethylpyrocarbonate-treated water. The RNA concentration and purity are determined at the absorbance of 260 nm (A_{260}) with a Nanodrop spectrophotometer (Thermo Fisher Scientific).

2.2.2 Detection Procedures

Among the numerous published RT-PCR methods for betanodavirus detection and identification, a majority focus on the RNA2 segment, which encodes the CP [34]. In the succeeding sections, two stepwise protocols are presented: one conventional PCR targeting RNA2 (which is valuable to laboratories without access to real-time PCR equipment) and one real-time RT-PCR targeting RNA1. Clearly, molecular procedures for VNN diagnosis are not limited to these two, and laboratories are advised to evaluate and adopt those most suited to their own circumstances.

2.2.2.1 Conventional RT-PCR

Kuo et al. [85] described the use of primers (203-F, 5′-GACGCGCTTCAAGCAACTC-3′, and 203-R, 5′-CGAACACTCCAGCGACACAGCA-3′) from the CP gene (of RNA2 segment) to amplify a 203 bp fragment from betanodaviruses.

RT is conducted with 2 µL of the extracted total RNA (TRIzol reagent) and Moloney murine leukemia virus reverse transcriptase (Promega) in accordance with the manufacturer's protocol.

PCR amplification may be performed with AmpliTaq Gold® PCR Master Mix (Applied Biosystems) in 25 µL volumes containing 2 µL of cDNA, 0.4 µM of each primer (203-F and 203-R), 1 µL of bovine serum albumin (BSA) 1%, and 2.5 mM $MgCl_2$.

PCR cycling conditions include 94°C for 4 min (initial denaturation), 45 cycles of 94°C for 30 s, 55°C for 30 s, and 72°C for 30 s and a final hold at 72°C for 5 min.

Amplification products are resolved on 1.5% agarose gels. Samples showing a 203 bp band are considered positive for betanodaviruses.

Note: If desired, the primer set (203-F and 203-R) can be applied in SYBR green-based real-time qPCR. PCR mixture (25 µL) is made up of 12.5 µL of 2× SYBR gren master mix (Applied Biosystems), 5 µM (each) forward and reverse primers, and 2 µL cDNA. Amplification and detection is performed in 96-well plate using GeneAmp 2700 thermocycler coupled with a GeneAmp 7000 sequence detection system (Applied Biosystems) in wells of a 96-well plate. The thermal profile consists of 1 cycle of 95°C for 2 min, 40 cycles of 95°C for 15 s, 60°C for 1 min, and 72°C for 20 s. The fluorescence of SYBR green against the internal passive reference dye ROX (ΔR_n) is measured at the end of each cycle. A sample is considered positive when the ΔR_n value exceeds the threshold value. The threshold value is set at the midpoint of the ΔR_n versus the cycle number plot. For all the amplifications described in this study, the threshold value of ΔR_n is set as 0.25. The threshold cycle (C_T) is defined as the cycle at which a statistically significant increase in R_n is first detected. The copy number of the VNN sample is determined by normalizing the C_T values of the samples and then extrapolating the normalized C_T values to the standard curve of the corresponding virus. VNN-infected and healthy grouper had C_T values of 12–24 and 29–32, respectively.

2.2.2.2 Real-Time RT-PCR

Baud et al. [73] describe a generic real-time RT-PCR for detection and quantification of betanodaviruses in clinical specimens. The primers (oPVP154: 5′-TCCAAGCCGGTCCTAGTCAA-3′ and oPVP155: 5′-CACGAACGTKCGCATCTCGT-3′), each containing one base degeneration, amplify a 168 or 171 nt fragment from a conserved region at the 3′ end of the RNA1 segment, which is detected with the TaqMan tqPVP16 probe (Cy5-CGATCGATCAGCACCTSGTC-BHQ2). While the tqPVP16 probe and primer oPVP155 are located within the subgenomic RNA3, the primer PVP154 shares only 7 nt with this molecule.

An RT-PCR mixture (25 µL) is made up of 600 nM of each primer, 400 nM of probe, 5 µL of RNA, and 1× of Quantitect Probe RT-PCR master mix (Qiagen). Amplification and detection are conducted using CFX96 (Bio Rad) or RotorGene 6000 (Corbett), with the following parameters: 50°C for 30 min, and 95°C for 10 min, and then 40 cycles of denaturation/extension at 94°C for 15 s and at 60°C for 60 s.

Ct values are obtained starting with 10-fold dilutions of total RNA extracted from cell culture inoculated with an RGNNV strain.

Note: This RT-PCR enables detection of genotypes representative of the four recognized species of betanodaviruses, as well as five reassortants between RGNNV and SJNNV. Due to its rapid, sensitive, and specific features, the assay has potential for routine application in different geographic regions and host species. Sequencing analysis of the amplified product will yield genotyping data of the specimen.

2.3 CONCLUSION

Betanodaviruses are responsible for causing VNN or VER in marine finfish and some freshwater species worldwide, with mortalities of 80%–100%. While younger life stages are especially vulnerable, some older fish are also affected. As betanodaviruses are neuropathogenic (with a tendency to attack the brain, spinal cord, and eye), infected fish often display abnormal behavior (e.g., spinning or whirling, abnormal posture, muscle tremors) before succumbing to the disease. Since other diseases may also induce similar clinical signs, it is important to have VNN diagnosed early and appropriate control measures implemented promptly. Among the diagnostic methods available (light and electron microscopy, virus isolation, serology, and nucleic acid amplification), RT-PCR appears to be a standout, in terms of rapidity,

Downloaded From Vet-eBooks.com

sensitivity, and specificity [86]. Given the high frequency of mutations in betanodavirus populations, it is important to analyze the sequencing variations in outbreak isolates and update the primers and probes if necessary. In addition, if false-negative PCR results are suspected, use of another technique (e.g., cell culture, or another PCR targeting a different region of the genome) may be helpful.

3.1 INTRODUCTION

Taura syndrome (TS) of peneid shrimp was described in 1992 in *Penaeus vannamei* harvested from shrimp farms near the Taura River in Ecuador [1]. TS later spread to many countries, including the United States, Taiwan, China, Thailand, and Indonesia [2–4]. The viral etiologic agent, Taura syndrome virus (TSV), was identified in 1994 through infectivity studies using specific pathogen-free *P. vannamei* as the host [5]. The principal hosts of TSV are white shrimp *P. vannamei* and blue shrimp *P. stylirostris*. However, other shrimp species such as *P. setiferus*, *P. monodon*, *P. chinensis*, *P. aztecus*, *P. duorarum*, *P. indicus*, and *Metapenaeus ensis* can be infected by the virus [6–12]. The disease often results in cumulative mortalities ranging from 40% to >90% of cultured populations of postlarval, juvenile, and subadult shrimp. Shrimp with TS are typically small juveniles weighing between 0.05 g and less than 5 g [6,8,13]. The horizontal transmission of TSV by cannibalism or contaminated water has been documented [5,6,8,14], but vertical transmission has not been experimentally verified. Currently, there are no vaccines or chemotherapy treatments available. Therefore, to reduce the risk of TSV infection during shrimp farming, screening of brood stock and spawned eggs/nauplii using polymerase chain reaction (PCR) has been applied. The development of specific pathogen-free shrimp stocks of *P. vannamei* and *P. stylirostris* has proven to be the most successful husbandry practice for the prevention and control of TS [15].

3.1.1 Classification

Characteristics of TSV virions include a buoyant density of approximately 1.338 g mL^{-1} in CsCl, icosahedral morphology, a size of 31–32 nm in diameter, and a positive sense single-stranded RNA (ssRNA) genome that is polyadenylated at the 3′ end [16]. Therefore, the virus was initially classified as a member of the family *Picornaviridae* [5,16]. However, genomic characterization and sequence comparison revealed that TSV is closely related to the cricket paralysis-like virus [17]. Presently, TSV has been classified by the International Committee on Taxonomy of Viruses into the novel genus *Aparavirus* in a new family *Dicistroviridae* in the order *Picornavirales* [18].

3.1.2 Genome Organization, Biology, and Epidemiology

TSV is small, with a nonenveloped icosahedral shape. The ssRNA genome is 10,205 nucleotides in length, excluding the 3′-poly(A) tail, and contains two large open reading frames (ORFs) separated by an intergenic region (IGR) of 207 nucleotides [17]. The amino acid sequence of ORF1 consists of helicase, a protease, and an RNA-dependent RNA polymerase (RdRp). ORF2 contains the sequences of structural proteins, including three major capsid proteins, VP1 (CP2, 55 kDa), VP2 (40 kDa), and VP3 (24 kDa). ORF1 and ORF2 represent 92% of the TSV genome, and the remaining 8%

Downloaded From Vet-eBooks.com

consists of an untranslated region (UTR). In the 3′-UTR, no putative polyadenylation signal (AAUAAA) was identified [17]. Sequence homology of the IGR between TSV and other members of the cricket paralysis-like viruses suggested that TSV ORF2 was translated by an internal ribosome entry site (IRES) [17]. Unlike other IRES-mediated translation initiations, the IGR-IRES-mediated initiation of translation in discistroviruses was shown to occur in the absence of base-pair interactions between the initiation codon and the anticodon triplet in initiator methionine tRNA (Met-tRNAi). Therefore, the IRES did not require an AUG initiation [19]. It has been shown that TSV translation from IGR-IRES started from a non-AUG start codon and did not involve initiator methionyl-$tRNA^{Met}$. Translation from the TSV IGR-IRES initiated with alanyl-$tRNA^{Ala}$ even though there was an in-frame AUG codon positioned two codons upstream of the GCU-alanine codon of the TSV structural polyprotein [20].

In the absence of initiation factors, TSV IGR-IRES elements can recruit ribosomes and direct protein synthesis in a reconstituted system containing only purified ribosomal subunits, eukaryotic elongation factors 1A and 2, and aminoacylated tRNAs [20]. A computational-based structure search suggested that TSV had an internal stem-loop structure in the predicted IRES, and *in vitro* translation analysis showed that TSV had a structurally distinct IGR-IRES [21]. The IGR-IRESs contain three pseudoknots, one of which, called pseudoknot I (PKI), is essential for the function of IGR-IRES [22]. A cryomicroscopy structure analysis revealed that PKI of TSV IRES occupied the ribosomal decoding center at the aminoacyl (A) site in a manner similar to that of the tRNA anticodon/mRNA codon. Moreover, the structure indicated that TSV IRES initiated translation by an unprecedented mechanism. Specifically, the ORF of the IRES-driven mRNA was established by the placement of the tRNA–mRNA-like structure in the A site, whereas the 40S P site remained unoccupied during the initial step [23].

VP1 (equivalent to capsid protein 2; CP2) demonstrates greater variation in its amino acid sequence (3.5%) than VP2 (CP1) and VP3 (CP3) (both 0.8%) [24]. Therefore, the CP2 region has been used to establish the genetic relationship among TSV isolates. Currently, at least four genotypic variants have been identified according to the sequence of the VP1 structural protein. These variants are the Americas group, the Southeast Asian group, the Belize group, and the Venezuelan group [12,25,26]. In 2010, a newly emerged strain of TSV isolated from Colombian shrimp farms called CO 10 was analyzed. The phylogenetic analysis based on the CP2 amino acid sequence indicated that the CO 10 strain forms a new cluster and differs from the previous Colombia isolates. The results revealed the diversity of TSV CP2 in the Americas group leading to two new subclusters in South America (Venezuela and Colombia) and a new subcluster in Mexico in the Central America variant [27].

Infection of TSV occurs in tissues derived from the ectoderm and mesoderm. Infection in the cuticular epithelium was most prevalent in shrimp with acute infections, and the infection in lymphoid organs was observed in shrimp with chronic infections. Histological analysis revealed no signs of infection of TSV in the enteric organs [10,28–30].

In TSV vector studies, it has been demonstrated that the feces of seagulls (*Larus atricilla*) can contain infectious TSV particles for up to 6 h after consumption of viral-infected shrimp tissues. Therefore, this wild seabird may serve as a vector for transmission of TSV to aquatic environments [31]. In addition, the water boatman *Trichocorixa reticulata* (*Corixidae*), an aquatic insect collected from ponds with active TS, was shown to be TSV positive using *in situ* hybridization (ISH) assay in the gut [6,32].

A study on potential carriers of TSV was conducted in Thailand with five common native crustaceans found near shrimp ponds including two palaemonid shrimp species, *Palaemon styliferus* and *Macrobrachium lanchesteri*, and three crab species, *Sesarma mederi*, *Scylla serrata*, and *Uca vocans.* The results showed that *U. vocans*, *S. serrata*, and *S. mederi* gave strong reverse transcription polymerase chain reaction (RT-PCR) at 10, 15, and 50 days (d), respectively, after feeding with TSV-infecting *P. vannamei* carcasses. Also after feeding, a strong RT-PCR reaction was observed in *P. stylirostris* at 5 d postchallenge but no reaction occurred at 15 d. In the case of *M. lanchesteri*, a light RT-PCR reaction was observed at 2 d after feeding but no reaction occurred at 15 d. These results suggest that these crabs and palaemonid shrimp species can pose a risk as potential carriers for TSV transmission [33].

TS first appeared in Ecuador in 1992 [1] and may have caused up to US$100 million worth of damage [6]. TS has spread progressively to the United States, including the states of Hawaii, Texas, and Florida [34]. It was estimated that the outbreaks of TS in Southern and Central Texas led to US$10 million losses [6]. TS also caused an impact on shrimp farms in other countries in South and Central America, including Peru, Honduras, Guatemala, El Salvador, Brazil, Nicaragua, Belize, and Mexico [34]. TSV may have spread from South America to Asia due to importation of infected live *P. vannamei*, which became a primary shrimp species in Asia during the 1990s. The first TS outbreak in Asia occurred in Taiwan in late 1998 to early 1999, and shrimp production dropped abruptly to as low as 10% of the volume produced in early 1998. It was assumed that TSV was transferred to Taiwan by contaminated postlarvae and spawners from Ecuador and elsewhere [2]. In Thailand, the first TS outbreak was confirmed in 2003 after legal importation of *P. vannamei* in mid-2002. During that time, over 150,000 brood stock shrimp were officially imported from China and Taiwan [35]. In 2004, mass mortality of *P. vannamei* shrimp cultured in Korea occurred, and it was suggested that TSV was introduced to Korea via imported stocks of *P. vannamei*. Based on the partial nucleotide sequences of VP1, two Korean TSV isolates were 96%–99% similar to those of TSV isolates from the Americas, Taiwan, and Thailand [36].

During the mid-1990s, TSV caused devastation to the shrimp industries of Ecuador and Colombia. At that time, 20%–30% of shrimp survived, and various staff including technicians and researchers speculated that the survivors could be genetically resistant animals. Therefore, one of

Downloaded From Vet-eBooks.com

the major shrimp producers in Colombia initiated a program to select the survivors from infected ponds and used them as parents for the next generation in a simple mass selection process. Within two to three generations, the success of this simple scheme increased survival rates to previous levels [37].

In response to TSV outbreaks in the United States, the U.S. Marine Shrimp Farming Program initiated a selective breeding program to improve TSV resistance in *P. vannamei*, operated by the Oceanic Institute (OI). From 1995 to 1998, the OI (Waimanalo, Hawaii, United States) operated a breeding program based on a selection index weighted equally for growth and resistance to TSV. One line demonstrated an 18.4% increase in survival to TSV after one generation of selection compared with unselected control families [38]. The OI had been selecting *P. vannamei* for TSV resistance for over 15 generations, and several families per generation exhibited 100% survival after exposure [39]. Over the past decade, several shrimp breeding programs have distributed TSV-resistant brood stock to commercial shrimp hatcheries worldwide. Therefore, the availability of TSV-resistant shrimp is of great benefit to the shrimp farming industry, and TSV is no longer considered to be a major threat in many shrimp farming regions [40].

The first transcriptomic study in hemolymph and hemocytes of TSV-resistant and susceptible *P. vannamei* was recently conducted using high-throughput RNA-seq. The comparison of gene expression between resistant and susceptible shrimp revealed several differentially expressed genes involved in the immune response activity. These included (1) pathogen recognition through cues such as immune regulators, adhesive proteins, and signal transducers, (2) coagulation, (3) proPO pathway, (4) antioxidation, and (5) protease [41].

3.1.3 Clinical Features and Pathogenesis

TSV infection in *P. vannamei* exhibits gross pathology in three distinct phases including acute, transition, and chronic phases.

During the acute phase of disease outbreak in *P. vannamei*, onset of mortality is often sudden and massive with moribund shrimp approaching the pond edge and surface water. Moribund shrimp in the acute phase demonstrate symptoms such as a soft shell, pink to red coloration due to the expansion of red cuticular chromatophores especially in the tail fan, and visible necrosis of the epithelial tissue. Infected shrimps are lethargic, stop feeding despite having an empty gut, and typically survive less than 24 h. However, the acute phase in a shrimp farm pond may last for several days in an affected population. Death often occurs in the acute phase during molting [6,42,43].

In the transition phase, some affected shrimp may recover from the infection. The shrimp typically demonstrate randomly distributed variably sized melanized lesions in or under the cuticle where the acute phase necrosis occurs. Shrimp with these black lesions are at some risk of mortality during their succeeding molt. Shrimp that survive the next molting process typically look normal and the lesions disappear from the cuticle. In the transition phase, death may also occur due either to osmotic failure as a consequence of widespread destruction of cuticular epithelium or to systematic infection from opportunistic bacteria [6,42,43].

In the chronic phase, shrimp may carry TSV throughout their life as a persistent infection. They may appear and behave normally but will show slightly less tolerance to low salinity stress than uninfected shrimp. The lymphoid organ of *P. vannamei* in this phase usually has spheroids (proliferative nodules of pale staining), vacuolated cells, and a lack of the central vessel that is typical for normal lymphoid organ tubules [6,42,43].

3.1.4 Diagnosis

3.1.4.1 Conventional Techniques

Histopathology changes in acute TSV-infected shrimp present as multifocal areas of necrosis in the cuticular epithelium and subcuticular connective tissue. Infection in the underlining muscle, heart, and lymphoid organ is occasionally observed. Pyknotic and karyorrhectic nuclei are scattered throughout the infected areas. Cytoplasmic remnants of the necrotic cells are abundant and present as spherical inclusion bodies that range from 1 to 20 μm in diameter and are often described as "peppered" or "buckshot" in appearance. In hematoxylin and eosin (H&E) staining, the inclusions show eosinophilic to pale basophilic remnants [6,42,43].

Shrimp that survive the acute infection may undergo the transition phase in which the typical acute-phase cuticular lesions decline in both abundance and severity. In the affected areas, infiltration and accumulation of hemocytes at the site of necrosis are conspicuous and become melanized, giving rise to the irregular black spots. Invasion of the *Vibrio* spp. may be observed on the corrosive cuticle. The lymphoid organ may appear normal with H&E staining [43,44].

In shrimp with chronic infection, the irregularly shaped and sized melanized lesions on the cuticle mostly disappear and display no gross signs of infection. The lymphoid organ in the chronic phase usually has spheroids, which are proliferative nodules of pale staining, vacuolated cells, and lack of a central vessel. When assayed via ISH with TSV probe or immunohistochemistry with monoclonal antibodies (MAbs), some cells gave positive signals for the virus [10,43,44].

3.1.4.2 Molecular Techniques

The early molecular assays consist of ISH and RT-PCR following the successful identification of TSV-specific gene targets [29,45,46]. The ISH method has been used for the routine histopathology diagnosis of TSV infection. However, false-negative results may be obtained if the shrimp tissues were preserved in Davidson's acetic acid–formaldehyde–alcohol solution for more than 24–48 h. The highly acidic pH (~3.5–4.0) of Davidson's fixative causes acid hydrolysis of TSV genomic RNA leading to false-negative probe results [28]. This problem can be avoided by using a neutral pH (~6.0–7.0)

Downloaded From Vet-eBooks.com

fixative called RNA-friendly fixative or through proper fixation (24–48 h) in Davidson's solution [28].

In the case of RT-PCR, Nunan et al. [46] designed a pair of primers called 9992F and 9195R based on a clone from TSV cDNA library. Using the one-step RT-PCR approach, the primers amplify a 231 base pair (bp) sequence of the TSV genome. Primer 9992F is located near the 3′ end of the IGR, and primer 9195R is located in the VP2 (CP1) gene of the TSV genome [17,46]. This RT-PCR assay allows detection of all known TSV genetic variants [43] and is recommended by the Office International des Epizooties (OIE) [15] for surveillance and diagnostic purposes.

An improved RT-PCR assay was developed by Navarro et al. [47] using newly designed primers, designated 7171F and 7511R, which amplify a 341 bp fragment. The detection limit of the improved RT-PCR assay was 20 copies of the TSV genome, 100 times more sensitive than the RT-PCR using the 9992F/9195R primers recommended by OIE. The primers 7171F/7511R were demonstrated to successfully detect TSV isolates from four phylogenetic lineages including Belize, the Americas, Southeast Asia, and Venezuela and displayed no cross-reactivity to infectious hypodermal and hematopoietic necrosis virus (IHHNV), white spot syndrome virus (WSSV), yellow-head virus (YHV), or infectious myonecrosis virus (IMNV) [47]. In addition to single RT-PCR methods, multiplex RT-PCR for detection of TSV and WSSV was developed and could be used to detect coinfection with WSSV and TSV in *P. vannamei* [48].

In addition to gel-based conventional RT-PCR, quantitative real-time RT-PCR assays were developed [49–51]. The real-time RT-PCR, using primers and a TaqMan probe designed from the ORF1 region of the TSV genomic sequence, demonstrated amplification with TSV isolates from Hawaii, Texas, Colombia, Mexico, Belize, Indonesia, and Thailand. No amplification was observed with RNA from healthy shrimp or an isolate of YHV. This real-time RT-PCR method has a detection limit of 100 copies and could be used to detect both acutely and chronically infected shrimp [49]. This TaqMan probe RT-PCR assay has been recommended by OIE [15]. The real-time multiplex PCR method was also developed for the detection of WSSV, IHHNV, and TSV using three sets of oligonucleotide primers and TaqMan probes specific for each virus. However, the assay has a sensitivity of 2000 copies of TSV, which is 20 times lower than that afforded by the single RT-PCR assay described earlier [50].

The SYBR Green RT-PCR was evaluated for TSV detection, and the results indicated that increasing the amplicon size from ~50 to ~70–100 bp enhanced its specificity and sensitivity [51].

The alternative nucleic acid amplification techniques, including nucleic acid–based amplification (NASBA) and loop-mediated isothermal amplification (LAMP), were also employed for specific detection of TSV [52–55]. NASBA coupled with dot-blotting procedure was approximately five times less sensitive than that of commercial nested RT-PCR kit IQ2000 TSV Detection and Prevention System (Farming IntelliGene Technology Corporation, Taiwan). No false-positive reaction was obtained with nontarget shrimp RNA viruses including gill-associated virus (GAV), YHV, and IMNV [52].

The agarose gel–based RT loop-mediated isothermal amplification (RT-LAMP) demonstrated 10 times more sensitivity than the RT-PCR recommended by OIE but less sensitivity than the nested RT-PCR IQ2000 kit. No amplification was observed with nucleic acids from other shrimp pathogens including YHV and WSSV [53]. The colorimetric dot-blot hybridization (DBH) was used to detect RT-LAMP amplicons and exhibited the same sensitivity as the nested RT-PCR IQ2000 method. There was no cross-reaction with other shrimp viruses, including WSSV, IHHNV, IMNV, GAV, monodon baculovirus, and hepatopancreatic parvovirus. However, in some cases, tRNA samples or very low concentrations of the target templates could lead to the production of the aberrant products. Due to the utilization of hybridization probe specific to LAMP products, the DBH has the capacity to eliminate false-positive reactions [55].

Further development of RT-LAMP combined with lateral flow dipstick (LFD) for detection of LAMP amplicons was demonstrated [54]. This strip detected biotin-labeled LAMP products that had been hybridized with a fluorescein isothiocyanate (FITC)-labeled probe. Without relying on special equipment, the LFD is immersed into the appropriate buffer containing LAMP amplicons and the results are available within 10 min. This assay had a detection limit comparable to that of nested RT-PCR and exhibited high specificity to TSV with no cross-reactivity with WSSV, IHHNV, or YHV [54].

As the early RT-LAMP procedures included a step in which the reaction tube must be opened for further detection, the risk of contamination between samples could occur. Given the LAMP amplification produced magnesium pyrophosphate ($Mg_2P_2O_7$) by-products correlated with the amount of amplified LAMP amplicons, resulting in turbidity, a portable turbidimeter was designed and used to measure the turbidity without opening the reaction tubes. The results showed that this RT-LAMP coupled with turbidimeter is equally sensitive to agarose gel RT-LAMP and IQ2000-nested RT-PCR kit, with reduced contamination risk [56].

Recently, a hyperbranched rolling circle amplification (HRCA) assay combined with a strip test was developed for TSV detection. The sensitivity was approximately 10 copies, 100 times higher than that of RT-PCR. The HRCA test was TSV-specific and showed no cross-reaction to shrimp viruses including WSSV, YHV, and IHHNV [57].

3.1.4.3 Immunological Techniques

Chicken and mouse polyclonal TSV antisera and MAbs were produced using purified TSV as the antigen [58]. One of the MAbs designated 1A1, specific to VP1, was used to detect TSV via western blot dot and immunohistochemistry. However, while this MAb can react with TSV isolates from Taiwan, the United States, and Hawaii, it does not recognize TSV isolates from Mexico, Nicaragua, Belize, or Venezuela [25,26,59]. MAbs against recombinant structural capsid proteins, including VP1, VP2 and VP3, were also developed [60–62].

Downloaded From Vet-eBooks.com

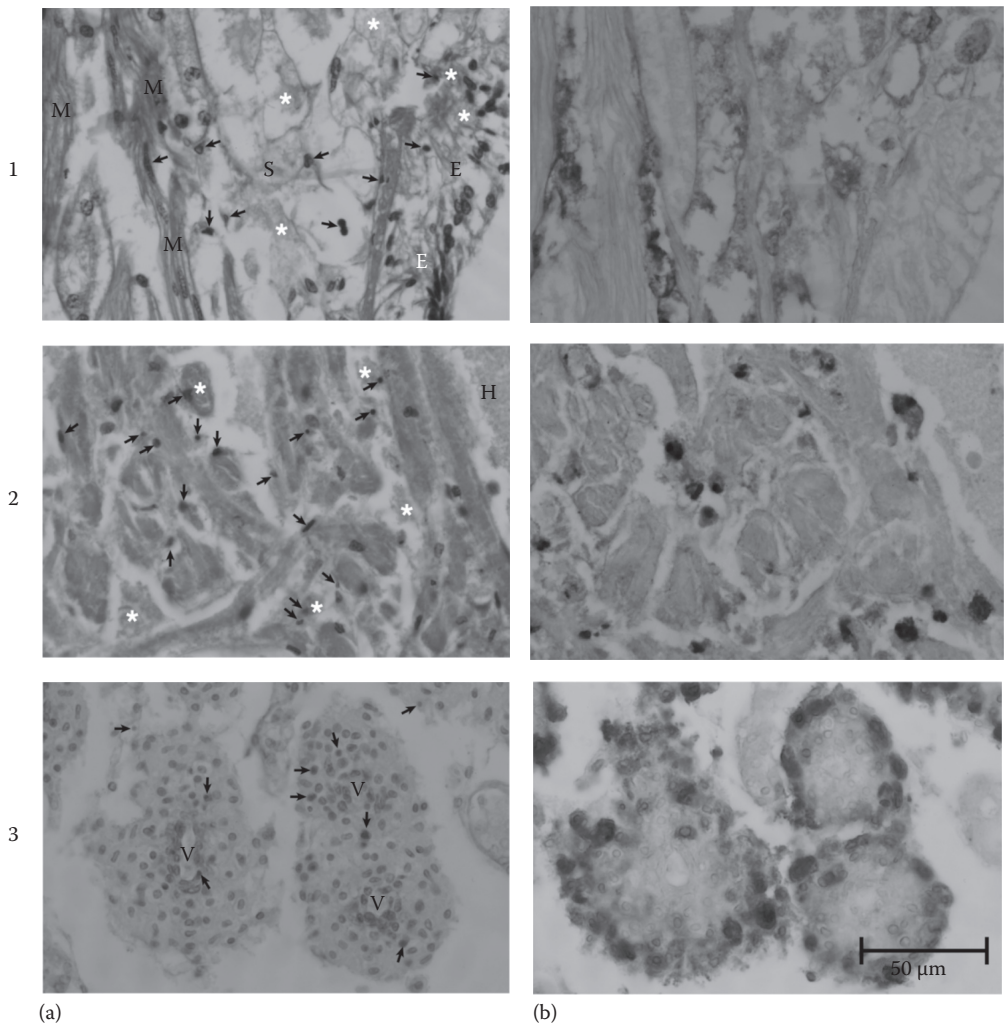

FIGURE 3.1 Histopathology and immunohistochemistry of tissues from naturally TSV-infected *P. vannamei* with asymptomatic infection in (1) cuticular epithelium, (2) heart, and (3) lymphoid organ. Two consecutive sections: (a) tissues were stained with hematoxylin and eosin (H&E) and (b) tissues were immunohistochemically stained with monoclonal antibody specific to VP2 of TSV and counterstained with eosin. Positive immunoreactivity appeared as brown staining. Intensely basophilic staining of pyknotic and karyorrhectic nuclei (arrow) and eosinophilic cytoplasmic remnants referred as "buckshot" appearance (*) are scattered in the lesion areas. *Note*: Lymphoid organ (3) demonstrated histologically normal in H&E staining; however, it demonstrated strong immunoreactivity of TSV infection. E, epithelium; S, subcuticular connective tissue; M, skeletal muscle; H, hemolymph; V, central vessel.

Through immunohistochemistry, these MAbs could be used to detect chronic and light TSV infection (Figure 3.1). It is likely that the combination of MAbs-specific to VP1, VP2, and VP3 may be useful for the detection of most TSV isolates from various geographic regions.

3.2 METHODS

3.2.1 Sample Preparation

RT-PCR methods are recommended by the OIE for TSV monitoring and diagnostic purposes. Tissue samples such as hemolymph, pleopods, or whole small shrimp can be used for RT-PCR assays. Various commercial RNA extraction kits are available for TSV RNA isolation from fresh, frozen, and ethanol-preserved tissues.

In case of the High Pure RNA Tissue Kit (Roche, Penzberg, Germany), 400 μL of Lysis/Binding Buffer is added to the appropriate amount of tissue (max. 20–25 mg) in a nuclease-free 1.5 mL microcentrifuge tube. The tissues are disrupted and homogenized using a rotor–stator homogenizer, and the lysate is centrifuged for 2 min at maximum speed in a microcentrifuge. The supernatant is mixed with 200 μL of absolute ethanol. Next, the mixture is applied to the spin column combined with the collection tube (maximal volume 700 μL) and centrifuged at maximal speed (13,000 × *g*) for 30 s, and then the flow-through is discarded. For each isolation, 10 μL of DNase I working solution is mixed with 90 μL of DNase incubation buffer, and the prepared solution is added to the spin column combined with the collection tube and incubated at 15°C–25°C for 15 min. The column is washed via the addition of 500 μL Wash Buffer I, centrifuged at 8000 × *g* for 15 s,

Downloaded From Vet-eBooks.com

the flow-through is discarded, and the washing step is repeated with Wash Buffer II. Then, the column is washed by the addition of 300 µL Wash Buffer II and centrifuged at 13,000 × *g* for 2 min, and then the flow-through is discarded. Finally, the spin column is placed onto a new 1.5 mL microcentrifuge tube and 100 µL of elution buffer is added directly to the spin column and centrifuged at 8000 × *g* for 1 min. The eluted RNA can then be used for RT-PCRs or stored at −80°C for later analysis.

3.2.2 Detection Procedures

3.2.2.1 Gel-Based RT-PCR

Two oligonucleotide primers, designated 9992F and 9195R, are used in the RT-PCR, for specific amplification of a 231 bp product. The method outlined in the succeeding text for TSV detection is based on that described by Nunan et al. [46].

Primers	Product	Sequence	GC	Temperature
9992F	231 bp	5′-AAG TAG ACA GCC GCG CTT-3′	55%	69°C
9195R		5′-TCA ATG AGA GCT TGG TCC-3′	50%	63°C

The GeneAmp® EZ rTth RNA PCR kit (Applied Biosystems, Forster City, CA, USA) is used for the amplification reactions described in the succeeding text. The TSV positive and negative controls should be performed along with the no-template control.

3.2.2.1.1 Procedure

1. Prepare the RT-PCR reaction mix as follows (volumes listed are per specimen). (*Note*: Vortex and spin down all reagents before opening the tubes.)

Component	Volume (µL)
Diethyl pyrocarbonate (DEPC)-treated water	Variable
dNTPs (300 µM each)	Variable
9992F (0.46 µM)	Variable
9195R (0.46 µM)	Variable
Manganese acetate (2.5 mM)	Variable
5× EZ buffer	10
rTth DNA polymerase 2.5 U	1
RNA sample	10
Total volume	50

2. Add the RT-PCR reaction mix to a 0.2 mL PCR tube.
3. Spin the sample tubes in a microcentrifuge at 14,000 × *g* for 30 s at room temperature.
4. Place the sample tubes in a thermal cycler. RT may then proceed at 60°C for 30 min, followed by 94°C for 2 min. After the completion of RT, the samples are amplified for 40 cycles using the following conditions: denaturation at 94°C for 45 s, annealing/extension at 60°C for 45 s, and final extension at 60°C for 7 min.
5. Following the termination of the RT-PCR reaction, pulse spin the reaction tubes to pull down the condensation droplets at the inner wall of the tubes.
6. Analyze a 10 µL of the PCR products using 2.0% agarose gel, stained with ethidium bromide (0.5 g mL^{-1}), and electrophoresis in 0.5× TBE (Tris, boric acid, ethylenediaminetetraacetic acid). Then, visualize the sample under an ultraviolet light source.

3.2.2.2 Quantitative RT-PCR

The detection of TSV using quantitative RT-PCR is rapid, sensitive, and specific. The sensitivity of qRT-PCR is approximately 100 copies of the target sequence in the TSV genome [49]. The qRT-PCR method outlined in the succeeding text follows the procedure described by Tang et al. [49]. The designed primers and TaqMan probe are specific to the ORF1 region of the TSV genome (GenBank AF277675). The primers TSV1004F (5′-TTG GGC ACC AAA CGA CAT T-3′) and TSV1075R (5′-GGG AGC TTA AAC TGG ACA CAC TGT-3′) generate a 72 bp DNA fragment. The TaqMan probe TSV-P1 (5′-CAG CAC TGA CGC ACA ATA TTC GAG CAT C-3′) is labeled with fluorescent dyes 5-carboxylfluorescein (FAM) on the 5′ end and *N,N,N′,N′*-tetramethyl-6-carboxyrhodamine (TAMRA) on the 3′ end (Applied Biosystems, Cat. no. 450025). The TSV-positive control and the no-template control should be included in each run.

3.2.2.2.1 Procedure

1. Extract RNA from shrimp tissue using the method described earlier.
2. Prepare the qRT-PCR reaction mix as follows using TaqMan One-Step RT-PCR master mixture (Applied Biosystems, part no. 4309169). (*Note*: Vortexing and spinning down the reaction mix before use is recommended.)

Component	Volume (µL)
2× Master mix without uracil-N-glycosylase (UNG)	12.50
40× MultiScribe and RNase Inhibitor Mix	0.63
TaqMan probe TSV-P1(0.1 µM)	Variable
TSV1004F (0.3 µM)	Variable
TSV1075R (0.3 µM)	Variable
RNA sample (5–50 ng)	Variable
DEPC-treated water	Variable
Total volume	25

3. Place the reaction tubes in the GeneAmp 5700 Sequence Detection System (Applied Biosystems); ABI PRISM 7000, 7300, and 7500 (newer models and brands are also suitable).
4. Perform the qRT-PCR cycling consisting of RT at 48°C for 30 min, initial denaturation at 95°C for

Downloaded From Vet-eBooks.com

10 min, 40 cycles of denaturation at 95°C for 15 s, and annealing/extension at 60°C for 1 min.
5. Interpret the results from the threshold cycle obtained from real-time fluorescence measurements using a charge-coupled device camera. Samples will be interpreted as negative if the Ct (threshold cycle) value is 40 cycles or greater, whereas samples with Ct value lower than 40 cycles are interpreted as positive.
6. To confirm the results, the qRT-PCR product can be electrophoresed on a 4% agarose gel with ethidium bromide staining and exposed to UV light. The DNA fragment at 72 bp can be observed in the positive samples. (Optional)

3.3 CONCLUSIONS

TSV is a major viral pathogen in cultured white shrimp *P. vannamei*. First recognized in Ecuador in 1992 and later spread to many countries, TS disease usually results in mortalities between 40% and over 90% of infected shrimp. Based on genomic characterization and sequence comparison, TSV is classified to the novel genus *Aparavirus* in a new family *Dicistroviridae* (in the order *Picornavirales*). The ssRNA genome of TSV contains two ORFs separated by an IGR. It has been suggested that TSV ORF2 is translated by an IRES located within IGR. Currently, at least four genotypic lineages have been identified, including ones in Mexico, Southeast Asia, Belize/Nicaragua, and Venezuela/Aruba, according to the sequence of the VP1.

For molecular detection, OIE recommends the use of RT-PCR with a pair of primers called 9992F and 9195R, which can detect all known TSV genetic variants, and qRT-PCR using primers and TaqMan probes designed from the ORF1 region of the TSV genomic sequence for TSV surveillance and diagnostic purposes. However, several assays such as LAMP or monoclonal antibody-based techniques were developed for TSV detection with different sensitivities. The commercial nested RT-PCR kit is also available.

As no vaccine or chemotherapy treatment are presently available, breeding programs to improve TSV resistance in *P. vannamei* plays an important role in the control of TS. During the past several years, the shrimp breeding programs have distributed TSV-resistant brood stock to shrimp hatcheries worldwide, giving great benefit to the shrimp farming industry. As a consequence, in many shrimp farming regions, TSV is no longer considered a major threat.

4.1 INTRODUCTION

Honeybees (*Apis* species) belong to the order *Hymenoptera*, which diverged from Diptera and Lepidoptera about 300 million years ago.[1] Apart from the consumable bee products (i.e., honey, royal jelly, propolis, bee wax, and pollen), honeybees play a crucial role as a key pollinator for plants and thus maintain natural ecosystems. Due to their importance to man, the complete genomes for the European honeybee (*Apis mellifera*), together with its pathogens and parasites,[2] were sequenced by 2006 to give insights into host–parasite relationships, transmission, and management of diseases to promote global bee populations.

Bee diseases are caused by microorganisms such as bacteria, fungi, protozoa, and viruses. Recently, bee viruses have garnered great interest as they could be found in seemingly healthy honeybee colonies; colonies may even contain multiple viruses that have potential to spread out by both horizontal and vertical transmission routes. It is believed that viruses are partly responsible for bee mortality especially when bee colony is weakened by parasitic bee mites known as *Varroa destructor*.[3,4] The unexplained incidence of rapid loss of adult bee populations or colony collapse disorder (CCD) has been a global concern since 2006.[5] Some beekeepers reported the losses of 50%–90% of bees[6] and many areas have suffered from the colony loss (including the United States, Canada, France, Sweden, and Germany[7,8]). A metagenomic survey recently detected Israeli acute paralysis virus (IAPV) in the United States, suggesting its connection to colony mortality.[9] It is widely believed that the causes of bee losses are multifactorial, ranging from biological (e.g., virus, Nosema) to environmental factors (e.g., pesticides and nutrition). In view of the detrimental effects of bee viruses, it is necessary to better understand the relationship between honeybees and viruses for proper disease management and prevention of further colony losses.

Bee viruses are small and nonenveloped, and most of them have positive-sense single-stranded RNA. Based on their biophysical properties, they have been classified as picornavirus-like[10] along with other insect viruses, for example, Drosophila C virus,[11] cricket paralysis virus,[12] and aphid lethal paralysis virus.[13] The first bee virus discovered and reported was Sacbrood virus (SBV); it was described as a filterable agent that could cause the Sacbrood disease in honeybee after passing through fine unglazed porcelain filters.[14] Later, chronic bee paralysis virus (CBPV) and acute bee paralysis virus (ABPV) were found and isolated.[15–17] Since 1999, complete genomes of bee viruses have been accumulated, leading to their categorization on the basis of genomic structures. SBV,[18] deformed wing virus (DWV), Kakugo virus (KV),[19] and *Varroa destructor* virus (VDV-1)[20] are classified into the genus *Iflavirus*, which has a single large open reading frame (ORF) that encodes both structural and nonstructural proteins called monocistronic. The family *Dicistroviridae*, having the characteristic of two nonoverlapping ORFs (dicistronic), includes black queen cell virus,[21] ABPV,[22] Kashmir bee virus (KBV),[23] and IAPV.[24] CBPV has not yet been classified into any group due to lack of a full description of its

Downloaded From Vet-eBooks.com

genomic data. However, based on the deduced amino acid sequences of its conserved RNA-dependent RNA polymerase (RdRp) domains, CBPV appears to be phylogenically close to the *Nodaviridae* and *Tombusviridae* family clusters.[25]

Bee paralysis virus is aptly named based on clinical symptoms observed during infection. Infected bees become weak, tremble, and are unable to fly; therefore, they often crawl on the ground and may be seem *en masse* in front of hives. In severe case, the colonies collapse leaving the queen and a few workers on the neglected comb, which is reminiscent of CCD.[26] Paralysis in bees has been observed far back as Aristotle recorded hairless black bees having a dark and shiny appearance. The etiological agent, CBPV, was later confirmed and described.[17] Currently, two types of bee paralysis have been fully described: (1) acute bee paralysis, which is caused by ABPV and IAPV that are capable of killing the bees in a short time, and (2) chronic bee paralysis, of which CBPV is the causative agent. In this chapter, these bee paralysis viruses and characterization method are described.

4.1.1 Classification and Genome Organization

RNA viruses contain only RNA as their genetic materials. Their classification is based on virus particle structure, genome, viral replication, host organism, and pathology. RNA virus has evolved to be a genetic element, protected by capsid proteins that can replicate in host cells. The RdRps, which are absent in cellular organisms, are universal and vital elements among RNA viruses. Thus, they are conserved and used as a standard tool to determine the evolutionary relationships among RNA viruses. The RdRps can recognize different origins of replication at the 3′ termini of both plus and minus sense RNA strands to replicate viral genomes. RNA viruses lack proofreading machinery; therefore, coupled with a rapid, short replication time, a high mutation rate can be expected. RNA virus evolution can be more than a millionfold faster than its host. This suggests that the viruses facilitated independent and rapid evolution, resulting in better adapted host transmissibility. The RNA viruses are also known to have a quasi-species population structure.

In view of the genomic structure, ABPV is classified in the genus *Aparavirus* in the family *Dicistroviridae* along with KBV and IAPV.[27] They have a dicistronic genome organization, composed of two nonoverlapping ORFs that are spaced by an intergenic untranslated region (UTR). The 5′ proximal ORF encodes a nonstructural precursor that is autoproteolytically cleaved into an RNA helicase, cysteine protease with a chymotrypsin-like fold (Pro), and RdRp. The 3′ proximal ORF encodes capsid proteins (VP1-4) and has a poly-A tail (Figure 4.1). The intergenic UTR is known to contain an internal ribosome entry site (IRES) that initiates efficient translation.

Differences in the structure of intergenic internal ribosomal entry sites can be used to classify members of *Dicistrovirida*e. *Aparaviruses* belong to Type II, which is based on the 5′ region sequence (UGAUCU and UGC Type I, UGGUUACCCAU and UAAGGCUU Type II). In addition, the structure of IRES elements in the two genera is also distinguished by the presence of an additional stem loop in the 3′ region of the intergenic region of IRES of *Aparavirus* but not in *Cripavirus*. The IRES site can facilitate production of the capsid protein. ABPV and IAPV have similar genomes; when excluding the poly-A tail, they are 9470 nt[22] and 9487 nt,[24] respectively. ABPV, IAPV, and KBV

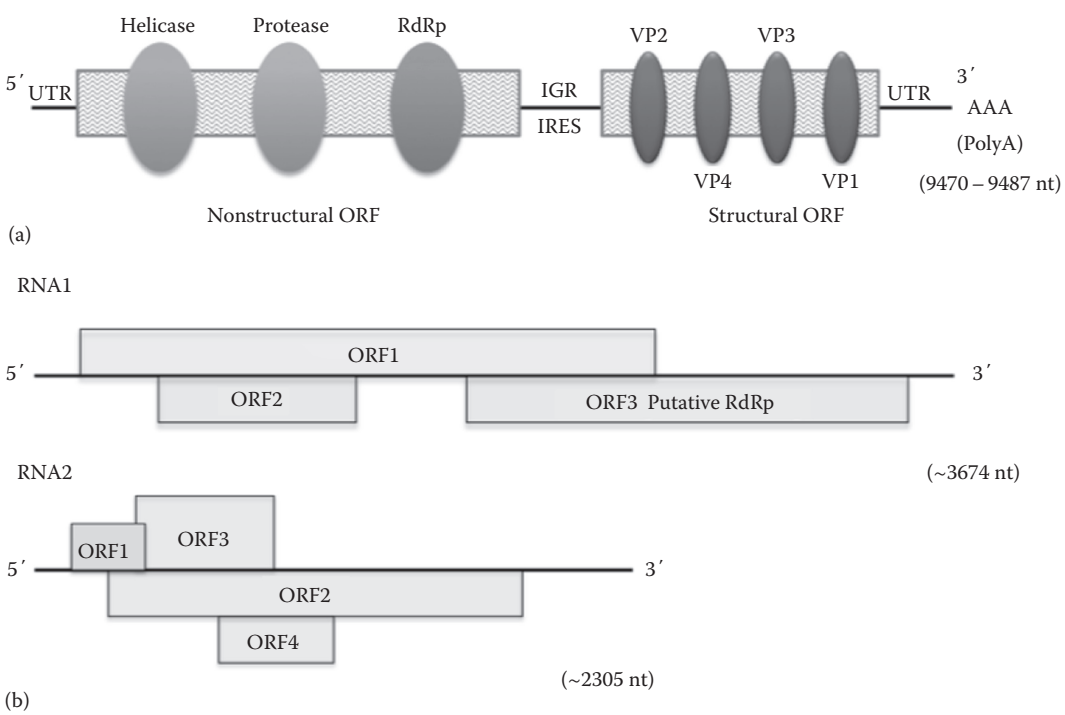

FIGURE 4.1 Genome organizations of (a) ABPV and IAPV and (b) CBPV.

Downloaded From Vet-eBooks.com

are considered a closely related virus complex with common origins.[28] Most ORF sequences of IAPV share high similarities (more than 65%) with its closed relatives, KBV and ABPV; however, the homology of UTR sequences is weak among these three viruses.[24] The structural proteins among these three viruses also display high sequence identity. In contrast, antibodies of KBV, ABPV, and IAPV do not cross-react with proteins of these viruses; they are regarded as a unique viral entity.

CBPV is not yet classified into any genus or family, due to lack of full information about its genomic structure and protein function, despite sharing similarities with conserved RdRp sequence domains of the *Nodaviridae* and *Tombusviridae* families.[25] It is reported to be a positive single-stranded RNA virus with a characteristic segmented genome. The two RNAs were RNA1 (3674 nucleotides) and RNA2 (2305 nucleotides), which encode three and four putative overlapping ORFs, respectively.[29] The poly-A tails are not polyadenylated at the 3′ end as the ABPV genome, whereas the 5′ end has a cap structure that protects RNA from degradation by cellular exonuclease and ensure translation initiation by coupling with the cap-binding protein.

4.1.2 Morphology, Biology, and Epidemiology

ABPV and IAPV virions (size 30 nm) have icosahedral symmetry and do not have an envelope of distinct surface; conversely, CBPV virions (size 30–60 nm) are asymmetric.[30] These viruses are known to be host genus specific. Based on their genomes, ABPV and IAPV exhibit strong codon relatedness to the honeybee codon usage abundances, implying that viral proteins are more easily and highly expressed than if the codon usage abundances are unrelated like that of the fruit fly, red flour beetle, and mosquito.[31] This suggests that small host-specific viral genomes have the freedom to quickly optimize codon usage to successfully parasitize their preferred host. The optimization of codon usage toward highly abundant codons has previously been reported to occur in highly expressed genes[32]; optimization of honeybee viruses follows the same pattern. However, the viruses (ABP, IAPV, and KBV) belong to the family *Dicistroviridae*, which have more closely related codon usage than that of *Iflavirus* (KV, SBV, and VDV-1). This might be related to disease progression and virulence.[31] The main difference between ABPV, IAPV, and CBPV is that ABPV and IABPV cause sudden paralysis and death 1 day after infection, whereas CBPV displays lesser virulence and takes several days to kill the infected bees. CBPV also needs more viral titers to cause paralysis in the honeybee.[33]

When a virion attaches to the receptor of the host cell membrane, the RNA genome will be released into the host cell cytoplasm where replication of the viral genome occurs. The RNA also acts as mRNAs for the viral protein translation. By using the host translational machinery, the viral proteins are formed and the viral genome is replicated by using RdRp in the host cytoplasm. The newly formed positive strand RNA is assembled with the capsid proteins into progeny and ready to be released from the host cells. Interestingly, a segment of IAPV can be integrated into the honeybee (*A. mellifera*) genome and vice versa.[24] The RNA segment thus acts as the recombination hotspot, and therefore, it explains the evidence for closely related codon usage in honeybee and virus. Interestingly, once the segment of IAPV is incorporated into the bee genome, the bee could be resistant to subsequent IAPV infection.[24] Information on the pathogenicity and cellular investigation and infection is not yet fully understood due to the lack of bee cell line cultures.

ABPV was first discovered during a laboratory study to characterize CBPV. ABPV is infective when injected into adult bees at similar doses to CBPV. The viruses are able to cause signs of disease such as weak appearance with trembling movement and inability to fly; they eventually kill both pupae and adult bees (ABPV 5–6 days, CBPV 7–8 days).

External stresses, including mite parasitism, starvation, or host nutritional status, which impair the host defense mechanism, can worsen the infected bees' condition causing clinical symptoms and morbidity. "Bee mite parasitic syndrome" is often used to refer when *V. destructor* affects the colony health by triggering severe viral infections in the honeybee colony. It is interesting to note that in areas where *V. destructor* is absent (e.g., Uganda), no bee samples could be detected having some known bee viruses including CBPV, ABPV, and IAPV.[34] Mite parasitism is known to weaken the infested bee colonies. There is evidence that *V. destructor* mite is associated with ABPV, IAPV, and KBV, and these viruses can cause bee mortality when the colony is infested with *V. destructor*.[4,35,36] It is known that *Varroa* can vector the viruses.[37,38] Nevertheless, CBPV has not yet been reported to associate with the mite as there is lack of evidence for CBPV presence in the parasitic mite.[25]

Both brood and adult bee can be infected with bee viruses. Horizontal and vertical transmissions have been reported as means of the spread of viral diseases in honeybees. Horizontal transmission could occur via contact, airborne, and fecal-oral route from food (honey, royal jelly, and pollen), which is contaminated with the virus from infected individuals, for example, salivary gland secretion. High population density within a colony leads to high contact and trophallactic rates. ABPV, IAPV, and CBPV were detected in colony foods such as pollen, honey, and royal jelly, but CBPV was found only in pollen.[38,39] The viruses can be found in bee digestive tract and feces[39] reaffirming the source of infection where the virus could cross the epithelial barrier of the digestive tract and invade different tissues. The viral load in the digestive tract is therefore much higher when compared to other tissues.[39] CBPV is concentrated in the head and also found in the mandibular and hypopharyngeal glands.[40,41] Under experimental conditions, following application of the virus on the surface of the cuticle of its freshly denuded hair, the virus readily infects the bee from close contact, possibly by invading through the epidermal cytoplasm. Bee viruses can be vertically transmitted through eggs (i.e., surface of eggs and transovarian route), sperm, and semen. The viruses can be detected in the ovaries of queen, eggs, and semen.[39] IAPV, ABPV, and CBPV genomic loads can be detected in high levels especially in

Downloaded From Vet-eBooks.com

summer time when the bee colonies are under high population density, thus possibly increasing the chances of transmission.

The prevalence of ABPV has been investigated in many countries worldwide.[42] Strain differences from clinical samples of different geographical origin are known and confirm the geographical segregation among viral strains.[43] This is also shown in CBPV strains in the United States.[44] ABPV is also commonly found in apparently healthy bees[45] and is the second most prevalent virus in Austria.[45] These surveys were done in European countries[45–47] and Thailand.[48] IAPV was first discovered in Israel.[24] Recently, it was found that the virus was present in five out of thirty five colonies (14%) in France by using reverse transcription polymerase chain reaction (RT-PCR). It is unlikely that there is a link between IAPV and colony loss during winter in France. However, the role of the virus in bee mortality is still unknown.[49] CBPV was found to attack adult bees and cause abnormal trembling of the body and wings. Other symptoms include a hairless, shiny, darkened appearance of the bees; these individuals are frequently attacked by guard bees when they return to their colonies. CBPV has a sporadic distribution including in the United States.[35,42,44] It was proposed that CBPV has a predominantly horizontal transmission.[25]

Bee viruses can cause simultaneous multiple infections in apiaries; for example, in Thailand, two viruses (DWV and ABPV) were found in 17% of samples, three viruses were found in 13%, and four viruses were found in 4%. The four viruses were DWV, ABPV, SBV, and KBV in samples collected from apiaries in Lampang province that were heavily infested with *V. destructor* mites.[48] Simultaneous multiple infections by bee viruses in honeybees are common in France, China, the United States, and Brazil.[4,50–52]

Apart from *A. mellifera* populations, another eight species of honeybee can be found in Asia, such as *Apis dorsata*, *A. florea*, *A. andreniformis*, and *A. cerana*. *A. cerana* is native to Asian countries where local beekeepers harvest their honey for consumption. By screening for all bee viruses in these bee species, IABPV and CBPV were present in *A. cerana cerana* in China[53] and IAPV was found in *A. cerana japonica*.[54] KBV and CBPV were found in the adult worker bees of *A. cerana* in South Korea at low levels (1.56% and 0.44%, respectively).[55] Honeybee viruses were also present in non-*Apis* hymenopteran pollinator such as bumblebees. ABPV was detected in five bumblebee species.[56] In containment greenhouse experiments, IAPV in honeybee could infect the bumblebees and vice versa within a week by sharing a food source (pollen).[57] This suggests that IAPV can be spread to the apiary environment.

4.1.3 Clinical Features and Pathogenesis

Most infected bees show no clear symptoms. The pathological effects of the infection mostly described are based mostly on the artificial injection/infection of the virus into honeybees under laboratory conditions. The natural tissue tropisms of the viruses are still not well documented. However, it is reported that environmental factors, for example, starvation and stress arising from mite infestation, can hasten or aggravate the infection so that the bees show physical symptoms leading to mortality and eventually colony death. Environmental factors are considered to induce the changes from latent to lethal infection. Dicistrovirus prevalence and distribution in the honeybee populations is high; however, the symptoms or mortality are inconsistent. Virulence depends on the route of infection (e.g., infection of virus into the host hemocoel leads to rapid mortality). Varroa parasitism is associated with a lethal condition of the viruses. The virus particles can be injected during the mite feeding. Therefore, *V. destructor* are the vectors of viruses.[58] Infected bees may be asymptomatic or exhibit paralysis, uncoordinated movement, and death. APBV could cause bee mortality faster than CBPV.[17] Temperature is also important in the viral pathogenesis. ABPV-infected bees showed no symptoms at 35°C but died at 30°C.[59]

ABPV can be found in the brain tissue at high quantity in the dead bees.[60] Bees infected with IAPV also show shivering wings, paralysis, and death. IAPV can attack every stage and caste of honeybees and it replicates within all the bee tissues. However, it is concentrated in the gut and in the hypopharyngeal glands.[38] This explains the presence of IAPV in the food of bee colony. High viral load was also observed in the nerve tissues affecting the bee nervous system causing bees to exhibit paralysis, a typical nerve function impairment. The brood stage seems to be more susceptible to the viral infection than the adult bees.[38]

CBPV can damage the nervous system as it multiplies in the central nervous system, which contributes to the sensory processing, learning, memory storage, and control of motor patterns.[61–63] CBPV infects all developmental stages of honeybees. However, adult bees have high titers of virus than other brood stages, particularly in the old worker bees that function as guards at the entrance of the bee hive.[40] Interestingly, in the experimental viral injection of adult bees, the CBPV viral genome, without its capsid structure, is proved to be infectious. Naked CBPV RNAs of 10^9–10^{10} copies could replicate, produce viral particles in the host cells, and cause chronic paralysis symptom after 5 days of inoculation.[64]

Honeybees enlist different responses to defend viral infection. Adult bees tend to show a stronger response than the brood by altering gene expressions. Many studies focus on the immune response after infection. Immunity-related genes are triggered in adult bees more than that shown in brood after IAPV inoculation[38] so that the brood stage is more susceptible to infection than adult bees in which all defense mechanisms are fully developed.

4.1.4 Diagnosis

The virus can be present in an "inapparent" infection of seemingly healthy bees or appears as an "overt" disease, and paralysis symptoms can be misinterpreted as other diseases and chemical intoxication. Therefore, appropriate diagnostic methods are necessary to confirm the cause of the disease. Based on the morphology or physical property of the bee viruses, they have buoyant densities in CsCl in the range of 1.33–1.42 g/mL with the sediment coefficients between 100S and 190S.[58] CBPV is isolated by separation on

Downloaded From Vet-eBooks.com

a 10%–40% (w/v) sucrose gradient.[29] The purified virus can be later observed under an electron microscope. However, the virions of honeybee viruses are similar in size and shape when observed under the electron microscope, and bee colonies or individual bee could be infected by multiple viral populations.[38] Therefore, it is difficult to observe in the field if the bees are infected or to purify each viral group for identification of the etiological agent. More specific and sensitive methods have been developed for bee virus detection. The conventional serological methods have been used for many years to detect or differentiate bee viruses. Enzyme-linked immunosorbent assay (ELISA) has proved to be useful to differentiate bee viruses.[65–67] However, KBV and ABPV sometimes show similarities in their serological reactions.[67] In addition, serological-based techniques require antibody production. With more information on viral genomes and also on the development of molecular techniques, ELISA and other immunological-based techniques have now been superseded by more specific and sensitive techniques, either conventional RT-PCR or real-time PCR. The molecular methods are widely applied nowadays for bee viral detection in honeybee or closely related insect samples.

4.2 METHODS

4.2.1 Sample Preparation

4.2.1.1 Sample Collection

Adult bees can be collected in a clean plastic bag. It is also recommended to take at least two types of samples (adult bees from the hive entrance and inside the hive) when studying the prevalence of bee viruses.[41] Honeybee eggs and brood can be collected in a clean plastic bag. Individual bee larvae and pupae can be collected in microcentrifuge tubes. The chemicals such as RNAlater® that prevent RNA degradation, or ethanol, can be added to this stage to preserve the samples. The samples should be kept on ice during transportation and frozen until RNA extraction.

4.2.1.2 RNA Extraction Protocols

Protocol A (Guanidine isothiocyanate-phenol-chloroform extraction)

1. Crush and homogenize the samples in the TRI_{ZOL}® reagent (1 mL/100 mg of tissue; *caution*: TRI_{ZOL} is toxic with skin and if swallowed).
2. Add 200 µL of chloroform into the sample (1 mL), shake vigorously, and incubate at room temperature for 3 min.
3. Centrifuge the solution at 12,000 × *g* for 10 min at 4°C. Transfer the aqueous phase (containing RNA) to a fresh tube.
4. Add 500 µL of isopropyl alcohol into a tube and incubate the sample at room temperature for 10 min.
5. Centrifuge at 12,000 × *g* for 10 min and discard the supernatant. The RNA precipitate forms a gel-like pellet on the bottom of the tube.
6. Wash the RNA precipitate by adding 1 mL of 75% ethanol.
7. Centrifuge at 7500 × *g* for 5 min at 4°C and pour off the supernatant and dry.
8. Dissolve RNA in 50 µL of RNase-free water and store the sample at −80°C.

Alternatively, RNA extraction for individual insect samples can be quickly done for the real-time PCR reaction as described Boonham et al.[68] This method is aimed at high-throughput testing:

Protocol B (Chelex resin method)

1. Individual insects are homogenized in a 0.5 mL microcentrifuge tube (using pellet grinders and matching tubes, Treff) with 50 µL diethylpyrocarbonate (DEPC)-treated water and stored on ice.
2. Chelex resin (Chelex 100, Biorad) (50 µL of a 50% w/v slurry) is added to each sample.
3. The samples are heated at 94°C for 5 min on a thermocycler.
4. The tubes are centrifuged for 5 min to pelletize debris and the supernatant is stored at −20°C for further PCR reactions/detection.

The RNA extraction also could be carried out following the conventional method or using RNA extraction kits that are commercially available.

4.2.1.3 Reverse Transcription for Conventional RT-PCR: cDNA Synthesis Protocol

The protocol is to synthesize cDNA from the RNA extract. The cDNA is prepared with random hexamer primers that can generate a bias-free cDNA copy of all RNA population, which is suitable for the virus survey or screening. The following is a standard RT protocol for cDNA synthesis:

1. Prepare the mixture on ice.

Component	Volume (µL)
5× first strand buffer	4
Moloney murine leukemia virus (M-MLV) reverse transcriptase (200 units)	1
A random hexamer (50 ng/µL)	1
Deoxynucleotide triphosphate (dNTP) mix (10 mM)	1
Dithiothreitol (DTT) (0.1 M)	2
DEPC-treated water	10
Sample RNA template (0.5 µg)	1

2. Mix gently by pipetting and spin the tube briefly to make sure that the contents are at the bottom of the tube.
3. Heat the mixture to 50°C for 50 min and terminate the reaction at 85°C for 5 min or 70°C for 15 min.[69]
4. Dilute the cDNA solution tenfold with nuclease-free water for further amplification reaction.

Downloaded From Vet-eBooks.com

Alternatively, first-strand cDNA synthesis (Superscript® First-strand synthesis system for RT-PCR) (Invitrogen)

1. Prepare the RNA/primer mixture.

Component	Volume (μL)
RNA extract	1
Primer (50 μM oligo dT)	1
10 mM dNTP mix	1
DEPC-treated water	7

2. Incubate at 65°C for 5 min.
3. Place on ice for at least 1 min.
4. Prepare the cDNA synthesis mix.

Component	Volume (μL)
10× RT buffer	2
25 mM $MgCl_2$	4
0.1 M DTT	2
RNase OUT™ (40U/μL)	1
SuperScript™ III RT (200 U/μL)	1

5. Add 10 μL of the cDNA synthesis mix to each RNA/primer mixture.
6. Mix gently and incubate for 50 min at 50°C.
7. Terminate the reaction at 85°C for 5 min and chill on ice.
8. Collect the reactions by brief centrifugation and add 1 μL of RNase H to each tube.
9. Incubate at 37°C for 20 min and then the cDNA synthesis reaction can be used for further PCR reactions.

4.2.2 Detection Procedures

The difference of RT-PCR and real-time PCR is that the RT-PCR detects PCR products at an end point reaction but real-time PCR is used to detect the amplification reaction in real time. Real-time PCR is thus more sensitive and allows the quantification viral genome by Ct (threshold cycle values).

4.2.2.1 Conventional RT-PCR Protocol

Component	Volume (μL)
10× buffer	5
10 mM dNTP	1
50 mM $MgCl_2$	3
Primer F (10 μM)	2
Primer R (10 μM)	2
Taq polymerase (2.5 U)	0.5
cDNA	2
DEPC-treated water	34.5

Amplification is performed in a thermal cycler. The mixture is heated at 95°C for 2 min followed by 40 amplification cycles, each consisting of 30 s at 95°C, 45 s at 55°C, and 1 min at 72°C. Reactions are completed by a final extension step for 10 min at 72°C. The PCR products are viewed by 1.5% agarose gel electrophoresis. Fragment sizes are determined with reference to a 100 bp ladder. The primers used in the assay are shown in Table 4.1.

4.2.2.2 Real-Time PCR Protocols

Real-time PCR is conducted to quantify the viral numbers in the sample. There are two types of methods as follows:

4.2.2.2.1 SYBR® Green Assay

1. Amplification is performed in 10 μL reaction volumes consisting of the following:

Component	Volume (μL)
SsoFast EvaGreen supermix (SMX) (Biorad) (2 × real-time PCR mix contains dNTPs, Sso7d fusion polymerase, $MgCl_2$, EvaGreen dye, and stabilizers)	5
Primers (forward and reverse) 10 μM	1
Nuclease-free water	3
cDNA (template, diluted 1/10)	1

2. PCR reactions are carried out in a thermocycler, at 95°C for 30 s, 40 cycles of 95°C for 1 s, and 59°C for 5 s, followed by a melt-curve dissociation analysis.

4.2.2.2.2 TaqMan Assay

The master mix consists of the following:

Component	Volume (μL)
TaqMan buffer	2.5
$MgCl_2$	5.5
dNTP	2
Forward primer 300 nM	1
Reverse primer 300 nM	1
Probe 100 nM	0.5
AmpliTaq Gold (0.625 U)	0.125
MMLV (10 U)	0.125
Nuclease-free water	11.2

The reactions are set up in 96-well plates using TaqMan. For each reaction, 1 μL of the RNA extract is added to 24 μL of master mix in the appropriate well giving a final reaction volume of 25 μL. Plates are cycled using generic system conditions (48°C for 30 min, 95°C for 10 min, and 40 cycles of 60°C for 1 min plus 95°C for 15 s) within the 7900 Sequence Detection System (Applied Biosystems, Branchburg, New Jersey) using real-time data collection.

PCR products are then ligated into pGEM®-T easy vectors (Promega, USA) and transformed to *Escherichia coli* JM109 high-efficiency competent cells (Promega, USA) following the manufacturer's protocols. White bacterial

F, forward primer; R, reverse primer; T, probe. Probes consist of oligonucleotides with a 5′-reporter dye (FAM, 6-carboxyfluorescein) and a 3′-quencher (TAMRA, tetramethyl carboxyrhodamine).

colonies containing plasmids with inserts are selected and plasmid DNA is purified using the Wizard Plus SV Minipreps DNA purification system (Promega, USA). Purified plasmids are sequenced by DNA sequencing. The nucleotide sequences of amplicons are analyzed and compared with sequences published at Genbank, National Center for Biotechnology Information, NIH, in order to confirm specific amplification.

4.3 CONCLUSIONS

Honeybee virus paralysis diseases are known to cause bee death and colony collapse in honeybees worldwide. Due to the fact that the viruses can spread without showing any symptoms and simultaneous multiple infection commonly occurs, bee pathogen surveillance is therefore very important for efficient management schemes to prevent the spread of pathogens and diseases. This highlights the value of applying highly specific and sensitive detection/diagnosis methods. Given the current genomic knowledge of bee viruses, molecular diagnostic techniques are most efficient because of their high specificity and sensitivity. Furthermore, it is reliable and accessible to many laboratories compared to serological and other techniques. Nevertheless, RNA viruses are prone to mutate rapidly; therefore, the genetic variance of bee viruses should be studied further to correctly characterize the bee viruses. Host–parasite relationship is also an intriguing field of study, in particular when bee viruses can infect other insects outside their original host range.

5.1 INTRODUCTION

The genus *Iflavirus* includes diverse RNA viruses of arthropods, which have icosahedral nonenveloped virus particles about 26–32 nm in diameter (Figure 5.1a). Iflavirus virions contain a single copy of linear positive-sense 8–10 kb genomic RNA that possesses small genome-linked virus protein, Vpg, covalently linked to the 5′ terminus and poly(A) sequence at the 3′ terminus. Genomic RNAs of iflaviruses have extended 5′ untranslated region (5′UTR), reaching about 1 kb, which acts as an internal ribosome entry signal (IRES). The IRES is followed by a single open reading frame (ORF) coding for a large polyprotein, ranging in size from 2800 to 3200 amino acids (aa), with the structural proteins and the nonstructural proteins encoded by the 5′- and 3′-parts of the ORF, respectively (Figure 5.1) [1]. Iflavirus genomic RNA is infectious and serves as a template for the synthesis of viral polyprotein. The genus name is derived from the name of its type species, *i*nfectious *fla*cherie virus, a pathogen of the silkworm *Bombyx mori* [2].

In recent years, more viruses with iflavirus characteristics have been discovered in a variety of arthropod species mostly as a result of transcriptome sequencing (Table 5.1, Figure 5.2). Despite high variation between the polyproteins of different iflaviruses, they share a number of common features. The short *N*-terminal leader protein (L) of unknown function, which is highly diverse between iflaviruses, precedes more conserved block of the structural proteins with three domains typical for the capsid proteins of icosahedral picornaviruses (VP1, VP3, VP3) (Figure 5.1b) and the smallest structural protein VP4, which are arranged in the order VP2-VP4-VP1-VP3 in the polyprotein (Figure 5.1c). The structural proteins are proteolytically processed by the 3C protease domain encoded by the nonstructural block (Figure 5.1c), and precise processing sites have been experimentally determined for several iflaviruses, including deformed wing virus (DWV) [3] and *Lymantria dispar iflavirus* 1 [4] (Figure 5.1c). The C-terminal half of the iflaviral polyprotein contains domains with motifs typical for picornaviral 2C RNA helicase, a chymotrypsin-like 3C protease and 3D RNA-dependent RNA polymerase (Figure 5.1c) [5]. No experimental data are available on the procession of the nonstructural portion of iflavirus polyprotein, although it is suggested that the processing of the nonstructural proteins is facilitated by the 2C protease similar to the processing of the picornavirus polyproteins.

5.1.1 Classification

The genus *Iflavirus* covers a group of positive-sense ssRNA viruses in the family *Iflaviridae*, order *Picornavirales*. Currently, only six species are recognized in the genus *Iflavirus* according to the international committee on taxonomy of viruses (ICTV) report published in 2012 [1] (Table 5.1). However, at least 17 additional insect RNA viruses with fully sequenced genomes (or at least with fully sequenced protein-coding regions) may be considered as belonging to the genus *Iflavirus* according to

Downloaded From Vet-eBooks.com

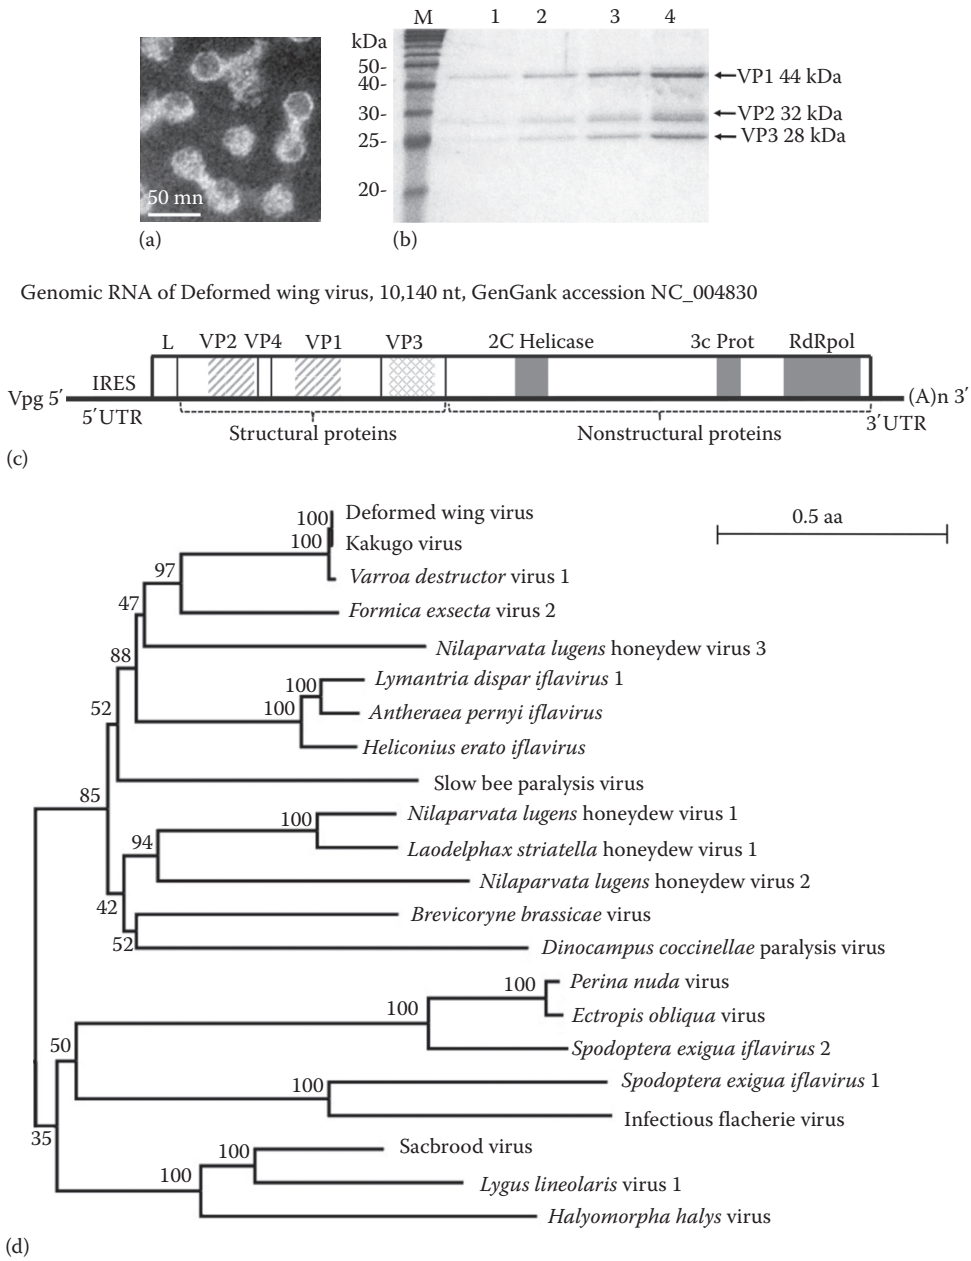

FIGURE 5.1 (a) Transmission electron photograph of deformed wing virus (DWV) particles, bar 50 nm. (b) sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) of DWV virions showing three major structural proteins, VP1, VP2, and VP3. Lane M, molecular weight protein markers; lanes 1–4, dilutions of virus preparation. (c) Organization of DWV genomic RNA. The long box represents the single open reading frame with the conserved domains indicated. Vertical lines represent identified cleavage sites. Conserved domains are indicated as follows: boxes in the VP2 and VP1 proteins shown are picorna-like capsid drug-binding pocket domains, box in VP3 is a CrPV capsid-protein-like domain, and dark boxes in the nonstructural part are picorna-like 2C helicase, 3C protease, and RNA-dependent RNA polymerase (RdRp) domains. (d) Phylogram of the recognized and putative members of the genus *Iflavirus*. Full-length polyprotein sequences of the iflavirus isolates listed in Table 5.1 were used. The tree was produced using the neighbor-joining method and evaluated with bootstrap analysis, 1000 replicates, percentage of bootstrap support if each branch is indicated. Branch length indicates evolutionary distance; scale bar shows 0.5 amino acid substitutions per site.

their genome organization and their being significantly different from other iflaviruses (nucleotide [nt] identity less than 90%) (Table 5.1). Iflaviruses are genetically diverse, as phylogenetic analysis showed that the viruses from different clades in Figure 5.2 have no regions of significant nt identity and only about 20%–30% aa identity. Among the evolutionarily close iflaviruses, similarity can be much higher; the nt and aa identity between closely related honeybee viruses DWV and *Varroa destructor* virus 1 (VDV-1) are as high as 85% and 95%, respectively; and lepidopteran PnV and EoV have 82% nt and 87% aa identity.

In respect to the number of the *Iflavirus* group members, it should be noted that the real number of iflaviruses is likely to

[a] References on detection, in addition to the genome organization reference.

be significantly higher than currently characterized and will continue to expand as more arthropod species are tested for the presence of viruses or subjected to transcriptome analysis. First, iflaviruses have currently been discovered only in economically important insect species, which have been specifically investigated for virus infections or subjected to comprehensive transcriptome analysis, such as several Lepidoptera species (moths and silkworm), as well as Lepidoptera cell lines, and Hymenoptera species (bees and parasitoid wasps). It is possible that the same species can act as a host to several *Iflavirus* species. For example, the honeybee *Apis mellifera*, one of the best investigated insect species, harbors a spectrum of iflaviruses, including DWV, closely related VDV-1 and DWV-VDV-1 recombinants [6], and more diverged slow bee paralysis virus (SBPV) and sacbrood virus (SBV), which, respectively, show only 26% and 19% aa identity with the DWV polyprotein. Second, iflaviruses have relatively limited host range. For example, DWV infects honeybees and non-*Apis* hymenopteran species, ranging from many solitary bees to bumblebees and wasps, but not Lepidoptera species [7]. Therefore, it is likely that unrelated arthropod groups harbor distinct *Iflavirus* species. Also, identification of iflaviruses is difficult because they often cause asymptomatic infections characterized by low level of virus. This makes molecular characterization the only feasible way to discover novel iflaviruses.

Iflaviruses are highly diverse; phylogenetic analysis of the complete iflaviral polyproteins shows three major clades (Figure 5.1d). Notably, there is no relationship between the relatedness of the host species and the degree of similarity between viruses, for example, viruses infecting the same species may be evolutionarily distinct, for example, evolutionarily divergent SBV and DWV infect honeybees. This may reflect complex evolutionary history of iflaviruses, which may include host range shifts and recombination events.

5.1.2 Epidemiology and Pathogenesis

Iflaviruses are transmitted vertically and horizontally. Members of this group may cause different degrees of symptom development, from asymptomatic to highly pronounced, corresponding to low or high levels of virus in the infected individuals. Usually, vertically transmitted iflaviruses do not accumulate to high levels and do not produce symptomatic infections. Iflaviruses that are transmitted horizontally often cause symptomatic infections with highly pronounced symptoms and insect death. Examples of such iflaviruses

Downloaded From Vet-eBooks.com

found in honeybees include orally transmitted SBV [8] and *V. destructor* mite–vectored DWV [9].

Deformed wing disease of honeybees is caused by pathogenic strains of DWV transmitted to honeybee pupae by *V. destructor* mite feeding on the hemolymph. This results in significant, thousandfold, increase of the levels of DWV, in particular, pathogenic strains of DWV-like viruses—recombinants with the VDV-1-derived structural genes and the DWV nonstructural genes [6,10]. Notably, depending on the route of transmission, the same virus, although not necessarily the same strains, could cause either symptomatic infection, characterized by high level of virus, or asymptomatic infection, low level of virus. Analysis of DWV infection in individual honeybees has shown that vertically transmitted genetically diverse strains of the virus usually accumulate to very low levels and infected bees remain asymptomatic, while horizontal transmission either by *V. destructor* mites or by artificial injection into honeybee hemolymph results in high levels of a limited number of DWV strains [10]. A similar picture emerged from the quantification of SBV in individual honeybees; asymptomatic bees were shown to harbor SBV, though at lower levels than those observed in individuals showing sacbrood disease symptoms [11].

5.1.3 Diagnosis

Members of the *Iflavirus* group are highly diverse viruses, making it impossible to devise a common method for iflavirus diagnosis. There are currently more than 20 characterized iflaviruses, and the number is likely to rise. Moreover, each *Iflavirus* species may contain a number of diverse isolates, which require modifications of the detection method, for example, use of different oligonucleotide primers for reverse transcription (RT)-PCR-based tests. Therefore, instead of listing methods for detection of all iflavirus strains, this chapter presents cost-effective, generic approaches that could be used (1) to discover novel iflaviruses or new strains of known iflaviruses in different arthropod species and (2) to devise methods for detection of particular iflaviruses or viral strains. The presented virus discovery methods specifically focus on characterization of genetic material associated with virus particles, rather than high-throughput transcriptome analysis, which also allows identification of novel RNA viruses. As an example, detailed methods describe discovery and detection of aphid iflaviruses and DWV-like viruses infecting honeybees. The same principles could be applied for detection of other iflaviruses.

5.1.3.1 Conventional Techniques

Electron microscopy is an essential tool for novel virus discovery. Visualization of virus particles in virus preparations is particularly important to confirm that the morphological characteristics of virus particles are typical for those of iflaviruses [4,6]. Nevertheless, the low concentration of virus particles in the asymptomatic individuals may make it difficult to detect virus particles in preparations from infected tissues. Immunological methods for iflavirus detection are not widely used for a number of reasons. It is often difficult to produce a sufficient amount of purified virus particles to raise antibodies. Also, serological tests may not be sufficiently sensitive to detect asymptomatic iflavirus infections. For example, ELISAs have been developed for the detection of DWV, but it could reliably detect only high levels of DWV, with the virus in asymptomatic bees being below the detection threshold [12]. Furthermore, polyclonal antibody–based techniques could be used to differentiate different virus strains.

5.1.3.2 Molecular Techniques

Due to difficulties in using conventional techniques for identification purpose, most of the iflaviruses are detected by molecular approaches, such as RT-PCR and real-time RT-PCR. Identification of iflaviruses and characterization of their novel strains are essential steps in devising detection methods for iflaviruses in previously uncharacterized arthropod species. Apart from relatively expensive characterization of transcriptome (cloning of expressed sequence tags or high-throughput sequencing using the RNA-seq approach) that requires generation and sequencing of a high number of clones or reads and considerable bioinformatics effort, it is possible to use virus particles isolated from relatively small number of insects, or even individual insects, as a source of encapsidated viral RNA for sequence-independent amplification of the viral complimentary DNA (cDNA). The amplified fragments can be cloned into a plasmid vector and sequenced. Usually a library has 10%–50% of virus-derived clones, which provides initial sequence data for characterization of novel viruses and strains. Once information of sufficient stretches of viral RNA is obtained, primers for RT-PCR and real-time RT-PCR detection assays should be designed.

5.2 METHODS

In this section, we will cover molecular methods for the identification of novel iflaviruses and/or strains of previously characterized iflaviruses. We will present details of the methods used for detection, characterization, and quantification of DWV isolates in honeybees at different stages of development. DWV is a good example for the demonstration of the general principles of iflavirus detection because, depending on the inoculation route and the virus strain, DWV may accumulate to either low or high levels [6,10]. Molecular procedures, such as RT-PCR and real-time RT-PCR, are the methods of choice because they allow detection of DWV in cases of high-level and low-level infections.

5.2.1 Sample Preparation

Individual adult honeybees, larvae or pupae, as well as *V. destructor* mites should be frozen at −80°C as soon as possible following collection, while still alive, to preserve viral and host mRNA for analysis. It is possible to freeze insects in liquid nitrogen before storage at −80°C. The ideal strategy for collection of honeybee samples depends upon the required life stage of the bees to be studied, adult bees can be collected from frames or the hive entrance, or, if larvae, pupae, or eggs are required, then whole or partial frames can be removed for sampling. If the insects cannot be kept alive and immediate

Downloaded From Vet-eBooks.com

freezing is not possible, RNA could be preserved in tissues using RNAlater solution (Ambion). In this case, the larvae could be placed directly to the RNAlater solution, while the exoskeleton of pupae and adult bees should be broken open to allow fast diffusion of RNAlater solution into the tissues. Small arthropods, like aphids or *V. destructor* mites, could be collected while alive, paced individually or as groups into Eppendorf tubes, quickly frozen to −80°C, and stored frozen until extraction.

5.2.2 Iflavirus Discovery

5.2.2.1 Isolation of Iflavirus Particles from Honeybees

Different arthropod host species, or even different populations of the same host species, may be infected with iflaviruses significantly different from those previously described. Therefore, where possible, virus diversity should be characterized. The method given in the following for purifying honeybee viruses is suitable for nonenveloped viruses, including iflaviruses [6]. DWV-like viruses can be purified from honeybees of any developmental stage, but the greatest yield comes from symptomatic (deformed wings, stunted abdomen) adult bees or pupae heavily infested with *V. destructor.*

5.2.2.1.1 Procedure

1. Homogenize 5 g of insect tissue, frozen or live, with 35 mL of 100 mM sodium phosphate buffer, pH 7.4 (NaP buffer), supplemented with 0.05% of Tween 20 using a pestle and mortar.
2. Centrifuge for 12 min in a high-speed centrifuge (10,000 rpm, 4°C).
3. Carefully remove and retain the supernatant, leaving the fat layer (top) and the unhomogenized tissue (bottom).
4. Carefully layer the cleared supernatant over a 20% sucrose cushion (2.5 mL, 20% sucrose in NaP buffer) in a 30 mL ultracentrifuge tube, Beckman SW28 rotor. Top up with NaP buffer so that liquid reaches 0.5 cm from the top of the tube.
5. Centrifuge at 28,000 rpm, 18°C, for 3 h 30 min, pour off the supernatant, resuspend the pellet in 2 mL of NaP buffer, and leave overnight at 4°C to ensure complete resuspension of the virus particles.
6. Set up a discontinuous cesium chloride (CsCl) density gradient in a 35 mL ultracentrifuge tube, Beckman SW28 rotor, by layering from the bottom 5 mL aliquots of CsCl with the following densities: 1.6 g/cm^3, 1.5 g/cm^3, 1.4 g/cm^3, 1.3 g/cm^3, and 1.2 g/cm^3. The CsCl solutions are prepared using saturated CsCl (1.9 g/cm^3 in dH_2O) mixed with NaP buffer in varying proportions to achieve required density. Carefully layer the resuspended sucrose cushion pellet containing the virus particles over the CsCl gradient after being mixed with enough buffer to reach 0.5 cm from the top of the tube.
7. Centrifuge for 18 h, 28,000 rpm, at 4°C, using Beckman SW28 rotor.
8. Carefully collect separate 1.5 mL fractions, starting from the top.
9. Weigh each 1.5 mL fraction to determine density, collect fractions with a density of 1.30–1.40 g/cm^3, pool them together, and dilute 5–10-fold with NaP buffer.
10. Centrifuge the diluted fractions for 3 h, at 4°C, 28,000 rpm, using SW28 Beckman bucket rotor.
11. Immediately remove supernatant and resuspend the pellet with 200 µL 0.1 M sodium NaP buffer, pH 7.4. Note that pellet could be invisible. Store at −80°C.

Depending on the amount of the starting tissue material and the yield, virus preparations could be used to raise antisera and/or to isolate viral genomic RNA for further applications, including conventional cDNA synthesis or sequence-independent amplification of cDNA to viral RNA or next-generation sequencing [6,10] or sequence-independent amplification of viral cDNA described as follows.

5.2.2.2 Sequence-Independent Amplification of Viral cDNA

This method was adapted from the procedure for identification of human viruses described by [13] and was successfully used for identification of novel RNA viruses in aphids [14,15].

5.2.2.2.1 Procedure

1. Homogenize up to 50 adult aphids (total weight 15 mg) previously stored at −80°C, with 15 mL of 100 mM sodium phosphate buffer, pH 7.0.
2. Clarify spin the homogenate at 350 × *g* for 10 min in a benchtop Eppendorf centrifuge.
3. Filter the debris-free supernatant through a 0.80/0.22 µm filter (Millipore).
4. Centrifuge at 45,000 rpm in a Ti80 rotor (Beckman) at 4°C, for 2 h 30 min.
5. Completely remove supernatant and resuspend practically invisible pellet with 100 µL of 20 mM sodium phosphate buffer, pH 7.0.
6. In order to remove traces of DNA contamination, combine 15 µL of the virus suspension, 12 µL of RNA-free water, and 3 µL of the 10× transcription buffer and 1 µL of DNAseI from Ambion in vitro transcription kit (Cat. No. 1344), and incubate for 30 min at room temperature.
7. Extract RNA with RNeasy Plant mini kit (Qiagen) according to the manufacturer's instructions, and elute with 50 µL of RNase-free water.

The RNA preparation extracted from virus particles is reversely transcribed to produce the first cDNA strand; the second cDNA strand is produced using Klenow fragment (3′ → 5′ exo-). In both reactions, the tagged random hexanucleotide primer, "Tag-N6" (5′-GCCGGAGCTCTGCAGATATCNNNNNN-3′), is utilized.

Downloaded From Vet-eBooks.com

First cDNA strand synthesis

Component	Volume (μL)
Column-purified encapsidated RNA	16
Oligonucleotide "Tag-N6," 10 μM	4

Incubate at 65°C for 5 min, then immediately chill in ice, and then add the following:

Component	Volume (μL)
5× first-strand buffer (Invitrogen)	8
Deoxynucleotide mix (5 mM each)	4
0.1 M DTT	2
RNaseOUT, Invitrogen (40 units/μL)	2
SuperScript II reverse transcriptase	2

Incubate at 25°C for 10 min and 42°C for 50 min.

For the second cDNA strand synthesis, which uses the same tagged hexanucleotide primer, incubate at 94°C for 3 min to denature, immediately chill in ice, add 5 units (1 μL) of Klenow fragment (3′ → 5′ exo-) (New England Biolabs), and incubate at 37°C for 1 h. Inactivate the enzyme by incubating at 75°C for 10 min.

To amplify the tagged cDNA fragments by PCR, set up 50 μL of the reaction by combining 5 μL of the tagged cDNA reaction, 5 μL of 10 μM primer 5′-GCCGGAGCTCTGCAGATATC-3′, and 2 μL of dNTP solution (5 mM each), 5 μL of Roche 10× PCR buffer, 32 μL of water, and 1 μL of Taq polymerase (Roche). After 5 min incubation at 94°C followed by 40 cycles (94°C for 1 min, 65°C for 1 min, and 72°C for 2 min), add a final 5 min incubation at 72°C. Separate the PCR products by agarose gel electrophoresis (1.2% gel on TAE buffer, 100 V for 30 min, stain with ethidium bromide). Extract the gel products ranging in size from 150 to 400 nt using QIAGEN gel extraction kit, and clone them into an AT cloning vector (e.g., pDrive vector, QIAGEN) to create a plasmid library. Sequence plasmids using Sanger dideoxy method, and carry out sequence similarity search using the BLAST program [16] to identify sequences coding for proteins with similarity to the viral proteins.

5.2.3 Detection Procedures

5.2.3.1 Isolation of Total RNA

Samples must remain frozen at all times, prior to the addition of guanidinium thiocyanate-phenol-chloroform (TRI Reagent, Ambion) to prevent RNA degradation.

1. Collect clean pestles, mortars, and spatulas. Fill Dewar flask with liquid nitrogen and move collect frozen bees/pupae (from −80°C into Dewar flask).
2. Cool ceramic pestles and mortar with liquid nitrogen; rest the mortar inside to cool.
3. Top the liquid nitrogen, place the first sample into the mortar, and gently tap to break it up. Keep covered in liquid nitrogen and grind the sample to a fine powder.
4. Allow the sample to "dry," and then immediately use a clean spatula to split evenly into two 1.5 mL microfuge tubes, and precool spatula and tubes in liquid nitrogen prior to use.
5. Place the tubes into the liquid nitrogen and move onto the next sample using a clean set of equipment.
6. Turn on the centrifuge to cool to 4°C. Take one aliquot of each sample to the 80°C for storage (to be kept as powder for protein or DNA analysis).
7. In the fume hood, add 1 mL TRI Reagent to each sample and mix well. Incubate for 5 min at room temperature.
8. Add 0.2 mL chloroform to each sample, shake for 15 s, and then incubate for 2 min at room temperature.
9. Centrifuge for 15 min, 12,000 rpm, at 4°C.
10. Transfer aqueous phase to fresh tube—this is the colorless liquid at the top of the tube. Dispose of (pink) phenol waste appropriately.
11. Add 0.5 mL isopropanol (propan-2-ol) and mix and incubate at −20°C for at least 1 h.
12. Centrifuge for 10 min, 12,000 rpm, at 4°C.
13. Remove the supernatant, leaving just the white pellet.
14. Add 1 mL of 75% ethanol, and vortex and centrifuge for 5 min, 12,000 rpm, at 4°C.
15. Carefully remove the supernatant, leaving just the white pellet, and air-dry pellet at room temperature for about 30 min.
16. Dissolve total RNA in 30 μL of RNAse-free water and store at −80°C.

Note: If sample has been stored in RNAlater solution (Ambion), then an additional step is required. The high salt concentration in the sample prevents RNA pellet formation. To avoid this difficulty, ensure all of the RNAlater solution is removed from the sample prior to homogenization, and, instead of pouring off all of the supernatant after the centrifugation with isopropanol (step 13), pipette off the top phase, and then precipitate the RNA contained within the bottom phase with the addition of 1 mL of 50% isopropanol. Recentrifuge and then proceed to the ethanol wash stage as per protocol.

Quantification of iflaviruses requires normalization to the levels of host mRNAs that are constitutively expressed at high levels, usually of ribosomal protein 49 (RP49) [6,10]. To ensure that transcript rather than genomic DNA is quantified and amplified, total RNA preparations should be treated with DNAseI (New England Biolabs). For DNAseI treatment, set up reaction with up to 5 μg of total RNA of 100 μL in 1× reaction buffer, add 2 units of DNAse I, and incubate at 37°C for 15 min, and then immediately run through an RNA purification column, "GeneJET RNA Purification Kit" (Thermo Scientific, Cat. No. K0731) or "RNeasy Plant Mini Kit" (QIAGEN, Cat. No. 74904), following the manufacturer's protocol.

Downloaded From Vet-eBooks.com

RNA samples could be extracted directly from small insects like aphids, *V. destructor* mites, or fragments of arthropod tissues up to 25 mg by using "GeneJET RNA Purification Kit" or QIAGEN "RNeasy Plant Mini Kit," according to the manufacturer's instructions. Live aphids or mites could be placed in Eppendorf tubes and immediately homogenized with guanidine thiocyanate–containing lysis buffers using a mini pestle. When frozen material is used, the lysis buffer could be added before directly to the frozen sample in the Eppendorf tube and immediately homogenized using a mini pestle.

5.2.3.2 Reverse Transcription

Molecular methods are based on the detection of the viral cDNA, a copy of DNA complementary to viral RNA, which is produced by RNA-dependent DNA polymerases. cDNA is more stable than RNA and could be stored at −20°C; therefore, it is advisable to produce cDNA immediately after RNA cleanup. To ensure that the same cDNA preparation could be used with different primers for detection and quantification of different viruses and host transcripts, the following protocol uses a random hexamer oligonucleotide primer to produce fully representative cDNA copies of the RNA population:

Component	Volume (μL)
DNAseI-treated column-purified RNA	10
Random hexamer (N6) primer (100 μM)	1
Deoxynucleotide (dNTP) mix (10 mM each)	1

Heat mixture to 65°C for 5 min and quickly chill on ice. Collect the contents of the tube by brief centrifugation and add the following:

Component	Volume (μL)
5× first-strand buffer	4
0.1 M DTT	2
RNaseOUT, Invitrogen (40 units/μL)	1

Incubate at 25°C for 2 min and then add 1 μL (200 units) of SuperScript II RT (Invitrogen), and mix by pipetting gently up and down. Incubate the tube at 25°C for 10 min and then at 42°C for 50 min, and finally inactivate the reaction by heating at 70°C for 15 min. cDNA samples are diluted in 1:5 dH_2O and stored at −20°C.

5.2.3.3 Nested PCR Detection of DWV, VDV1, and Their Recombinants

Identification of the strains of DWV-like viruses, in particular highly virulent VDV-1-DWV recombinants, requires cloning and sequencing of cDNA fragments [6,10]. The levels of DWV in asymptomatic bees may not be sufficient for direct amplification of the cDNA fragments for further characterization. Nested PCR, which includes amplification of a fragment of cDNA in two stages, first with a pair of "outer primers" and then with the pair of "inner primers" located within the reamplified region, allows amplification of low levels of template. In respect to DWV and VDV-1 infection, a highly characteristic region suitable for identification of the individual strains of DWV, VDV-1, and VDV-1-DWV recombinants is 1.3 kb fragments at the border between the structural genes (CP) and nonstructural (NS) gene blocks (corresponding to nucleotides 4926–6255 of the DWV genome; GenBank accession No. AJ489744). The outer and inner primer sequences are shown in Table 5.2.

Step 1—Using flanking primers "Nested-outer-universal-DWV-4700-For" and "Nested-outer-universal-DWV-6700-Rev" (Table 5.2).

For a 50 μL reaction volume mix

Component	Volume (μL)
GoTaq Green Master Mix, 2×	25
Forward primer (100 μM)	1
Reverse primer (100 μM)	1
cDNA template (diluted in 1:5 dH_2O)	5
dH_2O	18

Mix the components in a PCR tube and place into the thermal cycler for the following: 95°C, 2 min, 15 cycles (95°C, 30 s; 52°C, 1 min; 72°C, 2 min), 95°C, hold.

Step 2—Using DWV- or VDV-1-specific primer combinations. There are four possible inner primer combinations, allowing amplification of DWV, VDV-1, and VDV-1-DWV recombinants, including the nonrecombinant DWV ("Nested-Inner-DWV-4900-For" and "Nested-Inner-DWV-6500-Rev"); nonrecombinant VDV-1 ("Nested-Inner-VDV-4900-For" and "Nested-Inner-VDV-6300-Rev"), VDV-1 CP–DWV NS recombinants ("Nested-Inner-VDV-4900-For" and "Nested-Inner-DWV-6500-Rev"), and DWV CP–VDV-1 NS recombinants ("Nested-Inner-DWV-4900-For" and "Nested-Inner-VDV-4900-For") though the DWV CP-VDV-1 NS recombinant has never been detected.

Take 5 μL of the reaction in "Step 1" to serve as the template for each of these mixes in "Step 2":

For a 50 μL reaction volume mix

Component	Volume (μL)
GoTaq® Green Master Mix, 2×	25
Upstream primer (100 μM)	1
Upstream primer (100 μM)	1
Product from "Step 1" at 95°C	5
dH_2O	18

Mix the components in a PCR tube and place into the thermal cycler at 95°C for 2 min with 30 cycles (95°C for 30 s, 52°C for 1 min, 72°C for 2 min) and 72°C for 10 min.

The product of each reaction in "Step 2" can be analyzed by agarose gel electrophoresis (1% gel on TAE buffer, 100 V for 30 min, stain with ethidium bromide), to determine which strains of DWV-like viruses and which recombinants are present in the sample. Further information on virus identity for

phylogenetic analysis can be obtained by cloning these PCR products into a plasmid vector (e.g., pGemT-Easy, Promega) and sequencing the plasmid using the Sanger dideoxy method.

5.2.3.4 Real-Time PCR Quantification of DWV

Real-time PCR (or qPCR) allows accurate and simple quantification of DWV-like viruses within individual bees. With qPCR, fluorescent dyes are used to label PCR products during thermal cycling, and the accumulation of fluorescent products is measured in real time. Here, we describe how the SYBR Green qPCR approach can be used to quantify viral load in individual bees, normalized to a constitutively expressed housekeeping gene (actin).

For a 20 µL reaction volume mix

Component	Volume (µL)
Brilliant III qPCR Master Mix, low ROX	10
dH_2O	7.6
Forward primer (100 µM)	0.2
Reverse primer (100 µM)	0.2
cDNA template	2

Reaction conditions: 95°C for 3 min, 50 cycles (95°C for 10 s, 60°C for 30 s).

For absolute quantification of viral copy number, serial dilutions of known amounts of template can be included on the qPCR plate and their ct scores used to plot a standard curve. Sequences of the oligonucleotide primers used for qRT-PCR quantification of the structural genes and nonstructural genes of DWV- and VDV-1-types, four pairs in total, as well as for the amplification of honeybee and *V. destructor* actin are shown in Table 5.2.

5.3 CONCLUSION AND FUTURE PERSPECTIVE

A growing body of evidence suggests that iflaviruses are widespread in a variety of arthropods, including Hymenoptera species (important pollinators like honeybee and bumblebees and parasitoid wasps) and Lepidoptera species, including pests and silkworm, as well as aphids. Although in the majority of cases iflaviruses are not present at high concentrations and do not cause obvious symptoms, they still have an effect on insect physiology and survival and affect host fitness. Also, rapid selection of pathogenic strains of iflaviruses may take place as a result of major changes in virus transmission. A well-studied example is the selection of highly virulent strains of DWV and/or DWV/VDV-1 recombinants that severely affect honeybee health following introduction of the mite *V. destructor* [10,17].

The development of tests for novel iflaviruses is important for insect cell culture–based research. Recently, it was shown that the widely used cell line that is derived from the gypsy moth *Lymantria dispar* is persistently infected with an LdIV1 [4]. Taking into account the impact of virus infections, including iflaviruses, on arthropod physiology, health, fecundity, and interspecies interactions, there is a need to expand screening

Downloaded From Vet-eBooks.com

for novel and characterized iflaviruses. Technical advances in high-throughput analysis of transcriptomes, in particular RNA-seq [18], have made possible to comprehensively characterize diversity of RNA viruses in any species using material extracted from individual organisms. Molecular tests, RT-PCR and real-time RT-PCR, or oligonucleotide array–based tests [19] similar to those that are already developed for the identified iflaviruses (Table 5.1) could be devised for the screening of particular iflavirus or even particular strain in a large number of individuals when required, when new sequencing data become available.

6.1 INTRODUCTION

Avian encephalomyelitis virus (AEV) causes central nervous system (CNS) signs (including ataxia, incoordination, paralysis, and rapid tremors) with high morbidity and some mortality in young chicks [1–7]. AEV was first described in 1932 in 2-week-old chicks showing tremors [5]. However, in adult laying birds, AEV infection causes no neurologic signs, apart from a slight reduction in egg production [3,7]. Outbreaks of AEV infections were observed in Connecticut, Maine, Massachusetts, and New Hampshire, which led to the naming of avian encephalomyelitis (AE) as "New England disease." Since then, AE has been identified in many parts of the world [7]. AEV has a limited host range; chickens, pheasant, Coturnix quail, and turkeys have been shown to be infected [7–9]. AEV is transmitted vertically to the progeny, but infection with AEV by the fecal–oral route also occurs [3,10–12]. In the mid-1950s, AE was successfully controlled by immunization [13].

6.1.1 Classification, Morphology, and Chemical Composition

AEV is a member of the *Picornaviridae* family, which covers a large number of single-stranded RNA viruses organized in 21 genera [14]. Earlier studies [15] suggested that AEV belongs to the *Enterovirus* genus, but recent findings indicate that it shares high levels of protein homologies with the hepatitis A virus (HAV) [16]. Now, AEV has been tentatively classified as being a member of the *Hepatovirus* genus within the *Picornaviridae* family [17].

In addition to AEV, other notable viruses in the *Picornaviridae* family include poliovirus (human enterovirus C serotypes [PV-1, PV-2, PV-3]), human rhinovirus A, encephalomyocarditis virus, foot-and-mouth disease virus, HAV, human parechovirus (HPeV), equine rhinitis B virus, Aichi virus (AiV), and porcine teschovirus.

A purified virion particle of AEV has a diameter of 24–32 nm [18], is nonenveloped, and contains a single-stranded RNA genome of positive polarity [16,19]. It possesses a buoyant density of 1.31–1.33 g/mL and a sedimentation coefficient of 148 S [14–16,18]. The AEV genome is composed of 7032 nucleotides with an open reading frame of 6405 nts starting at nucleotide 495 [14,16]. AEV includes four structural proteins from the P1 region (VP1, VP2, VP3, and VP4) and seven nonstructural proteins from the P2 and P3 regions of the genome [16]. Shafren and Tannock [20] initially detected four virus-specific proteins with molecular weights of 43, 35, 33, and 14 kDa, respectively. One of the nonstructural protein-2As associated with AEV possesses a conserved motif shared with two other picornaviruses: HPeVs and AiV [21]. It has been shown that AEV is resistant to chloroform, acid, trypsin, and DNase and is protected against the effects of heat [22]. However, the AEV is susceptible to a single exposure to formaldehyde fumigation [23].

6.1.2 Pathobiology and Epidemiology

AEV is known to contain two distinct pathotypes: natural AEV field strains and embryo-adapted strains. (1) Natural AEV field strains are enterotropic. These strains infect chickens readily via the oral route and are shed in the feces. They are relatively nonpathogenic except in susceptible chicks infected by vertical transmission or by early horizontal transmission, in which case they cause neurologic signs. (2) Embryo-adapted strains are highly neurotropic and cause severe neurologic signs

Downloaded From Vet-eBooks.com

following intracerebral inoculation or parental routes such as intramuscular or subcutaneous inoculation. AEV-adapted Van Roekel (VR) strain can easily be replicated in chicken embryo brain cultures [20,24].

Both AEV pathotypes can replicate in embryos, but natural field strains do not cause obvious signs or gross lesions. On the other hand, adapted strains are pathogenic for embryos, causing muscular dystrophy and immobilization of skeletal muscles [25]. No differences in structural proteins have been observed between a field isolate and the embryo-adapted VR strain of AEV [26]. All chicken flocks eventually become infected with the AE virus, but the incidence of clinical disease is very low unless a breeder flock is not vaccinated and becomes infected with the AEV after the commencement of egg production. Turkey flocks apparently also experience high rates of natural infection based on serological surveys [8]. However, the rate of infection in pheasant and quail is not known [9].

6.1.3 Clinical Features and Pathogenesis

AE presents an interesting syndrome. In naturally occurring outbreaks, it usually makes its appearance when chicks are 1–2 weeks of age, although affected chicks have been observed at the same time of hatching. Affected chicks first show a slightly dull expression of the eyes, followed by a progressive ataxia from incoordination of the muscles, which may be detected readily by exercising the chicks [5]. As the ataxia grows more pronounced, chicks show an inclination to sit on their hocks. Some may refuse to move or may walk on their hocks and shanks. Fine tremors of the head and neck may become evident, the frequency and magnitude of which may vary. Exciting or disturbing the chicks may bring on the tremor, which may continue for variable period and recur at irregular intervals [4,5]. Ataxia usually progresses until the chick is incapable of moving around, and this stage is followed by initiation, prostration, and finally death [10]. Some chicks with definite signs of AE may survive and grow to maturity, and in some instances, signs may disappear completely. Survivors may later develop blindness from opacity giving a bluish discoloration to the lens [27]. There is marked age resistance to clinical signs in birds exposed after 2–3 weeks of age. Mature birds may experience a temporary drop in egg production (5%–10%) but do not develop neurologic signs. Virus may be propagated in the baby chick, chicken embryos from susceptible flocks, and a variety of cell culture systems. Several routes of inoculation in embryos have been used, but inoculation via the yolk sac at 5–7 days of embryonating egg is considered the method of choice [25]. Gross lesions are observed only with adapted strains.

Localization of the viral antigen using virus isolation, immunodiffusion, immunofluorescence, and enzyme-linked immunosorbent assay (ELISA) techniques has been reported by several investigators [3,20,28,29]. In young chicks exposed orally to field strains of AEV, primary infection of the alimentary tract is rapidly followed by a viremia and subsequent infection of the pancreas and other visceral organs (liver, spleen, heart, kidneys) and skeletal muscle and finally the CNS. Alimentary tract infections involve muscular layers, and pancreatic infections are found in both the acinar and islet, persisting more in the latter. Viral antigen is relatively abundant in the CNS where the Purkinje neuron and the molecular layer of the cerebellum are apparently the favored sites of virus replication. Chicks with clinical signs at 10–30 days of age tend to have viral antigen mostly in the CNS and pancreas; less amounts of antigen have been seen in the heart and kidney; and only very small amounts have been seen in the liver and spleen. Avian encephalomyelitis virus studies of various experimental infections of adult chickens revealed that no viral antigen was found in the CNS; presumably, this lack of infection correlates with the absence of clinical disease in infected adults [29]. On the other hand, the pathogenesis of AEV in young chicks, naturally occurring or experimental infection, has been clearly defined [28]. It was described that chicks infected at day 1 of age generally died, whereas those infected at day 8 developed paresis but usually recovered, and infection at day 28 caused no clinical signs [30].

6.1.4 Diagnosis

6.1.4.1 Conventional Techniques

Many methods have been developed for the diagnosis of AE, including virus isolation by intracerebral inoculation of 1-day-old chicks and yolk-sac inoculation of embryonated chicken eggs [6,25,31].

The brain is an excellent source of virus for isolation, although other tissues and organs induce the disease when injected into chicks [7,32]. Miyamae [33] found that in addition to the brain, the pancreas and duodenum were especially reliable sources of the virus. The need to titrate vaccine virus makes a sensitive method for virus detection very important. One system for virus assay is to inoculate embryos from a susceptible flock via the yolk sac at 5–7 days of age, allowing to hatch and observe chicks for signs of disease during the first 10 days [30,20]. When clinical signs appear, the brain, proventriculus, and pancreas should be examined for lesions as described in histopathology. Additionally or alternatively, the brain, pancreas, and duodenum of affected chicks can be examined for the specific viral antigen by immunofluorescence [34,35] or immunodiffusion tests [36,37].

Other methods for the diagnosis of AE include virus isolation by intracerebral inoculation of 1-day-old chicks and yolk-sac inoculation of embryonated chicken eggs [32,38]. Virus may be propagated in the baby chick, chicken embryos from susceptible flocks, and a variety of cell culture systems. Several routes of inoculation in embryos have been used, but inoculation via the yolk sac at 5–7 days of embryonating egg is considered the method of choice [32]. Various serologic methods have been developed, such as hemagglutination, complement fixation, indirect fluorescent-antibody technique, ELISA, virus neutralization, and agar-gel-precipitin tests [11,36,37,39–42].

However, isolation and serological methods are time-consuming and labor intensive. Furthermore, serological tests are often hampered by nonspecific reactions or cross-reactions.

Downloaded From Vet-eBooks.com

6.1.4.2 Molecular Techniques

In recent years, the cDNA probe [43] and polymerase chain reaction (PCR) methods have been applied as a rapid diagnostic tool for the detection of avian viral and bacterial pathogens [44–48]. In this study, we have developed and optimized a reverse transcription-polymerase chain reaction (RT-PCR) assay using primers targeting to the VP2 gene to detect AEV [49].

6.2 METHODS

6.2.1 Sample Collection

Virus propagation: When clinical signs appear, brain, proventriculus, and pancreas tissues should be collected from affected chickens.

Preparation of clinical samples

1. Mince tissue specimens and add penicillin (10,000 IU/ mL) and streptomycin (100 μg/mL).
2. Incubate the mixture at 4°C for 4 h.
3. Centrifuge the mixture at 1000 × *g* for 10 min.
4. Collect the supernatants.
5. Inoculate aliquots of 0.2 mL of supernatants into the allantoic cavity of 6-day-old embryonating specific-pathogen-free (SPF) eggs.
6. Collect the brains of infected embryos at 3 and 5 days postinoculation.
7. Resuspend tissues in phosphate-buffered saline (PBS) (10% w/v).
8. Disrupt brain tissues three times by freezing and thawing and store at –70°C.

Virus semipurification: Semipurified virus should be modified as described [38]:

1. The brains from six AEV-infected chick embryos can be suspended in 200 mL PBS.
2. Brain tissues should be treated with 0.5% (w/v) sodium dodecyl sulfate and disintegrated by shaking using glass beads for 30 min at 37°C.
3. It is followed by sonication for 20–30 s.
4. Virus suspensions are clarified by centrifugation at 1000 × *g* for 30 min at 4°C.
5. The supernatants are further centrifuged at 80,000 × *g* for 3 h at 4°C.
6. The resulting crude virus pellets should be resuspended in 1 mL of PBS.

These viral preparations will be used for extraction of RNA and stored at –20°C.

Negative pathogen controls for PCR assay: Infectious bronchitis virus (IBV), Newcastle disease virus (NDV), and adenovirus have been propagated in the allantoic cavity of 10-day-old SPF embryonated eggs [50]. Infectious laryngotracheitis virus (ILTV) is propagated on the chorioallantoic membrane in 10-day-old SPF embryonated eggs. Infectious bursal disease virus (IBDV) and reovirus grown in chicken embryo fibroblast monolayers using method described previously [47,48]. *Mycoplasma gallisepticum* (MG) is grown in Frey medium [51]. *Salmonella* sp. and *Escherichia coli* are grown in Luria–Bertani broth media [46].

Nucleic acid extraction: RNA extraction from AEV, IBV, NDV, IBDV, and reovirus is carried out using the Trizol LS manufacturer's protocol (Trizol LS, Life Technologies, Bethesda, MD). Deoxyribonucleic acid (DNA) from ILTV, adenovirus, MG, *Salmonella* sp., and *E. coli* are extracted using the phenol/chloroform/isoamyl alcohol solution (1:1:24 v/v) and purified (Gibco BRL, Grand Island, NY) using the method described by Pang et al. [50]. The concentrations of RNA and DNA determined by spectrophotometer using the Bio Mate 5 (Thermo Spectronic, Rochester, NY) and nucleic extractions are stored at –20°C.

Oligonucleotide primers: Pairs of primers that specifically amplify AEV are designated as

MK AE 1 (5′-CTT ATG CTG GCC CTG ATC GT-3′)

MK AE 2 (5′-TCC CAA ATC CAC AAA CCT AGC C-3′)

It is selected based on the published sequence data of AEV [14,16]. These primers flanked a 619 bp DNA sequence containing the VP2 gene. Primers are synthesized using Gibco (Invitrogen, Carlsbad, CA). Primers are aliquot into 50 μL volumes and stored at –20°C.

6.2.2 Detection Procedures

The following RT-PCR protocol has been modified from the previous report [49].

6.2.2.1 Reverse Transcription Reaction

1. Prepare the RT mix as follows (volume indicated per specimen) (*Note*: vortex and spin down all microcentrifuge tubes of RT-PCR components before use):

Component	Volume (μL)
10× PCR buffer (500 mM KCl, 200 mM Tris_HCl [pH 8.4])	2.0
25 mM $MgCl_2$	4.0
Bovine serum albumin (BSA) (0.5 mg/mL)	2.5
Deoxynucleotide triphosphate (dntp) mix (10 mM)	2.0
RNase inhibitor (20 units/μL)	1.0
Downstream primer (MKAE2) 50 pmol	1.0
Moloney murine leukemia virus, reverse transcriptase (50 units/μL)	1.0
Diethylpyrocarbonate (DEPC)-treated water	6.5
Total	20.0

2. Add this 20 μL RT mix to each 0.5 mL tube followed by the addition of 5 μL (50 ng) of the individual RNA sample.
3. Spin the tube briefly to ensure that no reagent droplets remain on the inner wall of the tube.

Downloaded From Vet-eBooks.com

4. Overlay the reaction mixture with one drop of mineral oil to prevent evaporation during the RT process.
5. Transfer the reaction tubes to a 42°C heat block for 30 min and then increase the temperature to 99°C for 5 min.
6. Rapidly chill the tubes on ice for 5 min.
7. The cDNA can be used directly in the PCR step or stored at –20°C.

6.2.2.2 PCR Detection of AEV

AEV is detected by PCR amplification of cDNA using primers MK AE 1/MK AE 2.

6.2.2.2.1 Procedure

1. Remove all aliquots of PCR reagents from the freezer. Vortex and spin down all reagents before opening the tubes.
2. Prepare the PCR reaction mix as follows:

Component	Volume (μL)
10× PCR buffer (500 mM KCl, 200 mM Tris_HCl [pH 8.4])	8.0
$MgCl_2$ 5 mM	8.0
BSA nuclease-free 0.5 mg/mL	2.5
Primer MK AE 1 60 pmol	1.5
AmpliTaq DNA polymerase 2.5 unit	6.0
DECP-distilled water	54.0
cDNA (RT reaction mix)	20.0
Total reaction	100.0

3. Turn on a thermocycler and preheat the block to 95°C.
4. Spin the sample tubes in a microcentrifuge at 10,000 × *g* for 30 s at room temperature.
5. Place the sample tubes in the thermal cycler for 35 cycles of 94°C for 1 min, 62°C for 1 min, 62°C for 1 min, and 1 cycle of 62°C for 10 min; keep at 4°C afterward.
6. Following amplification, pulse-spin the reaction tubes to pull down the condensation droplets at the inner wall of the tubes. The samples are now ready for electrophoresis or can be stored at –20°C.
7. Analyze the PCR products by agarose gel electrophoresis on 1.0% agarose gel in Tris/Borate/EDTA buffer at 80 V for 40 min [52].
8. Stain the gel with ethidium bromide and then visualize under ultraviolet light source.

Note: Negative control is included with clinical samples in order to confirm any possible contamination may have occurred during the PCR assay. The presence of 619 bp DNA product is indicative of AEV.

6.3 CONCLUSION

AEV is a single-stranded, positive-sense RNA virus that is capable of causing neurologic symptoms (e.g., ataxia, incoordination, paralysis, and rapid tremors) in young chicks, with high morbidity and moderate mortality. Additionally, this virus can reduce egg production in adult laying birds. Although outbreaks of AE were initially documented in Connecticut, Maine, Massachusetts, and New Hampshire, they have been subsequently shown to have a worldwide distribution. The implementation of immunization measures from the mid-1950s has largely put AE under control. Nevertheless, continuous vigilance and preparedness are necessary in order to minimize the damages from any future outbreaks of AE. Toward this goal, the availability of rapid, sensitive, and specific methods for the laboratory diagnosis of AEV infections is critical. Given the laborious and time-consuming nature of conventional techniques such as virus isolation and immunologic assays, the adoption of molecular techniques (e.g., RT-PCR) in routine diagnostic laboratories will enable prompt detection and identification of AEV and improve decision making in relation to the appropriate and effective control and prevention strategies against AE.

7.1 INTRODUCTION

Duck viral hepatitis (DVH) is an acute, rapidly spreading, highly fatal viral disease of young ducklings, 1–28 days of age [1]. The disease is characterized by clinical sign with opisthotonos and lesion of liver hemorrhages. All domestic ducklings are susceptible, with the exception of muscovies [2]. Ducklings under 3 weeks of age are highly susceptible. The disease may cause up to 90% mortality and is of economic importance to all duck-growing farms.

Previously, the causative agent of the disease was named duck hepatitis virus (DHV) and divided into three serotypes: DHV types 1 (DHV-1), 2 (DHV-2), and 3 (DHV-3) [1]. DHV-1 was first isolated by Levine and Fabricant from an outbreak of DVH in young white Pekin ducks on Long Island, New York, in 1949 [3], and later known to be worldwide in distribution [1]. This virus was classified as a picornavirus by Tauraso et al. [4]. DHV-2 and DHV-3 were originally recognized as separate serotypes because they induced DVH in ducklings vaccinated for DHV-1. DHV-2 was first described by Asplin in Norfolk, England, in 1965 [5]. This virus was shown to be distinct from DHV-1 by cross protection tests and therefore characterized as a new serotype of DHV. The disease caused by DHV-2 disappeared from commercial flocks by 1969 but reappeared in 1983/84 on three farms in Norfolk, England [6]. DHV-3-associated disease was first reported by Toth in 1969 and last observed in 1975 on a flock of white Pekin ducks on Long Island, New York [7,8]. The agent shared no common antigens with DHV-1 and DHV-2 in virus neutralization (VN) and fluorescent antibody (FA) tests and was characterized as the third type of DHV by Haider and Calnek [8]. It is generally considered that DHV-2 and DHV-3 have only been found in the United Kingdom and the United States, respectively. Recent characterization of several DHV-2- and DHV-3-like viruses from ducks in China suggested that DHV-2 and DHV-3 may have been introduced into countries outside the United Kingdom and the United States [9,10].

In 2007, two new serotypes of DHV were reported by Tseng and Tsai in Taiwan and by Kim et al. in South Korea independently [11,12]. The Taiwanese new serotype was first noted by Lu et al. in 1989–1990 and isolated from a mule duckling in 1990 and white Roman goslings in 2004 [11,13]. The Korean new serotype of DHV was isolated from ducklings in the years of 2003 and 2004 [12]. Similar to DHV-2 and DHV-3, discoveries of the two new serotypes were also associated with DVH outbreaks in ducklings vaccinated for DHV-1. The two viruses were shown to be both serologically different from DHV-1 in VN tests [11,12], but they have never been compared with each other. The sequence difference between the two viruses in capsid-coding regions (approximately 30% divergence in nucleotide) suggests that they may belong to different serotypes [14].

7.1.1 Classification, Morphology, and Genome Organization

Although DHV-1 was first isolated 64 years ago and initial studies indicated that this virus had many characteristics similar to members of the genus *Enterovirus* [1,3,4], little was known about this virus in its molecular characteristics and precise taxonomical position in the family *Picornaviridae* for a long time. The molecular cloning of DHV-1 genome in 2006–2007 led to dramatic progress in understanding the molecular virology and taxonomy of the virus. Based on its genomic structure and sequence similarity

Downloaded From Vet-eBooks.com

with previously known picornavirus genera, DHV-1 was proposed to be placed in a separate genus within the family *Picornaviridae* [15–17]. Meanwhile, the genome sequences of the two new DHV serotypes discovered in Taiwan and South Korea were also determined in 2007 [11,12]. Analyses of the complete genomes of both these viruses suggested that they would be classified in the same species as DHV-1 but as distinct genotypes (or serotypes) [11,12,14,18]. According to the *Ninth Report of International Committee for the Taxonomy of Viruses*, the three DHV types have been classified as members of the species *duck hepatitis A virus* (DHAV) in the genus *Avihepatovirus* in the family *Picornaviridae*. DHV-1 was renamed DHAV type 1 (DHAV-1), while the two newly discovered DHV serotypes were designated DHAV types 2 (DHAV-2) and 3 (DHAV-3), respectively [19].

Comparative sequence analysis of several DHAV strains indicated that the capsid sequences are highly conserved within the same type but highly divergent between different types. The nucleotide and amino acid identities within the same type are at least 90% and 92% in VP1, 94% and 96% in VP0, and 92% and 95% in VP3, whereas those between different types do not exceed 72% and 78% in VP1, 72% and 80% in VP0, and 74% and 83% in VP3, respectively [14]. In pairwise comparison of the 5′-untranslated region (UTR) sequences, DHAVs of the same type are also clearly distinguished from those of different types, and the limit of intratypic divergence appears to be about 7% nucleotide difference. In contrast, sequence variation among strains between types is considerably higher, ranging from 26% to 31%. Based on the sequence feature of 5′-UTR, an approach for molecular detection and typing of DHAV was reported by Fu et al. in 2008. This technique involved the amplification of an approximately 250 bp cDNA fragment from the 5′-UTR followed by nucleotide sequence determination and analysis of the amplified fragments. Classification based on the nucleotide sequence of the amplicon revealed that the sequence diverges by as much as 27%–36% between types. Within the same type, the partial 5′-UTR sequences are higher than 94% [18].

So far, data relating to molecular epidemiology of DHAV are limited. According to previous results obtained from serological tests, DHAV-1 is worldwide in distribution [1]; DHAV-2 has only been found in Taiwan, China [11]; and DHAV-3 has been reported in South Korean and mainland China [12,18]. Surveillance data of DHAV in China indicate that the DHAV-3 strains dominate as the cause of DVH outbreaks in recent years, although DHAV-1 is still circulating in China (GenBank EF093502.1).

The capsid protein precursor of DHAV-1 and DHAV-2 was predicted to be 731 amino acids (aa) in length, 2 aa shorter than that of DHAV-3. The subtle length difference between DHAV-3 and other DHAV types was found to be located at the VP1 region [11,14]. The DHAV virion was predicted to be composed of three structural capsid proteins (VP0, VP3, and VP1). The VP0 polypeptide does not appear to be proteolytically cleaved into VP4 and VP2 [11,12,15–17]. DHAV-1 has been estimated to be 20–40 nm in size [1], while the sizes of DHAV-2 and DHAV-3 have not been reported.

The genome of the DHAVs consists of positive-sense, single-stranded, polyadenylated RNA of 7689–7775 nucleotides (nt). Besides the 6 nt difference in VP1 mentioned earlier, the genomic length differences between the three types are mainly located at the UTRs. The polyadenylated genome contains a large open reading frame (ORF), encoding a putative polyprotein, which is preceded by a 5′-UTR and followed by 3′-UTR. The DHAV polyprotein appears to be cleaved into 10–12 mature products, forming its structural (VP0, VP3, and VP1) and nonstructural (2A, 2B, 2C, 3A, 3B, 3C, and 3D) proteins. A notable feature is the 2A protein, which contains three 2A motifs: (1) asparagine-proline-glycine-proline (NPGP) motif (related to the 2A of aphtho-, cardio-, erbo-, and teschoviruses), (2) avrRpt2-induced gene 1 like protein containing a GxxGxGKS nucleoside triphosphate binding motif, and (3) histidine and asparagine-cysteine box motif (similar to the 2A of parecho-, kobu-, and tremoviruses) [11,12,15–17]. It is therefore suggested by Tseng et al. in 2007 that DHAV may possess three putative 2A proteins [16]. However, it cannot be excluded that the 2A1 peptide sequence may be the carboxy-terminus of VP1, as is probably the case with the putative 2A1 of Ljungan virus (genus *Parechovirus*) [20]. It is also possible that 2A2 and 2A3 are a single multidomain protein [15,17]. The 5′-UTR was shown to possess a distinct hepacivirus/pestivirus-like internal ribosome entry site [21].

Originally thought to be a picornavirus, DHV-2 was characterized by Gough et al. in 1984/1985 as an astrovirus on the basis of morphology and cross protection tests [6]. A proposal was put forward that it should be renamed duck astrovirus (DAstV) [22]. The study by Todd et al., which showed that a 391 nt astrovirus-specific ORF1b was amplified from the DHV-2 M52 isolate, supported the view that DHV-2 belonged to an astrovirus [23]. DHV-3, originally regarded as a third serotype of picornavirus DHV [8], was identified by Todd et al. in 2009 as a second astrovirus in ducks because the 391 nt astrovirus-specific ORF1b sequence was also amplified from the DHV-3 X1222A Calnek isolate [23]. DHV-2 and DHV-3 are now classified as members of the genus *Avastrovirus* in the family *Astroviridae* [24]. Sequence comparison of the partial ORF1b region revealed that DHV-2 and DHV-3 share low nucleotide (64%) and amino acid (69%) identities with each other, suggesting that they may represent different avastrovirus species [23]. At present, the classification of avastroviruses is mainly based on genetic analysis of the complete capsid region at the amino acid level [24]. Due to the lack of the capsid sequences of DHV-2 and DHV-3, the taxonomic relationships of the two DAstVs to each other and to other avastroviruses remain to be resolved. The recent genomic characterization of a DHV-2-like isolate C-NGB and four DHV-3-like isolates represented by SL1 revealed that DHV-2 could be placed in species *Avastrovirus 2* together with turkey astrovirus 2, while DHV-3 may belong to an additional avastrovirus species [9,10,24].

The capsid protein of DAstVs is translated as one long precursor protein of approximately 81.7 kDa (DHV-2-like isolate C-NGB) and 80.7 kDa (DHV-3-like isolate SL1) [9,10], which is posttranslationally cleaved to form mature virion subunits

Downloaded From Vet-eBooks.com

in a mechanism that is not understood. Previous investigations have shown that DHV-2 is a small round, nonenveloped virus, 28–30 nm in diameter. The surface of the particles exhibits astrovirus-like morphology by Electron Microscope (EM) using negative staining [6]. However, DHV-3 appears to have a picornavirus-like morphology. Examination of duck kidney (DK) cells infected with DHV-3 by EM revealed crystalline arrays containing particles about 30 nm in diameter in the cytoplasm [8].

The genome of the DHV-2- and DHV-3-like astroviruses consists of positive-sense, single-stranded RNA. Excluding the poly(A) tail, the genomic lengths of the two DAstVs are 7722 and 7319 nt, respectively. The polyadenylated genome contains three ORFs, as well as a short 5′-UTR and a 3′-UTR. ORF1a and ORF1b encode the nonstructural proteins, which include several transmembrane helical motifs, a serine protease, a nuclear localization signal, and an RNA-dependent RNA polymerase motif. ORF2 encodes the capsid protein that is required for virion formation. By analogy to other astroviruses, a ribosomal frameshift signal can be observed in the overlap region of ORF1a and ORF1b of the DHV-2- and DHV-3-like astroviruses [9,10]. As a mechanism of virus evolution, recombination by avian astrovirus RNAs has been reported previously for turkey and chicken astroviruses [25–27]. Most recently, the DHV-2- and DHV-3-like isolates were shown to be closely related to different avastroviruses in different genomic regions, providing evidence that recombination events may have occurred during evolution of DAstVs [10]. Such phenomenon may complicate the classification of avastroviruses.

7.1.2 Transmission, Clinical Features, and Pathogenesis

As DHAV-1 is the most common virus reported in outbreaks worldwide, bulk of epizootiological data was obtained from studies on this particular virus. Transmission of the virus is usually by direct contact between birds or through fomites such as brooders, water, feed, and equipment. Egg transmission presumably does not take place [1]. However, a recent study in our laboratory revealed that DHAV-3 was easily detected from eggs produced by infected breeders, suggesting the possibility of egg transmission of DHAV-3 (GenBank KP995438.1).

The affected ducklings and recovered carriers are sources of infection. Recovered ducks can excrete DHAV-1 in feces for up to 8 weeks postinfection (PI) [1], which provides an extended opportunity for transmission of the virus to other birds. Although adult breeders on infected premises do not become clinical ill, they could be carriers. An epidemiological study in our laboratory indicated that a proportion of parent ducks may become infected and excrete DHAV-1, together with DHAV-3 and DHV-2-like astrovirus, throughout full laying period (GenBank KP995438.1). As a result, the ducklings may be infected by virus-contaminating eggs and brooders. Previous work by Asplin (1961) showed that DHAV-1 survived at least 10 weeks in uncleaned infected brooders and for longer than 37 days in moist feces stored in a cool shed [28]. Prolonged excretion after infection is likely to lead to high levels of viral contamination in brooders and farm environment. The wild birds, rodents, and workers as mechanical carriers may also play a role in spreading the disease [1].

DHAV-1 usually affects ducklings under 4 weeks of age and often much younger. Morbidity may be 100% and mortality is variable. In some broods, less than 1-week-old mortality may reach 95%. In ducklings 1–3 weeks old, mortality may be 50% or less. In ducklings 4–5 weeks old, morbidity and mortality are low or negligible. Adult breeders on infected premises do not become clinically ill and continue in full production [1].

The clinical signs are characterized by lethargy and ataxia. Infected ducklings lose their balance, fall on their sides, and kick spasmodically prior to death. At death, the head is usually drawn back in the opisthotonos position. Onset and spread of the disease are very rapid. Death occurs within 1–2 h after signs are noted. Practically, all mortality in a flock will occur within 3–4 days, with most deaths on the second day. Gross pathological changes are found chiefly in the liver, which is enlarged and exhibits punctate and ecchymotic hemorrhages. The spleen is sometimes enlarged and mottled. In some cases, the kidney is swollen and renal blood vessels congested. Microscopic changes are mainly observed in the liver and are characterized by extensive hepatocyte necrosis and bile duct hyperplasia, together with varying degrees of inflammatory cell response and hemorrhage [1].

The oral and respiratory mutes can be the portal of virus entry. The target organ appears to be the liver. Survivors from the disease are immune to further infection [1].

DHAV-2 and DHAV-3 can also cause severe diseases. Mortality exceeding 70% in 1-week-old white Roman goslings and up to 80% in Pekin ducklings were recorded for DHAV-2 and DHAV-3, respectively [11,29]. Severity of the disease caused by DHV-2 was shown to be associated with age of ducklings, with losses up to 50% in 6–14-day-old ducklings and between 10% and 25% in 3–6-week-old ducklings [1,5,6]. The disease caused by DHV-3 was observed to be less severe than DHAV-1 and mortality rarely exceeded 30% [1,7,8]. The clinical signs and pathological changes caused by these agents are similar to those of DHAV-1.

7.1.3 Diagnosis

The clinical and pathological observations are highly indicative of DVH. Therefore, diagnosis of the disease can usually be made based on the characteristic disease pattern in the flock and gross pathological changes. Initial diagnosis can be further confirmed by the recovery of virus from dead ducklings and the reproduction of the disease in susceptible ducklings [1]. As DVH may be caused by five different viruses, differential characterization of the causative agents is needed for definite diagnosis. However, cooccurrence of DHAV types 1–3, DHV-2, and DHV-3 disease outbreaks represents the main problem in differential diagnosis. Initial distinctions can be made from the responses of ducklings, embryonated eggs, and cell cultures to the isolated viruses [1]. More reliable methods of virus identification are serological tests or molecular techniques. These include VN tests, FA tests, reverse transcription polymerase chain reaction (RT-PCR), RT loop-mediated isothermal amplification

Downloaded From Vet-eBooks.com

(RT-LAMP), real-time quantitative RT-PCR, and nucleotide sequence analysis. Among these methods, RT-PCR and nucleotide sequence analysis are widely used for the detection and typing of DHAVs and differential identification of DAstVs in recent years [9,10,14,18,23,30–33]. Using these techniques, diagnosis of the disease can be made more rapidly, accurately, and confidently. It is suggested that these techniques could be used to replace the traditional serological tests.

7.1.3.1 Conventional Techniques

DHAV-1 and DHAV-3 can readily be recovered by inoculating infective liver suspensions into the allantoic sac of embryonated duck eggs. The viruses can also be isolated by inoculation into embryonated chicken eggs. However, duck embryos are preferable to chicken embryos, since duck embryo mortality and lesions occur soon after inoculation and at earlier embryo passages [1]. This is especially true for isolation of DHAV-3. Following passages, the proportion of embryos that die with specific lesions tends to increase [1]. Isolation and propagation of DHAV-1 using primary duck embryo liver (DEL) cells, primary duck embryo kidney (DEK) cells, and day-old DK cells have also been described [16,34–36]. Tseng and Tsai reported that DHAV-2 can be isolated by inoculation onto day-old DK cells [11]. The presence of DHAVs can be further confirmed by reproduction of typical signs and lesions by inoculation of the isolate into ducklings between 1 and 7 days of age that are susceptible to DHAVs.

Serological tests including direct FA test and various VN tests have been described for DHAV-1. The direct FA technique performed on livers of natural cases or inoculated duck embryos was considered as a rapid and accurate diagnosis of DHAV-1 infection [1]. The VN tests include those performed in chicken embryos, duck embryos, and ducklings as well as microneutralization assay in DK and DEK cells and plaque reduction assay in DEL and DEK cells [1,16,34–39]. The VN tests have been used for virus identification, titration of serological response to vaccination, and epidemiologic surveys. However, they have not been used extensively for routine diagnosis of DHAV-1 infection because the clinical disease is too acute and the VN tests are time consuming. Restriction of the practical application of the VN tests is also due to the traditionally described DHV-2 and DHV-3 that have only been observed in the United Kingdom and the United States, respectively, in the past. Following emergence of new types of DHAV, cross neutralization tests may assume greater significance for typing of DHAV if antisera against the three DHAV types are available. The VN tests performed in day-old DK cells and ducklings and in chicken embryos have been employed for comparison of serological relationship of DHAV-2 and DHAV-3 to DHAV-1, respectively [11,12].

DHV-2 may be recovered by inoculation of liver suspensions into the amniotic cavity of embryonated chicken or duck eggs. But these are difficult and expensive processes because the embryos may respond erratically only after four passages and no deaths may be seen during earlier passages. Diagnosis of DHV-2 infection can also be made by inoculation of infective liver suspension into susceptible ducklings, in which the response can be variable. A mortality rate of up to 20% may occur within a period of 2–4 days PI. VN tests in chicken embryos have been utilized for identification of DHV-2 isolate and detection of antibodies to DHV-2 in serum samples from survivors. But such tests were not routinely carried out because of the low and variable response of DHV-2 in embryonating chicken eggs [6]. Cross protection tests have been performed in ducklings; this technique was originally employed to distinguish DHV-2 from DHV-1 and to compare the antigenic relationship of DAstV isolated by Gough et al. to DHV-2 described by Asplin [5,6]. The most reliable diagnostic method for DHV-2 infection is EM examination of liver homogenates for the detection of astrovirus-like particles [1].

DHV-3 can be isolated by the inoculation of liver suspension onto the chorioallantoic membrane of embryonated duck eggs, which was considered as an effective method for diagnosis [1]. Alternatively, DHV-3 may be isolated in DK, DEL, or DEK cells. Although the virus does not cause cytopathic effect, the virus has been detected by a direct FA test [8]. The presence of DHV-3 can be confirmed by inoculation of infective liver suspensions into susceptible ducklings intramuscularly. The mortality rate may reach 20% with 60% morbidity. Intravenous inoculation is more effective [1].

7.1.3.2 Molecular Techniques

Following the successful cloning and sequencing of DHAV genome, various RT-PCR assays that were designed to amplify different genomic regions have been developed [18,30–33]. Using these assays, DHAV RNA, the most reliable marker for diagnosis of DHAV infections, can be readily produced from virus isolates and infective liver samples. Therefore, these molecular methods can be used for not only the identification of DHAV isolates but also the detection of DHAVs directly from clinical samples. Following nucleotide sequence determination and analysis of the amplified fragments, DHAV types can be identified. Type-specific RT-PCR assays have also been developed for rapid typing of DHAV. Considering that the 5′-UTR and capsid sequences are highly conserved within the same type but highly divergent between different types, the 5′-UTR and capsid regions are preferable to other genomic regions for molecular typing of DHAV [14,18]. Other molecular techniques such as RT-LAMP [40–42] and real-time quantitative RT-PCR [43,44], which is faster and more sensitive than standard RT-PCR, have recently been developed for rapid detection of DHAV-1 and DHAV-3.

In recent years, *Escherichia coli*–expressed DHAV VP1 proteins have been described. These VP1 proteins were subsequently used as antigens for development of indirect enzyme-linked immunosorbent assays (ELISA) that are suitable for investigations on serological epidemiology of DHAV infections [45,46]. Recent works in our laboratory demonstrated that VP1-based indirect ELISA has no type specificity, making it unsuitable for differential diagnosis of infections caused by different DHAV types. The VP1 proteins have also been employed to produce polyclonal and monoclonal immune sera that could then be utilized to establish ELISA-based

Downloaded From Vet-eBooks.com

diagnostic assays such as antigen-capture ELISA for detection of DHAV [47,48]. However, the limitation of ELISA-based diagnostic assays for DHAV detection is that only particular DHAV types for which specific monoclonal antibodies are available can be detected. Another issue that will need to be addressed is the ability of such tests to make differential diagnosis among different DHAV types.

For DAstVs, the molecular cloning and sequencing of a partial ORF1b region in 2009 led to a dramatic progress in understanding the classification of traditionally described DHV-2 and DHV-3 [23]. Using the partial ORF1b sequences as starting points, the DHV-2- and DHV-3-like astrovirus genomes have been successfully cloned and sequenced [9,10], which would be useful for development of molecular techniques for detection and characterization of DAstVs in both virus isolates and clinical liver samples. Specific RT-PCR assays have been developed for differential diagnosis between DHV-2- and DHV-3-like astroviruses [10]. An indirect ELISA for detecting antibodies of DHV-2-like astrovirus in duck sera has also developed [49].

7.2 METHODS

7.2.1 Sample Collection and Preparation

Liver sample should be collected from dead ducklings at postmortem for the purpose of diagnosis. DHAV and DAstV can be detected in the samples stored at −20°C and −80°C for many years. The liver sample is homogenized in phosphate-buffered saline (20%, w/v). After centrifugation at 12,000 × *g* at 4°C for 15 min, the supernatant is harvested and used for RNA extraction. The supernatant can also be stored at −20°C until use.

RNA can be extracted by using a commercial RNA extraction kit (e.g., TRIzol® Reagent, Life Techologies™). For TRIzol Reagent, RNA is extracted from supernatant of liver suspension following the manufacturer's instructions. Briefly, 250 μL of the supernatant is mixed with 750 μL of TRIzol Reagent in a 1.5 mL microcentrifuge tube, vortexed, and incubated at room temperature for 5 min. Then, 150 μL of chloroform is added, shaken vigorously for 15 s, and incubated at room temperature for 3 min. The mixture is centrifuged at 12,000 × *g* for 15 min at 4°C, and the aqueous phase is removed into a new tube. Then, 500 μL of isopropanol is added into the tube. After incubation at room temperature for 10 min, the tube is centrifuged at 12,000 × *g* for 10 min at 4°C. The resulting RNA pellet is washed with 1 mL of 75% ethanol, vortexed briefly, and centrifuged at 7500 × *g* for 5 min at 4°C. Finally, the obtained RNA pellet is air dried for 5 min, resuspended in 50 μL of RNase-free water, and used as template. The genomic RNA can be stored at −80°C until RT is performed.

7.2.2 Detection Procedures

Among the three types of DHAV, DHAV-2 has only been found in Taiwan, while DHAV-1 and DHAV-3 are cocirculating in South Korea and mainland China. Therefore, diagnosis and molecular epidemiological studies of DHAV conducted in mainland China have mostly focused on the detection of DHAV-1 and DHAV-3 as well as searching for new DHAV types in recent years. Due to discoveries of DHV-2- and DHV-3-like astroviruses in mainland China, molecular detection of DAstVs have also been taken into consideration for the purpose of diagnosis of DVH and epidemiologic surveys of astroviruses in ducks.

7.2.2.1 Reverse Transcription

7.2.2.1.1 Procedure

1. Add 5 μL of extracted RNA and 20 pmol of reverse primer into a 0.2 mL RNase-/DNase-free microcentrifuge tube and then incubate at 70°C for 5 min and at 4°C for 5 min.
2. Prepare the RT mix (RT-mix) as follows. For each sample, 19 μL of RT-mix is prepared.

Component	Volume (μL)
M-MLV Reverse Transcriptase 5× buffer	5
deoxy-ribonucleoside triphosphate (dNTP) mixture (10 mM each)	5
Recombinant Ribonuclease Inhibitor (40 U/μL)	1
M-MLV Reverse Transcriptase (200 U/μL)	1
Diethyl pyrocarbonate-treated water	7
Total	19

3. Add 19 μL of the RT-mix to the 0.2 mL tube in the first step, mix gently by flicking the tube, and spin the tube in a microcentrifuge at top speed for 30 s.
4. Place the tube in the thermal cycler for incubation at 42°C for 60 min, followed by an enzyme inactivation step at 94°C for 5 min.
5. The cDNA can be used directly in the PCR step or stored at −20°C for future use.

Note: RT is performed for DHAV and DAstV independently.

7.2.2.2 PCR Detection of DHAVs and DAstVs

For differential diagnosis between DHAV and DAstV, PCR is performed by using primers DHAV-F5/DHAV-R5 and DAstV-F/DAstV-R, respectively.

7.2.2.2.1 Procedure

1. Remove all aliquots of PCR reagents from the freezer. Vortex and spin down all reagents before opening the tubes.
2. Prepare the PCR reaction mix as follows. For each sample, 40 μL of PCR reaction mix is prepared.

Component	Volume (μL)
Forward primer (20 pmol/μL)	2
Reverse primer (20 pmol/μL)	2
2× PCR SuperMix	25
ddH_2O	11
Total	40

Downloaded From Vet-eBooks.com

Primer	Sequence (5′ → 3′)	Nucleotide Position	Expected Product (bp)	Specificity
DHAV-F5	GGAGGTGGTGCTGAAA	270–285[b]	250	DHAV
DHAV-R5	CCTCAGGAACTAGTCTGGA	519–501[b]		
DAstV-F[a]	GAYTGGACIMGITAYGAYGGIACIATICC	4528–4556[c]	438	DAstV
DAstV-R[a]	YTTIACCCACATICCRAA	4965–4948[c]		

[a] Primers reported by Todd et al. [23].
[b] Position in genome of DHAV-1 C80.
[c] Position in genome of DAstV C-NGB.

3. Add 10 μL of the RT product and 40 μL of the PCR reaction mix into a 0.2 mL PCR tube.
4. Turn on a thermocycler and preheat the block.
5. Spin the tube in a microcentrifuge at top speed for 30 s.
6. Place the sample tubes in the thermal cycler for amplification. PCR profile for DHAV comprises an initial denaturation at 94°C for 5 min, followed by 40 cycles of 94°C for 30 s, 50°C for 30 s, and 72°C for 30 s and a final extension at 72°C for 10 min. PCR profile for DAstV comprises an initial denaturation at 94°C for 5 min, followed by 45 cycles of 94°C for 1 min, 45°C for 1 min, and 72°C for 1.5 min and a final extension at 72°C for 10 min [23].
7. Analyze the PCR products by electrophoresis. For each sample, 8 μL of the PCR product is electrophoresed in a 1.5% agarose gel containing 0.5 mg/mL ethidium bromide in Tris-acetate-Ethylenediaminetetraacetic acid buffer at 130 V for 20 min. Visualize under ultraviolet (UV) light source or photograph under UV illumination with an imaging system.

Note: Negative and positive controls are concurrently included along with the test samples in order to determine whether the result is correct or wrong. The amplification of an approximately 250 bp product is indicative of DHAVs, while the amplification of a 438 bp product is indicative of DAstVs.

7.2.2.3 Sequence Analysis

Differential diagnosis among the causative agents of DVH can also be made by nucleotide sequence determination and analysis of the 250 and 438 bp fragments. Determination of the amplicons can be done by a sequencing company, using the purified PCR product as template in cycle sequencing reaction. Purification of the PCR products can be carried out by using a commercial gel extraction kit (e.g., QIAquick Gel Extraction Kit, Qiagen). The PCR products can also be sequenced after cloning. Briefly, the purified product is cloned into a vector (e.g., pGEM-T Easy Vector, Promega) and then transformed into competent *E. coli* (e.g., DH5α). After identification, plasmids extracted from the separated insert-positive clones are used for sequencing. Sequence identity and phylogenetic analyses should be performed to compare the sequence data with previously known sequences of the three DHAV types and the two DAstVs. For sequence analysis, the primer sequences should be removed from the sequences of the PCR products.

7.3 CONCLUSION

DVH is a severe disease of young ducklings because of the potential high mortality if not controlled. Up to now, members belonging to two virus families have been associated with the disease. Among the causative agents, DHAV-1 is known to be present in Northern America, Europe, and Asia, making this virus the most common cause of DVH. As newly discovered types of DHAV, DHAV-2 has only been reported in Taiwan, while DHAV-3 has been found in both South Korea and China. Although the traditionally described DHV-2 and DHV-3 are considered to be only present in the United Kingdom and the United States, respectively, recent characterization of several DHV-2-like and DHV-3-like astroviruses in China suggested that DHV-2 and DHV-3 were circulating outside the United Kingdom and the United States. Diagnosis of the disease can be readily made based on the clinical features and pathological changes. However, occurrence of similar disease outbreaks, caused by picornavirus DHAVs and astroviruses DHV-2 and DHV-3, offers the main problem in differential diagnosis. In the last century, characterization of DHAV-1, DHV-2, and DHV-3 strains relied mainly on the VN tests, EM examinations, and virus isolation, respectively.

Studies on molecular biology of DHAV began with the successful cloning of DHAV genome from several virus strains between 2006 and 2007. For DAstVs, the partial ORF1b sequences of DHV-2 and DHV-3 determined by Todd et al. in 2009 provide starting points from which the DHV-2- and DHV-3-like astrovirus genomes have been cloned and sequenced. The availability of the genomic sequences of DHAVs and DAstVs provides the possibility for development of new molecular techniques for detection and characterization of DHAV and DAstV strains both genetically and antigenically. The application of these sensitive methods for the detection of DHAV and DAstV in China contributes a greater recognition of molecular epidemiology of the viruses. More extensive surveillance for DHAVs and DAstVs in ducks of different species and in different geographic areas may enhance our understanding of molecular epidemiology and ecology of the viruses.

Traditional attenuated vaccine derived from serial passages in embryonated chicken or duck eggs has been reported for DHAV-1, DHAV-3, DHV-2, and DHV-3. All of them have been proven to be highly efficacious in controlling the disease caused by homologous virus. Among them, DHAV-1 vaccines derived from various strains of DHAV-1 have been used

Downloaded From Vet-eBooks.com

most commonly worldwide. It should be noted that such vaccines do not confer cross protection against the heterologous viruses. Therefore, a new vaccine consisting of a mixture of different strains of DHAV and/or DAstV should be developed in order to confer broad protection. Additionally, the implementation of different duck management procedures such as strict biosecurity and good sanitation may reduce the severity of the clinical effects.

8.1 INTRODUCTION

Foot-and-mouth disease virus (FMDV), a single-stranded positive-sense RNA virus in the genus *Aphthovirus*, family *Picornaviridae*, is responsible for causing foot-and-mouth disease (FMD, or hoof-and-mouth disease) in cloven-hoofed animals, including cattle, water buffaloes, pigs, sheep, and goats, and about 70 wildlife species. Characterized by a transient high fever (for 2–3 days), formation of blisters inside the mouth and on the feet, and lameness, FMD causes enormous economical losses in animal production through culling, trade restriction, and prevention measures.

Despite its first description from cattle in Venice in 1514 and concerted eradication efforts during the past few decades, FMD is still found in more than 100 countries in Asia, Africa, and parts of South America. This may be attributable to its high contagiousness, widespread occurrence, broad host range, existence of carrier status, short duration of immunity and low cross-immunity (due to antigenic diversity and tendency to undergo mutational changes), poor surveillance and diagnostic facilities, and inadequate control programs. In this chapter, we present a brief overview on FMDV in relation to its classification, morphology, genome organization, epidemiology, clinical features, pathogenesis, diagnosis, treatment, and control, together with stepwise molecular protocols for its identification and typing.

8.1.1 Classification

FMDV is a single-stranded positive-sense RNA virus classified in the genus *Aphthovirus,* family *Picornaviridae*, order *Picornavirales.*

With 50 species identified to date, the family *Picornaviridae* is divided into 29 genera: *Aphthovirus*, *Aquamavirus*, *Avihepatovirus*, *Avisivirus*, *Cardiovirus*, *Cosavirus*, *Dicipivirus*, *Enterovirus*, *Erbovirus*, *Gallivirus*, *Hepatovirus*, *Hunnivirus*, *Kobuvirus*, *Kunsagivirus*, *Megrivirus*, *Mischivirus*, *Mosavirus*, *Oscivirus*, *Parechovirus*, *Pasivirus*, *Passerivirus*, *Rosavirus*, *Sakobuvirus*, *Salivirus*, *Sapelovirus*, *Senecavirus*, *Sicinivirus*, *Teschovirus*, and *Tremovirus* [1].

In turn, the genus *Aphthovirus* is separated into four species: bovine rhinitis A virus (formerly bovine rhinovirus types 1 and 3, with 2 serotypes), bovine rhinitis B virus (formerly bovine rhinovirus 2, with 1 serotype), equine rhinitis A virus (formerly equine rhinitis virus 1, with 1 serotype), and FMDV (the prototype species, with seven serotypes: O, A, C, Southern African Territories 1 [SAT1] , SAT2, SAT3, and Asia 1).

At the present, seven immunologically distinct serotypes (containing >65 subtypes) are recognized within the FMDV species. Of these, serotype O (for Oise) was first identified in France; serotype A (for Allemagne) in Germany; serotype C also in Germany; serotypes SAT1, SAT2, and SAT3 in South Africa; and serotype Asia 1 in Pakistan. Following successive vaccination and control campaigns, some FMDV serotypes have been eradicated in a number of countries. As a consequence, the presence of various FMDV serotypes is now largely confined to China, Southeast Asia (SEA), Africa, Middle East, the United Kingdom, and South America (Table 8.1) [2].

Within each serotype of FMDV, a spectrum of subtypes/variants showing distinct antigenic, biological, and epidemiological characteristics has been identified using in vivo

Downloaded From Vet-eBooks.com

TABLE 8.1
Geographic Distribution of Foot-and-Mouth Disease Virus Serotypes

Geographic Location	Presence of FMDV Serotype						
	O	A	C	SAT1	SAT2	SAT3	Asia I
China	Yes	Yes	No	No	No	No	Yes
Southeast Asia	Yes	Yes	No	No	No	No	Yes
Africa	Yes	No	No	Yes	Yes	Yes	No
Middle East	Yes	Yes	Yes	No	No	No	Yes
United Kingdom	Yes	No	No	No	No	No	No
South America	Yes	Yes	Yes	No	No	No	No

cross-protection tests and in vitro serological assays. The in vivo cross-protection tests differentiate FMDV subtypes/variants through the ability or inability of one subtype to confer the same level of immunity to another subtype of the same serotype in experimental animals. Due to their high cost and reliance on the use of animals, in vivo cross-protection tests have been largely superseded by serological assays (e.g., enzyme-linked immunosorbent assay [ELISA] and virus neutralization test [VNT]), which provide a rapid and economical way to determine antigenic relationships among various FMDV isolates. Furthermore, sequencing analysis of the viral protein 1 (VP1) coding gene in FMDV genome facilitates a precise discrimination of FMDV genotypes (topotypes) at the nucleic acid level.

On the basis of up to 15% difference in VP1 coding sequences, FMDV serotype O is separated into eight genetically and geographically distinct genotypes (topotypes): Middle East–South Asia (ME-SA), SEA, Cathay, Indonesia 1, Indonesia 2, East Africa, West Africa, and Europe–South America (Euro-SA). In addition, using the criteria of nucleotide sequence variations within the VP1 coding gene of >7.5% and other phylogenetic differences, four different lineages are identified within the ME-SA topotype, including the pandemic PanAsia lineage.

Similarly, FMDV serotype A can be distinguished into 26 genotypes (topotypes) on the basis of >15% difference in VP1 coding sequence. Of the three distinct genotypes (topotypes) from Asia, Europe–South America (Euro-SA), and Africa, topotype Asia is the most prevalent in the Middle East and South Asia and contains a number of lineages (e.g., A_{15}, A_{22}, A-IRN87, A-IRN96, A-IRN99, A-Iran05).

Compared to serotypes O and A, the FMDV serotype Asia 1 appears to have a relatively low genetic and antigenic diversity. Previous studies indicated that serotype Asia 1 isolates collected between 1952 and 1992 from 18 groups, while those collected over the last two decades in India belong to seven lineages. Additionally, the examination of serotype Asia 1 isolates from 2003 to 2007 led to the identification of six groups. Another serotype Asia 1 group, designated as group VII and later as Sindh-08, is found in the West Eurasian region [2].

8.1.2 Morphology and Genome Organization

FMDV is a small, spherical, nonenveloped particle with a smooth surface and a diameter of 25–30 nm. Its capsid is composed of 60 copies of the capsomers organized in a tightly packed icosahedral structure (assemble with a triangulation number of three). Each capsomer comprises four structural polypeptides known as VP1, VP2, VP3, and VP4, with VP2 and VP4 originating from the cleavage of precursor VP0. Exposed on the surface of the virion, VP1–VP3 (24 kDa) fold into an eight-stranded wedge-shaped β-barrel that constitutes the majority of the capsid structure, whereas VP4 (8.5 kDa) is located inside the capsid [1].

The capsid encapsidates a nonsegmented, single-stranded, positive-sense RNA of 8500 nt in length, which includes the 5′ untranslated region (5′ UTR, of 500–1200 nt in length), a long open reading frame (ORF, about 7000 nt in length, encoding a single polyprotein), the 3′ untranslated region (3′ UTR, of 30–650 nt in length), and a poly "A" tail.

The 5′ UTR is linked to a 24 or 25 residue proteins known as VPg (encoded by 3B) that serves as primer in replication. The 5′ UTR contains a short fragment called S-fragment (360 bases), a poly "C" tract, a series of RNA pseudoknot structures, a *cis*-acting replication element (*cre*) (also known as the 3B-uridylylation site [*bus*]), and the internal ribosome entry site (IRES). IRES serves as ribosomal entering site due to the absence of 5′ cap (7-methyguanosine), with the translation initiation starting at two AUG codons separated by 84 nt following the IRES.

The polyprotein consists of one structural and eight nonstructural proteins (NSPs) organized in the order L-1ABCD-2ABC-3ABCD, which result from cleavage by viral proteases. Of these, the 1A, 1B, 1C, and 1D proteins are the components (VP4, VP2, VP3, and VP1, respectively) of the capsid. VP2 and VP4 are cleavage products of the precursor VP0 (1AB) during virion maturation and after the capsid is formed. The L, 2A, and 3C proteins are proteinases that internally cleave the polyprotein. The 2B, 2C, and 3A proteins interfere with host cell function. The 3B protein is the VPg protein. The 3D protein is the RNA polymerase. It is noteworthy that among the viral structural proteins, VP1 plays a key role in virus attachment and entry, protective immunity, and serotype specificity. Analysis of the VP1 sequence offers clues to the evolutionary dynamics and phylogenetic relationships among FMDV isolates.

The 3′ UTR follows the ORF termination codon and contains a short stretch of RNA that folds into specific stem-loop structures followed by a poly "A" tract of variable length. This 3′ UTR also serves as some functions in genome replication and is specific for each picornavirus. Poly "A" is likely involved in FMDV translation and replication.

8.1.3 Biology and Epidemiology

FMDV has the ability to hijack the host cellular machineries for its replication. After gaining entry to a susceptible host, FMDV particle binds to cell surface receptors, leading to the

Downloaded From Vet-eBooks.com

release of myristic acid, which is involved in the formation of a pore on the cell membrane to facilitate viral RNA injection. Within the cell, the RNA uncoats and a double-stranded RNA intermediate is generated from the positive-strand RNA genome by viral RDRP (RNA-dependent RNA polymerase). Initiated by IRES, the translation of viral proteins takes place in host cell ribosomes accompanied by a "shutoff" of cellular protein synthesis. The assembly of virus particles begins at 4–6 h after infection. Following death of the cell around 8 h postinfection, new virions are released.

FMDV is infective to >70 wild and domestic cloven-hoofed species, including cattle, water buffalo, sheep, goats, pigs, antelope, deer, bison, hedgehogs, mithun, yak, sambar, giraffes, elephants, and camels [3]. Llamas and alpacas may show mild symptoms, but do not pass it on to others of the same species. Mice, rats, and chickens may be infected under laboratory conditions, but not natural conditions.

FMDV is transmitted via contact with the infected host, body fluids, aerosols, fomites, fodder, motor vehicles, clothes and skin of animal handlers, standing water, uncooked food scraps, and feed supplements containing infected animal products. Cows can also catch FMD from the semen of infected bulls [4].

While cattle and sheep typically acquire the infection through respiration of aerosol containing the virus, swine are likely to be infected through ingestion or subcutaneous wounds. Some infected hosts (e.g., cattle and buffalo) may become asymptomatic and remain potentially contagious for up to 5 years, with the virus shedding in feces, urine, body fluids, and aerosols.

Among the seven serotypes, the most widely distributed viruses belong to serotypes O, A, and C, which are responsible for outbreaks in Europe, America, Asia, and Africa (Table 8.1) [5–7]. In particular, pandemic serotype O virus (the PanAsia strain) of the ME-SA topotype has been implicated in many recent FMD epidemics worldwide [8]. SAT1–SAT3 serotypes are mostly found in sub-Saharan Africa and maintained by African buffalo (*Syncerus caffer*). However, some limited outbreaks due to SAT1 viruses occurred in the Middle East and in Greece in the 1960s; and serotype SAT2 was associated with minor outbreaks in Yemen (1990), Kuwait and Saudi Arabia (2000), Northern African countries (Egypt and Libya), and Palestine and Bahrain in recent years [9–12]. Serotype Asia 1 is largely confined to Asia, despite its incursions into Greece in 1984 and 2000.

8.1.4 Clinical Features and Pathogenesis

With an incubation period ranging from 1 to 12 days, FMD is characterized by high fever (which declines rapidly after 2–3 days), appearance of blisters inside the mouth (leading to excessive secretion of stringy or foamy saliva and to drooling) and on the feet (with ruptured blisters causing pain and lameness), weight loss, swelling in the testicles of mature males, reduced milk production in cows, myocarditis (in calves), gastroenteritis (in pigs), and occasional death (about 2% in adults and 20% in newborns). Most infected animals eventually recover, but some remain asymptomatic carriers (with infectious virus present in the esophagus and throat fluids), which represent a source of infection for other animals [13].

In cattle, both oral and pedal lesions are evident, and in swine, pedal lesions dominate. In addition, pigs do not act as asymptomatic carriers. In sheep, milder signs are mostly found, with 25% of infected sheep showing no lesions.

In human FMD cases (due mostly to laboratory accidents), symptoms range from malaise, fever, vomiting, red ulcerative lesions (surface-eroding damaged spots) of the oral tissues, to vesicular lesions (small blisters) of the skin.

As the respiratory tract is the chief route of virus entry in natural infection, virus multiplication initially occurs in the pharynx epithelium, generating primary vesicles (or "aphthae") that affect cells from the epithelial stratum spinosum. From there, the virus spreads to different organs and tissues, leading to the production of secondary vesicles in the mouth and feet. After 1 week, the disease modulates gradually as a result of emerging humoral response from the host.

8.1.5 Diagnosis

FMD induces an acute, systemic vesicular disease in cloven-hoofed animals, which is clinically indistinguishable from vesicular stomatitis (VS), swine vesicular disease (SVD), and vesicular exanthema of swine (VES). Other diseases that may confuse with FMD include mucosal disease, malignant catarrhal fever, rinderpest, peste des petits ruminants, papular stomatitis, orf, blue tongue, and epizootic hemorrhagic disease. In addition, bacteria, chemicals, and mechanical trauma may be associated with stomatitis and pododermatitis. Therefore, use of laboratory methods is necessary for correct diagnosis of FMD [14,15].

Over the years, a variety of laboratory techniques have been developed for the identification and typing of FMDV, including virus isolation, serological assays, and nucleic acid detection.

8.1.5.1 Virus Isolation

Several stable cell lines (e.g., IBRS-2, MVPK-1 clone 7, LFBK cell line and baby hamster kidney 21 [BHK-21]) are suitable for FMDV isolation, although primary bovine thyroid cells represent a highly sensitive culture system for FMDV, facilitating detection of low amount of infectivity. It is notable that the use of BHK-21 cell line generally allows isolation of FMDV from only 10% to 30% of clinical materials. Another virus isolation technique involves inoculation of animals such as guinea pigs and cattle, which has been used previously for cross-immunity assessment of FMDV isolates [15].

8.1.5.2 Serological Assays

As faster, less expensive, and more precise alternatives to virus isolation, various serological assays have been developed for FMD diagnosis. These include complement fixation test (CFT), VNT, and ELISA. CFT was the test of choice for the diagnosis of FMD and virus typing until the 1970s, but its role has been largely taken over by more sensitive and easier to interpret tests such as ELISA. Considered as the

Downloaded From Vet-eBooks.com

gold standard for detection of antibodies to structural proteins of FMDV, VNT is a prescribed test for import/export certification of animals or animal products. Indirect ELISA detects FMDV antigen in infected cell culture fluid, mice carcass, and cattle tongue as well as antibodies in sera; sandwich ELISA using convalescent bovine immunoglobulin (Igs) as capture and anti-146S guinea pig sera as tracing sera offers a valuable means for detection and typing of FMDV directly from infected tissue culture and field materials. In comparison with conventional VNT, liquid-phase blocking ELISA using bovine convalescent sera is much more reproducible and less likely to be influenced by variations in tissue culture susceptibility. Therefore, it is no surprise that ELISA is considered by the World Organization for Animal Health (OIE) or Food and Agriculture Organization World Reference Laboratory for FMD as the preferred procedure for the detection of FMDV antigen and identification of viral serotypes. In a typical testing scheme, samples are first examined by ELISA, and ELISA-negative samples are inoculated into sensitive cell cultures followed by the confirmation of the virus serotype by ELISA [15,16].

Other types of serological assays include chromatographic strip, phage display, and biosensors. A monoclonal antibody-based chromatographic strip test for FMD diagnosis is as sensitive as the conventional antigen ELISA for the detection of FMDV in epithelial suspensions. Indeed, rapid chromatographic strip test and lateral flow device offer an added promise for pen-side diagnosis [17,18]. Phage display facilitates investigation on bovine antibody response to FMDV at a molecular level. An immunobiosensor using a piezoelectric crystal has been reported for FMD diagnosis and virus typing. The advantages of allosteric biosensor-based diagnosis are rapidity and potential for handling large number of samples and for automatic processing.

Another possible application of serological assays is in the differentiation of carrier animals from vaccinated animals. This is due to the fact that vaccinated animals do not produce antibodies to eight viral NSPs of FMDV, while infected animals do. Given that the 3D NSP may be occasionally present in the inactivated vaccine, the detection of antibodies to the 2C or the polyprotein 3ABC is a likely indicator of the previous infection (or carrier status), not a vaccinated host [19].

8.1.5.3 Nucleic Acid Detection

Given the time required for virus isolation (4–6 days) and serological assays (1 day + 4–6 days for virus isolation from initial ELISA-negative samples), nucleic acid–based detection methodologies have taken the spotlight. From early gene probe hybridization, nucleic acid amplification, to real-time platforms, we have witnessed the increasing sophistication of molecular tests and their evolution from pure research tools to workhorses in clinical diagnostic laboratories [20–23].

In particular, the development of reverse transcription polymerase chain reaction (RT-PCR) and its derivatives such as nested, multiplex, and real-time RT-PCR has opened new avenues for rapid, sensitive, and specific identification and typing of FMDV [24–28]. For example, use of multiplex PCR enables simultaneous identification of viral vesicular diseases (FMD, VS, SVD, and VES) and for the differentiation of seven FMDV serotypes [29]. In addition, the availability of different probe chemistries (DNA-binding fluorophores, 5′ endonuclease, adjacent linear and hairpin oligoprobes, and self-fluorescing amplicons) permits convenient, real-time detection and quantification of FMDV, with a much reduced risk of cross contamination [30]. Real-time PCR assays incorporating universal primers and fluorescent-labeled probes from the conserved region within the 5′ UTR or conserved gene regions within the RNA-dependent RNA polymerase gene (3Dpol) have been recommended by the OIE for FMDV detection [15,31].

Other nucleic acid amplification methods, such as nucleic acid sequence-based amplification (NASBA) and RT loop-mediated isothermal amplification (RT-LAMP), have also been shown to aid the detection of FMDV [32,33]. Recent assessment of NASBA electrochemiluminescence and NASBA-enzyme-linked oligonucleotide capture supports their use as a rapid and sensitive diagnostic method for the detection and surveillance of FMDV, whereas RT-LAMP enables rapid, specific, and sensitive detection of FMDV in laboratory as well as field condition.

8.1.6 Treatment and Prevention

No specific treatment is currently available for FMD. Although FMD is a disease of low mortality and high morbidity and most infected animals eventually recover with treatment, it exerts huge negative impacts on agriculture production and international trade, as well as economical burden associated with FMD control programs [34].

Therefore, apart from identification, quarantine, and culling of infected livestock, a most cost-effective way to prevent and control FMD is through vaccination. Many early vaccines have relied on inactivated FMDV, which is typically produced from live velogenic FMDV strain grown in BHK-21 cells, chemically inactivated (e.g., by aziridine or binary ethyleneimine), partially purified, and mixed with an oil or aluminum hydroxide/saponin adjuvant [35]. However, besides having inherent risk of introducing incompletely inactivated FMDV in naïve animals and causing outbreak, these inactivated vaccines suffer from the shortcomings of short shelf life, the need for adequate cold chain of formulated vaccines, and the difficulties of certain serotypes and subtypes to grow well in cell culture for vaccine production. Thus, alternative approaches are being taken to produce empty capsid vaccines, DNA vaccines, recombinant protein vaccines, and peptide vaccines, etc. [36].

8.2 METHODS

8.2.1 Sample Preparation

The tissue of choice for the laboratory diagnosis of FMD is epithelium or vesicular fluid. At least 1 g of epithelial tissue is collected from an unruptured or recently ruptured vesicle

Downloaded From Vet-eBooks.com

located in the tongue, buccal mucosa, or feet, and placed in a transport medium (consisting of equal amounts of glycerol, 0.04 M phosphate buffer, pH 7.2–7.6, 1000 IU penicillin, 100 IU neomycin sulfate, 50 IU polymyxin B sulfate, 100 IU mycostatin). Tissue culture medium or phosphate-buffered saline in the range pH of 7.2–7.6 may be used in place of 0.04 M phosphate buffer. The sample is kept refrigerated or on ice until arrival in the laboratory. If epithelial tissue is unavailable (in advanced or convalescent cases), oesophageal–pharyngeal (OP) fluid may be collected by a probang (sputum) cup or swabbing the swab [15].

Upon receipt, a suspension of the epithelium (ES) is prepared in 0.04 M phosphate buffer (10% concentration w/v). Total RNA may be extracted from ES, OP fluid, saliva, or culture supernatant by Trizol or QIAamp Viral RNA Mini Kit (Qiagen).

8.2.2 Detection Procedures

8.2.2.1 Conventional RT-PCR

Reid et al. [20] utilized an RT-PCR assay for FMD diagnosis with primers (F: 5′-GCCTG-GTCTT-TCCAG-GTCT-3′ and R: 5′-CCAGT-CCCCT-TCTCA-GATC-3′) from the 5′ UTR of FMDV genome.

8.2.2.1.1 Procedure

For RT, 2 μL of random hexamers (20 μg/mL) and 5 μL of nuclease-free water are added into a sterile 0.5 mL microcentrifuge tube. Added to the tube is a 5 μL of RNA purified by Trizol. After gentle mix by pipetting up and down, the tube is incubated at 70°C for 5 min and cooled at room temperature for 10 min. Each RT reaction mix is made up of 4 μL first strand buffer (5× conc.), 2 μL bovine serum albumin (acetylated, 1 mg/mL), 1 μL dNTPs (10 mM mixture each of dATP, dCTP, dGTP, and dTTP), 0.2 μL DTT (1 M), and 1 μL Moloney Murine Reverse Transcriptase (200 U/μL). A reaction mix of 8 μL is added to the 12 μL of random primer/RNA mix and then mixed by gently pipetting. The mix is incubated at 37°C for 45 min and kept on ice if the PCR amplification step is carried out shortly or stored at −20°C.

Each PCR mix is made up of 35 μL nuclease-free water, 5 μL PCR buffer (10× conc.), 1.5 μL $MgCl_2$ (50 mM), 1 μL dNTPs (10 mM each of dATP, dCTP, dGTP, and dTTP), 1 μL primer 1 (10 pmol/μL), 1 μL primer 2 (10 pmol/μL), and 0.5 μL *Taq* polymerase (5 units/μL). Then 45 μL of PCR mix and 5 μL of the RT product are added to a well of a PCR plate or to a 0.2 mL PCR tube. After spinning for 1 min, the PCR plate or tube is placed in a thermal cycler for PCR amplification with the following program: 1 cycle of 94°C for 5 min; 30 cycles of 94°C for 1 min, 55°C for 1 min, and 72°C for 2 min; and 1 cycle of 72°C for 7 min. After amplification, 20 μL aliquot of each PCR product is mixed with 4 μL of staining solution and loaded onto a 1.5% agarose gel. Upon electrophoresis, a positive result for FMDV is indicated by the presence of a 328 bp band.

8.2.2.2 Real-Time RT-PCR

Reid et al. [21] described primers (forward 5′-CACYT YAAGR TGACA YTGRT ACTGG TAC-3′ and reverse 5′-CAGAT YCCRA GTGWC ICITG TTA-3′) and TaqMan® probe (5′-CCTCG GGGTA CCTGA AGGGC ATCC-3′) from the 5′ UTR region for real-time PCR identification of FMDV.

8.2.2.2.1 Procedure

RT-PCR mix is prepared by using the Superscript III/Platinum *Taq* One-Step rRT-PCR Kit (Invitrogen). Each reaction (25 μL) is composed of 12.5 μL of 2× reaction mix, 0.5 μL of Superscript III/Platinum *Taq* Enzyme Mix (both supplied with the kit), 2 μL of each primer (20 pmol), 1.5 μL of probe (7.5 pmol), 1.5 μL of nuclease-free water (Promega), and 5 μL of purified nucleic acid. Amplification and detection are conducted in Mx4000 Multiplex Quantitative PCR System (Stratagene) with the following thermal cycling conditions: 60°C for 30 min and 95°C for 10 min, followed by 50 cycles of 95°C for 15 s and 60°C for 1 min. A sample with a value of CT32 is considered positive [31].

8.3 CONCLUSION

FMDV is the causative agent of a highly infectious disease in wild and domestic cloven-hoofed animals. Although clinical signs of FMD in adult animals are seemingly mild, and many infected animals often recover without treatment, the impacts of FMD lie in the loss of body weight and productivity in diseased or recovered livestock, trade restriction, and control cost. Therefore, it is crucial that FMD is correctly diagnosed and prevention measures are implemented. Toward this goal, various laboratory tests have been developed for the identification and typing of FMDV. Given the lengthy process and variability associated with virus isolation and serological assays, nucleic acid detection techniques (particularly RT-PCR) have been playing an increasingly prominent role in the routine detection and typing of FMDV.

9.1 INTRODUCTION

Encephalomyocarditis virus (EMCV) was isolated for the first time in 1945 in Miami, Florida, from a captive chimpanzee and a gibbon that died suddenly of pulmonary edema and myocarditis [1]. Mice inoculated with a filtered edema fluid from the gibbon or the chimpanzee displayed paralysis of the posterior members and myocarditis followed by death in a week. The pathogenic agent was at that time given the name of EMCV. The virus had probably been transmitted from wild rats living in proximity to the monkeys, as nearly 50% of the captured rats had antibodies against EMCV. In 1948, in the Mengo district of Uganda, Dick et al. [2] isolated Mengo virus from a captive rhesus monkey that had developed a posterior member paralysis. In 1949, cross-neutralization studies showed that Mengo virus, EMCV, Columbia-SK (discovered in 1939), and MM (discovered in 1943) were antigenically indistinguishable but differed from Theiler's murine encephalomyelitis virus (TMEV) [3]. Following the Panama epizooty of 1958, Murnane et al. [4] described the isolation of EMCV from swine for the first time. Since then, the virus has been isolated in many countries, in swine and in wild animals.

9.1.1 Classification

EMCV belongs to the *Cardiovirus* genus in the *Picornaviridae* family, which covers a total of 26 genera [5,6]. The *Cardiovirus* genus is divided into three species: EMCV, Theilovirus, and Boone cardiovirus [7–9]. EMCV is further separated into two serotypes named EMCV-1 and EMCV-2, the latter of which was recently discovered in a wood mouse (*Apodemus sylvaticus*) in Germany [10]. EMCV-1 serotype includes Colombian-SK virus, MM virus, EMCV, Mengo virus, and Maus-Elberfeld (ME) virus. Theilovirus is made up of 15 genotypically distinct viruses. Boone cardiovirus is a newly described species from laboratory rats [9].

9.1.2 Genomic Organization, Biology, and Epidemiology

9.1.2.1 Genomic Organization

EMCV is a nonenveloped virus with an icosahedral capsid of approximately 30 nm in diameter [11] and a genome consisting of a positive-sense single-stranded RNA. The EMCV RNA genome is approximately 7840 bases long and composed

Downloaded From Vet-eBooks.com

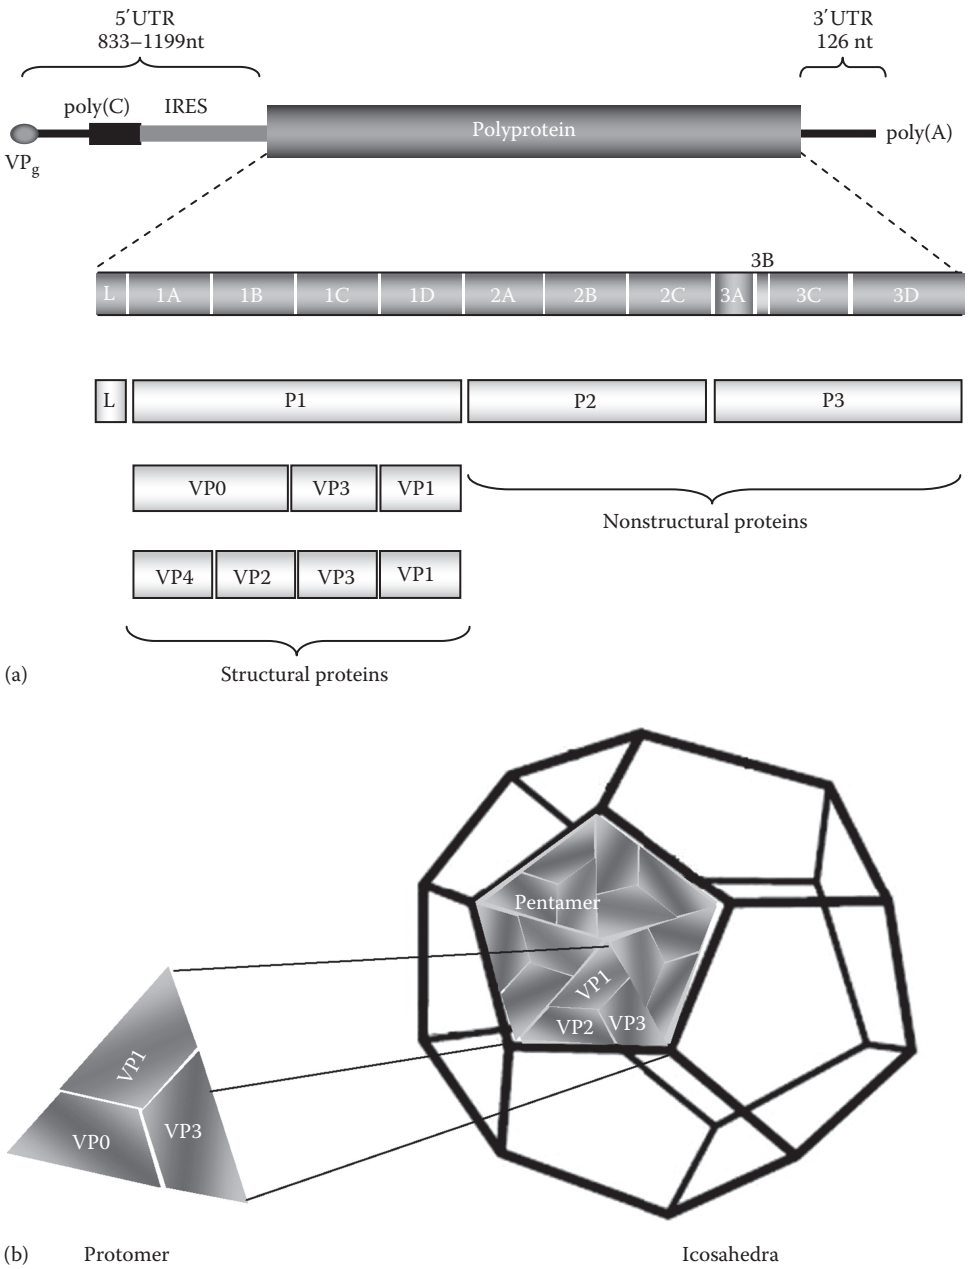

FIGURE 9.1 Structure and genomic organization of the encephalomyocarditis virus (EMCV). (a) Genome organization. The EMCV genome is a positive-sense single-stranded RNA shown with the viral protein (VP) VPg covalently linked to the 5′ end. The genomic RNA is composed of two untranslated regions with a poly(C) tract and internal ribosome entry site in the 5′ end, a poly(A) tail in the 3′ end and of a unique open reading frame that encodes for a single polyprotein. The polyprotein is processed to produce structural and nonstructural proteins. The P1 precursor is cleaved into capsid proteins (VP); P2 and P3 are cleaved to form the protease and the proteins that participate in viral RNA replication. (b) Diagram of the organization and assembly of EMCV capsid. The structural unit for the assembly of the capsid is the protomer made up of a single copy of VP1, VP3, and VP0 (precursor of VP2 and VP4). Protomers of 5 assemble into a pentamer, and then 12 pentamers form the icosahedra. During maturation, after genome encapsidation, VP0 is cleaved into VP2 and VP4. (VP4 is not visible in the schema because it is in the inner part of the capsid and interacts with the RNA).

of a unique coding region flanked by two untranslated regions (UTRs) of 833–1199 nucleotides (nt) and 126 nt in length at 5′ and 3′extremities (Figure 9.1a), respectively. The 5′ extremity is not capped but, rather, covalently linked to a viral protein (VP) of 20 amino acids (VPg) [8]. Starting approximately at 150 nt, there is a poly(C) tract, which can be of different length depending on the strain. Studies with Mengo virus in murine hosts suggest that the poly(C) length may play an important role in viral pathogenesis. However, LaRue et al. [12] reported that an EMCV strain containing a short poly(C) tract (7–10 nt) was pathogenic in mice, pigs, and cynomolgus macaques. Thus, the link between poly(C) length and pathogenesis is still controversial. Adjacent to this sequence, the RNA has a highly ordered structure made up of hairpin loops.

Downloaded From Vet-eBooks.com

This domain is part of an internal ribosome entry site (IRES) [13]. Picornaviral IRES fall into four classes. IRES elements vary in size and have different complex secondary structures and distinct requirements for cellular proteins that underscore their functions [14,15]. EMCV IRES is a type II IRES. It allows ribosome binding and thus the initiation of translation of the unique open reading frame that encodes a single polyprotein of 2292 amino acids. A polyA tail of heterogeneous length (20–70 nt) is present at the 3′ end.

9.1.2.2 Viral Proteins

EMCV proteins and precursors get their names from their positions in the polyprotein (Figure 9.1a): L (leader), P1 (precursor of the capsid proteins 1A, 1B, 1C, and 1D named viral protein [VP]4, VP2, VP3, and VP1, respectively, when they are part of the virion), P2 (precursor of the nonstructural proteins 2A, 2B, and 2C), and P3 (precursor of nonstructural proteins 3A, 3B, 3C, and 3D) [8].

The L protein is only found in *Cardiovirus* and *Aphthovirus*. It is composed of a zinc finger domain at the N-termini and an acidic domain in the C-termini and can be phosphorylated on residues Thr47 and Tyr41 [8,16]. Study of deletions introduced into the L protein has established that the Mengo virus L protein is not necessary for the multiplication of this virus in BHK21 cells. However, a decrease in replication and plaque size was noticed when viruses mutated in this protein were cultured on L929 cells [17]. Those results could be explained by the role of the L protein as a transcription inhibitor of the interferon (IFN)-α4 and IFN-β genes (IFN-α4 and IFN-β genes are activated early during antiviral response) [18] and by the fact that BHK21 cells, in contrast with L929 cells, do not produce IFN. Indeed, following phosphorylation by the casein kinase II, the L protein inhibits iron–ferritin-mediated activation of NFκB and thus inhibits the synthesis of IFN-α and IFN-β [18]. The L protein may also be implicated in decreasing cellular protein synthesis and may interfere with the nucleocytoplasmic traffic through the binding of Ran-GTPase (Ras-related nuclear GTPase) [16].

The viral capsid is composed of four structural proteins: *VP1*, *VP2*, *VP3*, and *VP4*. Cleavage of the P2–P3 precursor generates mainly nonstructural proteins but also the *VPg* protein (3B), which is associated with the 5′ termini of the viral genome. While nearly all processing of the polyprotein is mediated by the *3C* protease, cleavage between the 2A and 2B proteins is protease independent. In fact, during the translation process, the C-ter region of the 2A protein adopts an unstable conformation that induces the cleavage between the two proteins specifically at the N-P-G-P sequence [8]. Moreover, the *2A* protein is possibly involved in the decrease in cellular mRNA translation in infected cells and localize to the nucleoli [19]. The 2A was also shown to be required for viral pathogenesis and inhibition of apoptosis during EMCV infection [20]. Recently, Petty et al. [21] demonstrated binding interactions between L and 2A protein; thus both of these "viral security" proteins should not be considered independent of one another. The role of the *2B* protein, however, is not well established, but seems to be involved, along with the *2C*, in the formation of membranous vesicles during viral replication. On the other hand, it is well known that the 2B and 2C proteins and their precursor 2BC block the traffic of intracellular proteins from the endoplasmic reticulum to the Golgi and thus prevent the release of cellular proteins [8]. The EMCV "viroporin" 2B was shown to activate the NOD-like receptor family, pyrin domain containing 3 (NRLP3) inflammasome, a multiprotein complex containing the pattern recognition receptor NLRP3 that induces secretion of proinflammatory cytokines [22], and Hou et al. [23] demonstrated recently that the 2C protein along with the 3D protein are involved in EMCV-induced autophagy. Thus, these two nonstructural proteins are involved in host response to EMCV infection.

The 3AB precursor is associated to membranous vesicles by the *3A* protein. Its cleavage by the 3C protease liberates the 3B protein, which upon association with the RNA allows initiation of genome replication by the *3D* polymerase, which is the RNA-dependent RNA polymerase. EMCV replication is, however, regulated through the site-specific cleavage of the host poly(A)-binding protein by the 3C protease [24].

9.1.2.3 Three-Dimensional Structure and Assembly of the Capsid

Mengo virus has been crystallized and analyzed by x-ray diffraction [11,25]. Its viral capsid shows an organization similar to that of EMCV and other picornaviruses. The viral capsid is organized into an icosahedron with exactly 60 copies of each of the structural protein. The basic unit of the capsid is a protomer formed by the association of VP1, VP2, VP3, and VP4 (Figure 9.1b). The VP4 protein is located in the internal face of the capsid and interacts with the viral RNA. VP4 has a myristate domain in N-ter, necessary for protomers to assemble into pentamers.

The capsid is constituted of 12 pentamers; each one made up of 5 protomers. It is organized around symmetric axes of twofold, threefold, and fivefold symmetries. Five VP1 proteins are grouped around the fivefold symmetry axis, while VP2 and VP3 proteins alternate around the threefold symmetry axis.

9.1.2.4 Infectious Cycle

The viral cycle of EMCV is quite similar to that of the other picornaviruses (Figure 9.2). The first step is the attachment to a cellular receptor; VCAM1 (adhesion molecule of vascular cells) has been described as the EMCV receptor of murine endothelial cells. Mengo virus and EMCV are able to agglutinate human erythrocytes by virtue of their attachment to glycophorin A, the major sialoglycoprotein found at the erythrocyte surface. On nucleated human cells, the virus seems to attach via a sialoglycoprotein of 70 kDa, which is distinct from glycophorin A, but remains to be identified [8].

Interaction between the cellular receptor and viral capsid proteins induces conformational changes that affect contacts between pentamers and thus "prepare" the dissociation of the capsid. The exact mechanism of internalization

Downloaded From Vet-eBooks.com

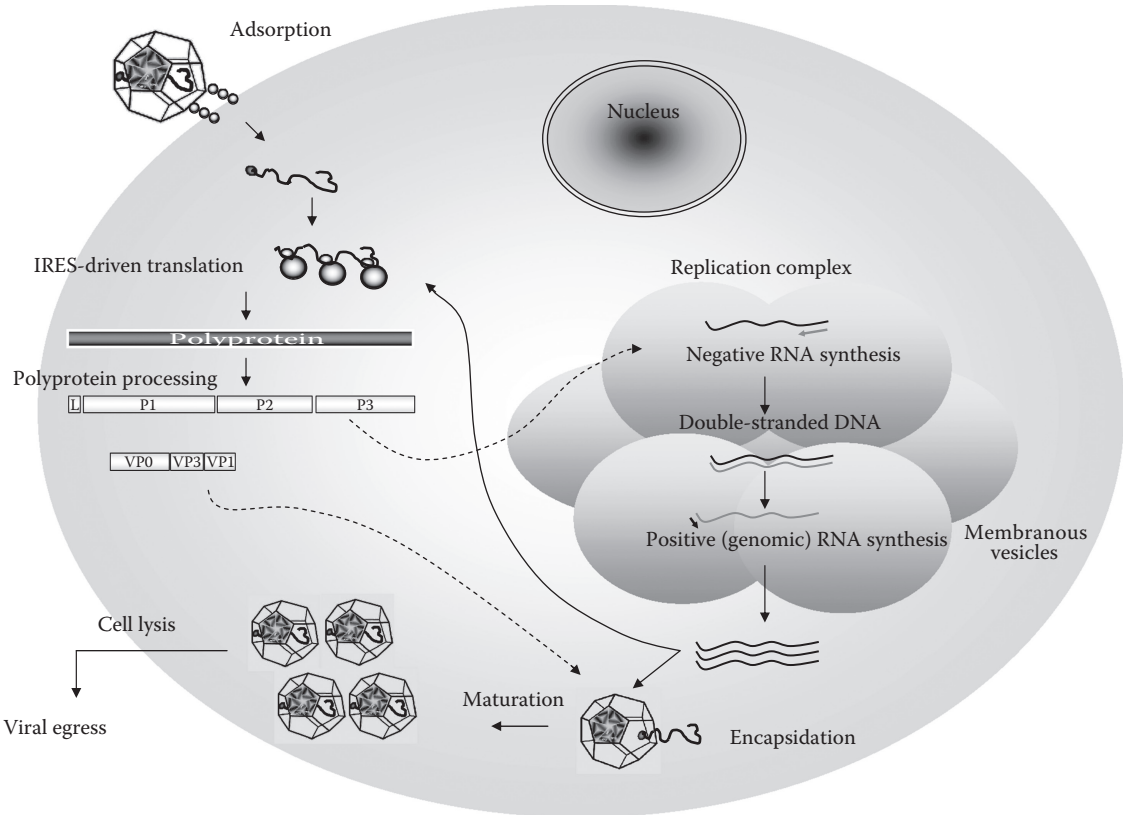

FIGURE 9.2 Encephalomyocarditis virus replication cycle. The virion binds to a cellular receptor. After uncoating, the genomic RNA is released by an unknown mechanism. Once in the cytoplasm, the viral protein (VP) VPg is detached to the 5′ end of the genome, the translation is initiated at the internal ribosome entry site, and the polyprotein is synthesized. The polyprotein is cleaved during and after the translation, leading to precursors or mature proteins. Some of those proteins go to the membranous vesicles where genome replication will occur. The positive genomic RNA is replicated into negative RNAs (linked to VPg in 5′ ends) that, in turn, serve as templates for the synthesis of positive RNAs. The new positive genomic RNAs will either serve for translation after removal of VPg or will be packaged into the procapsid. After RNA encapsidation, cleavage of the precursor VP0 into VP2 and VP4 allows maturation of the virion. Virions then egress by cell lysis.

and uncoating of the cardiovirus genome is poorly understood. Poliovirus and rhinovirus lose infectivity when cells are treated by chemical agents that increase the pH within endosomes, while *Cardiovirus* does not. This finding suggests that decapsidation of cardioviruses occurs at the cell membrane and may be due to the interaction between the virus and the cell receptor. Entry of the genomic RNA into the cytoplasm may depend on the myristoylated VP4 protein. Once the RNA is in the cytoplasm, the VPg protein is dissociated from the 5′ termini of the genome; the genome is then translated into VPs needed for the replication and the production of new viral particles [8].

The initiation of translation of EMCV is cap independent, thanks to its IRES that, with the help of some cellular factors (eukaryotic translation initiation factor [eIF]4G, eIF3, eIF4A), allows ribosome binding. EMCV uses different mechanisms to disrupt eIF4F complex formation, so to inhibit cap-dependent translation. For instance, during EMCV infection, the 4E-BP1 is dephosphorylated and sequesters eIF4E into an inactive eIF4E–4E-BP1 complex, thus inhibiting the eIF4E–eIF4G interaction [26,27] required for the initiation of translation of cellular mRNA.

Polyprotein cleavage is carried out by the 3C protease of EMCV. However, the first cleavage occurs during elongation, prior to the synthesis of the 3C protease, between the 2A and 2B proteins. This could be due to a ribosome jump to the NPGP sequence, located between 2A and 2B, so as to prevent glycine and proline binding [28]. Once the 3C protease is translated, it is immediately active and starts to cleave the polyprotein in *cis*. When detached from the polyprotein, 3C cleaves newly synthesized polyproteins in *trans*. In this manner, maturation occurs and VPs are produced. It is believed that viral genome replication is initiated once VP concentration reaches a certain threshold.

Synthesis of a negative-strand RNA from the positive-strand genomic RNA is the first step in the genome replication of the virus. This negative-strand RNA will serve as a template to synthesize the genomic RNA. Replication takes place in the cytoplasm, within replication complexes that are essentially made up of RNA-dependent RNA polymerase

Downloaded From Vet-eBooks.com

(3Dpol) linked to the 3C protease. Proteins 2B, 2C, and 3A induce the accumulation of membrane vesicles where, at the external part, units of replication associate. The 3AB precursor allows the anchorage of VPg and thus the initiation of synthesis. Regulatory mechanisms of EMCV RNA synthesis are not well known.

Encapsidation starts when the quantity of VPs reaches a certain threshold. Capsid precursor P1 is cleaved into VP0, VP1, and VP3 that spontaneously assemble into protomers and pentamers (see Section 9.1.2.3). Pentamers assemble with positive RNA to form virions. These virions become infectious when VP0 is cleaved into VP4 and VP2. Cells are lysed and thus virions are released. The length of the infectious cycle varies from 5 to 10 h, depending on several factors, such as viral strain, temperature, pH, host cell, and multiplicity of infection.

9.1.2.5 Epidemiology

9.1.2.5.1 Host Range, Distribution, and Transmission

EMCV can infect a wide range of animals, domestic as well as wild, including swine, boars, rodents, cattle, elephants, raccoons, marsupials, and tigers [29] and nonhuman primates such as bonobos [30], macaque [31], and orangutan [32]. EMCV within farms, zoological collection, and primate center cares is frequently fatal for a variety of animal species [33].

Of all domestic animals, pigs are the most sensitive to EMCV [34]; and swine infections have been responsible for severe economic losses on pig farms due to high mortality in piglets (myocarditis) and in sows (reproductive failure). Porcine EMCVs have been reported in many areas with swine industries including Europe and Asia [35]. In Europe, from 1986 to 1995, swine epizooties had been reported in Greece, Italy, and Belgium [36]. Serological investigations of swine herds and wild boars have been performed in France, Austria, the Netherlands, and Belgium and shown a seroprevalence ranged from 3% to 10% [36,37]. Interestingly, clinical EMCV outbreaks have never been reported in Sweden, although EMCV was detected by reverse transcription–polymerase chain reaction (RT-PCR) in 9% of rodents not in contact with farm animals as published recently by Backhans et al. [38].

Regarding Asia, epidemiological investigations were mostly conducted in China. Since its first detection in 2005 until 2012, six strains have been isolated from pigs of the Chinese mainland [39], and a porcine strain was recently isolated from northern China, showing a high pathogenicity in mice [40]. Serological survey conducted intensively in pig farms in China has shown a seroprevalence of neutralizing antibodies of 52%, with one farm in Beijing with 100% of tested animals giving positive results. Sows had the highest prevalence and could thus play an important role in the epidemiology of EMCV [41]. Serological investigations have also been conducted in Korean swine farms with a seroprevalence rate of 43.5% in pig herds compared to 9.1% in the total pig population [42].

Currently, two routes of infection are suggested for the introduction and spread of EMCV among domestic pigs (1) after reactivation of persistent EMCV infections or (2) by ingestion of feces or carcasses of infected rodents [43]. Rodents are indeed suspected to be the natural reservoir for the virus as they replicate and excrete virus until 29 days postinfection without any symptoms [44]. The presence of many infected rodents in contact with swine herds during EMCV epizooties suggests that they may play a key role in virus transmission [45,46]. Natural infections may be due to ingestion of contaminated food. In fact, horizontal transmission between swine during the short period of viremia seems limited, but should it occur might trigger the emergence of a major epizooty, depending on the viral strain and swine sensibility [47]. Wild boar may also play a critical role in EMCV epidemiology in domestic pigs [43].

9.1.2.5.2 Zoonotic Potential

Even if EMCV has often been described as a zoonotic agent, positive association with a human disease has not been established. Nevertheless, between 1940 and1950, childhood infections have been described in Germany and the Netherlands, associated with clinical signs like fever and encephalitis but no myocarditis. Different EMCV strains have been isolated after inoculation into rodents [48]. However, the appurtenance of these strains to the EMCV group had only been proved by serological tests without any virologic confirmation, and unfortunately those strains are no longer available for further characterization. Earlier, EMCV neutralizing antibodies had been discovered in seventeen soldiers that presented febrile symptoms for 3 days in Manila, and in three of four patients for whom several samples were available, a rise in antibody titers was demonstrated [49]. In 1948, following isolation of Mengo virus from a rhesus monkey, a researcher who was studying the virus and taking care of the infected animal developed a meningoencephalitis, from which he recovered. Later on, the virus was isolated from his blood [2]. In all of these cases, however, virus was isolated, but only from specimens obtained from nonsterile sites, thus precluding unequivocal attribution of the patient's symptoms to EMCV infection.

Since 1950 to 2009, no EMCV infections associated with clinical signs have been recorded. However, some serological studies made on healthy human populations revealed a prevalence of 2.3%–15%. In Austria, studies of prevalence in persons that work with animals revealed that 5% of employees were seropositive, as well as 15% of hunters [8]. More recently, a serological survey in Mexico among swine-specialist veterinarians revealed a prevalence of 27% (hemagglutination inhibition test) to 47% (viral neutralizing test) [50].

Brewer et al. [51] showed in 2001 that primary myocardial human cells are permissive to an EMCV strain isolated from aborted swine fetus. Hammoumi et al. [52] also reported that these cells as well as human spleen primary epithelial cells and human primary astrocytes are permissive to EMCV strains isolated from pig or rat.

In 2009, Oberste et al. [53] reported cases of human febrile illness in Peru, which were probably due to EMCV infection: in two febrile patients with nausea, headache, and dyspnea, EMCV was isolated from acute-phase sample, and subsequent molecular diagnostic was done. No other pathogens

Downloaded From Vet-eBooks.com

were detected from those patients using immunoglobulin M ELISA for flaviviruses, alphaviruses, bunyaviruses, arenaviruses, and rickettsia. Isolation of virus from an acute-phase serum sample strongly supports the role of EMCV in human infection and febrile illness. Same authors have reported that roughly one in five residents of Iquitos (Peru) had evidence for prior exposure to EMCV [54]. In addition, EMCV may be also a potential pathogen for human recipients in pig-to-human xenotransplantation [51,55].

9.1.2.5.3 Vaccine Strategies

Many attempts have been made to develop EMCV vaccines. In the past, adjuvanted vaccine was shown to be efficient in inducing high antibody titers in domestic and wild species. Moreover, a binary ethyleneimine-inactivated EMCV was licensed for use [56]. Recently, Chen et al. [57] have developed recombinant human adenovirus–based EMCV vaccines that can protect mice against a lethal challenge. This promising vaccine remains to be evaluated in swine. An alternative vaccine approach based on viruslike particles combined with an alum adjuvant was also proposed as a safe immunization strategy during sow gestation in order to prevent EMCV-induced reproductive failure in pig farms [58].

9.1.3 Clinical Features and Pathogenesis

Physiopathology of EMCV infection has been mainly studied in swine and rodents.

9.1.3.1 Swine

After an oral contamination, the initial target cells are monocytes, which may carry the infection from the tonsils to target organs. A few days postinfection, the virus can be isolated from the heart, brain, tonsils, salivary glands, spleen, liver, pancreas, lungs, kidney, and small intestine [59]. When piglets are infected "per os" the virus replicates in the intestine and can be detected as early as 24 h postinfection and for 3–5 days in the blood and feces. The high level of viruses in the spleen, lymph nodes, and mesenteric nodes indicates that viruses multiply in lymphoid tissues. On the other hand, it has been demonstrated that in infected piglets that survived EMCV infection, the virus can persist and be reactivated when animals are treated with dexamethasone [60]. Reactivated viruses became pathogenic for the animals, were excreted in feces, and were able to infect control negative piglets when housed together with treated piglets.

Usually, in pig and piglet, EMCV induces acute focal myocarditis with sudden death. Myocarditis is characterized by cardiac inflammation and cardiomyocyte necrosis. Other symptoms have been observed, such as anorexia, apathy, paralysis, or dyspnea [34,61]. Experimentally infected piglets showed high fever, followed by death within 2–11 days, or sometimes recovered with chronic myocarditis. Mortality in piglets before weaning can rise to 100% and decreases with aging [62]. Reproduction disorders including abortion, fetal death, or mummification have been described in infected females [63]. In dying piglets, during the acute-phase, cardiac disorders, including epicardial hemorrhages, are observed. Upon autopsy of experimentally infected piglets, hydropericardium, hydrothorax, lung edema, ascites, and lesions at the myocardium have often been described. The heart is often dilated and shows some focal areas of necrosis (with uneven grayish-white discoloration). In most cases, the virus is detected in the myocardium, even if myocardial lesions are small or absent. In piglets, histological analysis reveals myocarditis associated with scattered or localized accumulation of mononuclear cells, vascular congestion, edema, and myocardial fiber degeneration, with necrosis. In the brain, congestions are accompanied by meningitis, perivascular infiltration of mononuclear cells, and neuronal degeneration [64,65].

9.1.3.2 Rodent

In the rodent, EMCV infection can be asymptomatic [44], but mice can develop myocarditis, encephalitis, [66,67] member paralysis [12,68], or diabetes [69]. EMCV can also lead to reproduction disorders in pregnant mice [70] and testicular lesions in mice and hamster [71]. Genetic factors seem to influence the sensitivity of mice to EMCV infection [72]. It has been shown that males are more sensitive than females [73]. This difference might be due to the interferon immune response that happens earlier in females than in males after peritoneal injection [74].

9.1.4 Diagnosis

Until 1997, the diagnosis of EMCV infection was reliant on conventional methods like virus isolation from tissues and virus characterization by neutralization assay. This characterization is laborious and time consuming, and so research has been directed toward the detection of viral RNA by RT-PCR.

9.1.4.1 Conventional Techniques

The diagnosis of EMCV infection has traditionally been dependent on virus isolation and identification. Despite being technically straightforward, the virus is sometimes difficult to isolate, especially from pigs in the stage following development of circulating antibody. Furthermore, the virus could no longer be isolated from the blood or feces after 3 days of infection, when viremia disappears [75]. Thus, even if the virus persists for a long period in the heart or other organs, it is difficult to isolate owing to circulating antibodies [60]. Samples should be collected during the acute phase of infection and could be taken from tissue, such as the heart, as it is the main target organ in piglets, but also from the liver, kidney, or total blood.

Viral isolation is routinely performed on baby hamster kidney (BHK21) cell line or in mice. Briefly, homogenates of samples are inoculated into BHK21 cell monolayers. Then monolayers are examined daily for CPE for 72 h. Monolayers negative for CPE are passaged two more times to confirm negative virus isolation results. The viral isolation can also be performed by intracranial inoculation of mice with filtered crushed tissue or blood. Mice are examined daily for development of paralysis and then osculated for lesions in the brain and myocardium. Then, virus identification is performed by immunofluorescence on infected cell monolayers or by a viral neutralizing test.

Downloaded From Vet-eBooks.com

Serological diagnosis relies on a hemagglutination inhibition or a seroneutralization test. Antibody titer superior to 1/16 is taken to mean that the animal has been previously exposed to the virus [76]. The seroneutralization test has a good specificity for antibodies directed against EMCV, because no cross-reactivity has been found with 62 human enterovirus serotypes, 11 porcine enterovirus serotypes, and at least 27 other viruses.

9.1.4.2 Molecular Techniques

As is described previously, the EMCV genome is a single-stranded RNA. Thus to detect the virus using molecular techniques, RT must be proceeded before PCR. RT-PCR methods allow the detection of viral RNA by primer-directed enzymatic amplification of specific target RNA sequences and avoid the time-consuming step of virus isolation. One-step RT-PCR methods have been further developed to minimize the risk of cross contamination encountered with two-step RT-PCR procedures. In addition, PCR products can be sequenced, allowing not only unambiguous identification of EMCV, but also epidemiologic analyses. Furthermore, PCR products can be detected directly by real-time RT-PCR by addition of specific probe, or by using SYBR Green mix, or even by one-step RT loop-mediated isothermal amplification (LAMP) method. Since 1997, several molecular methods have been described for rapid diagnosis of EMCV infections in pigs [77].

9.2 METHODS

9.2.1 Sample Preparation and Viral RNA Extraction

In order to recover much viral RNA as possible, it is important to collect samples from suitable organs (i.e., where there might be virus at the highest concentration) and to apply an optimal RNA extraction method.

9.2.1.1 Clinical Sample Preparation

From live animals, blood, serum, or fecal samples should be used. Fecal extracts (10% w/v) are made in phosphate-buffered saline (pH 7.6) and clarified by centrifugation for 10 min at 4000 × *g* to eliminate larger fecal debris. From death or euthanized animals, samples from the heart, spleen, liver, lungs, brain, tonsils, salivary glands, pancreas, kidney, and small intestine can be collected [59]. Supernatants of homogenized tissue suspensions (10% w/v) are used for virus detection. However, the most suitable organ to detect EMCV is the heart.

9.2.1.2 RNA Extraction

Three different RNA extraction methods can be used [78]:

1. *Guanidinium thiocyanate method*: Total RNAs are recovered from sample by an extraction method using commercially available mixtures of acid guanidinium thiocyanate and phenol–chloroform (TRIzol® LS Reagent, GIBCO-BRL, Life Technologies), according to the manufacturer's recommendations.
2. *Magnetic beads separation method*: This method relies on virus capture from sample on magnetic beads via monoclonal antibody specific for EMCV (immunomagnetic capture) and genomic RNA extraction from the captured particles by heating. The antibody used should be an anti-EMCV directed against epitopes present in a wide range of EMCV isolates. This method should be used to perform diagnosis from fecal samples, because it allows removal of PCR inhibitors found in feces.
3. *Guanidinium isothiocyanate (GITC)–silica methods*: RNA is extracted from samples using RNeasy Mini Kit (Qiagen) or QIAamp Viral RNA Mini Kit for purification of viral RNA (Qiagen Ref. 52906) according to the manufacturer's recommendations. Viral RNA is bound to the silica membrane, and contaminants are removed in two wash steps. Pure viral RNA is eluted in small volume of a low-salt buffer or RNAse-free water.

9.2.2 Detection Procedures

The detection of EMCV viral nucleic acid from clinical samples was initially described by Vanderhallen and Koenen [77,79] who developed a two-step conventional RT-PCR using primers located in the 3D polymerase coding region. Oberste et al. [53] reported a similar two-step method for specific detection of EMCV in acute-phase serum of patients with febrile syndrome, after isolation of the virus on Vero-6 cell cultures. They used primer sets targeting the 5′ UTR, the VP1, or the 3D coding region. Pérez and Díaz de Arce [80] proposed further an optimized protocol and using primers designed to amplify a 165 bp fragment from the 3D coding region with an analytical sensitivity of 2 (EMCV) 50% tissue culture infective dose ($TCID_{50}$) per 50 µL.

With the objective to increase rapidity, sensitivity, specificity, and simplicity and to remove RT-PCR inhibitors, procedures had evolved toward one-step conventional RT-PCR and recently real-time methods, described in the following sections.

9.2.2.1 One-Step Conventional RT-PCR

Kassimi et al. [78] adapted the two-step RT-PCR method developed by Vanderhallen and Koenen [77] using the same primers (P1 and P2) in a one-step RT-PCR assay. They described application of this method on EMCV-infected cells and on clinical samples according to the method used for RNA extraction.

9.2.2.1.1 Procedure

1. Prepare the one-step RT-PCR mixture (50 µL) using the one-step RT-PCR Kit (Qiagen). To amplify genome from virus captured on magnetic beads, prepare a first mix (30 µL) containing 400 µM each of deoxynucleotide triphosphates (dNTPs), 600 nM of each primer, and 10 U of RnaseOut. Add the mix

Downloaded From Vet-eBooks.com

directly to the coated beads, heat at 100°C for 5 min, and chill on ice. Prepare a second mix (20 µL) containing 1× Qiagen one-step RT-PCR buffer and 2 µL of 1× Qiagen one-step RT-PCR enzyme mix. Add the second mix to the first mix just before the RT-PCR.
To amplify RNA extracted by GITC–silica, prepare a first mix (8.5 µL) containing 10 U of RnaseOut, 0.4 mM each of dNTPs, and 600 nM of each primer. Add the mix to the 30 µL RNA eluted from the column, heat at 65°C for 5 min, and chill on ice. Prepare a second mix (10 µL) containing the one-step RT-PCR buffer (1×) and Qiagen one-step RT-PCR enzyme mix. Add the second mix to the first mix just before the RT-PCR.

2. Reverse-transcribe at 50°C for 30 min; conduct PCR amplification for one cycle at 95°C for 15 min and 35 cycles at 94°C for 30 s, 60°C for 30 s, and 72°C for 1 min and a final extension of 72°C for 10 min.
3. Analyze the PCR product by agarose gel electrophoresis, or use the product directly for sequencing.

Note: Further comparative studies [78] allowed to determine that for samples that do not inhibit the RT-PCR, the RNA extraction using GITC–silica combined with the one-step RT-PCR is the best choice. Immunocapture combined with the one-step RT-PCR is more suitable for samples containing substances that may inhibit RT-PCR.

9.2.2.2 Real-Time RT-PCR

9.2.2.2.1 TaqMan Real-Time RT-PCR

Yuan et al. [81] developed a TaqMan-based real-time RT-PCR assay targeting the EMCV 3D coding region and applied it to clinical samples (sera and tonsils [n = 100]). Primers (EMC-F and R) and probe (EMCV-P) were designed using the Primer Express Software (version 3.0; Applied Biosystem, United States). The probe was labeled with 5-carboxyfluorescein (FAM) at the 5′-end and *N,N,N′,N′*-tetramethyyl-6-carboxyrhodamine (TAMRA) at the 3′-end (EMCV-F: 5′-TCATTCGCCATTTCAACCCA-3′, EMCV-R: 5′-GAGATACAAACCCGCCCTAA-3′, EMCV-P: 5′-FAM-TCCCATCAGGTTGTGCAGGC GA-TAMRA-3′). The standard curve established with a recombinant plasmid containing the 3D target gene sequence had a wide dynamic range of 10^1–10^6 copies/µL with a linear correlation R^2 of 0.996 and a slope of −3.128 between the Ct value and the logarithm of the plasmid copy number. The detection limit of the TaqMan RT-PCR assay is 1.4×10^2 copies/µL. No cross-reaction was observed with other porcine viruses.

9.2.2.2.1.1 Procedure

1. Extract RNA from 150 µL of supernatant from virus-infected BHK-21 cells or tissue samples using the RNA extraction kit (Qiagen, United States) following the manufacturer's instruction.
2. Prepare real-time RT-PCR mixture (25 µL final) with 1 µL of extracted RNA, 12.5 µL of FastTaqMan mixture (with ROX) (Cwbiotech, Beijing, China), 0.5 µL of Avian myeloblastosis virus (AMV) reverse transcriptase (Transgen, Beijing, China), 400 nM of each primer, and 200 nM of probe.
3. Carry out amplification and detection under the following conditions: RT step at 50°C for 20 min, PCR activation at 95°C for 3 min, and 40 cycles of amplification (5 s at 95°C and 40 s at 60°C). To analyze results, use the system software linked to the real-time thermocycler (Bio-Rad iQ5 was used to developed this real-time RT-PCR).

9.2.2.2.2 Real-Time RT-PCR

Carocci et al. [20] developed a real-time RT-PCR assay based on the use of two primers (TMF1 and TMR1) to amplify 90 bp located in the 3D region of the EMCV genome, by using a SYBR Green master mix (TMF1: 5′-GGGATCAGCTTTTACGGCTTT-3′, TMR1: 5′-TGCATCCGATAGAGAACTTAATGTCT-3′). The standard curve established with a recombinant plasmid containing EMCV genome had a linear correlation R^2 of 0.99 and a slope of −3.544 between the Ct value and the logarithm of the plasmid copy number. The detection limit of this real-time RT-PCR assay is 25 copies/5 µL. This method has been applied on infected cell culture and clinical samples.

9.2.2.2.2.1 Procedure

1. Extract RNA using RNeasy Mini Kit (Qiagen) as described by the manufacturer.
2. Prepare RT-PCR mixture with 2.8 µL of RNAse-free water, 10 µL of SYBR Green Quantitect RT-PCR master mix (QIAGEN Ref. 204243), 1 µL of each primer (TMF1 and TMR1 at 10 µM) at 0.5 µM final, 0.2 µL of RT enzyme (included in SYBR Green Quantitect RT-PCR master mix [QIAGEN Ref.204243]), and 5 µL of RNA.
3. Carry out amplification and detection under the following conditions: RT step at 50°C for 20 min, PCR activation at 95°C for 15 min, and 45 cycles of amplification (15 s at 94°C, 20 s at 55°C, and 10 s at 72°C) on LightCycler 480 (Roche).
4. Visualize target amplification by generating melting curve by incubating for 10 s at 95°C and for 1 min at 55°C and by raising the incubation temperature from 55°C to 95°C. Finally, let it cool down for 30 s at 40°C.

Alternative TaqMan protocol: Carocci et al. [20] designed a TaqMan probe annealing specifically between the TMF1 and TMR1 primers to an internal region of the PCR product (probe TM-FR1: 5′-FAM-CGATGCCAACGAGGACGCCC-MGB-3′). This method has been applied on RNA from infected cell culture or infected organ samples and remains to be validated.

Downloaded From Vet-eBooks.com

9.2.2.2.2.2 Procedure

1. Extract RNA using the QIAamp Viral RNA Mini Kit (Qiagen) as described by the manufacturer.
2. Prepare RT-PCR mixture with 4.1 µL of RNAse-free water, 12.5 µL of AgPath buffer (Life Technologies, AGPATH-ID One-Step RT-PCR ref. 4387391), 1 µL of each primer (TMF1 and TMR1 at 10 µM) at 0.4 µM final, 1 µL of TM-FR1 probe (10 µM) at 0.16 µM final, 1 µL of enzyme (included in AGPATH-ID One-Step RT-PCR), and 5 µL of RNA.
3. Carry out amplification and detection under the following conditions: RT step at 45°C for 10 min, PCR activation at 95°C for 10 min, and 45 cycles of amplification (15 s at 95°C, 1 min at 60°C) on real-time thermocycler. Sigmoid amplification curves with Ct values under 40 are considered as positives results as "detection of EMCV genome."

Note: Even though RT-PCR allows rapid diagnosis of EMCV in samples that often need two passages on cell cultures to be isolated, attesting to the good sensitivity of the assay, a negative RT-PCR test should be verified by virus isolation and virus neutralization test.

9.2.2.2.3 One-Step RT-LAMP

Yuan et al. [82] developed a RT-LAMP assay to detect EMCV RNA. This technique relies on the use of 4 specific primers targeting the EMCV 3D coding region (forward outer [F3] 5′-GGCAGATCTTGGAGGAAGC-3′, backward outer [B3] 5′-AAGACTTGACGGGCAACG-3′, forward inner [F1c-F2] 5′-GCCCGAATCATCTCCTGTGACA-CCTTGGCATCCATTCTGCTG-3′, backward inner [B1c-B2]5′-AATGCCTTTGAGCCACAGGGTG-GGCGTAGTGCTGTT TTACGT-3′). The detection limit of RT-LAMP is 2.2×10^{-5} ng of cell culture–extracted RNA per µL. No cross-reactivity with classical swine fever virus (CSFV), bovine viral diarrhea virus (BVDV), porcine circovirus type 2, porcine epidemic diarrhea virus, and porcine reproductive and respiratory syndrome virus (PRRSV) was observed.

9.2.2.2.3.1 Procedure

1. Extract RNA from samples by using QIAamp viral RNA kit (Qiagen, Valencia, CA) according to the manufacturer's instructions.
2. Prepare one-step RT-LAMP mixture (25 µL final) with 0.5 µL of RNAsin inhibitor, 2.5 µL of 10× *Bst* DNA buffer, 2.5 µL of $MgCl_2$ (25 mM), 3 µL of dNTPs (2.5 mM), 0.5 µL of F3 primer (10 µM), 0.5 µL of B3 primer (10 µM), 2.5 µL of F1c-F2 primer (10 µM), 2.5 µL of B1c-B2 primer (10 µM), 1 µL of RNA template, 1 µL of AMV reverse transcriptase (200 U/µL), 1.5 µL of *Bst* DNA polymerase (8 U/µL), and 7 µL of diethylpyrocarbonate (DEPC) treated water.
3. Incubate for 50 min at 62°C.
4. Detection of amplification product can be done on 2% agarose gel electrophoresis: migration results are ladderlike bands. Alternatively, products can also be visualized readily in-tube under UV light with the addition of SYBR Green I.

Note: Due to high amplification of loop-DNA targets, potential risk cross contamination should be taken into account.

9.3 CONCLUSION

Since its first isolation in 1958 from fatal case of swine, EMCV has been recognized worldwide as the causal agent for myocarditis in young pigs or reproductive failure in sows, with severe economic consequence for swine industry. Although EMCV is often described as a zoonotic agent, no association with human disease has been clearly established. Nevertheless, given the recent progress in xenografts, especially pig-to-human xenotransplantation, the safety concerns about porcine EMCV need to be explored.

Traditionally, the diagnosis of EMCV infection has relied largely on virus isolation and virus neutralization assay. The availability of molecular methods provides the opportunity to further improve EMCV diagnosis in terms of manipulation and time required. In particular, the application of one-step conventional RT-PCR and real-time RT-PCR protocols has enhanced the accuracy and speed of EMCV identification. Additionally, the development of one-step RT-LAMP offers a rapid, accurate, and inexpensive means to detect EMCV under field conditions. Overall, the increased use of molecular tools makes it possible to better characterize and compare emerging pathogenic viral strains for clinical diagnosis as well as field surveillance.

10.1 INTRODUCTION

Porcine teschoviruses (PTVs, genus *Teschovirus*, family *Picornaviridae*) are nonenveloped RNA viruses that infect swine populations. Complete genome sequence studies defined at least 13 distinct PTV serotypes (from PTV-1 to PTV-13),[1–3] although all of them belong to a single virus species, known as "porcine teschovirus."

Teschoviruses are transmitted by the fecal–oral route, and different studies indicate that PTVs are abundant and ubiquitous in healthy pig populations.[4–9] In fact, PTVs are generally nonpathogenic, and infected swine most often remain asymptomatic.[10] However, some virulent variants can cause a variety of clinical conditions, the most severe of which is a nonsuppurative viral encephalomyelitis known as "Teschen–Talfan disease."

Currently, PTV is considered an emerging virus threat for swine production in China and other Far Eastern countries.[11–15] Although most Teschen–Talfan disease outbreaks are caused by strains of PTV-1, no clear link has been found between pathogenicity and serotype so far.[11,13] Therefore, it is important to determine the serotype–genotype responsible for each outbreak so that pathogenic variants, recombinants, and newly emerging recombinant genotypes are clearly recognized and properly controlled. The laboratory methods are currently available for detecting and typing the known PTVs rapidly. However, new and sensitive techniques must be continuously updated in view of teschovirus' ability to evolve constantly.

10.1.1 Classification

PTV, the causal agent of Teschen–Talfan disease, is classified in the genus *Teschovirus* and family *Picornaviridae*.[16] Previously grouped within the genus *Enterovirus*, PTV is reclassified as belonging to the genus *Teschovirus* on the basis of (1) cytopathic effect (CPE), (2) physicochemical properties and replication in porcine cells, and (3) serological and molecular characteristics.[17–19]

Teschen is the name of the town in the Czech Republic where the disease was first documented in 1929.[20] In the 1930s–1950s, this swine disease was recognized as a particularly virulent, highly fatal, nonsuppurative form of encephalomyelitis that spread quickly throughout Europe and caused huge losses to the pig breeding industry.[21] Initially, it had numerous descriptive names as "Klobauk disease," "benign enzootic paresis," and "contagious porcine paralysis." Due to a gradual change in virulence, these viruses were associated with milder forms of the disease, first, in the United Kingdom, where it was called Talfan disease, and in Denmark, where it was called poliomyelitis suum.[10] At present, it is known as enterovirus encephalomyelitis or Teschen–Talfan disease. The last outbreaks of serotype 1 and other serotypes have been declared in Belarus, Canada, China, the United States, Haiti, Japan, Latvia, Madagascar, Moldova, Romania, Russia, Taiwan, Uganda, and Ukraine.[8,10–13,22–26] Enterovirus encephalomyelitis has not been reported in Western Europe since 1980 (Austria) and it is now considered rare. The disease did not meet the listing criteria notifiable and has been removed from the World Organisation for Animal Health (OIE) list in 2005.

Downloaded From Vet-eBooks.com

There are at least 13 distinct serotypes described: PTV-1 to PTV-13.[1–3] The last described genotype PTV-13 has been found in asymptomatic wild boar by pyrosequencing using 454 GS FLX technology.[3] The PTV-13 sequence shows great variability, especially in the VP1 protein and P1 polyprotein (66%–74% and 74%–76% amino acid identity, respectively), as compared to other PTV sequences available. PTV speciation process seems to be still in progress and new serotypes are being identified.[27] The genetic distance of PTV serotypes within each group is quite similar, suggesting that the evolution of teschoviruses proceeded in two steps. Subsequently, three subgroups evolved, which then split into 12 or more serotypes. The first monophyletic clade includes genotypes PTV-1, PTV-3, PTV-10, and PTV-11. Phylogenetic relationships among some of the different PTV serotypes, particularly PTV-5, PTV-7, and PTV-9, could not be resolved, while monophyly of PTV serotypes 2, 4, 6, 8, and 12 could be established[1,2] (Figure 10.1). The estimated mean rate of teschovirus VP1 evolution under an uncorrelated relaxed-clock model ranged from 2.03×10^3 to 2.95×10^3 nucleotide substitutions per site per year (ns/s/y) with a mean rate of 2.46×10^3. The common ancestor (tMRCA) for the genus *Teschovirus* can be placed around 500 years (385–659 years); the clade including serotypes 1, 3, 10, and 11 may have originated around 200 years (180–273 years), while the second clade (serotypes 2, 4, 6, 8, and 12) seems to have originated earlier, around 400 years (335–526 years).[2]

10.1.2 Morphology, Biology, and Epidemiology

Virions are small nonenveloped particles of 25–30 nm in diameter, with a capsid of icosahedral symmetry that is made up of 60 units (protomers), each consisting of three surface coat proteins and a fourth internal capsid protein (Figure 10.2). The genetic diversity of these protomers seems to be responsible for the idiosyncrasies such as antigenicity, receptor recognition, buoyant density, and pH stability.

The genome of about 7.0–7.2 kb in length contains one long open reading frame encoding a single polyprotein flanked by 5′- and 3′-nontranslated region (NTR), followed by a poly(A) tail. Viral translation starts at the initiator codons, more likely at nt 432 (AUG). The polyprotein ranges from 2203 to 2207 amino acids.[1] The initiation of translation in picornavirus genome is considered to be strongly related to tertiary structure of the internal ribosome entry site contained in 5′ NTR.[18] The first excision produces polypeptides P1, P2, and P3, which will be subsequently processed into 12 products: leader protease (L) of 13.6 kDa, coat protein VP4 (internal capsid protein-1A) of 7.4 kDa, three surface coat protein (VP2-1B of 31.1 kDa, VP3-1C of 26.8 kDa, and VP1-1D of 28.9 kDa), four nonstructural proteins (2A of 2.1 kDa, 2B of 16.4 kDa, 2C of 36.8 kDa, and 3A of 10.8 kDa), a genome-linked protein (VPg-3B) of 2.8 kDa, and a protease (3C) of 22.7 kDa and polymerase (3D) of 51.2 kDa.

The highly conserved L protein has a protease active site like that of foot-and-mouth disease virus. Likewise, 2A protein possesses protease activity and diverges in its structure and function compared with other nonstructural proteins. VP4 is located on the internal side of the capsid associated with the RNA core, whereas VP1, VP2, and VP3 are exposed at the virion surface being the most divergent proteins. The epitopes responsible of serotype differentiation are located mostly in exposed areas within outer capsid proteins (VP1–VP3).[28] 3D region encodes a functionally important protein in the virus life cycle, the RNA polymerase. Viral genomic RNA has a viral protein (VPg) bound at its 5′ end instead of a methylated nucleotide cap structure. The shorter 3′ NTR is highly conserved and is important in the initiation of minus-strand synthesis.

Teschoviruses are highly abundant and prevalent in domestic pigs and wild boar, the only known natural hosts. Other animal species are not known to be susceptible to infection.[7,29,30] Suckling or weaned pigs are affected more commonly than older (growing pigs). There is no evidence that PTVs are zoonotic. Most strains are nonpathogenic but, occasionally, virulent forms trigger outbreaks of severe nonsuppurative encephalomyelitis. Transmission of Teschen–Talfan disease takes place between infected and susceptible pigs through direct contact or indirectly by contaminated food and water, as well as fomites. Less virulent strains are widespread in conventional swineherds and are thought to be maintained in weaned piglets, which are infected shortly after weaning, when maternal immunity disappears and litter pigs from multiple groups are mixed.[22,31] Infection occurs by the oral or intranasal route, and the virus is shed in feces, urine, and oral secretions in large quantities. The infective dose is very small and, in addition, these viruses are especially persistent, surviving more than 5 months in the environment.[32] Fomites (boots, clothing, or vehicles) can transport the virus long distances between farms without difficulty. PTVs are resistant to heat, pH ranging between 2 and 9, chloroform, lipid solvents, and common disinfectants. These properties make their spread even easier. However, the ionizing radiation, phenol, sodium hypochlorite, 70% ethanol, and iodophor acid disinfectants are able to inactivate this virus.[10]

PTVs have been identified as potential indicators of swine fecal contamination in surface waters as these viruses are excreted abundantly by their hosts.[33,34] Moreover, coinfections of PTVs with common swine pathogens such as enterovirus G, porcine adenovirus, porcine sapelovirus (PSV), porcine circovirus type II (PCV2), porcine reproductive and respiratory syndrome virus, and classical swine fever virus are rather frequent, reflecting the multi-infection status in the field.[5–9] Cocirculation of several serotypes in a geographic area[2] and coinfection of at least two different PTV serotypes in the same animals or herds[8] are common too. The long-lasting persistence observed for PTVs may promote the emergence of viable recombinants by cellular coinfection of viral variants, representing a key factor contributing to the existing viral diversity.[11] Nevertheless, mutation seems to be one of the driving forces in the evolution of the PTVs[2] generating genetic variation.

10.1.3 Clinical Features and Pathogenesis

Although PTV infections are frequently asymptomatic, some strains have been associated with a wide variety of clinical conditions. The incubation period is variable, ranging between 5 and 40 days, but it depends on the virulence of the strain.[10,35] Mortality and morbidity are higher when animals are affected by a highly pathogenic strain (neurovirulent strains), up to 90% during the first days; however, milder strains cause variable mortality and morbidity. Currently, subclinical infections may be more common than clinically manifest diseases.

The disease is characterized by severe CNS disorder that courses with neurological symptoms. The clinical findings include fever and anorexia (not always), opisthotonos, nystagmus, locomotive disorders (hypersensitivity, tremors, clonic spasms, and ataxia), convulsions, paresis, and/or flaccid paralysis of the hindquarters that seldom progresses to total paralysis. Death occurs due to respiratory paralysis within 3–4 days after onset of nervous symptoms. Apart from neurological disease, teschoviruses may cause reproductive failure as stillbirths, mummification, embryonic death, and infertility (SMEDI syndrome),[36] respiratory disorders such as rhinitis and pneumonia,[37,38] enteral disease such as diarrhea,[39,40] myocarditis, and pericarditis,[41] and dermal lesions.[42]

Normally, the viral infection is limited to the gastrointestinal tract and associated lymphoid tissue (Peyer's patches) including the tonsils, where the virus initially replicates.[43] This is the case of piglets from immune sows, which are protected by maternal antibodies and will be replaced by own antibodies when developing active immunity. The virus can spread through the bloodstream (viremia) and reach the CNS, multiplying in the nerves in the absence of circulating antibodies. This situation can occur when the mother has not had contact with the virus, if the pig has not taken colostrum, or if the virus invades "naive" pigs for the first time, thereby affecting pigs of all ages.

No gross abnormalities are seen upon postmortem examinations. Sometimes, muscular atrophy and congestion of cerebrospinal meninges, and nasal mucosa can be perceived. Routine diagnostic pathological examination can confirm a multifocal nonsuppurative polioencephalomyelitis.[44] The degenerative pathological changes are observed in the gray matter of the diencephalon, cerebellum, medulla oblongata, and ventral horn of the spinal cord. The observed lesions are characterized by the presence of perivascular cuffing of the mononuclear cells (lymphocytes and plasma cells), meningitis, focal gliosis, satellitosis, neuronal necrosis, and neuronophagia.[10,12,24–26,45–49] These lesions, although not pathognomonic, support the diagnosis of Teschen–Talfan disease. The diagnosis can be confirmed by Immunohistochemistry (IHC) using specific antisera or monoclonal antibodies, allowing correlation of the pathological changes with the location of the agent.

Differential diagnosis includes Aujeszky's disease (pseudorabie), classical swine fever (CSFV-acute form), African swine fever, Japanese encephalitis, hemagglutinating encephalitis, edema disease (*escherichia coli* enterotoxemia), rabies, sapelovirus infection (PSV), bacterial meningoencephalitis (streptococcus suis), porcine reproductive and respiratory syndrome (highly virulent strains), salt poisoning, intoxication with lead or pesticides, toxins, and nutritional neuropathies.[10,50]

The health control measures include quarantines and movement controls, euthanasia of the animals affected, tracing of contacts, and ring vaccination. These measures should be implemented along with good husbandry practices (cleaning and disinfection) on the affected farms before restocking, in order to avoid the persistence of the virus in the environment. Humoral immune response is important in preventing PTV infection, and it has been suggested that immunosuppression derived from PCV2 coinfection may lead to clinical porcine teschoviral CNS disease. The clinical signs could be prevented by the use of inactivated or attenuated virus vaccines. Although active immunoprophylaxis was an important control measure in the past,[51,52] at present, commercially, there are neither vaccines nor treatment available.[10]

10.1.4 Diagnosis

For laboratory diagnosis of PTV infection, several methods are available. Diagnosis of the disease relies upon the observation of typical clinical signs plus histological lesions of the brain and spinal cord, together with identification of the virus in the CNS of affected pigs and detection of specific antibodies in the blood of convalescent animals. PTV infections are diagnosed by indirect immunofluorescence,[53,54] complement fixation,[55] virus-neutralization test (VNT) with standard antisera[56,57] and molecular detection and typing by reverse transcription polymerase chain reaction (RT-PCR), or a combination of RT-PCR and sequencing.[1,2,4,14,19,33,58–63]

10.1.4.1 Conventional Techniques

Generally, all PTV genotypes grow easily in cell culture. Monolayer cultures of primary porcine kidney or established

Downloaded From Vet-eBooks.com

cell lines derived from porcine tissue are suitable for isolation of PTV (e.g., PK-15 or IBRS-2).[64,65] Briefly, monolayers of cell at 90% of confluence growing in flask (25 cm^2) are inoculated with 500–1000 µL of inoculum previously processed (essentially, homogenized clarified and sterile filtrated). Viral adsorption is allowed for 1 h and 30 min at 37°C. After that, the inoculum is removed and the infected cell monolayer is supplemented with Dulbecco's modified Eagle's medium (DMEM) with 2% of fetal bovine serum plus antibiotics (penicillin–streptomycin) to avoid bacterial contamination. Then, the infection is allowed to proceed by incubation at 37°C and 5% CO_2 until CPE develops in the cell monolayer. If the sample contains PTV, a characteristic CPE will be observed under the phase contrast microscope after 3–4 days. The CPE is characterized by small foci of rounded bright cells. After several passages, the virus grows faster and more efficiently, producing a complete CPE. Then, these infected cultures must be clarified by gentle centrifugation (600 × *g* for 10 min at 4°C), aliquoted, and preserved at –70°C.[66] In these conditions, the virus is stable for many years and is often referred as to virus isolate. The isolation must be confirmed by using specific antisera, monoclonal antibodies, VNT, IFA test, or RT-PCR. Once the virus is propagated in cell culture, the determination of the infectivity titer is recommended. This can be conveniently measured by infecting a cell line grown in an appropriate format (multiwall plates are often used for this purpose) with serial dilutions of the virus isolate and determining the highest dilution producing CPE in 50% of the inoculated cells. The 50% endpoint dilution, which is expressed as $TCID_{50}$/mL, can be calculated by using the statistical method described by Reed–Muench.[67] Once an isolate has been identified as PTV, piglet inoculation is the only certain means of determining that the given isolate is pathogenic.[10]

For serological diagnosis by seroneutralization, also known as VNT, the standard strains and monospecific hyperimmune sera for all PTV serotypes must be available at the laboratory. Alternatively, a method for the detection and titration of antibodies specific for PTV is enzyme-linked immunosorbent assay (ELISA).[68] It is performed in microtiter plates using PTV grown in cell cultures as antigen. Serotyping of PTV with hyperimmune sera is difficult due to the significant cross-reactivity existing between PTV serotype-specific antibodies.[14]

10.1.4.2 Molecular Techniques

RT-PCR techniques have substituted the traditional immunological tests and become the gold standard for diagnosis of PTV infections. Molecular methods for the specific detection of PTVs range from conventional (gel-based) RT-PCR,[14,58] nested RT-PCR,[19] real-time RT-PCR,[33,59,61,63] to reverse-transcription loop-mediated isothermal amplification (RT-LAMP),[62] The optimal strategy for molecular typing of PTVs should involve one or more of the surface proteins. Since neutralizing epitopes have been identified in both VP1 and VP2,[60] genotyping methods targeting partial sequences of both VP1[4] and VP2[60] have been designed. Indeed, these regions accumulate a huge divergence between genotype sequences (Figure 10.3). New approaches based on the analysis of the complete VP1 protein-coding gene or whole structural region (P1) of the viral genome have allowed molecular epidemiological studies demonstrating the genetic diversity of PTVs found in pig populations and establishing phylogenetic relationships among PTV viruses[1,2] (Figure 10.1).

10.2 METHODS

10.2.1 Sample Collection and Preparation

Brain and spinal cord samples should be collected from pigs slaughtered at an early clinical stage of the disease. When not processed immediately, the samples should be placed in a solution prepared with equal parts of phosphate-buffered isotonic saline solution (PBS), pH 7.4, and glycerol. Pieces of tissue are minced to prepare a 10% (w/v) suspension in PBS. The suspension is centrifuged at 800 g for 10 min and the supernatant fluid is used for inoculation of cell cultures.[10] Alternatively, the homogenization can be carried out in a mechanical homogenizer such as TissueLyser (Qiagen): for that 0.1 g of feces or tissues is diluted in 900 µL of sterile PBS 1× supplemented by penicillin–streptomycin for 4 min at 30 Hz (cycles/s) and clarified by centrifugation at 600 × *g* for 10 min at 4°C. Also, homogenates can be sterilized by filtration using a filter with a pore diameter of 0.20 µm (Sartorius Stedim Biotech, Ministart®).[66] After that, the supernatant is ready for extraction of nucleic acids or for virus isolation.

For histological diagnosis, samples of cerebrum, cerebellum, diencephalon, medulla oblongata, and cervical and lumbar spinal cord should be collected. These tissues can be fixed in 10% neutral buffered formalin, paraffin embedded, sectioned at 4 µm, mounted on glass slides, and stained with hematoxylin and eosin following the process routinely in use for microscopic examination. For IHC, for example, dewaxed paraffin-embedded sections are subjected to a streptavidin–biotin complex peroxidase method using a Histfine Sab-PoTM Kit (Nichirei, Japan).[47] Heat denaturation is used for antigen retrieval.[45] Several primary antibodies like murine monoclonal anti-PTV1 (Talfan strain), rabbit anti-PTV1–7 (reference strains), and rabbit polyclonal antiserum against PTV-1 (VIR 2236/99 strain) have been applied.[45,47,66]

Paired serum samples are also helpful to assess seroconversions by either seroneutralization or ELISA. Also, stool samples collected from affected or nonaffected individuals can be valuable both in diagnostic strategy as well as in environmental investigations and epidemiological surveys.

Semiautomated workstation BioSprint 15 (Qiagen) can be used for obtaining viral RNA both from field samples and from experimental preparations previously processed (tissues, oral swabs, blood, feces, and cell culture isolates) following the manufacturer's instructions. The protocol may be modified by the addition of 1 µL of RNA carrier to increase the yield of purification. Likewise, viral RNA can be extracted using TRIzol reagent following the protocol described essentially by the manufacturers of TRIzol® LS Reagent Kit (Ambion). As positive control, an adequate dilution of the viral supernatants in culture medium (DMEM) to obtain a sharp band by electrophoresis and a threshold cycle (Ct) (in the case of real-time techniques) of 31 ± 2 should be prepared. Sterile deionized water (Milli-Q water) can be used as negative control.

10.2.2 Detection Procedures

10.2.2.1 Conventional RT-PCR

The following duplex RT-PCR protocol has been described by Palmquist (2002) and has been included as a detection method in OIE manual.[10] Using the same set of oligonucleotide primers allows to detect and differentiate simultaneously PTV and PSV on the basis of the size of the amplification product. The following protocol is an adaptation of this method using the commercial kit One-Step RT-PCR (Qiagen).

10.2.2.1.1 Procedure

1. Prepare the RT-PCR mix as follows: 5 µL of buffer 1× [Tris-Cl, KCl, $(NH_4)_2SO_4$, 2.5 mM $MgCl_2$], 0.2 mM dNTPs, 5 µL of Q solution 1×, 0.4 µM of each forward (1222-F: 5′-GTGGCGACAGGGTACAGAAGAG-3′) and reverse (1223-R: 5′-GGCCAGCCGCGACCCTGTCAG-3′) primers, 5 units of RNAse inhibitor (Applied Biosystems), and 1 µL of RT-PCR enzyme mix (Omniscript® and Sensiscript® Reverse Transcriptases, HotStartTaq® DNA polymerase). Then, add sterile water up to a volume of 23 µL of mix per reaction. Deliver 23 µL of the mix to each PCR tube. Tubes should be placed in a 96-well cooling block. Add 2 µL of the target RNA (sample) to the RT-PCR mix to complete the reaction final volume (25 µL). (*Note*: Vortex and spin down all microcentrifuge tubes of RT-PCR components before use and spin the tubes down briefly before putting them in thermocycler.)
2. RT and DNA amplification is carried in one step following the procedure described by the author: 30 min at 50°C, 15 min at 95°C, 40 cycles of 60 s at 94°C, 60 s at 56°C and 60 s at 72°C, and finally 10 min at 72°C.
3. Analyze the PCR products by electrophoresis through 3% agarose gel in TAE buffer at 150 V for 30 min.
4. Stain the gel with ethidium bromide or red gel and then visualize under ultraviolet light source. The presence of a 163 bp product is indicative of PTV, while the presence of a 180 bp product is indicative of PSV. Negative and positive controls are added in order to monitor the reaction procedure.

10.2.2.2 Real-Time RT-PCR

Real-time PCR methodology offers a number of advantages over traditional methods, such as its speed, sensitivity, and high throughput to analyze large numbers of samples without the need for gel electrophoresis at the end. The alignment of a conserved region (5′ noncoding region) of RNA sequences of all PTV prototype strains allowed to design a pair of oligonucleotide primers and a 5′ 6-FAM-3′ MGB labeled TaqMan probe for specific detection of all recognized PTV variants (i.e., serotypes) to date.[33,61]

Downloaded From Vet-eBooks.com

This TaqMan-minor groove binder (MGB) real-time RT-PCR method is performed using QuantiTect Probe RT-PCR Kit (Qiagen), as described in the following protocol:

1. Prepare the RT-PCR mix as follows: 12.5 µL of a QuantiTect Probe RT-PCR master mix 1× (containing Tris-Cl, KCl, $(NH_4)_2SO_4$, 8 mM $MgCl_2$, dNTP mix, a reference dye (ROX) and HotStartTaq DNA polymerase), 0.4 µM of each forward (PTV-F1: 5′-CACCAGCGTGGAGTTCCTGTA-3′) and reverse (PTV-R1: 5′-AGCCGCGACCCTGTCA-3′) primers, 0.25 µM of the TaqMan-MGB probe (PTV-S1: 5′-FAM-TGCAGGACTGGACTTG-3′-MGB), and 0.25 µL of QuantiTect RT mix (Omniscript and Sensiscript Reverse Transcriptases), and add sterile water up to a volume of 15 µL of mix per reaction. Deliver 15 µL of mix to each optical tube. Tubes should be placed in a 96-well cooling block. Add 10 µL of target RNA (sample) to the RT-PCR mix to complete the reaction final volume (25 µL). (*Note*: Vortex and spin down all microcentrifuge tubes of RT-PCR components before use and spin the tubes down briefly before putting them in thermocycler.)
2. Perform RT-PCR reactions using the following conditions: 30 min at 50°C for RT, 15 min at 95°C for enzyme activation followed by 45 cycles of 15 s at 94°C, and 1 min at 60°C. Fluorescence level is read at the end of each cycle step (6-carboxyfluorescein [FAM] and ROX channels). Ct values below 38 will be considered positive.

10.2.2.3 Genotyping Based on VP1 and VP2

Molecular typing targeting the VP1 and VP2 regions has been recognized as the best choice because of good correlation with the classical serotype classification.[69] Specifically, the amplification of genomic fragments derived from the VP1- or VP2-coding regions proved to be broad in range and suitable for serotype assessment and therefore constitute a useful diagnostic tool for molecular diagnosis of PTV strains.[4,6,60,61] In the following section, two different ways of virus characterization are described: one based on the amplification and sequencing of the whole VP1-coding region and the other based on the amplification and sequencing of a fragment of the VP2-coding region.

10.2.2.3.1 Typing by VP1

Teschoviruses are molecularly typed by amplification with two degenerate primer pairs described by La Rosa et al.[4] The second pair (398-primers-ID: 1299-F 5′-GCA TCHAAYGARAAYCC-3′ and 1302-R 5′-CCAAAYC CAAARTCYTG-3′) is used in case of failure of the first one (397-primer-ID:1298-F5′-CCNGCNGARACAGGHTGTG-3′ and 1301-R 5′-TTCCANGTRAANGARGG-3′). Moreover, when a weak band is obtained, a second PCR reaction could be attempted to improve the result. According to the protocol described by the authors, use 2 µL of viral RNA and 88 pmol of each primer. Thermocycling conditions for these reactions are as follows: RT at 42°C for 45 min; one cycle of template denaturation at 95°C for 2 min, primer annealing at 51°C for 1 min, and primer extension at 72°C for 1 min; and 35 cycles at 95°C for 1 min, 54°C for 1 min, and 72°C for 1 min, followed by one cycle of elongation for 10 min at 72°C. Bands of expected sizes of 431 bp (397-primer-ID) or 533 bp (398-primer-ID) are observed after electrophoresis on 2% agarose gel. Amplified cDNAs can be purified using High Pure PCR product Purification Kit (Roche), QIAquick Gel Extraction Kit (Qiagen), or ExoSAP-IT Kit (GE Healthcare) and then sequenced using the same primer sets as for RT-PCR assays. Sequences are edited using suitable assembler software such as SeqMan program (DNAstar, Lasergene) or Seqscape (Applied Biosystems). The consensus sequences of VP1 obtained are subjected to homology analysis using basic local alignment search tool (BLAST), searching for similarity as a first approach to PTV identification. Finally, multiple alignments can be carried out using Clustal or Muscle methods and phylogenetic analysis can be conducted by MEGA 5.05 or MrBayes 3.2à MEGA 5.05 or MrBayes 3.2 software programs in order to establish more accurate phylogenetic relationships between strains.

10.2.2.3.2 Typing by VP2

Kaku et al.[60] described a dominant antigenic site in the VP2 region of PTVs and designed a pair of degenerated primers to amplify about 320 bp by comparing the VP2 sequences of PTV prototype strains and field isolates. The single-step RT-PCR kit mentioned earlier (One-Step RT-PCR kit, Qiagen) is also used here for RT and cDNA amplification.

10.2.2.3.2.1 Procedure

1. Prepare the RT-PCR mix in the following way: 5 µL of buffer 1× [Tris-Cl, KCl, $(NH_4)_2SO_4$, 2.5 mM $MgCl_2$], 0.2 mM dNTPs, 5 µL of Q solution 1×, 0.6 µM of each forward (VP2-337F-puff: 5′-CACCARYTGCTTAARTGYKGTTGG-3′) and reverse (VP2-654R-puff: 5′-CACAGGGTTGCT GAAGARTTTGT-3′) primers, 5 units of RNAse inhibitor (Applied Biosystems), and 1 µL of RT-PCR enzyme mix (Omniscript and Sensiscript Reverse Transcriptases, HotStartTaq DNA polymerase). Then, add sterile water up to a volume of 23 µL of mix per reaction. Add 2 µL of target RNA (sample) to the RT-PCR mix to complete the reaction final volume (25 µL).
2. Carry out RT and cDNA amplification in one step with the settings described by the author: 30 min at 50°C, 15 min at 95°C, 40 cycles of 30 s at 94°C, 60 s at 51°C and 60 s at 72°C, and finally 10 min at 72°C.
3. Analyze the PCR products by electrophoresis through 2% agarose gel in TAE buffer at 150 V for 30 min. Stain the gel with ethidium bromide or

Downloaded From Vet-eBooks.com

red gel, and then visualize under ultraviolet light source. Amplicons of the expected size (~320 bp) are sequenced and analyzed in the same way as described for VP1.

10.3 CONCLUSION AND FUTURE PERSPECTIVES

PTVs are quite diverse, with some being pathogenic for domestic and wild suids, while certainly, most others are seemingly harmless. In addition, they are extremely ubiquitous, an endemic situation that is widely recognized, and cocirculation of different virus variants and even coinfections are frequently observed in swine populations. Indeed, the high potential of ssRNA viruses to undergo genetic changes through mutation and/or recombination mechanisms and their high replication rates is playing a role by continuously shaping their infectious behavior in their hosts.

From a diagnostic perspective, it is important to note that laboratory techniques are available for satisfactory detection and typing of the known range of PTVs. However, it is not unreasonable to assume that this range will be enlarged in the coming years, as more refined and sensitive techniques are being applied. For this reason, detection and typing techniques need to constantly take into account of all new variants of PTVs found and keep updated to cover its full range.

Similarly, sequence analysis and phylogenetic relation are powerful tools that play a critical role in the epidemiological investigation of PTVs. They facilitate comparisons between our strains and other strains circulating elsewhere so that the origin and possible pathogenicity of newly identified PTVs might be inferred. Nevertheless, current laboratory analyses are unable to assess the pathogenicity of a given PTV, without performing specific animal studies. Methods to correlate pathogenicity and possible genetic determinants of virulence are still lacking, and they are strongly needed in order to differentiate high and low pathogenicity PTV strains.

11.1 INTRODUCTION

Swine vesicular disease virus (SVDV) belongs to the *Enterovirus* genus within the family *Picornaviridae*. It causes an infectious and contagious disease in pigs called swine vesicular disease (SVD), characterized by the appearance of vesicles on the coronary bands of the feet, heels, skin, snout, tongue, lips, and teats, accompanied by fever. Its importance for animal health authorities relies in the fact that these signs are indistinguishable from those caused by other vesicular diseases of viral etiology affecting swine, including foot-and-mouth disease (FMD), vesicular stomatitis (VS), and vesicular exanthema of swine (VES), and therefore, differential diagnosis in the laboratory is essential to discern between them.

SVDV is closely related to coxsackievirus B5 (CV-B5),[1] a human virus, from which it is thought to derive from adaptation to pigs, possibly through changes in the receptor usage.[2] Although originally considered as zoonotic,[3] public health risk is negligible as its infection in humans has not been reported recently, and the late isolates of the virus have lost the ability to infect human cells,[2] thus decreasing its original zoonotic potential. So far, the disease, which was first described in Italy in 1966,[4] has only been reported in farmed pig populations in Europe and Far East Asia. In Europe, since 1994 and after a period of relatively high activity and broader geographic distribution, the disease was effectively cleared from most countries, except Italy, where SVD has been persistently reported causing occasional foci, and for this reason, intense surveillance and eradication plans are in place.[5] Remarkably, however, in the last 20 years, the disease has evolved to a milder form, usually asymptomatic. In Far East Asia, the disease is also likely to be present. The last reported case from this region occurred in Taiwan in 2000.[5]

SVD is highly contagious and spreads rapidly by direct contact with infected animals and by environmental contamination. This ability to spread, together with its clinical

Downloaded From Vet-eBooks.com

resemblance to FMD, made SVD one of the diseases listed by the World Organization for Animal Health (OIE) in the *OIE Terrestrial Animal Health Code*.[6] OIE-listed diseases are transmissible diseases that have the potential for very rapid spread, irrespective of national borders (often referred to as "transboundary diseases"), and are of obligatory declaration to the OIE due to their serious socioeconomic or public health consequences and impact in the international trade of animals and animal products. As the importance of SVD centers on its similarity to FMD, all biosecurity measures regarding SVDV handling, including diagnosis involving biologically active virus, must follow those in force for foot-and-mouth disease virus (FMDV) handling, that is, OIE containment group 4 (and equivalent biocontainment levels like BSL-3 and P3). This group includes "organisms that cause severe human or animal disease, may represent a high risk of spread in the community or animal population and for which there is usually no effective prophylaxis or treatment."[6] However, SVD is not a severe disease by itself, and as current diagnostic methods have evolved, the capability of differentiating SVD from FMD has improved, so the inclusion of this disease in the OIE list could be reevaluated in the future.

As SVD does not cause severe production losses, improved biosecurity plays a major role in the control and prophylaxis of the disease. The main sanitary measures in place are stamping out, restriction of pig movements (protection and surveillance zones), cleaning and disinfection, and restrictions on swill feeding and on importation of pig products from SVD-affected regions.[7] The often asymptomatic course of the infection presents a significant risk to livestock importation from countries where SVD status is not regularly assessed.

Vaccines against SVD are not available commercially, although experimental studies have been conducted to develop vaccines using different approaches.[8–12] In agreement with the status of SVD as an OIE-listed disease, where control is mainly achieved by stamping out and other sanitary measures, vaccination is disregarded, due to the general concern about the presence of specific SVDV antibodies in pigs, which would be raised after vaccination, and its generally mild course, discouraging investment in vaccine developments. Any attempt to develop a vaccine useful in the control of SVD has to consider the need for efficient methods to discriminate vaccinated from infected animals (differentiation of infected from vaccinated animals [DIVA] tests) accompanying the vaccine.

There is currently no treatment for SVD, although antiviral activity of pocket factor analogues in infections caused by enteroviruses (see Section 11.1.2.2) might open a valuable control strategy. Nonetheless, the low impact of this disease for swine health discourages investment in this type of approaches.

11.1.1 Classification

Taxonomically, SVDV (*Enterovirus* genus, *Picornaviridae* family) is considered a subspecies within the species CV-B5. Nucleotide sequence identity between both viruses is 75%–85%.[13] From their antigenic cross-reactivity, it was proposed as early as 1973 that SVDV arose in pigs by interspecies transmission of CV-B5 from humans.[14,15] Later, the analysis of nucleotide sequences of 45 isolates from outbreaks of Europe and Asia between 1966 and 1993 allowed estimating the date of the divergence of SVDV from CV-B5 between 1945 and 1965.[16]

11.1.2 Morphology and Biology

11.1.2.1 Virus: Structural and Genome Organization

The virion is a nonenveloped particle of 25–30 nm in diameter, with pseudospherical capsid of icosahedral T = 1 symmetry, which is composed of 60 protomers, each made up of one copy of each of the four structural proteins: VP1, VP2, VP3, and VP4. Underneath the capsid is a single-stranded positive sense RNA genome of approximately 7400 nucleotides,[17–19] whose organization is essentially identical to that of poliovirus 1, the type virus of the *Picornaviridae* family (Figure 11.1). Flanking a unique open reading frame encoding a precursor polyprotein of 2185 amino acid residues, there are two nontranslated regions, one at the 5′ end encompassing a highly structured region, the internal ribosome entry site, where the ribosome assembles to initiate the translation of the polyprotein, and one at the 3′ end also with a highly structured segment probably involved in RNA replication, followed by a chain of polyadenines (poly-A) of variable length. The precursor polyprotein of SVDV is processed in the cytoplasm of the infected cell to yield 11 functional viral polypeptides. The first excision produces polypeptides P1, P2, and P3. After further processing, P1 gives rise to the structural proteins VP1–VP4, whereas P2 and P3 yield the nonstructural proteins (Figure 11.1). In the mature virion, proteins VP1, VP2, and VP3 (33, 32, and 29 kDa), respectively,[20] are exposed on the surface, forming a compact proteic shell. These three capsid proteins share a tertiary structure, highly conserved among picornaviruses, that consists of an eight stranded β-barrel constituting its central hydrophobic core. Conversely, VP4 (about 7.5 kDa) is facing the inner side of the capsid, interacting with the viral RNA molecule. Among the nonstructural polypeptides, there are two viral proteases (2A and 3C), one RNA polymerase (3D), the VPg, which is covalently bound to the 5′ end of the RNA molecule and participates in its replication, and other proteins whose functions are not well determined (2B, 2C, 3A, 3B).

11.1.2.2 Antigenic Structure

SVDV displays two types of antigenic sites: (1) those defined by monoclonal antibody-resistant mutant analyses, grouping in up to seven different neutralizing epitopes in the surface of the capsid,[21–23] and (2) those defined by *pepscan* analysis, essentially comprising internal epitopes not involved in neutralization,[23,24] with one exception: one antigenic site at the N-terminal region of the VP1 protein, which is internal, but emerges to the surface upon virus interaction with the cell receptor and is involved in neutralization.[25] The 3D structure of SVDV capsid has been solved,[26,27] and this fact has enabled the fine mapping of the antigenic sites. A singular feature is the existence of a sphingosine molecule on each VP1 subunit,

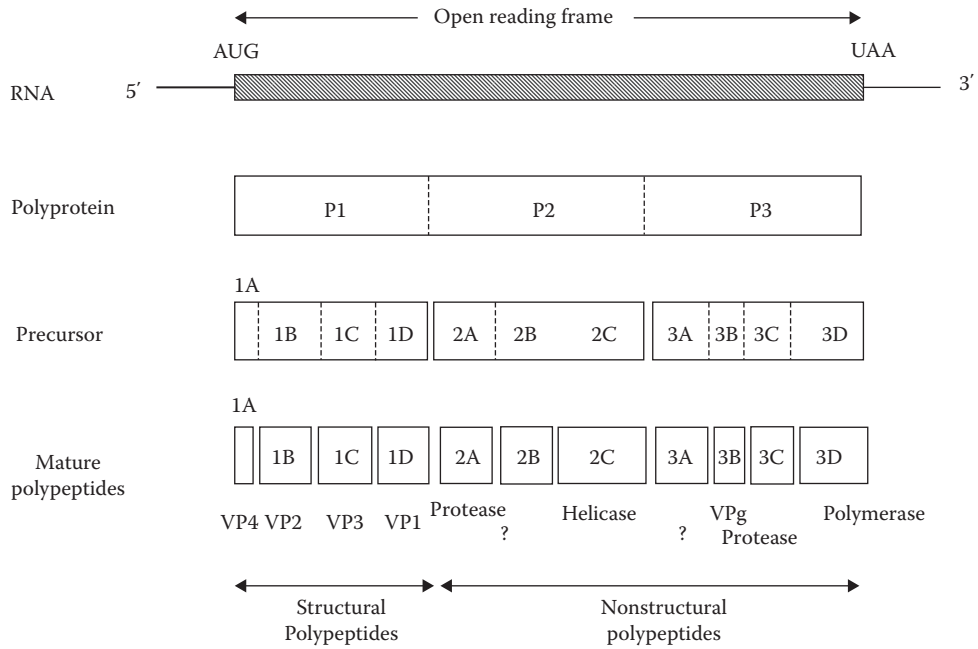

FIGURE 11.1 Genomic organization of SVDV and the posttranslational processing of polyprotein products. Discontinuous lines indicate the sites of proteolytic cleavage.

embedded in an internal cavity known as the "hydrophobic pocket" present in all enteroviruses studied, which contains lipids derived from cells known as "pocket factors," whose role is stabilizing the virus particle at the extracellular level.[28] Upon interaction with the receptor at the cell surface (see Section 11.1.2.3), these pocket factors are expelled, leading to unstable particles that, once internalized into the cell, undergo deep conformational changes, initiating virus uncoating and RNA release into the cytoplasm. Pocket factor analogues have been developed for use as antivirals,[28] but to date, no use in animal health is foresight for these compounds, at least in the near future.

11.1.2.3 Virus–Cell Interactions

All viruses belonging to the coxsackievirus B group, including SVDV, use a common surface molecule known as coxsackievirus–adenovirus receptor (CAR) as host cell receptor.[2,29] CAR is a 46 kDa transmembrane glycoprotein with two extracellular immunoglobulin-like domains, which also functions as an attachment molecule for adenovirus fiber proteins.[30] On the other hand, another surface molecule, DAF (decay accelerating factor, CD55), a 70 kDa protein involved in the control of homologous lysis by complement, has been postulated to act as a coreceptor used by some coxsackie B virus strains.[31–33] Evidence has been reported supporting also this role of DAF for SVDV but, interestingly, only earlier strains (It'66 and UK'72, isolated in Italy in 1966 and in the United Kingdom in 1972, respectively) are able to interact with DAF of human origin. By opposite, more recent strains (R1072, R1120, and SPA'93, isolated in Italy in the early 1990s and in Spain in 1993, respectively), have lost their ability to interact with human DAF and have not replaced this interaction with the, otherwise different, porcine homologous version of the human DAF molecule.[2] This finding suggests that in its adaptation to swine from humans, SVDV has lost certain capacity to interact with human cells. In fact, recent SVDV isolates, though able to interact with CAR, have lost the capacity of infecting human HeLa cells, still present in earlier isolates.[2] This phenotypic change has been suggested to involve a lower tropism for human cells and, consequently, a reduced zoonotic potential for SVDV.[34]

In addition to binding to cell surface glycoproteins, the interaction of many viruses with the cell surface is mediated in many instances by sulfated glycosaminoglycans, particularly heparan sulfate proteoglycans.[35] Among the picornaviruses, FMDV-heparin/heparan sulfate interaction has been attributed to an adaptation to cell cultures.[36] In SVDV, interaction with heparan sulfate glycosaminoglycan has been shown to mediate the attachment to the host cell, indicating that this molecule could act as receptor or coreceptor for this virus.[37] The importance of this interaction in the process of cell attachment and entry remains to be determined.

The mechanism of cell entry of SVDV is not fully characterized. Similar to other picornaviruses, the capsid of SVDV undergoes a series of conformational changes upon interaction with its receptor, leading to a structurally and antigenically altered particle named "A particle." In this process, the N-terminus of VP1 becomes externalized and VP4 is lost. As noted earlier, this process uncovers a cryptic epitope that is involved in neutralization.[25] Those "A particles" are the most abundant form of the intracellular virus in the early stages of infection and seem to be a necessary intermediate preceding the uncoating and release of RNA into the cytoplasm in picornaviruses.

11.1.2.4 Genetic and Antigenic Variation

SVDV is considered a relatively recently emerged virus variant of CV-B5, which adapted to pigs,[1,13,16] providing a good example of the concept that adaptations and species barrier crossing can go either to or from humans.[38] Serologically, all isolates belong to a single serotype. However, in its short history, the virus has evolved into at least four recognized antigenic variants that can be distinguished by different MAb, correlating with four genetically distinct groups: group 1 comprises the first isolate (It'66); group 2 includes European and Asian SVD viruses isolated in the 1970s and early 1980s; group 3 is constituted by Italian isolates of the 1980s and 1990s; and group 4, isolates circulating in the late 1980s and early 1990s in a broad territory of Europe.[39] As mentioned earlier, in recent years, SVD has been almost exclusively reported in Italy, where an intensive surveillance program is in place. As a result of this surveillance, a number of SVDV isolates have been studied, all of which belong to antigenic and genetic group 4,[5] while no representative of antigenic/genetic groups 1–3 has been isolated in the last 20 years, a fact that might indicate a possible extinction of these three groups.

11.1.3 Epidemiology

11.1.3.1 Geographic Range of Disease Occurrence

The first occurrence of SVD was reported in Lombardy, Italy, in 1966, where it was clinically recognized as FMD, but physical and chemical analysis showed that the causative agent was an enterovirus originally termed "porcine enterovirus,"[34] though eventually it was renamed as "swine vesicular disease virus." The next outbreak was reported in Hong Kong in 1971, in an FMD vaccine trial.[40] Since then, SVD has been reported in different European and Asian countries (Table 11.1). More recently, besides Italy, where SVD reoccurs every year, outbreaks of SVD have occurred in Portugal in 2003–2004 (Leiria district) and in 2007 (Beja district).[41] Currently, the European Union countries have been declared disease-free, except Southern Italy, where SVD is endemic despite eradication campaigns in place in this country since 1995.[5,42,43] Africa, North and South America, and Oceania have remained free of the disease, but in various Asian countries, the disease is likely to be present,[42,44] the last case of SVD from Far East Asia being reported from Taiwan in 2000.[42]

TABLE 11.1
Occurrence of SVD around the World

Country	Years of Report	Year of Most Recent Report
Europe		
Austria	1972–1976, 1978	1979
Belgium	1973, 1979, 1992	1993
Bulgaria	1971	1971
France	1973–1975, 1982	1983
Germany	1973–1977, 1979–1982	1985
Greece	1979	1979
Holland	1975, 1992	1994
Italy	1966, 1972–1984, 1988–1989, 1991–2010	2011
Malta	1975	1978
Poland	1972	1973
Portugal	1995, 2003–2004	2007
Romania	1972–1973	1987
Russia	1972	1976
Spain	1993	1993

11.1.3.2 Host Range

SVDV is considered to be highly contagious for pigs of all ages with variable morbidity, which can be as high as 80%–100% in individual pens, although it depends on a wide range of factors, including virulence of the viral strain involved, type of farm, and time elapsed between infection and detection, among others. Mortality is negligible. The susceptibility to natural infections has only been reported in swine (either wild boar or domestic pigs, including Euro-Asian pigs or American one-toed pigs).[45] Infections in nonswine species have been reported. Relatively high virus titers have been detected in the pharynx of sheep (but not in cattle) kept in close contact with SVD-infected pigs. Such sheep developed significant levels of neutralizing antibodies, indicating that they were infected, so the virus managed to replicate in their tissues, but without showing clinical signs. Despite this finding, sheep do not seem to play any role in the transmission of the disease.[46] Experimental infection has been induced in one-day-old mice being lethal to newborn mice.[4,47] Although SVDV is closely related to human CV-B5, and few cases of human illness have been reported caused by infections with earlier strains of SVDV, affecting people working in laboratories handling (and exposed to) high virus titers and/or infected pigs,[3] public health risk is not considered since, as mentioned earlier, the infection has not been reported in humans recently, and apparently, the virus has lost the ability to infect human cells, decreasing its original zoonotic potential.[2]

11.1.3.3 Disease Transmission and Virus Inactivation

The disease is transmitted mainly by direct contact with infected animals and their feces (fecal–oral route), fomites, and contaminated food. The virus resists fermentation and smoking processes used for conservation of certain food products,

Downloaded From Vet-eBooks.com

but is inactivated either after heat treatment (above 69°C) of pork products[48] or after treatment of cured ham for 1 year.[49] SVDV-contaminated environments have been shown to be as infectious as direct inoculation or contact with infected pigs. By opposite, airborne spread by aerosols from the lesions and skin is not an efficient way for SVDV transmission.[50,51] Nevertheless, inefficient disinfection of vehicles used in transport of pigs constitutes another important source of infection and disease dissemination from one farm to another.[43] A collective open drainage system or regular movements of infected pigs between pens increase the likelihood of spread within the farm, leading to the consideration of SVD as a "pen disease" rather than a "farm disease."[52]

The notable persistence and particular high stability of SVD virus particles play an essential role in the epidemiology of SVD.[53] The virus is resistant to most common alkaline or acidic disinfectants as well as to detergents and organic solvents such as ether and chloroform. Unaffected by desiccation and freezing, it can survive between 4 and 11 months over a pH range of 2.5–12 and temperature range of 12°C to –20°C. The inactivation of SVDV is achieved by heating at 56°C for 1 h, or by using disinfectants such as 1% sodium hydroxide (pH 12.4), 2% formaldehyde, and even 70% alcohol (allowing appropriate contact times).[54]

Once the infection is acquired, pigs secrete SVDV both orally and nasally, ceasing this secretion normally within 2 weeks. The virus is excreted in large amounts in feces starting up to 48 h before the onset of clinical signs and lasting usually around 10–20 days.[55] Nevertheless, occasionally excretion of the virus is observed during more time, even up to 70 days.[56] Furthermore, in certain circumstances (probably influenced by stress conditions), fecal excretion of the virus is resumed after cessation, and in this type of cases, the presence of the virus in feces has been observed up to 126 days after the initial infection.[57] Although the virus found in the tissues of infected pigs, particularly during the viremic phase, might bring on the contamination of pork products and introduce the disease agent into the food chain (particularly when the disease is not immediately recognized), in countries where this practice is not allowed, swill feeding is generally regarded as unimportant in the epidemiology of SVD.[43]

Generally, the highest viral shedding occurs from the vesicles within the first week after the infection,[51] and the virus does not persist in the tissues longer than 28 days following the infection. However, persistent infection of pigs has been observed experimentally using viral isolates of European origin, in which the virus remains in the tissues for longer than 3 months after the infection,[57,58] although it has proven difficult to reproduce these results due to the low frequency and lack of consistency observed for the phenomenon of SVDV persistency.[59] The epidemiological significance of persistent SVDV infection in pigs is uncertain. Experimental evidence indicates that in stress conditions like mixing of pigs from different pens, reactivation of latent virus infections for a short period of time is possible. However, to what extent this latency gives rise to epidemiologically relevant sources of infection remains unknown.

11.1.4 Clinical Features, Pathogenesis, and Immunity

This virus can enter the body through either broken skin lesions or mucous membranes of the digestive tract by ingestion of excreta or secretions from infected pigs.[60–62] The incubation period is usually 2–7 days, but it can extend longer if the dose of the virus is small. Viral replication starts in the primary site of infection, usually the gastrointestinal tract, spreading rapidly via the lymphatic system into the bloodstream at 1–2 dpi (days postinfection). This occurs evenly in pigs experimentally infected by direct inoculation of the virus as well as in pigs infected through contact with a contaminated environment.[51] The highest virus titers are found in the vesicles and tissues as lesions develop, decreasing as the antibody response rises, after the first week of clinical disease. The presence of circulating neutralizing antibodies, observed as early as 4 dpi, provides long-lasting protection against future reinfection. The tropism for epithelial tissues is well-known, but virus titers in the myocardium, brain, kidney, and spleen are higher than the titers in plasma or serum, being probably the sites of replication.[51,60,61] Similarly, the virus can be isolated from lymph nodes that may contain high viral titers[63] possibly due to either virus drainage from the tissues or local replication, or both.

Immunohistochemistry and in situ hybridization have been used to detect SVDV in epithelial and dermal cells and in infected tissues,[64] but more research must be implemented in order to know which cells are involved in SVDV replication, which would help to identify the mechanism behind the host tropism of the virus.[65]

As noted earlier, the development of neutralizing antibodies in the early stages of the infection is of paramount importance to impair virus dissemination throughout the body and limit the disease. IgM class antibodies dominate the earliest steps in the humoral immune response to SVDV. At 8–12 dpi, a switch to IgG occurs,[52,66] which provides a long-living immune protection to further SVDV infections. As only one serotype of SVDV is recognized, prior infection or vaccination with a given SVDV strain will be expected to protect against further infection with any other SVDV variant.

The importance of SVD relies on the fact that it is clinically indistinguishable from FMD, VS, and VES.[7] The differential diagnosis based on the observation of clinical signs is not feasible; thus, it is required to conduct specific laboratory investigations (see Section 11.1.5).

SVD courses most often as an acute, self-limited infection with the most perceptible clinical signs being the appearance of vesicles in the limbs, tongue, and snout. However, the infection may remain unnoticed since it is most frequently asymptomatic. Disease outcome may vary in appearance, and this variation poses some difficulties in the initial diagnosis. Affected pigs may show inappetence or even anorexia for 1 or 2 days, although this is not a consistent finding. Within 1–5 days after exposure, body temperature may rise to 41°C for 2–3 days; however, in experimental infection with European SVDV, pyrexia has not been observed.[53] Initially, blanching areas in the epithelium precede the formation of

Downloaded From Vet-eBooks.com

vesicles around the coronary bands and interdigital spaces and on the skin of the lower parts of the limbs, particularly at pressure points such as the knees. Vesicles may also appear on the snout, specifically on the dorsal surface, on the lips, tongue, and mammary glands, being less common in the oral cavity. Rupture of vesicles releases a straw-colored fluid (vesicular fluid) rich in infectious virus and reveals a shallow ulcer with a red hemorrhagic base. In few instances, punctiform ulcerative lesions have been found on the lower lips, but such lesions are not characteristic of the disease. Extension of the lesions on the coronary band may arise, and the hoof wall may separate from the underlying tissues, but the complete detachment of the hoof, as occurs with FMD, is uncommon.

Neurological signs have been observed, though rarely, in experimentally infected animals. They were reported as nonsuppurative meningitis and panencephalomyelitis, principally affecting the midst and forebrain. These neurological signs may include trembling, unsteady gait, back arching, and chorea (rhythmic jerking).[59,67] Isolation from an aborted fetus suggests that abortion may occur, but there is no evidence that the pregnant sow is relevant for the perpetuation of the disease and dissemination of the infection. Experimentally, abortion is not typically seen and the virus is unlikely to infect or cross the placenta.[68] Other disease signs include lameness, salivation, and moderate general weakening. Normally, infected pigs recover after the acute phase of the disease within 2–3 weeks, healing all the skin lesions completely. Frequently, the only evidence of infection in the pig after careful examination is a dark horizontal line on the hooves where the growth was temporarily interrupted.

SVD may be subclinical, mild, or severe depending on the virulence of the strain and husbandry conditions. Regarding virulence, differences in pathogenicity between different strains have been assigned to specific regions and even single point mutations in the virus genome. Differences in pathogenicity between the virulent J1'73 and the avirulent H/3'76 strains were mapped in a region comprising nucleotides 2233–3368 of the viral RNA, corresponding to the C-terminus of VP3, the whole VP1, and the N-terminus of 2A viral protease.[44] Moreover, two different amino acid changes within this region, that is, glycine at the VP1–132 and proline at the 2A-20 positions, were identified as determinants of the high virulent phenotype. With regard to husbandry conditions, more severe lesions are seen when pigs are housed on concrete, particularly damp concrete, than on straw bedding or in grass. In addition, young pigs tend to show more severe clinical signs than older pigs. The only postmortem lesions of SVD are the vesicles that can be seen in live pigs. Nevertheless, the subclinical evolution of the disease observed during the last 20 years must be remarked. In fact, the infection is normally detected only by evidence of virus in feces of healthy pigs or by detection of antibodies.

11.1.5 Diagnosis

As SVD is clinically indistinguishable from FMD and other vesicular diseases of pigs (hence its status as an OIE-listed disease), the correct differential diagnosis is laboratory-based and must be carried out using specific laboratory tests available. The standards for SVD diagnosis are described in the OIE *Manual of Diagnostic Test and Vaccines for Terrestrial Animals*.[7] Any vesicular condition in pigs may be caused by FMD; therefore, any sign of vesicular disease in pigs should be considered as FMD suspects until proven otherwise. Once suspicion of FMD is discarded, the diagnosis of SVD requires the facilities of a specialized laboratory, with appropriate biosecurity and biocontention measures. Countries lacking such facility should send samples for investigation to an OIE reference laboratory for SVD.[7]

The laboratory confirmation of SVD requires either the isolation of the virus or the detection of its genome or antigen, associated with the demonstration of specific antibodies.[53] A brief account of the current techniques and methods for the diagnosis of SVD is described in the following text, followed by a specific section describing the molecular methods implemented in the area in detail.

11.1.5.1 Conventional Techniques

In case of suspicion of the disease, samples of vesicular fluids and portions of vesicular lesion tissues are collected separately and aseptically in sterile containers. Fecal samples and serum from animals with or without lesions are collected for virus isolation, molecular analysis (usually, reverse transcription-polymerase chain reaction [RT-PCR]; see Section 11.1.5.2), and serological tests. Serum samples can be used for routine disease surveillance or export certification. Lymph nodes, thyroid and adrenal glands, kidneys, spleens, and heart tissues can be collected from slaughtered animals. Independent sets of sterile instruments should be used for sampling of each animal.

Virus neutralization test (VNT) and enzyme-linked immunosorbent assay (ELISA) are the techniques more commonly used for the detection of antibodies raised in response to SVDV infection. Various ELISA tests have been developed[66,69–71] including formats able to specifically differentiate IgM and IgG class immunoglobulins involved in SVDV binding.[66] Some of them are available commercially. While ELISA is the most appropriate technique for screening and has been shown to be efficient in large-scale serosurveillance programs,[63] VNT is currently the *gold standard* assay for confirmatory detection of antibodies to SVDV.[72] It is used to confirm the results after ELISA screening. Neutralizing antibodies can be detected as early as 3–4 days after experimental infection. The VNT is a laborious technique that requires 2–3 days to obtain the results. It is a quantitative test that is performed using IB-RS-2 cells or other susceptible porcine cells. The test measures the ability of serial dilutions of a given serum sample to neutralize (block) the infection of the cells by a known amount of infectious virus, previously titrated. It also needs inclusion of a reference antiserum of known titer, control cells, and infectious virus, which is used as antigen in the test.

Singleton reactors (SRs) are sera from individual pigs serologically positive for SVDV, but which have shown no clinical signs and for which there is neither a history of the disease on

Downloaded From Vet-eBooks.com

the holding nor contact with a known outbreak.[53] These SRs are very infrequent. In serological surveillance programs for SVD, about 1 in 220 tested samples yields positive by standard monoclonal antibody-competitive (MAC)-ELISA, and the gold standard VNT detects 1–3 SRs every 1000 sera tested. This low but consistent frequency of false-positive reactions is a common problem, provided that surveillance programs for SVD often analyze thousands of samples in some instances. The presence of an SR in a herd imposes restriction of movements to the farm in which it is found, leading to disruption of control measures and eradication programs and imposing quarantine restrictions to farms and bans for international trade.[53] The SR can be differentiated from true seropositive samples of infected pigs by resampling of the positive animals and their cohorts.[7] IgM class immunoglobulin is responsible for most SR reactions. The problem of SR can be reduced by applying a combination of VNT, MAC-ELISA, and isotype-specific ELISA.[73] The factors giving rise to SR sera are unknown; however, it seems likely that this condition is not due to a specific immune response to SVDV or other related viruses but to other responses resulting in a nonspecific IgM-mediated reaction.

Classical methods for identification of the virus rely on sandwich ELISA if sufficient antigen is present on the sample.[74] The antigen ELISA is the fastest and simplest test for SVDV detection in epithelium homogenates, where virus concentration is high enough to give a positive result in this test. However, the main drawback of this technique is its low sensitivity, making it unsuitable for the analysis of other types of samples. In particular, more sensitive tests are required for detection of SVDV in fecal samples, often the only available sample for virological diagnosis, since very frequently the infection courses without the development of vesicles/skin lesions. Virus isolation is the reference *gold standard* for virus detection and is used as a confirmatory method if a positive antigen ELISA or RT-PCR result is not associated with the detection of clinical signs of disease, the detection of seropositive pigs, or a direct epidemiological connection with a confirmed outbreak. If any inoculated culture subsequently develops a cytopathic effect (CPE), the demonstration of SVD antigen or genome in the culture supernatant by ELISA or by RT-PCR will suffice to make a positive diagnosis.[7]

The virus can be isolated from epithelium of skin lesions, fecal homogenates, and vesicular fluids. For this, the clarified homogenates are inoculated on monolayers of IB-RS-2 cells[75] or other susceptible porcine cells (SK6, PK-15), and these are examined daily for the development of CPE, for 2–3 days. The virus, if present in feces, is often found in small amounts, so its isolation from this type of sample often requires 2–3 successive blind passages and may be affected by other interfering enteric viruses that are highly prevalent in pig fecal samples.[76,77] If CPE is not observed after three blind passages, the sample is considered negative in virus isolation. The supernatant of the cell culture showing CPE is harvested and virus identification is performed by ELISA or RT-PCR.

11.1.5.2 Molecular Techniques

Several highly specific and sensitive RT-PCR techniques have been developed to detect SVDV RNA either in conventional and real-time formats, some of them enabling the simultaneous differentiation from FMDV and vesicular stomatitis virus (VSV).[55,64,78–83]

A recent development for multiplexing diagnosis is the nucleic acid–based multiplexed assay for detection of FMDV and ruling out for six other animal diseases that cause vesicular or ulcerative lesions in cattle, sheep, and swine (including SVD), based on a combination of magnetic bead-flow cytometry technology (Luminex) and RT-PCR.[84] Another approach in this regard uses solid-phase (chip) microarray technology combined with RT-PCR to address multiplexing of all the range of vesicular disease viruses.[85] This method enables the efficient detection and differentiation, including correct molecular serotyping of all known serotypes of FMDV, the two known serotypes of VSV and SVDV simultaneously.

Given that SVD has been occurring almost exclusively as a subclinical disease for a number of years, suitable samples for virus detection are feces, for which no differential diagnosis is required in relation to vesicular conditions. In fact, the unique molecular assay extensively validated in field conditions, particularly with feces samples, is the conventional one-step RT-PCR reported as reference test in the OIE manual.[7]

11.1.5.3 On-Site Devices

"On-site" or portable devices have also been incorporated to the range of SVDV diagnostic tools. These devices are sought aiming at enabling rapid virus detection and identification at the farm level, thus saving time from the first suspicion of the disease to its confirmation and the application of control measures.

A lateral flow device ("pen-side test") has been developed that showed a good performance in the detection of SVDV antigen in vesicular fluids and cell culture passage-derived supernatants.[86] Portable devices allowing "on-site" RT-PCR analysis have been developed and tested for its performance on detecting FMDV genome,[87] which could be suitable also for detection of other vesicular diseases, including SVDV, in the same setting, provided that there are RT-PCR techniques (specifically, fluorescence-based real-time formats are of particular utility in this regard) of enough sensitivity and specificity available. As explained in Section 11.2, there are a number of real-time RT-PCR techniques available for SVDV diagnostic, and their adaptation to portable devices should not be a problem. On the other hand, loop-mediated isothermal amplification (LAMP) assays provide some advantages in this regard with respect to classical or real-time RT-PCR methods, since they are faster and do not rely on expensive equipment such as portable thermal cyclers, providing robust performance in modestly equipped laboratories, as can be the case for field stations or mobile diagnostic units. A LAMP assay for the detection of SVDV has been recently developed,[88] although it needs to be improved in order to be able to detect all the circulating subgenomic lineages.

11.2 METHODS

11.2.1 Sample Collection and Preparation

11.2.1.1 Sample Collection

Samples of vesicular fluids and portions of vesicular lesion tissues are the target samples for SVDV detection if clinical signs of vesicular disease are present. These should be collected separately and aseptically in sterile containers from individual pigs. Virus load in vesicular fluids and lesions are typically high (usually in the range of 10^8–10^9 $TCID_{50}$/mL), and proper measures to avoid any material contamination should be taken.

Fecal samples are the specimen of choice in case subclinical SVD is suspected, which can be collected from individual pigs or from the floor of premises suspected to contain, or to have contained, pigs infected with SVDV. Although the amount of virus present in feces is usually low (<10^4 $TCID_{50}$/mL), it may be excreted by this route for up to 3 months after infection,[7] being suitable for RT-PCR analysis.

The procedure for selecting tissues and organs for virus isolation as described in Section 11.1.5.1 is used for collection of samples for molecular analysis. Samples from the muscle of infected pigs and certain uncooked pig products may also be needed to undergo testing in order to assess the presence of SVDV (see Section 11.1.3.3) and should be processed in the same way.

Once under the adequate biosafety laboratory facilities, a suspension of each individual sample (vesicular lesions, feces, organs) is prepared by grinding the sample using a sterile pestle and mortar adding a volume of sterile phosphate buffered saline or tissue culture medium and antibiotics enough to get a 10% homogenate. The homogenate is vortexed and further clarified by centrifugation at 2000 × *g* for 20–30 min, and the supernatant is collected for analysis, which should be previously filtered through a 0.45 μm filter. The treated samples are conveniently labeled, aliquoted, and stored refrigerated while diagnostic analysis is ongoing; the remaining material should be preserved and properly identified in an adequate freezer, preferably below −70°C.

11.2.1.2 Viral RNA Extraction

In the past, the viral RNA extraction was performed by the traditional organic procedure using phenol-chloroform and further alcoholic precipitation, which has been displaced by a variety of current commercial kits based on chaotropic salt lysis and silica nucleic acid affinity. Even more, the RNA extraction step can be achieved by manual or automated systems obtaining good quality RNA templates, which remove successfully the polymerase chain reaction (PCR) inhibitors present in the starting specimen.

Apart from the commercial kits mentioned earlier, the RNA can also be extracted by a virus immune-capture using an SVDV-specific monoclonal antibody (MAb) followed by guanidine thiocyanate lysis and ethanol precipitation.[89] This immune-capture technique has been shown to be effective with fecal samples enabling the immune-purification of the virus and the overthrow of PCR inhibitory substances; the procedure is described in detail in the following.

An ELISA plate is coated with SVDV-specific MAb 5B7 at saturated concentration diluted in a carbonate–bicarbonate solution (200 μL/well) and incubated overnight at +4°C. After the plate wash, each sample (feces suspension) is distributed into three wells (200 μL/well, 600 μL of sample in total). After 1 h incubation at 37°C with slow shaking, the plate is washed manually to avoid cross-contamination. The viral lysis is performed by adding approximately 100 μL/well of lysis buffer (4M guanidine thiocyanate, 25 mM sodium citrate, pH7, 0.5% SarKosyl). After 3–5 min incubation, the sample from the three wells (300–350 μL) is collected and transferred in a single tube. RNA is then precipitated by a classical ethanol precipitation protocol and then resuspended in 20 μL of RNase-free water.

RNA from homogenates of vesicular fluids or tissues is extracted using the QIAamp viral RNA kit (Qiagen, Hilden, Germany) following the manufacturer instructions.

11.2.2 Detection Procedures

Several molecular methods have been developed for SVDV detection (see Section 11.1.5.2), although RT-PCR technique is so far the most widely used for routine diagnostic purpose. Due to its high sensitivity and specificity, RT-PCR can be applied to any diagnostic specimen where SVDV presence is suspected. Several gel-based and real-time RT-PCR methods have been described for SVDV detection targeting different viral genome regions. Generic tests targeting conserved genome regions, such as 5′ NCR (noncoding region) or 3D gene, are preferred for diagnostic analysis to cover the range of viral genotypes. Methods amplifying variable genome regions, such as VP1 coding gene, are selected for further sequencing and molecular characterization of SVDV isolates. In this section, one conventional and one real-time RT-PCR assays for SVDV screening detection are described in detail.

11.2.2.1 Conventional RT-PCR Amplifying a 3D Gene Fragment

The described SVDV conventional RT-PCR method uses a primer set (SS4/SA2) designed in a highly conserved region within the viral 3D gene,[78] which ensures the detection of a wide range of SVDV isolates. This primer set amplifies a DNA fragment of 154 base pairs (bp), located from the nucleotide position 6875–7028 of the SVDV reference strain UKG 27/72 (GenBank accession no. X54521). The nucleotide sequences of the primers are described in Table 11.2.

In detail, the RT-PCR is performed using the commercial one-step RT-PCR kit (Qiagen, Hilden, Germany). RT-PCR mix is prepared in a final volume of 25 μL containing 2–5 μL of RNA sample, 1× one-step RT-PCR buffer, 1× Q solution (optional, but recommended if more specificity is needed), 0.2 mM dNTPs, 0.6 μM each forward and reverse primer (SS4/SA2), 0.2 U/μL RNAse inhibitor, 1 μL one-step RT-PCR enzyme mix. RT-amplification is then carried out in a single-tube one-step assay with the following incubation

program: 30 min at 55°C, 15 min at 95°C, 40 cycles at 94°C for 30 s, 57°C for 30 s and 72°C for 30 s, and a final extension step of 72°C for 7 min. Amplification products are then analyzed by electrophoresis on a 2% agarose gel containing 0.5 μg/mL ethidium bromide or other suitable DNA-intercalating agent such as GelRed™.

In a comparative study on positive fecal samples from many different outbreaks, the one-step RT-PCR showed the best performances with regard to the capability to reveal all the circulating genomic sublineages, with respect to the real-time RT-PCR targeting the 5′ NCR (described in the following section) and an RT-LAMP.[90]

11.2.2.2 Real-Time RT-PCR Amplifying a 5′ NCR Fragment

The real-time RT-PCR method described in this section for SVDV detection employs a primer set (SVD-2B-IR252-F/SVD-2B-IR332-R) and a specific TaqMan probe (SVD-2B-IR289-P) directed to the highly conserved 5′ NCR of the viral genome, allowing as well the detection of a wide range of SVDV isolates.[55] The primers define a short DNA fragment of 81 bp, located from the nucleotide position 252–332 of the SVDV reference strain UKG 27/72 (GenBank accession no. X54521). TaqMan probe employed for amplified product detection is labeled with a reporter at 5′ end [6-carboxyfluorescein (FAM)] and a quencher at 3′ end (6-carboxytetramethylrhodamine).

Since feces contain a high level of PCR inhibitors and are the main target sample for the molecular diagnosis, the incorporation of an internal control in the PCR analysis is highly recommended to avoid false-negative results. This could be an endogenous gene such as the β-actin, which can be detected at the same time than SVDV in a duplex RT-PCR test, like the method described here. Specifically, a primer set and a TaqMan probe described for the amplification of a 136 bp DNA fragment of the β-actin gene[91] are added to the RT-PCR mix to carry out the simultaneous and differential detection of both SVDV and internal control in a single tube. To this end, the TaqMan probe for the internal control is labeled with a different reporter dye, and in this case, ROX (6-carboxy-X-rhodamine) is selected for the 5′ end and a black hole quencher for the 3′ end.

Sequences of primers and probes are described in Table 11.2. In detail, the duplex RT-PCR is performed using the commercial *QuantiTect Multiplex RT-PCR NR kit (Qiagen, Hilden, Germany)*. RT-PCR mix is prepared in a final volume of 25 μL containing 5 μL of RNA sample, 1× QuantiTect Multiplex RT-PCR Master Mix, 0.9 μM SVD-2B-IR252-F forward primer, 0.3 μM SVD-2B-IR332-R reverse primer, 0.2 μM SVD-2B-IR289-P probe, 0.2 μM each β-actin forward and reverse primers (ACT-F1005-1029/ACT-R1135-1114), 0.1 μM ACT-P1081-1105 probe, 0.2 U/μL RNAse inhibitor, and 0.25 μL QuantiTect Multiplex RT Mix. RT-amplification is then carried out in a single-tube one-step assay with the following incubation program: 30 min at 50°C, 15 min at 95°C, and 45 cycles at 94°C for 15 s, and 60°C for 60 s. Amplification products are detected by fluorescence reading at the end of each cycle in FAM (SVDV) and ROX (β-actin) channels.

11.2.2.3 Molecular Characterization of SVDV Isolates

All SVDV isolates are classified so far in a single serotype, though four genetic groups can be differentiated based on genome sequence variability.[39] Sequencing of the viral 1D gene, coding the major structural protein VP1, and further sequence comparison to other SVDV isolates allow establishing epidemiological relationships between viral isolates, inferring the most probable origin of a disease outbreak and tracing the evolution of an epidemic.

Amplification of the viral 1D gene for further sequencing can be achieved by conventional RT-PCR test using primers (GSVD-3/NK44) described in Table 11.1, defining a 980 bp DNA fragment. The amplified product can be directly sequenced by employing the same primers or using internal primers (GSVD-3/GSVD-5) to refine the sequencing to a shorter fragment of 613 bp.

Phylogenetic analyses based on sequences of a portion of the 3D gene (RNA-dependent RNA polymerase) show

Downloaded From Vet-eBooks.com

clusterization of SVDV isolates overlapping with that obtained with 1D sequences.[92]

The databases of 1D and 3D gene sequences of SVDV isolates are held at the OIE reference laboratories (Pirbright, UK; Brescia, Italy).[7]

11.3 CONCLUSION AND FUTURE PERSPECTIVES

SVDV is the causative agent of the disease of pigs whose clinical resemblance to FMD highlights the need for its accurate identification and discrimination. This fact imposes severe restrictions to the movements of pigs for which convincing evidence of being free from the virus (or of antibodies raised to it) is not provided. This poses a significant burden for the trade of these animals, and for this reason, the disease may cause severe economic losses for the producers, even though it is in fact a mild disease from the clinical point of view. Differentiation from FMD, though not possible clinically, is feasible if appropriate diagnostic tests are applied. Improvement of the diagnostic techniques is making differential diagnosis of vesicular diseases more and more affordable, feasible, and easy, and nowadays, portable devices allow a rapid and accurate differentiation of SVDV from FMDV infections on-site. As these tests become affordable and availability of competent laboratory services become more and more accessible, the constraint originally imposed to SVD due to its similarity to FMD will lose its sense. This, together with the fact that in recent years SVD is predominantly asymptomatic, makes necessary to rethink the measures currently in place for the control of SVD.

12.1 INTRODUCTION

Astroviruses are small, round, nonenveloped viruses typically 25–35 nm in diameter with a positive-sensed, single-stranded RNA genome ranging in length from approximately 6.2 kb (human) to 7.7 kb (duck).[1] They are generally classified according to the species they infect, although species cross-over has been observed for some astroviruses, for example, astroviruses of chickens have been detected in turkeys.[2] Astroviruses have been discovered to infect many species including humans. The first observations of astroviruses in humans were in 1975 in the feces of children with diarrhea and gastroenteritis by Appleton and Higgens[3] and Madeley and Cosgrove, who named this group of viruses because of its characteristic star-like appearance.[4]

12.1.1 Classification

Astroviruses are classified in the family *Astroviridae*, with species infecting mammals forming the genus *Mamastrovirus* while those infecting birds forming the genus *Avastrovirus.* Currently, at least six species are identified in the genus *Mamastrovirus*, including bovine astrovirus (BAstV), feline astrovirus (FAstV), human astrovirus (HAstV), mink astrovirus (MAstV), ovine astrovirus (OAstV), and porcine astrovirus (PAstV). These viruses have been detected in the feces of cattle,[5,6] sheep,[7,8] deer,[9,10] pigs,[11,12] dogs,[13,14] mink,[15] sea lions,[16] rabbits,[17,18] rodents,[19,20] and bats.[21] For a recent review of human and mammalian astroviruses, see *Astrovirus Research, Essential Ideas, Everyday Impacts, Future Directions*.[22]

Classification of avian astroviruses is still somewhat in its infancy and, to date, only six different astroviruses are recognized as belonging to the *Avastrovirus* genus by the International Committee on Taxonomy of Viruses. The first report of disease caused by astroviruses was in ducklings in 1965;[23] however, it was not until the mid-1980s that it was recognized as an astrovirus by electron microscopy (EM).[24] This virus is referred to as duck hepatitis virus 2 (DHV-2) in older papers[25] but was reclassified as duck astrovirus serotype I (DAstV-1) more recently. A second avian astrovirus of ducks, antigenically and genetically distinct from DAstV-1, that also causes hepatitis in ducklings was reclassified as DAstV-2 after being previously known as DHV-3.[26]

There are two astrovirus species both associated with growth problems and kidney lesions in chickens. The first of these was isolated from a 1-week-old, normal broiler chick in 1976[27] and was subsequently termed avian nephritis virus[28] (ANV), but was originally described as a picornavirus and only later recognized as an astrovirus.[29] A second astrovirus species of chickens was discovered in 2004 and named chicken astrovirus[30] (CAstV), but earlier isolations of similar strains were described as enterovirus-like viruses.[26,31] Two astrovirus species were discovered in turkeys (TAstV): the first, turkey astrovirus serotype 1 (TAstV-1), in the UK in 1980[32] and the second, TAstV-2, was described in 2000.[33] In addition, avian astroviruses have been discovered in the feces of a number of wild birds including robins, shrikes, and great tits.[34]

Downloaded From Vet-eBooks.com

Sections 12.1.4.2 and 12.2.2 will focus on members of the *Avastrovirus* genus, although much of the understanding of the generalized features of astroviruses relating to morphology and biology have been derived from studies into human astroviruses and are assumed to also extend to avian astroviruses with some corroborative evidence.

12.1.2 Structure, Biology, and Epidemiology

Astroviruses are relatively simple viruses that share a generalized arrangement, in terms of both their component structures and their genomes. Astrovirus genome consists of only three open reading frames (ORF), the first two of which, ORF 1a and ORF 1b, encode nonstructural proteins including a protease (ORF 1a) and an RNA-dependent RNA polymerase (ORF 1b). The third ORF, ORF 2, encodes capsid protein, which is the most variable region of the genome, especially in the 3′ half.[35] There is a short 5′ untranslated region (UTR) prior to ORF 1a and a longer 3′ UTR after ORF 2. A polyadenylated tail at the extreme 3′ region completes the positive-sensed RNA genome, which, similar to messenger RNA, can be directly translated within the host cell.

While all astroviruses share this genetic arrangement, there are differences between species including overall genome length, the length of individual ORFs, and the frames in which the genomic or subgenomic transcripts are translated. In each arrangement exists a heptameric ribosomal frameshift signal (AAAAAAC) at the 3′ end of ORF 1a similar to those identified in retroviruses.[36] ORF 1b is in a different (+1) reading frame and the frame of ORF 2 determines which of three genomic arrangements the virus possesses: in ANV-like astroviruses, ORF 2 is in the same frame as ORF 1a; in CAstV-like genomes, ORF 2 is in the same frame as ORF 1b; and in DAstV-like astroviruses, ORF 2 is in a different reading frame to the preceding ORFs.[37]

Other notable sequences within the avian astrovirus genomes include a highly conserved 43-nucleotide-long s2m RNA stem-loop motif located at the 3′ end of the genome, which is also found in members of the *Mamastrovirus* genus, and picornavirus, calicivirus, and coronavirus families including SARS.[38] It appears to be one of the few mobile genetic elements found in viruses, and while its function is currently under investigation, the lack of the s2m motif in TAstV-2[33] and in certain mammalian astroviruses[20,21] would imply that it is not critical to astrovirus infection. There are short, conserved motifs in the 5′ UTR and in the region immediately upstream of ORF 2, which are possible promoter signals controlling transcription of the genomic and subgenomic messenger RNAs, respectively.

The morphology of astrovirus particles was originally observed by negative-stain EM of human astrovirus when a distinctive 5- or 6-pointed, star-shaped appearance was observed in about 10% of fecal preparations[3] (Figure 12.1). This characteristic morphology gave rise to the name astrovirus, from the Greek word *astron*, meaning stars. The star-like appendages are attributed to the capsid spikes that protrude from the capsid of the virion, which possesses a $T = 3$ icosahedral capsid symmetry comprised of 180 capsomers. The capsomers and spikes are formed from the translated product of ORF 2, VP90, which is matured posttranslationally by cleavage of VP90 into smaller subunits by cellular caspases[39] and the viral protease encoded in ORF 1a. Analysis of the capsid precursor protein across a range of human, avian, and animal astroviruses reveals a relatively conserved N terminal region from residue 1 to 415 followed by a hypervariable C terminal region.[35,40,41] The N terminus contains the protein region responsible for capsomer formation and ultimately capsid assembly, which requires a higher degree of stability out of functional necessity and therefore puts it under evolutionary restraint while the hypervariable C terminus, cleaved into smaller proteins, comprises the spikes, which interact with the hosts' immune systems; thus, genetic divergence to evade immune activity is advantageous.

Since some astroviruses can prove difficult to adapt to grow in cell culture, for instance, ANV, virus isolation is unsuitable and inconvenient as a diagnostic approach in most cases. Furthermore, since the characteristic star-like conformation is absent from many preparations of astroviruses, EM is also not a reliable tool for the diagnosis of avian astroviruses. Therefore, the majority of epidemiological data for avian astroviruses has been serological and, more recently, molecular in nature and predominantly relates to commercially farmed poultry especially chickens, ducks, and turkeys.

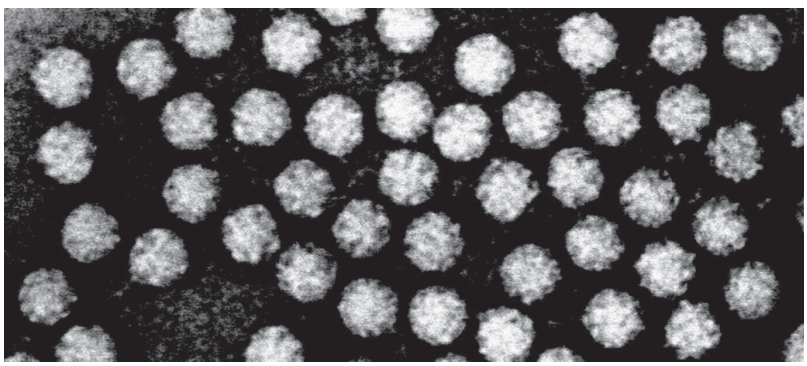

FIGURE 12.1 Negatively stained electron micrograph of turkey astrovirus displaying the characteristic star-like appearance. This morphology may not be present in most avian AstV preparations.

Downloaded From Vet-eBooks.com

The presence of ANV in commercial poultry was identified much earlier than that of the distinct astrovirus species, CAstV. An indirect immunofluorescence (IIF) test for ANV serotype-1 (ANV-1) was developed and used to screen historical sera from Japanese broiler flocks finding an incidence of 12%–17% in 35%–62% of flocks from 1975 to 1978.[42] A serological survey of small numbers of historical sera (1975–1983) from 139 farms in Northern Ireland (NI) comprising broilers, broiler breeders, and layer chickens detected ANV in 135 farms, many with 100% detection rate.[43] Additionally, two-thirds of nine NI turkey flocks were also found to have seroconverted against ANV by IIF.[43]

A seroprevalence investigation of four generations of commercial chickens from great-grandparent (GGP) to broiler flocks in the United Kingdom for two strains of CAstV with low cross-reactivity by IIF, and which belong to separate CAstV genogroups, CAstV A and CAstV B, according to capsid–RNA sequence determination,[35] found the widespread presence of both strains (CAstV A 96%, CAstV B 93%) in 24–28 broiler breeder flocks aged 23–26 weeks from three organizations, and in 78% of the serum samples from 10 broiler flocks, 100% of which contained positive sera.[44] Antibodies to CAstV were also found in pooled serum samples from 25 parent flocks from eight countries spread across Northern, Western, and Eastern Europe.[44] This study also found that CAstV infections were less common in UK GGP (21%) and GP (28%) flocks than in the broiler and parent flocks.

Although serological tests such as IIF and ELISA continue to be useful tools in the detection and surveillance of avian astrovirus infections in poultry, there are limits to their usefulness as they may not detect different serotypes.[45] Since the late 1990s, there has been a move to the use of molecular tests such as reverse transcription polymerase chain reaction (RT-PCR) to diagnose the presence of these viruses in flocks based on specific genetic sequences of the viral genomes, which can be designed for broad detection across genotypes. Initially, the tests detected single species of astrovirus, for example, RT-PCR tests based on the conserved ORF 1b and variable ORF 2 of TAstV demonstrated the widespread presence of TAstV in flocks affected with poult enteritis and mortality[46] across the United States and also in turkey and guinea fowl flocks from northern Italy, which, when the PCR products were identified by DNA sequencing, were similar to TAstV-2.[47]

More recently, molecular tests have been designed to detect the presence of multiple enteric viruses including different astroviruses simultaneously (TAstV-1, TAstV-2, CAstV, ANV, and avian rotavirus)[2,48,49] and have been used to monitor chicken and turkey flocks in the United States, where astroviruses, especially TAstV-2, appear widespread.[2,50,51] While TAstVs are associated with diarrhea and enteritis in young poults, in common with other avian AstVs, they are also detected in apparently healthy flocks as well as those with reduced performance.[50] Although the application of molecular tests has improved the sensitivity of diagnosis of TAstV-2 compared to more traditional techniques such as EM,[50] there is little information available comparing prevalence of TAstV-2 in healthy versus affected flocks, but a recent study by Jindal et al. reports that enteric viruses including TAstV-2 have a lower prevalence in healthier flocks.[52]

In contrast to other avian AstVs, which are not typically associated with mortality, infections by the two known AstVs of ducks, DAstV-1 and DAstV-2, are reported to cause a fatal hepatitis in young ducklings. Infections by DAstV-1, previously known as duck hepatitis virus II, have resulted in losses of up to 50% in commercial duck farms in the United Kingdom[25] and China.[37] A limited serological survey of three commercial flocks in China reported DAstV-1 seroprevalence of 63% and 51% in two flocks that had experienced DAstV-1 infections, while a third flock that had not shown symptoms of a DAstV-1 infection had a seroprevalence of 28% with positive test values that were noticeably lower than those from the two diseased flocks.[53]

The application of specific molecular tests for TAstV-1, TAstV-2, CAstV, ANV, and DAstV (types 1 and 2) to organ samples from 22 Croatian duck flocks including duck embryos detected the presence of TAstV-2, ANV, or CAstV in 13 flocks but did not detect the presence of DAstV or TAstV-1 in these samples. Of these, ANV was the most predominant AstV detected in 77% of the AstV-positive flocks.[54] A second study by this group subsequently identified the presence of TAstV-1 in duck embryos from two flocks, and ANV was detected in both duck and goose embryos from flocks affected by stunting and prehatching mortality.[55] Epidemiological data is not widely available detailing the cross detections of various AstVs in different species of poultry flocks, which raises the question of how to develop a robust yet cost-effective testing strategy for the thorough detection of several AstVs simultaneously in order to provide adequate surveillance of commercially important birds.

12.1.3 Clinical Features and Pathogenesis

Avian astroviruses are enteric pathogens transmitted by fecal–oral route along with other viruses and bacteria, which comprise the intestinal virome and microbiome. Being non-enveloped, AstVs are more resistant to cleaning and may be persistent in poultry houses where darkling beetles can act as vectors for them.[56] For example, CAstV has been detected by RT-PCR in washings from the surface of darkling beetles and from internal tissues.[56] Astrovirus infections usually occur within the first weeks of life, and some can also be vertically transmitted from naïve in-lay parent birds, and the earlier they are contracted the worse the outcome, although this will depend not only on the particular AstV species but also the specific strain of infecting AstV that can vary substantially in pathogenicity. Other important factors include the load (dose) of infectious virus received and the presence of other enteric pathogens.

Generalized clinical features of astrovirus infections are the association with enteritis and, in some cases, diarrhea. However, a number of avian AstVs are also associated with diseases of other organs including nephritis and hepatitis. While some outbreaks may be associated with high mortality,

Downloaded From Vet-eBooks.com

in general, mortality is low for the majority of avian AstV infections. Morbidity, giving rise to reduced weight gain, increased culling, impaired development (requiring longer rearing times), uneven flock performance, and poorer feed conversion rates, is a common problem causing substantial economic losses to commercial producers. In some instances, impaired weight gain can exceed 50% and may affect a significant proportion of a flock. There have been difficulties in trying to experimentally determine the nature and extent of the problems caused by individual AstVs in birds due to the more complex etiology of enteric diseases and the multifactorial conditions that are present in wild-type infections. In addition, many avian AstVs, for example, ANV, can prove difficult to isolate in cell culture causing further problems.

12.1.3.1 Avian Nephritis Virus

Although ANV is highly contagious, it typically results in subclinical infections of young broiler chicks; however, its clinical effects can range from subclinical to growth retardation to mortality. Histological changes occur primarily in the kidney as a result of ANV infections, causing lesions in the kidneys and, to a lesser degree, in the intestines, where small numbers of shrunken, degenerate epithelial cells were found near the base of the villi in 3–6-day-old chicks 1 day after oral inoculation with ANV-1.[57] The detection of ANV in other organs including the liver, pancreas, and spleen has also been reported.

Isolates of the G-4260 (aka ANV-1) and three other strains of ANV resulted in interstitial nephritis when orally inoculated into 1-day-old specific-pathogen-free (SPF) chicks.[58] A third of these chicks inoculated with G4260 died with visceral urate deposits, and all chicks inoculated with G4260 were significantly lighter than control birds and yet a second strain, termed IR-N, which was classified as the same serotype as G-4260, resulted neither in mortality nor in significant weight inhibition, which demonstrates the diversity in pathogenicity exhibited by different ANV strains. The two other strains, which were identified as a different serotype (ANV-2) to G-4260 based on levels of sequence diversity suggestive of serotypic differences, caused limited mortality and reduced weight retardation.[58] Subsequently, sequencing of the ORF 2 of ANV strains from problem flocks in the United Kingdom, Germany, and Belgium has identified four putative new serotypes based on similar levels of sequence differences that exist between ANV-1 and ANV-2, but no clinical information is available for these new serotypes.[41]

Recently, de Wit and colleagues reported on the isolation of 10 new ANV strains from chicken and turkey flocks suffering from runting–stunting syndrome (RSS) and locomotory problems over an 18-year period from Germany, the Netherlands, and United Arab Emirates, which cluster relatively tightly on the basis of shared amino acid identity of 93%–99% with the group representative, isolate 19.[59] The group is tentatively named ANV-3 since the closest match to published avian AstVs was 88% with ANV-1 by amino acid sequence although antibodies to isolate 19 have little or no cross-reactivity with ANV-1 and vice versa.[59] These strains were isolated from a variety of less common tissues including tracheas, cecal tonsils, tendons, and tibia of both turkeys and chickens, hock cartilage, joints, and synovial fluids suggesting that the tropism of this new ANV group may be wider than what has previously been observed for ANV-1 and ANV-2. Experimental inoculations of isolate 19 into 3-week-old SPF birds and the placing of noninoculated sentinel birds with the primary subjects resulted in limited diarrhea and some mortality, but the most common findings were interstitial nephritis and tubular degeneration although no symptoms were observed in the tendons.[59]

12.1.3.2 Chicken Astrovirus

CAstV was only recently recognized as a separate species from ANV when three similar isolates from Dutch broiler chicks with RSS were shown to be serologically distinct from ANV-1 and shared only 55% amino acid identity with ANV-1 in a region of the conserved nonstructural protein in ORF 1.[30] Subsequently, it has become apparent that, similar to other AstVs, there are many different strains of CAstV in circulation, again with varying degrees of pathogenicity and antigenic relatedness. These strains have been provisionally classified into two groups, CAstV A and CAstV B, according to a lower level of shared amino acid identity across ORF 2, where the hypervariable regions associated with antigenicity are located and which is supported by only a minor degree of cross-reactivity with the heterologous antisera.[35]

Similar clinical symptoms to those from ANV infections have been associated with CAstV infections of broiler flocks: diarrhea, enteritis, poor growth, and kidney disease. In addition, the involvement of CAstV in other symptoms such as poor feathering and clubbed down has been postulated but not conclusively demonstrated. In general, CAstV strains are not associated with mortality, but particular strains of CAstV, identified as a new subgroup of the CastV B group and designated Indian subgroup Bi, were implicated as the causative agent in outbreaks of visceral gout in week-old broiler flocks in India in 2011 and 2012 resulting in mortality approaching 40%.[60] Affected chicks presented with swollen kidneys, prominent ureters, visceral gout, and histopathological examinations revealed inflammation of the kidneys with necrosis and degeneration of epithelial cells in the proximal convoluted tubules.[60]

There is evidence also that some strains of CAstV may be vertically transmitted as in the case of the hatchability problem, "White Chicks."[61] This condition is characterized by weak, white chicks that fail to thrive and, since 2006, has led to increased embryo deaths annually and averaged a 29% reduction in hatchability in affected Finnish flocks over a brief period of about 2 weeks while the parent birds seroconverted against CAstV. Levels of CAstV RNA detected in the tissues of white chicks and dead embryos were high, while unaffected chicks were negative. The livers of white chicks were normal sized or smaller, greenish or mottled, with hypertrophic bile ducts. Inflammation was present in the heart, kidney, bursa, and perivascular tissue of the liver.[61] These strains have been identified also as a separate subgroup of CAstV B.[61]

Downloaded From Vet-eBooks.com

12.1.3.3 Turkey Astrovirus

There are two serologically distinct species of TAstV, types 1 and 2, which are both reported to be widespread in the United States, with TAstV-2 the more prevalent.[50] TAstV-2 is associated with two major disease syndromes affecting turkey production: poult enteritis complex or syndrome (PEC or PES) and poult enteritis mortality syndrome (PEMS).[33,50,52] Symptoms, which are generally mild to moderate, usually appear between 1 and 3 weeks and can last up to 14 days[62] and include diarrhea, listlessness, nervousness, litter eating, and, in keeping with other avian AstVs, reduced weight gain. Subclinical TAstV infections may occur in healthy flocks.

Poults experimentally infected with TAstV-2 presented with swollen intestines, watery and persistent diarrhea, transiently reduced bursa size in the first 9 days postinfection, and substantially reduced growth.[63] In a further experimental inoculation of 2-day-old SPF poults with three strains of TAstV-2 that were deemed representative of the three most commonly circulating TAstV-2 groups in a 2005 survey of U.S. farms, clinical features also included diarrhea and growth depression.[64] Additional observations included distended intestines containing watery contents and undigested feed, and dilated ceca with foamy contents. In the first 6 days postinfection, mortality of poults ranged from 15% to 25% for the three isolates and was associated with weakness arising from anorexia resulting from the poults' refusal to eat and drink.[64] The main histopathological findings were microscopic intestinal lesions of mild intensity, consisting of shrunken, degenerate cells in the villi and crypt epithelium and crypt hyperplasia with increased crypt depth. Mild villous atrophy and mild lymphocytic infiltration were most apparent in the jejunum; but inflammation was also observed in the pancreas, liver, spleen, and kidneys.[64]

12.1.3.4 Duck Astrovirus

There are two known AstVs of ducks, DAstV-1 and DAstV-2, which were previously termed duck hepatitis virus 2 and 3, respectively, and which were originally thought to be picornaviruses but were later shown to be AstVs: DAstV-1 firstly by EM diagnosis based on virion morphology[24] and both DAstV-1 and DAstV-2 by RNA sequence analysis of ORF 1b.[26] Both viruses can cause a fatal hepatitis in young ducklings, which in UK cases involving DAstV-1 infections in the 1980s resulted in losses of up to 50% up to 2 weeks of age and mortality of between 10% and 25% for ducklings aged between 3 and 6 weeks.[25] The ducklings died less than 2 h after the clinical signs first appeared and, although in good condition, many had opisthotonos. Symptoms included polydipsia and loose droppings that were whitish due to extreme urate excretion. The livers contained multiple hemorrhages and extensive necrosis of the hepatocyte cytoplasm was observed, as was bile duct hyperplasia. Blood vessels stood out strongly against the pale and swollen kidneys.[25]

Similar levels of 50% mortality in young ducklings were experienced in China in 2008 during an outbreak of duck hepatitis caused by DAstV-1[37] whereas low mortality rates were reported for two Chinese duck flocks recently infected by DAstV-1 at 3 weeks (4.67%) and 6 weeks (0.63%)[53] indicating a range of pathogenicities for different strains of DAstV-1 as seen with other avian AstVs. Reports of DAstV-2 infections appear less common than DAstV-1 and are reportedly less severe; however, an outbreak of duck hepatitis caused by DAstV-2 in the 1960s in Long Island, USA, resulted in losses up to 30%.[65]

12.1.4 Diagnosis

Astroviruses are one of a number of endemic viruses that can cause problems for the young of domestic poultry and are commonplace in commercial production units, although they are also present in subclinical infections. This complicates the process of diagnosis since the development of disease can be affected by a combination of factors, such as the susceptibility of breeds; the age of the birds when infected; the dose of virus they experience; the quality of their feed, which may promote or undermine their underlying gut health; and the combination of enteric pathogens they experience, including those that may be transmitted vertically as well as horizontally acquired infections. It may prove helpful to quantify specific AstV species and, where possible, identifying specific genotypes, and comparing these to known strains of clinical significance, is recommended.

12.1.4.1 Conventional Techniques

Astroviruses were first discovered in 1975 by the use of negative-contrast EM[3], and EM continued to be used to identify those avian AstVs that display the characteristic star-like morphology including TAstVs and DAstV-1[25,32] until the development of sensitive molecular tests from the late 1990s onward, which have largely replaced EM for routine diagnosis. There are difficulties with using EM directly on samples since not all AstVs are star-shaped and many preparations are indistinguishable from those containing other small, round viruses, and positive identification relies on the experience of trained operators. This process is time consuming, labor intensive, and relatively insensitive, so it is not suitable for testing large numbers of samples, although sensitivity can be enhanced by firstly propagating the virus in embryonated SPF eggs or, in some cases, primary cells, such as chick embryo liver cells, using purified sample homogenates.

The number and variety of conventional tests for diagnosis of specific astroviruses are relatively small, which is in part due to difficulties in producing convenient diagnostic tests through the limited availability of specific antibodies. An immunofluorescence (IF) test was developed and diagnosed the presence of DAstV-2 (DHV-III) virus in various tissues from experimentally infected ducklings,[66] and an indirect IF (IIF) test was used to examine the localization and intensity of the presence of ANV antigen in kidney and other tissues.[27,28] More recently, IIF tests were developed for detecting the two major groups of CAstV, Groups A and B, from chicken tissue samples.[35] However, these tests are labor intensive and required skilled operators to interpret the results,

Downloaded From Vet-eBooks.com

so more convenient tests have been developed, such as the enzyme-linked immunosorbent assay (ELISA), which can be automized to some degree and has the added benefit of more objective quantification through the analysis of optical densities by a colorimeter, which does not require subjective operator interpretation. An antigen-capture ELISA was described in 2005 for the detection of TAstV-2 antigen from fecal matter or gut contents,[48] but with limited availability of antibodies and a shift toward molecular detection of virus in recent years, most of the ELISAs developed have been produced to detect astrovirus antibodies in sera, which is a more convenient way to screen sera than the use of serum neutralization tests.

An ELISA for the detection of antibodies against ANV-1 was reported in 1991 using the G4260 strain grown in cell culture.[67] However, poor and inconsistent propagation of some avian AstVs in cell culture has led to an increase in the use of recombinant protein expression technologies to produce viral antigen. Recombinant protein technology has since been used to produce artificial viral antigen for two separate ELISAs for detection of CAstVs more recently[68,69] and also for DAstV[53] and for a Chinese-prevalent ANV strain that is genotypically different to both ANV-1 and ANV-2.[70] However, ELISAs based on single strains are unlikely to detect the full range of serotypic diversity exhibited by most AstVs.

12.1.4.2 Molecular Techniques

In keeping with diagnostic test development for other viruses, there has been a move toward the use of molecular techniques to provide rapid and sensitive results. One of the limitations when designing molecular tests is that they rely on available genetic sequence information, so in general, a test will only be as good at detecting diverse strains of a virus as the sequencing data that is available at that time. The first RT-PCR tests for TAstV were published in 2000, which detected the presence of TAstV RNA in samples from poults affected by PEMS.[46] The authors produced a pair of primers within the highly conserved ORF 1b region and a second pair in the more variable ORF 2 region, which is a useful strategy generally for avian AstVs depending on whether the primer pair is used to detect a wide range of strains, in which case a conserved region is better, or for amplification of very specific strains then a variable region would be recommended.

However, the level of sequence diversity is so extensive in avian AstVs, even within some relatively conserved nonstructural regions, that for broad coverage, it is necessary to compare the sequences of many strains and may also require the use of degenerate primers to detect as many different strains as possible. In primer regions, where different strains have different nucleotides at one or more sites, two or more individual primers can be produced, each containing one of the variant DNA nucleotides at a particular site, and these variant primers are then combined into one degenerate primer mix so that all variant permutations are covered. In degenerate primer nomenclature, these variant positions are given unique International Union of Pure and Applied Chemistry codes, for example, a cytosine or thymine at a single nucleotide position is denoted as a "y." The high levels of sequence diversity exhibited by astroviruses complicate primer design and, in some instances, a compromise between specificity and sensitivity may be required as primer locations may, by necessity, be restricted to more conserved areas that may not be the most sensitive. Empirically, testing several pairs of primers within conserved areas in order to compare performance is therefore advisable.

12.2 METHODS

The molecular methods for detecting avian astroviruses covered in this section are all PCR based and comprise conventional RT-PCR and real-time, quantitative RT-PCR (RT-qPCR). The workflow consists of sample preparation, RNA purification, and application of avian AstV RT-(q)PCR tests to the purified RNA. The choice of sample and the format in which it is sampled, for example, tissues, swabs, and fecal matter, will depend not only on the specific virus and its known tropism but also on the age of the birds; in general, AstV infections of poultry may only be detected for 2–3 weeks in the tissues but will be excreted for longer in fecal matter. To screen flocks for the presence of avian AstVs, especially more expensive and longer-lived birds such as GPs, the use of cloacal swabs is recommended or boot swabs could also be used, which are noninvasive and require less sampling to achieve adequate flock coverage.

12.2.1 Sample Preparation

Avian AstVs can be detected in a number of tissues, organs, and embryos in addition to intestinal contents and feces, all of which can be stored frozen at −20°C, or small amounts may be smeared onto FTA cards and stored in the short term at either +4°C, which is preferable, or at room temperature, which provide a convenient matrix for transportation. FTA cards are suitable for viral RNA preservation but appear to inactivate the virus making them unsuitable for virus isolation. In addition, the quality and quantity of recovered RNA may be less than that from fresh or frozen sample material, making FTA cards less suitable for large amplicons such as the capsid gene in ORF 2, although small amplicons can be successfully generated, which makes this substrate useful for real-time RT-qPCR tests. Cloacal swabs and fabric boot swabs have been successfully used for sampling of avian AstVs, although there is some debate as to whether wooden handled swabs contain substances that can inhibit the PCR process. Suitable tissues for sampling, in addition to feces, are described in Table 12.1.

Single or pooled swab tips are cut off and immersed in the minimal amount of room temperature phosphate buffered saline (PBS, pH7.2) needed to just cover them in a suitably sized container (0.5–5 mL depending on numbers and size of swab tips) for 15–30 min, followed by the addition of glass beads (5–10) and vortexing to produce a homogenate, which is then decanted for testing. Bootswabs, single or pooled in a small container, for example, beaker, are soaked in the minimal amount of PBS to cover them and incubated as for

Downloaded From Vet-eBooks.com

TABLE 12.1

swabs with occasional stirring. The homogenates may require centrifugation for 10–30 min at 2000 × *g* if the preparation still contains much solid matter after vortexing or stirring. Intestinal contents, meconium and feces, are made into a 10% homogenate in PBS (weight to volume), and then shaken vigorously or vortexed with glass beads and may require centrifugation as described to clarify. A small amount of tissue, ground in a mortar and pestle with a thin layer of sterile sand, is made into a 10% homogenate in PBS (weight to volume) and centrifuged as described earlier, which removes the sand and unground tissue. All supernatants are retained for use in testing.

12.2.2 Detection Procedures

Before molecular tests can be applied, the viral RNA must be purified from the clarified sample homogenate. Two of the most popular methods involve the use of proprietary RNA extraction kits that are either cartridge based or use the phenol–chloroform method. The advantage of the first method is that the RNA is conveniently eluted as a solution, which does not require further dissolving, but it is relatively expensive. The phenol–chloroform method is less expensive but requires dissolving a pellet of RNA, which, due to the minute amounts of RNA that are generally purified from these small viruses, is extremely small and practically invisible, making it difficult to dissolve by vigorous pipetting. Heating the RNA solution to 55°C for 10 min after the pipetting and then storing at −80°C for a few hours, preferably overnight, improves the RNA solubility. The amount of RNA obtained from avian AstVs is generally at subpicogram levels and therefore not readily quantifiable.

The choice of molecular tests for the detection of avian AstVs depends largely on the purpose for which the test is being run, for instance, a simple flock screening tool could make use of short amplicons in conserved regions to provide a broad detection range by either conventional RT-PCR or real-time RT-qPCR, whereas AstV phylogeny is probably most informative based on the highly variable ORF 2; the most reliably conserved regions within which to site primers are at the extreme 5′ and 3′ ends of the ORF, which produces a large amplicon greater than 2 kb.

Since the high degree of sequence variability typical of avian AstVs makes it difficult to design RT-PCR primers that can detect all strains from a particular species, a primer pair that can detect multiple strains from several species is all the more remarkable. Based on the relatively conserved ORF 1b, the degenerate primers AstVpol-For (5′-GAYTGGACIMGITAYGAYGGIACIATICC-3′) and AstVpol–Rev (5′-YTTIACCCACATICCRAA-3′) will amplify a fragment of approximately 434 bp, corresponding to nucleotides 3799–4233 in the genome of the G4260 strain of ANV-1 (GenBank accession no. AB033998) and allow detection of strains of ANV, CAstV, TAstV, and DAstV. This procedure can be used as a screening tool for unknown AstVs by conventional, gel-based PCR.[26] Furthermore, Tang and colleagues also designed a degenerate RT-PCR test (TAP-L1 and TAPG-R1) that generates a 597 bp fragment, corresponding to nucleotides 3550–4147 of the ANV-1 sequence, from TAstV-1, TAstV-2,[48] and ANV. But a similar drawback of both assays is their inability to distinguish which avian AstV has been detected without performing DNA sequencing on the amplicons.

A multiplex RT-PCR test has been designed that can detect TAstV-1 and TAstV-2 and ANV as well as avian rotavirus simultaneously in one reaction and differentiates on the basis of amplicon size;[49] therefore, sequencing of the amplicon is not necessary. A similar assay was designed to detect and distinguish ANV, CAstV, and avian rotavirus by the same authors.[49] A drawback of these tests is that they are relatively insensitive for all of the AstV species compared to the rotavirus, which, as the authors speculated, may be due to the use of degenerate primers for the AstVs but not for the rotavirus.[49] These multiplex assays were developed for use in flock screening where they suggest that lower sensitivity is less of an issue.[49]

In addition to the degenerate and multiplex assays, a number of conventional RT-PCR tests have been published for the detection of ANV,[71,72] CAstV,[73] DAstV,[55] and TAstV,[46,47] which are useful for screening of flocks. In addition, real-time RT-qPCR tests have been developed for both ANV and CAstV,[74] which can provide quantitative information regarding viral loads that may be helpful in determining the stage of infection and can shed light on whether infections are vertically or horizontally acquired. Another factor that can be helpful when investigating the clinical significance of an avian AstV infection is to determine which strain is present, and RT-PCR tests have been published that amplify all or part of the most variable region of the genome, ORF 2, including ANV,[41] CAstV,[35] DAstV,[53] and TAstV,[46] which facilitate comparisons with published strains associated with clinical significance.

12.3 CONCLUSIONS AND FUTURE PERSPECTIVES

Avian AstV infections are common in commercially farmed poultry where they are associated with PESs of turkeys, runting–stunting syndrome and kidney disease of chickens, hatchability problems in chicks, and a fatal hepatitis of ducklings. Equally, they can be detected in apparently healthy birds as subclinical infections, which suggests that other factors, such as the particular strain of AstV, the infecting virus load, or the

Downloaded From Vet-eBooks.com

presence of other pathogens, may be influencing the development of disease. Molecular tests are good for detecting virus but they may not detect disease. High AstV load may be necessary to correlate with clinical signs and so quantitative molecular tests, in particular, offer this facility. Avian AstVs display a high degree of genomic variability, especially in ORF 2, which codes for the immunogenic capsid protein, but even the more conserved areas are subject to substantial genomic instability, which makes designing comprehensive molecular tests that can detect multiple strains difficult. Molecular tests for avian AstVs are regularly being improved as the sequences from more strains become available through the public sequencing databases.

Recently designed molecular tests have recognized that other endemic viruses are often present as coinfections in poultry intestinal samples, such as avian reovirus, coronavirus, and rotavirus, and it is not uncommon for broiler chickens to be infected with both ANV and CAstV concomitantly.[74] Metagenomics is being used widely to research the communities of bacteria, known as microbiomes, that inhabit poultry guts, and a similar approach has started to investigate the communities of enteric viruses that populate the poultry gut. A recent metagenomic investigation of the intestinal tracts of turkeys from farms with a history of enteric disease by Day et al. has identified almost 20 genera of RNA enteric viruses in addition to bacteria, eukaryotes, and archaeotes.[75] Discovering which DNA viruses are also present and performing comparative metagenomics of the complete virome down to the strain level for birds with good and poor performance should start to reveal the underlying causes of these conditions and exclude benign strains or those resulting in subclinical infections. Improvements in the sequencing technologies, in particular achieving longer read lengths and the ability to tag individual sample preparations and multiplex them, combined with reductions in running costs and simplified bioinformatics analysis pipelines should turn comparative virome metagenomics into a routine diagnostic test in the not too distant future, which should be vastly more informative than current methods.

13.1 INTRODUCTION

Hepatitis E is a viral disease that presents as acute hepatitis in humans. The etiological agent is hepatitis E virus (HEV), first identified in the early 1980s.[1] The disease is an important public health issue in developing countries where it is frequently epidemic. Industrialized countries were previously thought to be free from HEV, with a limited number of cases reported only in people who had traveled to endemic areas. However, more recent studies have documented an increasing number of sporadic cases in developed areas, among patients who had no history of travelling to countries endemic for hepatitis E. Furthermore, a high anti-HEV seroprevalence has been detected among healthy individuals in nonendemic countries.

Since the early 1990s, serological evidence of HEV infection and virus detection have been reported in many animal species in both developed and developing countries, suggesting that these host species may become infected with HEV-like viruses.[1] In 1997, a swine HEV strain was identified for the first time in the United States. This swine HEV strain correlated genetically to two human HEV strains isolated in the United States during the same period from patients who had not traveled to endemic areas.[2] Since then, swine HEV strains have been isolated across the globe. A strict genetic correlation between human and swine strains from the same geographic region has been observed frequently, and cross-species transmission of swine strains to humans and of human strains to nonhuman primates has been demonstrated.[3] Furthermore, several seroepidemiological studies have reported high antibody prevalence to HEV in people working in direct contact with swine or wild boar.[3]

The first direct evidence of a possible zoonotic transmission of HEV was provided in Japan in 2003, when cases of hepatitis E were associated to the ingestion of uncooked meat or organs from pigs, wild boar, or deer.[4] More recently, a study conducted in France confirmed that 13 human cases of hepatitis E were eventually linked to the consumption of raw figatellu pig liver sausages.[5] The disease is now recognized as an emerging zoonosis.

13.1.1 Classification

HEV is currently classified within the only genus *Hepevirus* in the family *Hepeviridae*,[1] although it was considered previously as a member of the family *Caliciviridae*. Subsequent genetic analyses demonstrated that the virus is distantly related to members of the family *Togaviridae*. Thus, a separate family (*Hepeviridae*) has been created for HEV to differentiate from caliciviruses. Given the genomic and amino acid diversity observed among HEV strains of different origins, a proposal for the establishment of additional genus within the family *Hepeviridae* has recently been presented to the International Committee on the Taxonomy of Viruses (ICTV) for approval.[6]

HEV strains detected in humans and other mammalian species constitute the major group within *Hepeviridae*. Four genotypes (G1–G4) of mammalian HEV are presently recognized, which primarily infect humans, domestic pigs, wild boar, deer, rabbit, and mongoose.[3] However, genetically distant HEV strains have been identified lately in moose, red fox, camel, rat, ferrets, wild boar, bat, mink, and cutthroat trout (*Oncorhynchus clarkii*).[7] Although avian HEV strains share

Downloaded From Vet-eBooks.com

only 50%–60% nucleotide identity with mammalian HEV strains,[8] antibody cross-reaction with the capsid proteins of both groups of viruses was reported, suggesting the presence of common epitopes.[9] Nonetheless, avian HEV strains have never been associated with cases of infection in human beings.[10]

The proposed ICTV hierarchical system includes two genera in the family, named *Orthohepevirus* (all mammalian and avian HEV) and *Piscihepevirus* (for the cutthroat trout virus). The *Orthohepevirus* genus is divided into *Orthohepevirus A* (strains from humans, pig, wild boar, deer, mongoose, rabbit, and camel), *Orthohepevirus B* (strains from chicken), *Orthohepevirus C* (strains from rat, greater bandicoot, Asian musk shrew, ferret, and mink), and *Orthohepevirus D* (strains from bat).[6] The classification of genotypes and subgenotypes still remains included in the new taxonomic system. Despite the knowledge that different HEV genotypes occur, the virus seems otherwise to exist as a single serotype.[3]

In industrialized countries, autochthonous human cases are related to HEV strains belonging to genotypes 3 and 4,[1,11] which are still considered the only zoonotic genotypes. Genotype 3 was first identified in autochthonous human cases in the United States, when the two human strains US-1 and US-2 showed only 74%–75% nucleotide identity with the previously known genotypes 1 and 2 and were accordingly classified separately.[2] Since then, genotype 3 has been detected worldwide, associated to sporadic cases and small outbreaks in North America, Europe, Japan, and New Zealand. Consumption of raw pork meat or derivate products as liver sausage and exposure to pigs and wild boars are proposed as risk factors associated with HEV infection in industrialized countries.[12,13] Several papers confirmed the presence of genotype 3 HEV in raw pork liver sausage,[5,14,15] which in France has been reported to contain infectious HEV particles.[15]

HEV may contaminate surface waters and enter food production chains, in particular via shellfish culture areas and irrigation waters.[12] In fact, raw shellfish and vegetables cultivated in sewage-contaminated waters may be a significant source of HEV, and eating them shall be regarded as an additional risk factor for human infection.[16]

The other zoonotic genotype (genotype 4) is indigenous in Asia, where it was detected from both pigs and humans.[17] Genotype 4 is increasingly described as endemic in pigs in Asia and as cause of sporadic cases of hepatitis E in humans and of infection in the swine in China and Japan and recently in Europe.[17]

The recent and increasingly frequent detection of genotype 4 in Europe is of concern for public health and raises the question whether genotype 4 was somehow introduced into European domestic pigs and may be expected to spread further in European farms or whether it was transmitted through pig meat of Asian origin imported into Europe.[17]

13.1.2 Morphology and Genome Organization

HEV is a small (27–34 nm in diameter), icosahedral, nonenveloped, single-stranded, positive-sense RNA virus. The HEV genome is approximately 7.2 kb in length and presents a 7-methylguanosine cap followed by three overlapping open reading frames (ORFs) and a second noncoding region of approximately 65–74 nucleotides with a 3′ poly(A) tail. The genome length can vary slightly between animal strains although the genome organization seemed to be conserved in all these cases. The ORF1 (5073–5124 nt) codes for a nonstructural polyprotein of approximately 1690 amino acids, which is involved in viral genome replication and viral protein processing. The ORF3 (366–369 nucleotides) follows the ORF1 and overlaps the N-terminal portion of the ORF2 in a different reading frame, encoding a small phosphoprotein (pORF3). Recent studies have shown that pORF3 may be involved in virus release from infected cells.[18] The viral capsid protein encoded by ORF2 assembles into the complete virion. The virus capsid is made of 30 subunits containing homodimers of pORF2. Among the four major mammalian HEV genotypes, the sequence identity for the amino acid residues of the capsid protein is >85%, and most of the amino acid divergence is found in the N-terminal 111 residues. Expression of a truncated capsid protein lacking the first 111 amino acids and/or the C-terminal 59 amino acids using the baculovirus expression system in insect cells resulted in self-assembly of the capsid protein.[19]

13.1.3 Clinical Features and Pathogenesis in Swine

The pathogenesis of porcine HEV is largely unknown. As is the case for humans, also in the pig, it is not clear yet how the virus can reach the liver, once it has entered the host, and which its primary replication sites are. Although hepatocytes are the primary site for HEV detection,[2] little is known about viral detection and localization in the liver and extrahepatic tissues.[20] Using PCR or *in situ* hybridization in animals experimentally infected by the intravenous route, it was possible to detect viral RNA in several extrahepatic tissues such as lymph nodes, tonsils, spleens, stomachs, kidneys, salivary glands, lungs, and small and large intestines up to 20–27 days post-infection (pi), also in the absence of viremia. However, the negative-strand form of the virus genome, which is its replicative form, has been detected not only in the liver but also in the intestine principally and in the lymph nodes, between 7 and 27 days pi. Viremia can last for about 2 weeks, but the virus can be detected in the feces for a longer time, from 3 to 50 days pi. Seroconversion occurs about 2–3 weeks pi.[21,22] Tissues in which the virus first replicate and persists (from 3 to 27 days pi) are the liver, the small intestine, the colon, and the lymph nodes.[21] These observations, together with the fact that during experimental infections viral RNA can be detected in feces earlier than in the bile, and in quantities that are 10-fold higher, have led to argue that, after entering by the oral route and before inducing viremia, the virus replicates in the gastrointestinal tract.[22] Virological studies conducted on samples of serum and feces from swine herds have shown that HEV RNA can be primarily detected in pigs of 2–5 months of age, whereas animals younger than 2 months or older than 6–8 months are generally negative.[13] Considering these observations and given that maternal immunity is thought to last

Downloaded From Vet-eBooks.com

about 2 months, natural infection probably occurs as early as 1–3 months of age.[13,21,23]

In the swine, HEV is excreted in the feces as early as 7 days of postinfection, for about 3–4 weeks (with some differences between animal ages) with subsequent seroconversion and clearance of the infection by the immune system. Viremia follows after approximately 10–15 days since start of shedding and lasts for 1–2 weeks.[9,24] HEV infection seems therefore to be relatively short and self-limiting, resolving in a few weeks.[13,24] Pigs of any age are asymptomatic, whether infected with swine HEV naturally or experimentally.[22,23,25]

The HEV, at least the known genotype 3 strains, seems to be attenuated or at least not particularly virulent for domestic swine, while there is virtually no information available on its virulence in wild boar. The study of the disease in naturally or experimentally infected pigs has shown that HEV normally leads to subclinical infections with signs of hepatitis that can be detected only at histological analysis.[13,21,22] Some studies have highlighted a possible correlation between infection and liver damage,[25] and histopathological lesions have often been detected in the liver of experimentally and naturally infected animals.[21,22] These lesions include mild multifocal sinusoidal and periportal lymphoplasmocitary infiltrations and small areas of vacuolar degeneration and necrosis of hepatocites.[8,13,21] Hepatic inflammation and hepatocellular necrosis peaked in severity at 20 days pi.[21] In addition, slight subepithelial lymphohistiocytic cell infiltrations were observed in the gall bladder at 28 days pi.[24] An increasing trend in asparate aminotransferase (AST) and alanine aminotransferase (ALT) enzyme levels was also observed, which might suggest a slowly progressive development of liver damage occurring during HEV infection.[24]

In some cases, lymphoplasmocitary enteritis and multifocal interstitial lymphoplasmocitary nephritis have been detected. In experimentally infected animals, macroscopic lesions including mild to moderate enlargement of the mesenteric and hepatic lymph nodes have been detected sporadically.[21] In the ileum, a mild or moderate hyperplasia of Peyer's patches was observed. No lesions were observed in the spleen or pancreas.[24]

Passive maternal immunity has been shown to decline after 3–4 weeks of age, disappearing after 8–9 weeks. IgG seropositivity in piglets was associated with the serological status of the sows. However, it was uncommon to find seropositive animals below the age of 1–2 months, even if earlier results could have been biased by the low sensitivity of the serological tests used.[13]

The average time until antibody detection was found to be 2 weeks after the first HEV RNA detection in feces. Infected pigs develop an immune response against the virus that is characterized by an early IgM antibody response followed by an increase of IgGs approximately 1 week later. The IgM antibody titer decreases rapidly (1–2 weeks), whereas IgG concentration rises constantly for several weeks. The time determined before IgG development in pigs inoculated intravenously was 2-weeks of postinoculation at the earliest,[21,22] but times between 3 and 8 weeks of postinoculation were reported more often.[22]

In the field, seroconversion can be detected after the viremic phase at approximately 3–4 months of age (antibodies peak at 4 months), and animals show high serological titers until 5–6 months of age. At that time, the IgG titer starts to decline slowly.[11,13]

13.1.4 Diagnosis

For diagnosis of HEV infection, several methods are available. These include direct electron microscopy (EM), immune EM (IEM), enzyme immunoassay, immunofluorescence test, reverse transcription polymerase chain reaction (RT-PCR), real-time PCR, and nucleic acid sequence analysis. Among the different approaches, RT-PCR and nucleic acid sequence analysis are widely used for the detection and genotype identification of HEV.[26] These techniques have become the gold standard for diagnosis of HEV infections in the last decade.

13.1.4.1 Conventional Techniques

13.1.4.1.1 Direct Diagnosis

Detection of the virus has been performed originally by IEM, which provided the first evidence on the existence of HEV.[1] However, IEM has a low sensitivity compared to molecular detection methods and requires both expensive instruments and skilled personnel, which make it unsuitable for diagnostic routine.

Since the discovery of HEV, several attempts have been made to grow the virus *in vitro*, which at best led to only limited virus replication and low titers of progeny viruses. In general, the virus growth in cultured cells is very troublesome. Two main factors can hamper HEV growth *in vitro*: (1) the normally low viral load in test samples and (2) the virus integrity in the samples used for the *inoculum*. The first efficient cell culture systems for HEV that were capable of generating infectious HEV progenies in culture media were based on PLC/PRF/5 cells, derived from human hepatocellular carcinoma, and A549 cells, derived from human lung cancer. In the last few years, several papers reported attempts to cultivate different viral strains *in vitro* using additional cell lines of human or animal origin.[18] The experiments performed clearly demonstrated that both the initial day of appearance of HEV in the infected cell culture supernatant and its viral load (expressed in copy numbers, as determined by qPCR) were largely dependent on the original titer of the virus used for the inoculum. HEV could be first detected in the culture supernatant 8 days of postinoculation; however, it reached a concentration of 10^8 genome copies/mL only after several weeks (40–50 days).[18] The A549 and PLC/PRF/5 cell lines have been used in several studies, demonstrating efficient replication of both HEV genotypes 3 and 4 of both human and animal origin, including strains from swine and wild boar. Moreover, the virus progeny was infectious, as established by repeated passages in the same or other cell lines.[18,27] The PLC/PRF/5 cells used for monolayer cultures were also successfully used in a 3D growth system,[28] using special cell incubation conditions supported on microspheres. In addition, a recent study has further increased the number of cell lines permissive to

Downloaded From Vet-eBooks.com

HEV growth, describing successful viral replication also in the human hepatoma-derived cell line HepaRG, and the porcine embryonic stem cell–derived cell line PICM-19.[29]

Some studies conducted using cell culture have demonstrated that pork liver sausage and swine liver sold as food can contain infectious HEV,[15,27] identifying the risk for foodborne HEV transmission. However, the use of *in vitro* HEV cultivation to assess the risk in food items is still too cumbersome for being presently considered suitable for application in the practice, calling for further studies in order to develop more reliable and handy protocols.

13.1.4.1.2 Indirect Diagnosis

Analyses of serum specimens during human acute infection and experimental infection in animals showed a classical serological pattern in the course of infection, which included the appearance of anti-HEV IgM followed by IgG. In humans, IgM antibodies are detectable since the early phases of illness after the incubation period up to 5 months. Anti-HEV IgG immunoglobulins appear shortly after the IgM and can persist up to 1–14 years.[30] Anti-HEV IgM can be detected in 13-week-old pigs and also in pigs at slaughter age, albeit less frequently. However, the detection of the long-lasting IgG can be conveniently used for monitoring HEV spreading both among pigs, in which the disease is normally asymptomatic, and the general human population, where the disease can also be asymptomatic, subclinical, or not promptly identified. HEV-specific antibodies remain detectable over a much longer period of time than does viral RNA, which allow performing a diagnosis during a longer detection window. This can be particularly helpful during outbreak investigations, taking into account the long incubation time of infection.

Serological diagnosis is generally performed using enzyme-linked immunosorbent assay (ELISA), western blot, or rapid immune chromatographic kits,[10] in which either recombinant HEV proteins or synthetic HEV peptides corresponding to antigen epitopes of the structural HEV proteins, such as pORF2 and pORF3, are used as target antigens.[24,31] Among the two peptides, recombinant pORF2 was proven to be a more sensitive and specific antigen than was pORF3. Given the existence of a single serotype including all known HEV genotypes infecting humans and pigs, a same antigen of any origin can in principle be used to test all HEV genotypes. However, as suggested in several studies, the use of antigens homologous to the infecting HEV genotype might have a better reactivity in antibody testing on either human or animal sera.[26] This apparent discrepancy does not have a clear explanation, although it could be linked to the existence of minor diversity in some protein epitopes between different genotypes that otherwise share common neutralization epitopes.[26]

The antibody detection methods used most frequently are based on ELISA test platforms. Presently, several commercial ELISA kits are available for detecting both IgM and IgG antibodies, using recombinant viral antigens attached to the solid phase surface, in an indirect or double-antigen sandwich ELISA format. There are numerous examples of application of recombinant pORF2, with or without pORF3, in diagnostic assays. Different antigens have been used, including *E. coli*–expressed HEV proteins and virus-like particles expressed in recombinant insect cells[19] or in plant cells systems.[26]

With some modifications, these antigens have been used for detection of IgG, IgM, and IgA antibodies.[32] IgM antibody detection, which has relevant clinical implications, can be hampered by competition with IgG immunoglobulin, generally present at higher titers. To circumvent these problems and to differentiate the detection of IgM and IgG responses, a possible approach is the use of secondary antibodies directed against either the γ- or the μ-chains of immunoglobulins, respectively.[30]

Animal strains of HEV, particularly those belonging to genotype 3, are correlated genetically and antigenically to human and, to a lesser extent, also to avian strains. A large part of the tests adopted for the detection of anti-HEV antibodies in animals are commercial human HEV immunoassays, where the secondary antibodies are replaced with antisera specific for the animal species concerned. Alternatively, in some studies, HEV-specific antibodies in animals have been detected by in-house assays developed using recombinant pORF2 or pORF3 proteins, originating from different genotypes.[33,34] The ample literature available supports that several epitopes, especially present in pORF2, cross-react between different species and strains. A species-independent double-antigen sandwich ELISA was consequently developed and used to detect antibodies against HEV in swine, wild boar, and deer, resulting both sensitive and specific for the target HEV.[35] Currently, immunoassays commercially available for the detection of specific anti-HEV antibodies during acute infection differ dramatically in their sensitivity and specificity, which may explain the discrepancies in the HEV seroprevalence reported in different studies. In addition, false reactivity for anti-HEV IgM with other hepatotropic viruses such as Epstein–Barr virus and cytomegalovirus has been reported.[36]

13.1.4.2 Molecular Techniques

In the last years, the molecular detection of HEV RNA has been largely improved by developing new primers and protocols and is now considered to be the gold standard for identification of viremia and virus shedding in both humans and animals. The recent advance of next-generation sequencing, by whole sequencing of RNA in biological samples, has enabled the discovery of HEV strains in novel animal hosts and reservoirs. Nevertheless, a major diagnostic difficulty in human infection is related to the short periods of both viremia (up to 2 weeks) and virus shedding in feces (up to 4 weeks),[37] which hamper diagnostic approaches based only on viral RNA detection.

Methods for RNA detection, mostly RT-PCR in conventional or real-time formats, are independent on the genotype and the type of specimen to be tested. Several RT-PCR protocols have been developed, which vary in the length and the position of the HEV genome segment being amplified, as well as in their ability to detect one or more genotypes. However, most primers normally in use enable the amplification of genomes of all genotypes, targeting conserved sequences.

Downloaded From Vet-eBooks.com

Further analysis of the amplified PCR product for identification and characterization of the virus genotype is usually performed by nucleotide sequencing, by restriction with endonuclease enzymes, or by other detailed investigations following molecular cloning.

Recently, great improvement of diagnostic methods has been promoted by the implementation of several optimized real-time PCR protocols; this technique is not only able to quantify the virus load, but it also enhances significantly the rapidity, sensitivity, and specificity of the test.

The two real-time protocols most frequently used have been designed on the ORF2/ORF3 overlapping region and can be suitably used for detection of HEV genotypes 1–4.[38,39] However, a comparative study recently conducted by a WHO panel of laboratories expert in HEV detection showed some variability in the accuracy obtained with all these methods between different laboratories, in particular showing high interlaboratory variation in sensitivity. This study confirms the importance and need of multicentric standardization, as well as of suitable control materials to be used as international standards, for improving assays for quantitative determination of HEV RNA.[40]

13.2 METHODS

13.2.1 Sample Preparation

Nucleic acid extraction can be easily and efficiently performed using feces, serum, or a wide range of tissues. Several studies have proven that the highest sensitivity in HEV detection is achieved using swine samples such as bile, which cannot be obtained from live animals, followed by feces. The latter, together with sera, represents the type of sample used most commonly for monitoring virus circulation in pigs and for diagnosis in humans. Virus detection for risk assessment in food is generally performed in tissues such as liver, because the liver is used for producing sausage in many countries, but also in the intestine and lymph nodes.[20] Viral loads of 10^3–10^7 genome copies/g were estimated in positive liver, bile, and sausage samples.[14,41] Transmission of HEV through the consumption of contaminated food such as raw pork or wild boar meat or sausages has been described.[4,5] Nevertheless, as for hepatitis A, potential sources of contamination could be also in the crop field, including irrigation water, organic fertilizers, and human handling. Given the low infectious dose and complexity of the matrix (mainly for food and water) to be analyzed, methods for sample preparation should facilitate virus concentration, RNA recovery, and removal of inhibitors that might interfere with subsequent detection procedures.

In the last few years, several papers reported RNA extraction methods from food (i.e., sausages, pork chops) and water.[14,41–43] Most of the methods included the use of a process control, which is added to the samples before processing for monitoring the efficiency of the entire procedure. The viruses used as process control are genetically similar (at least in their genome organization) to the target virus and can be grown *in vitro*: those most commonly used are the feline calicivirus[44] or murine norovirus.[14] The process control used most commonly for hepatitis E is murine norovirus, which is co-concentrated and co-extracted with the target virus.

Different amounts of liver, sausage, and muscle have been used for HEV detection, ranging from 20 mg to 20 g.[41,43,45,46] Samples are chopped and homogenized in saline or lysis buffers and immediately processed for nucleic acid extraction. Fecal and bile samples should also be processed immediately after sampling or stored at −80°C. A 10% stool suspension is prepared in diethylpyrocarbonate (DEPC) water or saline buffer, and after vigorous shaking to release the virions and a centrifugation step to remove debris and bacteria, the supernatant is used for RNA extraction. The RNA virus extraction is obtained most commonly by commercial kits that are based on guanidine isothiocyanate (included in the lysis buffer) or using an organic solvent such as phenol–chloroform or chloroform–butanol[14,20,45] or solvents like Trizol. Virus concentration can also be carried out using 10% polyethylene glycol (PEG). Nucleic acid extraction is obtained by trapping RNA on magnetic silica or silica membranes. The eluted RNA is immediately processed for molecular detection or stored at −80°C.

As revealed by using the process control, the RNA recovery rate can vary remarkably depending on the matrix and the methods used, and the rate of recovery can range between 5.7% for dry pork liver sausages and 18% for *figatellu*[43] or other fresh liver sausages.[14] These recovery rates should be taken into account when performing a quantitative risk analysis.

13.2.2 Detection Procedures

For diagnosis of HEV infection in both animals and humans, analysis of RNA by nucleic acid amplification techniques is frequently used; this approach enables the identification of active infection during viremia (testing sera) and release of viruses (testing feces). Sequencing of amplified DNA is used to define the genotypes and subtypes and to determine the phylogenetic correlations among individual viral strains.

Several assays have been developed for the detection of HEV RNA, including conventional RT-PCR and nested RT-PCR protocols,[18,47] real-time RT-PCR,[39] and RT loop-mediated amplification.[48] Despite the high heterogeneity of the four genotypes infecting mammalians, all these assays are suitable for the detection of HEV genotypes 1–4. However, current methods of HEV nucleic acid detection have not been standardized, and different results have been observed in the performance of in-house tests,[49] thus confirming the necessity of control reagent panels to be used as internal controls for each specific genotype. The genotype 3 of HEV has been proposed as the best candidate for internal standard control, being the genotype most common worldwide.[40]

In addition to using positive controls, RT and PCR are also crucial steps to obtain an accurate detection of HEV RNA. Therefore, the detection of the process control should be first achieved to verify the efficiency of RNA extraction, and positive samples can then be further analyzed for the target virus. In addition, it is recommended to include a heterologous RNA or DNA as internal amplification control (IAC) in the samples

Downloaded From Vet-eBooks.com

to be analyzed. Several IACs have been designed, by including "probe" sequences not present in the HEV genome sequence.[50]

13.2.2.1 Conventional RT-PCR

The HEV genome is detected by RT followed by PCR and nested PCR or using a one-tube procedure, performing cDNA synthesis and the first PCR in a single step. This latter approach minimizes the handling of samples, reducing errors and contaminations.

Due to the low virus load, a nested PCR is often required in most samples, which is often decisive in case of low HEV RNA concentrations particularly in the swine. Moreover, due to the high genetic variability of HEV strains, detection by RT-PCR is performed using degenerate primers and analyzing different genomic regions.[49] Most protocols used for humans can be also applied satisfactorily in the case of animal testing, detecting strains belonging to genotypes 1–4. Most of the primers for universal use anneal in ORF2,[33,51] in the methyl transferase,[47] or in the conserved region of the RNA-dependent RNA polymerase[52] (Table 13.1). Recently, primers designed on genotypes 1–4 were found to detect suitably the novel HEV strains discovered in bats and wild rats.[53,54]

The cDNA synthesis is more frequently obtained using random hexamers, but gene-specific primer or oligo(dT) can also be used.

The RT step is carried out in reaction mixture containing buffer (composition depending on enzyme used), 0.01 M dithiothreitol (DTT), 1 mM dNTP, 50 pmol antisense primers or alternatively 0.5 μg of random primers, 20–40 U of RNase inhibitor, and 20–50 U of reverse transcriptase. The mixture is then incubated at 37°C or 42°C for 1 h, depending on the enzymes used. The resulting cDNA is immediately used for the PCR.

The one-step reaction mixture includes 0.3–0.7 μM sense and antisense primers, 1× buffer (the buffer composition can vary depending on the enzymes used), 1.5–2 mM $MgCl_2$, 1 mM dNTPs, and enzyme mix (including both RT and DNA polymerase). RT is followed by PCR using thermal conditions optimized for the enzymes and primers used. For the second round nested PCR, inner primers (0.1–0–3 μM), 1× buffer (the buffer composition can vary depending on the enzymes used), 1.5–2 mM $MgCl_2$ or $MgSO_4$, 1 mM dNTPs, and 0.2–2 U Taq DNA polymerase are used with an amount of first RT-PCR template DNA corresponding to 10% of the final reaction volume.

13.2.2.2 Real-Time RT-PCR

Real-time RT-PCR is considered to be up to 100-fold more sensitive than conventional RT-PCR[55] and is frequently used for HEV detection in both humans and animals. Several assays based on TaqMan probe have been developed, mainly targeting the ORF1-2-3 regions, where the probe and primers are targeted. The different assays designed are able to detect all four mammalian genotypes.[39,55] A recent paper reports the validation of a multiplex real-time protocol for distinguishing between genotypes 3 and 4.[56] Despite the overall suitability of universal primers for any type of HEV, some differences in sensitivity have been shown investigating different subtypes of genotype 3 HEV by two common quantitative real-time RT-PCRs.[57] As for conventional PCR, real-time procedures can be performed in a one-step format or by synthesis of cDNA using random hexameric primers followed by qPCR. The protocol designed by

[a] Primer positions are based on GenBank sequence accession no. M73218.

[b] Black hole quencher or MGB can be used instead of TAMRA.

Jothikumar and coworkers[39] (Table 13.2) is frequently used, being cited in 157 papers, and has been applied to human hepatitis E diagnosis and detection of HEV in food and animals.[40,45]

According to the kit used, the thermal conditions, final concentrations of primers and probe, and reaction mixture components can vary.

Depending on the RNA elution volume, most protocols use 2–10 µL of RNA, 1× optimized buffer (including reverse transcriptase and DNA polymerase, dNTPs, $MgCl_2$), 100–250 nM Primer HEV-F, 250 nM Primer HEV-R, 100 nM-5 µM Probe HEV-P, and 1× ROX dye. The use of an IAC is suggested. The detection of IAC is obtained by performing a multiplex reaction including probes, labeled differently, for the detection of the target virus and the IAC. Detection of both IAC and target virus, or IAC alone, confirms that the real-time reaction succeeded, whereas the reaction is to be considered inhibited in the absence of IAC signal.[45]

13.2.2.3 Sequencing and Phylogenetic Analyses

To identify the HEV strains detected and to further characterize the phylogenetic correlations between strains, the DNA amplicons obtained can be subjected to sequencing. To this purpose, a suitable amount of amplified DNA (i.e., 3–15 ng for PCR products of 100–500 bp) of high purity is needed. There are two different approaches that can be followed, that is, the direct sequencing of PCR products after gel extraction or purification or the cloning of the PCR products using a commercial vector and the sequencing of resulting recombinant plasmids. The sequences obtained are compared with GenBank entries, and phylogenetic analyses are performed using one of several specific software. HEV is currently divided into four mammalian genotypes and three provisional genotypes detected in animals. The first proposal indicated that strains differing in nucleotide sequence by >20% in the ORF2 region should be classified into different genotypes. The subtype classification is controversial and recent studies have shown inconsistencies within this classification. However, the first scheme classification of 24 HEV subtypes, including 10 subtypes (3a–3j) of genotype 3 and 7 subtypes (4a–4g) of genotype 4, is still accepted.[58]

Problems that are currently encountered during phylogenetic comparisons are related to the use of different genomic regions for sequencing by different groups, often performed with short-stretch genomic fragments (300 bp), and using different phylogenetic methods. Classification into subtypes should be confirmed by good bootstrap values supporting the phylogenetic groupings, applying a model test for choosing the most suitable phylogenic methods to be applied in each case, and possibly analyzing longer stretches of the genome, including different coding regions.

13.3 CONCLUSION AND FUTURE PERSPECTIVES

Given the increasing number of epidemiological and virological reports available in the literature, HEV infection shall be considered an emerging zoonosis. Both in Europe and Asia, the swine appears to be the major animal reservoir for the virus and therefore represents a possible important threat for public health. Infection can be acquired by eating infected meat products, but this transmission mode can in principle be prevented or largely contained because HEV is heat inactivated during cooking. Nonetheless, the possibility of cross contamination between raw meat products and the risk of environmental virus spread through pig farming manure should also be taken into consideration because of the possible contamination of vegetables and drinking or bathing waters. Waterborne HEV may eventually end up in contaminating filtrating edible mollusks, thereby increasing public health risks further. HEV transmission to humans can also occur by direct contact with infected animals, highlighting a greater infection risk for farmers, workers, and veterinarians who are in contact with pigs. Also indirect contact with instruments and tools contaminated with infected animal feces cannot be disregarded. Although many veterinary aspects of infection are not known yet, the enzootic nature of swine HEV infection and HEV ability to cross the species barrier emphasizes zoonotic transmission risks, together with food and environmental safety issues. Concerning the virus, the information available on the genetics and evolutionary links between animal and human strains is limited, particularly concerning animal strains. The host range restriction of the infection is not fully known, and the human cases associated with the ingestion of uncooked meat from wild species suggest that the role of wild animals in the epidemiology of disease should be further assessed.

Downloaded From Vet-eBooks.com

Despite the obvious health implications of this emerging zoonosis, information on the presence and circulation of HEV in pig herds or other animals is still insufficient, and both the natural history of infection in pigs and the economic impact of the disease on pig production also require further study. Evaluating the presence of HEV in other domestic and wild animal species is necessary, and genetic and epidemiological surveys of these viruses need to be conducted to assess the actual risks of zoonotic HEV transmission. Toward these aims, sensitive, specific, and inexpensive diagnostic tests represent a major need for the near future, and coordinated actions are desirable with large exchange of sequence and epidemiological data. Finally, the opportunity of vaccine strategies for control of disease in humans at risk should be evaluated, as well as a possible development of animal vaccines for containment of infection inside the food production and supply chain and in the environment.

14.1 INTRODUCTION

Respiratory diseases associated with infectious agents are a major problem in cats. Upper respiratory tract disease (URTD) has been the main cause of illness and health-associated euthanasia of cats in shelters in the United States. Bacteria like *Chlamydophila felis*, *Bordetella bronchiseptica*, and *Mycoplasma felis* are also frequently involved in URTD [12,37]. However, feline calicivirus (FCV) and felid herpesvirus type 1 (FeHV-1) are the main causes of respiratory disease in cats, and it is estimated that approximately 80% of URTD cases are due to one of the two viruses or both of them concurrently [12]. FCV infection has also been associated with oral ulcers and limping disease and to a severe disease-denominated virulent systemic disease (VSD), or FCV-VSD [31,36,37].

First described in New Zealand in 1957 [10], FCV is extensively distributed among the feline population worldwide. Wild and domestic members of the Felidae family are susceptible to FCV infection [36]. The prevalence observed in several countries among healthy domestic cats varied from 15% to 31%, while the prevalence among cats showing clinical signs of URTD was approximately 20%–53% [5]. Antibodies against FCV were also detected in wild feline such as puma, leopard, and jaguar [8]. A serologic survey performed in the southern region of Brazil demonstrated the presence of antibodies against FCV in 39.2% of 630 serum samples collected from domestic cats [17]. Furthermore, FCV was isolated alone or coinfecting with FeHV-1 in 34 (11.3%) of 302 samples from cats of the same region. An important observation is that 18 out of the 34 positive samples came from cats showing no clinical signs of disease, characterizing the carrier state [16].

Inactivated and attenuated vaccines against FCV are available, and most of them use a widely reactive FCV strain denominated F9 that originated from a virus isolated in 1970 [36,37].

14.1.1 Classification

FCV is a nonenveloped virus with a positive-sense RNA genome classified in the genus *Vesivirus*, family *Caliciviridae* [36,37], which consists of five related viral genera (*Lagovirus*, *Nebovirus*, *Norovirus*, *Sapovirus*, and *Vesivirus*). The term calicivirus is derived from the Greek word *calyx* (meaning cup or goblet), reflecting the fact that many calicivirus strains show visible cup-shaped depressions under electron microscopy. In turn, the genus *Vesivirus* comprises two recognized species, FCV, and vesicular exanthema of swine virus (VESV, the prototype species of the genus), in addition to the unclassified *Vesivirus*. Interestingly, VESV (see Chapter 16) causes a vesicular disease in pigs that is clinically indistinguishable from foot-and-mouth disease and swine vesicular disease (see Chapters 8 and 11).

FCV has a great variability but there is only one serotype [13,36]. Based on phylogenetic analysis of the FCV genome,

Downloaded From Vet-eBooks.com

no generally accepted genogroup or genotype classification can be put forward [36]. However, the presence of a genogroup was demonstrated among FCV strains isolated in a survey in Japan [38], and consistent clustering was observed among Australian strains when the whole capsid sequences were compared, but not when E-regions were analyzed separately [3]. It is also not yet possible to correlate any particular genome sequence with the different clinical manifestations caused by the viral infection in feline [13,36]. A number of epidemiological surveys performed in diverse geographic regions have shown that the most variable region at the genome sequence may vary its nucleotides from 20% to 40% among unrelated strains and 0% to 6% in epidemiologically related strains [36].

14.1.2 Morphology, Genome Organization, Biology, and Epidemiology

FCV has an icosahedral capsid about 27–40 nm [24,36,37]. The x-ray structure of a prototype of the *Vesivirus* genus, the San Miguel sea lion virus, has showed that the capsid of these viruses is formed by 180 copies of the VP1 protein and a few copies of VP2 [6]. The capsid protein of the *Caliciviridae* family are organized in 90 dimers forming 32 depressions, giving the viruses the characteristic arrangement suggesting the family denomination [6].

The FCV genome consists of a positive-sense RNA of about 7.7 kb, which is divided in three open reading frames (ORFs) [24,36,37]. According to strain FCV-F9, the part of the genome corresponding to the ORF1 maps approximately from nucleotide 20 to 5311, ORF2 from nucleotide 5314 to 7329, and ORF3 from 7326 to 7646 [25]. The 5′ end of the viral RNA genome is covalently linked to a VPg protein; the 3′ end of the genome is polyadenylated [18]. ORF1 is translated from the genomic RNA in a polyprotein precursor, while ORFs 2 and 3 are translated from subgenomic RNAs copied from the antigenomic RNA strand [18,24,40]. The subgenomic RNA copied from the antigenomic RNA is attached to VPg and is also polyadenylated [18]. ORF1 and ORF2 are cleaved by a 3C-like cysteine proteinase mapped to the C-terminal part of the ORF1 polyprotein [40]. The ORF3 codifies for VP2—a small capsid protein that is present in the capsid as 1–10 copies [31,36].

ORF1 is a very-well-conserved region localized at the 5′ end extending for about two-thirds of the genome [24,40]. The product of ORF1 is a 195 kDa polyprotein that is cleaved by a viral proteinase in five different sites resulting in six nonstructural proteins [40]. These proteins have been named according to their size or function as p5.6, p32, p39, p30, VPg, and Pro-Pol. Comparison of the FCV genome with the sequence of other members of the *Calicivirus* genus and functional studies have suggested the functions of some of the nonstructural proteins. Based on that evidence, p39 is an NTPase; Pro-Pol has proteinase and polymerase functions, respectively; and VPg, like *Picornavirus*, may play a role in the initiation of RNA translation by the cell machinery [24,40].

The main capsid protein is encoded by ORF2 that has been divided into six regions denominated A, B, C, D, E, and F [36]. The E-region is the most variable region of the genome, and it is further divided into one conserved region (conE) between two hypervariable regions (HVR) known as 5′ HVR_E and 3′ HVR_E [39]. The immunodominant epitopes eliciting neutralizing antibodies against the virus map to this region may also have a role in the viral evasion from the host immune response along with the persistent infection [21,34]. Conserved epitopes are identified within regions D and conE, but their role in antibody induction is unknown [34]. The product of ORF2 is a 73 kDa protein, further cleaved in the capsid protein of 60 kDa VP1, and a leader protein (LC) of 14.2 kDa, by an ORF1-codified proteinase [40].

The feline junctional adhesion molecule 1 (fJAM-A) was identified as the cell functional receptor bound by VP1 [27]. JAM-A is a member of the immunoglobulin superfamily apparently enrolled in apical tight junction assembly and leukocyte trafficking and platelet aggregation and expressed in epithelial cells, endothelial cells, leukocytes, platelets, and erythrocytes [23]. Further studies indicated that α-2,6-linked sialic acid may play a role as a component of the receptor for FCV on Crandell Rees feline kidney (CRFK) cells [41]. X-ray studies revealed that the VP1 is divided in two domains, S and P, and P is further divided in P1 and P2 subdomains [4]. Viruses with mutations in the P2 region were not able to bind to fJAM-A-soluble receptors, although these viruses bound to fJAM-A-expressing cells [27].

FCV has no other reservoir in nature besides feline [5]. Like other *Calicivirus*, FCV is very resistant in the environment at room temperature, and evidence showed that the virus maintains viability for more than 1 month at low temperature [36,37]. Then transmission of fomites from cages, water or feeding bowls, and others may happen. However, data from several studies have revealed that cats showing acute signs of the disease and carriers without any signs are the most important source of new infections [36]. Transmission occurs mainly through oral, nasal, and ocular secretions that carry a high load of the virus. After primary infection, the cat may become a carrier shedding the virus continually for months or years [36,37].

The prevalence of FCV is higher among cats living in places with dense populations compared to household cats. Epidemiological surveys showed that prevalence may vary from 50% to 90% among big populations of cats like those living in shelters, while a rate of 10% is commonly demonstrated in individual household cats [35]. The difference in prevalence may be attributed to reasons such as constant virus circulation, immune response pressure on the virus, and mutations occurring on the viral genome in carrier cats [36,37].

Immune response to the virus is directed against epitopes on the viral capsid major protein VP1 [34], and the antibody levels correlate well with protection against homologous but not heterologous viruses [20]. Following infection with FCV, neutralizing antibodies can be detected at 7 days postinfection [20], whereas it was also demonstrated that FCV infection may occur without detection of antibodies [28]. Existing vaccines protect against the disease but not against infection and the persistence of the virus. Due to the extensive antigenic variation, vaccines may not be protective against all the strains [36,37].

14.1.3 Clinical Features and Pathogenesis

FCV is mainly associated with acute oral disease and URTD, although a diverse range of clinical manifestations have already been described [31,36,37]. Cats exhibiting the acute oral disease usually display vesicles on the tongue, which further evolve to ulcers [36]. The oral disease may or may not be concomitant to mild respiratory disease resulting in oral and nasal discharges, and sometimes fever is detected [36]. In a number of cases, FCV infection is asymptomatic [36,37]. Infrequently, the infected cat may develop pneumonia [22]; however, severe and lethal respiratory disease occurs only among kittens [19]. A "limping syndrome" with lameness and fever characterized by the thickening of the synovial membrane and increased synovial fluid has also been observed [29].

In addition, since the 1990s, a severe systemic disease associated with high mortality has been described in different countries. This syndrome was earlier denominated as hemorrhagic-like fever and now known as FCV-associated virulent systemic disease or simply FCV-VSD [31,36,37]. The clinical signs of VSD are variable and may include severe respiratory tract disease; fever and ulcers on the oral cavity; cutaneous edema on the head, pinnae, and limbs; ulcerative lesions on the skin and paws; and jaundice [30,32,36,37]. Moreover, a systemic inflammatory response syndrome, intravascular coagulation, multiorgan failure [11], and necrosis of the liver, spleen, and pancreas have also been described [36]. The mortality rate is approximately 50%, but higher rates (67%) were also cited [11]. In contrast with other clinical manifestations of FCV infection, evidence suggests that adult cats are more susceptible, and the systemic disease is more severe in adults than kittens and young cats [19].

The most disturbing fact is that FCV vaccines currently in use apparently do not protect against FCV-VSD strains [36,37]. Another important finding about FCV-VSD isolated strains is that the virus apparently is more widely distributed on tissues than viruses isolated from other clinical manifestations [31]. The non-VSD strains are detected in skin epithelial cells, oral mucosa, and macrophages from joint fluid, while viruses isolated from VSD cases are detected in respiratory epithelial cells, pancreatic acinar cells, endothelial cells, and hepatocytes as well the tissues mentioned earlier [19,30,31].

FCV strains isolated from cats showing clinical manifestations of VSD are able to cause the same disease in experimentally infected cats. There is no consensus sequence that identifies the virus that causes VSD [31]. Research has been performed to find a molecular marker for FCV-VSD strains of the virus, but no consistent results have been demonstrated [31]. Evidence has suggested that mutations within the viral genome sequence may be the mechanism that generates the VSD strains of FCV; nonetheless, viruses isolated from different cases do not show sequence identity [1,31]. Then, mutation in different locations of the genome sequence could be responsible for the VSD phenotype [31], although host and immune factors may also play a role in this disease [36].

14.1.4 Diagnosis

Clinical diagnosis of FCV infection as well as FCV-VSD syndrome is largely reliant on clinical signs, epidemiology data such as morbidity and mortality, and macroscopic and microscopic lesions that result from biopsies. Use of laboratorial methods for direct detection of the virus, viral antigen, and viral genome is crucial to increase the accuracy of FCV diagnosis. The available diagnostic methods for FCV range from conventional techniques such as viral isolation in cell culture and serological assays to more complex and currently used molecular techniques such as real-time polymerase chain reaction (qPCR).

FCV and its antigens are commonly detected by virus isolation (VI), electron microscopy (EM), immunofluorescence assay (IFA), immunohistochemistry (IHC), and histopathology. IHC and IFA have proven useful for the detection of viral antigens present in the tissues. The main serology assays performed in order to detect antibodies against FCV are enzyme-linked immunosorbent assay (ELISA) and virus neutralization (VN). In addition, molecular techniques such as the sequencing of VP1 can also be used in the diagnosis of FCV-VSD [37].

The current diagnostic techniques and their application are briefly discussed in the succeeding text; nevertheless, VI and conventional reverse transcription PCR (RT-PCR) represent the most common methods used for FCV diagnosis [37,42,44].

14.1.4.1 Conventional Techniques

VI is a valuable method for detecting FCV infection since it reveals the presence of replicating virus. FCV replicates readily and shows rapid growth in feline-established cell lines as well primary cell culture [16,37]. CRFK cell line [7] is the most widely used for culture isolation of FCV. Primary cell culture obtained from ovarian, pulmonary, and kidney embryonic or fetus tissues allows high replication rates of the virus. However, the procedure to obtain these tissues is laborious and contamination is frequent. Furthermore, such cell cultures do not tolerate many passages *in vitro.*

The virus can be isolated from nasal, conjunctival, oral, and pharyngeal swabs from cats showing clinical signs of the disease [16,36]. In addition, the lungs, tonsils, fragments of lesions from the oral cavity, liver, skin, paw pad, pancreas, nose, lips, and pinnae may be used for diagnosing the FCV-VSD syndrome [30].

VI from persistently infected cats showing no signs of disease may be more difficult, and in this case, pharyngeal swabs are recommended [21]. In our experience, FCV was isolated from 18 nasal swabs from cats without any clinical manifestation at the time of collection, and four cats with FeHV-1 coinfection were confirmed by PCR [16]. FCV isolation may also fail due to the small amount of virions in the sample, virus inactivation during shipment from the place of collection until arrival at the diagnostic laboratory, or the presence of antibodies in extracellular fluids that prevent virus replication *in vitro* [12,36,37]. Figure 14.1 shows FCV cytopathic effect on CRFK cells.

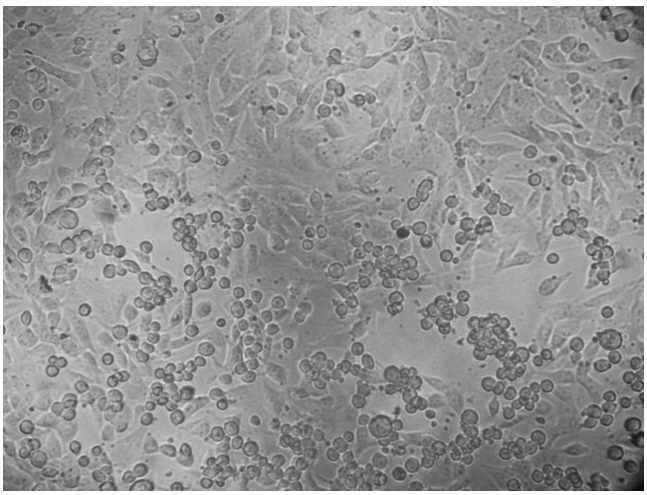

FIGURE 14.1 Cytopathic effect of feline calicivirus (FCV) in Crandell Rees feline kidney cells. FCV causes cellular rounding and detachment, lysis, and destruction of cell structure isolate SV65/90. (GenBank access number JX477806.1.)

EM offers a valuable approach for FCV detection although it often requires a high concentration of virus particles for a positive result. It implies that for successful results, the collection should be performed at the peak of viral replication, which normally corresponds to the period that cats are showing acute signs of the disease. EM may also be useful to confirm the presence of FCV after VI in cell culture. Figure 14.2 shows an electronic micrography of FCV isolate SV65/90 from a nasal swab of a cat aged 4 months from Southern Brazil.

IFA is usually performed to identify FCV after VI in cell culture. Polyclonal or monoclonal antibodies against the capsid protein may be utilized [30]. FCV1-43 is a primary monoclonal antibody against the capsid protein commonly used in IFA. This antibody is able to recognize the mature or the immature form of the capsid protein.

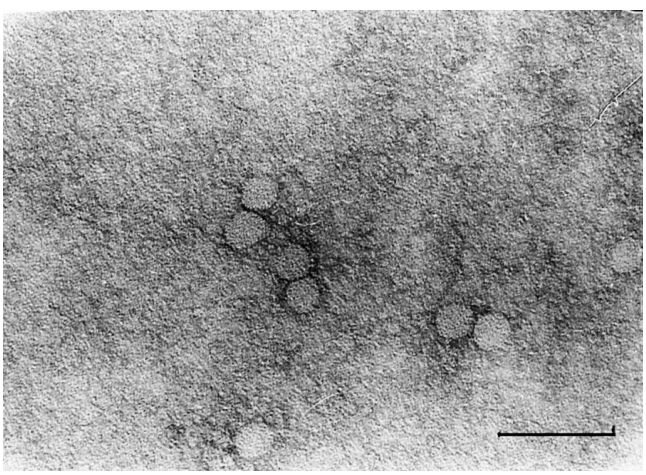

FIGURE 14.2 Electron microscopy of feline calicivirus (FCV) isolate FCV-SV65/90 (viral major capsid protein gene, partial cds_ GenBank access number JX477806.1). The bar equals to 90 nm.

IHC staining is a useful assay for postmortem specimens from cats with fatal URTD like severe pneumonia, FCV-VSD, or other conditions. IHC is widely applied for histopathology assays, but it is not a technique routinely performed in diagnostic laboratories. The use of the anti-FCV monoclonal antibody denominated FCV8-1C to perform IHC has been described [30].

Antibodies against FCV may be detected by VN or ELISA from serum, aqueous humor, and cerebrospinal fluid, although some cats survive a severe infection without developing detectable antibodies [37]. VN is widely used, because it is less expensive and easy to execute.

The antibody detection may have different objectives since it can be employed to support virus diagnosis and to evaluate the immune response regarding antibody titers from either vaccinated or infected cats. Serology may be used as an aid to viral diagnosis when paired serum samples are examined. However, difficulty in collecting sufficient amounts of blood from cats, the time required to obtain results, and low antibody titer in the convalescing are disadvantages associated with serological assays. Furthermore, the presence of antibodies may not correlate with active infection since the detection of antibodies fails to differentiate between the vaccinated and naturally infected cats [19,28,36].

The analysis of serology against FCV must be performed carefully either if it is used as an aid to the diagnosis of infection or to check protection against the virus by antibody titers. Levels of VN can be used to predict whether a cat is protected or not but must be interpreted properly, as false-negative results may be obtained if VN does not cross-react with the laboratory strains used in the test. Higher titers of antibodies may be observed with homologous strains than with heterologous strains [37]. When the strain used is not defined, it makes interpretation of the results difficult [9]. Consequently, the presence of specific antibodies is not a very useful resource to diagnose infection [12], and the absence of antibodies does not always correlate to unprotected host.

14.1.4.2 Molecular Techniques

Depending on clinical manifestations of FCV infection, RNA may be detected from nasal, oropharyngeal, or ocular swabs and tissue fragments obtained from biopsies or necropsy (mainly lung tissue and cutaneous scrapings) [37]. RT-PCR is widely applied for molecular diagnosis of FCV infection. qPCR has also been developed and it is another option when available. Genome sequencing is usually performed for research purposes, but it has also been applied for the diagnosis of FCV-VSD. Multiplex PCR to detect at the same time FCV and other feline infectious agents as herpesvirus type 1 (FeHV-1) and *Chlamydophila psittaci* may also be an option because these are agents commonly involved in feline respiratory disease [43].

The primers and viral strain used will determine the sensitivity of the techniques due to the genetic variability of the FCV genome [14,37,43,46]. It has been recommended to employ a large panel of strains for the optimization of molecular techniques in order to minimize false-negative results. The target gene as well as the primers (conserved or degenerated)

Downloaded From Vet-eBooks.com

used for amplification in molecular assays will depend on the purpose in each situation. The degenerate primers are useful to identify a wide range of FCV isolates, whereas conserved primers show better results in molecular analyses because they identify the correct or trusted genome sequence of the isolates. A similar approach may apply to the target gene used, since conserved genes are a good target for diagnosis/identification, while variable or highly variable regions (ORF2) are the target choice when studying the variability between isolates. An important point is that the primers should anchor in conserved regions at the start of the region to be amplified.

qPCR has higher sensitivity than conventional PCR and allows quantitation of the amount of virus in the sample. It is also less time consuming than conventional and nested PCR [1]. qPCR has been applied to the diagnosis of FCV as well as to FCV research. It may identify uniquely the virus strain aiding in molecular epidemiology and outbreak investigations. However, genetic markers associated with virulence, specifically hypervirulent strains, are not available [1,11].

Different qPCR protocols have been developed for FCV detection [1,14,47]. Helps et al. [14] were able to distinguish FCV isolates using SYBR Green I melting curve analysis. The assay was sensitive and allowed accurate quantitation of viral load [14]. qPCR using SYBR Green dye was further described by other research groups [45]. However, Abd-Eldaim et al. [2] found that applying a specific molecular probe in the TaqMan protocol increases the specificity of the assay and provides one more range of isolates detected. Both approaches will be presented in Section 14.2.

14.2 METHODS

14.2.1 Sample Collection

Swab samples (conjunctival, nasal, oral, and oropharyngeal) may be collected from cats with or without clinical signs of respiratory disease or oral lesions. Tissue fragments of lungs or oral lesions obtained from the autopsies are good samples to be analyzed by IFA or IHC.

14.2.2 Detection Procedures

14.2.2.1 Extraction of RNA

FCV RNA may be extracted from cell cultures inoculated with FCV or infected tissue fragments using TRIzol reagents (Invitrogen, Carlsbad, CA) following the manufacturer's protocol. After extraction, RNA is solubilized in 30 μL of ultrapure water with diethylpyrocarbonate and stored at −80°C until use. The QIAamp DNA Mini Kit (Qiagen, United States) has also been used to extract RNA from all samples.

14.2.2.2 Reverse Transcription

cDNA is synthesized in 20 μL of total solution containing the following: 2 μL of RNA (approximately 100 ng), 100 ng of random primers, 10× buffer from reverse transcriptase, 25 mM $MgCl_2$, 10 mM dNTPs, 0.1 mM DTT, 40 U RNaseOUT, and 200 U RT (SuperScript™ III RT, Invitrogen). The solution is incubated at 65°C for 5 min, 25°C for 10 min, 42°C for 50 min, and 85°C for 5 min. cDNA is used as a template for the PCR for FCV identification.

14.2.2.3 PCR for FCV Detection

ORF2 (regions B–F), which encodes the major capsid protein [36], is a common target used for amplification of FCV cDNA. The following protocol was adapted by Henzel et al. [16] from the paper described by Ohe et al. [25]. The amplified product is a fragment of 955 base pairs (bp) from the capsid gene. The primer sequences are 8F (forward) 5′-CACSTTATGTCYGACACTGA-3′ (position 6142 B region) and 8R (reverse) 5′-CTRGADGTRTGCARRATTT-3′ (position 7097 F region), based on the FCV-F9 strain (GenBank access number M86379). The primers used are degenerate and the letters S, Y, R, and D refer to C/G, T/C, A/G, and A/C/T, respectively. The PCR conditions used are as follows: 94°C for 5 min for the initial denaturation, followed by 35 cycles of three steps of 94°C for 45 s, 48°C for 45 s, 72°C for 45 s, and a final extension of 7 min at 72°C. The resulting PCR products are electrophoresed in 1.5% agarose gel, stained with ethidium bromide, and visualized under UV light.

14.2.2.4 Multiplex PCR

The following multiplex PCR protocol was developed in 2001 by Sykes et al. [43] for simultaneous detection of FCV, FeHV-1, and *Chlamydia psittaci*. RT-PCR/PCR is performed in a single tube of 25 μL. For the RT step, final concentrations are 10 mM Tris–HCl (pH 8.3); 1.5 mM $MgCl_2$; 50 mM KCl; 0.01% gelatin; 5 mM DTT; 200 μM of each of dATP, dTTP, dGTP, and dCTP; 2.5 U RNase inhibitor (Roche Diagnostics, GmbH, Mannheim, Germany); and 50 U Moloney murine leukemia virus reverse transcriptase (Promega Corporation, Madison, WI). The extracted sample and reverse primer mixture are added; reactions are incubated at 42°C for 1 h and then heated to 100°C for 5 min. And the following are added to each reaction: a mixture of 0.5 μg of each primer, FCV capsid protein (U13992), CalcapF (5′-TTCGGCCTTTTGTGTTCC-3′ position 6398), and CalcapR (5′-TTGAGAATTGAACACATCAATAGATC-3′ position 7061); FeHV-1 thymidine kinase gene (M26660), HerpF (5′-GACGTGGTGAATTATCAGC-3′ position 510), and HerpR (5′-CAACTAGATTTCCACCAGGA-3′ position 797); and 1 μg of each of primers from *Chlamydia psittaci* target gene ompA (X56980), ChlaF (5′-ATGAAAAA ACTCTTGAAATCGG-3′ position 364), and ChlaR (5′-CAA GATTTTCTAGACTTCATTTTGTT-3′) and 2.5 U of *Taq* polymerase (Promega). The following were the PCR conditions: 5 min denaturation at 95°C, followed by 40 cycles of 1 min at 91°C, 1 min at 56°C, and 1 min at 72°C. Water was the negative control, and a mixture of cell culture supernatants was the positive control [43].

14.2.2.5 Real-Time RT-PCR

The following protocol was extracted from Helps et al. [14]. qPCR is carried out using an iCycler IQ system (Bio-Rad). The primers were designed using MacVector 7.0 (Oxford Molecular) to amplify an 83 bp product from the ORF1

Downloaded From Vet-eBooks.com

region of the FCV genome (nucleotides 2452–2534 from accession number M86379). The PCR product contains a 20 bp region between the forward and reverse primer binding sites that are variable in sequence. The RT-PCR reaction consists of 12.5 μL of 2× Platinum QRT-PCR Thermoscript (Invitrogen), 100 nM FCV-reverse primer 5′-CATATGCGGCTCTGATGGCTTGAAACTG-3′, 2.5 mL template RNA, 2.5 mL SYBR Green I (1 in 100,000 final dilution) (Sigma), and water to 22.5 mL. After an initial incubation at 50°C for 30 min and 70°C for 10 min to allow RT, 2.5 mL of 1 mM FCV-forward primer 5′-TAATTCGGTGTTTGATTTGGCCTGGGCT-3′ is added to each reaction. To inactivate the Thermoscript and activate the Platinum Taq, the reaction is incubated at 95°C for 5 min and then for 45 cycles of 95°C for 5 s and 60°C for 10 s. Fluorescence is detected at 530 nm at each annealing step (60°C). Immediately following PCR, a melting curve was performed by raising the incubation temperature from 80°C to 90°C in 0.2°C increments with a hold of 10 s at each increment. All reactions are run in triplicate [14].

The following real-time RT-PCR protocol, which used TaqMan, was extracted from Abd-Eldaim et al. [2]. A 120 bp fragment located at nucleotides 1–120 of the FCV genome (50 untranslated region; part of ORF1) is used as target. Primers and probe-specific sequences used are FCV-forward 5′-GTAAAAGAAATTTGAGACAAT-3′ (position in genome FCV-F9 1–21), FCV-reverse 5′-TACTGAAGWTCGCGYCT-3′ (position 120–104), and FCV-probe 26–49 5′-FAM-CAAACTCTGAGCTTCGTGCTTAAA-TAMRA-3′. Briefly, 5 μL of the synthesized cDNA is amplified in 25 μL total volume reactions using OmniMix HS (ready-to-use, lyophilized universal PCR reagent beads containing hot start Taq [Ta-KaRa Bio, Japan]), containing 200 μM dNTPs, 4 mM $MgCl_2$, 25 mM HEPES (pH 8.0), 200 nM probe, and 300 nM of each primer. The assay was carried out in the Cepheid SmartCycler II System (Cepheid, United States) with the following parameters: an initial activation step for the hot start Taq polymerase at 95°C for 2 min, then 45 three-step cycles consisting of denaturation at 95°C for 15 s, annealing at 56°C for 60 s, and extension at 72°C for 30 s. A threshold value of more than 40 is considered a negative result. DNase/RNase-free water is used as a negative control [2].

14.2.2.6 Sequencing

Sequencing is generally performed for research purposes, for the diagnosis of FCV-VSD, and, also, for the detection of *vaccine breakdown strains* (VBS).

The method described in the succeeding text was employed to study the variability of isolates in the HVR of the ORF2 gene. Region B–F of the ORF2 gene of FCV strains and isolates is initially amplified by PCR as described earlier. The primers were designed based on the FCV-F9 strain complete genome, including FCV_Capfor 5′-TTCGGCCGTTTGTCTTCC-3′ (position 6401–6419 [region B of ORF2]) and FCV_Caprev 5′-TTGTGAATTAAAGACATCAATAGACCT-3′ (position 7080–7053 [region F of ORF2]). A 679 bp product is amplified [15]. In order to optimize the PCR reaction and, also, as a positive control, a commercial live attenuated vaccine can be used [16]. The negative control may consist of mock-infected CRFK cells. The PCR products may be purified with PureLink PCR kit (Invitrogen, Carlsbad, CA) and the purified product sequenced in a Megabace sequencer (Amersham Biosciences). The same primer sets that are used in the PCR assay can be used for the sequencing. The obtained sequence should be compared to published FCV sequences and the analysis conducted using evolutionary genetic analysis (MEGA4.0) [44].

The sequencing of the VP1 coding region has been used as an aid in the diagnosis of FCV-VSD [32], even though there are no sequencing markers identified so far. To amplify and sequence the E region of the FCV capsid gene, two specific primers are designed around the E region and their location on the sequence EU202915 was indicated (FCVCapseq4F [1127–1146] CAATC GACATTGGACTGAYA + FCVCapseq4R [1883–1902] GATA CACGGCAGADGARTCT). RT-PCRs are performed with the following conditions: 50°C for 30 min, 95°C for 15 min, 5 cycles of 94°C for 20 s/56°C for 20 s/72°C for 2 min, 5 cycles of 94°C for 20 s/54°C for 20 s/72°C for 2 min, 5 cycles 94°C for 20 s/52°C for 20 s/72°C for 2 min, 30 cycles of 94°C for 20 s/50°C for 20 s/72°C for 2 min, and 72°C for 10 min. PCR products obtained with this specific PCR are directly sequenced without cloning [32].

Sequencing may also be applied to detect isolates associated to the vaccine failures, VBS [26]. Sequencing of the 5′ HVR_E region of the capsid gene is often performed to differentiate field virus isolates from vaccine strains. Research executed applying the aforecited approach has found that a great part of the vaccine failure isolates are field viruses that differ from vaccine strains in 21.3%–38% [33].

14.3 CONCLUSION AND PERSPECTIVE

FCV is an important pathogen causing mainly respiratory and oral diseases in cats. FCV has also been eventually associated to a limping disease, jaundice, skin disorders, and, for the past few years, a virulent systemic disease (FCV-VSD). As an RNA virus, FCV shows high mutation rates due to the absence of the proofreading function of its polymerase. There is only one FCV serotype and genotype; yet mutation generates great genetic diversity, which may probably explain the wide variation of clinical manifestations, the poor efficacy of vaccines, and the difficulty to induce cross protection against different isolates, all of which may contribute to the viral persistence in the host.

The precise diagnosis of FCV will depend on the chosen technique and the sample collected; however, results should be interpreted carefully because in some situations, there is no correlation between the presence of the virus and clinical signs. It is due to the asymptomatic carrier state and also to the fact that cats vaccinated with live vaccines may occasionally shed the virus postvaccination. FCV laboratorial diagnosis is still performed mainly by VI and regular PCR. An idea to further facilitate the diagnosis could be the development of a fast method of FCV detection in the clinic. Rapid immunochromatographic tests, like the ones utilized in FIV

Downloaded From Vet-eBooks.com

and FeLV diagnosis, would help to avoid the introduction of FCV-positive cats to veterinary clinics and shelters.

The preference of cats as pets is growing worldwide, and only in Brazil, there is an estimated population of 23 million cats with the cat population growing at a rate of 8% a year. Brazil has the second largest cat population, only surpassed by the United States. Taking this into consideration, the future perspectives should involve studies with characterization of strains and reactive cross VN intending to generate outstanding vaccines that would prevent the disease in a larger percentage of the cat population. The new vaccines should be able to prevent a range of isolates including the novel isolates from the systemic syndrome (FCV-VSD). Besides, the research and development of antivirals to treat clinically ill cats would be another interesting issue to be explored.

15.1 INTRODUCTION

Caliciviruses (family *Caliciviridae*) are small, positive-sense, single-stranded RNA viruses that are associated with a wide range of economically important diseases in animals and humans. The family *Caliciviridae* is complex, consisting of five recognized genera (*Vesivirus*, *Lagovirus*, *Norovirus*, *Sapovirus*, and *Nebovirus*) in addition to several proposed genera (e.g., *Bavovirus*, *Nacovirus*, *Recovirus*, *Secalivirus*, and *Valovirus*).

Caliciviruses affecting swine belong to the genera *Norovirus*, *Sapovirus*, and *Vesivirus,* as well as *Valovirus*, which is a yet to be approved genus. Of these, vesicular exanthema of swine virus (VESV) in the genus *Vesivirus* causes a vesicular disease in pigs with the formation of vesicles on the epithelium of the snout, lips, nostrils, and tongue. Norovirus genogroup II (genotypes 11, 18, and 19, or GII.11, GII.18, and GII.19) in the genus *Norovirus* and sapovirus genogroup III in the genus *Sapovirus* are detected in feces of pigs with diarrhea, and also associated with asymptomatic gastrointestinal infections in pigs. Furthermore, St-Valérien-like viruses (SVVs) in the tentative genus *Valovirus* are found in the feces of asymptomatic swine of all ages.

Caliciviruses affecting bovine are norovirus genogroup III in the genus *Norovirus* and Newbury-1 virus in the genus *Nebovirus.* Norovirus GIII includes two genotypes (GIII.1 and GIII.2), with genotype 2 (GIII.2) containing Newbury-2 virus, which was once thought to be related to Newbury-1 virus of the genus *Nebovirus.* Unlike caliciviruses affecting swine that sometimes produce asymptomatic infections in the gastrointestinal system, caliciviruses affecting bovine are often responsible for inducing diarrhea, anorexia, xylose malabsorption, etc.

As VESV of the genus *Vesivirus* is discussed in Chapter 16, the focus of this chapter is caliciviruses that infect the gastrointestinal system of swine namely norovirus GII (GII.11, GII.18, and GII.19) and sapovirus GIII, which will be conveniently referred to as porcine caliciviruses here, while SVV of the tentative genus *Valovirus* will be mentioned briefly.

Although porcine caliciviruses are often implicated in mild or asymptomatic gastroenteritis in pigs, their importance in public health lies in their close genetic and antigenic relationships with human noroviruses (NoVs, particularly GII) that are predominant enteric pathogens of humans of all ages and human sapoviruses (SaVs) that are responsible for gastroenteritis in pediatric patients. The fact that human GII NoV-like RNA (GII.2, GII.3, GII.4, and GII.13) is occasionally detected in pigs highlights the risk of interspecies transmission. In addition, the cooccurrence of human NoV-like and porcine NoVs in pigs may facilitate the generation of novel recombinant strains with broader host ranges.

15.1.1 Classification

The family *Caliciviridae* (derived from the Greek word *calyx* meaning "cup" or "goblet," referring to cup-shaped depressions on virus surface) covers a group of nonenveloped, positive-sense, single-stranded RNA viruses, some of which are pathogenic to animals including humans, dolphins, reptiles, sheep, dogs, cattle, chickens, and amphibians. Currently, the

Downloaded From Vet-eBooks.com

family is composed of five genera: *Vesivirus*, *Lagovirus*, *Norovirus*, *Sapovirus*, and *Nebovirus*, although several tentative genera have been proposed but not approved (e.g., Atlantic salmon calicivirus, chicken calicivirus [Bavovirus], turkey calicivirus [Nacovirus], rhesus enteric calicivirus or Tulane virus [Recovirus], Secalivirus, and SVV [Valovirus]) [1–3].

Of the five recognized genera, the genus *Vesivirus* consists of seven species that infect dogs, cats, pigs, sea lion, walrus, and skunk (canine calicivirus, feline calicivirus [FCV], San Miguel sea lion virus (SMSV), skunk calicivirus, VESV, vesivirus Cro1, and walrus calicivirus). FCV causes respiratory disease in cats and is controlled by vaccination. VESV is responsible for causing a vesicular disease in pigs, which is characterized by the formation of vesicles on the epithelium of the snout, lips, nostrils, tongue, feet, and mammary glands. VESV only remains a concern among Californian pig farmers, given that the virus was eradicated in swine in the rest of the world in 1959. The source of VESV possibly comes from San Miguel Island sea lions, as an essentially similar virus (SMSV) was isolated from these sea lions in 1972, which causes typical signs of VESV in experimentally inoculated pigs.

The genus *Lagovirus* includes two rabbit-infecting species (European brown hare syndrome virus and rabbit hemorrhagic disease virus [RHDV]). RHDV is associated with a fatal liver disease in adult European rabbits (*Oryctolagus cuniculus*) worldwide, which contributes to significant economic losses in the rabbit meat and fur industry and has negative impacts on wild rabbit populations and its dependant predators.

The genus *Norovirus* contains a single species, Norwalk virus, which is further separated into five genogroups (GI, GII, GIII, GIV, and GV) on the basis of 45%–61% differences in capsid genes, with a tentative new genogroup (GVI) that includes human and canine NoVs being proposed recently. In addition, 31 distinct NoV clusters or genotypes are identified within the genogroups (8 GI, 19 GII, 2 GIII, 1 GIV, and 1 GV genotypes) on the basis of 14%–44% differences in capsid genes. NoV strains are determined within a genotype by 0%–14% differences in capsid genes. NoV nomenclature usually contains place names where they were first identified and also references to their genogroup and genotype. For example, the Farmington Hills strain (which was linked to gastroenteritis cases in Farmington Hills, MI) is referred to as a GII.4 (genogroup II, genotype 4) strain. While NoVs infecting humans belong to GI, GII, and GIV, those infecting animals belong to GII (swine), GIII (bovine, consisting of genotypes 1 and 2; genotype 2 contains Newbury-2 virus, which was once thought to be related to Newbury-1 virus of the genus *Nebovirus*), GIV (lions and dogs), and GV (mice) [4]. In particular, GII NoVs account for most NoV outbreaks in humans and are also associated with infections in finisher pigs. More specifically, porcine NoVs belong to GII genotype 11 (GII.11), GII.18, and GII.19; human NoVs comprise the other GII genotypes (1–10, 12–17). The close genetic and antigenic relationships between human and porcine GII NoVs and the occasional detection of human GII NoV-like RNA (GII.2, GII.3, GII.4, and GII.13) in pigs raise serious concerns of possible interspecies transmission [5]. Recent studies provided evidence on the cooccurrence of human NoV-like and porcine NoVs in commercially reared pigs, which could lead to novel recombinant strains with broader host ranges [6].

The genus *Sapovirus* includes a single species, Sapporo virus (discovered in 1977 in Sapporo, Japan), which is further divided into seven genogroups (GI–GVII), with another tentative genogroup (GVIII) being proposed [7–10]. SaVs have been identified in bats, California sea lions, dogs, pigs, and mink as well as humans, with GI, GII, GIV, and GV SaVs implicated in mild gastroenteritis in young children and GIII SaVs occurring in all age groups of pigs. Recent phylogenetic analysis of complete capsid sequences from 95 human and animal SaV strains available in GenBank suggested the existence of 14 genogroups. Specifically, GV includes human, porcine, and sea lion SaVs. Human SaVs belong to GI, GII, GIV, and GV. Porcine SaVs belong to GIII, GVI, GVII, GVIII, GIX?, GX?, and GXI? in addition to GV. GV and GVIII porcine SaVs appear to be more closely related to human SaVs than to other porcine strains, with GVIII SaVs becoming more genetically variable in the United States. Mink, dog, and bat SaVs belong to GXII?, GXIII?, and GXIV?, respectively. Previously unassigned porcine strains Po/F2-4, Po/F8-9, Po/DO19, and Po/2014P2 are classified into GVII, which forms at least three distinct genetic clusters in the capsid phylogenetic tree, including the prototypical GVII SaVs (Po/K7, Po/F2-4, and Po/DO19, respectively). In addition, Po/F16-7 is classified into GIX? (19), Po/K8 into GX?, and Po/2053P4 into GXI? [5].

The genus *Nebovirus* contains a single species, Newbury-1 virus, which is infective to cattle, resulting in fecal color change, increased fecal output, anorexia, and xylose malabsorption [11,12].

The proposed genus *Valovirus* covers a novel group of swine caliciviruses known as the SVV. These viruses were first identified in the feces of asymptomatic finisher swine in the province of Quebec, Canada, and showed an overall prevalence of 23.8% (range 2.6%–80.0%) in finisher pigs in North Carolina [13], as well as 10% in pig serum samples (including 3.3% [2/60]) in the 3–6 months age group, 8.4% (18/214) in the 7–10 months age group, and 12.6% (43/340) in the >10 months age group in Italy [14]. The pathogenic potential of SVV in pigs remains to be determined.

15.1.2 Morphology and Genome Organization

Caliciviruses are small, nonenveloped viruses of 27–40 nm in diameter. The capsid is composed of 180 capsid proteins and appears hexagonal/spherical with T = 3 icosahedral symmetry.

Beneath the capsid is a nonsegmented, polyadenylated, positive-sense, single-stranded RNA genome of 7.5–8.5 kb, whose noncapped 5′-terminus is linked to a VPg protein, followed by three open reading frames (ORF1–ORF3) and a 3′-terminus with a poly(A) tail [15].

ORF1 encodes a large polyprotein that is cleaved post- and cotranslationally by the virus-encoded cysteine proteinase (3C or NS6), yielding the nonstructural proteins

Downloaded From Vet-eBooks.com

(Hel, VPg, Pro, and POL). The VPg protein (typically 13–15 kDa in size) is involved in the initiation of protein translation from viral RNA.

ORF2 encodes the major capsid protein viral protein 1 (VP1), which is the key determinant of calicivirus antigenicity. The VP1 coding gene sequences have been used extensively for the identification of calicivirus genogroups and genotypes. For example, norovirus genogroups are defined by the differences of 45%–61%, genotypes by the differences of 14%–44%, and strains by the differences of 0%–14% in capsid genes.

ORF3 encodes the minor capsid protein VP2. A shorter, subgenomic RNA (sgRNA) is also produced from ORF3 during replication, which is 3′ coterminal to the genomic RNA.

Although most caliciviruses have three ORFs, mouse norovirus appears to be an exception, with a fourth overlapping ORF, which produces a virulence factor 1 within the VP1 coding region (ORF2). Furthermore, RHDV and some SaVs (GII and GIII) possess another capsid-coding region in frame with ORF1, so that VP1 can be synthesized as part of the large polyprotein from ORF1 and also as a single protein from OFR2. In addition, FCV genome encodes a leader capsid peptide at the 5′ end of VP1.

Analysis of the complete genome of a porcine calicivirus strain (Ah-1) prevalent in pig groups in Anhui Province, China, demonstrated the presence of a 9-nucleotide (nt) 5′ untranslated region (UTR), two partially overlapping ORFs, and a 70-nt 3′ UTR. ORF1 is positioned between nt 10 and 6775 and encodes 2255 aa protein. ORF2 is located between nt 6771 and 7286 and encodes 172 aa protein [16,17].

15.1.3 Replication and Epidemiology

In general, replication of caliciviruses is a multistepped process. The initial attachment of the virus to the host receptors mediates its entry via endocytosis. Inside the cell, the virus uncoats and releases the viral RNA into the cytoplasm. Initiated by VPg, translation of ORF1 polyprotein from the viral RNA and subsequent processing yield replication proteins, which facilitate synthesis of dsRNA genome from the genomic ssRNA(+). Transcription and replication from dsRNA genome generate viral mRNAs/new ssRNA(+) genomes. In addition, translation of sgRNA gives rise to the capsid protein and VP2, which are utilized for assembly of new virus particles, which are then released after cell lysis.

The RNA of calicivirus virion is infectious and serves as both the genome and viral messenger RNA. Transmission of caliciviruses is mostly through the fecal–oral route upon contamination of shell fish, leafy greens, soft red fruits, water, or fomites. Transmission by close contact or the respiratory route (aerosolized vomitus particles) is also possible. Caliciviruses have a worldwide distribution and infect a diversity of animals (including humans, cattle, pigs, cats, chickens, mink, reptiles, dolphins, and amphibians) [18,19].

NoVs and SaVs of the family *Caliciviridae* are emerging enteric pathogens in humans and animals. The prototype norovirus (Norwalk virus) was first identified as the cause of a gastroenteritis outbreak among schoolchildren in Norwalk, Ohio, in 1968, and subsequently characterized in 1972. Since then, a large number of NoVs belonging to different genotypes have been shown to be the culprit for acute gastroenteritis in humans of all ages. Due to their high infectivity, persistence in the environment, resistance to common disinfectants, and difficulty in controlling their transmission through routine sanitary measures, NoVs are the major foodborne and waterborne pathogens, causing extended outbreaks in human populations [20,21]. It is estimated that NoVs are associated with nearly 23 million infections per year in the United States alone, with 50,000 hospitalizations and 300 deaths. In developing countries, NoVs are responsible for over 1 million hospitalizations and 200,000 deaths in young children annually [20,21].

The first evidence of norovirus in pigs was obtained in 1980 [22,23]. The investigation of NoVs in three pig farms in North Carolina revealed a prevalence of 20% in finisher pigs [24]. Other studies showed a prevalence of 25% of porcine NoVs in Canada, 2%–6% in Europe, 9% in New Zealand, 8% in Brazil, and <1%–15% in Asia [25–31]. Recent identification of humanlike NoVs (GII.2, GII.4) in pigs that also harbor other swine NoVs implies the possibility of novel recombinant NoVs emerging in the future that show higher pathogenic potential and broader host specificity [32,33].

SaVs were first observed by direct electron microscopy in stools of diarrheic children in 1976. In 1980, a porcine SaV (Cowden strain, previously known as porcine enteric calicivirus [PEC]) was found from the fecal samples of diarrheic piglets by electron microscopy in the United States [23]. Since then, porcine SaVs have been described in South Korea, Japan, China, Czech, Hungary, Germany, Belgium, Italy, Canada, Brazil, Venezuela, etc. [26,34–52]. Originated from diarrheic piglets, the porcine sapovirus strains Cowden and LL14/02/US, representatives of sapovirus genogroup GIII, have the capacity to induce enteric diseases and lesions in experimentally infected pigs [53–55].

15.1.4 Clinical Features and Pathogenesis

Porcine caliciviruses (NoVs and SaVs) are implicated in gastroenteritis in pigs, as they were first identified from diarrheic piglets. More often, infection with porcine caliciviruses may be asymptomatic, as documented in a number of recent reports.

In cattle, infection with norovirus GIII.2 led to persisting diarrhea and prolonged fecal shedding, but with no significant intestinal lesions in Gn calves. On the other hand, norovirus GIII.1 induced remarkably severe atrophic jejunitis in conventional calves [56].

In humans, calicivirus infections commonly cause acute gastroenteritis (inflammation of the stomach and intestines), with vomiting and diarrhea being the main clinical symptoms. Other common symptoms include nausea, abdominal cramps, low-grade fever, and malaise. Compared to human norovirus infections, SaV infections have a shorter duration of viral shedding and are less associated with projectile vomiting.

Considering that porcine caliciviruses often cause persistent, asymptomatic infections, it suggests the host's inability to effectively clear the invading viral pathogens. One possible

Downloaded From Vet-eBooks.com

mechanism may be the ability of porcine caliciviruses to constantly mutate in areas predicted to be important for immune recognition during chronic infection (e.g., the hypervariable P2 capsid domain), which helps the virus to evade host immune surveillance functions and partially explains the repeated susceptibility to calicivirus infections. Alternatively, porcine caliciviruses may use its products to block or shut off some cellular signaling pathways in the host that are key to the normal immune responses. Indeed, there is evidence that the functionality of type I interferon signaling pathways is critical to prevent serious and even lethal infections.

15.1.5 Diagnosis

Diagnosis of porcine calicivirus infections is possible through electron microscopy, virus isolation, serological assays, and nucleic acid detection. Use of electron microscopy has been fundamental to the initial discovery of caliciviruses. The subsequent application of stable porcine kidney cell line (LLC-PK cells) in the presence of the intestinal content fluid filtrate from uninfected gnotobiotic pigs, or bile acids, has enabled better characterization of PEC [57]. More recently, the development of nucleic acid detection methods such as RT-PCR has made it possible to detect and subtype porcine caliciviruses from pigs with or without overt clinical symptoms [58–61].

15.2 METHODS

15.2.1 Sample Preparation

Fecal suspensions are prepared in minimal essential medium at 10% (wt/vol) (Invitrogen). The RNA is then extracted from 200 μL of the supernatants using a QIAamp Viral RNA Mini Kit (Qiagen). The RNA is eluted into 50 μL RNase-free water. Viral RNA may be also extracted from stool specimens using the TRIzol method (Life Technologies).

15.2.2 Detection Procedures

15.2.2.1 Conventional RT-PCR for Pan-Calicivirus Detection

Jiang et al. [62] designed a pair of primers (P290, 5′-GATTACTCCAAGTGGGACTCCAC-3′; P289, 5′-TGACAATGTAATCATCACCATA-3′) from the conserved region of calicivirus RNA polymerase gene for amplification of a specific 319 or 331 bp fragment in NoVs or SaVs, respectively. RT-PCR may be performed using the PrimeScript® One-Step RT-PCR Kit Ver.2 (Dye Plus) (TAKARA) with the following cycling programs: 45°C for 30 min and 94°C for 5 min, followed by 40 cycles of 94°C for 1 min, 48°C for 1 min and 20 s, and 72°C for 1 min, plus a final extension of 72°C for 10 min. The amplified products are separated by 2% agarose gel electrophoresis in the presence of SYBR safe DNA gel stain (Invitrogen) and are visualized under UV light. The presence of 319 or 311 bp is indicative of NoVs or SaVs, respectively [63].

15.2.2.2 Real-Time RT-PCR for Detection of GII NoVs

Wang et al. [64] described a one-step TaqMan RT-qPCR for detection of GII NoVs (consisting of both human- and animal-infecting NoVs) using primers COG2F (5′-CAR GAR BCN ATG TTY AGR TGG ATG AG-3′) and COG2R (5′-TCG ACG CCA TCT TCA TTC ACA-3′) and the probe RING2 (5′,6-FAM–TGG GAG GGC GAT CGC AAT CT–Black Hole Quencher) [65]. The 20 μL RT-PCR mixture is composed of 2 μL of sample RNA, 400 μM of deoxynucleoside triphosphates (dNTPs), 200 nM of each primer, and 100 nM of the probe by using a Qiagen One-Step RT-PCR kit (Qiagen). The assay is performed with the following cycling conditions: 1 cycle at 50°C for 30 min, 1 cycle at 95°C for 15 min, and 45 cycles at 95°C for 15 s and 57.5°C for 60 s in an Eppendorf Mastercycler RealPlex instrument (Eppendorf). The detection limit of this assay is 10 genomic equivalents (GE) per reaction (20 μL).

15.2.2.3 Real-Time RT-PCR for Detection of GIII SaVs

Wang et al. [64] developed a one-step TaqMan RT-qPCR for the detection of porcine genogroup III (GIII) SaVs. The forward primer (5′-CCA GAA GTG TTC GTG ATG GAG-3′; nt 5125–5145), reverse primer (5′-GCC CRG CTG GYT GGA CTG-3′; nt 5230–5213), and probe (5′,6-carboxyfluorescein [5′,6-FAM]–TGCGAGCAACCCAGAGGGCACTCA–Iowa Black fluorescence Quencher; nt 5169–5192) target the beginning of the major capsid VP1 gene in the SaV Cowden strain.

RT-PCR mixture (20 μL) is made up of 2 μL of sample RNA, 400 μM of dNTPs, 200 nM of each primer, and 100 nM of the probe by using a Qiagen One-Step RT-PCR Kit (Qiagen). The assay is carried out with the following cycling conditions: 1 cycle at 50°C for 30 min, 1 cycle at 95°C for 15 min, and 45 cycles at 95°C for 15 s and 57.5°C for 60 s in an Eppendorf Mastercycler RealPlex instrument (Eppendorf).

The assay detects ≥10 GE per reaction (20 μL) and is nonreactive with other genogroups of porcine SaVs or porcine NoVs.

15.3 CONCLUSION

The family *Caliciviridae* encompasses a diverse and complex group of positive-sense, single-stranded RNA viruses that are infective to a range of animals as well as humans. In humans, caliciviruses are responsible for diarrhea, which can be fatal in young children if loss of body fluids is not rectified and replenished. In swine, caliciviruses tend to cause mild or asymptomatic gastrointestinal infections. Nevertheless, considering the close genetic and antigenic relationships between human and porcine caliciviruses and the coexistence of these viruses in swine, there is a real danger that novel recombinant viruses with potent pathogenicity and trans-species capability may emerge in the future. Therefore, it is important to have sufficient preparedness to deal with these events if they do occur. This preparedness should include the ability to promptly and accurately identify and type porcine and human caliciviruses. Toward this end, various nucleic acid–based diagnostic techniques such as RT-PCR have been developed and have shown promise for direct detection and quantification of caliciviruses from swine and human specimens.

16.1 INTRODUCTION

Vesicular exanthema of swine (VES) was first recognized on five pig farms in California in April 1932 as a clinical syndrome that was indistinguishable from foot-and-mouth disease (FMD) [1]. Although experimental inoculation of material from these cases failed to reproduce vesicular lesions in either cattle or guinea pigs, the causative agent was presumed to be an atypical FMD virus. However, four novel immunologically distinct viruses were subsequently isolated, which were named VES viruses (VESV) A, B, C, and D, and one of these (VESV type B or 1934B) from 1934 is still available (at the Pirbright Institute, UK). Similar outbreaks (of up to 184 cases/year) were observed every year between 1933 and 1951 (except in 1937–1938). Typically, these outbreaks affected mainly (but not exclusively) garbage-fed pigs in California. Between 1940 and 1942, three immunologically distinct viruses were recovered, but these were subsequently lost or destroyed. A number of pig-passaged tissue samples of another VESV serotype, 101–143 (which was isolated at the Pirbright Institute from a sample collected from pigs in San Francisco stockyards in 1943), are still available, but it has not yet been possible to recover viable virus from these samples. On June 16, 1952, VES appeared at a biological manufacturing plant in Grand Island, Nebraska. The source of this infection was traced to Cheyenne, Wyoming, where pigs had been fed garbage from transcontinental trains that had originated in California. Unfortunately, before the disease was detected in Grand Island, VES-infected pigs had been shipped to Omaha stockyards and sold on. In a little over a month (by July 29), outbreaks had occurred in 19 states, and by September 1953, a total of 42 states and the District of Columbia had reported cases of VES. Outbreaks continued in California until 1955 and in New Jersey until 1956 [2]. In 1948, a new collection of VESV isolates was started and new serotypes were discovered almost every year. The viruses were named alphabetically and with the year that the serotype was first isolated as a suffix, namely, A48, B51, C52, D53, and E55. Due to the retrospective nature of this analysis, some of the isolates were named out of chronological sequence (see later text). Subsequently, four unique serotypes were detected on a single farm in San Mateo County, California, in December 1954 (H54) and May (I55), September (F55), and October 1955 (G55). It was speculated that pigs on this farm were persistently infected and that new serotypes evolved by mutation [2]. The VES outbreaks that occurred outside California were initially only caused by B51. However, in 1954 and 1956, two new serotypes (designated K54 and J56) appeared on two farms in Secaucus, New Jersey [3]. As these serotypes were not found elsewhere in the United States, it was postulated that these viruses had evolved from the B51 serotype [4]. On October 22, 1959, the U.S. Secretary of Agriculture announced that VES had been eradicated and subsequently classified as a reportable foreign animal disease [2].

In 1972, viruses were isolated from rectal swabs of California sea lions (*Zalophus californianus*) that had recently aborted and from the nose of an emaciated northern seal (*Callorhinus ursinus*) pup, all of which were collected from animals on San Miguel Island, off the coast of southern California [5]. The agent was named San Miguel sea lion virus 1 (SMSV-1) and was soon recognized as being closely related to VESV. Between 1972 and 1991, many more SMSV serotypes were isolated from a range of marine mammals; and there are now 16 SMSV serotypes (1–2 and 4–17; type 3 was found to be a

Downloaded From Vet-eBooks.com

mixture of types 1 and 2). Interestingly, a candidate enterovirus isolated from a California gray whale (*Eschrichtius robustus*) was subsequently reclassified as VESV-A48 [6,7]. In 1978 and 1979, a number of serotypically distinct SMSV-like viruses were isolated from various animals at the San Diego Zoo, including cetaceans [8], primates [9–11], and reptiles [12]. In 1981, another serotypically distinct SMSV was found in cattle in Oregon [13]. SMSV-5 and a serotypically novel virus (provisionally named McAll) have been isolated from cases of vesicular disease in humans [14]. Other VESV/SMSV-related viruses have been isolated from skunks [15] and rabbits [16].

16.1.1 Classification, Morphology, and Genome Organization

Classification: VESV belong to the species *vesicular exanthema of swine virus* in the genus *Vesivirus*, family *Caliciviridae* [17]. The family consists of four other genera, *Lagovirus*, *Nebovirus*, *Norovirus*, and *Sapovirus* [17]. Five unclassified caliciviruses (Atlantic salmon calicivirus, "Bavovirus," "Nacovirus," "Recovirus," and "Valovirus") may represent additional new genera. The *Vesivirus* genus contains one other recognized species, *Feline calicivirus*, and a number of unclassified viruses (including mink and canine caliciviruses), which may form at least two new vesivirus species (Figure 16.1). In this chapter, VESV and viruses related to the *vesicular exanthema of swine virus* species will be referred to as the VESV/SMSV complex. There have been more than 30 VESV/SMSV serotypes described; however, not all have been serologically compared with each other and the lack of general availability of certain prototype viruses (e.g., from SMSV-15 to SMSV-17) prevents a proper serological or genetic classification. Recent determination of the genome sequence of one of the atypical SMSVs, serotype 8 (KM244552), shows that it does not belong to the *vesicular exanthema of swine virus* species (Figure 16.1) [18]. Failure to detect SMSV-12 by VESV/SMSV-specific western blot assay [15] and reverse transcription polymerase chain reaction (RT-PCR) targeted to highly conserved genome regions [19,20] also suggests that this virus may not belong to this virus species.

Morphology and genome organization: VES virions are nonenveloped and measure 27–40 nm in diameter by negative-stain electron microscopy (NS-EM) and 35–40 nm by cryo-electron microscopy. Most, but not all, caliciviruses have 32 distinctive cup-shaped depressions (L. calix, cup) on their surface, generating the characteristic "Star of David" appearance by NS-EM. The capsid is composed of 90 dimers of the major structural protein VP1 arranged on a T = 3 icosahedral lattice. The x-ray crystal structure of SMSV-4 has been determined to 3.2 Å resolution [21].

VESV/SMSVs possess a single-stranded positive-sense RNA genome of c. 8300 nucleotides. The 3′ end of the genome is polyadenylated and at the 5′ end, a small virus-encoded protein (VPg) is covalently attached to the RNA via a tyrosine at residue 24 [22] (Figure 16.2). VPg is involved in both genome replication and translation, the latter via an interaction with elongation initiation factor 4E [23]. The genome has a very short 5′ untranslated region (19 nt) and encodes three open reading frames (ORFs) (Figure 16.2); ORF1 encodes the nonstructural proteins, ORF2 encodes the major capsid polypeptide (VP1), and ORF3 encodes a small basic protein (VP2) [17]. ORF1 and ORF2 of the VESV/SMSV complex are separated by 5 nt (CCACT/C). A 3′ coterminal subgenomic RNA of 2.2–2.4 kb is

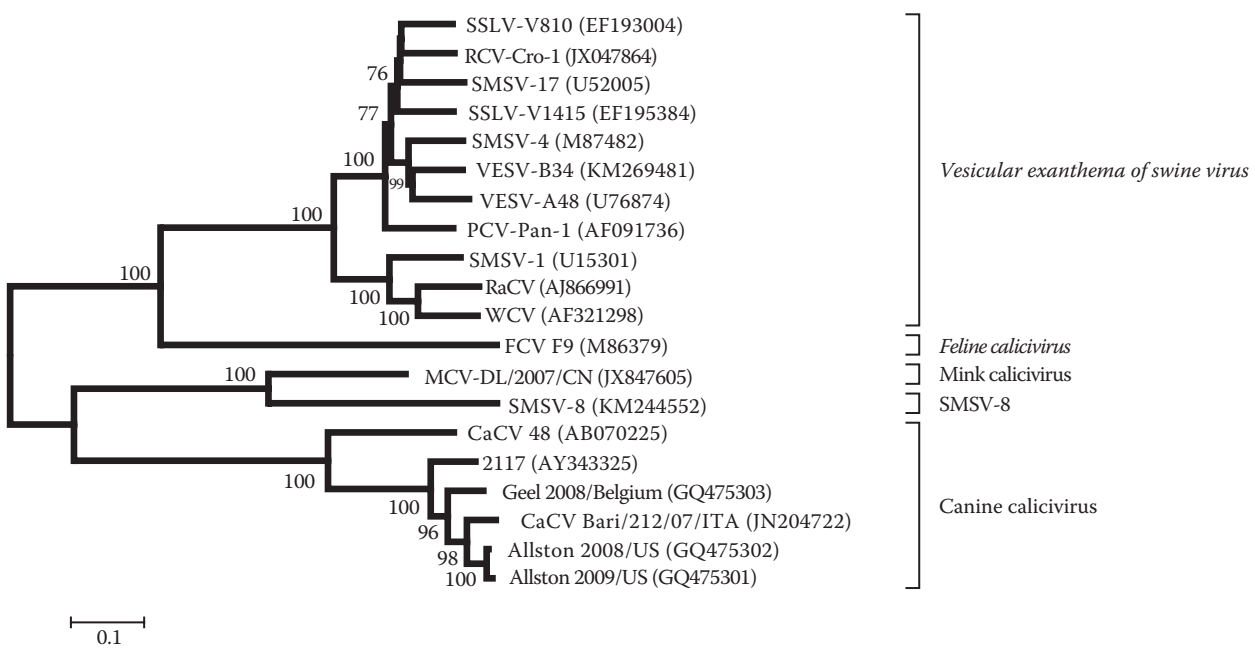

FIGURE 16.1 Genetic relationships between vesicular exanthema of swine virus, San Miguel sea lion virus, and related vesiviruses. Neighbor-joining tree (JTT amino acid substitution model) showing the relationship of the VP1 capsids. Accepted species of *Vesivirus* genus are indicated in italics to distinguish them from unclassified viruses. Tree calculated using MEGA 6.02.

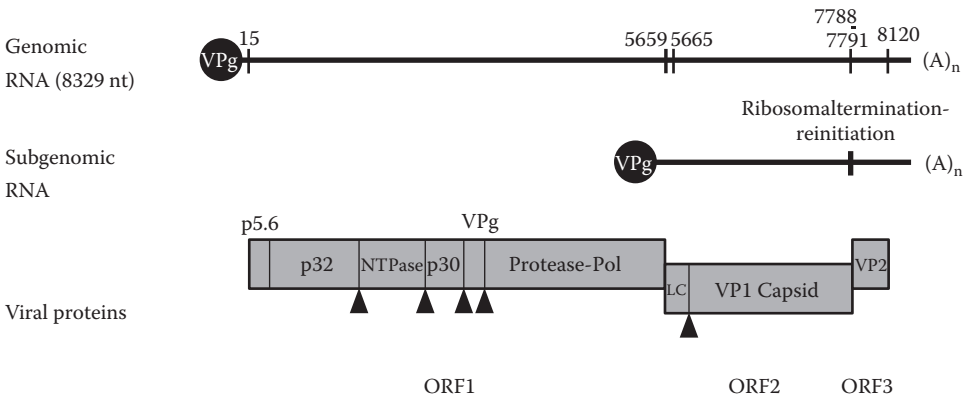

FIGURE 16.2 Genome organization of a typical vesicular exanthema of swine virus showing genomic and subgenomic RNA. Location of the three open reading frames and autoprotease cleavage sites (▲) are shown. Genome numbering in the figure is based upon VESV B1-34 (GenBank KM269481).

synthesized intracellularly and is apparently VPg linked. This also encodes the VP1 capsid polypeptide allowing an abundant expression of capsid proteins.

16.1.2 Transmission, Clinical Features, and Pathogenesis

16.1.2.1 Transmission

It has been suggested that the primary reservoir host of VESV/SMSV is the opaleye perch (*Girella nigricans*); however, other types of fish or poikilotherms from the Pacific Rim of North America and marine mammals (e.g., pinnipeds and cetaceans) might also serve as reservoirs [5,8,24–26]. Parasites such as the sea lion liver fluke (*Zalophotrema* sp.) and the fur seal lungworm (*Parafilaroides* sp.) may act as mechanical vectors [25,27]. VESV/SMSV is viable in seawater at 15°C for more than 14 days, suggesting that transmission may occur via contaminated water [28]. Although controversial, antibody surveys suggest that VESV/SMSV may be endemic in swine [26], cattle [29], and horses [30] in the United States. A carrier state has been suggested in pigs [4] and cattle [31], and is supported by the observation that primate calicivirus (PCV) Pan-1 (a member of the VESV/SMSV complex; see Figure 16.3) was isolated from the throat of a pygmy chimpanzee (*Pan paniscus*) after 6 months of infection [9].

With pigs, transmission occurs typically via direct contact with infected animals and their products and, less frequently, indirectly via contaminated feed, water, urine, and feces. In experimental settings, VESV/SMSV has been successfully transmitted by the application of virus suspensions to scarified skin of the snout or by intradermal, intranasal, and oral routes in pigs [1,32,33] and pinnipeds [33–35]. Additionally, the pig body louse (*Haematopinus suis*) may act as a mechanical vector, acquiring the infection from viremic pigs and transmitting to susceptible pigs [2]. The virus can remain intact/infectious in meat (even when decomposed) at a temperature of 7°C for 4 weeks and at –70°C for 18 weeks, and is not readily inactivated after 10 min at 80°C [1]. Therefore, with most cases of VES in pigs, the initial infection occurred by ingestion of virus-contaminated raw garbage containing waste from dead/slaughtered pigs, marine mammals, or fish. The incubation period under both experimental and field conditions is usually 24–72 h, but it can be as long as 12 days. Once infected, pigs remain contagious for approximately 5 days [32]. Horizontal transmission occurs readily, as vesicular fluid and vesicle epithelium contain large quantities of virus, which can be shed into the environment. Heavily contaminated premises may remain infectious for several months. Infection with VESV/SMSV by direct contact has also been reported in pinnipeds [35], cattle [13], and reptiles [12].

16.1.2.2 Clinical Features

The clinical signs of VESV/SMSV infections range from asymptomatic (e.g., opaleye perch and swine) to varying degrees of vesicular disease severity (e.g., swine, pinnipeds, and humans) depending on the host and the virus strain. Both natural and experimental VESV/SMSV infections have been associated with abortion (swine, pinnipeds, and cattle), pneumonia (swine, pinnipeds, cattle), diarrhea (swine and cattle), myocarditis (swine and pinnipeds), encephalitis (swine, pinnipeds, and primates), and hepatitis (swine and humans) [5,26,32,36]. The vesicular lesions caused by VESV/SMSV are indistinguishable from other vesicular diseases affecting swine, namely, FMD, vesicular stomatitis, and swine vesicular disease. These three diseases are highly infectious and require notification to the World Organization for Animal Health. In general, experimental infections of pigs with VESV and SMSVs are indistinguishable from each other, although some SMS viruses appear to be more pathogenic for pigs than some of the original VESV serotypes [32]. Disease in pigs is characterized by fever (40.5°C–42°C), the formation of vesicles in the oral cavity, and on the snout and feet (soles, coronary bands, and interdigital areas). Occasionally, vesicles also appear in the mammary glands of the sows. Vesicles are usually flat, blanched areas of 5–30 mm in diameter and raised 10–20 mm above the surrounding unaffected epithelium [1]. Vesicles that contain a clear fluid and a high quantity of virus rupture easily

Downloaded From Vet-eBooks.com

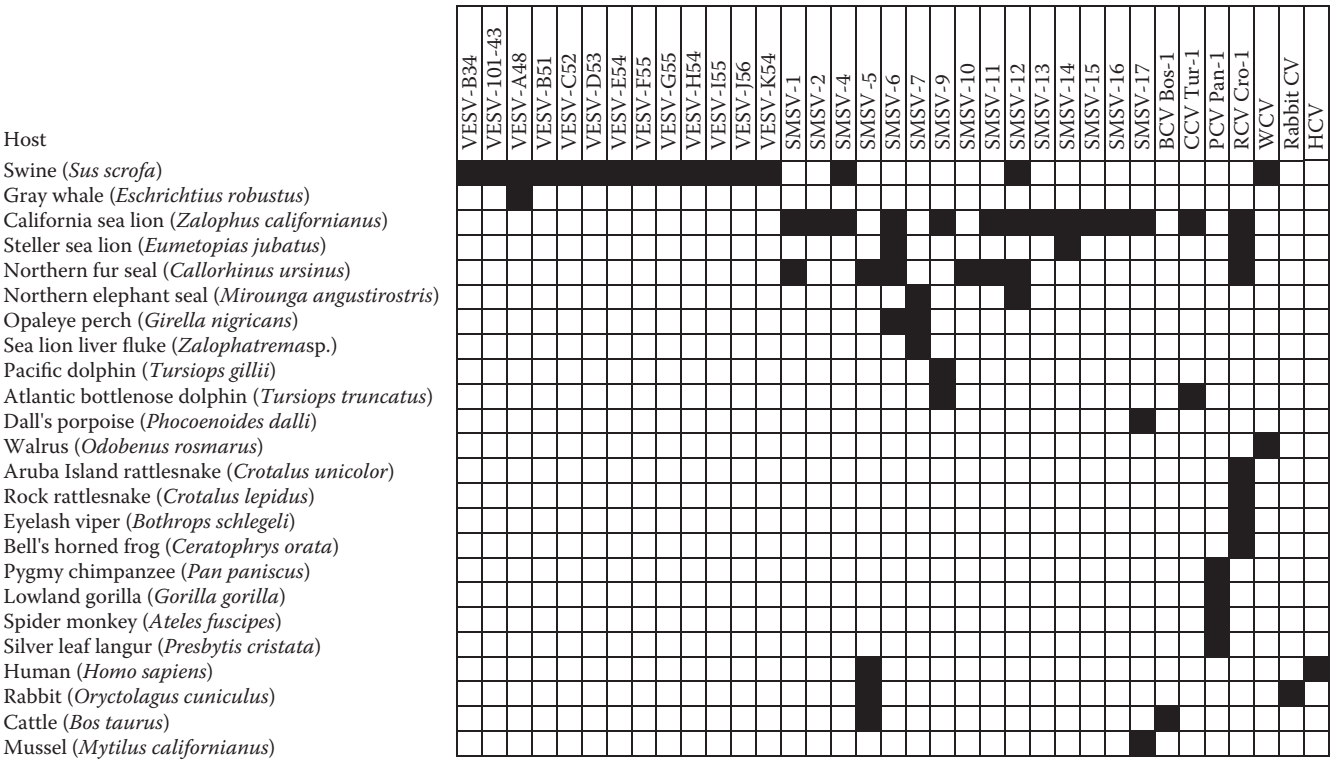

FIGURE 16.3 Broad species distribution of vesicular exanthema of swine viruses/San Miguel sea lion virus and related vesiviruses. Note: Shaded boxes in figure denote host species from which VESV/SMSVs have been isolated. (Data compiled from various publications [see listed references] and from the Laboratory for Calicivirus Studies list of Calicivirus, Oregon State University, Oregon, USA. [Vesiviruses cell culture adapted] isolated and in repository, http://www.kindplanet.org/smith/isolations.htm, Accessed on March 31, 2015.)

leaving raw, bleeding ulcers that are subsequently covered with a fibrinous membrane. Secondary vesicles may appear adjacent to the ruptured vesicles. Oral lesions cause excessive salivation, tongue protrusion, dysphagia, anorexia, and subsequent weight loss due to reduced food intake. Nasal lesions may cause airway obstruction and associated signs. Lesions in the feet cause swelling, inflammation, and lameness, which can be exacerbated by secondary bacterial infections. In severe cases, inflammation of the legs and joints may also occur. The vesicular forms of VESV/SMSV can appear concurrently with diarrhea in infected animals, as well as abortion, stillbirth, cessation of milk production, mortality in suckling piglets, and weakness or death in growing pigs. Morbidity ranges from 30% to 90%, but mortality in adult animals is low. Lesions normally heal in 5–7 days but can be complicated by secondary bacterial infections causing recovery to take up to 90 days. The hooves of previously infected pigs can have a dark horizontal line between the old and the healed wall, which is a characteristic mark of VES and other vesicular diseases.

Natural infections of pinnipeds with VESV/SMSV are associated with clinical signs, including vesicles (fluid-filled blisters) up to 25 mm in diameter on the hairless parts of the dorsal and ventral aspects of flippers and, less frequently, around the mouth and on the hairy regions of the body [33–35]. Vesicles may rupture leaving erosion or may regress without rupturing. Abortion and premature births, and possibly encephalitis and pneumonitis, occur in pinnipeds [5]. In humans, SMSV-5 caused systemic illness, including vesicular lesions on all four extremities [14].

16.1.2.3 Pathogenesis

Pathogenesis of the disease after intradermal inoculation of pigs can be divided into two phases: formation of "primary" lesions at the site of inoculation (12–48 h postinfection) accompanied by fever, followed by formation of "secondary" lesions (48–72 h later), at different locations to the primary lesions. These secondary vesicles may occur as a result of local spread of the virus from the primary lesions, or an effect of systemized viremia. Subcutaneous, intramuscular, and intravenous inoculations are followed by the development of vesicles at any susceptible site within 24–96 h. Vesicles consist of an accumulation of cell debris and fluid, as a consequence of viral replication in the cells of the epidermis, and spread to adjacent cells [1]. Inflammation occurs in subcutaneous connective tissues. The virus has been isolated from the draining lymph nodes of cutaneous lesions (such as mandibular, prescapular lymph nodes), as well as superficial inguinal lymph nodes [32,33]. Pigs remain infectious for about 5 days and the length of the viremia and the generation of neutralizing antibodies depend on the particular strain of the virus and the host [32–35]. In pigs, the viremia can be difficult to detect as it is intermittent, but never more than 4 days in length [32]. However, in pinnipeds, viremia may last up to 11 days [35]. Neutralizing antibodies in pigs

Downloaded From Vet-eBooks.com

appear 3–5 days after infection and can be maintained at high titers anywhere from 90 days to 30 months [2]; in pinnipeds, neutralizing antibodies may last for more than 75 days [35].

16.1.3 Diagnosis

Conventional techniques: As clinical differentiation of VESV from other notifiable vesicular diseases of pigs is impossible, numerous methods have been developed for the detection of VESV, including cell culture virus isolation [37], indirect immunofluorescence [38], indirect antigen ELISA [39], complement fixation [37,40,41], agar diffusion [37,41], cross-immunity challenges [3], and virus neutralization [3,37]. Before the advent of molecular assays such as RT-PCR [19,42,43] and real-time RT-PCR (rRT-PCR [20]), diagnosis was primarily based on the detection of VESV-specific antibodies. The most commonly used assays have been complement fixation [37,40,41] and virus neutralization [3,37]. However, as these assays can be time consuming (e.g., 4 days to obtain results by virus neutralization) and are dependent upon antiserum and cell culture availability, additional diagnostic methods were developed. These additional methods included VESV antigen detection by indirect immunofluorescence [38] and indirect antigen ELISA [39]. Although these assays did not eliminate the need for antiserum and cell culture, diagnostic results could be obtained rapidly, and as demonstrated previously [39], the antigen ELISA was more sensitive than complement fixation. An advantage of a number of these conventional assays (e.g., complement fixation, virus neutralization, and antigen ELISA) is the capability to determine the serotype of the VESV [3,39,40].

Molecular techniques: The development of conventional (agarose gel–based) RT-PCR assays for the detection of VESV/SMSV has enhanced the ability to diagnose VES; however, to ensure diagnostic sensitivity, these assays should be used in conjunction with virus isolation. An advantage of the conventional RT-PCR method is the ability to sequence the DNA amplicon. As the RT-PCR assays developed for VESV/SMSV are directed at both hypervariable and highly conserved regions of the genome, these assays provide tools to both detect and study the genetic relatedness of these viruses using phylogenetic reconstruction methods [19,42].

Increased diagnostic sensitivity has been achieved with the development of rRT-PCR assays for VESV/SMSV [20,44]. With this approach VES/SMS viruses can be detected in clinical samples without virus isolation. In addition, the VESV/SMSV-specific rRT-PCR assay can be performed in parallel with other assays used for the detection of FMDV, VSV, and SVDV, and therefore it can be applied as a differential diagnostic tool for these notifiable vesicular diseases [20]. Other methods for differential diagnosis of vesicular diseases, including a conventional multiplex RT-PCR assay [43] and microarrays [43,45], have been described but these methods are not currently used for routine diagnostics. Of these methods, rRT-PCR followed by DNA sequencing (as outlined later in Section 16.2.2) provides the most effective approach for the detection and characterization of VES/SMS viruses.

The use of next-generation sequencing is being used increasingly in molecular epidemiology studies of viruses as new approaches for obtaining full genome sequences are being developed. Recently, a new Illumina protocol for whole genome sequencing of positive-stranded RNA viruses, including caliciviruses, was described (Figure 16.4) [46]. In this protocol, the RNA in genomic DNA-depleted samples is transcribed using nonspecific primers and second-strand DNA is synthesized prior to library preparation. With this

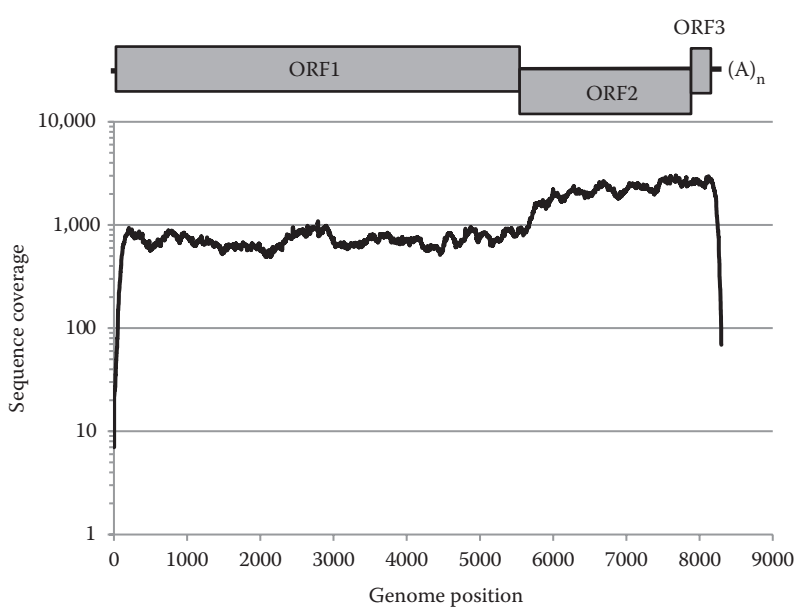

FIGURE 16.4 Sequence coverage of a complete vesicular exanthema of swine virus genome (VESV B1-34; GenBank KM269481) generated by a next-generation sequencing (Illumina) protocol. The genome is annotated to highlight the three different vesicular exanthema of swine virus open reading frames.

Downloaded From Vet-eBooks.com

approach, viral genome sequences can be obtained from a limited quantity of starting material and without the requirement for genome specific amplification.

16.2 METHODS

16.2.1 Sample Collection and Preparation

Vesicular epithelium is the preferred sample type for VES diagnosis; however, virus can be detectable at low levels in the blood of acutely infected pigs [47]. Epithelium samples should be collected into phosphate-buffered glycerine (pH 7.4) and stored at −20°C or below until processed. Tissue suspensions are prepared by grinding a small portion of vesicular epithelium in a mortar and pestle with sterile sand and phosphate-buffered solution (approximately 10% w/v; [39]). Suspensions are clarified by centrifugation and stored at −80°C. Viral antigens and/or genome may be detectable in these original suspensions. The original suspension can also be used to inoculate cells for virus propagation in susceptible cell culture systems. Porcine kidney cells such as PK-15 [37,38] and IB-RS-2 [39] are permissive to VESV/SMSV infection and develop cytopathic effect (CPE). Cell culture supernatant samples are clarified by centrifugation and stored at 4°C for immediate use or −80°C for long-term storage (also at −20°C in 50% glycerol).

16.2.2 Detection Procedures

16.2.2.1 Real-Time RT-PCR

Nucleic acid can be extracted from the original tissue suspension or from cell culture–propagated virus. Several methods have been used for the extraction of VESV RNA, including manual extraction with TRIzol (Gibco; [19]) or QIAzol (Qiagen; [43]), spin columns (RNeasy mini kits, Qiagen; [45]), and automated extraction with a MagNA Pure LC robotic machine (Roche; [20,48]). The following protocol is based on the one-step RT-PCR protocol for the diagnosis of FMDV and related vesicular diseases used at the Pirbright Institute (based on [49,50]).

16.2.2.1.1 Procedure

1. Dilute the primers and probe to the working concentrations. The primers and probe were developed for the universal detection of marine caliciviruses, including VESV, and target a conserved region of the RNA polymerase gene [20].

Oligo Name	Sequence (5′–3′)	Working Concentration (pmol/μL)
Forward primer	GAY GAC GGT GTY TAC ATY GTY C	10
Reverse primer	GGG AYI GGC GTT ATY TCA GCR T	10
Probe	CTG AAR CCG ACY CGG ACC GAC A	5

2. Prepare the one-step RT-PCR master mix in the following. Note: Gently mix all of the components with a pipette and spin down before use.

Component	Volume per Reaction (μL)
2× reaction mix	12.5
Nuclease-free water	1.5
Forward primer	2
Reverse primer	2
TaqMan probe	1.5
Superscript III RT/Platinum Taq mix	0.5
Total	20

3. Add 20 μL of master mix per well of the PCR plate (or PCR tube).
4. Add 5 μL of extracted/sample RNA per well and then seal the plate.
5. Spin the plate for 1 min.
6. Load the PCR plate in the real-time PCR machine and use the following program: 30 min at 60°C, followed by 10 min at 95°C, and then 50 cycles of 95°C for 15 s, and 60°C for 1 min.

Note: The cycling conditions listed earlier can also be used for FMDV$^{5'\ UTR}$ [51], FMDV^{3D} [52], and SVDV$^{2B\text{-}IR}$ [49] one-step RT-PCR assays. As such, RNA samples can be tested simultaneously for FMDV, SVDV, and VESV on a single PCR plate in three or four separate one-step RT-PCR assays.

16.2.2.2 Sequence Analysis

To investigate genetic relatedness of VESV/SMSV, RT-PCR amplicons of different parts of the genome can be sequenced and compared by phylogenetic analysis. A number of different conventional RT-PCR assays are suitable for the generation of amplicons for sequencing using the Sanger approach, including those listed in the following:

Targeted Region	Primer Name	Product Size (bp)	Nucleotide Variability	Sequence (5′–3′)	Reference
RNA helicase-like coding region	Hel1	357	Conserved	GTCCCAGTATTCGGATTTGTCTGCG	[42]
	Hel2			AGCGGGTAGTTCAGTCAAGTTCACC	
RNA-dependent RNA polymerase coding region	Pol1	419	Conserved	GCCTTCTGGTATGCCACTAACATCC	[42]
	Pol3			GGTGGAACGGTCCAATTTTCAGTG	
N-terminal capsid coding region	1F	768	Intermediate	GTGAGGTGTTTGAGAATTAG	[19]
	1R			ACATCAATTCCGCCAGACCA	
Capsid protein precursor gene—A region	A left	520	Intermediate	CCACTATGGCTACTACTCACACGC	[53]
	A right			TGTTGAACGACAGTGCCTTG	
Capsid protein precursor gene—E region	E left	666	Variable	TGATTCCACAACAACTGGTTGGTC	[53]
	E right			TGAGATGTCATCAGAATCTGGCTG	

Downloaded From Vet-eBooks.com

Prior to the sequencing procedure, the concentration of RT-PCR products must be quantified and unused primers and nucleotides must be removed from the reaction. This can be achieved with a commercial post-PCR purification kit, such as QIAquick PCR purification kit (Qiagen) or illustra GFX PCR DNA and gel band purification kits (GE Healthcare Life Sciences) used according to manufacturer's instructions. The concentration of the PCR product can be estimated using electrophoresis by running the sample in parallel to a standard DNA, or by using a spectrophotometer (e.g., NanoDrop, Thermo Scientific). Purified PCR products of known concentrations can be used as a template in cycle sequencing reactions, such as the protocol detailed in the following (BigDye Terminator v3.1 Cycle Sequencing Kit; Applied Biosystems, Foster City, CA).

16.2.2.2.1 Procedure

1. For each sequencing reaction, mix the following reagents:

Component	Volume per Reaction (μL)
Terminator ready reaction mix (v3.1)	0.5
5× sequencing buffer	2
Purified PCR product (~100 ng)	1
Sequencing primer (10 μM) (refer to the previous table)	1
Nuclease-free water	5.5
Total	10

2. Centrifuge at 14,000 × *g* for 30 s.
3. Incubate the sample in a thermocycler for 1 min at 96°C followed by 25 cycles of 96°C for 10 s, 50°C for 5 s, and 60°C for 4 min.
4. Purify the product of sequencing amplification by ethanol-EDTA precipitation, wash with 70% ethanol, and dry the pellet.
5. Resuspend the pellet in 20 μL formamide and analyze the nucleotide sequence of the DNA product using an automated DNA sequencer, such as ABI 3100 (Applied Biosystems, Foster City, CA).

After obtaining good-quality sequence data, compare the sequence to other publicly available sequences in the National Center for Biotechnology Information, GenBank, European Molecular Biology Laboratory, or DNA Data Bank of Japan databases. MEGA software [54] can be used to perform phylogenetic comparisons.

16.3 FUTURE PROSPECTIVE

In view of the widespread nature of the VESV/SMSV complex in the aquatic environment in the Pacific Ocean, the possibility that vesicular disease might reoccur in domesticated species (e.g., pigs) in the United States or elsewhere is real. Therefore, the maintenance of diagnostic testing laboratories and the development of new approaches that can be used to detect and characterize these viruses remain an important priority.

17.1 INTRODUCTION

The leukosis/sarcoma (L/S) group of diseases encompasses a variety of transmissible benign and malignant neoplasms of chickens caused by members of the family *Retroviridae* [1]. The term "leukosis" embraces several different leukemia-like proliferative diseases of the cells of the hemopoietic system due to avian leukosis virus (ALV), with an undertone that a leukemic blood picture is not always present [2,3]. The components of the hemopoietic system that may undergo neoplastic change include the lymphopoietic (lymphocytic) system, the erythropoietic (red cell) system, and the myelopoietic (myelocytic) system. Presenting signs of the leukosis are mostly nonspecific (loss of appetite, weakness, emaciation, diarrhea, pale wattles). Lymphoid leukosis (LL) has been the most common form of L/S group of diseases seen in field flocks, although more recently, myeloid leukosis has become increasingly prevalent.

ALV infection is commonly encountered in chicken flocks and is known to be of significant economic importance. Losses from ALV-induced diseases are attributed to two sources. First, the tumor mortality that usually accounts for 1%–2%, with occasional losses as high as 20% in some flocks. Second, subclinical infection by ALV, to which most flocks are subjected, produces a depressive effect on a number of key performance traits, including egg production and quality [4–6]. Economic losses due to ALV tumor mortality and reduced productivity were estimated to be in millions of U.S. dollars each year [7]. Currently, the virus is causing huge economic losses to the poultry industry in countries such as China [8,9].

17.1.1 Etiology

17.1.1.1 Classification

Viruses of the avian leukosis/sarcoma group (ALSV) belong to the genus *Alpharetrovirus*, subfamily *Orthoretrovirinae*, family *Retroviridae* (which contains another subfamily *Spumaretrovirinae*). Whereas the subfamily *Orthoretrovirinae* includes six genera (*Alpharetrovirus*, *Betaretrovirus*, *Deltaretrovirus*, *Epsilonretrovirus*, *Gammaretrovirus*, and *Lentivirus*), the subfamily *Spumaretrovirinae* consists of a single genus *Spumavirus*. In turn, the genus *Alpharetrovirus* is divided into nine species: *avian carcinoma Mill Hill virus 2*, *ALV* (the type species), *avian myeloblastosis virus*, *avian myelocytomatosis virus 29*, *avian sarcoma virus CT10*, *Fujinami sarcoma virus*, *Rous sarcoma virus* (RSV), *UR2 sarcoma virus*, and *Y73 sarcoma virus* [10]. In common with other members of this RNA virus family, ALVs are characterized by the unique possession of the enzyme reverse

Downloaded From Vet-eBooks.com

transcriptase that drives the generation of the DNA provirus that is integrated into the host genome during viral replication.

17.1.1.2 Virus Structure and Replication

Structurally, ALVs are simple viruses (Figure 17.1). From the 5′ end to the 3′ end of the genome are located four main genes, *gag/pro-pol-env*, which encode, respectively, the proteins of the virion group-specific (gs) antigens and protease, the enzyme reverse transcriptase, and the envelope glycoprotein. These structural genes are flanked by genomic sequences associated with the regulation of viral replication, which in the DNA provirus form the viral long terminal repeats (LTRs) that carry promoter and enhancer sequences. Some laboratory strains and field isolates of ALV also possess one (or rarely two) viral oncogene(s) inserted within the genome. Such viruses have acquired the oncogene by transduction of a cellular oncogene during oncogenesis. These viruses are usually genetically defective, with deletions within the genome, and require the presence of "helper viruses" (coinfecting nondefective ALVs) to enable replication. As with other retroviruses, replication of ALSV is characterized by the formation, under the direction of reverse transcriptase, of a DNA provirus that becomes linearly integrated into the host cell genome. Subsequently, the proviral genes are transcribed into viral RNAs, which are translated to produce precursor and mature proteins that constitute the virion.

17.1.1.3 Avian Leukosis Virus Envelope Subgroups

ALVs can be classified as endogenous (subgroup E) or exogenous viruses according to their mode of transmission. Exogenous ALVs from chickens can be classified into five subgroups (A, B, C, D, and J), on the basis of differences in the viral envelopes that affect antigenicity, as determined by induction of virus neutralizing antibodies, host range, and the ability to interfere with infection by other ALVs of the same or differing subgroups. The F, G, H, and I subgroups of ALV are found in ring-necked and golden pheasants, Hungarian partridge, and Gambel's quail, respectively. Viruses of subgroups A, B, C, D, and J are oncogenic, causing mainly lymphoid leukosis (subgroups A and B) or myeloid leukosis (subgroup J). Subgroup E viruses are not oncogenic. Viruses within a subgroup usually cross-neutralize to varying extents, although antigenic variants of subgroup J ALV exist that do not cross-neutralize. A partial cross-neutralization occurs between subgroup B and D viruses, but otherwise viruses in the different subgroups do not cross-neutralize each other.

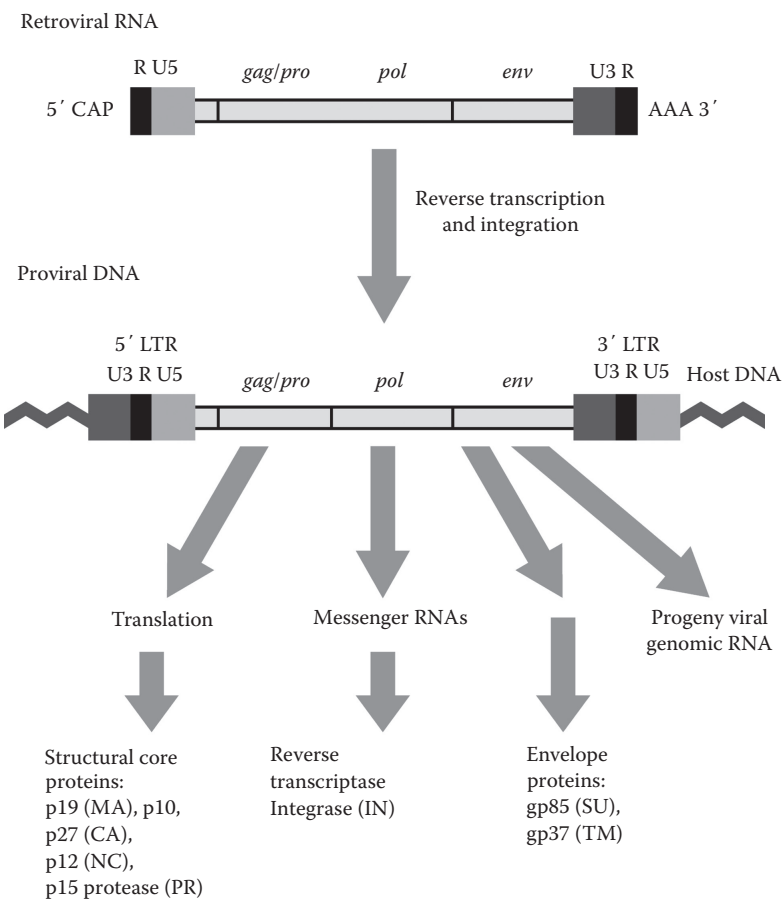

FIGURE 17.1 Key features of the viral RNA and proviral DNA forms of the genome of avian leukosis virus. CAP, 5′ end structure; AAA, polyadenylation of 3′ end; R, repeat sequence; U5, unique 5′ end sequence; U3, unique 3′ end sequence; LTR, long terminal repeat; MA, matrix protein; CA, capsid protein; NC, nucleocapsid protein; PR, protease; SU, surface protein; TM, transmembrane.

Downloaded From Vet-eBooks.com

Strains of ALSV can also be placed into two major classes in respect of rapidity of induction of tumors: *acutely transforming viruses* and *slowly transforming viruses*.

1. *Acutely transforming viruses* are those that carry viral oncogenes in their genome. These viruses can induce neoplastic transformation, *in vivo* or *in vitro*, within a few days or weeks. Depending on the oncogene possessed by the virus, acutely transforming ALVs induce different types of neoplasms, for example, v-myc, myeloid leukosis (myelocytoma); v-myb, myeloid leukosis (myeloblastosis); *v-erbB*, erythroid leukosis; and v-src, sarcoma [11–15]. Such ALVs are termed "acutely transforming," and neoplastic cells are induced within a few days after infection.
2. *Slowly transforming viruses* do not carry viral oncogenes. They induce tumors by activation of a cellular proto-oncogene to bring about neoplastic transformation and development of tumors over many weeks or months [12,15–18].

17.1.1.4 Pathogenicity

Strains of ALV often produce more than one type of neoplasm, and the oncogenic spectrum of each strain tends to be characteristic but often overlaps with responses to other strains. Viral factors including the origin and dose and host factors such as route of inoculation, age, genotype, and sex will influence the incidence and types of neoplasms induced.

17.1.2 Transmission and Epidemiology

Exogenous ALVs are almost ubiquitous in commercial chickens on a worldwide basis, although many primary egg-type and meat-type breeding companies institute ALV eradication schemes. Chickens are the natural hosts for all viruses of L/S group [19]; these viruses have not been isolated from other avian species except pheasants, partridges, and quail.

Exogenous ALVs are transmitted in two ways: vertically from infected hens to their offspring through the egg and horizontally from bird to bird by direct or indirect contact [7,9,20]. Although usually only a small percentage of chicks are infected vertically, this route of transmission is important in transmitting the infection from one generation to the next and in providing a source of contact infection to other chicks. Most chickens become infected by close contact with congenitally infected birds. Sources of virus from infected birds include feces, saliva, and desquamated skin. The period of survival of ALV outside the body is relatively short (a few hours), and consequently ALV is not highly contagious. Although vertical transmission is important in the maintenance of the infection, horizontal infection may also be necessary to maintain a rate of vertical transmission sufficient to prevent the infection from dying out [21]. The infection does not spread readily from infected birds to birds in indirect contact (in separate pens or cages), probably because of the relatively short life of the virus outside the birds. However, contact exposure at hatch was shown to be an effective method of spread of ALV-J among broiler breeder chickens [22–24] and was prevented by small group rearing [25].

Four classes of ALV infection statuses are recognized in mature chickens: (1) no viremia, no antibody (V−A−); (2) no viremia, with antibody (V−A+); (3) with viremia, with antibody (V+A+); and (4) with viremia, no antibody (V+A−) reviewed by [7,9,20,26]. Birds in an infection-free flock and genetically resistant birds in a susceptible flock fall into the category V−A−. Genetically susceptible birds in an infected flock fall into one of the other three categories. Most are V−A+, and a minority, usually less than 10%, is V+A−. Most V+A− hens transmit ALV to a varying but relatively high proportion of their progeny [9,20]. A small proportion of V−A+ hens transmit the virus congenitally and do so more intermittently; the tendency for congenital transmission of ALV in this category was found to be more frequent in hens with low antibody titer [27]. Congenitally infected embryos develop immunologic tolerance to the virus and after hatching make up the V+A− class, with high levels of virus in the blood and tissues and an absence of antibodies. By 22 weeks of age, up to 25% of meat-type chickens exposed to ALV-J at hatch were found to be V+A−, although this could be affected by a number of factors including the virus strain [28].

Birds from infected flocks, and products, such as eggs and meat, could spread infection to other flocks and locations. As ALV is vertically transmitted, infection may spread internationally in hatching eggs and day-old chicks, and spread in semen is possible. Importers need to guard against the introduction of ALV by requiring health certificates from the exporter relating to the specific disease and infection status of source flocks. Introduction of a new ALV into susceptible poultry populations could have serious consequences because of the absence of immunity and of effective control measures in breeding and production populations other than at the primary breeding level.

17.1.3 Clinical Features and Pathogenesis

Outward signs of the leukotic diseases are mostly nonspecific. They include loss of appetite, weakness, diarrhea, dehydration, and emaciation. In lymphoid leukosis especially, there may be abdominal enlargement. The comb may be pale, shriveled, or occasionally cyanotic. In erythroblastosis and myeloblastosis, hemorrhage from feather follicles also may occur. After clinical signs develop, the course is usually rapid, and birds die within a few weeks. Other affected birds may die without showing obvious signs.

Fully developed LL occurs in chickens of about 4 months of age and older. Grossly visible tumors almost invariably involve the liver, spleen, and bursa of Fabricius. Other organs often grossly involved include the kidney, lung, gonad, heart, bone marrow, and mesentery. The tumor cells are B cells, expressing immunoglobulin M (IgM) and other B-cell markers, which originate in the bursa of Fabricius but subsequently develop metastasis to other visceral organs.

Downloaded From Vet-eBooks.com

Natural cases of erythroblastosis (erythroid leukosis) usually occur in birds between 3 and 6 months of age. The liver and kidney are moderately swollen, and the spleen often is greatly enlarged. The enlarged organs are usually cherry red to dark mahogany and are soft and friable. The bone marrow is bright red and liquid. Affected birds are often anemic, with muscle hemorrhages and occasionally abdominal hemorrhage from a ruptured liver. The disease is an intravascular erythroblastic leukemia.

Myeloblastosis (myeloblastic myeloid leukosis) was predominately a sporadic disease of adult chickens. The liver is greatly enlarged and firm with diffuse grayish tumor infiltrates, which give a mottled or granular ("Morocco leather") appearance. The spleen and kidneys are also diffusely infiltrated and moderately enlarged. The bone marrow is replaced by a solid, yellowish-gray tumor cell infiltration. A severe leukemia exists, with myeloblasts comprising up to 75% of peripheral blood cells and forming a thick buffy coat and usually an anemia and thrombocytopenia.

Tumors of myelocytomatosis (myelocytic myeloid leukosis) are distinctive and can be recognized on gross examination with some degree of certainty. Characteristically, they occur on the surface of bones in association with the periosteum and near cartilage, although any tissue or organ can be affected. Myelocytomas often develop at the costochondral junctions of the ribs, on the inner sternum, on the pelvis, and on the cartilaginous bones of the mandible and nares. Flat bones of the skull are also commonly affected. Tumors may also be seen in the oral cavity, on the trachea, and in and around the eye [29]. The tumors are usually nodular and multiple, with a soft, friable consistency and of creamy color. In the disease caused by subgroup J ALV, myelocytomatous infiltration often causes enlargement of the liver and spleen and other organs, in addition to skeletal tumors [30] and myelocytic leukemia [31].

Hemangioma is found in the skin or in visceral organs in chickens of various ages. They appear as blood-filled cystic masses (blood blisters) or more solid tumors and consist of distended blood-filled spaces lined by endothelium or as more cellular, proliferative, lesions [32]. They are often multiple and may rupture, causing fatal hemorrhage [33]. More recently, many workers have reported the incidence of hemangiomas in layer chickens infected with ALV-J in China [34–36].

Renal tumors may cause paralysis due to pressure on the sciatic nerve. Sarcomas and other connective tissue tumors may be seen in the skin and musculature. When advanced, these various other tumors may be accompanied by the nonspecific signs given previously. Benign tumors may follow a long course, malignant tumors a rapid one.

In osteopetrosis, the long bones of the limbs are commonly affected. Uniform or irregular thickening of the diaphyseal or metaphyseal regions can be detected by inspection or palpation. The affected areas are often unusually warm. Birds with advanced lesions have characteristic "bootlike" shanks. Affected birds usually are pale and stunted and walk with a stilted gait or limp. In recent years, ALV has also been shown to be associated with the so-called fowl glioma [37], associated with cerebellar hypoplasia and myocarditis [38–42].

17.1.4 Diagnosis

17.1.4.1 Conventional Techniques

17.1.4.1.1 Virological Tests

As ALV is widespread among chickens, virus isolation and the demonstration of antigen or antibody have limited or no value in diagnosing field cases of lymphomas. However, assays for the detection of ALV are very useful in the identification and classification of new isolates, safety testing of vaccines, and testing pathogen-free and other breeder flocks for freedom from virus infection. Virus isolation is generally the ideal detection method (the so-called gold standard) since the technique can detect all ALVs and is the starting point for various other virus studies. Samples most commonly used for detection of ALV include blood, plasma, serum, meconium, cloacal and vaginal swabs, oral washings, egg albumen, embryos, and tumors [7,43,44]. Virus also can be isolated from albumen of newly laid eggs or the 10-day-old embryo of eggs laid by hens that are transmitting virus vertically, from feather pulp, and from semen. All ALSVs are very thermolabile and can be preserved for long periods only at temperatures below −60°C. Thus, materials used for biological assays for infectious virus should be collected and placed on melting ice or stored at −70°C until assayed. In contrast, samples for the detection of ALV gs antigens by direct assays can be stored at −20°C.

Considering that most strains of ALV produce no visible morphologic changes in cell culture, assays for the presence of ALV are based on the following: (1) detection of specific proteins or glycoproteins coded for by one or more of the three major genes of ALV—*gag*, *pol*, and *env* genes—(2) detection of specific proviral DNA or viral RNA sequences of ALV by the polymerase chain reaction (PCR) and reverse transcription (RT)-PCR, respectively. Several biological, molecular, and serological assays can be used for the detection of endogenous and exogenous ALVs.

As most ALVs produce no visible morphologic changes in culture, detection of ALV p27 forms the basis of several diagnostic tests for virus. Indirect biologic assays such as complement fixation (CF) for avian leukosis, ELISA for ALV, phenotypic mixing (PM), resistance-inducing factor (RIF), and nonproducer (NP) cell activation tests are used for the detection of ALVs. Of all such assays, ELISA is the most commonly used test. But, p27 is shared by both exogenous and endogenous viruses; hence, the assay cannot be used to differentiate between these two groups of viruses. All these biological assays require the use of chicken embryo fibroblasts (CEFs) with specific host range. CEFs that are resistant to infection with endogenous ALV (C/E) are desirable to use in tests for detection and isolation of exogenous ALV. Other cells, such as those resistant to subgroup A (C/A) and resistant to subgroup J ALV (C/J) [45], can also be used to confirm the subgroup of isolated ALV. Testing samples on CEFs that are susceptible to all subgroups of ALV (C/O) and those that are resistant to subgroup E (C/E) can be used in differentiating exogenous and endogenous ALV. If a positive test is obtained from using C/O but not C/E CEFs, the sample is positive for endogenous ALV. Positive tests using both C/E

Downloaded From Vet-eBooks.com

and C/O indicate the presence of exogenous ALV. Recently, a flow cytometry method using a highly specific alloantibody termed R2 has been described for the detection of endogenous ALV envelope in chicken plasma [46,47]. It should be noted that some tests such as CF and ELISA and possibly NP, PM, R(-)Q cell, and fluorescent-labelled antibody (FA) can be suitable for all leukosis and sarcoma viruses. The RIF test can be performed only on ALVs that are not rapidly cytopathogenic. Other tests are specific for certain virus strains. Rapid transformation of fibroblast cultures is produced only by certain RSV and of hematopoietic cell cultures only by defective ALV.

Direct [48] and indirect [49] immunofluorescence assay as well as flow cytometry [45,50] have been used to detect viral antigen in CEF cultures. Flow cytometry has also been shown to be a very useful tool in identifying the subgroup of ALV strains contaminating commercial Marek's disease vaccines [51–53]. Assays for RT activities have been used for the detection of oncogenic RNA viruses including all ALSVs [54]. Detection of this enzyme, either directly using a correct template for detecting enzymatic activity [55,56] or indirectly using radioimmunoassay [57], is an indication of the presence of the virus. Test for adenosine triphosphatase activity specifically for avian myeloblastosis virus has also been reported.

17.1.4.1.2 Characterization of ALV Subgroups

ALV isolates belonging to different subgroups can be characterized using the following methods:

1. Viral interference assays, which test the ability of an isolate to interfere with the formation of transformed foci in C/E CEF cultures by RSV of known subgroup.
2. Virus neutralization assays, in which an isolate is placed in a subgroup according to susceptibility to neutralization by chicken antisera with known subgroup neutralizing activity. The isolate or the RSV pseudotype is exposed to antiserum and then examined for growth or focus formation, respectively, in C/E CEF cultures. An RSV pseudotype is an acutely transforming RSV that can be created by coating a replication-defective RSV with the viral envelope of an ALV and hence endowing the virus with the subgroup characteristics of the ALV, in this case of the isolate. Fluorescent antibody staining of infected cultures using antisera against different subgroups is also used. These methods are usually satisfactory, although in the case of subgroup J isolates, in which *env* gene mutations and consequent antigenic changes are frequent, subgroup J antisera may fail to neutralize new variants. However, mouse monoclonal antibodies have been developed that appear in fluorescent antibody tests to detect a wider range of subgroup J isolates.
3. Host range assays, in which an isolate, or the RSV pseudotype, is placed in a subgroup according to the ability to grow in, or transform, respectively, CEFs of varying ALV subgroup susceptibility phenotypes. For example, a subgroup A ALV would be identified if the virus grew in C/E CEFs but did not grow in C/AE CEFs (resistant to subgroups A and E). This method relies on the availability of CEF phenotypes that exclude certain ALV subgroups. Naturally occurring CEFs that exclude subgroup J have never been detected, although workers in the United States have developed a C/J CEF line that stably expresses J *env* gene [18].
4. PCR assays specific for various ALV subgroups have been developed [16,37,38], as discussed later.

17.1.4.1.3 Serological Assays

Detection of antibodies against ALV is used in flock surveillance to detect the presence or absence of infection by exogenous ALV and to identify particular classes of birds in epidemiological studies and ALV eradication programs. Plasma, serum, and egg yolk are suitable samples for the detection of antibodies to ALSVs. Virus neutralization and antibody ELISA can be used as described in the following:

1. Virus neutralization tests. Antibody is detected by its ability to neutralize infectivity of ALVs of known subgroup or of the RSV pseudotypes. Usually, a 1:5 dilution of heat-inactivated (56°C for 30 min) serum is mixed with an equal quantity of a standard preparation of RSV of a known pseudotype. After incubation, the residual virus is quantitated by any one of many procedures, the cell culture assay being the most commonly used. A microneutralization test to assay for residual virus can be used for the detection of ALV antibody [44]. The test can be conducted in 96-well plates, and the neutralization of the virus is determined by ELISA on culture fluids [58]. Positive ELISA indicates no antibody, whereas a negative ELISA indicates neutralization of ALV and the presence of antibody. Although virus and antibody within subgroups usually cross-neutralize, antibodies against variant viruses may fail to neutralize a representative subgroup virus. This has been observed particularly with subgroup J, due to virus mutation, and is a limitation to the use of virus neutralization (VN) tests. These tests are slow requiring 7–10 days and are technically demanding.
2. Antibody ELISA tests. Viral antigens may be used in ELISA tests to detect sub-gs ALV antibodies. Tests for antibodies to subgroups A, B, and J are commercially available. The subgroup J antibody ELISA uses recombinant *env* antigen produced in baculovirus system and appears to detect antibodies to all variant viruses studied. The antibody ELISA tests are rapid (requiring one day), specific, and suitable for large-scale testing.

17.1.4.2 Molecular Techniques

A more effective control of ALV infections mainly depends on the early detection and removal of infected birds to

Downloaded From Vet-eBooks.com

reduce contact with infected birds and the incidence of horizontal spread. Therefore, achieving rapid detection of infection is imperative in the effective control of the spread of ALVs. PCR-based methods had been developed to provide a rapid tool for the detection and identification of ALV's proviral DNA and viral RNA including subgroup E viruses. RT-PCR has also been used to detect several subgroups of ALV [59,60]. A specific PCR for ALV subgroup A can be used to detect proviral DNA and viral RNA in various tissues from ALV-infected chickens [61]. Reverse transcriptase–nested PCR (RT-nested PCR) test that amplifies a fragment of the LTR of exogenous ALV subgroups A, B, C, D, and J, but not endogenous retroviral sequences, has been described [62]. Several primers specific for the detection of the most commonly isolated ALVs, particularly subgroup A [63], and the new subgroup ALV-J [64–66] have been developed. Other primers specific for endogenous, subgroup E ALV can also be used to detect cell culture infected with endogenous ALV-E, but not those infected with exogenous ALV of subgroups A, B, C, D, and J [44]. Multiplex PCR is a useful technique for the rapid differential diagnosis of avian viruses and the detection of multiple infections of avian viruses under field conditions. Recently, a sensitive and specific multiplex PCR method for the detection of ALV-A, ALV-B, and ALV-J has been developed [67]. This novel method allows for three very common subgroups of exogenous ALVs (ALV-A, ALV-B, and ALV-J) to be detected and differentiated in one reaction. Real-time RT-PCR using the H5/H7 primer pair has been shown to be highly reproducible [68,69]. The rapid detection and quantification of ALV-J with proviral DNA [69] as well as ALV-A and ALV-B (duplex real-time RT-PCR) [60] using TaqMan-based real-time PCR method have also been reported.

As further modification of PCR tests, loop-mediated isothermal amplification (LAMP) method for ALV subgroup A and J has been developed [70,71]. The LAMP method was developed by Notomi et al. [72]. This novel technique generally requires isothermal conditions and four different primers for DNA amplification [72,73] and has been applied to the detection of several pathogens. The LAMP reaction requires 30–60 min and can be performed at a single temperature ranging from 60°C to 65°C. LAMP does not require the DNA denaturation, annealing, and extension PCR cycles [72,73]. In addition, the results can be ascertained easily by the naked eye [73,74].

17.2 METHODS

17.2.1 Sample Preparation

The most commonly used samples for proviral DNA extraction include cultured cells and clinical samples such as cloacal swabs, albumen, feather shaft, blood, tissue samples, and tumors. For the extraction of DNA from cultured cells, 1×10^6 infected cells were pelleted by centrifugation at $1000 \times g$ for 10 min. The resulting pellet was resuspended in 200 µL of lysis buffer (4 M guanidine hydrochloride, 25 mM sodium citrate, 1% sarkosyl) and extracted with 300 µL phenol/chloroform/iso-amyl alcohol (25:24:1) three times. The DNA was precipitated with isopropanol in the presence of 2 M ammonium acetate and centrifuged for 10 min at $10{,}000 \times g$ in a microcentrifuge. The pellet was washed with 70% ethanol and dried at room temperature. Subsequently, the DNA was resuspended in nuclease-free water and stored at –20°C. For the extraction of DNA from blood, 25 µL of whole blood was lysed in addition to 200 µL of lysis buffer, and 25 µL of this was diluted to 200 µL of water and then phenol extracted as for cultured cells. DNA from the feather shaft was obtained by incubating 5–10 mm portions in lysis buffer at 37°C overnight, followed by the extraction of DNA. Tissue samples, homogenized in phosphate-buffered saline containing 1000 units/mL of penicillin and streptomycin, were centrifuged at $6000 \times g$ for 5 min at 4°C, and an aliquot of the supernatant was subjected to proviral DNA extraction as described.

The total RNA from the virus stocks, serum samples, feather shaft, chicken egg albumen, and cell lysate can be extracted using a commercial reagent such as TRIzol according to the manufacturer's recommendations. After resuspension in diethyl pyrocarbonate–treated water, the RNA sample was transcribed with reverse transcriptase according to the manufacturer's protocol. The cDNA was treated with RNase H and the concentration was measured. Both the RNA and cDNA samples were stored at –70°C until use.

17.2.2 Detection Procedures

17.2.2.1 Conventional PCR Detection of ALV

The PCR is the most common DNA-based test used for detection and identification of ALV including subgroup E viruses. Most sequences used for developing primers are located in the *pol*, *env*, and LTR regions. Several pairs of primers were designed and tested for the detection of ALV subgroups by PCR [53,66,75,76]. The sequences of the primers, the target subgroups, and the expected size of PCR products are listed in Table 17.1. Of those, the forward primers H5 and all were conserved across several ALV subgroups so that they can be used in combination with several sub-gs reverse primers as detailed in the table. The PCR conditions can be referenced to the original publications accordingly.

17.2.2.2 Multiplex PCR Detection of ALV

In the multiplex PCR method for the detection of the major ALV subgroups A, B, and J [67], a common forward primer, PF, and three downstream primers, AR, BR, and JR were designed to amplify 715 bp for subgroup A, 515 bp for subgroup B, and 422 bp for subgroup J simultaneously in one reaction (Table 17.1). The common forward primer PF, based on the 3′ region of the pol gene, was conserved across ALV-A, ALV-B, and ALV-J. The downstream primers were chosen from the *env* gene, which allows for discrimination of the three subgroups.

The DNA samples or cDNAs from RT reaction prepared earlier were used as templates in PCR reactions with different

pair/group of primers accordingly. PCR amplification was carried out as described, and the products were analyzed by 1.0% agarose gel electrophoresis. To further confirm the result and gain the detailed sequencing information, the PCR products from the gel were excised and purified using commercial DNA gel extraction kit. The purified DNA can be cloned into TA cloning vector for sequencing or sequenced directly using the same primer for PCR. The specificity and the divergence of the sequences obtained with respect to the corresponding sequences of ALV subgroup were determined using BLAST [77]. For DNA alignment and phylogenetic analysis, the nucleotide sequences were aligned with reference sequences from GenBank using the ClustalW program, version 1.8 [78]. A neighbor-joining tree can be drawn using the MEGA program, version 3.1 [79], with confidence levels assessed using 1000 bootstrap replications.

17.2.2.3 Quantitative PCR Detection of ALV

For the detection and quantitation of ALV subgroup A and B, a duplex quantitative real-time RT-PCR was developed [59]. The assay detected as few as 56 gp85 cDNA copies and was 100-fold more sensitive than a conventional RT-PCR. A highly conserved region within gp85 was used to design primers and the TaqMan probe using Beacon Designer software version 7.0 (Palo Alto, CA). β-*actin* was used as a reference gene. The sequences of the primers and probes were listed in Table 17.2. For construction of standard curves, two conventional RT-PCR products of *gp85* and β-*actin* genes with the same primers used for TaqMan were cloned, and the plasmid DNAs were prepared as described [60]. The duplex quantitative RT-PCR (qRT-PCR) was performed in a 25 μL reaction system containing 2.5 μL of 10× buffer, 2 μL of 2.5 mmol/L deoxynucleoside triphosphates (dNTPs), 1 μL of 10 μmol/L R-F primer, 1 μL of 10 μmol/L R-R primer, 0.5 μL of 5′-6-carboxy-fluorescein (FAM)-labeled gp85 probe, 1 μL of 10 μmol/L β-R primer, 1 μL of 10 μmol/L β-F primer, 0.5 μL of 5′-6-carboxy-X-rhodamine (ROX)-labeled β-actin probe, 0.5 μL of 5 U Hotstart ExTaq polymerase, 1 μL of template DNA, and 14 μL of distilled water. The amplification was run using a Rotor Gene 3000 Real-time Thermal Cycler (Corbett Research, Australia) with the following protocol: 94°C for 3 min followed by 40 cycles of 94°C for 15 s and 61.3°C for 50 s. The serially diluted recombinant plasmids, gp85 and β-actin, together with the cDNA of samples for the detection, were tested simultaneously. The copy numbers of virus and housekeeping genes were extrapolated from the standard curves for *gp85* and β-*actin* genes for each run.

For ALV-J quantification, Kim et al. developed and modified a quantitative competitive RT-PCR (QC-RT-PCR) method and a real-time RT-PCR method [68,80]. QC-RT-PCR method is based on coamplification of ALV-J genomic RNA and a known amount of a synthesized RNA competitor. The real-time RT-PCR method used the H5/H7 primer pair. These methods are very specific, sensitive, easy to perform, highly reproducible, and rapid compared with conventional method with 50% tissue culture infective dose ($TCID_{50}$) [68]. To improve the sensitivity, a TaqMan-based real-time PCR method for the rapid detection and quantification of ALV-J with proviral DNA (Table 17.2) was developed [69]. The forward primer ALV-JNF was designed against the 3′ region of the *pol* gene, which is conserved among several subgroups but not in the EAV family, according to the ALV-J sequence (HPRS-103; GenBank accession number Z46390.1). The reverse primer ALV-JNR was designed from a well-conserved region of the *gp85* gene of ALV-J, which could be distinguished from other subgroups. The TaqMan probe was a 23-bp oligonucleotide located downstream of ALV-JNF. Real-time PCRs were performed with a LightCycler 480 real-time thermocycler (Roche Instrument Center, Switzerland). To obtain optimal specific fluorescent signals, the annealing temperature and primer, probe, and Mg^{2+} concentration were optimized. The reaction was performed in a 25 μL system containing 1 μL of cDNA, 2.5 μL of 10× *Ex Taq* buffer, 2 μL of dNTP (2.5 mM), 1 μL of $MgCl_2$ (75 mM), 1 μL of ALV-JNF (10 pM), 1 μL of ALV-JNR (10 pM), 0.5 μL of probe (10 pM), 1 unit of *Ex Taq* HS (TaKaRa, China), and the appropriate volume of double-distilled water (ddH_2O). The real-time PCR was carried out with a predenaturation step at 95°C for 5 min and amplification for 40 cycles at a melting temperature of 95°C for 10 s and an annealing/elongation temperature of 65°C for 40 s. Fluorescent signals were collected during the elongation step. A 214 bp fragment of ALV-J was amplified with the primer pair ALV-JNF/ALV-JNR and then cloned into the pMD-18T vector (TaKaRa) to obtain the recombinant plasmid pMD-JNS. The concentration of the plasmid was determined with a UV spectrophotometer, and the plasmid copy number was calculated using the following formula: number of copies = (concentration in ng × 6.022×10^{23})/(genome length × 10^9 × 650). Serial dilutions from 1×10^1 to 1×10^{10} copies/μL of the plasmid standard DNA were used to produce a standard curve.

17.2.2.4 LAMP Detection of ALV

LAMP is a type of *Bst* polymerase–dependent nucleic acid amplification technology based on isothermal strand displacement amplification. Compared to conventional PCR using two primers, this technology has high specificity since it requires 4 (or 6) primers to identify 6 (or 8) specific domains. LAMP assay has been developed for simple, rapid, and sensitive detection of ALV-A and ALV-J [70,71].

The online software Primer Explorer V4 (https://primerexplorer.jp) was used to design the LAMP primers (including a pair of outer primers, F3 and B3; a pair of inner primers, forward inner primer [FIP] and back inner primer [BIP]; and a pair of loop primers, loop forward [LF] and loop back [LB]) within the gp85 as shown in Table 17.3 for ALV-A detection. A Loopamp DNA Amplification Kit (Eiken Chemical Co., Ltd., Tokyo, Japan) was used for the LAMP reaction. Each 25 μL reaction system contained the following: 12.5 μL of the reaction mix, 1 μL of *Bst* DNA polymerase, 1.6 μM of each inner primer (FIP and BIP), 0.8 μM of each loop primer (LF and LB), 0.2 μM of each outer primer (F3 and B3), 1 μL of fluorescent detection reagent (FDR, Eiken Chemical Co., Ltd., Tokyo, Japan), and 1 μL of DNA as template. Incubation at 65°C for 45 min was selected as the optimal reaction condition after optimization of different temperatures (61°C, 63°C, 65°C, and 67°C) and different time periods (45, 60, 90, 120 min). A Loopamp Realtime Turbidimeter LA-320C (Eiken Chemical Co., Ltd., Tokyo, Japan) was used to measure the turbidity and determine the reaction temperature and time. Using this method, 20 copies of viral nucleic acid sequence were detected within 45 min, which was 100 times more sensitive than conventional PCR. The fluorescent dye fluorescent detection reagent was added during the preparation of the reaction solution, this enabled the results to be assessed directly based on color changes (orange for negative and green for positive) without opening the lid of the reaction tube, which reduces the possibility of contamination.

Primers specific for ALV-J LAMP detection were designed using Primer Explorer V3 software (https://primerexplorer.jp) based on the *pol* and gp85 regions of the prototype strain of ALV-J, HPRS-103, which effectively avoid amplification of other subgroups and the EAV-HP family. The four primers consisted of one pair each of forward and reverse outer primers (F3 and B3) and forward and reverse inner primers (FIP and BIP) (Table 17.3). The 25 μL LAMP reaction was carried out with a set of specific primers containing 1.0 μM (each) FIP and BIP, 0.25 μM (each) F3 and B3, 0.8 mM each dNTP, 0.4 M betaine (Sigma-Aldrich, Inc., MO), 20 mM Tris-HCl, 10 mM KCl, 10 mM $(NH_4)_2SO_4$, 6 mM $MgSO_4$, 0.1% Tween 20, 8 U of Bst DNA polymerase (New England Biolabs), and 1 μL DNA template. The mixture was incubated at 63°C for 45 min in a water bath and terminated by incubation at 84°C for 5 min. The LAMP products were detected by several methods: 2% agarose gel electrophoresis with UV light transillumination, observation of turbidity, and naked-eye determination of color change after addition of SYBR Green I dye (2 μL per reaction tube) under normal light conditions (Cambrex BioSciences, Inc., ME). After the addition of SYBR Green I dye to the terminated reaction, the color indicating the positive reaction changed to yellowish green, whereas indicators of negative reactions remained reddish orange. The addition of SYBR Green I dye to the completed LAMP reaction mixture was advised for easy handling. The detection limit of the LAMP assay was 5 copies (approximately 0.02 fg) per reaction during a 45 min reaction, whereas that of conventional PCR was 100 copies per tube. Thus, the sensitivity of the LAMP assay was at least 20-fold higher than that of conventional PCR. Detection of positive samples by the use of the LAMP assay (26/49) demonstrated the higher sensitivity of this assay in comparison to conventional PCR (21/49) and virus isolation (19/46).

17.3 CONCLUSION

ALVs are still considered ubiquitous in commercial chickens, notwithstanding the eradication programs instituted by many primary breeding companies. With few exceptions, infections occur in all chicken flocks. No commercial vaccine is available for the protection of chickens from infection with ALV. Recombinant ALVs expressing subgroup A and J envelope glycoproteins have been produced that could have potential as vaccines to protect against horizontal transmission. Congenitally infected chicks are immunologically tolerant and, thus, cannot be immunized, even if a suitable vaccine was available. These chickens constitute major source of ALV transmission and are the most likely to develop neoplasms.

Control of AL/SV infection depends mainly on early detection and removal of virus-shedding birds to reduce spread of congenital and contact infection in other birds. There are a number of biological, molecular, and serological assays that can be used for the isolation and identification of ALV. These assays are based on the detection of proteins coded for by one or more of the three major genes of ALV: *gag*, *pol*, and *env*. Biological assays for the isolation and identification of ALV including virus neutralization tests require the use of CEFs with specific host range and take more than a week to obtain results. Biological and molecular assays, but not direct assays based on the detection of gs p27, can be used to differentiate between endogenous and exogenous ALV. It has been suggested that the unusually high rate of horizontal transmission and the high frequency of molecular and antigenic variation of ALV-J may interfere with the success of eradication programs of ALV-J in broiler breeder flocks.

In recent years, there have been several reports of ALV-J outbreaks in parent and commercial layer flocks as well as some local breeds in China. Meanwhile, strains of ALV-A and ALV-B have been isolated in China, especially from the native chicken breeds, which suggest the widespread and complex nature of ALV infection in China. In addition, the coinfection of ALV-A and ALV-J as well as ALV-A and ALV-B detected provides a potential opportunity for recombination between different ALV subgroups [75,81]. Moreover, three strains (JS11C1, JS11C2, JS11C3), suggested to be a new subgroup K of ALV (but not confirmed) that is different from all six known subgroups, have been isolated from Chinese native chicken breed "luhua" in 2012 [82]. Thus, it is essential to have a continuous epidemiological surveillance in place to detect new variants potentially escaping the current detection methods.

18.1 INTRODUCTION

Bovine leukosis (lymphosarcoma, leukemia, or lymphoma) is one of the most frequent neoplastic diseases of cattle. Two types of bovine leukosis are recognized on the basis of their epidemiology: enzootic bovine leukosis and sporadic bovine leukosis. The enzootic form, which is caused by bovine leukemia virus (BLV), is the most frequent. The sporadic bovine leukosis, which includes the juvenile, thymic, and cutaneous forms of the disease, is not associated with BLV or any other infectious agents [1].

First described in 1871, bovine leukemia only attracted significant attention in the early twentieth century in several European countries, notably Denmark and Germany, where clusters of herds with a high incidence of a similar disease suggested a viral etiology. However, the viral etiology of this disease was not described until 1969 [2].

BLV is the type species of the genus *Deltaretrovirus* in the *Retroviridae* family. This genus also covers human T-cell leukemia viruses (HTLV-1 to HTLV-3) and simian T-cell leukemia viruses (STLV-1 to STLV-3), some of which are associated with proliferative or neurologic diseases of human and nonhuman primates [2,3]. Deltaretroviruses share many particular molecular and biological properties: they infect and transform lymphocytes *in vivo* and *in vitro*, cause disease only in a low percentage of infected hosts and after a long latency period, and do not induce viremia or detectable antigens *in vivo*; and in addition to the structural classical retroviral genes (*gag–pol–env*), they harbor open reading frames (ORFs) that codify accessory and regulatory proteins. Given these similarities, BLV infection in animals is regarded as a useful model for the study of the HTLVs and their associated diseases [3–5].

The majority of infected cattle remain asymptomatic throughout their lives, and only a small fraction (usually less than 5%) of the infected individuals develop malignant lymphoma. Persistent lymphocytosis (PL), a benign proliferation of lymphoid cells, is developed in approximately 30% of BLV-infected cattle [1].

Infection by BLV is widespread in all continents, except in Europe, where most of the member states of the European Economic Community are officially free of BLV [5]. BLV infection constitutes an important economic problem in the dairy cattle industry, due not only to the mortality of cattle suffering from lymphosarcoma but also to the regulatory restriction in the international trade of cattle and their by-products.

Bovine lymphosarcoma is an invariably fatal disease, for which no effective treatment currently exists. Despite advances in research on experimental vaccines, there is as yet no vaccine commercially available for the control of enzootic bovine leukosis.

18.1.1 Classification, Morphology, and Genome Organization

BLV is a complex exogenous oncogenic retrovirus with transacting activity that principally infects B lymphocytes. According to the present classification of viruses, BLV is the type species of the genus *Deltaretrovirus* in the family *Retroviridae*. This genus also includes viruses from human and nonhuman primates (collectively grouped in the species

Downloaded From Vet-eBooks.com

primate T-lymphotropic viruses 1, 2, and 3) that share biological and molecular characteristics with BLV [6].

Morphologically, BLV virions are type C particles with a diameter between 60 and 125 nm and have a three-layered structure: an inner core composed of genome–nucleoprotein complex with helical symmetry, surrounded by an icosahedral capsid composed primarily of the p24 protein (CA p24) codified by the *gag* gene. The CA p24 protein appears to be a major target for the host's humoral immune response. The external envelope, derived from the cell membrane, contains the transmembrane and surface glycoproteins (TM gp30 and SU gp51), both codified by the virus. While TM gp30 is poorly immunogenic, it is a key factor during the fusion between the virion envelope and new target lymphocytes [7]. The SU gp51 induces an important humoral immune response, a property used for diagnostics. Specific antibodies directed to three conformational epitopes (designated F, G, and H) located in the amino terminal moiety of the SU gp51 molecule exhibit neutralizing activity. This region of the SU gp51 also contains the putative receptor-binding domain for the recognition of the specific receptor in the target cells. The cellular receptor for BLV still remains elusive [8].

The virus particle is diploid, that is, it contains two copies of positive ssRNA. Genomic RNA is 8420 bp long and presents a 5′ CAP and a polyadenylated tail in its 3′ end [9]. The structural genes (*gag*, *pol*, and *env*) are flanked by the long terminal repeats (LTRs) in the proviral form of the virus. The 5′ LTR contains several *cis*-acting elements involved in the regulation of BLV transcription. BLV is a complex retrovirus that, apart from encoding *gag*, *pol*, and *env* genes, present in all retroviruses, encodes several other regulatory and accessory proteins in ORFs. The regulator of expression (p18 REX) and the transcriptional activator of viral expression (p34 Tax) proteins are both codified by a double-spliced mRNA. Other accessory proteins are R3 and G4, of 5.5 and 11.6 kDa, respectively, codified by separate mRNAs. These accessory proteins are dispensable for infectivity *in vivo* but essential for viral propagation and pathogenicity [10]. The analysis of five fully sequenced isolates of BLV from different regions of the world showed that they are >95% homologous at the nucleotide level [11]. The phylogenetic and similarity analyses performed on a conserved region of the *env* gene allowed the classification of BLV isolates into seven genotypes [12].

18.1.2 Biology, Transmission, and Epidemiology

The major target of the virus is the B lymphocyte [13,14], although evidence of BLV infection in other cell types such as monocytes and macrophages has been reported both *in vivo* and *in vitro* [15,16]. In cattle, the majority of infected B cells express the CD5 marker [17–19]. Soon after infection of a target cell, the RNA genome is copied into DNA by the virus-encoded reverse transcriptase. The provirus then integrates into the host genomic DNA. The integrated provirus is by far the most commonly detectable viral form observed in persistently infected animals. It is believed that once the specific immune response is developed, the replicative cycle is blocked or abolished and the virus replicates only by mitotic expansion of provirus-carrying cells [20].

BLV integrates randomly in the cellular genome and therefore insertional mutagenesis is not the mechanism of transformation of infected cells [8]. It also lacks a known oncogene, as in rapidly transforming retroviruses. An intriguing fact is that infection of cattle proceeds without any evidence of viral protein expression. In effect, BLV virions or viral proteins cannot be detected in the peripheral blood by any currently available method [21]. Moreover, evidence for the presence of viral transcripts in peripheral blood cells is controversial [22–25]. It is believed that the virus is repressed at the transcriptional level *in vivo* and that the virus can be easily derepressed upon *in vitro* culture for a few hours [1]. Repression of the viral expression may be due, at least in part, to a suboptimal enhancer sequence located in the proviral 5′ LTR. An elusive plasma factor related to fibronectin could also be responsible for the repressed state in which BLV is maintained *in vivo* [26–29]. It seems that the repression of the viral expression is a mechanism that BLV has evolved to evade the immune surveillance and hence to persist in its host and in nature.

BLV naturally infects cattle, zebus, buffalos, and capybaras and can be experimentally transmitted to sheep, goats, rabbits, chickens, pigs, and rats (reviewed in [30]). Humans do not seem to be susceptible to BLV infection; however, human cells have been infected with BLV *in vitro* [31]. Although sheep are not natural hosts for BLV, they are considered a very good animal model for studying BLV pathogenesis, as they are sensitive to BLV infection and develop the disease much earlier and with higher frequency than cattle (almost all infected sheep develop lymphosarcoma after being experimentally infected) [10].

BLV has worldwide distribution. Most Western European countries have controlled the infection by following the implementation of strict control measures. On the other hand, in the Americas, where the animal health sanitary authorities have not implemented compulsory control or eradication programs, prevalence of BLV infection ranges from 25% to 50% at the individual level for most countries, affecting 80%–90% of the herds (reviewed in [5]).

Since infectious, cell-free BLV is rarely produced *in vivo* and is very unstable, most susceptible cattle are thought to become infected by exposure to infected lymphocytes and not by a cell-free virus. Thus, infected lymphocytes from blood, milk, or any other secretion or excretion may potentially transmit the infection upon contact with susceptible cattle. *In utero* vertical transmission occurs by transplacental infection after immune competence of the fetus is established (i.e., the third month of gestation). This way of transmission is infrequent under natural conditions, occurring in 3%–8% of calves born to infected cows and most frequently in cows having PL [32,33]. Colostrum contains infected lymphocytes, but it is not a common way of transmission, likely due to the protective role of the antibodies it contains. Transmission of BLV to calves by feeding bulk milk from infected cows has been documented, being the susceptibility of calves dependent on the presence of specific antibodies obtained from the

Downloaded From Vet-eBooks.com

dam's colostrum and the age of the calf [33,34]. In natural conditions, iatrogenic procedures that involve the contact of infected blood like dehorning, castration, venipuncture, and application of ear tags are risk factors highly associated with BLV transmission, when practiced without proper disinfection of material [33].

18.1.3 Pathogenesis and Clinical Features

After a variable period of 2–8 weeks upon infection, cattle develop humoral and cellular immune responses to capsid and envelope proteins that are inefficient to clear the infection. Once established, the immune responses efficiently abolish the viral replicative cycle, and the virus replicates only by mitotic division of provirus-carrying cells. Hence, the virus persists indefinitely throughout life [20].

BLV infection is characterized by the "iceberg principle" typical of many viral diseases. The infection is asymptomatic in the majority (approximately 70%) of infected cattle, while one-third of the infected cattle develop a permanent and relatively stable increase in the number of B lymphocytes in the peripheral blood termed PL. PL is the result of the accumulation of untransformed B lymphocytes and thus is considered a benign condition. Cattle with clinical manifestations of disease, usually less than 5% of infected cattle, are represented by the tip of the iceberg.

It is believed that the disease (lymphoma or lymphosarcoma) and the subclinical stage of PL are results from a complex interplay between the virus and the animal. From the beginning, it was observed that lymphosarcoma and PL appeared more frequently in familial clusters. Epidemiological data indicate that both conditions are under the control of host genetic factors [1]. The molecular basis for the genetic resistance and susceptibility of cattle to the development of PL was mapped to the major histocompatibility complex (MHC) class II BoLA DRB3.2 gene [35,36]. Among the asymptomatic BLV-infected cattle, some are particularly resistant to the *in vivo* spread of BLV, maintaining a very low proviral load in the peripheral blood [37]. This condition is also strongly associated with the MHC class II BoLA DRB3.2 gene, suggesting that the cellular immune response is important in controlling the *in vivo* spread of BLV [38].

Polymorphism in the promoter region of the tumor necrosis factor-α (TNF-α) gene, which is located within the class III region of the MHC, has also been associated with the progression of the disease in BLV-infected cattle. A single nucleotide polymorphism at position −824 in the TNF-α gene, which determines low transcriptional activity, has been associated with lymphosarcoma induced by BLV and high proviral load in BLV-infected cattle [39]. In the early phase of infection, high levels of TNF-α may contribute to the elimination of BLV [40].

The clinical form of the disease results from the accumulation of transformed lymphocytes in one or more organs after a long latency period of 1–8 years. This form is rarely seen in animals under 2 years of age and is most common in the 4–8-year age group. The pathologic condition is a multicentric lymphosarcoma. Lesions can be localized in almost any organ, but the abomasum, heart, visceral and peripheral lymph nodes, spleen, uterus, and kidneys are most frequently affected. Lesions can be observed as white firm tumor masses or as a diffuse tissue infiltrate in any organ. The latter pattern results in an enlarged pale organ. There may be an accompanying lymphocytosis and some degree of anemia. The presence of large numbers of immature or abnormal lymphocytes is a more reliable indication of the presence of the disease. The clinical signs and the duration of the illness are variable, depending on the localization and speed of grow of tumors. In most cases, the course is subacute to chronic, initiated by a marked loss of weight and appetite and weakness. The beginning of the disease often concurs with parturition and the consequent lactation is compromised. Most frequent signs are decreased milk production, external and internal lymphadenopathy, and posterior paresis. Other signs that may be present are fever, bilateral or unilateral exophthalmos, and diarrhea. In 5%–10% of the cases, the course is peracute, and the affected animals suddenly die without any previous evidence of disease. This clinical presentation may be due to the involvement of adrenal glands or an internal hemorrhage caused by a spleen rupture or breakage of an abomasal ulcer [41].

The mechanisms by which BLV induces PL and cellular transformation are not fully understood. Tumors are mostly monoclonal for BLV integration within a single animal, but the virus does not seem to have preferential integration sites among tumors from different animals. Most often, the CD5 marker is expressed on tumor cells [30]. BLV does not carry any known oncogene, but a number of experimental observations indicate that Tax protein can act as an oncogene [4].

PL is the result of a disruption of the target cell homeostasis, which is a complex balance between proliferation and apoptosis rates. As a consequence of impaired cell proliferation and decreased cell death, the B-cell turnover is reduced in PL cattle [42]. This situation finally leads to the accumulation of infected cells in the blood.

The role of TNF-α in the progression of BLV-induced lymphocytosis is related to an augmented expression of the cytokine and imbalance of TNF-α receptors. TNF-α is augmented in peripheral blood mononuclear cells (PBMCs) from BLV-infected cattle and induces proliferative responses and inhibition of apoptosis by acting on TNF-α type II receptors, whose expression is elevated in BLV-infected cattle and PL cattle [43,44]. T-cell-derived IL-2 may also be implicated in the development or maintenance of PL [45]. An indirect role of p34 Tax in this process has been proposed on the basis of its interaction with the cellular protein tristetraprolin, which is a posttranscriptional repressor of TNF-α expression. p34 Tax, by interacting with tristetraprolin, could inhibit its repressor activity, resulting in an augmented expression of TNF-α [46].

The imbalance in B-cell homeostasis may contribute to the accumulation of mutations that finally lead to the tumoral transformation. Mutations of p53 tumor suppressor gene have been found in approximately half of BLV-induced tumors in cattle [47–49]. Inactivation of p53 by mutation appears to be one of the critical events in the transition from PL to the

Downloaded From Vet-eBooks.com

tumoral phase [10]. An increased relation in B-cell leukemia/lymphoma-2 (Bcl-2)/bax expression has also been implicated in disease progression [50].

The p34 Tax protein is a key contributor on the oncogenic potential of BLV. It is believed that Tax plays a role in the initiation of tumorigenesis, but it does not seem to be essential for the maintenance of the transformed phenotype [30]. Apart from its action on the transcriptional activation of viral expression, Tax has been shown to immortalize primary rat embryo fibroblasts and to cooperate with the Ha-ras oncogene in cellular transformation [51]. This property is also present in the BLV G4 protein [52]. The mechanism by which Tax induces transformation is not fully understood. The cytokine-independent growth induced by Tax in ovine B cells correlates with increased Bcl-2 levels and signaling through NF-κB [53]. Tax also inhibits the base excision DNA repair of oxidative damage, thus allowing the accumulation of mutations in cellular DNA [54].

To unravel the functional role of Tax, insights into the Tax-responsive genes have been carried out by microarray-based gene expression analysis. Studies using the ovine model, human cDNA microarrays and Tax-transfected human cells showed that Tax deregulates a broad network of interrelated pathways rather than a single B-lineage-specific regulatory process. Differentially expressed genes include genes related to apoptosis, DNA transcription, and repair; proto-oncogenes; cell cycle regulators; transcription factors, stress response, and immune response; and small Rho GTPases/GTPase-binding proteins [55,56]. Using the ovine model, genes known to be associated with human neoplasia, especially B-cell malignancies, were extensively represented [56]. Genes related to the immune response, mainly of the interferon family of antiviral factors, were preferentially downregulated by Tax [55].

18.1.4 Diagnosis

Due to the absence of viral expression and viremia in BLV-infected animals, direct identification of BLV or its antigens in peripheral blood leucocytes requires *in vitro* culture of these cells. This methodology involves separation of mononuclear cells in a Ficoll-Paque gradient and subsequent culture for at least 24 h. For this reason, the molecular methods, mainly the PCR, have been widely used to identify proviral sequences in PBMCs from infected cattle and are currently regarded as the most useful and rapid approach for direct detection of BLV. The PCR combined with restriction fragment length polymorphism (RFLP) and/or sequencing is used to study the genomic variability of the virus. Finally, as virtually all infected cattle develop antibodies to viral antigens, serological tests are commonly used for the diagnosis of BLV infection in cattle over 6–9 months of age.

18.1.4.1 Conventional Techniques

Methods for the direct detection of BLV, as stated earlier, require the isolation and short-term (24–48 h) culture of PBMCs and subsequent identification of the virus or its antigens by electron microscopy, immunological methods, or syncytia infectivity assay. The observation of budding particles by electron microscopy in short-term cultures of lymphocytes from cattle with PL or lymphosarcoma was decisive in the discovery of BLV and most useful in the early studies on BLV infection. This technique is not specific and, due to the cost and expensive equipment required, is no more used for diagnostic purposes. Other techniques used for the identification of BLV in the cultured PBMCs (reviewed in [1]) are the syncytia infectivity assay [57,58], the radioimmunoassay, immunoperoxidase assay [59,60], and ELISA. From these, only the detection of BLV antigen by ELISA has, nowadays, practical application for assessing the cattle with higher risk of transmitting the infection [61,62]. The selective culling of cattle on the basis of antigen expression in PBMCs cultures, as determined by ELISA, could aid in the control of BLV infection in heavily infected herds [63].

The sheep bioassay has proven to be the most sensitive test to detect infective BLV, however, due to the time required and cost, is restricted to the research area. In the sheep bioassay, blood or any other fluid such as milk, colostrum, and urine is inoculated in lambs, and infection is confirmed by seroconversion (detection of anti-gp51 antibodies) and reisolation of the virus from PBMCs. This test has been used to determine the level of infectivity of different body fluids and to demonstrate protection in vaccination trials [64–66]. This method is also used to confirm infection when conflicting results from serological and PCR methods arise [67,68].

Serological methods for the detection of specific antibodies in serum or milk are among the most practical, economical, and widely used approaches to the diagnosis of BLV infection in cattle older than 6–9 months of age. Serological tests developed early after the discovery of BLV including the agar gel immunodiffusion (AGID) test and the radioimmunoprecipitation (RIP) tests using gp51 and p24 as antigens were followed by several ELISAs in more recent years. The AGID test was rapidly adopted and widely used because of its simplicity and specificity. Extensive comparative studies have shown that the RIP test using gp51 as antigen was the most sensitive test for the identification of infected cattle, followed by RIP using p24 as antigen [69,70]. False-negative AGID results are frequent in samples from cows in the periparturient period or in those cattle that develop low titers of antibodies. Several indirect and blocking ELISAs have been developed and are commercially available in many countries [68,71,72]. Antibodies against the envelope gp51 usually reach higher titers compared to the p24 antigen; hence, ELISA tests using gp51 as antigen are preferred. Due to the relatively expensive equipment and hazards regarding the use of radioactive isotopes, the RIP has been gradually replaced by the gp51-ELISAs. The ELISA has the additional advantage that can be used not only in serum or plasma but also in individual or pooled milk. As antibody titers in milk are significantly reduced compared to serum, the sensitivity of the ELISA to be used in pooled milk samples is critical. Herds with infection rates as low as 2.5%–5% gave positive result in the pooled milk ELISA [68,73]. Although most of the ELISAs are significantly more sensitive compared to the AGID, both the ELISA

Downloaded From Vet-eBooks.com

and AGID are prescribed for international trade by the World Organization for Animal Health [74]. Anti-BLV antibodies passively acquired by calves upon ingestion of colostrum persist until the age of 6–9 months. During this period the only way to detect the infection is by a direct method, such as PCR.

18.1.4.2 Molecular Techniques

The detection of the integrated BLV provirus by PCR is generally used as a complement to serology for confirmatory testing. The main applications of PCR are (1) diagnosing infection in calves below 6–9 months of age due to the interference of colostral antibodies with serological methods, (2) early diagnosing before specific antibodies are developed, (3) clarifying inconsistent or doubtful results obtained by serological tests, (4) differentiating between clinical cases of sporadic and enzootic lymphomas, and (5) confirming the etiology of tumor cases from material obtained at slaughterhouses. PCR has also been used as an alternative to the sheep bioassay to ensure that cattle used in the production of whole blood vaccines or cell lines are free from BLV.

Many variants of the PCR method including simple amplification [75–77], nested PCR [68,78], ELISA-PCR [79,80], *in situ* PCR [81], and loop-mediated isothermal amplification [82] have been developed to detect or semiquantify the BLV provirus. It is well established that, for diagnostic purposes, in order to achieve an acceptable level of sensitivity, it is necessary to carry out the PCR in a nested format. Variable efficiencies in the detection of the provirus by PCR have been observed, depending on the target gene and primers used. The best results have been obtained with primers targeting the *pol* and *env* regions [78,83–85], due to high sequence conservation between strains. Over the last decade, real-time PCRs (qPCRs) using TaqMan chemistry have been developed to quantify BLV provirus [83–86].

The PCR is highly sensitive for the diagnosis of BLV infection when compared to ELISA, mainly because of the detection by PCR of infected cattle at the initial stage of infection, before seroconversion [75,78,87]. However, the possibility of BLV infection should not be excluded by a negative PCR result in PBMCs alone. Negative PCR results in serologically positive cattle have been reported [68,78,88–90]. This situation may be due, at least in some cases, to an extremely low proviral load in the peripheral blood in genetically resistant infected cattle [38]. Conversely, cattle carrying the provirus without a detectable serological response of antibodies have also been reported; however, there is no agreement if this situation is associated or not with a particular genotype of the virus [91–93].

BLV-infected cattle are more consistently detected by PCR from the blood compared to milk leukocytes [84,94]. Lew et al. [83] further showed that the sensitivity and specificity of the PCR were improved when the DNA was extracted from purified PBMCs (compared to whole blood) by using a commercial kit (compared to a conventional DNA extraction method). The extraction of DNA from PBMCs by commercial column-based methods is specially recommended for real-time PCR.

18.2 METHODS

18.2.1 Sample Collection and Preparation

The peripheral blood is obtained by jugular or coccygeal venipuncture in individual syringes either with sodium heparin (5 U/mL) or with sodium citrate (4% final concentration). PBMCs may be obtained using a ficoll–diatrizoate gradient (Ficoll-Paque from GE Healthcare). An alternative and economical procedure is used to obtain total leucocytes from the blood, with similar results for PCR. The buffy coat layer obtained from 10 mL of each blood sample, or 3 mL of whole blood, is mixed for 1 min with 11 mL of cold ammonium chloride buffer (150 mM NH_4Cl, 8 mM Na_2CO_3, 6 mM EDTA) to lyse the erythrocytes. After centrifugation ($1000 \times g$ for 7 min at 4°C), the leukocytes are washed once with phosphate-buffered saline and may be stored as a pellet at –20°C or used immediately for DNA extraction.

DNA extraction for conventional PCR can be performed by a phenol–chloroform procedure, followed by ethanol precipitation, as described in [95]. For real-time PCR, extraction of DNA by the use of high-quality commercial kits (illustra blood genomicPrep Mini Spin Kit, GE Healthcare; DNeasy Blood and Tissue Kit, Qiagen) is recommended. When using the illustra blood genomicPrep Mini Spin Kit from GE Healthcare, we obtain the peripheral blood leukocytes from 3 mL of blood as explained earlier and follow the instructions of the manufacturer (protocol for 1 mL of blood with the following modifications: volume of Proteinase K and lysis buffer and time of incubation at the stage of lysis are doubled). Quantification of DNA can be carried out by measuring the absorbance at 260 nm. Purified genomic DNA is stored at –20°C.

18.2.2 Detection Procedures

The nested PCR method described by Fechner et al. [78] has been reproduced in many laboratories and is one of the procedures recommended by the World Organization for Animal Health for the international trade of cattle. However, nested PCR is laborious and time consuming, and there is always the risk of contamination by amplicon carryover. The introduction in recent years of equipment and reagents that enable to follow the reaction in real time has favored the application of the real-time PCR for the detection and quantification of pathogens. A qPCR employing SYBR Green® chemistry, which allows the detection and quantification BLV *pol* sequences, is also described.

18.2.2.1 Nested PCR for the Detection of BLV *env* Sequences [78]

The method described is based on primer sequences matching the *env* gene of BLV, according to the sequence available from GenBank accession no. K02120 (Table 18.1). This region is highly conserved among BLV isolates. In order to avoid contamination with amplicons, which is a serious problem in nested PCR, special precautions should

Downloaded From Vet-eBooks.com

be adopted. DNA isolation and preparation of amplification mixtures should be carried out in a separate room and with different micropipettes from that used in postamplification procedures. When possible, amplification mixtures are prepared under a biological cabinet that is previously irradiated with UV light.

18.2.2.1.1 Procedure

1. Dilute DNA samples to 25 ng/μL, so as to have 500 ng in 20 μL.
2. Prepare the reaction mix for the first round as follows: Before pipetting, vortex and spin down all the reagents. Volumes are indicated for a 50 μL reaction, but they can be scaled down to a 20 μL reaction. One negative control (DNA from a BLV-free bovine), one positive control, and no template control (double-distilled water) should be added in each experiment. Calculate the final volume of the reaction mix by multiplying the indicated volumes by the total number of samples including controls, plus one. External primers used for the first round of PCR are *env*-1F and *env*-2R (Table 18.2).
3. Add 30 μL of the PCR mixture and 20 μL of each DNA sample or control to each tube.
4. Spin the sample tubes in a microcentrifuge at 14000 × *g* for 30 s at room temperature.
5. Place the tubes in the thermal cycler. Set the program for the first round of PCR in the thermal cycler: initial incubation at 94°C for 2 min; 40 cycles of 95°C for 30 s, 62°C for 30 s, and 72°C for 1 min; and final extension at 72°C for 4 min.
6. Prepare the reaction mix for the second round of PCR. The PCR mixture is prepared with the same components and quantities indicated for the first round, except that the volume of distilled water is augmented to 34.75 μL per reaction. Internal primers used for the second round are *env*-3F and *env*-4R.
7. Add 47 μL of the PCR mixture and 3 μL of the product of amplification from the first round of PCR to each tube. Spin the tubes and place them in the thermal cycler.
8. Set the program for the second round of PCR in the thermal cycler: initial incubation at 94°C for 2 min; 40 cycles of 95°C for 30 s, 70°C for 30 s, and 72°C for 1 min; and final extension at 72°C for 4 min.
9. Spin down the PCR tubes and load 10 μL of each PCR product with 10 μL of 2× loading buffer in the wells of a 1.5% agarose gel. Load 10 μL of a 100 bp ladder to check the size of the amplification products.
10. Analyze the PCR products by electrophoresis in tris–borate–EDTA buffer. Run the gel at 100 V for approximately 30 min to 1 h or until the dye has reached the limit of the gel.
11. Stain the gel by placing it in a container with ethidium bromide solution at 0.5 μg/mL in agitation for 15–20 min.
12. Visualize the amplification products under UV illumination.
13. Interpretation of results:
    Controls: Check the absence of amplification in the nontemplate and negative controls. An amplification product of the expected size (444 bp) should be observed in the positive control lane.

Samples giving an amplification product of the expected size are considered positive for BLV infection.

Note: Further confirmation of the specificity of the amplification products can be performed by sequencing or by RFLP analysis [91].

TABLE 18.1
Sequence and Position of Primers for BLV *env* Nested PCR

Primer	Sequence (5′–3′)	Nucleotide Position	Amplicon Length (bp)

18.2.2.2 Real-Time PCR for the Detection of BLV *pol* Sequences

The protocol described is used to amplify a 59 bp fragment of the *pol* gene of BLV using primers pol-F and pol-R. The amplification is monitored by incorporation of SYBR Green dye; subsequent melting curve analysis allows checking for specificity. This protocol has been set up in an ABI 7500 Real-Time PCR System (Applied Biosystems) using the 7500 Software v.2.0.6, but should work well in any other similar equipment (Table 18.3).

TABLE 18.3

18.2.2.2.1 Preparation of DNA from Samples and Standard Curve

DNA from samples should be adjusted to a concentration of 10 ng/μL.

To prepare the standard (calibration) curve used to quantify BLV copy number, DNA is extracted from the fetal lamb kidney (FLK) cell line [96], which harbors 4 proviral copies per cell. DNA extracted from Vero cell line is used as a source of BLV-negative DNA to compensate the DNA input. A dilution containing 10,000 BLV copies in 3 μL is prepared by mixing 500 ng of DNA extracted from FLK cells with 500 ng of DNA from Vero cells in a final volume of 100 μL of UltraPure DNase/RNase-Free Distilled Water. Four serial 10-fold dilutions are prepared in DNA from Vero cells at a concentration of 10 ng/μL, so as to obtain standards with 1000, 100, 10, and 1 BLV proviral copies in 3 μL.

18.2.2.2.1.1 Procedure

1. Calculate the amount of reactions to be done. All reactions should be carried out in triplicate. For quantification of copy number, the whole standard curve (from 10,000 to 1 BLV copies) should be run. A negative control (DNA from BLV-free cattle) and a nontemplate control are always included.
2. Thaw all the solutions and reagents, spin them down and mix by pipetting up and down, and then store on ice.
3. Prepare the PCR mixture in a 2 mL tube on ice by adding the following components. Volumes are indicated for a 20 μL reaction. Multiply the indicated volumes by the number of reactions to be run, plus one (Table 18.4).
4. Mix the solution carefully by pipetting up and down. Add 17 μL of the mixture in each of the PCR optical tubes or wells of the optical microplate.
5. Add 3 μL of template DNA (10 ng/μL). UltraPure water is added in nontemplate control tubes/wells. Mix carefully by pipetting up and down.
6. Seal tubes with optical tube caps or microplates with optical adhesive foil. If possible, centrifuge microplates or tubes at 1000 × *g* for 1 min.
7. Program the real-time PCR equipment following the operator's manual of the supplier with the following cycling conditions: initial incubation at 50°C for 2 min and 95°C for 10 min, followed by 40 cycles of 95°C for 15 s and 60°C for 1 min. Melting curves are performed after amplification, in order to test specificity.
8. Place the tubes or microplate in the instrument and start the reaction.

TABLE 18.4
Real-Time PCR Mixture

Component	Volume (μL)	Final Concentration
SYBR Green Master Mix (Rox) (2×)	10	1×
Primer pol-F (10 μM)	0.6	0.3 μM
Primer pol-R (10 μM)	0.6	0.3 μM
UltraPure DNase-Free Distilled Water	5.8	
Total	17	

18.2.2.2.2 Analysis and Interpretation of Results

Examine the amplification plot (ΔRn vs. cycle) and correct baseline and threshold values. Examine the standard curve (C_t vs. log concentration of template); the slope of the regression line should be near −3.32, which indicates 100% amplification efficiency. Efficiency values between 90% and 110% are acceptable. A value of R^2 >0.99 is desirable. It may be necessary to omit any well from the analysis that differs significantly from the average of associated replicate wells to fit these requirements. Examine melting curves of amplified products; a peak at 76.8°C ± 0.1°C is indicative of specific amplification.

Following this methodology, mean Cq values of 24.3, 27.9, 31.2, and 33.8 are obtained for the standards with 10,000, 1,000, 100, and 10 proviral copies. Samples giving a Cq value >36 are considered negative by this qPCR. Calculation of proviral copy number in positive samples is carried out by interpolation within the calibration curve. Samples giving Cq values that fall out of the dynamic range (i.e., below the Cq obtained in the standard with 10,000 proviral copies) should be diluted in BLV-negative DNA at a concentration of 10 ng/μL and retested to determine their copy number.

18.3 CONCLUSIONS AND FUTURE PERSPECTIVES

BLV infection is an important veterinary problem in those countries that have not implemented control or eradication programs, like the United States, Canada, and majority of the countries in South America. In this situation, the virus has spread, and nearly 80% of the dairy herds are infected, with high infection rates in most cases.

Molecular and serological methods developed to diagnose BLV infection have been instrumental for the identification and characterization of infected cattle capable of maintaining very low levels of proviral load [37]. These cattle, which carry the BoLA DRB3.2*0902 marker, are believed to be naturally resistant to the spread of the virus and not capable of transmitting BLV under normal dairy farm conditions [38]. The study of the basis of this natural resistance to BLV spread is of paramount importance not only to fully understand the virus–host interplay but also to delineate preventive or therapeutic strategies to control this pathogen.

Given the wide spread of the virus in many countries where the infection has not been early controlled, the classical control program (test and eliminate) is not effective, due to an unfavorable cost/benefit relationship. A control and eradication program based on the marker-assisted selection of resistant cattle has been recently proposed. It appears that this strategy, which is at the experimental level, would be economically feasible for the control of BLV infection in heavily infected herds [97].

Downloaded From Vet-eBooks.com

A potential therapeutic treatment has been proposed, based on the fact that inhibition of histone deacetylases induces the expression in latently infected cells. This approach is also founded on the premise that the lack of viral expression protects infected cells from immune clearance and that once expression is induced, the immune system should eliminate infected cells. This therapy has proven to be efficient in tumor regression in the sheep model, but its efficacy in infected cows is presently unknown [98].

19.1 INTRODUCTION

Visna–maedi virus (VMV, also known as maedi–visna virus [MVV] or ovine lentivirus) and caprine arthritis–encephalitis virus (CAEV) are retroviruses that affect small ruminants (sheep and goats). They are grouped together as small ruminant lentiviruses (SRLVs), due to their genomic and antigenic similarities [1].

VMV was first isolated by Sigurdardottir and Thormar [2]. The infection by this virus causes a chronic and generally subclinical disease called visna–maedi (VM). Clinical symptoms can present in the form of respiratory, nervous, joint, and/or mammary signs. Maedi refers to the respiratory signs (interstitial pneumonia) and visna alludes to the nervous form (progressive inflammatory disease of the central nervous system).

CAEV was first isolated by Crawford and colleagues [3] from goats showing joint and nervous clinical signs, from which the disease gets its name (caprine arthritis–encephalitis [CAE]). The clinical form associated with the infection is usually arthritis; however, any of the other clinical forms can be present in affected animals.

19.1.1 Classification

VMV and CAEV belong to the genus *Lentivirus*, subfamily *Orthoretrovirinae*, family *Retroviridae*. SRLVs have been classified according to their phylogenetic relationships into five groups: A, B, C, D, and E [4]. The genotype A includes VMV-like strains, genotype B comprises CAEV-like strains, genotype C contains SRLV isolated in Norwegian sheep and goats, genotype D is found in Spanish and Swiss sheep, and finally genotype E is present in Italian goats [5].

19.1.2 Morphology, Biology, and Epidemiology

SRLV particle is composed of an envelope and a core (Figure 19.1), with a diameter of 90–120 nm. The envelope is formed by a bilayer of phospholipids derived from the host cell and by glycoproteins codified by the gene *env* of the viral genome. These glycoproteins are surface protein (SU) or gp135SU and transmembrane protein (TM) or gp46TM [1]. The SU (gp135SU) is a very glycosylated protein that is attached through noncovalent sites to the hydrophobic end of the TM [6]. Four immunodominant epitopes have been identified in TM, three of which are associated with clinical arthritis [7], and gp46TM has been used successfully in enzyme-linked immunosorbent assay (ELISA) for the detection of antibodies. This protein is responsible for the fusion between the viral envelope and the lipid membrane of the host cell [8]. The core contains the viral RNA and is formed by three proteins codified by the gene *gag*. The capsid (CA)

Downloaded From Vet-eBooks.com

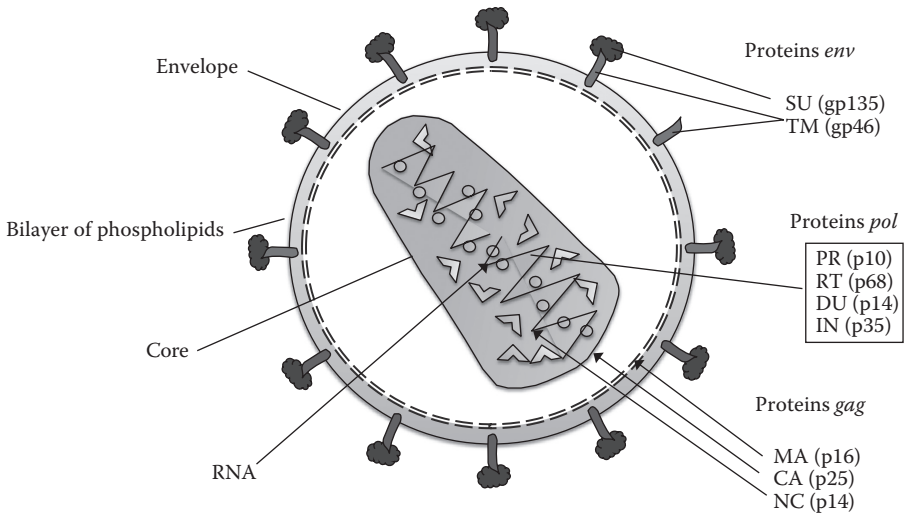

FIGURE 19.1 Structure of a typical lentivirus.

protein (or p25CA) induces the production of antibodies in the host; thus, it is used in ELISA methods. The other two proteins are matrix protein (MA) or p16MA and nucleocapsid protein (NC) or p14NC. Inside the capsid, there are the reverse transcriptase, dUTPase, integrase, and protease, necessary for the transcription and viral integration (Figure 19.1).

The genomes of VMV and CAEV consist of around 9,000 to 10,000 nucleotides (nt). They are constituted by two independent linear strands of positive-sense RNA and contain three structural genes (*gag*, *pol*, and *env*), which synthesize viral proteins and regulatory accessory genes (*vif*, *rev* and *nef*, and *vpr-like* in some strains). Accessory proteins regulate viral replication. SRLV replicates by producing a DNA intermediate called "provirus" that integrates into the host cell genome. The proviral DNA is flanked by long terminal repeat (LTR) sequences that contain promoters that initiate the transcription of the DNA [1].

SRLVs may infect goats and sheep; both viruses were considered previously to be species specific, but some studies have shown that they can be transmitted between goats and sheep [9]. SRLV infections are widespread worldwide with the exception of Iceland [10]. Considering each virus separately, VMV is spread across the world except in Iceland, Australia, and New Zealand [11]. Seroprevalence is variable between and within countries. Seroprevalence in the United States and Canada was estimated to be 28% of the sheep and 61% of the flocks [12]. Studies in Spain have reported that between 12% and 66% of the animals and 30% and 100% of the flocks are infected, but prevalence varies according to the region [13]. Seroprevalence of CAEV varies between countries from 5.2% to 42% in the goats and from 4% to 73% in the flocks. Studies showed that 31% of goats in the United States [14], 42% in Switzerland [15], 12.5% in Syria [16], 1.9% in Turkey [17], 8% in Brazil [18], and 5.2% in the Sultanate of Oman [19] are infected. In addition, 73% of the flocks in the United States [14], 35% in Brazil [18], and 4% in Italy [20] are affected. SRLV prevalence is higher in developed countries, possibly related to the practice of feeding lambs with a pool of colostrum/milk, which facilitates the spread of the infection [21], and to the intensive farming [22].

Transmission may occur among animals of the same flock or from mother to offspring [23] through body fluids, mainly lung secretions (aerosol droplet infection) [24], and shedding of virus particles, infected macrophages, and epithelial cells in the colostrum and milk [25]. However, it is not clear whether the SRLVs are transmitted between animals as free virions or within the infected cells [1]. Other routes such as venereal and transplacental transmission have not been fully demonstrated [23,26].

Currently, no effective treatment or vaccine has been developed against SRLV infections. Therefore, the most effective means of controlling the infection is an early diagnosis and preventing viral transmission through effective prophylactic measures [1].

19.1.3 Pathogenesis and Clinical Features

19.1.3.1 Pathogenesis

Although SRLV may infect a variety of cells, the major targets are those of the monocyte/macrophage lineage, where viral expression is closely dependent on the differentiation of monocyte to macrophage, and dendritic cells. Other additional cell targets can act as viral reservoirs, including epithelial cells of the mammary gland, which may be correlated with the transmission of the infection through milk [1].

Once the virus has entered the body, there is a short phase of postinfection viremia. In this stage, transitory immunopathological alterations take place. The virus infects macrophages and dendritic cells of the respiratory or intestinal mucosa, depending on the site of entry. The dendritic cells migrate to the lymph nodes where the virus is transferred to the macrophages. When these cells leave the lymph node, they spread the infection to other organs [1]. It is possible that the infected macrophages enter the bone marrow where they can infect myeloid cells or stromal cells. This would cause a continuous production of infected cells, which translates into the lifelong chronic infection [1]. The replication in monocytes and macrophages does not take place until these cells differentiate in the target organs [27] and is thought to depend on specific transcription factors that bind

Downloaded From Vet-eBooks.com

sequences in the LTR, thus triggering replication. This mechanism allows continual SRLV replication in the tissues and the ensuing immune response causes a chronic inflammation that originates the pathological changes observed in target organs of SRLV-infected animals [1].

The main alteration in affected tissues is the infiltration by mononuclear cells (lymphocytes, macrophages, and plasma cells) [1].

The final stage of the pathogenesis begins when the clinical disease starts. Depending on the clinical form, the animal can die in a short time or remain chronically infected. In spite of the high prevalence in some flocks, clinical signs usually are hardly noticeable, as there are many factors that influence the pathogenesis, mostly the viral strain, the age and breed of the animal, the exposure route, the secondary infections, and the management conditions.

19.1.3.2 Clinical forms

SRLV-infected sheep and goats develop a slow progressive inflammatory disease affecting the lungs, nervous system, joints, and/or mammary glands. In general, the process caused by SRLV is subclinical; however, a small percentage of the animals can develop one or more clinical forms associated to the location of the pathological alteration. Progressive wasting and, in some cases, cachexia are signs that may also accompany the main disease. Usually, the respiratory and mammary forms are predominant in VM, whereas the nervous and joint forms are more important in CAE. The disease does not progress uniformly in all individuals and may depend on the infecting virus strain, the host's genetics, and the breed, as some breeds are more likely to develop some clinical signs than others [28].

Respiratory disease in infected animals is characterized by lymphocytic interstitial pneumonia and fibrosis of the lungs. Lungs are enlarged and heavy, up to three times the normal size, uniformly swollen, with rounded edges, rubbery texture, grayish-yellow coloration, and dry surface. The lungs can show well-demarcated pale-gray areas of consolidation. At the histological level, the lesion is characterized by chronic interstitial pneumonia with the infiltration of lymphocytes, monocytes, macrophages, and plasma cells into the interalveolar septum, which contributes to their thickening, and hyperplasia of the perialveolar smooth muscle. The first stage of the disease usually passes unnoticed, but the affected animals are delayed if the flock is moved. As the lesions progress, the clinical signs are dyspnea, abdominal breathing, extension of the neck, dilation of the nostrils, and breathing through the open mouth. Nasal discharge is only present concomitant to the secondary bacterial infections.

The mammary form is characterized by subclinical, indurative, chronic, diffuse, bilateral, nonsuppurative, and nonpainful mastitis, with enlarged mammary lymph nodes. Histologically, it is a chronic interstitial mastitis, characterized by the infiltration of mononuclear cells around the acinus and milk ducts.

Chronic progressive arthritis has a higher incidence in goats than in sheep. The most affected joints are the carpus and/or tarsus. However, other joints, such as the atlantooccipital and coxofemoral joints, may be affected as well [14]. The first clinical sign is arthritis with joint enlargement, with edema and congestion of the synovial membrane and joint capsule, which causes the thickening of both structures [14]. The arthritis is characterized by mononuclear cell infiltration, with villous hypertrophy, angiogenesis, and necrosis of the synovial membrane [1].

The nervous disease is more frequent in goats than in sheep, where it is rarely seen. The disease is characterized by meningoencephalitis, astrocytosis, microgliosis, and focal secondary demyelination in the brain and spinal cord [1]. Affected animals may present lack of coordination, hind limb paresis, and ataxia.

19.1.4 Diagnosis

As no gold standard diagnostic test exists for SRLV infection, a combination of clinical signs, pathological lesions, and laboratorial testing are relied upon for SRLV diagnosis. Due to the fact that SRLV infections may be asymptomatic and that clinical signs are not specific to SRLV, the antibody and virus detection are indicated for early diagnosis [11]. Laboratory diagnosis can be done using either indirect techniques, which detect antibodies, or direct or etiological techniques, which detect the virus itself or its nucleic acid. The World Organisation for Animal Health (OIE) has recommended the use of either agar gel immunodiffusion (AGID) or ELISA for the detection of specific antibodies [11,29]. Virus detection can be achieved using molecular biology techniques such as polymerase chain reaction (PCR), reverse transcription PCR (RT-PCR), and real-time PCR (rtPCR) or quantitative PCR (qPCR) for provirus detection.

19.1.4.1 Conventional Diagnosis

19.1.4.1.1 Clinical and Epidemiological Diagnosis

It is based on the presence of the different clinical forms (mammary, arthritis, pulmonary, and nervous forms) and epidemiological features of SRLV infection, such as age of presentation and chronic nature of the processes.

SRLV-induced respiratory disease must be differentiated from ovine pulmonary adenomatosis ("jaagsiekte"), parasitic lung infections, and caseous lymphadenitis.

The mammary form must be differentiated from contagious agalactia produced by *Mycoplasma agalactiae*. Differential diagnosis in neurological cases includes listeriosis, scrapie, rabies, louping ill, parasitic infections of the central nervous system, and brain tumors. The differential diagnosis for animals with arthritis may include traumatic arthritis and infectious arthritis caused by *Mycoplasma* species [30].

19.1.4.1.2 Pathology Diagnosis

It is only reliable in animals with pulmonary disease, and it is based on microscopic observation of lesions.

19.1.4.1.3 Serological Diagnosis

Serological diagnosis is the most commonly approach to detect SRLV infection. Some of the diagnosis techniques used

Downloaded From Vet-eBooks.com

are AGID, radioimmunoprecipitation assay (RIPA), western blot (WB), and ELISA. Being the first serological tests developed for the diagnosis of SRLV, RIPA and AGID are usually regarded as reference standards for confirmation [31]. WB and RIPA are mainly used to confirm inconclusive results.

19.1.4.1.4 AGID

AGID has a specificity of 100% but low sensitivity, and it is often related to a subjective interpretation. Other disadvantages are the inapplicability for the determination of antibodies in milk, lack of automation, and subjective interpretation of the results [10]. The test is run with whole virus, which needs to be concentrated from culture supernatants and treated with detergents [32] to inactivate it and to expose internal epitopes. The most widely used test contains CA (p25 for VMV or p28 for CAEV) and gp135SU, which results in two precipitation bands. Due to the antigenic and genomic similarities between VMV and CAEV, the test reagents may be used for both viruses.

19.1.4.1.5 RIPA

RIPA requires, as in the case of AGID, that the peptide and protein components of tissues are solubilized and denatured with detergents. Antibodies are added to cellular lysates or tissue homogenates to form antigen–antibody complexes. These complexes are precipitated by a solid-phase immune sorbent, usually formed by a second antibody bound to Sepharose (an insoluble particulate resin), or by protein A (surface protein of *Staphylococcus aureus* with great affinity for the Fc fragment of the Ig) bound to Sepharose. The complexes are pelleted by centrifugation and washed and detected by polyacrylamide gel electrophoresis with sodium dodecyl sulfate (SDS-PAGE) with radiolabeled-specific antibodies [33].

19.1.4.1.6 Western Blot

WB involves the separation of viral proteins by SDS-PAGE before being transferred to a nitrocellulose membrane. When they are exposed to the sheep serum, specific antibodies will remain attached to the nitrocellulose membrane in the bands where viral proteins have migrated [33] and are detected using enzyme-labeled antisheep immunoglobulin antibodies. In general, it is considered as a good reference test with very high specificity and sensitivity [31,32] and is used to confirm inconclusive results.

19.1.4.1.7 ELISA

ELISA has been widely used for the detection of SRLV, and more than 30 publications describing different ELISA techniques are available [32]. ELISA used for the detection of SRLV can be classified into two categories: indirect ELISA that uses whole virus or recombinant proteins (or synthetic peptides) as antigens, and competitive ELISA that uses monoclonal antibodies (p25CA, p16MA, p14NC, and gp46-50TM) [32].

ELISA, for the detection of SRLV infections, is relatively easy to apply, and its cost is quite reasonable [10]. Some shortcomings associated with ELISA as well as with other serological methods are the possibly prolonged time between infection and a detectable humoral immune response. In addition, antibody titers fluctuate throughout the animal's life, which may also make the detection difficult. Moreover, young animals infected at birth that have been fed with milk or colostrum containing maternal antibodies for at least 2 or 3 months may stay seronegative until they are between 6 and 12 months of age [10]. Also, it has a low sensitivity in detecting antibodies in the early stages of the infection with non-genotype A isolates [34]. For this reason, it is recommended to develop a specific ELISA according to the predominant strain in each geographical area [11].

19.1.4.1.8 Coculture and Virus Isolation

Different laboratories have applied direct diagnostic methods such as viral isolation, a very laborious and expensive method whose main disadvantages are the lack of permissive cell lines and limited viral production in cultured cells. Although this method is definitive in positive samples, it is not suitable for large-scale studies and has the possibility of false negatives, which hamper its routine use. It is performed by coculturing infected fluids or cells [11]. A sample suspicious to be infected by SRLV is cultured in vitro with a cell line that allows viral replication (usually fibroblasts or goat synovial membrane cells), and the presence of virus is confirmed by the detection of cytopathic effect (syncytium formation) or by reverse transcriptase activity in cell supernatants [10].

19.1.4.1.9 Other Techniques for the Detection of Viral Proteins or Viral Genomes

Immunohistochemistry: It is based on the detection of viral antigen in tissues using labeled antibodies [25]. Its disadvantages are that it is expensive and cumbersome and that it needs to be done postmortem.

In situ *hybridization*: It consists on the detection of viral nucleic acids in suspicious tissues using probes labeled radioactively or with fluorochromes. It is expensive and cumbersome, and it is not used routinely.

19.1.4.2 Molecular Techniques

Molecular techniques represent an alternative to overcome the shortages of serological diagnosis. As in other retroviruses, the RNA genome of SRLV is transcribed into DNA by the reverse transcriptase, and it integrates in the genome of the host cell in the form of provirus. This proviral DNA may be detected in many tissues and fluids by PCR. Some of the samples from which proviral DNA may be extracted include the lung, bronchial alveolar fluid, colostrum, milk, peripheral blood mononuclear cells, mammary gland and udder, brain, carpal synovial membrane, heart, kidney, liver, spleen, lymph nodes, semen, testes, uterus, oviduct, cumulus cells, and bone marrow [31]. Viral RNA may be detected in exudates that contain free viral particles after it is transcribed

Downloaded From Vet-eBooks.com

in vitro into DNA, using RT-PCR. However, SRLV RNA has not been directly detected in the tissues cited earlier [31].

19.1.4.2.1 PCR

Several PCR techniques have been developed for the diagnosis of SRLVs. As discussed in the introduction, SRLVs have high mutability, and thus it is difficult to find a standard PCR technique. The efficiency of PCR depends on the specificity of the primers designed. Target sequences for PCR primers include LTR, *gag*, *pol*, and *env* regions. In addition to conventional one-step PCR (cPCR), nested PCR (nPCR) and seminested PCR (snPCR) (involving two or more amplification rounds) have been developed in order to increase the sensitivity [10]. Comparison of some PCR techniques are summarized in Table 19.1.

19.1.4.2.2 Reverse Transcription PCR

Unlike PCR that detects integrated DNA, RT-PCR parts from RNA that is transcribed to double-stranded DNA by reverse transcriptase. From this point on, the reactions are like PCR. Its advantage is that it amplifies the virus itself, but the levels of free extracellular SRLV particles are usually low. For this reason, the amplification from DNA may be more effective.

19.1.4.2.3 Real-Time or Quantitative PCR

rtPCR or qPCR is increasingly used in routine laboratories for the detection and quantification of viral nucleic acids in different cells or tissues, including diagnosis for SRLV, for which some techniques have been developed in the last few years [35–37 among others]. Even though qPCR allows the quantification of the DNA target and limits the risks of amplicon contamination [30], its efficacy is limited due the high mutability of the SRLV. For this reason, its use in routine diagnosis is not widespread (Table 19.1) [10].

19.2 METHODS

19.2.1 Sample Collection and Preparation

Sample preparation varies according to the type of sample and detection method. In general, the samples used more often are blood and milk. However, tissues from affected organs are used sometimes to confirm results.

19.2.1.1 Milk Samples

Milk is taken aseptically from the udder in sterile containers after disinfecting the end of the nipple with 70% alcohol and discarding the first foremilk. The samples are kept at 4°C during the transport to the laboratory. Upon arrival to the laboratory, DNA is extracted immediately from 1 mL. The procedure is easier if milk samples are kept refrigerated till just before extraction. Several 1 mL aliquots can be stored in Eppendorf tubes at –20°C. When needed, they can be thawed in a 37°C water bath.

19.2.1.1.1 Procedure

1. Add 0.5 mL of cold PBS to 1 mL milk sample.
2. Centrifuge at 4000 rpm for 10 min.
3. Separate the thick cream layer from the walls of the Eppendorf tube with a sterile needle or toothpick and discard this layer.
4. Discard the underlying supernatant.
5. Repeat washing with PBS three times.
6. Count the number of cells.

19.2.1.2 Blood Samples

Blood samples are collected by venipuncture from the jugular vein into the vacuum lithium heparin tubes. Similar to

TABLE 19.1
Comparison between Different Polymerase Chain Reaction Techniques

PCR	Primers Location into the Viral Genome	Comparison between Techniques	Reference
cPCR	*gag* and *pol*	*pol*-PCR is more sensitive than *gag*-PCR.	[38]
snPCR	*pol* and LTR	LTR-PCR is more sensitive than *pol*-PCR.	[39]
nPCR	*gag* and *pol*	*gag*-PCR is more sensitive than *pol*-PCR.	[40]
snPCR	*gag*	*gag*-PCR is less sensitive than AGID.	[41]
snPCR	*pol*	High sensitivity, by using degenerate primers.	[42]
nPCR	*gag*	*gag*-PCR is more sensitive than AGID in seronegative animals.	[43]
nPCR	*gag* and LTR	*gag*-PCR is more sensitive than LTR-PCR.	[44]
cPCR	*env* and *pol*	*env*-PCR is more sensitive than *gag*-PCR.	[45]
cPCR	LTR	LTR-PCR has a sensitivity of 98% with reference to AGID and ELISA.	[46]
cPCR	LTR, *gag*, and *env*	LTR-PCR is more sensitive than *gag*-PCR and *env*-PCR.	[47]
cPCR	*gag*	*gag*-PCR is less sensitive than AGID.	[48]
cPCR	*gag*	*gag*-PCR is more sensitive than the ELISA and WB.	[49]
nPCR	*gag*	*gag*-PCR increases its sensitivity when used along with hybridization.	[50]

milk, blood samples are kept at 4°C during the transport to the laboratory.

1. Treat sample with a lysis buffer (10 mM $KHCO_3$, 460 mM NH_4Cl, 0.1 mM EDTA·$2H_2O$) to lyse red blood cells.
2. Once lysed (obvious change in the color and density of the blood), centrifuge the samples at 5000 rpm for 5 min.
3. Discard the supernatant.
4. Wash the pellet with PBS and centrifuge at 10,000 rpm for 3–5 min. This process is repeated until a clean pellet is obtained (minimum of three washings).

19.2.1.3 DNA Extraction

1. Add 0.5 mL of extraction buffer (200 mM Tris-HCl, pH 7.5, 250 mM NaCl, 25 mM EDTA, and 0.5% SDS) to the blood or milk sample pellet. Vortex vigorously until the pellet is resuspended and incubate on ice for 10–15 min.
2. Centrifuge 8 min at 4000 rpm.
3. Decant the supernatant into another Eppendorf tube and add 0.25 mL of phenol and 0.25 mL of chloroform/isoamyl alcohol (24:1). Invert several times.
4. Centrifuge at 14,000 rpm for 3 min.
5. Transfer very carefully the upper aqueous layer (above the interface) into another Eppendorf tube. Make sure that no material from the interface is transferred.
6. Add 0.5 mL of chloroform/isoamyl alcohol and invert repeatedly.
7. Centrifuge at 14,000 rpm for 3 min.
8. Transfer carefully the upper aqueous layer to a clean Eppendorf tube. Add 500 µL of cold isopropanol to precipitate DNA.
9. Invert repeatedly. If the amount of DNA is high, a cotton-like substance will be seen in the tube.
10. Centrifuge at 14,000 rpm for 3 min.
11. Discard the supernatant. Add 1 mL of cold 96%–100% ethanol. Centrifuge as above.
12. Discard the supernatant. Let the pellet dry completely to eliminate all ethanol remains that may hamper the PCR.
13. Resuspend the pellet in 40 µL of double-distilled water (ddH_2O).

Alternatively, QIAamp® DNA Blood Mini Kit (Qiagen) can be used for DNA extraction.

19.2.2 PCR Detection

In this chapter, we describe a nested LTR-PCR technique that has been used in several studies throughout the years. It was first developed in 2000 by Ryan and colleagues and is still in use (Table 19.2) [52,53].

19.2.2.1 Procedure

1. Thaw all the PCR reagents, vortex them, and spin briefly.
2. Prepare the PCR reaction mix as follows (nPCR is performed in reaction mix volumes of 22 µL):

	First PCR
Diethylpyrocarbonate (DEPC)-treated water	16 µL
PCR buffer 10× containing $MgCl_2$ (2 mM)	2.5 µL
Deoxynucleoside triphosphate (dNTP) mix at a final concentration of 0.225 mM each	0.5 µL
Primer LTR External forward (EFW) at a final concentration of 1 mM	1 µL
Primer LTR External reverse (ERV) at a final concentration of 1 mM	1 µL
Taq DNA polymerase at 0.04 U/µL	1 µL

3. Add 3 µL of DNA to the mix.
4. Always include a positive and a negative control; positive controls could be DNA extracted from a sample of a positive animal or from a tissue culture infected in vitro. A negative control could be prepared by adding water instead of DNA to the PCR mix or could be DNA extracted from a negative animal.
5. Preheat the block of the thermocycler to 94°C and set the conditions to the following: initial denaturation step at 94°C followed by 30 cycles of 94°C, 55°C (hybridization), and 72°C (extension), consecutively, each for 30 s, followed by a final extension step of 10 min at 72°C.

TABLE 19.2
Primers Used for the Long Terminal Repeat Polymerase Chain Reaction [52]

Primer	Sequence (5′–3′)	Nucleotide Position	Expected Product (bp)
LTR EFW	ACTGTCAGGRCAGAGAACARATGCC	8914–8938	
LTR ERV	CTCTCTTACCTTACTTCAGG	328–309	
LTR IFW	AAGTCATGTAKCAGCTGATGCTT	9049–9071	203
LTR IRV	TTGCACGGAATTAGTAACG	129–111	

R = A or G; K = G or T.

Downloaded From Vet-eBooks.com

6. Spin the samples at 14,000 rpm for 30 s at room temperature.
7. Prepare the PCR reaction mix for the second round as follows:

	2nd PCR
DEPC-treated water	16 µL
PCR buffer 10× containing $MgCl_2$ (2 mM)	2.5 µL
dNTP mix at a final concentration of 0.225 mM each	0.5 µL
Primer LTR internal forward (IFW) at a final concentration of 1 mM	1 µL
Primer LTR internal reverse (IRV) at a final concentration of 1 mM	1 µL
Taq DNA polymerase at 0.04 U/µL	1 µL

8. Add 1 µL of the first reaction and 2 µL of DEPC water.
9. Spin the sample tubes at 14,000 rpm for 30 s at a room temperature.
10. Repeat PCR as done earlier except that the extension should be at 50°C.
11. After the amplification, spin down briefly the PCR tubes to pull down the condensation droplets at the inner wall of the tubes.
12. The PCR products may now be analyzed or stored at –20°C.
13. Resolve the PCR products using 2% agarose gel electrophoresis in tris-acetic acid-EDTA (TAE) buffer at 100 V for 30 min.
14. Stain the gel with ethidium bromide (or similar nonmutagenic intercalating dyes) and visualize the results using an ultraviolet light source.

19.2.3 SRLV Cloning, Sequence Analysis, and Genotype Identification

Following diagnosis and confirmation of a positive sample, sequence analysis can be carried out in order to identify the specific genotype that is causing the infection.

19.2.3.1 Procedure

1. Perform a PCR technique with primers selected from the LTR, *env*, *pol*, or *gag* region, following a procedure similar to the one described earlier.
2. PCR amplicons are determined using 1.5% agarose gels electrophoresis, and bands of the expected size are cut out and purified with QIAquick Gel Extraction Kit (Qiagen).
3. DNA bands are cloned into the vector pGEMT-easy® (Promega) following the manufacturer's instructions.
4. Transformed colonies (*Escherichia coli* XL1-Blue) are grown overnight at 37°C in LB medium (1% Bacto Tryptone, 0.5% yeast extract, and 1% NaCl) with 100 µg/mL ampicillin.
5. Screening of positive clones is made by restriction enzyme digestion (EcoRI).
6. Purified plasmid DNA from bacterial culture is performed using the Quantum Prep® Plasmid Miniprep Kit (Bio-Rad) according to the manufacturer's instructions.
7. Sequencing of purified plasmid DNA is done using an ABI PRISM 310 Genetic Analyzer (Applied Biosystems) or similar sequencer.
8. Partial sequences from LTR, *env*, *pol*, and *gag* regions are aligned with the ClustalW2 and PHYLIP programs (or similar) and phylogenetic trees produced by the neighbor-joining method with Kimura's correction, using 1000 bootstrap confidence.

19.3 CONCLUSION

SRLV infections are prevalent worldwide, affecting the production and animal welfare of sheep and goats. For that reason accurate diagnosis is important. However, diagnosis is difficult because there is not a *gold standard* diagnostic test. Several studies have shown the efficacy of combining ELISA and PCR techniques to detect SRLV infection. This combination of diagnostic tests increases the number of animals detected and therefore the effectiveness of monitoring and control programs of the disease.

20.1 INTRODUCTION

Equine infectious anemia (EIA) has an almost worldwide distribution and is considered to be a significant threat to the equine industry as evidenced by the fact that it is one of the 11 notifiable equine-specific diseases listed by the World Organisation for Animal Health. Disease signs in horses consistent with EIA were first described in 1843[1] with a more comprehensive account of each clinical phase coupled with the demonstration that it is a blood-borne infection published by Vallée and Carré.[2] Moreover, these authors established that EIA was caused by a "filterable agent" making it one of the first diseases recognized as having a viral etiology (equine infectious anemia virus [EIAV]).

Diagnosis is complicated by the fact that clinical signs are generally nonspecific and vary considerably between individual animals and possibly even between equid species.[3] Although equids remain infected for life, most are able to control viral replication to such an extent that they eventually become free of overt disease signs and are therefore classified as "inapparent carriers." This common feature of EIA complicates detection and contributes to inadvertent spread of the disease. At present, there are no effective commercially available vaccines against EIA and so control is solely dependent on the identification and removal or quarantine of infected animals.

The first practical diagnostic assay, the agar gel immunodiffusion (AGID) or "Coggins test," for the disease was developed in the 1970s,[4,5] but despite its age and the fact that it is an indirect, serological procedure, it remains the only officially recognized test in many countries throughout the world. With the exception of Italy and Romania that have instigated national surveillance programs for all equids 6 months or older, EIA testing in most countries is restricted to selected equine populations. These generally include breeding stock, animals that participate in sporting events, animals for sale at public auction, and animals that are being transported across state lines (e.g., in the United States) or national boundaries unless restricted by free trade agreements such as within the European Union. In cases where EIA control programs have been effectively instigated, the incidence of disease in tested equine populations is usually low. When routine testing in the United States began in 1972, approximately 100,000 samples were evaluated with 4% identified as positive. In 2012, there were 1,443,959 EIA tests and only 36 (0.0025%) positive cases were discovered. However, despite the apparent success of current EIA control programs, there is considerable room for improvement.

Recent studies have highlighted the fact that while the AGID test has an enviable reputation for specificity, it is prone to delivering false-negative results. For example, in comparative experiments conducted as part of the Italian National Surveillance Program, it was demonstrated that when serum samples were screened by enzyme-linked immunosorbent assay (ELISA) instead of AGID, the number of EIA positive cases identified increased by 17%.[6,7] However, while more sensitive serological assays are available for EIA diagnosis, including ELISA and immunoblot, they all suffer from the disadvantage of a delay between the time of exposure to EIAV and the development of detectable humoral responses. Unfortunately, while equine cells of the monocyte/macrophage lineage are believed to comprise the predominant host cell type for EIAV, *ex vivo* cultures of these cells are too insensitive and too variable in terms of viability for routine

Downloaded From Vet-eBooks.com

use in conventional virus isolation techniques.[8] Although field strains of EIAV have been adapted to replicate in equine or canine fibroblastic cell types, this is a time-consuming, inefficient process that invariably produces a significant number of mutagenic changes in the viral genome resulting in an attenuated phenotype *in vivo*.[9] Therefore, direct diagnosis of EIAV infections must at present rely on the detection of viral structural components with the most commonly selected target for investigators being nucleic acid.

20.1.1 Classification, Morphology, and Genome Organization

EIAV has been described as the "country cousin" of human immunodeficiency virus (HIV) because like its famous relative, it is classified in the genus *Lentivirus*, subfamily *Orthoretrovirinae*, family *Retroviridae*.[10] As its name suggests, lentiviruses (*lente*-, Latin for "slow") involves a long incubation period. These viruses both incorporate their genetic information into the DNA of the host cell and have the unique ability to infect nondividing cells, making them one of the most efficient gene delivery vectors. At present, five serogroups (i.e., bovine, equine, feline, ovine/caprine, and primate lentivirus groups) are recognized within the genus *Lentivirus*, reflecting the vertebrate hosts with which they are associated. Besides EIAV, other notable lentiviruses include HIV-1, HIV-2, feline immunodeficiency virus, and visna–maedi virus.

Electron microscopy of EIAV preparations reveals a mixture of 115 nm diameter oval and circular particles in which the typical lentiviral conical core is encased by a proteinaceous matrix that in turn is bounded by a lipid membrane containing numerous 6–8 nm projections (Figure 20.1a).[11,12] Within the core are two copies of a single-stranded genomic RNA molecule that after infection undergo a reverse transcription (RT) reaction by virally encoded reverse transcriptase and RNase H enzymes to produce double-stranded proviral DNA. As with all retroviruses, this proviral DNA

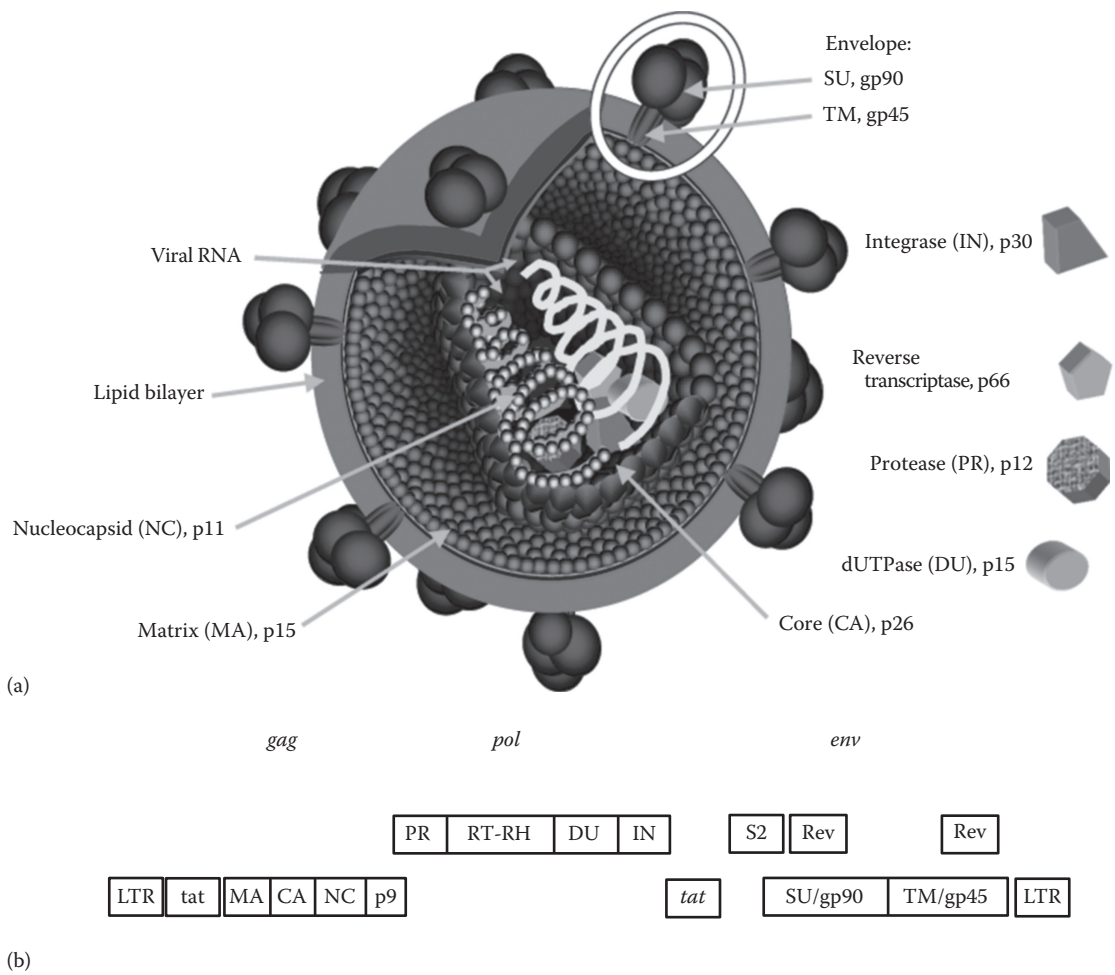

FIGURE 20.1 (a) Model of an equine infectious anemia virus (EIAV) particle showing the location and identity of the structural proteins. Although envelope glycoproteins (SU/TM) are depicted as comprising a trimeric structure as in HIV-1,[97,98] this has not been verified for EIAV. Antigens used in approved serological diagnostic tests, albeit not in all countries, are labeled. Both TM and p26 are included as antigens in one EIA-ELISA test approved for use in the United States. However, because these antigens are combined, this test does not discriminate between antibodies produced against TM and p26. (b) EIAV proviral genome organization showing the relative positions of the long terminal repeats, the three major genes (*gag, pol*, and *env*), and the additional open reading frames encoding (Tat, Rev, and S2).

may become integrated into host cell chromatin via the action of the EIAV integrase protein such that it is transcribed as if it were a normal cellular gene.

All complete EIAV proviral DNA molecules sequenced to date are approximately 8200 base pairs in length giving EIAV the honor of having the shortest genome of any extant lentivirus discovered to date with, as expected, the prototypical retroviral genome organization (Figure 20.1b) in which the major genes *gag*, *pol*, and *env* are bounded by long terminal repeats (LTR).[13–17] However, lentiviruses are classified as complex retroviruses because they contain small open reading frames (ORF) encoding so-called ancillary proteins in addition to the three major genes. The number of ORFs and the functions of the ancillary proteins they encode differ between lentiviruses with only Rev (essential for export of unspliced and singly spliced viral RNA transcripts from the host cell nucleus) being common to all members of the genus. Although all lentiviruses contain an ORF designated *tat*, the function(s) of the protein it encodes may differ. In most cases, this ORF encodes a transactivator protein (Tat) that is essential for transcription of the viral genome; however, in the small ruminant lentiviruses, the encoded protein promotes cell cycle arrest and therefore may be analogous to the Vpr protein of HIV-1.[18,19] Polypeptides encoded by the other ORFs appear to be involved in pathogenesis and/or combating retroviral restriction factor (RRF) host cell defense systems.

In addition to being the smallest living lentivirus in terms of genome size, EIAV also possesses the simplest genomic organization containing just three additional ORFs encoding Tat, the second exon of Rev, and S2 (Figure 20.1b), with the latter being a unique feature within lentiviruses. In contrast, HIV-1, which is one of the most genetically complex lentiviruses, has six ORFs coding for accessory or regulatory proteins. Furthermore, EIAV is the only surviving lentivirus that does not possess an additional ORF encoding a Vif ortholog. This ancillary lentiviral protein promotes degradation of host retroviral defense proteins in the apolipoprotein-β editing complex 3 family or APOβEC3–cytidine deaminase proteins. These molecules are incorporated into progeny retroviral particles where they can introduce potentially lethal mutations in the viral genome by converting cytidine to uracil. The absence of a Vif ortholog in EIAV is somewhat unexpected since horses possess more APOβEC3 genes than any other nonprimate species.[20] However, despite possessing just 84% of the coding capacity of HIV, EIAV is, from the virus point of view, a highly successful pathogen, and just like its more famous relatives, it establishes persistent infections by resisting all host-specified defense mechanisms.

20.1.2 Epidemiology

At more than 400 million years old, members of the family *Retroviridae* are ancient and perhaps not surprisingly have an enormous host range that includes all known vertebrates.[21] In contrast, the current host range of lentiviruses is limited to equids, bovids, wild and domestic small ruminants, wild and domestic *Felidae*, African nonhuman primates, and man, suggesting the genus arose only relatively recently in evolutionary terms. Indeed, it has been calculated based on nucleotide substitution rates that lentiviruses emerged around 1 million years ago.[22] However, discoveries such as the observation that similar defective endogenous lentiviral proviruses are present within the genomes of European rabbits and hares despite these being separate leproid species for 12 million years[23,24] suggest that calculations based on nucleotide substitution rates underestimates the age of lentiviruses by at least an order of magnitude. Nonetheless, compared to other members of the *Retroviridae*, lentiviruses are probably "recent arrivals," and this may account for the fact that within the *Perissodactyla*, only the *Equidae* act as hosts for this retroviral genus. The assumption being that early members of this family were exposed to a lentiviral infection sometime after divergence from the rhinoceros and tapir (55–40 million years ago) but as EIAV infects all equids, before the speciation of modern equines (2–4 million years ago).

With the exception of Iceland that operates a strict "closed horse herd" policy, EIA occurs worldwide with outbreaks being recently reported in Asia, Europe, North America, and South America.[14,25–31] On the basis of discussions with veterinarians and animal health-care professionals from different countries, it appears that the incidence of EIA in routinely tested equid populations such as performance horses is relatively low (2%–0.0025%). However, in equids not subjected to regular testing, prevalence may be much higher such as >30% reported in a survey of farms located in the Pantanal region in Brazil.[31] In the United States, new cases of EIA are almost always found in animals offered for sale for the first time at public auction after living their lives on a single farm.

Unfortunately, there is a relative paucity of information concerning the molecular epidemiology of EIAV, and to date, only four complete genomic sequences from field isolates have been published: $EIAV_{LIA}$ from China, $EIAV_{IRE}$ from Ireland, $EIAV_{MIY}$ from Japan, and $EIAV_{WY}$ from the United States. These share ≥80% nucleotide sequence identity and show no evidence of recombination with one another, and phylogenetic analysis suggests that each comprises a separate monophyletic group or clade.[16,17] Therefore, it appears as if all four have evolved independently since diverging from a common ancestor. These observations suggest that the global molecular epidemiology of EIAV is likely to be extremely complex, an assertion supported by the type of analysis shown in Figure 20.2 where 19 *gag* sequences encoding the matrix protein (p15) are found to comprise 13 monophyletic groups. Based on this level of complexity, it might be anticipated that the design of universally successful molecular diagnostic assays and vaccines will be difficult in the case of this virus. However, we should keep in mind that the current phylogenetic reconstructions for EIAV are all based on a very limited set of sequences, and that the picture may change considerably as more sequences from geographically distinct origins become available.

Differences in the extent of nucleotide or amino acid sequence identity between EIAV field isolates are not distributed evenly throughout the genome. In some cases such as Gag

Downloaded From Vet-eBooks.com

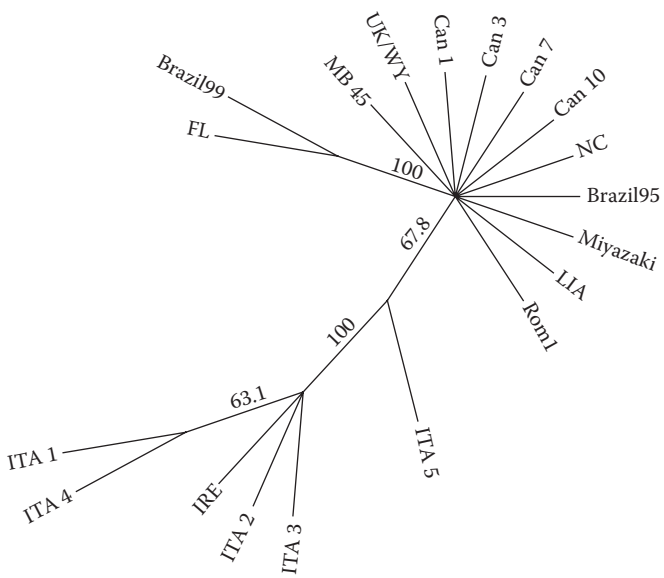

FIGURE 20.2 Phylogenetic analysis of equine infectious anemia virus (EIAV) isolates based on nucleotide sequences encoding Gag p15 (matrix protein). A phylogenetic tree of aligned EIAV *gag* p15 sequences was constructed by the neighbor-joining method with bootstrap values determined over 1000 iterations. Branch lengths are proportional to the distance existing between sequences. The *gag* p15 sequences included in the analysis are from Canada (Can 1, 3, 7, 10 [GenBank accession numbers EF418582, EF418583, EF418584, EF418585]), China (Liaoning [LIA] [GenBank accession number AF327877]), Ireland (IRE [GenBank accession number JX480631]), Italy (ITA 1, 2, 3, 4, 5 [Genbank accession numbers EU240733, EU375543, EU375544, EU741609, GQ265785), Japan (Miyazaki [GenBank accession number JX003263]), Romania (Rom 1 [GenBank accession number GQ229581]), and the United States (Wyoming UK/WY [GenBank accession number AF033820]). In addition, sequences were included from Florida (FL), North Carolina (NC), Brazil (Brazil 95, 99),[29] and Argentina (MB 45).

p26, Gag p11, and the *pol* gene products, it is relatively high (79%–89% amino acid identity), whereas in Gag p9 and S2 amino acid, identity is <50%. The fact that there is a high level of amino acid sequence identity between isolates in Gag p26 is fortunate because this antigen forms the basis of almost all commercially available serological assays for EIA including the AGID (Coggins) test. However, while there are certainly genetic differences between geographically distinct EIAV isolates, almost all of the structural/functional motifs within viral proteins that were identified mainly using laboratory-generated derivatives of the $EIAV_{WY}$ strain are either preserved or contain highly conservative amino acid substitutions.[16,26,29,32] For example, despite less than 50% amino acid sequence identity, all Gag p9 molecules analyzed to date contain a "late domain" or YPDL motif consisting of tyrosine (Y), proline (P), aspartic acid (D), and leucine (L)[14,16,26,29,33] that have been shown to be essential for the release of progeny virions from the host cell.[34,35] Analysis of the immunologically important surface unit (SU) envelope glycoprotein (gp90) demonstrates that amino acid substitutions between strains are distributed throughout the molecule with the exception of the amino terminus including the six amino acid signal peptide and the relative positions of 16 cysteine residues suggesting that disulphide bridges are essential to the structural and functional integrity of this viral glycoprotein.[16,32] As with all retroviruses studied to date, the EIAV reverse transcriptase lacks "proofreading" ability in terms of 3′–5′ exonuclease activity and is error prone with a tendency to produce A:C mismatches.[36] Furthermore, initial viral replication occurs in the cytoplasm where host cell-proofreading activities are absent. This combination creates an environment where there is a high probability that mutations will be introduced during the production of proviral DNA molecules from the genomic viral RNA, resulting in the rapid generation of a population of related but genetically diverse viruses ("quasispecies"). Compared with homogenous viral populations, such quasispecies are better equipped to deal with multiple selective pressures such as that exerted by the immune system. Consequently, within infected equids, the genetic composition of the EIAV population changes with time, although this is limited by the requirement to preserve the structural and functional properties of many viral proteins along with some secondary structural motifs within viral nucleic acids. In general terms, it has been shown that during the course of infection, *gag* and *pol* remain relatively conserved, while extensive genetic variation occurs in *env* and in ORF 3 encoding the second exon of Rev.[37–40] Somewhat surprisingly, Gag p9 and S2, the two proteins with the lowest amino acid sequence identity between EIAV isolates and therefore presumably possessing considerable potential for change, are extensively conserved over time within individual infected hosts.[41] An important factor contributing to the initiation and maintenance of a persistent infection is that the SU envelope glycoprotein of EIAV can undergo major "antigenic drift"[42,43] meaning that each febrile episode in an infected animal is associated with a different antigenic variant or "immunological escape mutant." This conclusion is supported by the fact that the nucleotide sequences of SU molecules differs within each clinical episode.[39,40,44] However, unlike the relatively uniform distribution observed between EIAV strains, nonsynonymous nucleotide substitutions occurring during the course of an infection are not randomly distributed but are generally restricted to eight hypervariable domains.[39]

20.1.3 Transmission

EIAV is generally considered as a blood-borne disease although viral nucleic acids have been detected in swabs taken from nasal passages, the buccal cavity, and genitalia.[28] Under natural conditions, it appears to be transmitted predominantly by blood-feeding insects comprising members of the *Tabanidae* (horseflies), *Chrysops* (deer flies), and *Stomoxys calcitrans* (stable flies).[45–50] Mosquitoes are unlikely to play a major role in EIAV transmission because lentiviruses, unlike some virus types, cannot migrate from the insect gut to the salivary gland in order to be injected into a new host and therefore, once ingested by mosquitoes, are probably destroyed by digestive enzymes. Importantly, EIAV does not replicate in insect tissues and so transmission is purely mechanical with efficiency

Downloaded From Vet-eBooks.com

determined in part by the volume of the blood meal that is retained on hematophagous insect mouthparts. Consequently, size of the inoculum is an important factor for efficient transmission although even in the case of large horseflies such as *Tabanus fuscicostatus*, the volume of blood retained post-feeding is very limited and estimated at only 10 ± 5 nL.[51] As these flies generally need just a single blood meal to complete their life cycle, transmission of EIAV can only occur if feeding is interrupted, for example, by defensive reactions of the equid in response to a painful bite, so that the fly travels to a second host in order to feed to repletion. The primary factor determining whether a fly will return to the original or seek a new host is distance. It has been demonstrated that 99% of horseflies will return to their original target if no other equid is positioned less than ~45 m (50 yards) away.[50] In those jurisdictions, particularly in the United States, where euthanasia is not mandatory, it is required that EIAV-infected equids are quarantined at a minimum of four times this distance (~183 m) from all uninfected equines.

As a result of low residual blood meal volumes, the innate behavioral characteristics of insect vectors and the fact that EIAV probably does not survive significantly longer than 30 min on fly mouthparts,[47] natural insect-mediated transmission appears to be a relatively inefficient process only having a high probability of occurrence when susceptible animals are in close proximity and when the donor equid experiences clinical episodes associated with high levels of blood-associated virus (see Section 20.1.4). In contrast, iatrogenic transmission is highly effective with man potentially having the greatest influence on the dissemination of EIAV worldwide. Recent examples include the high-profile 2006 outbreaks of EIA in Ireland and Italy that originated from the administration of contaminated horse blood products to thoroughbred foals.[27] Furthermore, reuse of veterinary equipment without sterilization is commonplace in many countries. It is worthwhile remembering that residual blood volumes in hypodermic syringes are likely to be 1,000–10,000-fold higher than found on horsefly mouthparts and that EIAV remains infectious in syringe needles for at least 96 h.[52]

In addition, to insects and man, EIAV has been reported to be transmitted *in utero* although this only seems to occur if the mare experiences a febrile episode during gestation suggesting that high tissue-associated viral loads are required before the placental barrier is crossed.[53] The fact that healthy EIA-free foals can be born and until weaned remain in close proximity, even in areas with high insect-vector populations, demonstrates that inapparent carrier mares, in which viral loads are low, do not present a major risk to their offspring.

Although a blood-borne etiology for EIAV has been extensively documented, the recent finding of viral p26 major capsid antigen expression in alveolar and bronchiolar epithelial cells of the lung parenchyma coupled with an associated interstitial disease[54] suggests that airborne transmission could also occur with this virus. This is certainly not an unreasonable hypothesis as this is the major route for transmission of small ruminant lentiviruses in domestic sheep and goats.[55] Therefore, secretion into the lumen of the equine lung could result in the exhalation of EIAV in droplets. However, further studies are required to determine if and under what circumstances airborne transmission of EIAV can occur although it is interesting to note that nose-to-nose contact as a behavioral form of greeting frequently occurs between equids in the same social group.

20.1.4 Clinical Features and Pathogenesis

From the beginning of the early twentieth century,[2] EIA has consistently been described in the literature as comprising of three clinical phases. The first is designated the acute stage, it lasts 1–3 days and is usually characterized by fever and thrombocytopenia. The second or chronic phase consists of multiple sequential disease episodes in which fever and thrombocytopenia may be accompanied by one or more of the following: anemia, edema, depressed neurological reactions, petechial hemorrhaging on mucous membranes, and cachexia. Eventually after 12–24 months, the frequency of these episodes gradually diminishes, and the equid enters a prolonged third or inapparent carrier stage where there are no overt clinical signs. Although this classical pattern of disease progression is frequently observed in experimental infections,[44,56,57] the situation may be very different in the field where clinical signs can be extremely variable ranging from unresolvable high fever resulting in death to cases where there are either no disease signs or they are so mild as to go unnoticed by owners. In addition to potential differences in pathogenicity between virus strains, man may play a significant role in determining clinical outcome because exposure to high inoculum levels of EIAV, as is likely to occur during iatrogenic transmission, can significantly enhance disease signs.[58]

In common with other lentiviruses, the host cell tropism of EIAV includes cells of the monocyte/macrophage lineage although progeny virus production only occurs following differentiation into mature tissue macrophages or dendritic cells.[59] However, in contrast to HIV, but in common with small ruminant lentiviruses, EIAV cannot infect $CD4^+$ T-helper lymphocytes, and so it does not induce long-term immunodeficiency in equids. Furthermore, some EIAV strains may infect endothelial cells,[60] and as outlined earlier, viral p26 antigen is expressed in lung alveolar and bronchiolar epithelial cells of persistently infected horses[54] although the significance of this relatively new discovery in terms of progeny virus production and transmission remains to be determined.

During the acute and chronic stages of EIA, induction of clinical disease signs is dependent on tissue-associated viral loads. When these reach a threshold level that experimentally equates with plasma-associated EIAV RNA burdens of 5×10^7 to 1×10^8 copies/mL,[61] they trigger release of proinflammatory cytokines that include tumor necrosis factor-α (TNFα), interleukin 1-α and 1-β (IL-1α, IL-1β), IL-6, and transforming growth factor-β (TGFβ). IL-6 and TNFα induce febrile responses by activating the arachidonic pathway to increase production of prostaglandin E2 (PGE2), while TNFα/TGFβ contributes to thrombocytopenia by suppressing equine megakaryocyte growth and TNFα promotes anemia

Downloaded From Vet-eBooks.com

by downregulating erythropoiesis.[62–65] Furthermore, in some species, TNFα induces severe thrombocytopenia by stimulating release of platelet agonists including thrombin, plasmin, and serotonin.[66] At later stages, adaptive immune responses may also contribute to pathogenesis by immune-mediated destruction of antibody-coated platelets, phagocytosis of complement C3-coated erythrocytes resulting in the presence of hemosiderin granules in macrophages, and thickened glomerular tufts within the kidney caused by excess levels of C3.[67–69] Induction of oxidative stress produced by changes in glutathione peroxidase and uric acid levels might also play a role in the pathogenesis of EIAV infections by escalating inflammatory responses while simultaneously decreasing immune cell proliferation.[70]

As demonstrated by experiments in foals with severe combined immunodeficiency, resolution of clinical signs following exposure to EIAV is dependent on adaptive immune responses.[71,72] In experimentally infected, immune competent horses or ponies, humoral responses against EIAV are detectable at 14–28 days postinfection (pi) using sensitive immunoblot or ELISA assays. However, antibodies with viral-neutralizing activity are usually not observed until 38–87 days pi and may not reach maximal levels until 90–148 days pi.[42,56] Therefore, as virus-specific cytotoxic T-lymphocytes are detectable by 14 days pi,[73] it is generally believed that cell-mediated and not humoral immune responses are responsible for the initial control of EIAV replication. Early immune responses are "strain specific," and as discussed earlier, each febrile episode is associated with an antigenically distinct virus population derived from the original infecting virus.[42,43] Therefore, the equid immune system is forced into a cycle of "catch-up" where it must respond to the emergence of each new dominant variant in the viral population. Fortunately, this cycle does not continue indefinitely and is eventually broken (enabling infected equids to become inapparent carriers) by maturation and broadening of the immune response from strain specific to strain cross-reactive.[42,56,74,75] The requirement for active adaptive immune responses for maintenance of the inapparent carrier state is evidenced by the increase of plasma-associated virus load and recrudescence of disease after corticosteroid-induced immunosuppression.[76–78]

20.1.5 Diagnosis

The variation in disease signs that are observed between individual cases precludes diagnosis of EIA based solely on clinical profile. Furthermore, there is no universally accepted virus isolation or viral component detection techniques. Therefore, identification of EIAV-infected equids is currently dependent on indirect, serological methods.

20.1.5.1 Conventional Techniques

In most countries, the AGID ("Coggins") test is the "gold standard" for determining the serological status of equids to EIAV, and only those animals producing positive reactions in this assay are considered, on an official basis, to be seropositive for this virus. However, as discussed earlier, AGID test can produce a significant number of false-negative reactions,[6,7] a sensitivity issue in part caused by the relatively large amounts of antigen/antibody complexes required to form visible lines of precipitation. Furthermore, in the case of weak reactors, interpretation of AGID results can be highly subjective creating a situation where a serum sample is classified as "positive" in one laboratory but "negative" in another.[6,7] Although some nations such as the United States and more recently the European Union permit alternative serological testing procedures based on the ELISA format (both competitive and noncompetitive), samples producing positive reactions usually have to be confirmed by AGID before an official diagnosis is given. Almost all commercially produced AGID and ELISA test kits for the serological diagnosis of EIA employ recombinant forms of the viral p26 major core protein derived from the $EIAV_{WY}$ strain as the detection antigen. Recombinant forms of p26 have also been used in several published noncommercial EIA-ELISAs along with an immunochromatographic lateral flow test.[7,79–82] In addition to the p26 protein, ELISA and fluorescence polarization assays have been developed using recombinant antigens or synthetic peptides based on the SU or Transmembrane (TM) envelope glycoproteins. These antigens have less than 65% amino acid sequence identity between EIAV strains, and none of these assays have as yet been officially adopted as approved diagnostic tests.[30,83–86] However, one of the most sensitive serological diagnostic procedures discovered to date is an immunoblot test based on gradient purified whole viral antigen derived from $EIAV_{PV}$, a fibroblast-adapted variant of the $EIAV_{WY}$ strain.[87] Although $EIAV_{WY}$-like viruses share less than 80% nucleotide sequence identity with the other full-length EIAV genomes sequenced to date,[32] the $EIAV_{PV}$ antigen has successfully detected virus-specific antibodies in field cases of EIA in Europe, Asia, and North and South America.[7,27,30,33,88] At the present time, the EIAV-immunoblot test is not officially approved, although in the United States Department of Agriculture EIA Uniform Methods and Rules, it is described as a "supplemental laboratory test" that "may be used to resolve equivocal results on official laboratory tests." However, currently, this test can only be performed at the National Veterinary Services Laboratory, Ames, Iowa, and the University of Kentucky. Samples are considered positive in the EIAV-immunoblot test if they react with two or more of the three major viral antigens SU, TM, or p26.

On the basis of experiences gained during the National Surveillance Program, it is probable that Italy will adopt a three-tiered strategy for EIAV diagnosis. In this, all samples are subjected to initial screening using an ELISA-based test[7] with those found positive for EIA confirmed by AGID. In the few cases where the results do not agree, additional immunoblot tests are performed using the $EIAV_{PV}$ antigen. Therefore, in contrast to an AGID only system, screening is accomplished using a potentially more sensitive technique that, particularly when combined with an ELISA reader, produces less subjective results. Moreover, the increased tendency that EIA-ELISA tests have for producing "false-positive" results is counteracted by the use of AGID and/or EIA immunoblot.

20.1.5.2 Molecular Techniques

The major disadvantage of indirect serological techniques is the delay between exposure to a pathogen and the development of detectable humoral responses, referred to as the "serological window." Although most experimentally EIAV-infected equids become seropositive (even in AGID tests) by 45 days pi, delays as long as 157 days have been occasionally reported in field cases.[27] Importantly, tissue-associated viral loads can reach their highest levels in the days immediately following the initial exposure; therefore, in recently infected equids, there is a high risk for transmission before they become detectable in any of the currently approved diagnostic tests. Indeed during the 2006 EIA outbreak in Italy, a farm was declared "free" of the disease by AGID testing following a 90-day quarantine period only to have new cases appear a short time later.[26] Consequently, there is a significant requirement for the development of direct methods of detection particularly in cases where recent exposure is suspected. To meet this need in the absence of reliable, sensitive virus isolation techniques, researchers have focused on the development of methods to detect EIAV nucleic acids either in the form of proviral DNA or viral RNA. To date, these methods have all been based on the polymerase chain reaction (PCR) involving either direct amplification with proviral DNA or, in the case of viral RNA, following production of complimentary DNA (cDNA) by RT. However, with EIAV, DNA amplification techniques such as PCR face two major hurdles. The first is these techniques depend on the presence of extensive nucleotide sequence identity between the oligonucleotide primers and the target DNA with mismatches resulting in decreased sensitivity or even complete inhibition of the amplification process. As described earlier, EIAV sequences are highly variable between geographically distinct isolates,[16,29,32] and in individually infected animals, some regions of the viral genome undergo significant mutational changes over time.[37,39] Consequently, before successful PCR-based assays can be developed, it is essential to identify highly conserved regions within the EIAV genome, a process hindered by the current lack of published nucleotide sequence information for this virus particularly in regions outside of the *gag* gene. The second major hurdle facing the development of direct molecular diagnostic assays for EIAV is that tissue- and blood-associated viral loads in inapparent carriers are often at extremely low levels[89,90] making detection difficult even for highly sensitive techniques such as PCR. Nonetheless, a number of PCR-based assays have been described for EIAV.[25,26,28,29,33,91–94] Unfortunately, the earlier assays were developed when almost all published sequences were derived from variants of the $EIAV_{WY}$ strain and so may be of limited use for diagnosis in the field.[91,92] The TaqMan-style assay described by Cook et al.[92] was designed in and around sequences (slippery sequence and pseudoknot) responsible for the ribosomal frame-shifting event that is required for the translation of the *pol* gene[95] in the belief that these will be highly conserved between isolates. However, it has since been discovered that although the slippery knot and pseudoknot motifs are conserved, the surrounding sequences encoding Gag p9 vary extensively between different EIAV isolates.[28,29] Therefore, this real-time RT-PCR assay is only effective for detection of viral RNA from $EIAV_{WY}$-like strains. Although the oligonucleotide primers described by Nagarajan and Simard[25] successfully detected proviral DNA from seropositive horses in Canada, resulting in them becoming recommended reagents for detection of EIAV viral nucleic acids by the OIE, they failed because of a significant number of mismatches (Figure 20.3) to amplify proviral sequences from EIA-seropositive horses in Europe[26,28] and Japan.[33] Recently, however, several PCR-based assays have been reported that have successfully detected viral-specific nucleic acids from seropositive field cases of EIA.[7,26,28,29,33,93,94] It should be noted that some of these published assays[29,93] were designed to amplify entire EIAV *gag* gene sequences and therefore should perhaps be considered as analytical rather than diagnostic assays. In addition, to amplifying viral nucleic acids from EIA field cases, some recently described PCR-based assays have been reported to correlate well with conventional serological diagnostic tests even with samples collected from clinically inapparent equids.[26,33]

20.2 METHODS

20.2.1 Sample Collection and Preparation

Febrile episodes of EIA are correlated with high viral loads in most tissues including blood[89] and therefore provide the best conditions for detection of viral nucleic acids. Under such favorable circumstances, the only problem facing the application of PCR-based techniques is the extent of nucleotide sequence identity between the oligonucleotide primers and the target sequences within the viral genome. However, tissue-/blood-associated viral loads decline by at least 1000-fold coupled with the resolution of overt clinical signs,[61,89] thereby adding the limits of detection to the difficulties that must be overcome before molecular-based methods can be used for routine EIAV diagnosis. In experimentally infected inapparent carrier horses, the organs with the highest levels of EIAV nucleic acids appear to be the liver and spleen.[89] This also seems to be the case in naturally infected equids as shown by the detection of EIAV proviral sequences by a single-stage PCR in spleen DNA samples collected from all 22 seropositive horses, whereas less than 20% of these animals were PCR positive using DNA isolated from peripheral blood mononuclear cells (PBMC) samples.[94] Unfortunately, difficulties associated with performing routine biopsies on these organs, especially if large numbers of animals are involved, limits their usefulness for diagnosis. Consequently, PBMCs as a source of proviral DNA and plasma for viral RNA are currently viewed as the most practical sample materials for detection of EIAV infection. Although some authors have reported that PCR-based amplification of EIAV sequences is accomplished more reliably from PBMC DNA,[26,33] viral RNA has been successfully

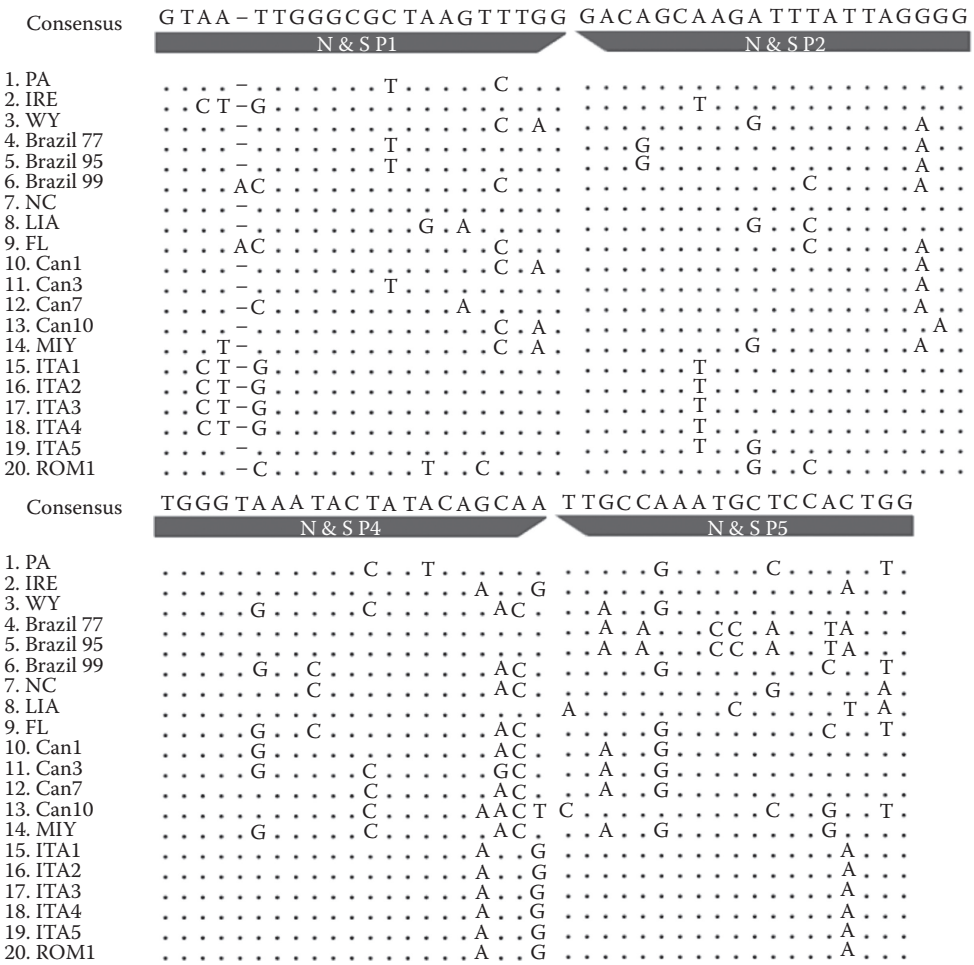

FIGURE 20.3 Variation between different viral isolates in binding regions of oligonucleotide primers currently recommended by the World Organisation for Animal Health. Binding regions for the current World Organisation for Animal Health–recommended oligonucleotide primers N and SP1, N and SP2, N and SP4, and N and SP5[25] are shown for American, Asian, and European equine infectious anemia virus isolates (GenBank accession numbers AB008196, AF016316, AF327877, EF418582, EF418583, EF418584, EF418585, EU24073, EU375543, EU375544, EU741609, GQ265785, GQ229581, GQ855755, JX480631, and JX003263[29]). A dot indicates nucleotide sequence identity, whereas a dash indicates a deletion.

detected by nested RT-PCR in plasma samples obtained from asymptomatic, naturally EIAV-infected Romanian horses. This suggests the need for further studies to compare sample source materials, nucleic acid extraction techniques, and different PCR-based methods.

At present, there are no standardized protocols for nucleic acid isolation and purification prior to analysis for EIAV nucleotide sequences, and several methods have been described. DNA from PBMC has been isolated directly from whole blood using a GenElute Blood Genomic DNA Kit (Sigma, St. Louis, MO)[26] or DNeasy Blood and Tissue Kit (Qiagen, Germantown, MD).[33]. Alternatively, some researchers have attempted to enrich PBMC prior to nucleic acid extraction by pretreating whole blood samples for 10 min with red cell lysis buffer (154.98 mM ammonium chloride [NH_4Cl], 9.99 mM potassium hydrogen carbonate [$KHCO_3$], 1.27 mM ethylene diamine tetra-acetic acid [EDTA]).[94] Similarly, a number of commercially available methods have been described for extracting EIAV RNA from plasma samples collected by jugular venipuncture into evacuated glass tubes containing EDTA. These include the High Pure Viral RNA Kit (Roche Molecular Biochemicals, Indianapolis, IN) and the QIAamp Viral RNA Mini Kit (Qiagen).[7,28,29]

20.2.2 Detection Procedures

The oligonucleotide primer sequences (and probe sequences in the case of real-time TaqMan assays) along with the published thermocycling conditions of recently described PCR-based assays for EIAV are shown in Table 20.1. Assay conditions will vary depending on the source of the PCR reagents. Furthermore, subsequent analysis demonstrates that none of the oligonucleotide primer binding sequences described to date are completely conserved between viral isolates although there appears to be higher levels of nucleotide sequence identity within the LTR R/U5 and 5′ untranslated

region than within Gag protein coding sequences (Figure 20.4). However, this conclusion is based on a very small number of published sequences and must be confirmed by additional studies.

The fact that there does not appear to be a "universal" PCR-based system for EIAV suggests that researchers attempting to detect nucleic acid sequences from field cases of suspected exposure to this virus should not limit themselves to a single published assay. Furthermore, they might consider testing a range of annealing temperatures in each assay using a temperature gradient and/or design "degenerate" primers based on published sequences to overcome potential mismatches. However, equids as with all mammals possess significant amounts of retroviral-derived material in their chromosomal DNA. Therefore, particularly when using cellular DNA as a template in PCR-based assays, it is possible that lowering annealing temperatures and/or using degenerate primers will result in false-positive amplification of sequences that are not of EIAV origin. Although these can usually be excluded on the basis of size, modified PCR assays should be tested using samples obtained from EIAV seronegative animals and all DNA products sequenced to determine their authenticity.

20.3 CONCLUSION AND FUTURE PERSPECTIVES

EIAV possesses the smallest, least complex genome of any extant lentivirus, and yet it is a highly successful pathogen (from a viral perspective) establishing persistent infections by resisting or evading host-defensive responses. Furthermore, with its widespread distribution, this virus poses a significant threat to most of the world's equine populations. The lack of pathognomonic signs or lesions coupled with the fact that most EIAV-infected equids eventually become inapparent carriers enhances the risks of inadvertent transmission and complicates diagnosis by, with currently available technology, necessitating the use of laboratory-based testing procedures.

Conventional direct diagnostic techniques such as virus isolation in equine macrophage cultures derived from bone marrow biopsies or PBMC are not practical for routine use and therefore confirming exposure to this virus is at present dependent on indirect serological methods with most countries reliant exclusively on the AGID or "Coggins" test. This 40-year-old assay has a well-deserved reputation for specificity, but recent studies have confirmed that it is prone to producing false-negative results.[6,7] Although the probability of detecting EIAV-infected equids is improved by adoption of

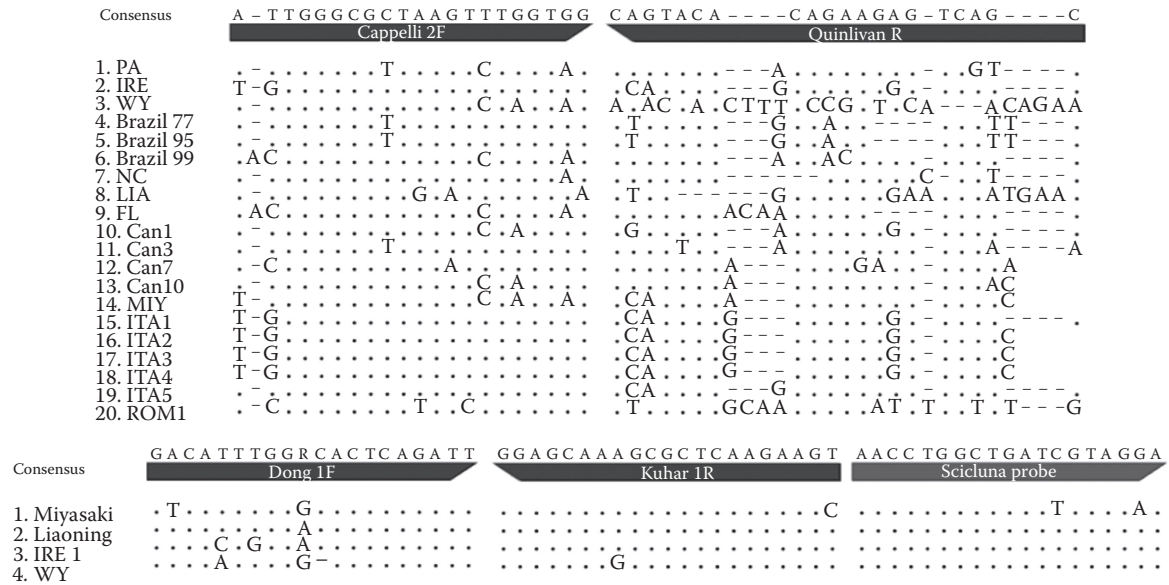

FIGURE 20.4 Examples of variation within primer or TaqMan probe binding regions of recently described PCR-based assays for equine infectious anemia virus. Primer binding regions for PCR-based assays described by Cappelli et al.[26] and Quinlivan et al.[28] are within the viral *gag* gene (comparison sequences: GenBank accession numbers AB008196, AF016316, AF327877, EF418582, EF418583, EF418584, EF418585, EU24073, EU375543, EU375544, EU741609, GQ265785, GQ229581, GQ855755, JX480631, and JX003263[29]) whereas those by Dong et al.,[33] Scicluna et al.,[7] and Kuhar et al.[94] are located within the U3 region of the 5′ long terminal repeat and/or the 5′ untranslated region for which less comparative nucleotide sequence information is available (GenBank accession numbers AF327877, AF016316, JX480631, JX003263). A dot indicates nucleotide sequence identity, whereas a dash indicates a deletion.

a three-tier diagnostic system in which all serum samples are initially screened by less subjective, potentially more sensitive EIA-ELISA with confirmation by AGID followed by immunoblot testing if required,[6,7] there is an urgent need for direct techniques that can detect infected equids shortly after exposure to EIAV without having to wait for production of virus-specific antibodies.

To fulfill this requirement, a number of PCR-based tests for detection of EIAV nucleic acids have been described although these have yet to be validated against viral strains from different geographical regions. In addition, alignment studies using published EIAV sequences suggest that none of the primer binding sites (or probe binding sites in the case of TaqMan-type real-time PCR assays), described to date, including those currently recommended by the OIE, are located in regions of the viral genome that show complete conservation between isolates. However, three of the PCR assays described to date have primer (and TaqMan probe in the case of[7]) binding sites within the LTR U5 domain and/or the 5′ untranslated region,[7,33,94] areas of the EIAV genome that appear to contain the highest levels of nucleotide sequence identity between strains. Unfortunately, this conclusion is based on limited experimental information but, if confirmed by additional studies, suggests that one or more of these assays, perhaps with modifications such as the use of degenerate primers (or probes) to compensate for the relatively small amounts of nucleotide variation present in these regions of the viral genome, could form the basis of a viable direct diagnostic test for EIAV. Alternatively, these regions of the viral genome could be used to design new amplification primers and detection probes.

While correct primer (and probe) design is obviously important for the detection of EIAV nucleic acids using either conventional PCR-based techniques or some of the newer approaches such as isothermal amplification, efficient sample material extraction/purification to ensure maximum recovery is also a critical parameter especially in the case of inapparent carriers where viral loads are expected to be low. In some cases, it might even be worth investigating if detection rates can be improved by sequence-independent amplification of viral RNA.[96] Finally, some researchers have reported that for most inapparent carriers, EIAV sequences can only be amplified from DNA extracted from PBMC and not from plasma RNA preparations suggesting that during this stage of the disease proviral, DNA in PBMC is more abundant than plasma-associated viral RNA.[26,33] However, this finding is not universal and so it must be determined if these discrepant results reflect differences in horse/viral populations or methodologies.

In view of the extent of genetic variation between geographically distinct EIAV strains, development of broadly reactive nucleic acid detection techniques for this virus will almost certainly require international, multicenter collaborative efforts. The laboratories involved will need to carefully evaluate different viral nucleic acid extraction and amplification techniques using a broad range of samples. Furthermore, they will need to determine if proviral DNA, viral RNA, or both should be the preferred starting material.

21.1 INTRODUCTION

Feline immunodeficiency virus (FIV) is a retrovirus that is responsible for an immune disorder in cats throughout the world. Clinically, FIV infection is characterized by an acute phase with fever, leucopenia, gingivitis, and generalized lymphadenopathy, followed by a latent phase without obvious symptoms, and a last, symptomatic phase with CD4+ lymphocyte depletion and increased susceptibility to opportunistic infections and neoplasia. Given the occurrence of two other retroviruses in cats, that is, feline leukemia virus (FeLV) and feline foamy virus (FeFV), that induce similar clinical symptoms to FIV, it is important that FIV infection is accurately diagnosed for implementation of appropriate disease management and prevention. The purpose of this chapter is to present a brief overview on FIV relating to its classification, morphology, genome organization, epidemiology, clinical features, pathogenesis, treatment, and prevention, together with a streamline molecular protocol for FIV identification.

21.1.1 Classification

FIV is a member of the genus *Lentivirus*, family *Retroviridae*, which covers a group of retroviruses with the unique property of transcribing their RNA into DNA after entering a cell. Subsequent integration of the retroviral DNA into the chromosomal DNA of the host cell allows its propagation in situ. Of the two subfamilies within the *Retroviridae* family, the subfamily *Orthoretrovirinae* is divided into six genera (*Alpharetrovirus*, *Betaretrovirus*, *Deltaretrovirus*, *Epsilonretrovirus*, *Gammaretrovirus*, and *Lentivirus*), whereas the subfamily *Spumaretrovirinae* is made up of a single genus (*Spumavirus*). The genus *Lentivirus* consists of 10 recognized species that are organized into five groups: bovine lentivirus group (bovine immunodeficiency virus [BIV] and Jembrana disease virus), equine lentivirus group (equine infectious anemia virus [EIAV]), feline lentivirus group (FIV and puma lentivirus), ovine/caprine lentivirus group (caprine arthritis–encephalitis virus [CAEV] and maedi–visna virus [MVV]), and primate lentivirus group (human immunodeficiency virus 1 [HIV-1, the type species], human immunodeficiency virus 2 [HIV-2], and simian immunodeficiency virus [SIV]). It is notable that members of the genus *Lentivirus* (lenti-, Latin for "slow") cause immunodeficiency and/or multiorgan diseases in respective hosts, which are characterized by a long incubation period before onset of clinical symptoms, disease progression despite a strong host immune response, and a predictably deadly outcome.

Based on their cellular tropism and disease manifestations, members of the genus *Lentivirus* may be separated into two groups. The first group includes HIV-1, HIV-2, SIV, FIV, and BIV, which infect lymphocytes and cells of the monocyte/macrophage lineage, leading to immunodeficiency syndrome. The second group contains EIAV, MVV, and CAEV, which replicate predominantly in macrophages, leading to multiorgan disease.

Phylogenetic analysis of the envelope (*env*), group-specific antigen (*gag*), and polymerase (*pol*) genes has enabled further identification of five subtypes (A, B, C, D, E) in addition to a putative subtype F within the FIV species [1]. Of these, subtypes A and B commonly occur in the United States and Canada; subtypes B, C, and D are present in Asia; subtypes A, B, C, and D are found in Europe; subtype A is identified in Australia and Africa; and subtypes B and E are detected in South Africa [2].

21.1.2 Morphology and Genome Organization

Similar to other lentiviruses, FIV is an enveloped, spherical to pleomorphic particle of 80–100 nm in diameter. The virion contains a host cell–acquired membrane (the lipid bilayer) from which viral glycoproteins protrude as spike-like projections (8 nm). Mature capsid is composed of 1572 capsid proteins.

The genome of FIV is dimeric, comprising two identical, linear, positive-sense, single-stranded RNA of about 9400 nt each. Typical of genome structures found in other retroviruses, the FIV genome is organized in the order 5′-LTR-gag(MA-CA-NC)-pol(PR-RT-DU-IN)-vif-orfA-rev-env-rev-LTR-3′ [3].

The long terminal repeats located at the 5′ and 3′ ends are about 600 nt in length, which include the U3, R, and U5 regions. The 5′ end is capped and contains a primer binding site. The 3′ end has a polypurine tract and poly-A tail.

Of the open reading frames contained in the FIV genome, the *gag*, *pol* (polymerase), and *env* genes are found in all retroviruses, the *vif* (viral infectivity factor) and *rev* (regulator of virion expression) genes are lentivirus-specific accessory genes, and the *orf-A* gene is a FIV-specific accessory gene (which is thought to have functional overlap with the *vpr*, *vpu*, and *nef* genes in HIV-1).

The Gag polyprotein encoded by *gag* is cleaved into matrix (MA, also known as p15), capsid (CA, p24), and nucleocapsid (NC, p13) proteins. Cleavage between CA and NC generates a 9 aa peptide, and cleavage at the C-terminus of NC produces a 2 kDa fragment (p2). Structurally, the purified FIV CA protein p24 is comprised mainly of α-helices, appearing as monomeric at low concentration and dimeric at high concentration. During virus assembly, the CA protein p24 is packaged into a viral core (the protein shell of a virus, protecting the viral genome) and the MA protein forms a shell underneath the lipid bilayer [3].

The Pol polyprotein is translated from *pol* via ribosomal frame-shifting mechanism. Cleavage of Pol by the viral protease produces protease (PR, p55, and p61 dimers), reverse transcriptase, deoxyuridine triphosphatase (dUTPase or DU), and integrase (IN). FIV dUTPase reduces levels of dUTP by converting it to dUMP, a precursor for dTTP synthesis, and thus limits uracil misincorporation during reverse transcription (RT). In dividing cells, cellular dUTPase levels are higher and dUTP levels are low, but in nondividing cells, the opposite is true. FIV IN contains three domains: N and C terminal domains (for 3′ end processing and joining) and a catalytic domain in the core [3].

The Env polyprotein (150 kDa) encoded by *env* is processed into a 130 kDa molecule with the removal of a leader peptide (L, of 174 residues). The 130 kDa Env precursor is further cleaved into surface unit (SU, gp95) and transmembrane (TM, gp38) glycoproteins. While FIV SU mediates binding to the cell surface receptors, TM promotes fusion of the viral and cellular membranes during virus entry. Being heavily glycosylated, the SU and TM glycoproteins may mask potential neutralizing epitopes that are recognized by the B cell and increase the virus resistance to host's neutralizing antibodies [4].

The Vif protein promotes viral replication by binding host APOBEC3 (A3) cytidine deaminases and inducing their degradation via proteasome. Without A3 degradation, the virus is prone to G-to-A hypermutation and yields reduced amount of RT products, leading to low or no viral replication [5].

The Rev protein binds to a highly structured *cis*-acting RNA element known as the Rev responsive element (RRE) and helps (1) shuttling of viral structural protein mRNAs from nucleus to cytoplasm, (2) interacting with the RRE to suppress mRNA splicing, (3) increasing stability and translation level of the incompletely spliced viral mRNAs, and (4) enhancing viral RNA encapsidation, facilitating structural protein expression and genomic RNA production [6].

The OrfA protein (77 aa) encoded by *orfA* (also known as *orf2*) is a multifunctional protein involved in transactivation of viral protein expression, virion formation and infectivity, cell cycle arrest, and downregulation of cell surface expression of the primary FIV receptor CD134 [5].

21.1.3 Replication and Epidemiology

Like other lentiviruses, FIV replicates in two ways: lytic and latent replications. Lytic replication occurs in the nucleus and begins with virus attachment via the SU glycoprotein to host receptor CD134. This initial binding changes the shape of the SU protein, which facilitates interaction between SU and the chemokine receptor CXCR4. This interaction then results in the fusion of viral and cellular membranes (which is mediated by TM glycoprotein) and subsequent viral nucleocapsid entry into the host cell cytoplasm [7]. Inside the cell, the virus uncoats partially, and a linear dsDNA molecule is synthesized from ssRNA (+) genome by the reverse transcriptase. The viral dsDNA enters the nucleus and is covalently and randomly integrated into the cell's genome by the viral integrase (provirus). Transcription of provirus by Pol II yields viral spliced and unspliced RNAs, and further translation of spliced viral RNAs produces Rev and other proteins. Nuclear export of the incompletely spliced RNA is mediated by Rev, and translation of unspliced viral RNAs generates Env, Gag, and Gag–Pol polyproteins. New virion is assembled at the host cellular membrane with packaging of the viral RNA genome. After budding through the plasma membrane, the virions are released. Proteolytic processing of the precursor polyproteins by viral protease ushers in maturation of the virions [3].

Latent replication takes place with a provirus integrated in the host chromosome. Driven by the promotor elements in the 5′ LTR, provirus transcribes into the unspliced full length mRNA, which serves as genomic RNA for packaging into virions or as a template for translation of gag and gag (pr) pol (1 ribosomal frameshift) polyproteins. The incompletely spliced mRNA encodes Env and the accessory protein Vif. Rev is then cleaved into SU and TM envelope proteins, which escort unspliced and incompletely spliced RNAs out of the nucleus of infected cells, and are subsequently incorporated into virions [8].

First isolated in 1986 from domestic cats (*Felis catus*) with immunodeficiency-like syndromes in a Northern California

Downloaded From Vet-eBooks.com

cattery, FIV has been shown to be widely distributed in the world, infecting many of the 37 *Felidae* species, such as European wild cat, African wild cat, desert cat, black-footed cat, jungle cat, pallas cat, puma, cheetah, bobcat, ocelot, Geoffroy's cat, lion, leopard, and tiger. [9–19].

The primary mode of FIV transmission is deep bite wounds and scratches, with blood-tainted saliva from the infected cat entering the other cat's bloodstream. Other means of transmission include blood transfusion and artificial insemination [20]. Occasionally, FIV may be vertically transmitted from pregnant females to their offspring in utero, usually during passage through the birth canal or when the newborn kittens ingest infected milk. This is especially so if the queen is undergoing an acute infection.

Risk factors for FIV infection are being of the male sex, adulthood, and outdoor access. Males are more likely to be infected than females due to the bite wounds from fights over territory.

Cats with FIV are persistently infected in spite of their ability to mount antibody and cell-mediated immune responses.

21.1.4 Clinical Features and Pathogenesis

The initial stage (or acute phase) of FIV infection in domestic cats is accompanied by mild symptoms, such as fever, lethargy, poor coat condition, anorexia, pyrexia, enteritis, stomatitis, dermatitis, conjunctivitis, respiratory tract disease, and peripheral lymphadenopathy.

Lasting several days to a few weeks, this initial stage is followed by the latent asymptomatic stage, in which the infected cats may appear healthy for months or years. Factors that influence the length of the asymptomatic stage include the virulence of FIV subtype (A–E), exposure to other pathogens, and the age of the cat [21].

With the increasing depletion of CD4+ T cells and inversion of CD4/CD8 ratio, the infection progresses to the last, symptomatic phase (commonly known as the feline acquired immune deficiency syndrome, or FAIDS). Impairment of the cat's immune functions renders it vulnerable to secondary infections and neoplasia, with cats becoming infected with bacteria, viruses, protozoa, and fungi that usually do not affect healthy animals. The emergence of secondary infections and heightened susceptibility to neoplasia are responsible for many of the symptoms associated with FIV. These include gingivitis (inflammation of the gums), stomatitis (mouth inflammation), and chronic rhinitis; hyperthyroidism and diabetes mellitus; persistent diarrhea; uveitis and chorioretinitis; progressive weight loss and severe wasting; lymphomas (mostly B-cell lymphomas), cutaneous squamous cell carcinoma, anemia, leukemia, fibrosarcoma, and mast cell tumors; hypergammaglobulinemia; abortion of kittens; psychotic behavior, twitching movements of the face and tongue, compulsive roaming, dementia, loss of bladder and rectal control, disturbed sleep patterns, nystagmus, ataxia, seizures, intention tremors, and other neuropathological disorders; and death.

Histologically, chronic ulcero-proliferative gingivostomatitis is evidenced by invasion of plasma cells and lymphocytes in the mucosa accompanied by variable degrees of neutrophilic and eosinophilic inflammation. Pathological findings in the caudate nucleus, midbrain, and rostral brain stem include the presence of perivascular infiltrates of mononuclear cells, diffuse gliosis, glial nodules, and white matter pallor.

With proper care, FIV-infected cats can live many years and commonly die at an old age from causes unrelated to FIV infection.

Although the primary cellular targets of FIV are monocytes and monocyte-derived macrophages, the Env protein produced by FIV preferably binds CD134 (OX40), which is largely present in activated CD4+ T cells. Shortly after entry to the host via bite wound, the virus travels to the local lymph nodes, where it reproduces in T lymphocytes. The virus then spreads to other lymph nodes in the body, and its tropism extends further to both CD8+ T cells and B cells, leading to a generalized but usually temporary enlargement of the lymph nodes, along with fever [22].

By replicating in lymphocytes, FIV causes reduction in CD4+ T cells through decreased production secondary to bone marrow or thymic infection, lysis of infected cells (cytopathic effects), destruction of virus-infected cells by the immune system, or death by apoptosis [23,24]. This alters the ratio of CD4 and CD8 T cells [25]. As CD4+ cells have critical roles in promoting and maintaining both humoral and cell-mediated immunity, their reduction weakens host immunosurveillance mechanisms against microbial pathogens and neoplasia, leading to secondary infections and tumor development [26,27]. In addition to immunosuppression, FIV-infected cats may also develop immune-mediated diseases such as hypergammaglobulinemia and hyperproteinemia due to an overactive immune response. Hypergammaglobulinemia reflects polyclonal B-cell stimulation with an excessive antibody production against chronic/persistent infection. Instead of neutralizing the invading pathogens, these overproduced antibodies form antigen–antibody complexes, which deposit in narrow capillary beds, leading to glomerulonephritis, polyarthritis, uveitis, and vasculitis.

Abnormal neurologic function and virus-induced CNS lesions result from neuronal damages by FIV, such as neuronal apoptosis, effects on the neuron supportive functions of astrocytes (the most common cell type of the brain), toxic products released from infected microglia, and cytokines produced in response to viral infection. One of the most important functions of astrocytes is the regulation of extracellular glutamate, a major excitatory neurotransmitter that accumulates as a consequence of neuronal activity. FIV infection of feline astrocytes may inhibit their glutamate-scavenging ability and result in excessive accumulation of extracellular glutamate that contributes to increased susceptibility to oxidative injury, alterations in mitochondrial membrane potential (and disruption of feline astrocytes by FIV infection in the energy-producing capacities of the cell), neuronal toxicity, and death. Occasionally, neurologic signs may be also attributable to opportunistic toxoplasmosis and cryptococcosis.

21.1.5 Diagnosis

Felidae species are susceptible to a number of viruses, including three from the family *Retroviridae*, that is, FIV of the genus *Lentivirus*, FeLV of the genus *Gammaretrovirus*, and FeFV of the genus *Spumavirus*. Differential diagnosis should include these viruses. Although both FIV and FeLV may produce similar clinical symptoms in cats, FIV is associated mainly with B-cell lymphoma, while FeLV causes mainly T-cell lymphoma. In addition, FIV sometime induces immune-mediated diseases such as hyperglobulinemia, while FeLV rarely does so [28,29].

Therefore, it is critical that laboratory methods (e.g., virus isolation, serological assays, and nucleic acid detection) are applied for accurate differentiation of FIV from FeLV and other viral pathogens [30,31].

Considered the gold standard for FIV infection, virus isolation from peripheral blood lymphocytes is a reliable and definitive diagnostic test, but its routine use is hampered by the high cost and lengthy time required [32].

Serological assays detect the presence of antibody (typically against FIV p24 and p15) in the blood of infected cats using an ELISA (e.g., SNAP® FIV/FeLV Combo and PetChek FIV antibody test; IDEXX Laboratories, Westbrook, Maine). Most cats will show detectable antibodies to FIV within 60 days of exposure. Western blot and immunofluorescent antibody assays may be employed as confirmatory tests in seropositive cats with no history of FIV vaccination [33].

Nucleic acid detection procedures such as PCR identify parts of FIV's genetic material (RNA or DNA) and provide a valuable means of determining a cat's true infection status, especially for FIV antibody–positive cats that have an unknown vaccination history or that have been vaccinated against FIV but still suspected to be infected [34–36]. Real-time PCR assay for FIV (e.g., FIV RealPCR™, IDEXX Laboratories) permits quantification of viral DNA in peripheral blood leukocytes [37,38]. Nevertheless, a negative PCR for FIV RNA may possibly reflect a level of viral nucleic acid below the limit of detection or a strain of FIV that is not detected by the test. For this reason, PCR targeting FIV proviral DNA integrated into the genome of infected cells is preferred. Indeed, the development of a *gag*-targeted dual-emission fluorescence resonance energy transfer (FRET) PCR has been shown to reliably and sensitively detect and differentiate FIV subtypes A, B1, C, D, and B2/E (which have identical target sequence) [39].

21.1.6 Treatment and Prevention

FIV is a cat lentivirus with structural, genomic, and pathogenic parallels to HIV. Approaches that have been explored for the development of antiretroviral drugs against HIV infection will enhance the design of FIV-specific treatment. With the goal to interrupt the key steps in the virus replication cycle, anti-HIV drugs have focused on the following areas: (1) inhibition of virus attachment to host cell surface receptors and coreceptors to stop virus entry into susceptible cells; (2) inhibition of fusion of the virus membrane with the cell membrane; (3) blockade of RT of viral genomic RNA; (4) interruption of nuclear translocation and viral DNA integration into host genomes; (5) prevention of viral transcript processing and nuclear export; and (6) inhibition of virion assembly and maturation. This has led to the commercial availability or clinical trials of several classes of anti-HIV drugs (e.g., fusion or entry inhibitors, nucleoside reverse transcriptase inhibitors (NRTI), non-NRTI, NRTI, viral IN blockers, and PR inhibitors). Nonetheless, the effectiveness of these anti-HIV drugs against FIV is yet to be assessed [40–42].

Therefore, current management of FIV infection in cats centers on proactive actions such as (1) neutering/spraying of asymptomatic FIV-infected cats to avoid fighting and virus transmission, (2) housing infected cats in individual cages and proper sterilizing of needles and surgical instruments used on FIV-positive cats, (3) adopting only infection-free cats into a household with uninfected cats, (4) feeding cats with nutritionally complete and balanced diets to enhance natural immunity, (5) avoiding uncooked food (raw meat and eggs and unpasteurized dairy products) that may contain foodborne microbial pathogens, and (6) vaccinating cats against possible infection [40,43].

The first commercial vaccine against FIV (Fel-O-Vax FIV®, Fort Dodge Animal Health, Fort Dodge, IA) has been marketed since 2002 in the United States and several other countries. Based on formalin-inactivated whole viruses of FIV subtype A (Petaluma) and subtype D (Shizuoka), the vaccine has been shown to protect against FIV subtype B, but only partially against FIV subtype A challenge [44,45].

Furthermore, Lymphocyte T-Cell Immunomodulator (manufactured and distributed exclusively by T-Cyte Therapeutics, Inc) is a strongly cationic glycoprotein (50 kDa) with the capacity to regulate CD-4 lymphocyte production and function. By increasing lymphocyte numbers and interleukin-2 production in animals, it aids in the treatment of cats infected with FeLV and/or FIV and the associated symptoms of lymphocytopenia, opportunistic infection, anemia, granulocytopenia, or thrombocytopenia [43].

21.2 METHODS

21.2.1 Sample Preparation

Whole blood samples are collected by either jugular or saphenous venipuncture into EDTA tubes before transportation in insulated containers packed with ice bricks.

Total nucleic acid may be extracted by glass fiber matrix binding and elution with the High Pure PCR template preparation kit (Roche Molecular Biochemicals). For each sample, 400 µL EDTA whole blood is mixed with an equal volume of binding buffer (6 M guanidine-HCl, 10 mM urea, 20% [vol/vol] Triton X-100, 10 mM Tris-HCl, pH 4.4), and nucleic acid is eluted in 40 µL elution buffer [39].

Downloaded From Vet-eBooks.com

21.2.2 Detection Procedures

Wang et al. [39] developed a real-time PCR for detection and quantification of FIV serotype. While the upstream and downstream primers hybridize at the 5′ end of the *gag* gene, the most conserved region of the FIV genome, the probes (F1-ABCE, F1-D, F2-ABCE, and F3-D) hybridize to the polymorphic regions of the *gag* amplification target and allow maximum differentiation of FIV subtypes (Table 21.1).

21.2.2.1 Procedure

PCR buffer (1×) is composed of 20 mM Tris-HCl, pH 8.4, 50 mM KCl, 4.5 mM $MgCl_2$, 0.05% Nonidet™ P-40, 0.05% Tween®, 20, 0.03% acetylated bovine serum albumin, and 200 µM each dATP, dCTP, dGTP, and 600 µM dUTP. Master mixtures are prepared freshly from 10× PCR buffer, 5× oligonucleotide mixture, 50× nucleotide mixture, and enzymes. Each 20-µL reaction contains 15 µL of 1.33× master mixture, 5 µL of sample nucleic acids, 1.5 U Platinum® *Taq* DNA polymerase (Invitrogen), 0.2 U heat-labile uracil-N-glycosylase (Roche Applied Science), and 0.0213 U ThermoScript™ reverse transcriptase (Invitrogen). Primers are used at 0.8 µM, Lightcycler Red 640 probes are used at a concentration of 0.2 µM, and the carboxyfluorescein probes are used at 0.1 µM. For convenient pipetting, ThermoScript reverse transcriptase is used at a 1:140 dilution in storage buffer.

PCR is conducted on a LightCycler 1.5 real-time PCR platform with software version 3.53 (Roche Applied Science). Thermal cycling is preceded by a 20 min RT step at 55°C, followed by a 5 min incubation at 95°C. Thermal cycling consists of a step-down protocol of 6 cycles for 12 s at 64 or 60°C, for 11 s at 72°C, and for 0 s at 95°C; 9 cycles for 12 s at 62 or 58°C, for 11 s at 72°C, and for 0 s at 95°C; 3 cycles for 12 s at 60 or 56°C, for 11 s at 72°C, and for 0 s at 95°C; and 40 cycles for 8 s at 54 or 50°C. Fluorescence acquisition is undertaken for 11 s at 72°C and for 0 s at 95°C.

TABLE 21.1

F3-D	CCATCTAAAATTTCCTTCCCCGA ACTTC-(Cy5.5)

[a] Y represents C or T, R represents A or G, S represents C or G, and W represents A or T.

After completion of the PCR, the melting temperature (T_m) of probe hybridization to the targets is determined by melting curve analysis as the peak of the second derivative of the fluorescence released during a temperature increase from 35°C to 75°C. In channel F2/F1, subtypes A and C can be discriminated by their higher T_ms (58°C–60°C) from those of the B subtype (T_m = 54°C) and the D subtype (no melting peak). Fluorescence F3/F1 demonstrates distinct T_m differences between FIV-A (45°C), FIV-B1 (49°C), FIVB2/E (52°C), FIV-C (55°C), and FIV-D (68°C) subtypes.

Note: This *gag* gene-based dual-emission FRET real-time PCR identifies FIV genotypes by differential melting temperatures of partially mismatched FRET probes at two fluorescence emission wavelengths. In addition, the assay allows conclusive discrimination between FIV antibody-positive cats from natural infection and cats with antibody positivity by vaccination.

21.3 CONCLUSION

Being one of the most common infectious agents of cats, FIV is associated with a severe immune disease that resembles acquired immune deficiency syndrome (AIDS) in humans. Conventional approaches for diagnosis of FIV infection have depended on virus isolation and serological assays. In view of the high cost involved in cell culture and the difficulty of using serological methods to differentiate naturally infected cats from vaccinated cats, molecular techniques (especially PCR) have been increasingly utilized in routine diagnostic laboratories for detection and quantification of FIV RNA and proviral DNA, the latter of which is integrated into the genome of infected cells.

22.1 INTRODUCTION

Feline leukemia virus (FeLV) is a single-stranded, positive-sense RNA of the family *Retroviridae* that is associated with proliferative, degenerative, and malignant diseases of myeloid, erythroid, and lymphoid origins in cats worldwide. Despite having a relatively simple genome, FeLV is capable of producing variants of enhanced pathogenic potential through genetic recombinations with endogenous FeLV (enFeLV)-related sequences in the feline genome. By suppressing the host immune system and predisposing cats to secondary infections, FeLV is responsible for up to 85% of mortality in persistently infected felines within 3 years of diagnosis.

22.1.1 Classification

FeLV is classified in the genus *Gammaretrovirus*, subfamily *Orthoretrovirinae*, family *Retroviridae*, which includes another subfamily *Spumaretrovirinae*. Members of the family *Retroviridae* are characterized by their unique ability to transcribe their RNA into DNA upon entry into host cell and integrate their DNA (provirus) into host chromosomal DNA as an alternative means of propagation and also a potential source of oncogenic development. Taxonomically, the subfamily *Orthoretrovirinae* is made up of six genera (*Alpharetrovirus*, *Betaretrovirus*, *Deltaretrovirus*, *Epsilonretrovirus*, *Gammaretrovirus*, and *Lentivirus*), while the subfamily *Spumaretrovirinae* is currently composed of a single genus (*Spumavirus*).

Within the genus *Gammaretrovirus*, four major groups are recognized: *mammalian virus group* (FeLV, gibbon ape leukemia virus, guinea pig type C oncovirus, porcine type C oncovirus, and murine leukemia virus), *replication-defective virus group* (Finkel–Biskis–Jinkins murine sarcoma virus, Gardner–Arnstein feline sarcoma virus, Hardy–Zuckerman feline sarcoma virus, Harvey murine sarcoma virus, Kirsten murine sarcoma virus, Moloney murine sarcoma virus, Snyder–Theilen feline sarcoma virus, and Woolly monkey sarcoma virus), *reptilian virus group* (Viper retrovirus), and *avian (reticuloendotheliosis) virus group* (chick syncytial virus, duck infectious anemia virus, spleen necrosis virus, nondefective REV-A, and defective REV-T) [1].

Furthermore, phylogenetic analyses of FeLV *env* and *gag* gene sequences led to the identification of at least three subgroups within the species: FeLV-A, FeLV-B, and FeLV-C. FeLV-A subgroup includes naturally occurring, horizontally transmissible viruses that spread cat-to-cat in nature. Once considered as of low pathogenicity, FeLV-A is clearly involved in neoplastic diseases (typically thymic lymphoma of T-cell origin, after a protracted asymptomatic phase). FeLV-B and FeLV-C subgroups are thought not

Downloaded From Vet-eBooks.com

to be horizontally transmissible in nature but arise *de novo* through recombination between FeLV-A and enFeLV-related elements in the feline genome. Specifically, FeLV-B arose through recombination in the *env* region between FeLV-A and enFeLV sequences present in the feline genome, and FeLV-C arose through deletion and mutation of the FeLV-A *env* gene. Whereas FeLV-B is commonly found in tissues from lymphoma relative to asymptomatic infected cats or other disease conditions, FeLV-C is associated with pure red cell aplasia (nonregenerative anemia). There is evidence that FeLV-A is able to transmit efficiently between cats, but FeLV-B and FeLV-C replication *in vivo* often requires the presence (assistance) of FeLV-A, despite their full replication competency *in vitro*. Indeed, FeLV-B and FeLV-C viruses are often identified alongside a concurrent FeLV-A infection [2]. In addition to FeLV-B and FeLV-C, other subgroups such as FeLV-AC, FeLV-T, and FeLV-D have been occasionally described in the literature. These subgroups may be also derived from recombination events taking place between FeLV-A and enFeLV sequences [3–6].

Recent examination of nonrecombinant full-length (1.9 kb) *env* genes from FeLV isolated in Japan and other parts of the world allows the definition of three genotypes (I–III) in line with three well-known subgroups. Genotype I is further divided into seven clades (GI/Clade1, GI/Clade2, GI/Clade3, GI/Clade4, GI/Clade5, GI/Clade6, and GI/Clade7). Genotype II appears to form a single clade with limited number of strains (n = 7) analyzed. Notably, Genotypes I and II strains came exclusively from Japan. Group III is separated into two clades: GIII/Clade1 and GIII/Clade2, with strains isolated in Europe, South America, and the United States, including known FeLV strains such as FeLV-A clone 945, FeLV-A 61E, FeLV-T 61C, FeLV-A Glasgow-1, FeLV-A Richard (pFRA), FeLV-AC FY981, FeLVs derived from Iberian lynx, Brazilian FeLVs, and the exogenous FeLV components of the FeLV-C/Sarma and FeLV-B GA strains. However, GM35 sequences from Gunma Prefecture did not fit in any of the major genotypes [7]. These findings suggest that FeLV has undergone extensive evolutionary diversification within Japan, and the genetic distinctness of Japanese FeLV strains may indicate a long history of geographical isolation from the rest of the world [7].

22.1.2 Morphology and Genome Organization

FeLV is an enveloped, spherical particle of 80–100 nm in diameter. The virion possesses densely dispersed surface projections, which appear as small distinctive glycoprotein (gp70) spikes evenly covering the surface of the virion.

The genome of FeLV is dimeric, containing two monopartite linear ssRNAs(+) of about 8.3 kb each, which is organized in the order of 5′-LTR-gag(MA-CA-NC)-pol(PR-RT-IN)-env(SU-TM)-LTR-3′.

The long terminal repeats (LTRs) located at the 5′ and 3′ ends measure about 600 nt in length and include the U3, R, and U5 regions. The 5′ end is capped and contains a primer binding site; the 3′ end consists of a polypurine tract and a poly-A tail. The U3 possesses the transcriptional promoter and potent enhancer sequences that can act on adjacent viral genes as well as cellular genes at the sites of proviral integration. If host genes with oncogenic potential are activated by the LTR, malignancy may arise [8].

The *gag* (group-specific antigen) gene encodes a 65 kDa Gag polyprotein, which plays a part in budding and is processed by the viral protease during virion maturation outside the cell into four subunits: a 15 kDa matrix protein (MA, p15), a 12 kDa RNA-binding phosphoprotein (pp12), a 30 kDa capsid protein (CA, p39), and a 10 kDa nucleocapsid protein (NC, p10). Matrix protein p15 targets Gag and gag–pol polyproteins to the plasma membrane and also mediates nuclear localization of the preintegration complex [9]. Capsid protein p30 forms the spherical core of the virion that encapsulates the genomic RNA–nucleocapsid complex. Nucleocapsid protein p10 is involved in the packaging and encapsidation of two copies of the genome and binds to conserved elements within the packaging signal, located near the 5′ end of the genome.

The *pol* (polymerase) gene encodes a polyprotein that is cleaved into three proteins: protease (p14), reverse transcriptase (p80), and integrase (p46). These enzymes are involved in posttranslational modification of viral proteins and synthesis of viral RNA and DNA during viral assembly.

The *env* (envelope) gene (1.9 kb) encodes an 85 kDa polyprotein (Env), which is cleaved into two functional units: surface unit (SU, gp70) and transmembrane (TM, p15E) glycoproteins [10]. Residing on the particle surface and anchored to the TM protein, the SU protein is ideally situated to attach to the host cell surface and to interact directly with the receptor. FeLV SU protein consists of an amino-terminal receptor-binding domain (RBD) followed by a proline-rich region (PRR). Within RBD, two variable regions (designated VRA and VRB) exist, with VRA being the primary determinant of receptor binding and VRB being a secondary determinant required for efficient infection. PRR mediates conformational changes that are necessary for virus entry. In infected cell, gp70 may block viral receptors to prevent further infection by the same subgroup [11].

22.1.3 Replication and Epidemiology

Replication of FeLV involves several steps. The virus utilizes the SU glycoprotein to attach to host receptors (i.e., thiamine transporter FeTHTR1 for FeLV-A, phosphate transporters FePiT1 or FePiT2 for FeLV-B, heme transporter FLVCR for FeLV-C, and FePiT1 plus cofactor FELIX for FeLV-T), and the TM glycoprotein to mediate fusion with cell membrane [12,13]. Following internalization, the virus uncoats partially and uses the reverse transcriptase to yield linear dsDNA molecule from ssRNA(+) genome. Entering into the nucleus when the nuclear membrane is disassembled at mitosis, viral dsDNA is then integrated covalently and randomly into the cell's genome by the viral integrase (forming so-called provirus). Driven by in the promoter elements in the 5′ LTR, provirus is transcribed by Pol II into unspliced mRNA that will serve as

Downloaded From Vet-eBooks.com

genomic RNA to be packaged into virions or as a template for translation of gag and gag–pro–pol (1 ribosomal readthrough of the gag gene termination codon). The unspliced mRNA is transported out of the nucleus and translated into the Env, Gag, and Gag–Pol polyproteins. These proteins and unspliced mRNA are packaged into new virions at the host cellular membrane. After budding through the plasma membrane, the new virions are released. Subsequent proteolytic processing of the precursors (polyproteins) by viral protease results in mature virions [1].

Since its initial discovery in domestic cats in 1964, FeLV has been shown to be widely distributed [14–16]. Apart from domestic cats, a number of wild and captive cats (including lynx, cheetahs, and lions) are also susceptible to FeLV infection [17–19]. However, FeLV appears to be species specific and does not infect either humans or dogs. Depending on various geographical and risk factors (e.g., young age, poor health/vaccination status, and high population density), the prevalence of FeLV in domestic cats ranges from 2.9% to 18.9% in Asia (e.g., 2.9% in Japan, 6% in Taiwan and Thailand, 14.7% in Singapore, and up to 18.9% in Malaysia), 3.4% to 5.3% in North America (e.g., 3.4% in Canada and up to 5.3% in Raleigh, FL), and 4.6% in Egypt.

FeLV is shed in very high quantities in saliva and nasal secretions, urine, feces, milk, and blood, but only survives a few hours outside a cat's body. Its main route of transmission is via saliva during aggressive behaviors (fighting/biting) or exchange of bodily fluids (saliva, nasal secretions, and semen) through mating, mutual grooming, blood transfusion, or shared litter box or food dish. Vertical transmission from infected mother cat to kittens may occasionally occur *in utero*, via saliva during grooming, or via milk feeding [1].

22.1.4 Clinical Features and Pathogenesis

22.1.4.1 Clinical Features

Named after a tumor that first attracted the attention of veterinary scientist, FeLV induces a variety of clinical symptoms, including tumors, anemia, immunosuppression, hematologic disorders, neuropathy, reproductive disorders, and fading kitten syndrome [1].

During the early stages of FeLV infection, cats may exhibit no signs. With the cat's health progressively deteriorating over time (weeks, months, or even years), various clinical symptoms may appear, including loss of appetite; lethargy; poor coat condition; litter box avoidance; progressive weight loss; severe wasting; enlarged lymph nodes (lymphadenopathy); fever; pale gums and other mucus membranes; inflamed gums (gingivitis) and mouth (stomatitis); bladder, skin, or upper respiratory infections; breathing difficulty; abscesses; diarrhea and vomiting; jaundice (yellow color in the mouth and whites of eyes); seizures, behavior changes, and other neurological disorders; anisocoria (uneven pupils) or other eye problems; liver disease; aplastic anemia (pancytopenia); abortion of kittens or other reproductive failures (in females); and neoplasia (thymic, alimentary, and multicentric tumors) [20,21].

Interestingly, of 8642 FeLV-infected cats presented to veterinary teaching hospitals in North America, stomatitis (and coinfection with feline immunodeficiency virus [FIV] infection, feline infectious peritonitis [FIP], upper respiratory infection, and hemotropic mycoplasmosis) was observed in 15% of the cases, followed by anemia (11%), lymphoma (6%), leukopenia or thrombocytopenia (5%), and leukemia or myeloproliferative diseases (4%) [22].

At the nucleic level, FeLV proviruses from lymphomas typically show 2–3 tandem direct repeats of enhancer elements in the LTR, whereas FeLV LTRs derived from non-neoplastic disease or weakly pathogenic strains contain only a single copy of the enhancer or other repeated elements such as the upstream region of the enhancer in MDS and AML and the 21-bp triplication in non-T-cell disease [23].

22.1.4.2 Pathogenesis

FeLV infection in cats is a recurrent illness interspersed with periods of relative health. The manifestation of clinical signs is associated with the progression of infection stages, that is, abortive, regressive, progressive, and local infections [24]. There is evidence that changes in FeLV LTR and SU gene are particularly relevant to its pathogenesis, contributing to distinctive clinical features and oncogenic mechanisms.

22.1.4.2.1 Abortive Infection

Upon entry into the host, FeLV initially replicates in the local lymphoid tissue in the oropharyngeal area. However, viral replication in the case of low dose infection is largely terminated by an effective humoral and cell-mediated immune response from immunocompetent/healthy cats ("regressor cats"). These asymptomatic cats have high levels of neutralizing antibodies in the blood, but neither FeLV antigen nor viral RNA or proviral DNA is detectable. Nevertheless, the virus may still be found later in tissue samples of these cats.

22.1.4.2.2 Regressive Infection

Following an effective immune response, virus replication is contained prior to or shortly after bone marrow infection. Some FeLVs manage to spread through infected mononuclear cells (lymphocytes and monocytes). Infected cats have detectable free antigen in plasma by enzyme-linked immunosorbent assay (ELISA) and shed virus in saliva. However, viremia is terminated within weeks or months (so-called transient viremia). Bone marrow cells in cats with residual viremia may still be infected, with hematopoietic precursor cells developing into granulocytes and platelets that carry the virus to the entire body. Although the viremia may be eliminated afterward, proviral DNA integrated in cellular chromosomal DNA (e.g., bone marrow stem cells) will be maintained in the host cells. This condition is called "latent infection" (now considered a part of the regressive infection). Antigen-negative, provirus-positive cats may be considered FeLV carriers, and following reactivation, they can act as an infection source.

Downloaded From Vet-eBooks.com

22.1.4.2.3 Progressive Infection

Without being contained early in the infection, FeLV replicates extensively in the lymphoid tissues and then in the bone marrow and mucosal and glandular epithelial tissues, resulting to "persistent viremia," a condition now known as progressive infection. Cats with progressive infection manifest various clinical signs/diseases, and up to 85% of cats die within 3.5 years. Progressive infection can be distinguished from regressive infection by the presence of higher viral load in the peripheral blood for 16 weeks and longer after infection.

22.1.4.2.4 Focal infection

Rarely occurring in the field, focal infection (or "atypical infection") is observed in 10% of experimental infections. It is characterized by a persistent atypical local viral replication (e.g., in mammary glands, bladder, eyes), leading to intermittent or low grade production of antigen and weakly positive or discordant results in antigen tests [1].

It is noteworthy that neonatal kittens are most vulnerable to FeLV infection, with marked thymic atrophy appearing after infection ("fading kitten syndrome"), leading to severe immunosuppression, wasting, and early death (due mostly to leukemias, lymphomas, and nonregenerative anemias). Mature cats acquire a progressive resistance toward FeLV and tend to have abortive or regressive infections, or progressive infections that are accompanied by milder signs and a more protracted period of health.

FeLV has the capacity to induce both cytoproliferative (e.g., lymphoma or myeloproliferative disorder) and cytosuppressive (e.g., immunodeficiency or myelosuppression) disease. Its ability to cause malignancy is attributable to the fact that the FeLV DNA (provirus) inserted/integrated into host genome near a cellular oncogene [e.g., *c-myc*, *flvi-1*, *flvi-2* (contains *bmi-1*), *fit-1*, *pim-1*, and *flit-1*] may activate its overexpression, resulting in uncontrolled proliferation of these cells (clone). In addition, FeLV may incorporate cellular oncogene sequences to form a recombinant virus (e.g., FeLV-B, FeSV), which may induce neoplasms once inside a new cell [25,26]. For example, FeSV, a recombinant virus between the FeLV-A genome and cellular oncogenes (such as *fes*, *fms*, or *fgr*), is associated with fibrosarcomas in cats in the presence of FeLV-A as a helper virus that supplies proteins (such as Env) [27]. Due to FeSV, fibrosarcomas often grow rapidly and produce multiple cutaneous or subcutaneous nodules that are locally invasive and metastasize to the lung and other sites [28,29].

The ability of FeLV to cause thymic atrophy and depletion of lymph node paracortical zones is likely responsible for immunosuppression, leading to decreased response to T-cell mitogens, prolonged allograft reaction, reduced immunoglobulin production, depressed neutrophil function, and complement depletion, with increased vulnerability to secondary infectious diseases and decreased tumor surveillance functions.

The mechanisms for FeLV to induce hematopoietic disorders may include interruption or inactivation of cellular genes in the infected cells, alteration in expression of neighboring genes, and induction of antigen expression on the cell surface, leading to an immune-mediated destruction of the cell.

The neurologic signs observed in FeLV-infected cats are largely due to lymphoma and lymphocytic infiltrations in the brain or spinal cord leading to compression or FeLV-induced neurotoxicity, as a polypeptide of FeLV-C envelope has been associated with dose-dependent alterations in intracellular calcium ion concentration, neuronal survival, and neurite outgrowth.

22.1.5 Diagnosis

Cats infected with FeLV often show anemia, immunodeficiency, leukemia, lymphoma, and other symptoms that are similar to those caused by FIV and feline foamy virus. In addition, FIV and feline corona virus causing FIP may co-occur with FeLV in cats [30,31]. Several features may be exploited to distinguish between FeLV and FIV, including FeLV's tendency to cause symptomatic illness instead of FIV's usual asymptomatic infection and FeLV's association with T-cell lymphoma in comparison with FIV's linkage to B-cell lymphoma. However, laboratory methods based on the detection of virus or viral antigen in the plasma, serum, or whole blood are indispensable for accurate identification of FeLV and for differential diagnosis of diseases caused by FeLV, FIV, and other viral pathogens.

22.1.5.1 Virus Isolation

Virus isolation is a useful technique for the production of a large quantity of viruses of high purity for subsequent confirmation of FeLV by electron microscopy, serological, and/or molecular assays. Typically, Vero cells are grown in Dulbecco's Modified Eagle's Medium (DMEM; Invitrogen) supplemented with 10% fetal bovine serum (FBS; Invitrogen) at 37°C in the presence of 5% CO_2. Before infection with the virus, the cells are washed with phosphate-buffered saline and inoculated with viral specimen for 6 h in DMEM containing 5% FBS at 37°C in 5% CO_2. After 4 days, the culture media is changed and incubated until 80%–90% of the cells are floating or lightly attached to the T-75 flask (typically 10 days postinfection). The viruses are harvested, purified by density gradient ultracentrifugation (3% sucrose), and used in serological or molecular assays.

22.1.5.2 Serological Assays

A number of serological assays have been developed for the diagnosis of FeLV infection. These include indirect immunofluorescence assay (IFA), ELISA, virus neutralization test, passive hemagglutination test, complement fixation test, lateral flow rapid test, and Western blot [32]. IFA detects FeLV structural (gag) antigens in the cytoplasm of infected leukocytes and platelets during the progressive phase of the infection (secondary viremia, usually 6–8 weeks after initial infection), and cats with IFA-positive results generally have a poor long-term prognosis. ELISA detects FeLV extracellular p27 capsid antigen in plasma or sera, which is present in progressive infection (with persistent antigenemia) but variable during early viremia and with latent infections [33].

Downloaded From Vet-eBooks.com

22.1.5.3 Nucleic Acid Detection

The use of molecular techniques such as PCR to detect FeLV RNA and provirus DNA provides a rapid and reliable approach for diagnosing FeLV infection, as exogenous viral RNA and endogenous provirus DNA represent superior predictors of progressive and latent infections, respectively [34–39].

Recent development of a real-time PCR targeting a 74 bp sequence within the FeLV U3 LTR portion permits specific detection and quantification of exogenous FeLV provirus sequences present in blood leukocytes [40]. In addition, the application of a multiplex reverse transcription PCR (RT-PCR) assay permits the differential diagnosis of FeLV vaccine and wild strains [41].

A combination of qPCR detecting FeLV DNA (in the blood, bone marrow, saliva, and tissues) and ELISA detecting p27 capsid antigen enables discrimination of cats with detectable nucleic acids and undetectable antigenemia (latent infections) from cats with both detectable nucleic acids and antigenemia (active infections).

Interestingly, cats with progressive infection become persistently positive for the provirus and viral RNA and have high viral loads, whereas cats with regressive infection have lower provirus and viral RNA loads than cats with progressive infection. Only rarely, the provirus becomes undetectable with regressive infection. Moreover, cats with regressive infections are negative for FeLV antigen using ELISA and IFA and also negative in blood culture; however, FeLV proviral DNA is detected in the blood by PCR.

22.1.6 Treatment and Prevention

As no specific cure is available for virus infection, lymphocyte T-cell immunomodulator (manufactured by T-Cyte Therapeutics, Inc.) and Interferon-ω (omega) (manufactured by Virbac) may be employed as a treatment aid for FeLV infection. Secondary infections and neoplasia may be treated as the situation demands [42].

Keeping healthy cats indoors and away from FeLV-infected cats represents an important way to control the spread of the disease. Other useful measures involve housing infected cats separately, adopting only infection-free cats into households with uninfected cats, etc.

Vaccination offers another effective tool to prevent FeLV infection. Currently, four FeLV vaccines (e.g., ATCvet, Purevax FeLV) are commercially available in the United States. Purevax FeLV (manufactured by Merial) is a recombinant live virus originated from a bird host, which does not replicate in mammals [42].

22.2 METHODS

22.2.1 Sample Preparation

Samples are collected from cats that are sedated with ketamine hydrochloride (11 mg/kg). Blood, buffy coat cell pellets, plasma, and tissues (thymus, tonsil, retropharyngeal lymph nodes, bone marrow, spleen, and mesenteric lymph nodes) are collected and stored at −80°C.

Peripheral blood mononuclear cells (PBMCs) are isolated from the blood by Ficoll-Hypaque (Histopaque-1077; Sigma Diagnostics) density gradient centrifugation, separated into 1×10^6 PBMC/mL aliquots, and stored at −80°C. DNA is purified from PBMC using QIAamp DNA Blood Mini Kit (Qiagen) and eluted in 100 μL of elution buffer, and DNA concentrations are determined spectrophotometrically [43].

DNA is extracted and RNA digested from tissues using a QIAamp® DNA Mini Kit and RNase A (Qiagen), respectively, eluted in 100 μL of elution buffer, and quantified spectrophotometrically.

Viral RNA is extracted from plasma using High Pure Viral RNA Purification Kit (Roche), while genomic DNA is isolated from whole blood using Qiagen DNA extraction kit (Qiagen) [44].

22.2.2 Detection Procedures

22.2.2.1 Real-Time PCR Detection of FeLV DNA

Torres et al. [43] described a real-time PCR assay to amplify exogenous and not enFeLV sequences within the U3 region of FeLV-A/61E LTR. The forward primer (5′ AGTTCGACCTTCCGCCTCAT 3′, nt 241–260) and reverse primer (5′ AGAAAGCGCGCGTACAGAAG 3′, nt 308–289) cover a 68 bp fragment. The corresponding probe (5′ TAAACTAACCAATCCCCATGCCTCTCGC 3′, nt 262–289) is labeled with the reporter dye, FAM (6-carboxyfluorescein), at the 5′ end and the quencher dye, TAMRA (6-carboxytetramethylrhodamine; Applied Biosystems) or Black Hole Quencher-1 (BioSource International, Inc., Camarillo, CA), at the 3′ end. Both probes are blocked at the 3′ end to prevent extension, and they give similar performance in the assay.

22.2.2.1.1 Procedure

The 25 μL reaction mixture is composed of 400 nM of each primer, 80 nM of fluorogenic probe, 12.5 μL of TaqMan Universal PCR Master Mix (Applied Biosystems), 3.5 μL of PCR-grade H_2O, and 5 μL of sample or plasmid standard DNA. The master mix is supplied at a 2× concentration and contained AmpliTaq Gold DNA Polymerase, AmpErase Uracil N-glycosylase (UNG), dNTPs with dUTP, and optimized buffer components.

Amplification and detection are performed in triplicate using an iCycler iQ Real-time PCR Detection System (Bio-Rad Laboratories, Inc.). A template control (no DNA, PCR-grade H_2O only) and a negative control (FeLV-naïve SPF cat DNA) are included in every reaction plate. Thermal cycling conditions consist of 2 min at 50°C to allow enzymatic activity of UNG and 10 min at 95°C to reduce UNG activity, to activate AmpliTaq Gold DNA Polymerase, and to denature the template DNA, followed by 40 cycles of 15 s at 95°C for denaturation and 60 s at 60°C for annealing/extension.

22.2.2.2 Real-Time RT-PCR Detection of FeLV RNA

Torres et al. [44] utilized the primer–probe set mentioned earlier to detect FeLV RNA.

Downloaded From Vet-eBooks.com

22.2.2.2.1 Procedure

The 25 µL one-tube reaction mixture is made up of 400 nM of each primer, 80 nM of fluorogenic probe, 12.5 µL of TaqMan® One-Step RT-PCR Master Mix (Applied Biosystems), 0.625 µL of MultiScribe™ Reverse Transcriptase and RNase Inhibitor Mix (Applied Biosystems), 2.875 µL of PCR-grade H_2O, and 5 µL of sample or RNA standard. The master mix is supplied at a 2× concentration and contained AmpliTaq® Gold DNA Polymerase, dNTPs with dUTP, and optimized buffer components.

Amplification and detection are conducted in triplicate using an iCycler iQ™ Real-time PCR Detection System (Bio-Rad Laboratories, Inc.). Every reaction plate contained a negative control (FeLV-naïve SPF cat RNA), a template control (no RNA, PCR-grade H_2O), and an extraction control (extracted PCR-grade H_2O). Thermal cycling conditions include 30 min at 48°C for the RT reaction and 10 min at 95°C to activate AmpliTaq® Gold DNA Polymerase and to denature the template cDNA, followed by 40 cycles of 15 s at 95°C for denaturation and 60 s at 60°C for annealing/extension.

Note: The threshold cycle (C_T) value of each nucleic acid sample is compared with the standard curve of the coamplified standard template to determine the viral loads of the samples. End-point dilutions of the standard templates yield lower detection limits of 5 copies/DNA qPCR reaction and 10 copies/RNA qPCR reaction (1150 RNA copies/mL plasma).

The RNA qPCR enables detection of viral RNA in the absence of antigenemia, and the DNA qPCR appears to be more closely correlated to the p27 ELISA [45].

22.3 CONCLUSION

Transmitted by saliva (bites), FeLV is a deadly feline pathogen with widespread distribution. Having the ability to recombinate with endogenous proviral sequence in the cat genome, FeLV infection causes a complex spectrum of clinical diseases, including anemia, immunodeficiency, leukemia, and lymphoma [46,47]. As clinical presentations of FeLV infection resemble to those caused by FIV and other microbial pathogens, laboratory methods are required for correct diagnosis. While ELISA offers a convenient technique for detection of FeLV antigens and antibodies, PCR facilitates identification of both exogenous and enFeLV RNA and DNA. Therefore, a combined application of ELISA and PCR enables rapid and reliable diagnosis of FeLV infection and contributes to improved control and prevention of this important feline pathogen.

23.1 INTRODUCTION

Reticuloendotheliosis is a neoplastic disease of poultry caused by a group of reticuloendotheliosis viruses (REVs) belonging to the genus *Gammaretrovirus*, family *Retroviridae*. Affecting a variety of avian species such as chicken, turkey, duck, goose, pheasant, and peafowl, reticuloendotheliosis is characterized by immunosuppression, runting–stunting syndrome, chronic lymphomas, and chronic neoplasm, which resemble both Marek's disease and avian leukosis. Interestingly, the etiologic agent for Marek's disease is Marek's disease virus (MDV) of the genus *Alphaherpesvirus*, family *Herpesviridae*, and that for avian leukosis is avian leukosis virus (ALV) of the genus *Alpharetrovirus*, family *Retroviridae*. These avian oncogenic viruses have a huge economic impact on poultry industry worldwide, and their overlapping disease profiles make differential diagnosis on clinical ground difficult, if not impossible. As the topics on MDV and ALV are covered in Chapters 17 and 87, the main focus here is REV.

23.1.1 Classification

REVs are classified taxonomically in the genus *Gammaretrovirus*, subfamily *Orthoretrovirinae*, family *Retroviridae*. The family *Retroviridae* is noted for its unique ability to transcribe viral RNA into DNA inside the host cell and to integrate its DNA (provirus) into host chromosomal DNA for propagation. Historically, classification of retroviruses was based on the morphological features detected by electron microscopy, which led to the identification of four groups (A–D). Type A retroviruses ("intracisternal particles") are nonenveloped, immature particles that are found only inside cells (possibly representing endogenous retrovirus-like genetic elements). Type B retroviruses are enveloped, extracellular particles with a condensed, acentric core and prominent envelope spikes. Type C retroviruses are similar to type B, but have a central core and barely visible spikes. Type D retroviruses are slightly larger (up to 120 nm in diameter), with less prominent spikes. However, this morphology-based classification scheme has been largely superseded by sequence-based phylogenetic analyses.

Currently, two subfamilies (*Orthoretrovirinae* and *Spumaretrovirinae*) are recognized within the family *Retroviridae*. Whereas the subfamily *Orthoretrovirinae* includes six genera (*Alpharetrovirus*, *Betaretrovirus*, *Deltaretrovirus*, *Epsilonretrovirus*, *Gammaretrovirus*, and *Lentivirus*), the subfamily *Spumaretrovirinae* consists of a single genus (*Spumavirus*).

In turn, the genus *Gammaretrovirus* is separated into four major groups: *mammalian virus group* (feline leukemia virus, gibbon ape leukemia virus, guinea pig type C oncovirus, porcine type C oncovirus, and murine leukemia virus), *replication defective virus group* (Finkel–Biskis–Jinkins murine sarcoma virus, Gardner–Arnstein feline sarcoma virus, Hardy–Zuckerman feline sarcoma virus, Harvey murine sarcoma virus, Kirsten murine sarcoma virus, Moloney murine sarcoma virus, Snyder–Theilen feline sarcoma virus, and woolly monkey sarcoma virus), *reptilian virus group* (viper retrovirus), and *avian (reticuloendotheliosis) virus group* (chick syncytial virus [CSV], duck infectious anemia virus [DIAV], spleen necrosis virus [SNV], nondefective REV-A, and defective REV-T).

Downloaded From Vet-eBooks.com

As type C retroviruses, *avian (reticuloendotheliosis) virus group* (REVs) comprises a number of strains, including CSV, DIAV, SNV, nondefective REV-A, and defective REV-T. Apart from defective REV-T, all known REV strains belong to a single serotype, with limited variation in genetic sequences. Nonetheless, on the basis of neutralization tests and differential reactivity with monoclonal antibodies, three REV subtypes have been noted. In addition, REV strains can be further defined by their ability to replicate in cell culture. While most field isolates are nondefective for replication in cell cultures and possess no viral oncogene, a laboratory strain (defective REV-T) is known to be a defective replication in cell cultures and possesses a viral oncogene (*v-rel*). This oncogene appears to be the source of acute reticulum cell neoplasia in experimental chicks, which gave the name reticuloendotheliosis to the virus group. The recent isolation of 10 additional REV strains from wild birds in Northeast China further highlights the complexity of the *reticuloendotheliosis virus group* [1].

23.1.2 Morphology and Genome Organization

Like other gammaretroviruses, REVs possess enveloped, spherical virions of about 100 nm in diameter. The envelope is dotted with small projections (spikes) consisting of a virus-encoded glycoprotein (surface unit [SU]), which evenly cover the surface of the virion. The outer envelope glycoprotein (SU) is linked by disulfide bonds to the transmembrane (TM) glycoprotein, which holds the SU protein in the envelope. Underneath the envelope is the amorphous matrix (MA) protein followed by the icosahedral capsid (CA). Inside the CA is the conical, electron-dense core, which is made up of RNA genome, nucleocapsid (NC) protein, reverse transcriptase, and integrase (IN) [2].

The genome of REV comprises two identical molecules of linear, single-stranded, positive-sense RNA of 8284 nt, which is organized in the order of 5′-LTR-gag-pol-*env*-LTR-3′. These two molecules are physically linked as a dimer by hydrogen bonds [3]. The detailed nucleotide locations of REV genes and noncoding sequences are as follows: long terminal repeat (LTR), 1–543; primer binding site (PBS), 544–933; *gag*, 934–2433; *pol*, 2434–6015; *env*, 5952–7712; polypurine tract (PPT), 7713–7741; and LTR, 7742–8284 [4].

The gag precursor protein is 499 amino acids long and is cleaved into 4 structural proteins, matrix (MA, p12) extending from amino acids 2 to 114, p18 (RNA binding phosphoprotein) from amino acids 115 to 199, capsid (CA, p30) from amino acids 200 to 442, and NC (p10) from amino acids 443 to 494. The CA p30 (30 kDa) protein encapsulates the genomic RNA-NC complex and is the major REV group-specific antigen [5–10].

The pol precursor protein is 1193 amino acids long, and is cleaved into two proteins: reverse transcriptase/ribonuclease H and IN. During replicative cycle, reverse transcriptase (with associated RNase H activity) reverse transcribes the RNA genome into viral DNA, which is then integrated into the host chromosome as the provirus by IN.

The *env* precursor is 587 amino acids long with a signal peptide of 36 amino acids located in the NH2 terminal region, and is cleaved by cellular furin on amino acid 398 to produce SU (gp90) and TM (gp20) glycoproteins. The mature envelope protein (Env) consists of a trimer of SU–TM heterodimers attached by a labile interchain disulfide bond. Associated with the extravirion surface through its binding to TM, SU binds to a specific receptor on the surface of the host target cell. This interaction triggers the refolding of TM, facilitating its fusion with host cell plasma membrane, and subsequent entry of the NC into the cytoplasm.

23.1.3 Biology and Epidemiology

Originated from a retrovirus that circulated in ancestral mammals, REVs have undergone recombination events to assume their current identity. The extremely low genetic diversity among all avian REVs isolates and sequences points to their very emergence from a single founder in birds [11].

REVs are mostly transmitted horizontally through fecal–oral route. By integrating their DNA (provirus) into the nuclear DNA of the host cell, REVs find an effective way to propagate and maintain in poultry host. Occasionally, REV infection of germ cells permits their integration into host germ line, which may be vertically inherited as host alleles (so-called endogenous retroviruses [ERVs]). Indeed, vertical transmission of REV has been documented in chickens and turkeys. The virus has been transmitted accidentally through the use of contaminated vaccines [12–14]. The fact that partial or complete genomic insertions of REV are observed in the genome of other avian viruses—fowlpox virus (FPV) and MDV—suggests an alternative means of REV maintenance [11,12,15–26].

Since the isolation of the prototypic strain from a turkey in 1957, REV has been shown to infect a range of avian species, including domestic poultry (e.g., chickens, turkeys, ducks, geese, and quail) and game birds and waterfowl, including peafowl, pheasants, partridges, prairie chickens, and mallards [27–30].

Serologic surveys have shown seropositive prevalence rates of 3.3%–40% in chicken flocks, which tend to increase with the age of the birds. Although infection is widespread, REV outbreaks occur only sporadically, are relatively rare, and are frequently associated with REV-contaminated vaccines, such as FPV vaccines [31]. Chicken flocks that seroconvert after 10 weeks of age are usually without clinical disease or viral shedding to progeny.

23.1.4 Clinical Features and Pathogenesis

The nondefective strains of REV induce three distinct syndromes in poultry: nonneoplastic runting, chronic lymphoid neoplasms (e.g., B and T lymphomas), and acute reticulum cell neoplasia (reticuloendotheliosis).

Clinical manifestations of the runting syndrome include weight loss, paleness, occasional paralysis, and abnormal feathering. Typically, the runting syndrome occurs 4–10 weeks after the administration of contaminated vaccines to

Downloaded From Vet-eBooks.com

1-day-old chicks. The abnormal feather lesion ("Nakanuke"), with the barbules being compressed to the shaft over a small part of its length, may be of diagnostic value [32].

Acute and chronic neoplasia may involve lymphoid organs, the liver, the spleen, the intestine, and the heart, as well as the reticulum cell. Regardless of type or host species, the tumors are usually composed of uniform, large, lymphoreticular cells. In chickens, bursa-related B-cell tumor may appear similar to lymphoid leukosis caused by ALV, whereas nonbursal (T-cell) lymphomas with shorter latent periods and lesions may resemble superficially those of Marek's disease.

Other clinical signs due to REV infection include anemia, immunosuppression, bursal and thymic atrophy, and enlarged nerves. In turkeys, prominent lesions include enlarged livers and nodular lesions on the intestines.

Gross examination of the liver with tumor from REV-infected chicken reveals the massively enlarged, hemorrhagic liver. Multifocal irregular pale areas are present on the cut and uncut surfaces. The hepatic parenchyma contains large neoplastic lumps or multicentric and expansive nodular lesions, suggestive of degeneration, cell lysis, and massive infiltration of neoplastic lymphoid cells. Histopathological examination of tumor samples using hematoxylin and eosin stain (H&E) shows the characteristic REV reticular cells proliferation and infiltration, and blood vessel dilation and congestion.

23.1.5 Diagnosis

MDV, ALV, and REV represent important avian oncogenic viruses with significant economic impact on poultry industry. MDV causes skin and visceral tumors in addition to immunosuppression, neurological symptoms, and ocular lesions. ALV is associated with lymphoid leukosis, primarily in the bursa of Fabricius and visceral organs, as well as late-onset myelocytomatosis, resulting from infection with ALV subgroup J (ALV-J). Although not yet as ubiquitous as ALVs and MDVs, REV is responsible for inducing bursal and T-cell lymphomas in chickens and turkeys, of which the T-cell lymphomas of chickens are not easily be distinguished from Marek's disease and the chronic B-cell lymphomas are largely indistinguishable from those of lymphoid leukosis. Furthermore, the REV-induced runting syndrome may be confused with immunosuppressive syndromes caused by other viral agents. This emphasizes the need to use laboratory methods to differentiate REV from ALV and MDV.

Traditionally, laboratory differentiation of avian oncogenic viruses is based on virus isolation (using DF1 cells or chicken embryo fibroblast cells) and histopathological examination of tumor tissues [33]. Liver histopathology may reveal typical pathognomonic lesions of REV, with severe congestion in the central and portal veins, hepatic sinusoids associated with degeneration and necrosis in the hepatocytes, and massive number of pleomorphic lymphoid cells and reticular cell infiltration replacing the hepatic parenchyma.

Due to the time and specialized skills required for conducting these classic tests, serology, immunohistochemistry, and, more recently, nucleic acid amplification have been developed for rapid and accurate detection of REV in avian blood and tissue samples.

The commonly used serological assays include agar gel precipitin test, indirect fluorescent antibody test, enzyme-linked immunosorbent assay (ELISA), and serum neutralization test. ELISA is a sensitive and reliable method for detecting REV antigens (e.g., p30 group-specific antigen) and antibodies, and commercial ELISA kits for antibody detection (e.g., FlockChek) are available.

Nucleic acid detection procedures such as in situ hybridization, PCR, and microarrays allow detection of REV RNA and proviral DNA from clinical specimens [34,35]. With excellent speed, sensitivity, specificity, and reproducibility, PCR represents the method of choice for the diagnosis of avian oncogenic viruses including REV. The use of PCR and its derivatives (e.g., nested PCR, multiplex PCR, real-time PCR, reverse transcription polymerase chain reaction (RT-PCR)) has facilitated precise discrimination of replication-defective and replication-competent REV provirus, and REV field and vaccine strains [36–39].

23.1.6 Treatment and Prevention

No effective treatment is currently available for REV infection in poultry. Prevention measures include rapid diagnosis, removal of potential transmitter hens, rearing progeny under isolated conditions, and vaccination of naïve flocks. Several studies have clearly demonstrated that the gp90 protein of REV is immunogenically potent and capable of inducing sustained high levels of neutralizing antibodies against REV. Vaccination with gp90 protein (in recombinant format and/or DNA vaccine construct) protects chicken from viremia after REV challenge [40–43].

23.2 METHODS

23.2.1 Sample Preparation

Blood samples are collected aseptically from the infected chickens. The liver and spleen are excised from poultry postmortem.

Genomic DNA may be extracted by phenol–chloroform. Briefly, 10 µL of whole blood is added to 500 µL of 1× STET buffer (100 mM NaCl, 10 mM Tris–HCl [pH 8.0], 1 mM ethylenediaminetetraacetic acid [pH 8.0], and 5% Triton X-100) and 20 µL of proteinase K (20 mg/mL) and incubated for 15 min at 56°C. Then, 500 µL of buffered phenol–chloroform–isoamyl alcohol 25:24:1 is added, and the sample is vortex mixed and then centrifuged for 5 min at 12,000 × *g*. The aqueous phase is collected and transferred to a new tube, and then 500 µL of chloroform–isoamyl alcohol (24:1) is added, vortexed, and centrifuged for 5 min at 12,000 × *g*. The aqueous phase is transferred to a new tube, and the DNA is precipitated by adding 100% ethanol (1:2, v:v) and 3 M sodium acetate (pH 5.2 [1:0.1, v:v]), mixed by inverting several times, and incubated at −20°C for at least 2 h. The DNA is pelleted by centrifugation at 12,000 × *g* for 5 min, air-dried, and resuspended in 90 µL of nuclease-free water [36].

Downloaded From Vet-eBooks.com

Alternatively, genomic DNA may be extracted from blood sample, tissue, or cell culture using Qiagen DNA Kit (Omega). DNA is eluted into 50 μL elution buffer and stored at −80°C.

23.2.2 Detection Procedures

23.2.2.1 Conventional PCR

23.2.2.1.1 Protocol of Jiang et al. [1]

Jiang et al. [1] utilized primers RF (5′-GCCTTAGCCGCCATTGTA-3′) and RL (5′-CCAGCCTACACCACGAACA-3′) designed from LTR for specific PCR amplification of a 383 bp fragment from REV proviral DNA in wild birds.

PCR mixture is prepared using PrimeSTAR HS DNA polymerase (Takara Biotechnology) with the proviral genomic DNA as template. PCR conditions consist of an initial denaturation cycle for 5 min at 95°C, followed by 35 cycles of denaturation for 30 s at 94°C, annealing for 30 s at 53°C, and an extension for 1 min 20 s at 72°C, with a final extension of 10 min at 72°C. The products are detected by agarose gel electrophoresis.

Note: A second pair of primers (gp90U: 5′-CAGGAATTCATGGACTGTCTCACC-3′ and gp90L: 5′-AGAGTCGACCTTATGACGCCTAGC-3′) from REV gp90 gene may be utilized for result verification if desired.

23.2.2.1.2 Protocol of El-Sebelgy et al. [39]

El-Sebelgy et al. [39] employed primers LTRF2 (5′-GCGCTGGCTCGCTAACTG-3′) and LTRR2 (5′-TTCGATCTCGTGTTTGTTCGTGATT-3′) to amplify a 200 bp amplicon from REV LTR.

PCR mixture (50 μL) is composed of 25 μL Master Mix (Taq PCR Master Mix, Promega), 1 μL forward primer, 1 μL reverse primer, 22 μL nuclease-free water, and 1 μL extracted DNA. PCR amplification is conducted in Applied Biosystems GeneAmp PCR System 9700, with the following program: initial denaturation cycle at 94°C for 5 min, 40 cycles of denaturation at 94°C for 30 s, annealing at 58.5°C for 30 s, extension at 72°C for 45 s, and a final extension cycle at 72°C for 5 min. The PCR product is separated by electrophoresis of 5 μL product in 1.5% agarose in 1× TAE, and ethidium bromide is added to a concentration of 0.5 μg/mL for nucleic acid visualization.

23.2.2.2 Real-Time PCR

23.2.2.2.1 Protocol of Sun et al. [36]

Sun et al. [36] developed a duplex real-time PCR for sensitive and specific detection of REV in whole blood samples. The primers and probes come from the envelope protein gene (*env*) and the LTR region of REV (Table 23.1).

PCR mixture is made up of 10 pmol of each *env* primer, 20 pmol of each LTR primer, 3 pmol of *env* probe, 6 pmol of LTR probe, and 3 μL of template DNA in a 25 μL final reaction volume. A no template control and a PCR amplification control (DNA from an REV-positive sample) are included as negative and positive controls, respectively. The PCR amplification and fluorescence detection are carried out in a real-time PCR thermocycler, with initial incubations at 50°C for 2 min and 95°C for 10 min, followed by 40 cycles at 95°C for 15 s and 60°C for 60 s. Fluorescence is collected during the second step (annealing/extension) of the PCR process.

LTR-probe	VIC-ACAAACACGAGATCGAACTA-MGBNFQ	

23.2.2.2.2 Protocol of Li et al. [41]

Li et al. [41] described a real-time PCR for REV detection and quantification targeting a 146 bp fragment of REV gp90 gene with primers (gp90F and gp90R) and probe (gp90P) labeled fluorescently with FAM at 5′ end and with BHQ1 at 3′ end (Table 23.2). The inclusion of primers (actinF and actinR) and probe (actinP) from chicken β-actin gene provides an internal control to monitor the efficiency of DNA extraction and PCR amplification (Table 23.2).

Real-time PCR mixture (25 μL) is made up of 2.5 μL of 10× Ex Taq Buffer, 2 μL of dNTP (2.5 mM), 3 μL of $MgCl_2$ (25 mM), 1 μL of each primer (10 pM), 0.5 μL of probe (10 pM), 1 U of Ex Taq HS (TaKaRa), 1 μL of DNA, and appropriate amount of ddH_2O.

The mixture is subjected to predenaturation at 95°C for 5 min, followed by 40 cycles of denaturation at 95°C for 10 s, annealing at 55°C for 30 s, and elongation at 72°C for 20 s, using LightCycler®480 (Roche Diagnostics).

The fluorescent signals are measured during the elongation step. Negative control is set up by substituting the DNA template with ddH_2O. In each run, a series of dilutions of the

plasmid standard is also included along with DNA samples. The Cp value is determined using the second derivative method of the LightCycler software, version 1.5.0 (Roche Diagnostics).

Note: This TaqMan real-time PCR method enables rapid, efficient, and reliable detection and quantitation of REV in the blood. With a minimum detection limit of 10 proviral DNA copies, this assay is 100 times more sensitive than conventional PCR for REV detection.

23.3 CONCLUSION

REVs are responsible for nonneoplastic runting, chronic lymphoid neoplasms, and acute reticulum cell neoplasia in both domestic and wild poultry species. Given the similarities of clinical symptoms caused by REV to those by MDV and ALV, it is important that these oncogenic viruses are correctly and rapidly identified. While conventional laboratory methods (e.g., virus isolation, histopathological examination, and serological assays) have proven valuable for the diagnosis of REV infection, their obvious shortcomings (as exemplified by their time-consuming and variable nature) render them pale by comparison to the new generation molecular techniques. Indeed, application of real-time PCR allows not only rapid detection but also accurate quantification of REV RNA and proviral DNA from blood and tissue specimens. This has greatly enhanced our capacity in dealing with this important poultry pathogen in terms of rapid response to potential REV outbreaks and implementation of appropriate control and prevention measures.

24.1 INTRODUCTION

Border disease (BD) is a major viral disease of sheep and goats caused by border disease virus (BDV). The disease is first recognized in the border region of England and Wales [1], and the clinical signs of infected sheep herds mainly include barren ewes, abortions, stillbirths, and the birth of small weak lambs. Affected lambs can show tremor, abnormal body figure, and hairy fleeces (also called "hairy shaker" or "fuzzy"), so the disease has also been referred to as "hairy shaker disease" [2]. The disease is widely distributed in the world. Prevalence rates in sheep vary from 5% to 50% between countries and from region to region within countries [3].

24.1.1 Classification, Genome Organization, and Morphology

24.1.1.1 Classification

BDV is a helical, enveloped, positive-sense single-stranded RNA (+ssRNA) virus, and belongs to the genus *Pestivirus* within the family *Flaviviridae*. In addition to BDV, the *Pestivirus* genus also includes three related species responsible for livestock diseases: bovine viral diarrhea viruses-1 (BVDV-1), BVDV-2, and classical swine fever (hog cholera) virus (CSFV) [4]. These viruses share physical, chemical, and biological characteristics and also partially share common antigens. These viruses have been confirmed to infect across species. The antibodies against pestivirus have been detected in more than 40 ruminant species including cattle, sheep, and goats, and cross-species reactions have also been observed [5]. BDV and BDV infections are now full appreciated because of the development of molecular biological techniques.

Historically, the viruses in the genus *Pestivirus* have been named and classified based on host species origins. BDV hosts are sheep and goats, BVDV-1 and BVDV-2 are bovine related, and CSFV infects pigs [6]. Since it is later discovered that pestivirus could easily infect cross-species, this earlier classification scheme has serious limitations and falls short in practical application. This is further evident with more unclassified pestiviruses being discovered recently, including "Hobi-like" pestiviruses of bovine origin, mainly detected

Downloaded From Vet-eBooks.com

from contaminated fetal calf serum [7–10], the pestivirus pronghorn from antelope [11], and Bungowannah virus from pigs [12]. These additional pestiviruses have been postulated to form novel groups/species.

Genotyping and phylogenetic analysis of pestiviruses is widely used for pestivirus grouping. Typing is crucial for classifying novel viruses and revealing their evolutionary history. Based on phylogenetic studies of the sequences of the 5′ untranslated region (UTR) and/or N^{pro} available in GenBank [13,14], BDV isolates are divided into seven phylogenetic groups. BDV-1 is present in sheep from the United States [15], the United Kingdom [16], Australia [17], and New Zealand [18]. BDV-2, BDV-3, and BDV-4 are now in Europe [8,19–21] and BDV-5 and BDV-6 in France [22]. Isolates from Turkey form BDV-7 [23]. The four BDV isolates from goats and sheep in China belong to the BDV-3 group [24,25].

Some pestivirus strains previously considered as BDV have been reclassified into the other pestivirus species based on the phylogenetic types; one pestivirus isolate from goats showing the BD-type signs in Korea is identified as the BVDV-2 genotype [26]. Several pestiviruses, isolated from lambs and kids with BD-like syndromes in Italy during the 1990s and characterized as BDV [27], have been recognized as BVDV-1 or BVDV-2 strains [28]. In addition, five BVDV positive-diagnosed UK cattle between 2006 and 2008 are classified as BDV positive, and two of them belong to the BDV-1a group, and the other three to the BDV-1b group [13]. The suspected BVDV-1 isolate FNK2012-1 from swine in Japan is clustered into BDV genotype 1 [29].

One valuable genotyping method is based on pestivirus 5′ UTR sequences and their secondary structure variation, analyzed with the palindromic nucleotide substitutions. Of the 536 pestivirus strains examined by using this method, 131 strains are clustered as BDV species and further classified into at least 8 genotypes [30]. Based on this knowledge, one software tool for the numerical taxonomy of the genus *Pestivirus* has been developed. Analysis of 543 pestivirus isolates led to the discrimination of 9 species including BVDV-1, BVDV-2, BVDV-3, CSFV, Pronghorn, Giraffe, Bungowannah, BDV-1, and BDV-2. Interestingly, while 131 strains typed as BDV-1 come from sheep, Pyrenean chamois, cattle, pig, reindeer, and wisent, 5 BDV-2 strains are from sheep and goats [31].

Antigenic typing is also used to cluster BDV strains. Eighteen BDV strains including two atypical porcine pestiviruses (lower reaction with the monoclonal antibodies [mAbs] specific for CSFV or BVDV) can be divided into three groups with mAbs against the BDV proteins E2, E^{rns}, or NS2/3 [14]. Four Italian BDV isolates are recognized and grouped with the mAbs known to cross-react with referenced BDV-1 and BDV-5 strains. However, all four isolates also show varied reaction with a distinct set of mAbs against E2, E^{rns}, and NS2/3 for the antigenic characterization of BDV, BVDV, and CSFV [32].

24.1.1.2 Genome Organization

The complete genome sequences of genotypes BDV-1, BDV-2, BDV-3, BDV-4, BDV-5, and BDV-7 have been determined [25,33–37]. The full sequences of the reported BDV strains comprise a single-stranded positive-oriented RNA genome (+ssRNA) being a length of ~12.3 kb, which is similar to the other species of the genus *Pestivirus*. The 3′ terminus of the genome is not polyadenylated but terminates with a short poly(C) tract. There is an internal ribosome entry site at the 5′ end to control translation initiation. The genome of the first sequenced BDV strain BD31 isolated from a lamb with hairy shaker syndrome is 12,268 nucleotide (nt) long and has a single open reading frame (ORF) of 11,688 nt beginning at nucleotide 357 [38]. BDV strain Aveyron [37] is 12,284 nt and contains one 11,700 nt large ORF with a 5′ UTR being 370 nt long and a 3′ UTR of 214 nt. The single ORF encodes one viral polyprotein of 3,899 amino acids (aa) length. The Japanese BDV-1 strain FNK2012-1 comprises 12,327 nt containing a large ORF of 11,685 nt [29]. The genome of BDV strain H2121 isolated from Pyrenean chamois and typed as BDV-4 is 12,305 nt long with the ORF encoding 3,899 aa with 76 nt long 5′ UTR and 229 nt long 3′ UTR [36]. In the polyprotein, the mature viral proteins are arranged in the following order (from the N to C terminus): N^{pro}, C, E^{rns} (E0), E1, E2, p7, NS2-3, (NS2), (NS3), NS4A, NS4B, NS5A, and NS5B. The polyprotein is cleaved by viral and cellular proteases into four structural proteins: the nucleocapsid protein (C) and three envelope glycoproteins E^{rns}, E1, and E2, plus at least 7–8 nonstructural proteins (N^{pro}, p7, NS2, NS3, NS4A, NS4B, NS5A, and NS5B) [37,39,40]. Of the glycoproteins, E2 is the major immunodominant envelope protein and induces major neutralization antibody response in animals.

Two phenotypes of BDV strains: cytopathogenic (cp) and non-cp (ncp) have been identified by their effects on cell cultures [41–43]. There are insertions of (cp) Cumnock and (cp) Moredun comprising 387 and 333 nt, respectively; which are from host cellular components (Jiv-coding insertions) at an identical genomic region encoding the C-terminal part of NS2 [44]. The BDV-4 isolate Chamois-1 has four additional aa (AEVG) insertion in the N-terminal region of the gene encoding NS2 and grows without cytopathic effect (CPE) capability [36]. BDV-5 strain Aveyron also contains an unknown original insertion of four aa (KAPD) in the C-terminal region of NS2 and has CPE function [37]. The two viruses produce significantly larger amounts of NS3 protein than other BDV strains based on Western blot analysis [36,37].

Comparison of complete coding sequences of BDV strains shows that the different strains of BDV may share more than 75% nucleotide sequence identities except for some BDV-7 strains, 70% to <75% with CSFV strains, 67%–70% with BVDV-1, and less than 67% with BVDV-2 viruses [25,37]. However, pestiviral proteins have higher identities than the corresponding nucleotide sequences. The BDV isolates show >85% identity in the entire polyprotein sequences, which is notably higher than that observed in CSFV strains and other pestiviruses [36]. The viral proteins of pestiviruses also demonstrate varied levels of homology. While NS3, NS4A, NS4B, and E1 are the most conserved pestiviral proteins, E2, p7, and NS5A appear to be less conserved. The protein NS2 varies due to insertions of the host protein factors [34,36,45].

24.1.1.3 Morphology

BDV particles are very similar to the other viruses in the genus *Pestivirus*. The mature BDV virion is roughly circular and about 40–46 nm in diameter with a 20–25 nm core [46]. The virions contain three virus-encoded membrane proteins (E^{rns}, E1, and E2) in addition to the capsid proteins (C) binding with viral genome RNA. The buoyant density is about 1.115 g/mL in sucrose gradient [41]. The virus is inactivated by heating to 60°C for 90 min and sensitive to ether treatment [47]. BDV isolates exist in two kinds of biological phenotypes according to their effects on cell cultures. Most BDV strains do not produce CPE. However, a few cp BDVs are isolated from sheep [41,42], but one of them has been confirmed to be undistinguishable from BVDV *in vitro* [42]. The BDV strains can grow in many ovine and bovine primary cells and cell lines, and now BDV isolation is usually performed on these cell lines. The BDV Japan FNK2012-1 isolated from pigs also grows in porcine primary cells and cell lines; however, it grows better in bovine and ovine cells [29].

24.1.2 Epidemiology, Transmission, and Pathogenesis

24.1.2.1 Epidemiology

BD in sheep occurs in Europe, North America, Australia, and New Zealand [3]. BDV infections have also been found in Asian countries including India, Turkey [23], Japan [48], and China [24]. Antibody prevalence rates among adult sheep vary from 5% to 50% between countries and the regions within countries. As in Northern Ireland, 5.3% of 918 ewe sera from 30.4% of 92 flocks in 10 regions are positive for BDV antibody. The geographical variations are very significant, with flock prevalence ranging from 0 in the Enniskillen region to 70% in the Coleraine. The seropositive proportion is not influenced by infections of BVDV-1 on the farms [49]. Presence of BDV is positively detected in 8 of the 25 commercial flock farms in Northern Spain (32%) [50]; 17.6% (29/165) of samples from sheep are seropositive for BDV in Japan. And the mean seropositive prevalence in individual herds range from 5.0% to 42.9% in 9 sampling groups with no statistical difference in the prevalence among sheep from 3 to 6 years old [48].

Similar clinical and pathological characteristics are observed in goats experimentally and naturally infected with BDV as are found in sheep. Compared to sheep BDV infections, the BDV infections of goats are not diagnosed much but recognized increasingly. Despite the relatively few clinical reports, serologic surveys of BD on goats without clinical BDs in Canada in 1984 show that about 16% of goats are positive in specific antibody reaction and 2.6%–45.5% variation between areas [51]. The specific antibodies to pestivirus including BVDV-1 and BDV are 11.5% of individual prevalence and 31.3% of flock prevalence in 549 goats in 80 flocks from four regions of Austria in 2006 [52]. BDV seropositivity is 63.6% of the surveyed goats in Eastern and Southeastern Anatolia of Turkey [53]. Sera from 34 of 126 dairy goat farms in Netherlands are 27% positive for BDV with a herd prevalence of 32% (ranging from 1% to 100%) [54]. In Switzerland, 5059 sera from 382 sheep herds and 503 sera from 54 goat flocks are about 9% and 6% positive for BDV, respectively [55]. It should be noted that previous serosurveys have great difficulty in distinguishing BVDV infection from BDV infection. Three previous BDV isolates from goats are reclassified as BVDV-1 by 5′ UTR and N^{pro} gene sequencing and typing [6]; and the BD-like diseases reported in Korea were confirmed to be BVDV-2 virus infections [26]. Only a few cases of goat BDV infections have truly been identified. The experimental infections of BDV in pregnant goats are performed in 1975 [56] and in 1987 [57], respectively. The first case in goats naturally infected with BDV occurs in 1982 [58]. BD outbreaks in five herds of goats are caused by contaminated vaccines in Norway [59]. Detection of BDV in goats with diarrhea is first confirmed and further classified as BDV-3 infection in China in 2013 [24]. One BDV-3 isolate is obtained from 2 Italian goat herds, and positive antibodies are detected in 61/67 and in 38/169 goats, respectively [45].

Since 2001, disease outbreaks associated with BDV-4 infection have been observed in chamois. The infections result in a significant reduction of the chamois population in the French and Spanish Central Pyrenees [60–63]. Two epidemiological pathways of BDV chamois infection were noted in the Val d'Aran and Pallars Sobirà (VAPS) and Cerdanya, Alt Urgell, Berguedà and Solsonès (CAUBS) areas of Spain. The endemic infections in the VAPS area have resulted in frequent BD outbreaks and significant decrease of chamois numbers; however, lower BDV prevalence allows chamois population to quickly recover in CAUBS [64].

Bovines are infected with BDV in nature [13,65], and most of these infections have been confused with BVDV infections. Only by use of sequencing and genotyping methods can BDV infections be precisely determine in samples from infected cattle [66]. Australian V/TOB isolate of bovine origin, different from other BVDV isolates in antigenicity, is genotyped as one BDV [6]. Cattle showing BVDV signs are also diagnosed with BDV infection between 2006 and 2008 in the United Kingdom [13]. Persistent infection (PI) of BDV in cattle is detected in one bull that grows slower and is smaller in size than the healthy animals at the same age in New Zealand [67]. However, BDV infects calves when the previously seronegative calves mingled with PI BDV sheep in fields [68,69]. Furthermore, direct contact between bovines and PI sheep more easily allows infection by BDV than direct oral inoculation of virus culture [70].

Apart from the high seroprevalence of pestivirus infections, rare cases of BDV infections have been recorded in other farm animals and wild ruminants. Pigs are infected with BDV in nature and experimentally. BDV-infected pigs show no clinical signs; the viremia is usually detected from 2 to 10 days postinfection (dpi), and antibodies are induced from 14 dpi and continue to increase subsequently. The first BDV isolated from pigs with hemorrhagic lesions was genotyped by N^{pro} gene homology [71]. Recently, two new BDV isolates have been isolated: one is from a BDV persistently infected pig in Japan [72] and another in Spain [73].

Downloaded From Vet-eBooks.com

In Japan, the BDV isolated pig farm has a >58.5% seropositivity rate of the surveyed pigs against CSFV E2 group antigen without CSFV infection history [72]. In addition, one BDV isolate has also been characterized in captive zoo reindeer and bison in 2003 [19].

24.1.2.2 Transmission

BDV is usually very sensitive to environmental conditions outside its hosts and cannot survive for a long period. There are at least two transmission pathways for BDV in susceptible sheep flocks [74,75]: vertical and horizontal transmission. Direct contact (feeding or oral–nasal route) easily accelerates horizontal transmission due to excretion of viruses from infected animals. Vertical transmission is via placenta and more crucial for animals, which may cause PI in newborns during the defined pregnant period when fetuses with immature immune systems are infected with the viruses [76]. The diseased and PI sheep are the sources of disease, and PI animals are more dangerous [77,78]. PI lambs are the most potent source of infections because the animals are viremic and constantly excrete viruses [45]. BDV infection usually results in presentation of PI lambs in sheep flocks. Recently, other species of PI BDV animals are also detected such as PI cattle [67], PI pigs [72], and PI goats [45], but the exact models of virus transmission are not clear yet.

BDV cross-species transmissions occur exactly as for the other pestiviruses. Sheep BD outbreaks have been caused by transmission of virus from cattle to sheep [68,79]. Calves can seroconvert and induce antibody response against BDV when kept together with infected sheep [69]. BDV can naturally infect pigs reared in the same facility with experimentally infected animals, and the infections induce the pigs to produce protective antibody response against wild CSFV challenge [80]. Wild boar (*Sus scrofa*) in Europe may be infected with BDV and show positive neutralizing antibodies [81].

Pestiviruses, including BDV contaminants in modified live virus (MLV) vaccines, may be one important transmission mode for BDV in animals if MLV vaccines are produced in the cells and sera derived from virus-infected ovine, goats, and other animals. The Ch1Es cell line of caprine origin, contaminated with BDV, is detected by reverse transcription polymerase chain reaction (RT-PCR) in 1995 [82]. Outbreaks of BD in sheep and goats have been associated with the use of such vaccines [83,84].

24.1.2.3 Pathogenesis

Adult, immunocompetent small ruminants can produce strong immune responses against BDV intrusion and do not show any signs of acute infection. When pregnant animals are infected with BDV, the viruses can infect the embryo or fetus via the placenta. The outcome of fetal BD infection depends largely on the gestation period of infection. In early gestation, the virus infection easily kills the embryo, resulting in the fetus being resorbed or aborted. In most cases, persistent viremic BD lambs happen, which are mainly infected prenatally before maturation of immune system between about 60 and 85 days of gestation in sheep (80 and 100 days in goats) [85]. The fetuses are immunotolerant and the virus may grow and exist widespread in all organs. The animals, if they survive, are usually persistently infected for life. When the infection happens in the later stages of gestation and the fetuses have a mature immune system, the infections usually damage the fetal central nervous system and result in hypomyelination, degeneration of oligodendroglial cells by direct damage, or indirect functions such as changing hormone secretion and the inflammation of the nervous system [86]. The infection in later stages of gestation also affects fetal development, and the bones and muscles may be damaged [87,88]. In addition, BDV infections in pregnant goats result virtually exclusively in abortions and malformations in fetuses and neonates. Therefore, PI goats are rarely found [23].

PI sheep have significantly more CD8+ T lymphocytes, and the total numbers of CD4+ cells are not significantly changed. The proportions of lymphocyte subpopulations are altered with a very high ratio of the CD8+/CD4+. Peripheral lymphocytes and the lymphocytes expressing class I MHC antigen are significantly reduced [89,90].

Evasion of the innate immune system is crucial for the establishment of BDV PI in affected lambs. Activating caspase-3-related apoptosis happens in BDV-infected sheep. Many Terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL) positive and activated caspase-3 elements are found in affected glial cells, endothelial cells, and neurons of BD animals [91]. Activated caspase-3 in neuronal cells commonly plays major roles in neuroprotection and neurodamage by mediating sublethal challenges for apoptotic disintegration of the nuclear matrix [92]. The strong activation and distribution of caspase-9, similar to activated caspase-3, in the BD animals suggests that the intrinsic pathway of apoptosis may play important roles in the occurrence and progression of the disease [91].

24.1.3 Clinical Symptoms and Pathologic Changes

24.1.3.1 Acute Infection

Normally, healthy newborn and adult sheep and goats infected with BDV only appear with mild or without clinical symptoms [93]. Some infected animals have slight fever and a mild leukopenia without diagnostic characteristics. The animals have a short viremia detectable between 2 and 10 dpi and produce specific positive antibody response after 14 days.

Occasionally, during the outbreaks of BDV in new regions, sick animals show high fever, anorexia, conjunctivitis, nasal discharge, dyspnea, profound and prolonged leukopenia, and sometimes with serious diarrhea. Morbidity and mortality are high in these situations [24,94–97]. Recently, BDV-infected European chamois were shown to have depression, weakness, and movement difficulties. The animals have abnormal behavior; absence of flight reaction; asymmetric patches on the head, neck, and trunk; and different degrees of alopecia with skin hyperpigmentation. Chronic wasting is also a common feature in all affected chamois [60,63].

24.1.3.2 Fetal Infection

The BDV infected fetuses show different clinical BD symptoms and fetal death may occur at any stage of pregnancy, and more commonly during early gestation. The mortality of BD

Downloaded From Vet-eBooks.com

lambs and kids is usually high during birth and the early periods of life. At the later stage of gestation, abortion of larger fetuses, stillbirths, and the premature births of small, weak babies are often seen. Infection in goats is less common with abortion being the main presenting sign [2,87,88].

The live affected lambs and kids may be normal or PI. The affected young lambs have small stature, domed heads, are weak, and present paralysis. The diseased animals have difficulty standing up and walking, with ataxia or not, and show uncoordinated movements and posterior wobbling with involuntary muscular tremors [23,50,59,98]. One of the most conspicuous characteristics is abnormal fleece, consisting of long and straight birth coats as "hairy shaker" in many sick lambs. The affected lambs may also have short legs. With careful nursing, a proportion of BD lambs can survive and become normal. The hair changes disappear in 9–12 weeks and the nervous symptoms gradually recover by 20 weeks of age [2,23]. The animals appear to be tolerant of the virus and usually remain PI for life. Typically, there is no or little inflammatory reaction. However, the BD animals often grow slowly under normal field conditions [2,96].

The infected maternal animals manifest subclinical or mild symptoms except for characteristic features such as placentitis and high rates of abortion, stillbirth, or the premature births of small and weak lambs. The birth rates of babies have been low, generally without lambs at lambing time, or with signs of BD in young animals present in the flocks, that is normally the first sign of BD.

No gross lesions are observed at necropsy of the infected lambs and kids. Spinal cord cross-sectional areas are significantly reduced at all four levels and in both grey and white matter [99]. Macroscopical changes are observed. Fetal anomalies include cerebellar hypoplasia, hydranencephaly, porencephaly, and arthrogryposis. Cotyledons are small or immature, with areas of pinpoint grayish necrosis [50,78,86,91].

In the mucosal cases of BDV infections, the tonsils and lymph nodes are usually edematous, enlarged, and hemorrhagic. A few round, hyperemic ulcers can be found on the hard palate and pinpoint shallow erosions on the soft palate. The esophagus and parts of the large intestines show numerous oval and linear mucosal ulcers [24,91,95,100]. In BD chamois, the most consistent microscopic changes are in the skin and the brain. Skin lesions include severe alopecia with follicular atrophy, hyperplasia, and melanosis with evident orthokeratotic hyperkeratosis. The brains consistently appear with edema, diffuse moderate spongiosis, and neuronal degeneration and death [62].

24.1.4 Diagnosis

A variety of techniques may be employed for BDV diagnosis, especially in PI animals. These include virus isolation, virus neutralization test (VNT), immunohistochemistry, indirect or direct immunofluorescence assay (IFA), enzyme-linked immunosorbent assay (ELISA), agar gel immunodiffusion test, RT-PCR, nested RT-PCR (nRT-PCR), and real-time RT-PCR (qRT-PCR) [49,72,98,101–104]. ELISA and VNT are frequently used for serological investigation, while virus isolation, nucleotide acid detection assays (RT-PCR, nRT-PCR, and qRT-PCR), and IFA are always used for agent examination. Furthermore, nucleotide sequencing plus phylogenetic analysis of RT-PCR products is frequently used for identification and genotyping of clinical BDV strains [16,23,105].

24.1.4.1 Conventional Techniques

Serological testing is widely used to determine the prevalence of BDV infection in a flock, region, or country, especially in previously BDV-free areas. Antibody positive results usually imply the introduction and prevalence of field BDV. VNT is commonly used but is work intensive and time consuming, and thus not suitable for detection of large numbers of samples. Both cytopathic and noncytopathic strains of BDV can be used for the VNT, but cytopathic BDV (e.g., Moredun, 137/4) is recommended because of the simplicity of operation. Furthermore, because of the cross-reactivity between antibodies against different pestivirus members, a differential VNT is recommended in which sera are titrated out against viruses from each of the four *Pestivirus* groups, that is, BDV, BVDV-1, BVDV-2, and CSFV.

ELISA is the most valuable screening tool and is suitable for large-scale epidemiological investigation. The mAb-capture ELISA has been developed [106]. mAb VPM22 bound to 96-well microplates is used to capture antigen from detergent-solubilized BDV-infected cells. Diluted test sera are added for BDV-specific antibody detection. The results have good qualitative correlation with the VNT. Recently, a blocking ELISA applied to bulk-tank milk samples has been developed for the detection of BDV positive dairy sheep flocks [107]. ELISA kits that specifically detect antibodies targeting p80/125 protein, common to all BVDV and BDV strains (e.g., Synbiotics, Pourquier, IDEXX), can be used [64,102]. BDV-specific commercial ELISA kits are also available now (e.g., Svanova) [49]. In clinical investigation, ELISA kits for pestivirus and BDV-specific ELISA/VNT can be combined and used for more efficient and precise screening. The less sensitive agar gel immunodiffusion assay may also be used.

Viral antigen detection is important to identify the PI animals. The most sensitive and reliable way to confirm BDV infection is to isolate infectious virus from clinical samples. Commercial ELISA kits detecting pestivirus p125/p80 antigen (e.g., Synbiotics) can be used to detect antigen in PI sheep. In 1990, a mAb-capture ELISA is developed to detect specific antigen in leukocytes of sheep persistently infected with BDV. Blind trial is conducted to compare the specificity of the ELISA with virus isolation, and there is total agreement between the two tests [108]. However, the ELISA is usually not sufficiently sensitive to detect acutely viremic animals.

24.1.4.2 Molecular Techniques

Following the development of molecular biology and sequencing of pestivirus genomes, nucleic acid amplification methods (RT-PCR, nRT-PCR, and qRT-PCR) are increasingly used for diagnosing BDV infection. Pan-pestivirus primers (primers 324/326) are valuable for detecting all species of pestivirus and thus can be used for preliminary test, but the positive

results need further sequence analysis to exclude BVDV existence [109]. Accompanied with the genome sequencing of several BDV strains and comparing them with those of other pestiviruses, BDV-specific primers have been designed and validated for RT-PCR [13,16,104]. The specific primers can be used alone in RT-PCR or following the use of pan-pestivirus primers in nRT-PCR (Table 24.1). The nRT-PCR method not only increases the specificity and sensitivity but also the possibility of sample contamination. An nRT-PCR is also developed to distinguish three ruminant pestiviruses, BVDV-1, BVDV-2, and BDV. The consensus PCR product is subjected to second PCR using type-specific primers and is able to differentiate the three ruminant pestiviruses [110]. A closed one-tube RT-PCR assay has also been developed, which is very sensitive and less prone to giving false-positive results compared to nRT-PCR.

qRT-PCR, which uses BDV-specific primers, or plus specific fluorescent probes, has advantages in high specificity, sensitivity, and prevention of contamination. A one-step qRT-PCR has been designed to detect and type BDV, BVDV-1, and BVDV-2 in ovine samples [103]. This qRT-PCR is validated on clinical samples and shows more sensitive than virus isolation and nRT-PCR, which also reduces the potential cross-contamination of samples. In addition, the results of qRT-PCR virus typing agree completely with sequencing. Substitution of different fluorescent probes results in specific tests for BDV or BVDV-2 [111]. A platform included a TaqMan qRT-PCR for the universal detection of pestiviruses, and a microarray assay that can use the amplicons produced in the qRT-PCR to identify the specific pestivirus has been reported. This assay combines the advantages of qRT-PCR with the multiplexing capability of microarray technology [112] and will be an efficient screening tool.

24.2 METHODS

24.2.1 Virus Isolation

24.2.1.1 Sample Preparation

To isolate infectious virus from viremic animals, sterile serum can be used directly. However, it is necessary to wash leukocytes from anticoagulated whole blood samples repeatedly before cocultivating them with susceptible cells in order to increase sensitivity. Tissues (spleen, thyroid, thymus, kidney, brain, lymph nodes, and gut lesions) collected from dead animals should be homogenized in phosphate-buffered saline (PBS) or culture medium, centrifuged at 8000 rpm for 10 min to remove debris, and the supernatants would be passed through 0.45 μm filters before inoculating onto cell monolayers.

Semen can also be examined for BDV but must be diluted at least 10-fold.

24.2.1.2 Isolation Procedure

A series of primary ovine cell cultures (e.g., kidney, testes, and lung) and semicontinuous cell lines derived from fetal lamb muscle, whole embryo [83], or sheep choroid plexus can also be used. Several bovine cell cultures (e.g., testicular, embryonic tracheal, or turbinate cells) and cell lines (e.g., Madin–Darby bovine kidney) may also be used. However, they are less sensitive for the primary isolation and growth of some BDV strains. It is necessary that the cells and fetal bovine serum used for virus isolation are pestivirus-free (no antipestivirus activity and no pestivirus).

A practical sensitive isolation procedure is as follows, and it should be optimized for maximum sensitivity when different field strains are isolated.

1. Subconfluent cell monolayers cultured in flask or plate are washed three times with Hanks' balanced salt solution and then inoculated with prepared samples to adsorb for 2 h at 37°C.
2. Cultures are washed with Hanks' balanced salt solution or medium, and an appropriate volume of maintenance medium is added.
3. Cultures are incubated for 5–7 days at 37°C and examined for CPE daily.
4. Cultures are frozen and thawed and passaged more times as before.
5. After three to five passages, cultures could be tested for virus presence by RT-PCR (24.2.2), immunofluorescence, or immunoperoxidase methods (24.2.1.3).

Downloaded From Vet-eBooks.com

24.2.1.3 Immunofluorescence or Immunoperoxidase Assay

1. Cells are seeded onto plastic plates or cover slips, and virus is inoculated. Controls of negative cells and standard BDV-inoculated cells must be included.
2. Three to five days later, the culture medium is removed, and the cells are washed gently with PBS, air dried, and fixed with acetone or ethanol (previously cooled to –20°C) for 20 min.
3. The acetone or ethanol is removed, and the cells are gently washed two or more times with PBS.
4. Antibodies (e.g., BDV antiserum, BDV mAb) diluted in PBS with 1% Tween 20 (PBST) are added. The plates or slips are incubated at 37°C for 30–60 min in a humid atmosphere.
5. Primary antibodies are removed, and the cells are washed three times with PBS + Tween20(PBST).
6. Fluorescence- or HRP-conjugated secondary antibody diluted in PBST is added and incubated at 37°C for 30–60 min in a humid atmosphere.
7. Secondary antibodies are removed, and the cells are washed three times with PBST.
8. For immunofluorescence assay, positive cells are determined under fluorescence microscopy.
9. For immunoperoxidase assay, substrate (e.g., 3-amino-9-ethyl carbazole [AEC]) is added for color development, and positive cells (brown) are examined under the microscope. AEC stock solution: AEC (0.1 g) dissolved in dimethylformamide (15 mL). AEC working solution: add 0.3 mL stock solution to 4.7 mL membrane-filtered acetate buffer (0.05 M, pH 5.0), and then add 5 µL 30% H_2O_2.

24.2.2 RT-PCR

24.2.2.1 Sample Preparation

RT-PCR is used widely for diagnosing BDV infection.

1. Serum can be used directly.
2. Anticoagulated whole blood samples should be washed repeatedly to separate the leukocytes.
3. Tissues samples should be homogenized in PBS and centrifuged at 8000 rpm for 10 min to remove debris.

All samples would be stored at –70°C until RNA extraction.

24.2.2.2 Detection Procedure

24.2.2.2.1 RNA Extraction

Total RNA is extracted by the conventional guanidinium isothiocyanate–phenol–chloroform extraction method (e.g., TRIzol, Invitrogen) or other commercially available kit (e.g., QIAamp Viral RNA Mini kit, Qiagen).

For QIAamp Viral RNA Mini Kit, 140 µL samples are mixed with 560 µL of AVL viral lysis buffer. The mixture is incubated at room temperature for 10 min, and 560 µL of ethanol is added. The mixture is applied onto the spin column, centrifuged at 6000 × *g* for 1 min, and 500 µL of AW1 buffer is added. The column is centrifuged at 6000 × *g* for 1 min to remove unbound materials and washed with 500 µL of AW2 buffer. Then, the column is centrifuged at full speed for 3 min and placed into a new 1.5 mL microcentrifuge tube. Next, 60 µL of AVE buffer is added and the column is incubated at room temperature for 1 min. Then, the column is centrifuged at 6000 × *g* for 1 min to elute viral RNA. The obtained RNA is used as a template for RT-PCR amplification. The RNA can be stored at –70°C until RT-PCR assay is performed.

24.2.2.2.2 Reverse Transcription

For two-step RT-PCR, either random hexamers or specific primers may be used in RT stage (*Note*: Oligo(dT) is not suitable). Many commercial RT kits are available, and RT may be performed according to the following basic protocol:

1. Prepare the RT mix in 0.2 mL tubes as follows (Table 24.2), according to the number of samples.
2. Aliquot 15 µL of RT mix to each 0.2 mL tube and 5.0 µL of individual RNA sample.
3. Spin the tubes briefly to ensure that no reagent droplets remain on the inner wall of the tubes.
4. Transfer the reaction tubes to a 42°C water bath for 30–60 min, and then increase temperature to 85°C for 5 min to inactivate the reverse transcriptase.
5. Place the tubes on ice for 5 min.
6. The cDNA can be used directly or stored at –20°C for future use.

24.2.2.2.3 PCR Amplification

1. Prepare the PCR reaction mix as follows (Table 24.3), according to the number of samples you detected.
2. Add 22.0 µL of PCR mix and 3.0 µL of cDNA into a 0.2 mL PCR tube. Positive and negative controls must be included.
3. Spin the sample tubes in a microcentrifuge.
4. Place the sample tubes in the thermal cycler, and the reaction procedure is denaturation at 94°C for 5 min; 35 cycles of denaturation at 94°C for 30 s, annealing at 54°C for 30 s, and extension at 72°C

TABLE 24.2
Reverse Transcription Volumes Indicated per Specimen

Component	Volume (µL)
RNase-free water	3.5
2× reaction buffer	10.0
Reverse transcriptase	0.5
Random primer/specific reverse primer	0.5
RNase inhibitor	0.5
Total	15.0

Note: The volume of each component could be changed according to the instructions of the kits you choose and the RNA concentration.

Downloaded From Vet-eBooks.com

TABLE 24.3
Polymerase Chain Reaction Volumes Indicated per Specimen

Component	Volume (μL)
RNase-free water	17.25
10× reaction buffer (containing $MgCl_2$)	2.5
dNTPs mix (2.5 mM)	1
Forward primer (20 pmol/μL)	0.5
Reverse primer (20 pmol/μL)	0.5
Taq DNA polymerase	0.25
Total	22.0

Note: The RT-PCR can also be done in a single PCR tube as one-step RT-PCR format using commercially available kits.

for 45 s; and is terminated with a final extension of 10 min at 72°C.
5. Analyze the PCR products by agarose gel electrophoresis through 1.5% agarose gel and further sequencing.

24.2.2.2.4 nRT-PCR

nRT-PCR is commonly used to increase the specificity and sensitivity of clinical detection. The reaction could be done as in the following procedure:

1. Using pan-pestivirus primers (324/326) (Table 24.1) in the primary RT-PCR for about 25–30 cycles as RT-PCR method (Section 24.2.2.2.3).
2. Using BDV-specific primers (PBD1/PBD2) (Table 24.1) in a secondary PCR with the diluted products (at least 1:10 dilution) of primary RT-PCR as template and with more volume of RNAse-free water added to keep the final volume of 25 μL; for the method, refer to Section 24.2.2.2.3.
3. The products are checked on 1.5% agarose gel electrophoresis and further sequencing.

24.2.2.2.5 qRT-PCR

Since the technique is very sensitive and also easy to be contaminated during operation, one-step qRT-PCR is commonly recommended. The primers and probe [103] listed in Table 24.1 might be used.

1. In one-step qRT-PCR, the commercially available kit can be used according to the manufacturer's instructions. Prepare the reaction mix as follows (Table 24.4), according to the number of samples you detected. The reactions are done in triplicate or duplicate.
2. Add 23.0 μL of reaction mix and 2.0 μL of RNA into a qRT-PCR tube. Positive, negative, and blank controls must be included.
3. After a short spin, put on the machine for qRT-PCR operation: one cycle at 45°C for 5 min (RT step); one cycle at 95°C for 2 min; followed by 40 cycles of 95°C for 15 s and 60°C for 30 s.
4. Data are collected and summed as described in the machine instructions. Samples are usually considered positive if the cycle threshold value is 35 cycles or less. It is better to determine positivity by setting up the positive curve at the same reactions.

TABLE 24.4
Real-Time Reverse Transcription Polymerase Chain Reaction Volume as Each Sample

Component	Volume (μL)
RNase-free water	8.0
2× reaction buffer	12.5
Forward primer (20 pmol/μL)	0.5
Reverse primer (20 pmol/μL)	0.5
Probe	0.5
Dye	0.5
Enzyme mix	0.5
Total	23.0

24.2.2.2.6 Sequencing

For final BDV detection using the gene RNA amplification, gene sequencing must be performed to distinguish between various pestivirus species. There are usually two procedures for sequencing the final PCR products. Direct sequencing of the amplified DNA is fast but may lead to some mistakes because of the short PCR products. Another method is to clone the PCR products into a PCR plasmid before sequencing. Here, PCR plasmid cloning is briefly introduced as follows:

1. The PCR-amplified DNAs are purified with DNA purification methods.
2. Purified DNA is ligated with PCR plasmid in 10 μL volume at 4°C overnight (TA cloning requires only a short time).
3. Cloned plasmids are transformed into competent *Escherichia coli* cells (such as TOPO-10 or DH5α) by "hot-shocking" technique.
4. Transformed cells are grown on lysogeny broth (LB) plates containing penicillin.
5. Five to six colonies are chosen for PCR checking, and three positive colonies are used for sequencing (the specific primers for BDV or common plasmid primers can be used).

Sequencing of BDV gene amplified products can be done by companies or by the lab themselves. The sequencing methods are performed according to standard procedures by companies or as detailed in other descriptions for other viruses in this volume.

The sequenced data of virus genomic amplifications are *Blast* with the information in *GenBank* and determined whether BDV or other pestiviruses, and also being which genotype basically.

24.3 CONCLUSION AND FUTURE PERSPECTIVES

BDV has worldwide distribution and has become endemic in small ruminant populations in rearing areas and can cross-infect other animal species including cattle and pigs. BDV belongs to the genus Pestivirus, similar to BVDV and CSFV. Viruses within the genus have relatively high levels of homology in their genomes and share cross-reactive immunogenicity in serological assays. Nearly all BDV isolates are ncp in cell culture with a very few cp BDV isolates reported. There are no defined serotypes but BDV strains from sheep exhibit considerable antigenic diversity. Until now, BDV isolates have been divided into at least seven genotypes and more may be identified later. Clinical signs mainly are maternal productive syndromes and infected lambs showing "hairy shaker disease" signs. The acute mucosal disease cases have occasionally occurred in new BDV outbreaks in sheep and goats. Vertical transmission plays an important role in the epidemiology of the disease. Infection of fetuses can result in the birth of PI lambs, which are the most potent source of infection. There are different serological methods that have been developed and detail introduced in World Organization for Animal Health (OIE) protocols [3]. Great achievements in molecular biological techniques have recently been made based on the BDV genome sequences. These methods, including RT-PCR, nRT-PCR, and qRT-PCR combining with sequencing, are more accurate, rapid, and sensitive for BDV detection, and also help to identify out BDV infections in cattle and pigs and differentiate BDV from other pestivirus species. Sequencing plus phylogenetic analysis has been one of the most used typing methods for BDV isolates around the world.

With of the recent rapid development of sheep and goat industries in the world, especially in developing countries, it is urgently important to pay more attention to the prevention and control of BDV infections. Until now, there have not been any systematic procedures for BDV infection control. The BD control programs should ideally consist of comprehensive strategies and measures. It is very important to maintain absence of PI animals within herds and to cut off the infectious source for breeding or trading purposes. Establishing accurate commercial BDV detection kits might be considered. The ELISA based on specific mAbs for BDV and the automatic viral RNA detection methods are useful for large numbers of sample screenings. There is no available commercial vaccines for BD. Inactivated vaccines have been developed for use in sheep; but they require regular boosters to maintain strong protection against field challenge [113,114]. The BDV E2 gene, encoding the major immunological antigen, has larger sequence diversity and significantly effects immune results. Effective vaccines must be considered, which either consist of viral strains exhibiting a wide degree of cross-protectively or incorporate several viral strains. Effective BDV vaccines must also be effective at stopping transplacental spread of the virus. Treatment strategies may be another consideration for prevention and control of BDV infections [101]. The two important diseases of pestivirus (CSFV and BVDV) have been successfully controlled or eradicated in several countries. Effective technique can be used for BDV prevention, and also will be practical and achieved. In the near future, it may be possible to develop comprehensive strategies to improve current control, intervention, and treatment methods for BDV infections; this will greatly benefit the small ruminant industry.

25.1 INTRODUCTION

First described as "an apparently new transmissible disease of cattle" in 1946 [1], bovine viral diarrhea virus (BVDV) has become one of the most widespread viral pathogens of cattle. Since 2007, bovine viral diarrhea has been listed by the International Office of Epizootics as a reportable disease of cattle. Despite its moniker, the effects of BVDV infection are manifested not only in the gastrointestinal tract but also in the respiratory, reproductive, cardiovascular, lymphatic, immune, integumentary, or central nervous systems [2] of cattle, as well as several domestic and feral mammalian species of the order *Artiodactyla* [3]. The virus is responsible for a wide variety of clinical syndromes, but infection may also be subclinical or asymptomatic, emphasizing the need for accurate and efficient diagnostic tests. This is especially true in the case of persistent infection, where animals may appear phenotypically normal but consistently shed high amounts of live virus, playing a significant role in the epidemiology of the virus. The clinical and economic importance of BVDV as a livestock pathogen demands fast and accurate diagnostic tests at both the herd and individual animal levels.

25.1.1 Classification

BVDV is the prototypical virus in the *Pestivirus* genus of the *Flaviviridae* family. In 1993, the virus was established as the causative agent of severe morbidity and mortality in adult cattle and veal calves in Canada [4]. Subsequent genomic characterization of virus isolates from the outbreak revealed large differences in sequence homology to known BVDV strains [5], leading to the division of BVDV into two distinct genotypes, BVDV1 and BVDV2. The two viruses were first separated by their phylogenetic differences [6]. Although antigenic differences in the two species have also been demonstrated, the two species remain serologically cross-reactive.

Both species can be further divided into subgenotype groupings through phylogenetic analysis of conserved regions

Downloaded From Vet-eBooks.com

of the genome although the clinical significance of such groupings is unknown [7,8]. Phylogenetic analysis allows the characterization of BVDV1 into at least 11 groups (Figure 25.1); subtypes 1a and 1b are the predominant strains in North America [7,9]. Classification of BVDV2 isolates into subgenotypes is less common due to the smaller number of described isolates [10]. Two subgenotypes of BVDV2 have been reported in North America with type 2a more commonly isolated than type 2b [11].

Viral isolates from either BVDV genotype can be characterized by their activity in cultured epithelial cell lines. Infection with cytopathic (CP) isolates causes vacuolation and cell death in cultured cell monolayers, whereas infections with noncytopathic (NCP) stains do not. Biotype is not an accurate predictor of *in vivo* pathogenicity [12]. In nature, NCP strains predominate. The CP strains are believed to arise from NCP strains by mutagenesis, and the CP strain and its NCP counterpart are known as a viral pair. This occurs most commonly as a result of a recombination event where extra pieces of genetic code are inserted into an NCP genome. However, not all biotype changes are associated with a recombination event as CP viruses without insertions have been identified [13]. Consequently, CP strains are more variable in length than NCP strains [14,15]. Biotype is not an indicator of virulence as animals infected with either CP or NCP strains exhibit a wide range of clinical syndromes.

25.1.2 Morphology and Genome Organization

The BVDV virion is typical of the pestiviruses and measures 40–60 nm in diameter with genomic ribonucleic acid (RNA) and the nucleocapsid protein contained in the central core of an icosahedral capsid [16]. Two glycoproteins are anchored in the membranous envelope with a third peptide loosely attached by undefined interactions. The BVDV genome consists of a single strand of positive-sense RNA. Unlike most eukaryotic messenger RNA, the BVDV genome lacks a 5′ methylguanosine cap, instead possessing a 5′ untranslated region (UTR) of approximately 380 nucleotides [17]. Likewise, a 229–273 untranslated nucleotide sequence on the 3′ end of the genome (3′ UTR) takes the place of a 3′ polyadenine tail. The genome of approximately 12.5 kb encodes a lone open reading frame that is translated into a single polyprotein of approximately 3900 amino acids. CP strains of the virus commonly contain insertions, duplications, and other rearrangements resulting in larger genomic RNAs [16]; however, nucleotide deletions have resulted in genomes smaller than the type strain [15,18]. Both viral and host endoproteinases are involved in co- and posttranslational processing of the polypeptide product into at least 11 mature viral proteins (Figure 25.2). The individual proteins in order from 5′ to 3′ are the amino-terminal autoprotease (N^{pro}), the nucleocapsid or core protein (C), the

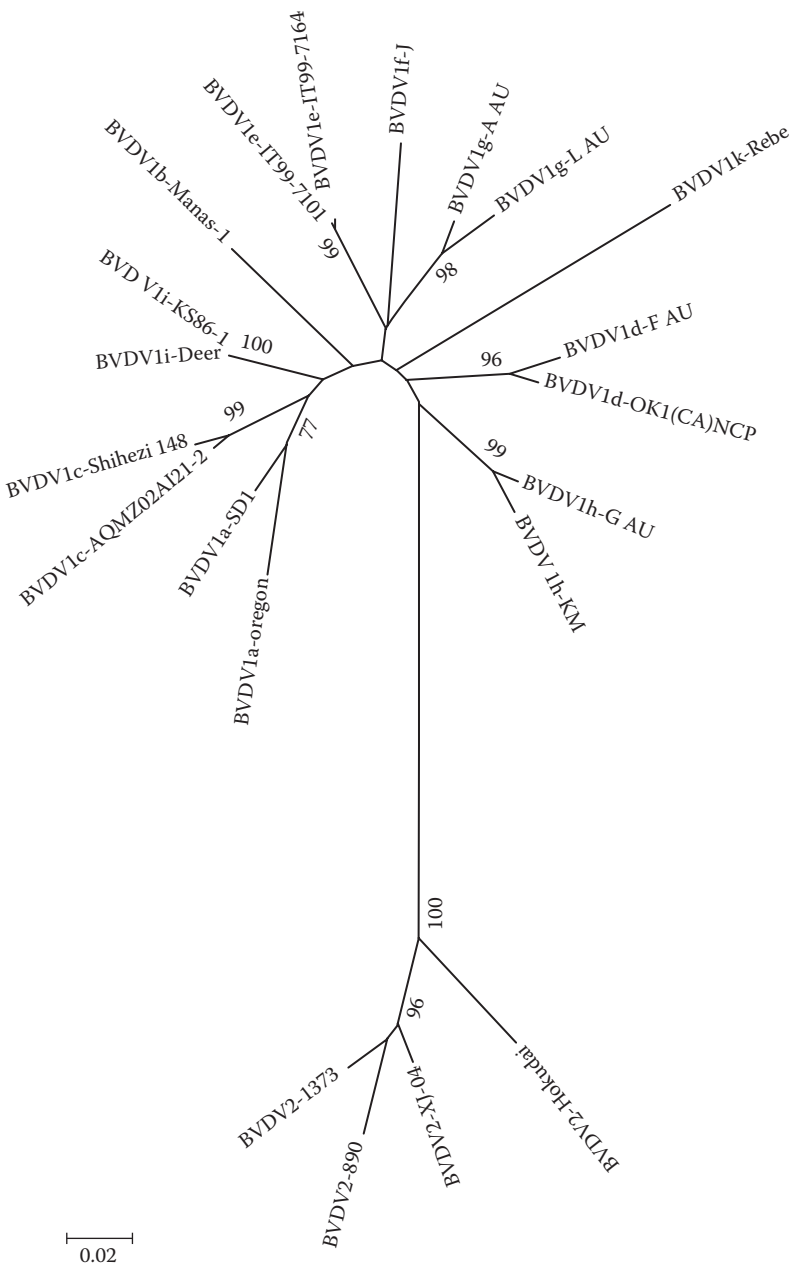

FIGURE 25.2 Diversity of selected strains of bovine viral diarrhea virus based on genetic homology of the 5′ untranslated region. (Reprinted from Newcomer, B.W. and Givens, M.D., *Antiviral Res*., 100, 133, 2013. With permission.)

ribonuclease-soluble envelope glycoprotein (E^{rns}), the primary envelope glycoprotein (E1), the secondary envelope glycoprotein (E2), protein p7, the fused second and third nonstructural proteins (NS2-3), the amino- and carboxy-terminal portions of the fourth nonstructural protein (NS4A, NS4B), and the amino- and carboxy-terminal portions of the fifth nonstructural protein (NS5A, NS5B) [18].

The BVDV capsid containing the single-stranded RNA genome is enveloped in a host-derived lipid membrane and is comprised of the four virion-encoded structural proteins, core (C), E^{rns}, E1, and E2. The nucleocapsid, or core, protein is comprised of 102 amino acids and functions in the processing and packaging of genomic RNA into the nascent virion [18]. The E^{rns} envelope glycoprotein is made up of 227 amino acids. The amino-terminus, created when the nucleocapsid protein is cleaved from the polypeptide chain, contains a signal sequence for translocation into the endoplasmic reticulum. Infected cattle generate high levels of antibody to the E^{rns} protein, which forms the basis of some commercially available diagnostic tests for BVDV. However, these antibodies are somewhat limited in their ability to neutralize the virus. The E1 protein is not highly immunogenic and functions primarily in viral cell entry in conjunction with E2 [19]. As the immunodominant protein, E2 is extremely antigenic, and exposure to the protein through vaccination or natural infection results in the stimulation of neutralizing antibody production in exposed cattle [18]. In addition to being variable in length, the amino acid sequence contains three hypervariable regions believed to reflect immunologic selective pressure. The high antigenicity of the protein has led to the study of E2 subunit vaccines as a potential alternative to conventional vaccines that would allow differentiation of vaccinated animals from those naturally infected; to date, this potential has yet to be realized commercially.

The first nonstructural protein to be translated is the N^{pro} autoprotease. In addition to its role as a protease, the protein is also involved in the suppression of host immune defenses via interference with production of type I interferon through the activity of interferon regulatory factor 3 [20]. All proteins necessary for viral replication are nonstructural [18]. The role of protein p7 is not fully understood, but the protein likely functions in late-stage assembly and viral release, much like the analogous protein of hepatitis C virus. The remaining nonstructural proteins (NS2-3, NS4, and NS5) are each subject to posttranslational processing that yields two distinct peptides. High levels of neutralizing antibodies to NS2-3 are seen after natural infection with BVDV or following vaccination with a modified-live vaccine [18]. Cleavage of the protein yields the second (NS2) and third (NS3) nonstructural proteins, and constitutive expression of NS3 is a hallmark of CP strains as the cleavage rate of the protein falls dramatically shortly after infection with NCP strains. The NS3 protein includes the protease and helicase domains of NS2-3 and is one of the more widely studied proteins of BVDV. The NS4 protein is cleaved by the NS3 protease to yield NS4A, a cofactor to the serine protease activity of NS3, and NS4B of unknown function. The NS5 protein is incompletely cleaved to yield NS5A and NS5B, which functions as the RNA-dependent RNA polymerase [18].

25.1.3 Clinical Features and Transmission

Clinical disease caused by BVDV infection can take several forms and is a source of significant economic losses in cattle worldwide. The clinical effects of BVDV are manifested in the respiratory, gastrointestinal, reproductive, cardiovascular, lymphatic, immunologic, integumentary, or central nervous systems of the affected cattle throughout the world. However, reproductive losses and respiratory disease associated with BVDV infection are thought to have the largest negative economic impact for producers. Economic losses are substantial in both the beef and dairy industries. Clinical manifestations of BVDV infection are often broadly discussed in the categories of (1) transient infection, (2) infection of the reproductive tract, and (3) persistent infection.

25.1.3.1 Transient Infection

Transient infection occurs when the virus infects seronegative, immunocompetent cattle and may result in any of several different clinical syndromes that are influenced by viral strain and several host factors (e.g., age, immune status, gestational status). Clinical signs due to acute BVDV infection include depression, inappetence, fever, decreased milk production, oculonasal discharge, and oral ulcerations [2]. Despite its name, BVDV infection resulting in diarrhea is poorly characterized and inconsistently seen in transient infections, particularly of adult cattle. Immunosuppression may lead to secondary bacterial infections, particularly of the respiratory tract, and qualities that enhance the pathogenesis of other viral or bacterial pathogens. Consequently, BVDV has been implicated along with other pathogens (e.g., *Pasteurella multocida*, *Mannheimia haemolytica*, parainfluenza-3 virus, bovine respiratory syncytial virus) in the pathogenesis of the bovine respiratory disease complex [21].

In the mid-1990s, a syndrome caused by acute BVDV infection marked by severe thrombocytopenia and hemorrhage was described [5]. Mortality rates in both mature cattle and heifers were higher than commonly seen in previous outbreaks of BVDV, reaching 9% and 53%, respectively [4]. The viral isolates responsible for the outbreak were classified as BVDV2 due to differences in sequence homology from previous BVDV isolates, although hemorrhagic diatheses can result from infection with strains of either viral genotype. Due to the highly varied nature of BVDV-associated disease, clinical diagnoses of BVDV infection should be confirmed with laboratory diagnostic testing as both false-positive and false-negative diagnoses are common when the diagnosis is based solely on clinical signs.

25.1.3.2 Reproductive Tract Infection

Transient infection of susceptible, pregnant females as BVDV may result in fetal infection as the virus is able to readily cross the placenta and infect the fetus. The effect of infection on the fetus is largely determined by the stage of gestation when the dam is infected. Abortion or early embryonic death occurs commonly in earlier stages of gestation, due, at least in part, to endometrial inflammation resulting from the viral infection.

Downloaded From Vet-eBooks.com

Persistent infection may occur if the dam is infected between 45 and 125 days of gestation and is discussed in detail in the following section. Transplacental infection between 100 and 150 days of gestation commonly results in congenital defects, particularly central nervous system malformations due to the ability of BVDV to cross the blood–brain barrier. Cerebellar hypoplasia is the most notable sign seen, but other congenital defects include growth retardation, hypomyelinogenesis, hydranencephaly, hydrocephalus, microencephaly, microphthalmia, ocular cataracts, retinal degeneration, optic neuritis, alopecia, hypotrichosis, brachygnathism, thymic aplasia, and pulmonary hypoplasia [22]. Infections that occur in the last trimester are generally neutralized by the fetus's immune response but may result in abortion.

In 1998, a new face was added to the multifaceted spectrum of clinical BVDV syndromes when a seropositive, nonviremic bull at an AI center was found to have a unique, localized persistent testicular infection (PTI) [23]. Since then, only one other report exists of a similarly infected bull, also found at a bull stud [24]. Bulls with PTI are nonviremic but consistently shed virus in the semen that is detectable using routine virus isolation techniques. The virus is confined to the testicular tissue of affected bulls where it is associated with both Sertoli and germinal cells [24]. Although the prevalence of bulls with PTI is thought to be very low, their presence may go undetected as the infection does not result in clinical signs. Consequently, unless these bulls are identified through appropriate diagnostic testing, they can propagate the spread of BVDV through the presence of infectious virus in their semen. The pathophysiology of PTI in bulls is currently not fully understood and remains a topic of further research.

25.1.3.3 Persistent Infection

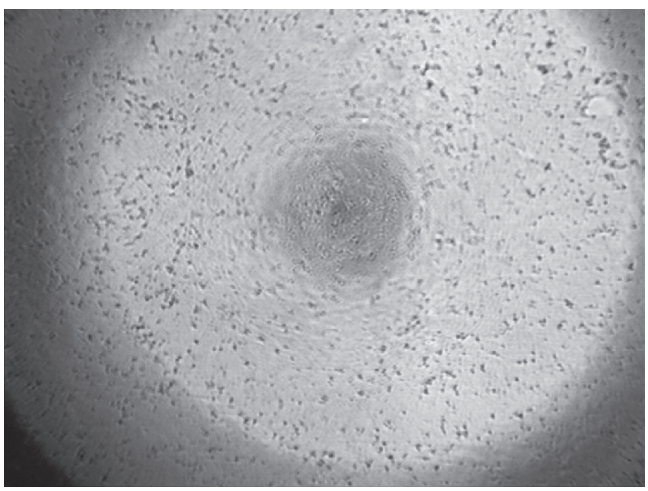
Infection of the fetus with an NCP strain of the virus between the end of the embryonic stage of gestation and before the development of fetal immunocompetence (45–125 days of gestation) may result in persistent infection [2]. Persistently infected (PI) animals consistently shed high levels of live virus and are thus important in the epidemiologic aspects of BVDV propagation. Immunotolerance characterizes persistent infection; PI animals do not mount an immune response to the infecting NCP strain although seropositivity to heterologous viral strains may be seen. Cows that are PI will invariably give birth to PI calves. At birth, many PI animals are weak and ill thrifty and most die before 1 year of age. However, others may not show signs of disease and serve as important reservoirs of the virus for transmission to susceptible cohorts. The identification and removal of PI animals is one of the cornerstones of BVDV management, and consequently, diagnostic tests must be able to differentiate transient and persistent infections to be the most useful in making decisions regarding BVDV control at the herd and individual animal levels.

Mucosal disease (MD) is a syndrome unique to PI animals that are superinfected with the CP strain of BVDV homologous to the NCP infecting strain. Such strains may arise by mutation of the original infecting strain or may come from external sources such as modified-live vaccines or herdmates [25]. Development of MD is almost always fatal although recovery of isolated cases has been described [26]. Death may be preceded by widespread ulceration of the upper gastrointestinal tract and hemorrhagic lesions in the abomasum and elsewhere [2]. Multiple forms of MD have been described, including acute MD, chronic MD, and delayed onset MD [26].

25.1.3.4 Transmission

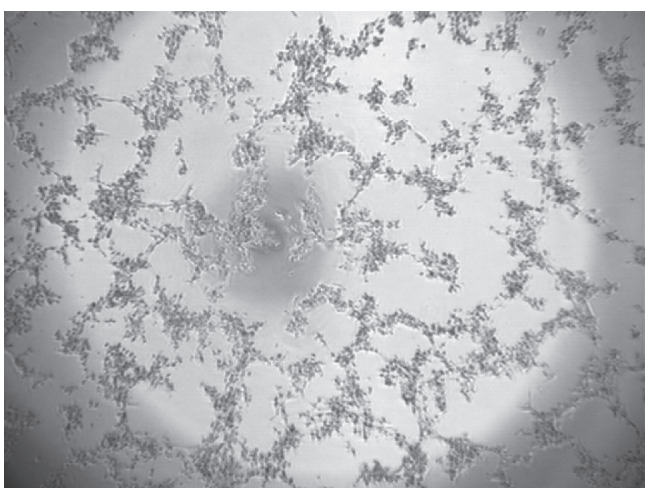
Animals are usually infected through the respiratory or gastrointestinal mucosa; subsequent primary viremia results in widespread dissemination of the virus. Although typically much shorter, viremia may last up to 15 days [27] and is often accompanied by pyrexia and leukopenia. Leukopenia in affected cattle is characterized by lymphopenia and potentially neutrophilia [28]. Tropism of BVDV is incompletely understood, but the virus is most reliably isolated from cells of hematopoietic or lymphoid tissue (e.g., white blood cells, spleen) but can also be found in tissues from multiple organ systems. The lymphotropism exhibited by BVDV affects cells of both the innate and adaptive immune systems [2]. The PI animal serves as the principal viral reservoir and the major source of infection to other cattle through direct contact with bodily secretions including saliva, urine, tears, feces, milk, and semen. Mechanical and arthropod vectors are also capable of viral transmission. Airborne transmission in the absence of direct contact is not a major route of transmission and occurs only over very short distances. Venereal transmission is possible from bulls experiencing transient, testicular, or persistent infection and calves born to PI dams are consistently PI themselves. The virus is capable of infecting several wildlife species of the order *Artiodactyla*, and cross-species transmission to cattle has been documented in specific experimental situations although the risk of interspecies transmission remains largely uncharacterized.

25.1.4 Diagnosis



A definitive diagnosis of BVDV infection is only made through laboratory testing due to the diverse clinical and subclinical syndromes displayed by infected animals. Several tests are available, and selection of the appropriate test will be dictated by several factors, including the management system of the affected farm, financial constraints, and availability of tests at a given laboratory [2]. Since not all available tests are appropriate for each clinical situation, care should be made when selecting a test in order to reach a successful solution quickly and efficiently [29]. Most BVDV testing focuses on the detection and identification of PI animals in order to remove the said animals from the herd to limit virus shedding and spread; not all tests are appropriate for identification of PI animals. Essentially all diagnostic tests for BVDV fall into one of four main categories: virus isolation, antigen detection, serology, and molecular techniques.

Downloaded From Vet-eBooks.com



25.1.4.1 Conventional Techniques

25.1.4.1.1 Virus Isolation

Historically, isolation of live virus from tissues or secretions of infected animals is considered the "gold standard" of diagnostic test for BVDV. While the test is still widely used in research, in many diagnostic settings, it has been replaced by tests that are more economical and have a shorter turnaround time. The best application of the test is to confirm infection in an individual animal showing clinical signs of transient infection. Many cells from several different species will support the growth of BVDV in culture but cell lines used in BVDV isolation assays are generally limited to bovine turbinate, bovine testicle, and Madin–Darby bovine kidney cells [29]. Infection with CP strains of BVDV results in characteristic cytopathic effects (CPE) in cultured monolayers; cells display vacuolization and apoptosis within 48 h of infection (Figure 25.3). However, most field strains of BVDV are of the NCP biotype and do not result in observable CPE. Consequently, alternative visualization techniques such as immunofluorescence or immunostaining must be employed to detect infected cells.

(a)

(b)

FIGURE 25.3 Microscope photographs (100×) of Madin–Darby bovine kidney cell cultures 72 h after infection with a noncytopathic (a) or cytopathic (b) strain of BVDV.

White blood cells extracted from whole blood samples are the preferred sample when collecting samples from the live animal for detection of BVDV by virus isolation [29]. Serum samples are also commonly used although false-negative results may be obtained as a result of the presence of serum-neutralizing antibodies in the serum. In one study of 23 separate diagnostic laboratories using seven sample–test combinations, virus isolation performed on serum resulted in the lowest consistency in detecting positive samples and the lowest level of agreement between laboratories [30]. Nasal swab samples may also be subjected to virus isolation assays as live virus is often shed in the nasal secretions of infected cattle. Tissue from the lymphoid organs such as the thymus, spleen, Peyer's patches, and mesenteric lymph nodes is the preferred sample to be collected from a dead animal or aborted fetus for submission for virus isolation [29]. A single virus isolation test is not capable of differentiating persistent and transient infections. Isolation of virus from samples obtained from an animal at least 3 weeks apart is indicative of persistent infection.

25.1.4.1.2 Antigen Detection

Direct antigen detection is generally less sensitive and less reliable than virus isolation techniques; however, antigen detection assays are generally quicker and more economical to perform than virus isolation assays [29]. Antigen detection tests are generally used as screening tests to detect PI animals although additional testing may be warranted in certain circumstances due to the occurrence of false positives. Commonly used antigen detection methods include antigen capture ELISAs (ACE) and immunohistochemistry (IHC) techniques. IHC techniques have been the traditional test for the detection of PI animals and are still widely used although the more recent development of economical and user-friendly ACE kits are being used more routinely. Most commercial IHC testing is performed on fresh or formalin-fixed tissue samples commonly taken from the ear and referred to as "ear notches." While IHC tests are primarily carried out by trained personnel at diagnostic laboratories, commercially available ACE kits have been used cow-side for the identification of PI animals. Several studies have demonstrated a high level of sensitivity for the commercial ACE kits when used as a screening test to detect PI animals [30,31]. Commercial ACE kits rely on monoclonal antibodies targeting the E^{rns} glycoprotein of BVDV; consequently, differing strains of BVDV may not be detected by the test [32].

25.1.4.1.3 Serology

Serologic tests can be used to demonstrate previous exposure to the virus, but care must be taken when interpreting the results as serologic tests are unable to differentiate antibodies produced in response to natural exposure versus those produced after vaccination or those present as a result of passive transfer through the ingestion of maternal colostrum [2]. However, in the right circumstances, serologic testing may prove beneficial

Downloaded From Vet-eBooks.com

to assess compliance with a vaccine protocol or to assess the herd's exposure status to BVDV [29]. In unvaccinated herds or in regions where the virus has been eradicated, testing of seronegative sentinel animals may be useful to determine herd exposure. The serum neutralization assay is the most commonly used serologic test for BVDV infection and can be used to differentiate exposure to BVDV1 and BVDV2. However, comparison of results between different laboratories is complicated as results will differ to some degree depending on the similarity of the infecting and reference strains. Additionally, anti-BVDV antibodies may be detected by various ELISA tests although these are no longer routinely used in most laboratories. Serologic assays are of little value in detecting PI animals as such individuals do not mount an antibody response to the infecting strain of the virus.

25.1.4.2 Molecular Techniques

Although virus isolation is regarded as the historical "gold standard" of BVDV diagnostic assays, the technique has largely been supplanted by the use of reverse transcription polymerase chain reaction (RT-PCR). The advantages of RT-PCR relative to virus isolation include high sensitivity, rapid turnaround time, low relative cost, obviation of the need for dedicated cell culture laboratory space and equipment, and the ability to distinguish the various genotypes and subgenotypes of BVDV. Additionally, RT-PCR is not adversely affected by the presence of neutralizing antibodies in serum samples. Commercially available kits with simple viral RNA extraction steps have encouraged the acceptance of RT-PCR as the primary herd screening assay used by many diagnostic laboratories. Additionally, RT-PCR can be used to detect BVDV in a wide variety of samples including serum, whole blood, milk, tissues, nasal swabs, semen, follicular fluid, and embryos [33]. The RT-PCR assay should be validated for each sample type as poor RNA extraction will adversely affect the sensitivity of the assay [29]. Detection of viral nucleic acid does not necessarily mean that infectious virus is present in the sample; thus, clinicians must take care to interpret assay results in conjunction with the clinical scenario.

The high sensitivity of the RT-PCR assay has made the testing of pooled samples an effective and economical means of screening whole herds or other groups of animals. The assay is sensitive enough that a single viremic sample in a pool of 100 negative sera has been detected by RT-PCR with the sensitivity of the assay estimated to exceed that of virus isolation by 10^1–10^4-fold [34]. However, sensitivity of the test decreases as the number of samples included in the pooled aliquot increases leading to controversy as to the optimal number of samples to be included in each pooled test. Pooling of milk samples for BVDV detection by RT-PCR is also done commonly due to the ease of sample collection and economic benefit of batch testing combined with the superior test sensitivity of RT-PCR. However, when using pooled samples, it is important to remember which samples are not included in the assay. For example, when testing for BVDV infection on a dairy using bulk tank milk samples, the results will evidently not reflect the infection status of any nonlactating animals (e.g., bulls, dry cows, heifers) on the farm. Recently, a diagnostic test using RT-PCR has been described for nonlactating animals that do not require individual sampling [35]. By swabbing consumption surfaces and assaying the swabs by RT-PCR, the investigators were able to determine if PI animals were present in a group of cattle. While promising, this test is not yet available on a commercial basis.

Several molecular diagnostic test protocols have been described for the detection of BVDV in laboratory and clinical samples. Quantitative RT-PCR (RT-qPCR) and standard RT-PCR protocols for the detection of BVDV have been well described and the choice of specific protocol will be determined by the equipment available, goal of the diagnostic test, and operator preference. Sequencing of the amplicon following standard RT-PCR allows for genetic sequencing and identification of the isolate (sub)genotype, while RT-qPCR provides a quantitative assessment of viral load in the sample. Multiplex PCRs are performed commonly in diagnostic laboratories for the detection of multiple pathogens, including BVDV, in a single clinical sample.

25.2 METHODS

25.2.1 Sample Preparation

25.2.1.1 Serum

Serum samples should be collected in sterile blood collection tubes without anticoagulants. The sample is left to sit at room temperature for <2 h to allow for clot formation, and serum is collected by centrifugation at 200 × *g* (1100 rpm) for 20 min. Samples that are assayed immediately may be aliquoted into sterile tubes and stored at −80°C until the time of testing.

25.2.1.2 White Blood Cells

Whole blood samples are collected in sterile blood collection tubes containing EDTA. The samples are centrifuged at 700 × *g* (2020 rpm) at 4°C for 30 min. The buffy coat band containing the white blood cells is extracted using a sterile Pasteur pipette and placed in a 15 mL centrifuge tube containing 10 mL of 0.15 M NH_4Cl. After mixing, the tube is centrifuged at 700 × *g* (2020 rpm) at 4°C for 10 min and the supernatant is poured off. To the remaining sample, 10 mL of minimum essential media (MEM) is added and mixed before centrifugation at 700 × *g* (2020 rpm) at 4°C for 10 min a final time. The supernatant is removed and the white blood cell pellet is resuspended in 0.5 mL of MEM. The sample may then be passaged or submitted directly to RNA extraction. White blood cell samples should not be frozen before RNA extraction.

25.2.1.3 Nasal Swab Samples

For nasal swab samples, one nasal swab is placed in a sterile tube containing 3 mL of MEM + 0.1 gentamicin and allowed to sit for at least 1 h at 4°C before processing. Samples not to be immediately processed may be allowed to sit in the solution for longer periods (up to at least 48–72 h) at 4°C. Immediately before RNA extraction, the tube is agitated gently and the nasal swab removed; RNA is extracted from the media.

Downloaded From Vet-eBooks.com

25.2.1.4 Semen

Raw semen samples are partially extended (1:8) in egg yolk–citrate extender by adding 250 µL of raw semen to 1750 µL of the extender [36]. The extended semen sample is then processed through a Sephacryl S-400 column according to the manufacturer's instructions before RNA extraction is initiated.

25.2.1.5 Tissue Sample

Various tissues can be assayed for the presence of BVDV viral nucleic acid using RT-PCR including tissue samples obtained at necropsy, testicular biopsy samples, and ear notch samples. For a tissue sample that measures approximately 1 cm × 1 cm, add the tissue and 3 mL of MEM to a stomach bag and stomach at high speed for 2 min. Additional MEM may be added for larger samples. If necessary, the resulting contents may be centrifuged gently to remove gross particulate matter. The supernatant may then be stored at −80°C or submitted directly for RNA extraction.

25.2.1.6 RNA Extraction

An efficient and simple method of RNA extraction that is validated for each sample type to be tested is a requirement for achieving highly sensitive results by RT-PCR. Several kits are commercially available for RNA extraction (e.g., QIAamp Viral RNA Mini Kit, Qiagen, Valencia, CA). When testing multiple sample types, validation of the chosen extraction kit for each sample type is advised to minimize the opportunity for false-negative test results.

In our laboratory, the High Pure RNA Isolation Kit (Roche, Indianapolis, IN) is used for the extraction of RNA from buffy coat samples while the QIAamp Viral RNA Mini Kit has been used effectively on infected uterine tubal cells, embryo sonicate fluid, follicular fluid, cell culture supernatant, serum, semen, and nasal swab and tissue samples. RNA extraction is performed according to the manufacturer's instructions for each kit. Briefly, for the QIAamp Viral RNA Mini Kit, 140 µL of the sample supernatant is added to 560 µL of the viral lysis buffer. Incubation at room temperature for 10 min is followed by the addition of 560 µL of absolute alcohol to the sample. Then, 630 µL of the solution is added to the spin column and centrifuged (all centrifugation is performed at 25,000 × *g*) for 1 min. The sample is then successively washed by adding 500 µL of AW1 and AW2 buffer with a centrifugation step after each wash lasting 1 and 3 min, respectively. Finally, the RNA is eluted by the addition of 60 µL of AVE buffer and centrifuged for 1 min after incubation at room temperature for 1 min. The RNA may be used immediately for RT-PCR or stored at −80°C until RT-PCR will be performed.

25.2.2 Detection Procedures

25.2.2.1 Standard RT-PCR

The following protocol is a nested RT-PCR (RT-nPCR) assay performed in a single closed-tube reaction modified from a previously published report [37].

1. The following mixture is aliquoted into the cap of a 200 µL tube and allowed to dry for 2 h at room temperature:

Order	Reagent	Concentration	Volume (µL)
1	Trehalose	22% w/v	5.0
2	Deoxynucleotide mix (dNTP)	10 mM	1.0
3	Taq polymerase	5 U/µL	0.25
4	BVDV 180 primer 5′-CCTGAGTACAGGGDAGT CGTCA-3′	50 µM	0.4
5	Hepatitis C virus (HCV) 368 primer 5′-CCATGTGCCATGTACAG-3′	50 µM	0.4

2. The RT-PCR master mix is then prepared as follows (volumes shown are per PCR):

Order	Reagent	Concentration	Volume (µL)
1	RNAse-free water		25.5
2	$MgCl_2$	25 mM	8.0
3	10× PCR buffer		5.0
4	dNTPs	10 mM	2.0
5	BVDV 100 primer 5′-GGCTAGCCATGCCCTTAG-3′	5 µM	1.0
6	HCV 368 primer 5′-CCATGTGCCATGTACAG-3′	5 µM	1.0
7	Triton X-100	10% stock	1.0
8	Dithiotreitol (DTT)	100 mM	0.25
9	RNAsin	40 U/µL	0.25
10	Taq polymerase	5 U/µL	0.5
11	M-MLV reverse transcriptase (MMLV RT)	200 U/µL	0.5
	Total		45

3. Briefly, 45 µL of the master mix is added to a thin-walled PCR tube in a frozen (−20°C) rack and overlaid with 2 drops (50 µL) of mineral oil.
4. Then, 5 µL of extracted RNA is added to the master mix through the oil layer for a total.
5. The tube is then subjected to the following cycle parameters: 37°C for 45 min, 95°C for 5 min, and then 20 cycles at 94°C for 1 min, 55°C for 1 min, and 72°C for 1 min, followed by a final elongation cycle of 72°C for 10 min.
6. The tube is inverted several times and then centrifuged at 14,000 × *g* for 12 s.
7. Then, 30 cycles are run at 94°C for 1 min, 55°C for 1 min, and 72°C for 45 s before a final elongation step of 72°C for 10 min.
8. The amplicons are maintained at 4°C until visualization of the PCR products is achieved by agarose gel electrophoresis.

25.2.2.2 Quantitative RT-PCR

The following protocol is currently used in our laboratory and uses the iTaq Universal SYBR Green One-Step Kit in a 96-well-plate format.

1. The RT-qPCR master mix is prepared as follows:

Reagent	Concentration	Volume (μL)
One-step SYBR Green reaction mix	1×	10
iScript reverse transcriptase		0.25
RNAse-free water		4.15
BVDV forward primer 5′-TAGCCATGCCCTTAGTAGGAC-3′	0.3 μM	0.3
BVDV reverse primer 5′-GACGACTACCCTGTACTCAGG-3′	0.3 μM	0.3
Total		15

2. In each well of the plate, 5.0 μL of extracted RNA template is added to the 15 μL of the master mix.
3. The thermocycler is programmed for the following cycle parameters: the plate is held at 50°C for 10 min and then 95°C for 1 min followed by 39 cycles at 95°C for 10 s and 56.5°C for 30 s.
4. The melting-curve analysis cycle is then performed at 65°C–95°C in 0.5°C increments with each step lasting 2–5 s.

25.3 CONCLUSIONS AND FUTURE PERSPECTIVES

BVDV is one of the primary viral pathogens of cattle and continues to cause significant economic losses to cattle producers worldwide. Despite causing a wide variety of clinical syndromes, the lack of pathognomonic symptoms following infection dictates the need for sensitive and specific diagnostic tools that are practical, scalable, and economical. In several countries and geographic regions of the world, voluntary or mandatory BVDV eradication programs have been implemented. Diagnostic sensitivity and specificity is important to the success of such programs as well as for surveillance activities following eradication. In areas where BVDV infection is endemic, diagnostic accuracy will continue to play an important role in control of the virus and viral transmission. Particularly important in the epidemiology of BVDV infections is the presence of PI animals. Thus, diagnostic tools must not only be able to determine the presence or absence of viral infection from clinical samples but, when infection is detected, to be able to classify the infection as a transient or persistent infection.

With the first description of the genomic sequence of the virus in 1988 [38], the era of molecular diagnostics was initiated. Since that time, advances in diagnostic detection have led to the widespread use of RT-PCR as the principal diagnostic assay for BVDV infection in many laboratories. Compared to virus isolation, the historical gold standard for the diagnosis of BVDV infection, RT-PCR has high sensitivity, rapid turnaround time, low relative cost, and no need for dedicated cell culture laboratory space and equipment. However, virus isolation and other conventional diagnostic tools are not without their benefits and should not be overlooked or forgotten by the diagnostician dealing with BVDV.

Current diagnostics are unable to readily differentiate infected from vaccinated animals. With a continued effort in many areas to eradicate the disease, future labors will focus on the development of assays to distinguish between field and vaccinal exposure. Additionally, the involvement of BVDV in multiagent infections, particularly in bovine respiratory disease, supports the continued development and use of multiplex RT-PCR assays to determine the presence or absence of multiple pathogens from a single clinical sample. The impact of BVDV infection on cattle health in populations worldwide underscores the continued need for accurate and economical diagnostic assays to safeguard cattle health and well-being.

26.1 INTRODUCTION

First recognized in Tennessee, United States, in 1810, classical swine fever (CSF, alternatively known as hog cholera, pig plague, or swine fever) is a highly contagious, fatal disease of pigs, wild boar, and collared peccaries. The etiological agent for CSF is a single-stranded and positive-sense RNA virus in the genus *Pestivirus* of the family *Flaviviridae* with the namesake of classical swine fever virus (CSFV). Typical clinical symptoms include fever, skin lesions, convulsions, and death (usually within 15 days, especially in young animals), which are indistinguishable from those of African swine fever (see Chapter 91). Once widely spread in many parts of the world, CSF has been successfully eradicated from Canada, the United States, Australia, and New Zealand, but still occurs in Asia, South America, Eastern Europe, and Russia, with significant economic impacts through production losses, trade bans, surveillance, and prevention costs.

26.1.1 Classification

CSFV is a member of the genus *Pestivirus*, family *Flaviviridae*. The family *Flaviviridae* (*flavus* means "yellow" in Latin, derived from yellow fever virus, a type virus of the family) consists of four genera (*Flavivirus*, *Hepacivirus*, *Pegivirus*, *Pestivirus*). In turn, the genus *Pestivirus* (*pestis* means "plague" in Latin) comprises four recognized species (bovine viral diarrhea virus genotype 1, bovine viral diarrhea virus genotype 2, border disease virus (BDV), and CSFV) together with five proposed species (antelope pestivirus, bovine viral diarrhea virus genotype 3 [atypical bovine pestivirus], Bungowannah pestivirus, giraffe pestivirus, Hobi pestivirus, and Tunisian sheep virus)] [1–6].

Composed of a single serotype, CSFV is further divided into three major groups (genotypes) and 10 subgroups (subtypes) (i.e., subgroup 1.1, 1.2, 1.3; subgroup 2.1, 2.2, 2.3; subgroup 3.1, 3.2, 3.3, 3.4) based on phylogenetic analysis of the polymerase gene NS5B, the envelope glycoprotein gene E2, and the 5′ nontranslated region (NTR) [7,8]. Additionally, distinct strains that circulate in certain countries/regions may be identified within subgroups as clades (e.g., clade 2.1a, 2.1b, and 2.1c). In general, genotype 1 encompasses the highly virulent, historical strains that were isolated from various parts of the world and still occur in South and Central America as well as the Caribbean Sea; all live-attenuated vaccine strains also belong to genotype 1. Genotype 2 includes the strains that are largely found in Europe and that have caused epidemics since the 1980s. Genotype 3 contains the strains that are mainly distributed in Asia (e.g., Taiwan, Korea, Japan, and Thailand) [9]. Genotypes 2 and 3 strains are often of moderate to low virulence and account for mild CSF that may be overlooked or dismissed as other viral disease at the early stages, contributing to the delay in implementation of necessary control measures and also the increase in disease prevalence [10]. There is evidence that some CSFV strains may switch from the historical group 1 or 3 to the more recently

Downloaded From Vet-eBooks.com

prevalent group 2 in Europe and Asia, further complicating the diagnostic and preventive efforts [11,12].

Differing from other flaviviruses by the presence of the N^{pro} autoprotease, members of the genus *Pestivirus* are infective to nonhuman mammals, including various bovine (cattle, sheep, and goats), and swine species, resulting in diseases of varying severity (from subclinical to overt clinical syndromes such as fever, diarrhea, hemorrhagic syndrome, abortion, and death). It is notable that while most *Pestivirus* species are capable of infecting animals out of their natural host, CSFV is the only species that is restricted to domestic pigs and wild boars.

26.1.2 Morphology and Genome Organization

CSFV possesses an enveloped, spherical virion of 40–60 nm in diameter. Formed during maturation and assembly of the virion by budding through membranes of infected cells, the lipid envelope is covered by dimers with a T = 3-like organization.

The genome of CSFV consists of a monopartite, linear, single-stranded, positive-sense RNA of 12.3 kb in length, which is made up of a large open reading frame (ORF) flanked by 5′ and 3′ NTRs. The detailed arrangement of CSFV RNA is as follows: 5′-NTR-Npro-C-E^{rns}-E1-E2-p7-NS2-3-NS4A-NS4G-NS5A-NS5B-NTR-3′. Translation of the ORF results in a 3898-amino-acid polyprotein, which is further processed by viral Npro, NS2, and NS3 proteinases and by host signal peptidase to generate four structural (C, E^{rns}, E1, and E2) and eight nonstructural (N^{pro}, p7, NS2, NS3, NS4A, NS4B, NS5A, and NS5B) proteins (Table 26.1) [13–15].

Unlike some other flaviviruses that carry a methylated nucleotide cap at their 5′ UTR, CSFV has a noncapped 5′ UTR (375 nt), which includes an internal ribosome entry site (located between 60 and 375 nt) with binding sites for NS3 and NS5A and is involved in the initiation of cap-independent translation as well as RNA replication. The 3′ UTR (232 nt) in CSFV is uracil rich, contains two NS5A binding sites (3′ UTRSL-1 and 3′ UTRSL-2), but lacks a poly A tail (an indication for the absence of posttranscriptional modifications).

In addition to mature structural proteins and nonstructural proteins, disulfide-linked heterodimers (E^{rns} -E2 and E1-E2) and homodimers (E2-E2 and E^{rns} -E^{rns}) may be observed in CSFV virions. Furthermore, two precursor proteins E2-P7 (60 kDa, 443 aa) and NS2–3 (120 kDa, 1140 aa) are produced from the polyprotein, which may play accessory roles in virus replication and which are present in infected cells but not in pelleted virions [16].

26.1.3 Replication and Epidemiology

Upon entry into the host, CSFV utilizes E(rns) and E2 envelope glycoproteins for attaching to host cellular receptors (heparan sulfate [HS] and laminin receptor [LamR], which interacts

TABLE 26.1
Characteristics of CSFV Structural and Nonstructural Proteins

Gene	Protein	Size	Function
Npro	Npro (N-terminal autoprotease)	23 kDa, 168 aa	Cysteine protease for cotranslational cleavage from the nascent downstream nucleocapsid protein C; antagonist of host IFN-α/β induction pathway
C	C (capsid or core protein)	14.3 kDa, 99 aa	Enhancement of CSFV RNA replication; regulation of SUMOylation pathway for immune evasion
E^{rns}	Erns (envelope protein RNase secreted) or E0 glycoprotein	44 kDa, 227 aa	Attachment to laminin receptor on cell surface; endonuclease/ribonuclease; inhibition of RNA and protein synthesis in host cells; induction of apoptosis of lymphocytes; inhibition of early-stage immunization of host
E1	E1 (envelope) glycoprotein	33 kDa, 195 aa	Involvement in virus attachment and invasion
E2	E2 (envelope) glycoprotein	55 kDa, 373 aa	Type I transmembrane protein; involvement in virus attachment and invasion; primary neutralizing antigen
p7	P7 (nonstructural protein)	7 kDa, 70 aa (E2-P7, 60 kDa, 443 aa)	Viroporin; involved in infectious virus production (budding process and virus packaging), but not associated with virus particles
NS2	NS2 (nonstructural protein)	54 kDa, 457 aa (NS2–3, 120 kDa, 1140 aa)	Autoprotease; involvement in Cyclin degradation and synthesis; activation of NF-κB; upregulation of IL-8; antagonization of type I IFN response
NS3	NS3 (nonstructural protein)	75 kDa, 683 aa (NS2–3)	Multifunctional protein with serine protease, RNA helicase, nucleoside triphosphatase (NTPase) activity; involvement in viral transcription and translation
NS4A	NS4A (nonstructural protein)	11 kDa, 64 aa	Cofactor of NS3 serine protease; involvement in RNA replication and formation of infectious virion
NS4B	NS4B (nonstructural protein)	30 kDa, 347 aa	NTPase; essential role in RNA replication
NS5A	NS5A (nonstructural protein)	56 kDa, 497 aa	Replicase component; stimulation of virus replication and inhibition of virus translation (i.e., switch from translation to replication); induction of host cell autophagy and reactive oxygen species production
NS5B	NS5B (nonstructural protein)	78 kDa, 718 aa	RNA-dependent RNA polymerase (RdRp); initiation of translation; replicase (production of negative-strand RNA from positive-strand RNA); nucleotidyl transferase

with E[rns] protein) [17]. This leads to the fusion between the viral envelope and the cell plasma membrane and the subsequent endocytosis mediated by clathrin. Inside the cytoplasm, the viral nucleocapsid is removed, and the positive-sense genomic ssRNA is translated (via cap-independent mechanism) into a polyprotein, which is cleaved into four structural and eight nonstructural proteins. Synthesis of a complementary RNA(–) from the genomic ssRNA(+) and formation of a dsRNA genome occur at the surface of endoplasmic reticulum. Transcription/replication of the dsRNA genome results in viral mRNAs/progeny ssRNA(+) genomes, which are incorporated into new virus particles. The new virion buds at the endoplasmic reticulum, migrates to the Golgi apparatus, and exits the cell via the secretory pathway. While NS3, NS4A, NS4B, NS5A, and NS5B are required for RNA replication, all mature proteins (except Npro) and the precursor NS2–3 play critical roles in the life cycle of CSFV [18–20].

CSFV initially infects the host via the oronasal route, and its first replication takes places in the tonsils, where it infects the crypt epithelial cells, macrophages, lymphocytes, and endothelial cells. It then spreads to the regional lymph nodes and disseminates systemically via the bloodstream to the spleen, kidneys, distal ileum, brain, etc. Congenitally, infected piglets are inapparent carriers, which are persistently viremic, and shed the virus for 6–12 months before dying. With a positive polarity, CSFV RNA is infectious and serves as both transcriptional and translational templates.

CSFV survives for 3 days at 50°C and 7–15 days at 37°C, for 3–4 days in decomposing organs and 15 days in decomposing blood and bone marrow, for up to 4 weeks in winter in pens, for 17 to >180 days during salt curing and smoking, for months in refrigerated meat, and for years in frozen meat. The virus is sensitive to drying and ultraviolet light and readily inactivated by heating at 65.5°C for 30 min or at 71°C for 1 min. In addition, it is rapidly killed by pH at pH < 3.0 or pH > 11.0, and is susceptible to ether, chloroform, β-propiolactone (0.4%), chlorine-based disinfectants, cresol (5%), sodium hydroxide (2%), formalin (1%), sodium carbonate (4% anhydrous or 10% crystalline with 0.1% detergent), ionic and nonionic detergents, and strong iodophors (1%) in phosphoric acid [21].

Secretions and excretions (oronasal and lachrymal discharges, urine, feces, and semen), blood, and tissues of sick or dead animals represent the main sources of infection. Ingestion, contact with the conjunctiva or mucous membranes, skin abrasions, genital transmission, artificial insemination, percutaneous blood, and transplacenta are typical routes of transmission. The virus may be spread by farm visitors, veterinarians, and pig traders; by indirect contact through premises, implements, vehicles, clothes, instruments, and needles; by wind (up to 1 km); and by ingestion of insufficiently cooked waste food. The farming practice of keeping semi-feral pigs in Southeast Europe may be another risk factor [22].

CSFV infection appears to be limited to domestic pigs, feral pigs, and wild boars. As wild boar populations may harbor the virus, domestic pigs in the nearby area are at a high risk. CSF has been previously found in all continents. Following adoption of compulsory vaccination or slaughter and eradication policies, a number of countries have declared CSF-free, including Canada (1963), the United States (1978), the United Kingdom, Western Europe, Australia, and New Zealand as well as Japan (2007). Currently, CSF is present in much of Asia, Central and South America, parts of Eastern Europe (e.g., Latvia and Russia), and South Africa [23,24]. In China, CSFV subgroups/subgenotypes 2.1 (particularly clades 2.1b and 2.1c), 2.2, 2.3, and 1.1 have been identified [25,26].

26.1.4 Clinical Features and Pathogenesis

CSF is a highly contagious hemorrhagic viral disease of pigs, with a diverse range of clinical signs. The disease severity may be influenced by the virulence of CSFV strains, age, and immune status of susceptible hosts. In general, strains of high virulence are responsible for acute (i.e., rapid), serious disease, while strains of intermediate or low virulence induce subacute or chronic (i.e., long-lasting) diseases. Younger piglets tend to be more severely affected than older pigs. The incubation period of CSF varies from 2 to 14 days, but clinical signs may not be apparent until after 2 to 3 weeks [27].

26.1.4.1 Acute Disease

Appearing in a small number of growing pigs, the initial nonspecific signs include high fever (40°C–42°C), anorexia, lethargy, depression, sleepiness, reluctance to get up or to eat, and walk/stand with heads down and tails limp. In the few days that follow, increasing numbers of pigs become affected. Clinical signs may change from slight constipation to a yellow-grey diarrhea and conjunctivitis (inflammation of the eye surface) with thin to thick discharges, resulting in some of the eyelids being completely closed and adhered. Younger piglets may shiver and huddle together. Further disease progression may render the affected pigs very thin and weak, with a staggering walk (due to damage in the spinal nerves), a drunken walk (due to partial paralysis of the hind end), and a tendency to be in a sitting or lying position. As a result of hemorrhages, the color of affected pigs' skins may turn purple, first on the ears and tail, then the snout, lower legs, belly, and back, and affected pigs may go into convulsions and die in 5–20 days [28].

26.1.4.2 Subacute and Chronic Disease

The growing pigs with subacute disease may show similar but less severe signs to those with acute disease. These include dullness, capricious appetite, pyrexia, diarrhea for up to 1 month, ruffled appearance, growth retardation, apparent recovery with eventual relapse, and death within about 3 months. Some older animals may show transient pyrexia and inappetence and recovery with lifelong immunity.

26.1.4.3 Congenital Disease

This form of disease tends to occur in piglets in the sow's uterus through transplacental route. This often involves sows with inadequate vaccination (e.g., with original attenuated virus vaccines) or infection by CSFV strain of low virulence. Piglets may be stillborn, mummified, deformed, aborted,

Downloaded From Vet-eBooks.com

or weak. Some piglets may be born apparently healthy (if the virus crosses the placenta before the piglets' immune systems have developed) and grow on to be persistent carriers without clinical signs. After several weeks or months of age, the piglets may develop typical but milder clinical signs (tremor, weakness, runting, and poor growth) without high temperatures, and succumb to the disease in 12 months [28].

In the field, CSF is often manifested as subclinical infections or coinfections with other viruses and/or bacteria.

Postmortem examination may reveal many small hemorrhages throughout the body and larger hemorrhages in the lymph nodes, the lungs, and the skin. The tonsils may show inflammation and necrotic foci. The kidney surfaces are covered with bloody spots, like mottled ducks' eggs. The spleen may have dark raised areas of dead tissue (multifocal infarction of the margin), which may be pathognomonic. The lungs may show severe pneumonia, hemorrhage, and pleurisy due to secondary bacterial infection. The stomach and gut may contain brightly colored liquid. The inner lining of the large intestine near its junction with the small intestine is raised (the so-called button ulcers, which are often seen in subacute/chronic form of the disease and are unique to CSF). The bladder may also display multiple red spots. In congenital form of the disease, lesions may include central dysmyelinogenesis, cerebellar hypoplasia, microencephaly, pulmonary hypoplasia, hydrops, and other malformations [21].

CSFV proteins Npro, Core, Erns, E1, E2, P7, and NS4B have been shown to be related to virulence [29,30]. The systemic hemorrhage seen in CSF is a result of CSFV-induced necrosis of endothelial cells with subsequent vasculitis and hemorrhaging, together with severe anemia, thrombocytopenia, and disturbance of fibrinogen synthesis. The immunosuppression results from downregulation and necrosis of bone marrow hematopoietic cells and lymphocytes [31].

26.1.5 Diagnosis

Differential diagnoses for CSF include other febrile and/or hemorrhagic diseases of pigs, such as African swine fever and other diseases producing septicemias (e.g., salmonellosis, streptococcosis, pasteurellosis, actinobacillosis, erysipelas, eperythrozoonosis, and *Haemophilus parasuis*), hemorrhage (porcine dermatitis and nephropathy syndrome, hemolytic disease of the newborn, coumarin poisoning, and thrombocytopenic purpura), runting (postweaning multisystemic wasting syndrome, enterotoxicosis, swine dysentery, and campylobacteriosis), abortion (pseudorabies virus, encephalomyocarditis virus infection, porcine reproductive and respiratory syndrome, and parvovirus), and nervous signs (viral encephalomyelitis and salt poisoning).

Pigs suspected with CSFV infection should be confirmed by laboratory tests (virus culture, serology, and molecular techniques). Suitable samples include the tonsils, spleen, lymph nodes, kidney, and blood [32].

Virus isolation is often conducted on porcine kidney cells (i.e., PK 15 and SK6 cells) with clarified organ suspension or with whole blood, buffy coat, plasma, or serum. As CSFV does not produce cytopathic effects, it needs to be confirmed by immunofluorescence or immunoperoxidase tests.

Serology is routinely used for diagnosis and surveillance of CSF as CSFV antigens are detectable 2–15 days postinfection and antibodies are detected in blood 2–3 weeks after infection and as long as animals survive. The commonly used serological assays include virus neutralization tests (VNT), direct fluorescent antibody test (FAT), indirect hemagglutination test, and enzyme-linked immunosorbent assays (ELISA).

VNT is useful for CSF diagnosis. However, because VNT relied on cultured virus for detection, it is time consuming and not routinely applied. FAT provides a rapid way to detect CSFV antigen, although it may cross-react with BVDV of cattle and BDV of sheep, either of which may sometimes infect pigs. Due to its relatively low sensitivity, antigen capture ELISA based on Erns glycoprotein is mainly used for herd checking. ELISA employing E2 glycoprotein is widely utilized to screen for antibodies during and after outbreaks, to monitor CSFV infections in wild boar, and to test coverage of immunization of wild boars after vaccination.

Molecular techniques such as PCR provide the most sensitive method for detection of CSFV both in early infection and for a longer period in recovering pigs [33–41]. Targets for diagnosis of CSF by reverse transcription polymerase chain reaction (RT-PCR) include the 5′ NTR (as exemplified by pestivirus-specific primers 324/326, which amplify a 288 bp fragment), the E2 glycoprotein gene, the NS5B nonstructural protein gene, and the Npro gene [42,43]. In addition, the use of SYBR green and TaqMan probes in real-time RT-PCR allows convenient detection of amplification products and enables improved differentiation of infected from vaccinated animals [44–50].

26.1.6 Treatment and Prevention

No specific treatment is available for CSF, and antibiotic therapy is helpful in relieving symptoms due to secondary bacterial infections.

In case of CSF outbreak, it is important to slaughter all pigs on affected farms, safely dispose carcasses and bedding, disinfect farm equipment and surrounding areas, control pig movements, and trace possible source of infection [51].

Prevention of CSV is achieved by adopting two strategies: nonvaccination stamping out policy and systematic prophylactic vaccination program [52].

Nonvaccination stamping out policy has been successfully applied in Europe that led to the eradication of CSF in most EU countries. However, given the high cost associated with nonvaccination stamping out policy, many other countries utilize systematic prophylactic vaccination program to control and prevent CSF.

Live attenuated vaccines containing the C strain (Chinese strain) is widely used to control the disease in endemic areas. These vaccines are usually produced in primary bovine testicle cells or continuous swine testicle cells and tested for quality and efficacy in rabbits. In comparison with the subunit E2 vaccine that only induces production of an antibody against

Downloaded From Vet-eBooks.com

CSFV, the C-strain vaccine upregulates the antibody level and also activates T-cell responses [53,54]. Pigs often develop protective immunity 1 week to 10 days after vaccination, and the immunity lasts for 2–3 years [55]. Suckling piglets are protected by colostrum from vaccinated sows for about 6–8 weeks, and vaccination may be carried out after 8 weeks [56].

26.2 METHODS

26.2.1 Sample Preparation

Whole blood is collected in 5 mL plastic EDTA tubes, and whole blood for serum is collected in 10 mL plastic blood serum tubes.

RNA may be extracted from whole blood or different fractions of whole blood (WBC, RBC, serum, or plasma) using commercial kits such as QIAamp® Viral RNA Mini kit. Briefly, up to 200 µL sample is added with 20 µL of proteinase K and 200 µL of the kit-supplied AVL lysis buffer supplemented with 28 µg of the kit-supplied carrier RNA. The content is mixed and incubated at 56°C for 15 min to complete cellular lysis. Next, 250 µL of 96%–100% ethanol is added to the crude lysate, and the entire content applied onto the kit-supplied spin column and centrifuged. In subsequent steps, the spin column with bound RNA is washed twice with 500 µL of high-salt wash buffer AV1, once with 500 µL of low-salt wash buffer AV2, and finally with 500 µL of 96%–100% ethanol. The washed RNA is eluted from the column with 50 µL of the kit-supplied elution buffer AVE. An additional washing step between the low- and high-salt washes with a customized high-salt wash buffer consisting of 2 M sodium chloride plus 2 mM EDTA may be also employed to remove PCR inhibitors [57].

About 0.2–0.5 g of tissue samples (tonsil, pharyngeal/mesenteric lymph nodes, spleen, kidney, or distal ileum) are homogenized in 1.5 mL PBS using an Omni-TH Tissue Homogenizer (Omni International), and RNA is extracted from homogenate using the QIAamp Viral RNA Mini kit (Qiagen).

26.2.2 Detection Procedures

26.2.2.1 Conventional RT-PCR

Das et al. [57] described the use of primers (forward: 5′-TGCCCAAGACACACCTTAACC-3′ and reverse: 5′-GGCCTCTGCAGCGCCCTAT-3′) from the highly conserved 5′-untranslated region (UTR) of the CSFV genome for diagnosis of CSF.

RT-PCR mixture (25 µL) is made up of 0.2 µM forward primer, 0.4 µM reverse primer, 1 µL of RT-PCR enzyme mix, 12.5 µL of the kit-supplied 2× buffer, 2.5 µL of template RNA, and nuclease-free water (up to 25 µL).

Thermocycling parameters consist of 1 cycle of RT at 55°C for 30 min, 1 cycle of heat denaturation at 95°C for 2 min, 35 cycles of heat denaturation at 95°C for 5 s, annealing at 60°C for 30 s, and extension at 72°C for 15 s, followed by a final extension of amplification at 72°C for 2 min.

The amplified product is separated by agarose gel, stained and visualized under UV light.

TABLE 26.2
Identity of RT-PCR Primers and Probes

Target	Primer/Probe	Sequence (5′–3′)
CSFV	CSF100-F	ATG CCC AYA GTA GGA CTA GCA
	CSF-Probe 1	FAM-TGG CGA GCT CCC TGG GTG GTC TAA GT-BHQ1
	CSF192-R	CTA CTG ACG ACT GTC CTG TAC
IC	EGFP1-F	GAC CAC TAC CAG CAG AAC AC
	EGFP1-HEX	HEX-AGC ACC CAG TCC GCC CTG AGC A-BHQ1
	EGFP2-R	GAA CTC CAG CAG GAC CAT G

26.2.2.2 Real-Time RT-PCR

Haines et al. [58] employed primers (CSF 100-F and CSF 192-R) and probe (CSF-Probe 1) from the 5′ UTR of CSFV for diagnosis of CSF (Table 26.2). The inclusion of internal control primers (EGFP1-F and EGFP2-R) and probe (EGFP1-HEX) allows monitoring of RNA extraction and amplification efficiency (Table 26.2).

RT-PCR mixture (25 µL) consists of 8.4 µL RNA extract, 12.5 µL 2× reaction mix, 5 mM $MgSO_4$, 5 U RNAsin, 50 nM ROX, and 0.5 U Superscript III reverse transcriptase/Platinum Taq mix, together with 600 nM of CSF100-F and CSF 192-R primers, 200 nM of CSF-Probe, 1, 200 nM of EGFP1-F and EGFP2-R, and 100 nM EGFP-HEX probe.

Amplification is conducted in Mx3005P QPCR System (Agilent Technologies) with the following conditions: RT at 50°C for 15 min, incubation at 95°C for 2 min, then 50 cycles of denaturation at 95°C for 15 s, and annealing and extension at 60°C for 1 min. After amplification, a threshold cycle (C_T) value is assigned to each sample.

Note: This one-step, real-time RT-PCR detects 4.9 copies of CSFV and is suitable for routine diagnosis of CSF.

26.3 CONCLUSION

CSF is a highly contagious viral disease of domestic and wild swine, presenting with acute hemorrhagic fever and respiratory, gastrointestinal, and neurological symptoms, which lead to high mortality and significant loss of productivity. Given the clinical similarities between CSF and other diseases such as African swine fever, it is essential to use laboratory tests to correctly diagnose CSF. While virus isolation and serological assays have contributed greatly to the identification of CSFV in the past, their slow turnover and low sensitivity are increasingly limiting their continued application, especially in a time when frequent international trades and population movements have made it feasible for once-isolated, sporadic cases of infection to rapidly spread to other parts of the world as pandemics. With the capacity to specifically amplify from a single copy of gene fragment, RT-PCR circumvents the shortcomings of virus isolation and serological tests and enables much improved CSFV identification, subtyping, and differentiation of infected from vaccinated animals.

27.1 INTRODUCTION

Louping ill (louping, derived from an old Scottish word "loup," which means to spring into the air, reflecting the key effect of the disease in sheep) is a tick-transmitted viral disease of primarily sheep and occasionally other hosts. The causal agent louping ill virus (or LIV) is a single-stranded positive-sense RNA virus belonging to the *Flaviviridae* family. Affecting the central nervous system (CNS), louping ill (also known as ovine encephalomyelitis, infectious encephalomyelitis of sheep, or trembling ill) is characterized by a biphasic fever, muscular tremors, ataxia (particularly of the hindlimbs), depression, coma, and death. The disease is prevalent in the rough hill grazing land of the British Isles where the sheep tick, *Ixodes ricinus*, is present. However, similar diseases of sheep caused by related viruses have been recently reported in Norway, Spain, Turkey, and Bulgaria.

27.1.1 Classification

LIV is classified within the order *Mononegavirales*, family *Flaviviridae*, and genus *Flavivirus* [1]. Viruses within this genus are transmitted by vectors, particularly arthropods. The most prominent members are transmitted by mosquitoes or ticks. LIV is grouped with the tick-borne viruses and is transmitted by the common sheep tick, *I. ricinus*. It is closely related to tick-borne encephalitis virus (TBEV), which as its name suggests is a collection of viruses transmitted by hard ticks and causes encephalitis [2]. The TBEV complex of viruses has been considered by some authors as forming a single virus species consisting of a number of types [3]. These viruses are found along a global cline coincident with temperate latitudes of the Northern Hemisphere [4]. However, the varying phenotypic properties of the virus and distinct genetic differences suggest that the designation of viruses within the group as species or subspecies is unresolved. It is certainly true that LIV shares many properties with TBEV including a conserved polyprotein 3414 amino acids in length (for detail, see Section 27.1.2), the same tick host, and the causative agent of a febrile illness that can develop into a neurological disease. However, certain features of LIV mark it apart from TBEV. First, and most relevant to this volume, is its virulence for domestic livestock, especially sheep (*Ovis aries*) [5,6] and red grouse (*Lagopus scoticus*), a feature not shared by TBEV. A number of viruses within the TBEV complex share this virulence for sheep and goats including Spanish sheep encephalitis virus (SSEV), Greek goat encephalitis virus, and Turkish sheep encephalitis virus. There have also been reports of encephalitic disease in sheep from Bulgaria. Second, LIV is found almost exclusively in the British Isles, whereas TBEV has never been isolated in these islands, although it is reported throughout continental Europe and Asia. Finally, TBEV causes significant human morbidity and mortality while the zoonotic potential of LIV is limited with most evidence being restricted to serological studies in humans and laboratory-acquired infections [7,8].

27.1.2 Biology and Epidemiology

LIV is exclusively transmitted by life stages of the tick *I. ricinus*. There are three stages to the tick life cycle. The juvenile ticks (larva and nymph) feed on small mammals although it is not certain which species are critical to persistence of LIV, and a recent report has suggested that they may not play a role in LIV transmission as they are not abundant at upland sites [9]. The hare (*Lepus timidus*) is susceptible

Downloaded From Vet-eBooks.com

to LIV infection; although considered a nonviremic host, it is still capable of transmitting the virus [10]. The adult tick feeds on large ungulates such as deer and livestock. The distribution of LIV within the British Isles shows a strong association with areas associated with upland farming of sheep (Figure 27.1). Moorland is particularly favorable for ticks as the thick layer of vegetation provides a humid environment that enables all stages of the tick to avoid desiccation. During spring and autumn, juvenile and adult ticks emerge and climb vegetation in a behavior described as questing. When a suitable mammal passes, the tick clambers onto the host and inserts its mouth parts into the skin. The tick will remain on the host, feeding for a number of days until it becomes fully engorged. If the tick is infected with LIV, this is transmitted to the host. Infection in mammals results in a viremia of short duration and variable level dependent on the host [11]. The highest levels of viremia are observed in sheep. Infection during cofeeding is believed to be more important for infection of ticks, a process where an uninfected tick becomes infected when it feeds in close proximity to an infected tick [12]. From the perspective of diagnosis, blood samples are rarely useful for detection of virus in livestock as the viremia has usually declined to undetectable levels when neurological signs develop and disease is suspected. However, serological testing is useful in confirming recent infection.

Until recent times, LIV was considered exclusive to the British Isles. However, an LIV isolate has been reported in Norway, and recent serological studies suggest that it is cocirculating with TBEV in parts of Southern Norway [13]. A further report of a virus isolated in goats from Spain [14] concluded that this virus was distinct from SSEV and might be LIV, suggesting that the distribution of LIV and closely related viruses that cause encephalomyelitis in ovines is more extensive than previously thought.

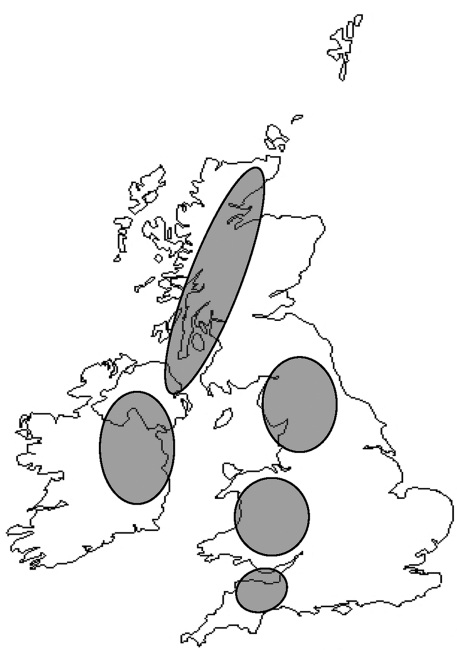

FIGURE 27.1 Map of the British Isles showing main areas where LIV is detected. Shaded area indicates distribution of louping ill disease in the British Isles. These areas correspond closely to upland sheep grazing moors.

27.1.3 Clinical Features and Pathogenesis

Sheep are particularly susceptible to disease following infection with LIV [15]. The early manifestation of infection is pyrexia that is often not recognized in livestock. This often subsides but is then followed by the onset of neurological signs. These include nonspecific behaviors such as panting and nibbling, followed by more overt signs such as circling, unprovoked leaping, and ataxia. There is no effective treatment for infection and, during the later stages, animals become recumbent and some die. Those that survive exhibit sequelae such as torticollis and limb paralysis. Other domestic animals can be infected with LIV including cattle [16], horses [17], and South American camelids [18].

Infection follows the bite of an infected tick. Local replication at the bite site leads to viremia that is associated with fever. In sheep, neuroinvasion is associated with disease signs. The mechanism of entry of LIV into the CNS has not been studied but once within the CNS, extensive virus replication occurs. LIV readily replicates in neuronal cells, and widespread lesions are observed in the brain of infected sheep. Experimental infections have indicated a short incubation period from infection to death of only 9 days [5].

27.1.4 Diagnosis

The primary serological test for LIV infection is the hemagglutination inhibition (HAI) test. This was originally developed by Clark and Casals [19] for investigating a range of arthropod-borne viruses and subsequently adapted by Williams and Thorburn [20] to measure LIV seroprevalence. The method has the benefit that it is not species specific and can be applied to a range of domestic and wildlife species [9]. An alternative to measuring seroprevalance is the plaque reduction neutralization test. This method takes longer to perform, typically 3–5 days, and involves culture of both virus and cells [21]. The serum sample is mixed with a fixed quantity of virus and added to a cell monolayer, then incubated with a gel overlay that restricts the spread of nonneutralized virus. In the presence of virus-neutralizing antibody, the monolayer remains intact, whereas if neutralizing antibody is absent, discrete areas of the monolayer or plaques form.

Until the 1990s, detection of virus itself was limited to immunohistochemical detection in fixed brain tissue or isolation from infected tissue in a cell line such as Vero or porcine kidney cells. The development of a cytopathic effect in the form of cell lysis indicates the presence of a virus. However, confirmation that LIV is the causative agent required further analysis including the molecular detection techniques described in later text.

Downloaded From Vet-eBooks.com

The development of virus-specific detection techniques such as reverse transcription polymerase chain reaction (RT-PCR) has greatly improved the ability to detect and differentiate viruses. RT-PCR has been used to amplify fragments of the LIV genome for the purposes of complete genome sequencing [22,23] and subsequent phylogenetic analysis [24]. Recently, RT-PCR has been used to detect LIV diagnostically. The first RT-PCR assays used for virus detection were developed in the 1990s [25]. This has been updated with a TaqMan real-time assay that rapidly detects virus in mammalian and avian samples, including blood and neurological tissue [26]. An alternative RT-PCR approach is to use degenerate primers, where alternative bases are included at a particular position, capable of amplifying all members of the *Flavivirus* genus. Such universal primer sets have been reported in numerous papers, mainly amplifying conserved region of the NS5 gene. Two methods have been applied to the detection of LIV [27,28]. Complete methodologies can be found in published papers but critical details of each RT-PCR, including primer sequences and amplification conditions, are provided in Table 27.1.

An alternative to RT-PCR is RT loop-mediated amplification, a method for amplifying short specific fragments of RNA that has the benefit that it requires a single temperature. This method has been used extensively to detect both human and animal viruses [29] based on isothermal amplification of target cDNA through binding of a set of 4 primers and the strand-displacement polymerase activity of the enzyme *Bst1*. Reverse transcriptase is included in the reaction to enable RT of the virus genome. Both RT and amplification occur at a single temperature, 65°C. A series of concatenated products are generated that when separated on an agarose gel gives a distinctive "ladder." Six primer sets were designed based on a 200 bp sequence within the LIV NS5 gene. Each was assessed using a small panel of archived LIV isolates. Assays 3 and 4 amplified laboratory isolates from Scotland and Northern England but not from Wales. A further primer set was designed (designated LIV6, see Table 27.2), which amplified isolates from all three regions. A protocol for this technique is provided in Section 27.2.2.

27.2 METHODS

27.2.1 Sample Preparation

The neurological signs characteristic of louping ill reflect infection of the CNS, and virus can be detected throughout the brain and spinal cord [30]. Viral RNA can be extracted using a range of methods, including TRIzol (Invitrogen). Using the TRIzol protocol, a small quantity of brain or spinal cord is homogenized in TRIzol solution and centrifuged with added chloroform. This leads to effective partitioning of RNA in an upper aqueous phase and allows sufficient recovery of total RNA from a sample of ovine spinal cord to sequence a complete LIV genome [23].

TABLE 27.2
LIV Primers for RT-LAMP

Assay	Primers	Sequence (5′–3′)
LIV6	LIV6F3 (outer primer)	GGCCATCTGGTACATGTGG
	LIV6B3 (outer primer)	GCGGTGTCATCATCTGCGTAG
	LIV6FIP (inner primer)	AGTGGAGGAGGAGTTGAGGGGAA TTTTGGCCTCCATTCAAGGTTCAT
	LIV6BIP (inner primer)	GGACTCTCTGGAAGCCCAGTGATT TTGCCGCTTCCTGGAGTTTG

27.2.2 Reverse Transcription Loop-Mediated Amplification (RT-LAMP)

Five μL of extracted RNA are added to LAMP mastermix (GeneSys Ltd) with additional ThermoScript Reverse Transcriptase (Invitrogen) in a total volume of 25 μL. A complete list of the reaction mix is provided in the following:

Isothermal master mix		15 μL
ThermoScript RT		1 μL
Inner primers	LIV6F3 (5 picomoles)	1 μL
	LIV6B3 (5 picomoles)	1 μL
Outer primers	LIV6FIP (50 picomoles)	1 μL
	LIV6BIP (50 picomoles)	1 μL
RNA template		5 μL

The mixture is incubated at 65°C for 60 min in a water bath, heat block, or standard thermal cycler, and the amplification products are detected on an agarose gel. Figure 27.2a shows the result of separate amplification products on an agarose gel stained with DNA-binding dyes (ethidium bromide or SYBR safe, Invitrogen). RT-LAMP positive samples give a distinctive ladder appearance representing the concatenated products of variable length generated by the loop primers during the amplification process.

Alternatively, addition of the intercalating dye, SYBR green, into the master mix enables RT-LAMP products to be detected in real time in a manner similar to real-time RT-PCR (Figure 27.2b). In this case, LIV was detected in RNA extracted from the spinal cord of a ewe with neurological disease. Initial amplification was observed after 10 min and the reaction reached completion by 20 min.

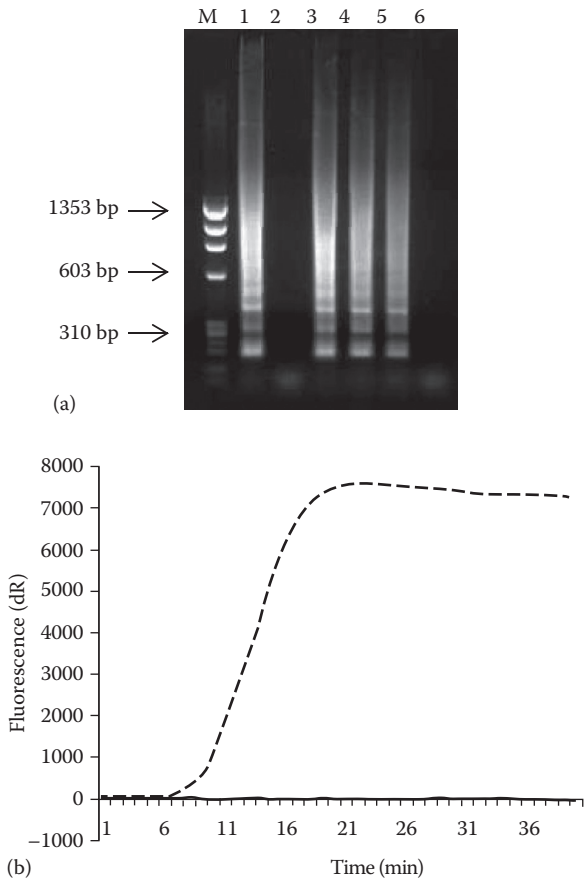

FIGURE 27.2 Detection of LIV RT-LAMP amplification products. (a) Detection of LIV in RNA samples extracted from sheep brain by agarose gel electrophoresis. M, DNA molecular weight markers (ϕx Promega, size of molecular markers are indicated in base pairs—bp); 1, LIV strain LI/31; 2, no template control; 3, LIV isolate Penrith 1 2009; 4, LIV isolate Penrith 2 2009; 5, LIV isolate Aberystwyth 2009; 6, no template control. (b) Detection of LIV RNA extracted from the spinal cord of a ewe (dashed line) using real-time detection. A no-template control has been included for comparison (solid line).

27.3 CONCLUSIONS AND FUTURE PERSPECTIVES

LIV is a neglected disease due to its relative rarity, limited distribution, reduced market prices for sheep, low zoonotic potential, and the availability of an effective vaccine. However, the disease persists and continues to kill hundreds of sheep and grouse every year [15]. Serology, in the form of the HAI test, is still used routinely to confirm the presence of LIV in sheep flocks and has recently been used to suggest the presence of an LIV-related virus in Northern Spain [14]. Immunohistochemistry can also be used to confirm encephalitis and, through the use of specific antibodies, to confirm infection. This and virus isolation in tissue culture are useful but relatively slow, expensive techniques. Methods such as RT-PCR and RT-LAMP have been developed to confirm diagnosis in fallen livestock, particularly sheep, more rapidly. Other livestock species, horses and camelids, are also susceptible to infection in areas where ticks are abundant. A diagnosis of LIV should be considered in these species, especially if there is evidence of neurological disease. RT-PCR has been the method of choice in recent years due to its rapid turnaround time and application for a range of samples (brain, blood). Alternative methods such as RT-LAMP remain at the experimental stage but could in the future be adapted for pen-side methods that could be applied at the farm level.

Downloaded From Vet-eBooks.com

LIV cases within England, Wales, and Scotland are reported every year to the APHA, and there is no evidence that this will decline despite the availability of a vaccine and tick management strategies [31]. Recent seroprevalence studies indicate that the virus also persists in Ireland [32]. This virus will continue to cause disease in livestock for the foreseeable future. Although neglected, LIV continues to present a number of challenges. Its distribution had appeared restricted to the British Isles although there is evidence for its presence in tick populations of Southern Norway [13]. TBEV is present throughout continental Europe but absent from the United Kingdom. The reason for this sharp separation is not clear. Sheep movements are believed to be responsible for the dispersal of LIV to different regions of the British Isles [24]. Such a method may also explain the introduction of the virus from the continent. The recent report of a closely related virus detected in goats in Northern Spain [14] that is distinct from the previously described SSEV [33] may suggest a possible common ancestry for these viruses.

A further question is the varied virulence between LIV and TBEV for ovines and humans, respectively. Despite close examination of the genomes of both viruses and comparative studies in sheep, there is as yet no strong explanation for the differences in pathogenesis between each virus. There have been reported cases of human infection with LIV although these have been rare in recent years. It is possible that this is due to underdiagnosis of human encephalitis. If this is true, then access to rapid detection methods, such as those described in this chapter that can be adapted for both human and veterinary use, will be of great benefit in diagnosing cases of neurological disease.

28.1 INTRODUCTION

West Nile virus (WNV) is a zoonotic pathogen that affects birds, horses, and humans, as well as other vertebrates worldwide. Maintained in a mosquito–bird–mosquito transmission cycle, WNV infection in birds may lead to death within 24 h of symptom onset. In humans and horses, WNV is responsible for causing fever, meningitis, and encephalitis, with long-term sequelae, or death a possibility. Due to its nonspecific clinical presentations, it is vital that specific and sensitive laboratory methods are available and applied for differential diagnosis of West Nile disease. This will help prevent the further spread of this emerging disease.

28.1.1 Classification

WNV is a member of the genus *Flavivirus*, family *Flaviviridae*, which covers monopartite, linear, single-stranded, positive-sense RNA viruses of 9.6–12.3 kb in length. Within the family *Flaviviridae*, four genera are recognized: *Flavivirus*, *Hepacivirus*, *Pegivirus*, and *Pestivirus*. Consisting of >60 viruses, the genus *Flavivirus* is organized into tick-borne viruses, mosquito-borne viruses, and viruses with no known arthropod vector [1].

The tick-borne viruses are further separated into two groups: (1) *mammalian tick-borne virus group* (Absettarov virus, Alkhurma virus, deer tick virus, Gadgets Gully virus, Kadam virus, Karshi virus, Kyasanur forest disease virus, Langat virus, louping ill virus, Omsk hemorrhagic fever virus, Powassan virus, Royal Farm virus, Sokuluk virus, tick-borne encephalitis virus, Turkish sheep encephalitis virus) and (2) *seabird tick-borne virus group* (Kama virus, Meaban virus, Saumarez Reef virus, Tyuleniy virus).

The mosquito-borne viruses are divided into eight groups: (1) *Aroa virus group* (Aroa virus and Bussuquara virus), (2) *dengue virus group* (dengue virus and Kedougou virus), (3) *Japanese encephalitis virus group* (Alfuy virus, Bussuquara virus, Cacipacore virus, Japanese encephalitis virus [JEV], Koutango virus [KOUV], Murray Valley encephalitis virus, Rocio virus, St. Louis encephalitis virus, Usutu virus, WNV, and Yaounde virus), (4) *Kokobera virus group* (Kokobera virus), (5) *Ntaya virus group* (Bagaza virus, Baiyangdian virus, duck egg drop syndrome virus, Ilheus virus, Israel turkey meningoencephalomyelitis virus, Jiangsu virus, Ntaya virus, and Tembusu virus), (6) *Spondweni virus group* (Zika virus), (7) *yellow fever virus group* (Banzi virus, Bouboui virus, Edge Hill virus, Jugra virus, Saboya virus, Sepik virus, Uganda S virus, Wesselsbron virus, and yellow fever virus), and (8) *viruses without known vertebrate host* (Aedes flavivirus, Barkedji virus, Calbertado virus, cell fusing agent virus, Chaoyang virus, Culex flavivirus, Culex theileri flavivirus, Donggang virus, Ilomantsi virus, Kamiti river virus, Lammi virus, Marisma mosquito virus, Nakiwogo virus, Nhumirim virus, Nounane virus, Spanish Culex flavivirus, Spanish Ochlerotatus flavivirus, and Quang Binh virus).

Downloaded From Vet-eBooks.com

Viruses with no known arthropod vector are differentiated into three groups: (1) *Entebbe virus group* (Entebbe bat virus and Yokose virus), (2) *Modoc virus group* (Apoi virus, Cowbone Ridge virus, Jutiapa virus, Modoc virus, Sal Vieja virus, San Perlita virus), and (3) *Rio Bravo virus group* (Bukalasa bat virus, Carey Island virus, Dakar bat virus, Montana myotis leukoencephalitis virus, Phnom Penh bat virus, and Rio Bravo virus).

Composed of a single serotype, WNV is classified into five distinct lineages [2,3]. Lineage 1 consists of two clades: 1a and 1b, with clade 1a including isolates from Africa, Europe, the Middle East, Asia, and the Americas; and clade 1b being represented by the Australian Kunjin virus [4]. Lineage 2 isolates are detected primarily in sub-Saharan Africa and Madagascar, with recent incursions into Europe (Greece, Hungary, and Italy) and Russia [5]. Lineage 3 contains a single isolate from the Czech Republic border region near Rabensburg, Austria [6–8]. Lineage 4 is present in the Caucasus region of Russia. Lineage 5 (formerly clade 1c) is identified in India only [9,10]. Other isolates that may form putative lineages of WNV include KOUV from Senegal, a group of isolates from Spain, and a variant Kunjin virus from Sarawak, Malaysia [11]. It is noteworthy that only lineages 1, 2, and 5 have been associated with significant outbreaks in humans [12].

28.1.2 Morphology and Genome Structure

WNV possesses a spherical virion of about 50 nm in diameter, which is covered by an envelope made up of two viral glycoproteins (envelope protein E and membrane protein M), with the exodomains of envelope (E) protein dimers showing a head-to-tail position on the outer surface of the virion membrane. Beneath the envelope is an icosahedral core (made up of capsid protein C) of 30 nm in diameter that encases a linear ssRNA(+) of approximately 11,000 nt in length [1,13,14].

The genome of WNV contains a single, long open reading frame (ORF) flanked by two untranslated regions (UTR), one each at the 5′ and 3′ ends. The 5′ UTR (of 96 nt in length) carries a methylated nucleotide cap, while the 3′ UTR (of 337–649 nt in length) lacks a polyadenylation tail, but terminates with a conserved CU_{OH} instead. The ORF (of 10,301 nt in length) encodes a polyprotein of 3,430 aa (consisting of C-prM-E-NS1-NS2a-NS2b-NS3-NS4a-NS4b-NS5), which is processed co- and posttranslationally by the viral serine protease complex (NS2B-NS3) and various cellular proteases into 10 mature proteins, including 3 structural proteins (capsid [C], premembrane [prM, which later matures into membrane M], and envelope [E]) and 7 nonstructural proteins (NS1, NS2a, NS2b, NS3, NS4a, NS4b, and NS5) [13,14].

C (123 aa) is a key component of viral capsid. prM (167 aa) acts as a chaperone for envelope protein E during intracellular virion assembly and is cleaved by host furin to release pr peptide and M in the last step of virion assembly. After cleavage of prM, E (417 aa) dissociates from M and homodimerizes. E is involved in binding to host cell surface receptor for virus internalization through clathrin-mediated endocytosis, as well as in membrane fusion between virion and host endosomes [15].

NS1 (352 aa) is a glycoprotein containing three conserved *N*-linked glycosylation sites and multiple conserved cysteines that form disulfide bonds essential for virus viability. NS1 monomers are soluble and hydrophilic while NS1 homodimers associate with membranes. In addition, NS1 may be also secreted by mammalian cells as a soluble hexamer [14].

NS3 (619 aa) comprises a serine protease (175 aa) at its *N*-terminal, which is active only when complexed with NS2B. The NS3-NS2B protease complex cleaves the viral polyprotein at multiple sites. The *C*-terminal domain of NS3 has been shown to possess RNA-stimulated nucleoside triphosphatase, ATPase/helicase, and 5′-triphosphatase activities [14].

NS5 (905 aa) contains an *S*-adenosyl methionine methyltransferase (MTase) domain at its *N*-terminal region, which has both N7 and 2′-*O* MTase activities and also acts as a guanylyltransferase. In addition, NS5 contains conserved sequence motif characteristic of all RNA-dependent RNA polymerases at its *C*-terminal region [14].

On the other hand, NS2a (231 aa), NS2b (131 aa), NS4a (149 aa), and NS4b (256 aa) are small, hydrophobic proteins without obvious enzymatic activities. These proteins facilitate the assembly and/or anchoring of viral replication complexes on the endoplasmic reticulum membrane [14].

28.1.3 Biology and Epidemiology

WNV was first isolated in 1937 from the blood of a febrile patient in the West Nile district of Uganda (currently Nile Province). Subsequently, outbreaks due to this virus were recorded in Israel (1951–1952, 1957 and 1962, 1998–2000), France (1962–1965, 2000), South Africa (1974 and 1983–1984), Algeria (1994 and 1997), Morocco (1996), Romania (1996), Tunisia (1997), and Russia (1999). In 1999, WNV was detected in New York, United States, and soon spread to large parts of America including southern Canada, Mexico, Cayman Islands, Guadeloupe Islands, El Salvador, Cuba, Colombia, and Argentina [12,14–18].

WNV is maintained in nature in an enzootic transmission cycle between wild birds (reservoir) and mosquitoes (vector). Wild birds acquire the virus after being bitten by an infected mosquito belonging to several ornithophilic species of the *Culex* genus (e.g., *Culex pipiens*, *Cx. nigripalpus*, *Cx. quinquefasciatus*, and *Cx. restuans*). Crows and magpies, house sparrows, house finches, and other passerines often develop viremia 2–7 days after infection. WNV may persist in the skin for an undetermined period of time, allowing mosquito vector (e.g., *Aedes vexan* and *Ochlerotatus* spp.) that feed both on birds and mammals to transmit the virus. Significant mortalities due to WNV have been observed in domestic geese, migrating white storks, lappet-faced vulture, and white-eyed gull. In addition, birds may acquire the virus via mosquito-independent transmission such as ingestion of infected mosquitoes, mice, and birds, as well as contaminated water.

WNV can be transported over long distances in migratory birds. Resting in wetland areas, migrating birds may come in

Downloaded From Vet-eBooks.com

contact with the local mosquito species, possibly initiating a local amplification cycle. In temperate regions, the virus may overwinter in female mosquitoes as well as in birds, so there is no need for continuous reintroductions [10].

In the enzootic areas of Europe and North America, WNV infection builds up in wild birds in the spring and early summer, with peak mortality in birds appearing from the midsummer to early fall. One to a few weeks after bird mortality begins, human and horse cases may emerge. The overwintering of the virus in mosquitoes may be another contributing factor for seasonal reemergence of the WNV. The virus can be transmitted vertically from infected female mosquitoes to a small percentage of their eggs, helping virus survival through the winter. However, in the tropics, WNV infection in birds may persist year-round, and recently infected birds migrating north may reintroduce the virus the following spring.

Apart from wild and domestic birds, WNV is infective to humans, horses, rodents, reptilians, and amphibians. In humans, besides mosquito bites, WNV may also be transmitted via transplanted organs, blood transfusions, skin wounds, breastfeeding, or during pregnancy (from mother to child) [19]. In general, humans, horses, and other mammals do not develop a sufficient viremia to allow mosquito infection, and they are considered dead-end hosts for WNV. On the other hand, some infected reptiles and amphibians may develop adequate blood concentrations of virus for mosquito transmission to occur [20].

28.1.4 Clinical Features and Pathogenesis

WNV infection in birds typically lasts a few hours to a few days, with clinical manifestations ranging from nonspecific signs, ocular disease (e.g., anisocoria and impaired vision), lethargy and ruffled feathers, regurgitation of feedstuffs, decreased appetite, complete anorexia, enteritis, decrease in body weight, polyuria and biliverdinuria, external hemorrhage from the mouth or cloaca, dull mentation, unusual posture, inability to hold head upright, torticollis, opisthotonus, seizures, to death (within 24 h of the symptom onset in highly susceptible species, such as corvids). Some parrots may display persistent neurological signs after recovery (e.g., ataxia, tremors, abnormal head posture, circling, and convulsions) [19,21–23].

In horses, the majority of the infections are asymptomatic, and only about 10% of infected horses suffer from a severe neuroinvasive disease that is characterized by encephalitis, paralysis of the limbs, facial tremors, and death (in one-third of the cases). Gross visceral lesions are nonspecific, and the most significant histologic lesions are nonsuppurative meningoencephalomyelitis, particularly in the brainstem and spinal cord (including occasional meningitis, focal spinal ventral horn poliomalacia, dorsal and lateral horn poliomyelitis, leukomyelitis, asymmetrical ventral motor spinal neuritis, and frequent olfactory region involvement). The most significant histologic lesions in this case were nonsuppurative [24–26].

In humans, with an incubation period of 2–14 days, WNV infections may be either asymptomatic (80%) or evolve into West Nile fever (20%) or severe West Nile disease (<1%). The high number of nonsymptomatic cases may increase the risk of WNV transmission through blood donation or organ transplants.

West Nile fever, the mild form of the disease, lasts 3–6 days and may show signs such as fever, malaise, anorexia, nausea, vomiting, eye pain, headache, body aches, myalgia, occasional skin rash (on the trunk of the body), and swollen lymph glands. In a small number of cases (<1%), severe West Nile disease (also called West Nile encephalitis or meningitis or West Nile poliomyelitis) may present with encephalitis, meningitis, and acute flaccid paralysis. Encephalitis due to WNV may show depression, altered levels of consciousness, lethargy, changes in personality, and fever. Typical signs of meningitis consist of headache, fever or hypothermia, rigidity, Kernig (the leg cannot be fully extended in a sitting position) or Brudzinski signs (flexion of the neck leads to flexion of the hip and knee), stupor, disorientation, photophobia, phonophobia, tremors, convulsions, muscle weakness, coma, and paralysis. Fatality rates in patients showing the neurological manifestations may approach 4%–18%, and neurological deficits may linger in this group of patients [19].

Microscopic examination of brains from affected humans reveals the activation of resident microglia; perivascular and parenchymal accumulation of macrophages, $CD4^+$ and $CD8^+$ T cells and B cells; formation of microglial nodules; reactive proliferation of astrocytes; and eventual neuronal cell death [12,27].

28.1.5 Diagnosis

Given the emergence and reemergence of WNV in various parts of the world, and the nonspecific signs induced, it is important that laboratory methods are developed and applied for its identification and surveillance. Virus isolation, serological assays, and nucleic acid detection are excellent examples of laboratory methods that have proven valuable for diagnosis of WNV infection in mosquito, cerebrospinal fluid (CSF), serum, blood, and other specimens.

28.1.5.1 Virus Isolation

WNV can be grown on Vero, RK-13, CHO, ATC-15, and AP61 cells. Typically, aliquots of clarified supernatant of test tissues or serum are inoculated into confluent monolayers and observed daily for evidence of cytopathic effects (CPEs). If CPEs are not evident, serological (indirect fluorescence assay [IFA] with WNV-specific MAbs) or molecular (reverse transcription polymerase chain reaction [RT-PCR]) tests may be performed to confirm the identity. Although virus isolation takes 6 days and requires level 3 biosafety containment and samples of good quality (infectious virus-containing samples), it remains a valuable method for WNV detection in mosquito pools, and vertebrate and avian samples.

28.1.5.2 Serological Assays

Serological assays offer a rapid approach for the diagnosis of WNV infection. Antigens for these assays may be prepared

Downloaded From Vet-eBooks.com

from WNV-infected cell culture (e.g., Vero/C6/CHO/ATC-15 cells) supernatants, WNV-infected suckling mouse brains, or recombinant proteins (e.g., E, DIII of E protein, NS1 and NS3 and NS5, and flavivirus-like particles from prM and E proteins).

Plaque reduction neutralization test (PRNT) at the 90% plaque reduction level offers a confirmation and a titration method of WNV-specific Abs (from serum or CSF). The demonstration of a fourfold increase in Abs titers comparing acute and convalescent sera using PRNT is a clear indication of WNV infection. PRNT is conducted in a biosafety level 3 laboratory. Briefly, heat-inactivated CSF or serum samples are tested at 1:100 final dilution. Equal volume of serum and medium containing 100 plaque-forming units of WNV are incubated for 75 min at 37°C before inoculation onto confluent monolayers of Vero E6 cells grown in 25 cm^2 flasks. After the inoculum is adsorbed for 1 h at 37°C, cells are overlayed with agarose-containing medium and incubated for 72 h at 37°C. Then, a second agarose overlay containing 0.003% neutral red dye is applied to each flask for plaque visualization. After a further overnight incubation at 37°C, the number of virus plaques per flask is assessed. Endpoint titers are determined as the greatest dilution in which >90% neutralization of the challenge virus is achieved. Samples with reciprocal 90% neutralization titers of >10 were considered positive.

Immunohistochemistry (IHC) may be performed on variable tissues and animal tissues, and remains useful for specific confirmation of WNV infection in fatal WN encephalitis cases or in bird disease. The recently improved IFA affords a cost-effective and sensitive detection of both IgM and IgG anti-WNV Abs.

Enzyme-linked immunosorbent assay (ELISA) is currently the mostly widely applied primary screening method for WNV diagnosis. Three types of ELISA are in common use: IgG, MAC-ELISA, and epitope-blocking ELISA. The IgM antibody-capture ELISA (MAC-ELISA) detects early antibodies (IgM), permitting diagnosis of acute infections (sera sampled 8–45 days after infection) from serum or CSF and differentiation between old and recent infections. ELISA and IFA protocols (incorporating urea treatment of antigen–antibody complexes) for determination of IgG avidity help differentiate between recent and past infections. However, IgG ELISA is less specific for arboviral antigen than IgM. Epitope-blocking ELISA is an antibody competition assay that is species independent and has been tested with success in multiple avian species and domestic animals. ELISA has the advantages of being rapid, reproducible, and less expensive than PRNT, IHC, indirect hemagglutination assay (IHA), and IFA. However, it tends to show cross-reaction with other flaviviruses, especially those from the same serocomplex. Thus, confirmation by PRNT is necessary for ELISA-positive sera.

28.1.5.3 Nucleic Acid Detection

Nucleic acid–based techniques such as RT-PCR represent a powerful alternative for WNV detection [28–31]. RT-PCR enables in vitro amplification of WNV RNA from minute amounts of the starting material, in a variety of formats, including (1) standard RT-PCR, (2) nested RT-PCR, (3) multiplex RT-PCR, and (4) real-time RT-PCR [32–37]. To further verify the identity of WNV, the amplified products from the standard or nested RT-PCR protocol can be sequenced. Other nucleic acid detection methods include nucleic acid sequence–based amplification, loop-mediated isothermal amplification, and branched DNA.

RT-PCR has been utilized for the detection of WNV in serum, CSF, fresh tissues, and formalin-fixed human tissues. Briese et al. [38] utilized two primer–probe sets from the NS3 and NS5 protein sequences for real-time RT-PCR detection of 50–100 WNV molecules. Lanciotti and Kerst [39] reported a real-time RT-PCR assay targeting the E gene with a sensitivity of 0.1 PFU of viral RNA. As viremia begins within a few days after the infection and usually precedes the clinical signs, detection of viral RNA provides a clear indicator of recent infection. Nevertheless, viral RNA detection has limited value in late diagnosis since viremia is short lived [40–48].

28.1.6 Treatment and Prevention

Currently, there is a lack of specific treatment for WNV infections in humans and animals. Administration of neutralizing antibody may help alleviate the clinical symptoms of WNV encephalitis in WNV-infected patients, while use of antibiotics reduces the damages caused by secondary bacterial infection.

A number of vaccine candidates with varied efficacy are being developed to prevent WNV infection. These include DNA-based vaccines, live chimeric/recombinant vaccine constructs, live attenuated virus, and inactivated or subunit vaccines. DNA vaccines expressing the prM and Env proteins from WNV or the domain III (DIII) region of the Env protein have been tested in both mice and horses. DNA vaccine constructs encoding for single-round infectious particles or a full-length cDNA copy of the attenuated Kunjin strain of WNV are also being evaluated [49,50].

In the absence of approved vaccines for WNV, vector management remains an important option to prevent and control outbreaks of the disease. Clearly, this requires a strong organizational backbone and coordination between the different stakeholders, skilled technicians and operators, appropriate equipment, and sufficient financial resources [51].

28.2 METHODS

28.2.1 Sample Preparation

WNV RNA may be extracted from blood, tissues, and mosquitoes using either the traditional phenol–chloroform protocol or commercial kits based on a silica gel–based membrane or other principles.

For RNA extraction from mosquitoes using Qiagen RNeasy Kit, pools of 10–50 individual mosquitoes are homogenized in diluent containing 20% fetal bovine serum,

Downloaded From Vet-eBooks.com

50 μg of streptomycin per mL, 50 U of penicillin, and 2.5 μg of amphotericin B per mL in phosphate-buffered saline in a Spex CertiPrep (Metuchen, NJ) 8000-D mixer mill for 3 min. Alternatively, 50 mg (3 by 3 by 6 mm) of vertebrate tissues is homogenized in 700 μL of RNeasy lysis buffer in a Spex CertiPrep 8000-D mixer mill for 3 min. RNA is extracted from 350 μL of homogenized samples. The extracted RNA is eluted in a total volume of 50 μL of RNase-free water.

28.2.2 Detection Procedures

28.2.2.1 Standard RT-PCR

Lanciotti et al. [52] designed a pair of primers (forward: 5′-TTGTGTTGGCTCTCTTGGCGTTCTT-3′, nt 233–257 and reverse: 5′-CAGCCGACAGCACTGGACATTCATA-3′, nt 616–640) from the C-terminal portion of the C gene and the N-terminal part of the prM gene for amplification of a 408-bp fragment from WNV RNA.

28.2.2.1.1 Procedure

1. Standard RT-PCR mixture (50 μL) is composed of 1× reaction buffer, 0.4 mM dNTPs, 0.6 μM primers (forward and reverse), 1× Q solution, and 1 μL of reverse transcriptase-DNA *Taq* polymerase enzyme mix (One-Step RT-PCR Kit, Qiagen), 5 μL of RNA eluate extracted with RNeasy (or 20 μL of RNA eluate extracted with ABI Prism 6700 workstation).
2. The mixture is incubated at 50°C for 30 min to synthesize the first-strand cDNA, at 95°C for 15 min to inactivate the reverse transcriptase and to activate DNA *Taq* polymerase, 35 cycles of 94°C for 45 s, 56°C for 45 s, and 72°C for 1 min for PCR amplification, and a final elongation at 72°C for 10 min.
3. The RT-PCR products (20 μL) is analyzed on a 1.5% agarose gel with TAE buffer and stained with ethidium bromide (0.5 μg/mL).

Note: The sensitivity of this standard RT-PCR can be increased by approximately 10-fold with a nested PCR using internal primer set (forward: 5′-CAGTGCTGGATCGATGGAGAGG-3′, nt 287–308 and reverse: 5′-CCGCCGATTGATAGCACTGGT-3′, nt 370–390) [42]. Briefly, nested PCR mixture (25 μL) is made up of 1× reaction buffer, 0.2 mM dNTPs, 0.3 μM inner primers, 1 μL of first round RT-PCR template (diluted 10,000-fold), and 0.625 U of *Taq* DNA polymerase (the *Taq* PCR Core Kit, Qiagen). The mixture is subjected to an initial 94°C for 3 min; 22 cycles of 94°C for 45 s, 58°C for 45 s, and 72°C for 1 min; and a final 72°C for 10 min. The resulting product (15 μL) is analyzed on a 1.5% agarose gel.

28.2.2.2 Real-Time RT-PCR

Jiménez-Clavero et al. [44] described a real-time RT-PCR protocol based on a 5′-Taq nuclease-3′ minor groove binder DNA probe (TaqMan MGB) for the detection of WNV lineages 1 and 2. The primers and probe set are directed to a highly conserved sequence within the 3′ NC region of the WNV genome. A second TaqMan MGB probe detects WNV lineage 2 isolates whose genomes differ in two nucleotide positions from lineage 1 genomes (Table 28.1).

28.2.2.2.1 Procedure

1. WNV is grown in Vero cells or baby hamster kidney-21 cells. Viruses are titrated by a standard limiting dilution assay. Viral RNA is extracted from the clarified supernatants of virus cultures, or 0.1 mL suspensions of the lyophilized infected plasma using High Pure Viral Nucleic Acid Extraction Kit.
2. The TaqMan MGB-RRT-PCR mixture (25 μL) is composed of 2 μL of isolated RNA, 12.5 μL of 2× QuantiTect Probe RT-PCR Master Mix, 0.625 μL of QuantiTect RT Mix, 0.4 μM of WNV-specific primers (WN-LCV-F1 and WN-LCV-R1), and 0.25 μM of the fluorogenic TaqMan probes (WN-LCV-S1 and WN-LCV-S2) and is RNase free.
3. The mixture is subjected to an RT step at 50°C for 30 min, a hot start at 95°C for 15 min, and 45 cycles of 95°C for 15 s and 60°C for 1 min using Smart Cycler II equipment and software.

Note: The assay detects WNV isolates belonging to lineage 1 with clade 1a and clade 1b (Kunjin) as well as lineage 2 (B956) with a sensitivity of 0.01–0.001 pfu/tube. Performed in 96-well format, this assay is suitable for the large-scale surveillance of areas where both WNV lineages 1 and 2 exist or potentially spread. By contrast, the TaqMan RRT-PCR of Lanciotti and Kerst [39] using 3′ NC primers and probe set and tetramethylrhodamine as a quencher detects only lineage 1 clade 1a isolates, and not Kunjin (clade 1b) and B956 (lineage 2).

TABLE 28.1
TaqMan Minor Groove Binder Real-Time RT-PCR Primers and Probes

Primer/Probe	Sequence (5′–3′)	Nucleotide Positions	Specificity
WN-LCV-F1	GTGATCCATGTAAGCCCTCAGAA	10,597–10,619	
WN-LCV-R1	GTCTGACATTGGGCTTTGAAGTTA	10,649–10,672	
WN-LCV-S1	FAM-AGGACCCCACATGTT-MGB	10,633–10,647	WNV lineage 1
WN-LCV-S2	FAM-AGGACCCCACGTGCT-MGB	10,633–10,647	WNV lineage 2

Downloaded From Vet-eBooks.com

28.2.2.3 Phylogenetic Analysis

Bakonyi et al. [53] employed a universal JEV group–specific primer pair from the NS5 and 3′ UTR (forward primer: 5′-GARTGGATGACVACRGAAGACATGCT-3′ and reverse primer: 5′-GGGGTCTCCTCTAACCTCTAGTCCTT-3′) for RT-PCR amplification followed by sequencing for phylogenetic analysis of WNV isolates.

28.2.2.3.1 Procedure

1. Brain specimens from diseased goose and goshawk are homogenized in ceramic mortars by using sterile quartz sand, and the homogenates are suspended in RNase-free distilled water. Samples are stored at −80°C until nucleic acid extraction.
2. RT-PCR mixture (25 μL) is composed of 5 μL of 5× buffer (final $MgCl_2$ concentration 2.5 mmol/L), 0.4 mmol/L of each dNTP, 10 U RNasin RNase Inhibitor (Promega), 20 pmol of the genomic and reverse primers, 1 μL enzyme mix (containing Omniscript and Sensiscript RTs and HotStarTaq DNA polymerase) (One-Step RT-PCR Kit, Qiagen), and 2.5 μL template RNA.
3. RT is carried out at 50°C for 30 min, followed by denaturation at 95°C for 15 min. The cDNA is then amplified in 40 cycles of 94°C for 40 s, 57°C for 50 s, and 72°C for 1 min. The reaction is completed by a final extension at 72°C for 7 min.
4. After RT-PCR, 10 μL of the amplicon is electrophoresed in a 1.2% TAE agarose gel at 5 V/cm for 80 min. The gel is stained with ethidium bromide and bands are visualized under UV light and photographed. Product sizes are determined with reference to a 100 bp DNA ladder (Promega).
5. The PCR products of the expected sizes are excised from the gel, and the DNA is extracted by using the QIAquick Gel Extraction Kit (Qiagen). Fluorescence-based direct sequencing is performed in both directions on PCR products using the ABI Prism Big Dye Terminator Cycle Sequencing Ready Reaction Kit (Perkin-Elmer) and an ABI Prism 310 Genetic Analyzer (Perkin-Elmer). Nucleotide sequences are identified by basic local alignment search tool (BLAST) search against gene bank databases.

28.3 CONCLUSION

WNV is a flavivirus with the capacity to induce significant mortality in birds and horses as well as long-term sequelae and occasional death in humans. Diagnosis of West Nile disease has previously relied on virus isolation and serological assays. Due to the lengthy time and specialized skills required for conducting these tests, nucleic acid detection methods, especially RT-PCR, have been developed as rapid, specific, and sensitive alternatives for improved identification and typing of WNV. Being amenable to automation, RT-PCR provides a complete solution for nucleic acid extraction, amplification, and product detection, thus dramatically increasing the throughput and versatility of diagnosis, especially for the confirmation of a recent infection. Surveillance and preventive measures are an ongoing need to reduce the public health impact of WNV in areas with favorable transmission conditions.

29.1 INTRODUCTION

29.1.1 Classification, Morphology, and Genome Organization

29.1.1.1 Classification

The family *Togaviridae* is comprised of four genera: *Alphavirus* (26 species), *Rubivirus* (1 species), *Pestivirus* (3 species), and *Arterivirus* (1 species) [1,2]. The alphaviruses include at least seven antigenic complexes, two of which will be reviewed in this chapter: Western equine encephalitis virus (WEEV) and Eastern equine encephalitis virus (EEEV), and five others—the Middelburg virus, Ndumu virus, Semliki Forest virus, Venezuelan equine encephalitis virus (VEEV), and Barmah Forest virus [3]. EEEV is the sole species in the EEEV antigenic complex. North and South American antigenic varieties can be distinguished serologically [4], geographically, epidemiologically, ecologically, genetically, and by level of pathogenicity. In view of clear biologic and genetic differences, South American EEEV was recently reclassified as a separate species named Madariaga virus (MADV) [5]. North American EEEV (Lineage I) is found mainly in the Eastern United States, Canada, and the Caribbean Islands [6], and the isolates form a highly conserved lineage. In addition to MADV, there are old reports of EEEV isolations made in the Philippines, Thailand, the Asiatic region of Russia, and the former Czechoslovakia [7].

The WEEV complex forms a monophyletic group and includes the prototype virus, WEEV, as well as Buggy Creek virus, Fort Morgan virus (FMV), and Highlands J virus (HJV) in North America, Aura virus in South America, and Sindbis virus (SINV) and Whataroa viruses in the Old World. The Aura virus is most distant by neutralization test [8]. HJV is the sole representative of this complex on the East Coast of the United States, while WEEV complex viruses have not been reported in tropical regions of Central America. Genetic variations among selected WEEV strains isolated in California since 1938 were analyzed by sequencing the E2 protein, leading to the identification of four major lineages [9]. Apparently, WEEV arose by a single recombination event within the E3 gene between a member of the EEEV lineage and the SINV lineage approximately 1300–1900 years ago (Figure 29.1) [10]. The envelope glycoproteins and a portion of the 3′ nontranslated region were derived from a SINV-like ancestor, while the capsid and nonstructural proteins were derived from the EEEV ancestor. Aura virus, a New World member in the WEEV complex, SINV, and Whataroa virus are not recombinants.

SINV, sindbis virus; EEEV, eastern equine encephalitis virus. (Adapted from Hahn, C.S. et al., *Proc. Natl. Acad. Sci. USA*, 85, 5997, 1988. With permission.)

WEEV strains can be divided into high-virulence and low-virulence pathotypes following intranasal [11] and subcutaneous [12,13] infection of mice, and these differences correlate with amino acid differences concentrated in the structural genes. It has been hypothesized that epizootics may arise by mutation of avirulent strains circulating enzootically [14].

29.1.1.2 Morphology and Genome Organization

All alphaviruses are similar on a molecular level, both structurally and functionally. The virion is roughly spherical, enveloped, 65–70 nm in diameter, and has icosahedral symmetry. The virion has an outer glycoprotein shell surrounding a host-derived lipid bilayer and a core consisting of the viral RNA, complexed with the capsid protein. The genomic RNA is single-stranded, positive-sense, nonsegmented, capped on the 5′ end, and polyadenylated on the 3′ end. The length of the complete genome is approximately 11.7 kb, not including the cap and tail, the latter regions averaging approximately 70 nucleotides. The RNA is infectious and can initiate replication in a susceptible cell [15]. When released into the cytoplasm of the host cell, the 49S RNA serves as messenger for translation of three of the four nonstructural proteins and template for transcription of replicative intermediate RNA. The genome contains two open reading frames. The nonstructural proteins (nsP1, nsP2, nsP3, and nsP4) are translated directly from the 5′ two-thirds of the genomic RNA, and the structural proteins at the 3′ end by a subgenomic mRNA, 26S RNA. A junction region is situated between the structural and nonstructural regions [16]. There are four nonstructural proteins: nsP1, nsP2, nsP3, and nsP4; the structural proteins include the capsid, E3, E2, and E1. The latter two proteins are glycoproteins that form a functional dimer on the envelope of the virus [17] and a heterodimer in the infected cell [18]. E2 contains the major neutralization epitope [19], while E1 contains the major fusion activity [20]. Replication takes place in the cytoplasm of the infected cell.

29.1.2 Biology and Epidemiology

Passerine birds are the predominant vertebrate hosts for WEEV and EEEV, leading to widespread geographic distribution; but otherwise, WEEV and EEEV differ antigenically and ecologically. The first report of an epizootic of equine encephalomyelitis dates back to 1831 when more than 75 horses died in Massachusetts [21]. During a major equine outbreak of the disease in coastal areas of Delaware, Maryland, New Jersey, and Virginia in 1933, the virus was isolated from horses for the first time [22].

Studies in the 1930s showed that mosquito species including *Aedes*, *Culex*, and *Coquillettidia* were capable of transmitting EEEV from one vertebrate to another [23–25]. An outbreak of human disease in 1938 resulted in 30 cases of fatal encephalitis in children living in the Northeastern United States, where a concurrent outbreak was occurring in horses. During this outbreak, EEEV was isolated from the central nervous system (CNS) of humans [26,27]. In 1949, for the first time, the virus was isolated from a naturally infected mosquito (*Coquillettidia perturbans*) in Georgia and shortly thereafter in Louisiana from *Culiseta melanura*, the most common mosquito vector of EEEV [28,29]. In the 1930s outbreaks, there was a suspicion that birds were involved in the transmission cycle, and finally the virus was isolated for the first time from a wild bird in 1950 [30]. Since then it has been shown that many birds are susceptible to EEEV infection [31] and outbreaks of encephalitis have been recorded in pigeons (*Columba livia*) and exotic birds such as pheasants, Pekin ducks (*Anas platyrhynchos domestica*), and chukars (*Alectoris chukar*) [32–35], among others.

In North America, EEEV is found mainly in the eastern half of the United States with most transmissions occurring near freshwater hardwood swamps in states along the Atlantic seaboard and the Gulf Coast, and in the Great Lakes region [36,37]. Between 1964 and 2007, approximately 254 EEEV infections were confirmed in the United States [38]. The greatest numbers of these cases occurred in Florida, Massachusetts, Georgia, and New Jersey. The virus also has been isolated from mosquitoes in other eastern and central states [39–42] (see Figure 29.2) and in South America.

In most northern states, cases of EEE in horses and humans occur in the period between July and October [43], and in Florida, they occur year-round, but mainly between

May and August. Generally, wild birds, pheasants, or horses are infected prior to human infections. Epizootics occur every 5–10 years when populations of epizootic and enzootic mosquito vectors increase [36,44,45].

EEEV is rural in distribution and virus activity is generally observed in forests and wetlands. In North America, the main transmission cycle involves *Cs. melanura* as the principal endemic vector [46–48] and possibly the overwintering host, and passerines, wading birds, and starlings as primary amplifying hosts [47,49,50]. Humans, equines, and other small mammals and domestic fowl are dead-end hosts because, in general, viremia in these hosts is not high enough to infect mosquitoes. However, in South America, MADV, which cycles between small mammals and mosquitoes, does mount a high enough viremia to infect mosquitoes [4]. This virus has been isolated primarily from *Culex* mosquitoes, and even though in certain areas mosquito surveillance suggests enzootic circulation and the seroprevalence is reported as being fairly high, human disease is very rare [51–53]. It has been hypothesized that the paucity of human disease due to MADV in South America is a result of South American strains not being highly pathogenic [54].

The first epizootic of WEE was noted in the United States in 1912 when 25,000 horses died from encephalitic disease in the Central Plains [55]. At this time, intermittent activity had been observed in the plains and agricultural regions of Western and Central United States and across South-Central Canada from approximately Lake Superior to the Rocky Mountains, as well as British Columbia [56]. The causative agent, WEEV, was first isolated in 1930 from a horse (*Equus caballus*) in Merced County, California, during an epizootic that infected approximately 6000 animals with a 50% case fatality rate [57]. Most WEEV activity is found within the range of *Culex tarsalis*, but the virus also can be isolated in Central and South America [58] (Figure 29.2).

The first human isolate was made in 1938 from the brain of a fatal case in a child [59]. The incidence of WEE in humans and equids peaked during the mid-twentieth century. Major human epidemics occurred between the Mississippi River delta and the Rocky Mountains, where the June isotherm is higher than 21.1°C. In the subsequent decades, the number of human cases declined to fewer than one to two annually, with no cases detected since 1994. Using a mouse model, there is no evidence of change in virulence of the virus suggesting that ecological factors affecting the exposure of humans and horses are more likely the cause for the decline in cases [12]. Greater adoption of personal protective measures or increased use of air-conditioning may have contributed to the drop in cases [60]. Development of vector control programs and widespread use of an equine vaccine are responsible as well for decreased infection rates in equines and humans.

WEEV is maintained in an enzootic cycle generally between *Culex tarsalis* mosquitoes and songbirds, especially finches and house sparrows, in agricultural regions of North America, but the transmission cycle has not been well characterized in South America. A late season enzootic cycle between *Aedes melanimon* and black-tailed jackrabbits has been observed [61]. Equines and humans are dead-end hosts in that they do not mount sufficiently high viremias to infect mosquitoes. It is not definitively known how the virus overwinters, but genetic analyses of isolates from California over time and space suggest the virus most likely is maintained in separate geographic areas of the state through local persistence in enzootic foci [9].

HJV, an east coast member of the WEEV complex in the United States, has a natural cycle and geographic distribution similar to that of EEEV and is transmitted by *Cs. melanura* mosquitoes to songbirds in freshwater swamps. However, unlike EEEV and WEEV, HJV does not generally cause disease in horses and is not known to have been a significant causative agent of disease in humans. However, in the past, some cases of HJV in the Eastern United States may have been mistakenly identified as WEEV [62]. FMV, transmitted between cliff swallows (*Petrochelidon pyrrhonota*) and house sparrows (*Passer domesticus*) that occupy nests in swallow colonies, and cimicid bugs (Hemiptera, *Cimicidae*, *Oeciacus vicarius*), has been detected only in western states of the United States, specifically CO, SD, WA, and western TX, but is most closely related to HJV serologically [63]. Both these viruses, when unpassaged, are attenuated in infant mice, and mammals in general. The Buggy Creek virus has the same ecological niche as FMV and is closely related genetically [64]. It appears from phylogenetic analysis that they may be strains of the same virus [65].

29.1.3 Clinical Features and Pathogenesis

As their name suggests, WEEV and EEEV cause encephalitis in humans and horses although their virulence and incidence vary. The case fatality rate of WEEV in horses ranges from 3% to 50%, while that of EEEV is estimated at 70% to 90% [66]. Horses infected with EEEV or WEEV may or may not show symptoms. In symptomatic cases, infection with either virus begins with fever, dullness, lethargy, and loss of appetite followed by various degrees of excitability and rapidly progresses to drowsiness, apparent blindness, nystagmus, head pressing, circling, ataxia, paresis, depression, seizures, and coma in fatal cases [36]. Neurological sequelae are common in surviving horses infected with EEEV [46].

Emus (*Dromaius novaehollandiae*) [67], ostriches (*Struthio camelus*), whooping cranes (*Grus americana*) [68], and swine (*Sus domesticus*) can also be infected with EEEV/WEEV and develop clinical disease. However, the infections in these species may present with prominent abdominal visceral lesions such as hemorrhagic enterocolitis and splenic and hepatic necrosis resulting in hepatitis and/or gastrointestinal tract disease, rather than encephalitis. Pheasants (*Phasianus colchicus*) and emus are particularly susceptible to EEEV infections [69,70]. In emus, EEEV causes multiple organ hemorrhage, hepatocellular necrosis, lymphoid necrosis, and necrotizing vasculitis in the spleen, as well as necrosis of endothelial cells [67,69]. Necrosis of the liver, lung, spleen, intestines, kidney, lung, adrenal gland, and gonads is observed in infected whooping cranes [68]. Experimentally infected

Downloaded From Vet-eBooks.com

starlings are more susceptible to EEE-related deaths with a mortality corresponding to peak viremia [49]. Mortality in whooping cranes, house sparrows (*Passer domesticus*), cowbirds (*Molothrus ater*), grackles (*Quiscalus quiscula*), and red-winged blackbirds (*Agelaius phoeniceus*) is relatively high, whereas the bobwhite quail (*Colinus virginianu*) and white-throated sparrows (*Zonotrichia albicollis*) have a high survival rate [68,71]. Songbirds are the enzootic vertebrate hosts of EEEV in North America where significant mortality is observed among penned exotic game birds [47,72]. Among birds, younger cases have a greater cerebral tissue sensitivity to the virus, are more viremic, and are therefore more susceptible to CNS disease.

Natural EEEV infection has been reported in cows, sheep, dogs, and white-tailed deer [41,73–75]. In sheep, front limb incoordination progressed to paralysis of the front and hind limbs within 2 days. The clinical signs in sheep are similar to that of horses except that the reported sheep remained alert until euthanized whereas horses are generally dull and somnolent [74]. In dogs, it appears that the disease first manifests with pyrexia, anorexia, and diarrhea and rapidly progresses to clinical signs including recumbency, nystagmus, depression, and seizures [75]. Multiple EEEV-infected white-tailed deer displayed various combinations of clinical signs including head tilt, ataxia, confusion, circling, blindness, prostration, dyspnea, and emaciation [41]. The differences in pathologic manifestations of virus infection in different species include genetic differences in susceptibility to infection and immunologic response to viral infection, exposure to different viral strains that vary in pathogenicity, naiveness to viral infection, and differences in exposure to infected vectors due to variations in weather, habitat, and ecology.

Although not extensively studied, there are some recent investigations of EEE and WEE in animals. The pathogenesis of EEE and WEE, similar to other alphavirus encephalitis cases, appears to be characterized by three phases: an initial peripheral phase of virus replication and spread, the neuroinvasion phase, and a terminal CNS phase in which the virus spreads within the brain, infects primarily the neurons, and results in an often fatal neurodegenerative state [76]. Neuroinvasiveness and encephalitis of EEEV have been studied in murine and hamster models [77]. It appears that the virus invades the CNS of infected animals via infected leukocytes or the vascular route by passive transfer across the blood–brain barrier [77]. Young mice infected with EEEV develop a biphasic disease course with initial viral replication in peripheral tissues followed by viremia, widespread infection of neurons, CNS invasion, and encephalitis characterized by seizures [77]. In mouse brain, there is widespread neuronal necrosis, rarefaction of the adjacent neutrophil in the gray matter, and some white matter tracts. Outside the brain, EEEV also targets fibroblasts, skeletal muscle, and myocytes, osteoblasts, ovarian stromal cells, and keratinocytes, among other cells. In the hamster model, neurons are the main viral target in the brain and the first antigen positive neuronal cells are in the basal ganglia and brainstem with the virus subsequently infecting periventricular and perivascular neurons and the hippocampus [78]. In horses, both the cerebellum and brainstem are affected. The inflammatory cell infiltrate consists of neutrophils, lymphocytes, macrophages, and plasma cells scattered throughout the gray and white matter or arranged in perivascular cuffs [79]. Additionally, multifocal hemorrhage, vasculitis, and meningitis have been identified [79]. Nonsuppurative encephalitis and vasculitis have been noted in birds. In sheep, lesions were observed in both grey and white matter and consisted of multifocal glial nodules, neuronal necrosis, neuronophagia, perivascular cuffing, and multifocal lymphocytic meningitis [79]. In dogs infected with EEEV, the gray matter of the cerebral cortex and midbrain shows random distribution of perivascular cuffs of lymphocytes, plasma cells, and a few histiocytes and neutrophils [75].

Experimental infection of cynomolgus macaques (*Macaca fascicularis*) with EEEV resulted in elevated serum levels of blood urea nitrogen, sodium, and alkaline phosphatase, and prominent leukocytosis. The leukocytes were primarily granulocytes [80]. In addition, the onset and severity of neurological signs were similar to what is seen in human EEEV cases and also in cynomolgus macaques experimentally infected with WEEV [80,81].

In mouse models of WEE, virulent viral strains caused histological lesions in the brain characterized by laminar or multifocal neuronal necrosis, edema, mild infiltrates of lymphocytes in the meninges and subependymal areas, and occasional fibrin thrombi [13]. Less virulent strains caused limited neuronal necrosis and exhibited glial nodules and perivascular cuffs [13]. In adult hamsters infected with WEEV, lethal disease was characterized by tachypnea, conjunctivitis, incoordination, and seizures [82]. Encephalitis affecting all parts of the brain, especially the olfactory regions, was accompanied by high titers of virus in the brain. Neuronal necrosis, infiltration of meninges by lymphocytes, astrocytosis, microgliosis, hemorrhage, and spongy degeneration was observed in brain lesions [82]. Neurologic disease caused by WEEV has been reported in turkeys, emus, and an opossum [83–85]. In emus, clinical signs varied from mild to severe and included anorexia, lethargy with sternal recumbency, ataxia, muscle tremors, head tilt, unnatural positioning of the head on the back, acute onset of paralysis, and lateral recumbency with paddling [84].

29.1.4 Diagnosis

The diagnosis of EEE and WEE is challenging because the clinical signs of the diseases are nonspecific and any of a panel of viral and nonviral agents could be responsible [86]. However, accurate diagnosis is important because although there is no specific treatment available, steps can be taken (e.g., vaccination and vector control) to prevent further spread of disease. Furthermore, surveillance in animals is helpful in preventing spread to humans as frequently animal infections foreworn infections in humans.

The diagnosis of disease in animals is generally based on clinical history, serological testing, virus isolation, molecular testing, and identification of characteristic histopathological changes in the brains of infected animals.

29.1.4.1 Conventional Techniques

The identification of alphaviruses including EEEV and WEEV has traditionally been achieved by inoculation of cell culture or suckling mouse brain and identification of the specific isolate using immunofluorescence assays.

29.1.4.1.1 Virus Isolation

Virus isolation is generally performed on Vero cells since the cell line is easy to culture and most arboviruses can be amplified on these cells. Virus-positive samples are identified further by indirect immunofluorescence assay and/or reverse transcription-PCR (RT-PCR) [87]. EEEV is a select agent and also requires BSL-3 containment. Many diagnostic laboratories are therefore not equipped to isolate EEEV. In animals as well as humans, cells in several organs are infected with EEEV. However, the CNS tissue remains the target tissue for virus isolation and immunohistochemical evaluation.

29.1.4.1.2 Enzyme Immunoassay

The enzyme immunoassay (EIA) procedure is a simple, rapid, and accurate assay for the detection of EEEV antigen in mosquito pools and blood and brain specimens from infected birds [88,89]. For EEEV detection, the protocol involves coating plates with polyclonal mouse EEE-specific capture antibody, addition of blocking solution followed by addition of the test specimen. If there are EEE-specific antigens present in the specimen, they will bind to the polyclonal capture antibody. The addition of polyclonal rabbit EEE-specific detection antibody and goat anti-rabbit IgG conjugated to enzyme followed by a substrate will complete the reaction. During the first 24 h after an infection, virus isolation is more sensitive than an EIA. However, 24 h or longer after infection, the EIA is more sensitive in identifying infected birds [89].

The IgM antibody capture ELISA (MAC-ELISA) test was developed to specifically detect IgM antibody, which is produced early in an immune response [90] and is therefore a valuable method for detecting acute infections. MAC-ELISA assays have been developed for the detection of EEEV and WEEV [91], and the versatility of the assay lends itself to combining multiple assays [92].

Interpretation of serological results based on one serum specimen is difficult without a supporting clinical history or if an animal has been vaccinated.

29.1.4.1.3 Immunohistochemical Assay

Virus antigen can be detected in fresh or formalin-fixed paraffin-embedded tissue using immunohistochemical staining. The assay requires antibody to EEEV antigen, serum-blocking solution, biotinylated secondary antibody, enzyme conjugate, and substrate/chromogen mixture and slides can be examined via light microscopy [79].

29.1.4.1.4 Plaque Reduction Neutralization Test

The plaque reduction neutralization test (PRNT) is considered the gold standard procedure for the identification of arboviral antibody, and protocols are well established [93,94]. The test can help to distinguish false-positive results arising from ELISAs and other serologic assays. The disadvantage of performing PRNTs is that they have a long turnaround time, they are labor intensive, and a live virus is needed for the procedure, and this is a problem for performing testing for EEEV because, as previously discussed, this virus has to be handled in a BSL-3 containment facility with select agent security. Some of the latter issues can be overcome by using attenuated chimeric viruses with equivalent antigenic makeup in a relatively benign backbone such as that of SINV [95].

29.1.4.2 Molecular Techniques

The detection of viral nucleic acid in serum or cerebrospinal fluid has been increasingly used in recent decades for alphavirus diagnosis. The detection of nucleic acid is only effective during the viremic phase of the disease, which generally lasts 3–5 days. As the immune response develops and the virus is cleared, it becomes difficult to detect an infection by molecular methods, and therefore after the viremic phase, a negative result using a molecular test is not an indication of absence of a particular infection.

Various molecular methods including PCR and real-time PCR have been used for the detection of EEE and WEE viruses. The advantages of using molecular methods such as PCR are their superior speed, sensitivity, and specificity. The disadvantages are that virus will only be detected during the viremic stage, as discussed previously, and that depending on the primers used, different strains of the viruses may not be detected. For this reason, primers and probes should be designed in conserved regions of the genome. Even so, viral genomes, especially those of RNA viruses, mutate, thus making assay design challenging.

One strategy for ruling in or ruling out alphavirus infection is to perform a genus-specific RT-PCR assay followed by species-specific RT-PCR or sequencing to determine the species. Pfeffer et al. [96] developed an alphavirus genus-specific seminested RT-PCR assay, which targets the NSP1 gene. An alternative generic nested PCR assay targeted the NSP4 gene and was followed by sequencing to detect and identify members of the *Alphavirus* genus [97]. Of late, a generic alphavirus diagnostic assay has been developed that includes more recently identified alphavirus strains and targeted the NSP4 region of the genome [98]. The limit of detection for the assay was 50 gene copies for EEEV and 5 gene copies for WEEV [98].

In the 1990s, several PCR assays for the detection of EEE and WEE viruses were designed, but they were unable to distinguish between closely related heterologous alphaviruses [99–101]. A more sensitive and specific RT-PCR assay was developed that targeted the E2 gene of EEEV and WEEV [102]. The EEE RT-PCR assay was a nested PCR assay and detected approximately 30 RNA molecules, and the WEE assay was a seminested PCR assay that detected approximately 20 RNA molecules [102].

Real-time RT-PCR assays have been developed for the detection of alphaviruses. Real-time RT-PCR assays are rapid and have improved sensitivity compared to traditional methods such as conventional PCR, IFA, ELISA, and

Downloaded From Vet-eBooks.com

virus isolation. In addition, multiplexing is possible as different target sequences can be detected simultaneously using several fluorophores within the same reaction. Despite the possibility for multiplexing, in general, real-time RT-PCR diagnostic assays for WEEV and EEEV are not multiplexed together as the two viruses occur in geographically distinct areas, which do not overlap. One of the exceptions is a duplex real-time PCR assay targeting the NSP3 sequence of WEEV and the E3 sequence (encoding an envelope protein) of EEEV, which was developed in China [103]. The assay had a sensitivity of one copy/reaction for each virus, which was 10 times more sensitive than virus isolation [103]. No cross-reaction was observed against other encephalitic viruses including the Japanese encephalitis virus, tick-borne encephalitis virus, Chikungunya virus, dengue virus (DENV), yellow fever virus, and Saint Louis encephalitis virus (SLEV) [103].

The emergence of the West Nile virus (WNV) in the United States in 1999 led to the development of a multiplex nested RT-PCR assay to detect EEEV and WNV in horse tissue and tissues of other mammalian and bird species [104]. The primers targeted the highly conserved E2 region of EEEV and resulted in the amplification of a 565 base pair (bp) followed by a 140 bp region, which could be detected by gel electrophoresis [104]. The assay was 100-fold more sensitive than cell culture and did not cross-react with the related alphaviruses WEEV or VEEV [104].

In 2003, a comparison of three molecular methods showed that nucleic acid sequence-based amplification (NASBA), standard RT-PCR, and TaqMan real-time PCR were all useful in detecting WEEV and EEEV in mosquito and vertebrate tissue samples [105]. All three methods were shown to be reproducible and specific with the TaqMan assay being the most sensitive, followed by the NASBA assay [105]. It should be noted that sensitivity was determined using plaque forming unit (pfu) values rather than copy number and is therefore not entirely accurate. With a turnaround time of 4 h, both the TaqMan and the NASBA assays are rapid, especially compared to traditional methods of virus isolation and immunofluorescence, which can take approximately 1 week to complete [105]. In 2011, the EEEV TaqMan assay failed to detect four isolates of EEEV in Connecticut due to mutations in the probe binding sites, indicating that a single nucleotide substitution within the probe binding site may lead to TaqMan assay failure [106]. In order to improve the reliability of molecular detection of rapidly evolving viruses, it is therefore advantageous to develop multitarget TaqMan assays and create backup targets for virus detection. In addition, assays should be continually monitored and redesigned if mutations in viral targets arise too frequently [106].

A multilocus RT-PCR assay for the detection of New and Old World alphaviruses was reported in 2007 [107]. The resultant amplicons were analyzed by electrospray ionization mass spectrometry and base compositions of the amplicons were used to assign the viral subtype [107]. This assay is an accurate, rapid, high-throughput assay that can be used for surveillance purposes and has the added advantage of being able to detect previously uncharacterized alphaviruses.

Multiplex assays to detect EEEV with other arboviruses have also been developed. For example, a duplex assay to detect EEEV with SLEV, which targeted the conserved E1 gene of EEEV, was developed [108]. This assay was specific and reproducible and had a sensitivity of 5 gene copies [108]. The control used for the assay was a short RNA transcript that allowed the assay to be performed in a BSL-2 laboratory overcoming the requirement to handle genomic EEEV RNA in a BSL-3 environment by nonselect agent approved personnel [108]. A quadruplex real-time PCR assay targeting the envelope and nonstructural protein of both EEEV and WNV is regularly used in NYS to perform surveillance for these two viruses in mosquito and mammalian specimens, and is also specific and reproducible [109].

Commercially available kits such as the BioinGentech Veterinary PCR kits (Concepcion, Chile) are available for the detection of both EEEV and WEEV RNA in animals. These kits include reagents for the isolation of RNA as well as standard RT-PCR reagents and controls. They are reported as being reliable and accurate, and with a turnaround time of 3 h, they are rapid and therefore convenient for performing diagnostic testing in horses.

29.2 METHODS

29.2.1 Sample Preparation

29.2.1.1 Animal Specimens

Animal samples (tissue and serum) for nucleic acid testing must be collected and either shipped immediately on a cold pack to the laboratory for testing, or frozen and then shipped frozen to the laboratory. Samples must not be kept at room temperature for long periods of time nor be repeatedly freeze-thawed; either treatment will compromise the test results.

29.2.1.2 Mosquito Specimen Collection for Surveillance

CDC light traps baited with dry ice, and gravid traps, are most commonly used to collect adult *Cx. tarsalis* for WEEV, and predominantly *Cs. melanura* for EEEV detection, during the transmission season. Trapped mosquitoes must be transported to the laboratory, where they should be immobilized by chilling for subsequent identification, or anesthetized with Trimethylamine™ and sorted according to genus, species, and sex. Identified mosquitoes should be grouped into pools of 50 or fewer (pools of same species and sex) and placed into 2 mL safe-lock microfuge tubes, each containing one 4.5 mm diameter zinc-plated steel BB, and shipped to the testing laboratory on dry ice [110].

29.2.1.3 Sample Processing

The methods used for processing of either animal or surveillance specimens for analysis are based on specimen type and assay. Except for serum samples, the initial step usually involves homogenization of material. For RT-PCR assays, RNA is

Downloaded From Vet-eBooks.com

extracted, ideally by homogenization in the presence of a lysis buffer that creates a highly denaturing environment, which will inactivate RNases released from the tissue. However, if the specimen cannot be divided and is to be used for virus isolation as well as RNA purification, it must be homogenized in a medium that will not inactivate the virus. For example, when brain tissue is to be tested by both cell culture and RT-PCR, separate excisions can be processed for the two assays. Mosquito samples, however, cannot be split easily and are therefore generally first homogenized in phosphate-buffered saline (PBS) or culture medium, with aliquots of the homogenate subsequently taken for RNA purification and cell culture assay. Tissue can be homogenized by mixer mill (Retsch, MM 301; Retsch, Inc., Newtown, PA), placing the sample (20 mg or less) in a 2 mL safe-lock microfuge tube (Eppendorf, Westbury, NY) containing two stainless steel beads (5mm; Qiagen, Valencia, CA), and up to 1 mL of PBS, culture medium, or lysis buffer. The tubes are placed in prechilled 24-well adapter racks (TissueLyser adapter set; Qiagen) homogenized for 30 s at 24 cycles/s, and then placed on ice for 5 min. After clarification by centrifuge, the homogenate is ready for virus isolation or purification of viral RNA.

29.2.1.4 Nucleic Acid Extraction

Multiple methods for RNA extraction are in use depending on the preference of the individual laboratory. TRIzol LS (Life Technologies, Gaithersburg, MD) has been used for many years and is a reliable method for extraction of RNA. In addition, many kits are available, including the QIAamp Viral RNA mini kit (Qiagen), MagMAX viral RNA Isolation kit (Life Technologies), MasterPure RNA Extraction kit (Epicentre,, Madison, WI), E.Z.N.A. Viral RNA kit (Omega Bio-Tek, Norcross, GA), High Pure Viral Nucleic Acid Kit (Roche Diagnostics, Indianapolis, IN), and ZR Viral RNA kit (Zymo Research, Irvine, CA). RNA extraction can also be performed with fully automated instruments including m2000 (Abbott Laboratories, Abbott Park, IL), MagNA Pure LC 2.0 (Roche Diagnostics), BioRobot M48 (Qiagen), MagMax Express Magnetic Particle Processor (Life Technologies), and NucliSENS easyMAG (bioMerieux, Durham, NC). Automation of the extraction procedure reduces technician hands-on time and errors and can minimize contamination issues. Automation is obviously suitable for high-throughput processing.

At least one negative extraction control should be included in each set of samples to be extracted for detection of potential cross-contamination. An internal control must also be used for the extraction process to identify inefficient nucleic extraction and possible PCR inhibition. Some specimen types such as blood and serum are inhibitory to PCR; for these matrices, a negative result in the viral assay does not necessarily denote absence of viral RNA. In such cases, inhibition of the internal control PCR will alert the technician. Additionally, occurrence of a Ct value outside the acceptable range for the internal control will draw attention to errors that could have arisen in the nucleic acid extraction process.

We have developed a method based on spiking a lysed sample before the extraction process with a known amount of transcript RNA from a portion of the green fluorescent protein (GFP) gene [108]. Once the nucleic acid is extracted, a real-time RT-PCR assay is performed to detect the GFP RNA [108]. Test results are valid if the Ct value of the GFP real-time RT-PCR assay falls within the predefined range.

For extraction of nucleic acid from tissue samples, including animal tissue and mosquito homogenate, we use the MagMax RNA Viral Isolation kit (Life Technologies) on a Tecan Evo 150 liquid handler (Tecan, Morrisville, NC). Following homogenization and centrifugation, RNA is extracted from an aliquot of the homogenate according to the manufacturer's instructions in a final elution volume of 50 µL. To minimize RNA degradation, samples should be kept chilled during the various stages of the procedure.

29.2.2 Detection Procedures

29.2.2.1 Real-Time RT-PCR for Detection of EEEV

The assay described here was published in 2013 and targets conserved regions of E1 and NS1 of EEEV [109]. As published, the assay can also include primers and probes to detect WEEV but the absence of these components will not negatively impact the assay. The assay is performed using two sets of primers and probes targeting EEEV (Table 29.1). The E1 probe was a minor groove binder labeled with 6-carboxyfluorescein (6-FAM) at the 5′ end, and the NS1 probe is labeled with Cyanine 5 and a black hole quencher (BHQ) at the 3′ end. To eliminate the possibility that the presence of enzyme inhibitors in the sample contributes to negative PCR results, a separate real-time RT-PCR for GFP should be performed with the primers and probes (GFP forward, GFP reverse, and GFP probe) listed in Table 29.1 [111]. The GFP probe is labeled with the reporter 6-FAM at the 5′ end and the quencher 6-carboxy-tetramethyl-rhodamine [TAMRA] at the 3′ end.

29.2.2.1.1 Procedure

1. Prepare the reaction mix using 10 µL mastermix from Quanta Biosciences (Gaithersburg, MD) qScript XLT One-Step qRT-PCR Toughmix kit, 5 µL template, 0.3 µL of 100 µmol/L each primer and 0.06 µL of 25 µmol/L probe, and deionized water to a final volume of 25 µL [109].
2. Incubate the mix at 50°C for 5 min, followed by 30 s at 95°C then 45 cycles of 95°C for 10 s, and 60°C for 1 min on an ABI 7500 real-time PCR machine (Life Technologies).
3. Prepare a separate RT-PCR mix consisting of universal buffer (Life Technologies), the forward and reverse primers at 900 nM each, and 250 nM probe for detection of GFP [111].
4. Incubate the mix at 48°C for 30 min, followed by 95°C for 10 min, 45 cycles of 95°C for 15 s, and 60°C for 1 min on an ABI 7500 or 7900 instrument (Life Technologies).

GFP probe	6-FAM-TGTGCCCATTAACATCACCATCTAATTCAACA-TAMRA	525	Tavakoli et al. [111]

EEEV, eastern equine encephalitis virus; GFP, green fluorescent protein; 6-FAM, 6-carboxyfluorescein; MGB, minor groove binder (Applied Biosystems); BHQ1, black hole quencher; TAMRA, 6-carboxy-tetramethyl-rhodamine. EEEV sequence is from GenBank accession number KJ659366 (EEEV/Culicidae/USA/2708/2007). WEEV sequence is from GenBank accession number AF214040 (strain 71V_1658). GFP sequence is from GenBank accession number EU341596 (cloning vector pGFPm-T).

Note: EEEV is a select agent and its RNA is infectious; therefore, work with culture or RNA must be done in a select agent–approved BSL-3 laboratory. For construction of a positive control for the assay suitable for use in a BSL-2 laboratory where diagnostic assays are performed on patient or animal specimens, the target sequence for the real-time PCR assay can be cloned into the PCR-Blunt II-TOPO plasmid (Life Technologies) [108]. The plasmid can be used to transcribe a control RNA transcript containing the real-time PCR target sequence in the RiboMax large-scale RNA production system—T7 (Promega, Madison, WI) [108]. The purified transcript should be quantified by measurement of the absorbance at A260 nm. A negative RT-PCR control in which water is substituted for sample should be included in each PCR sample set, for the detection of potential PCR cross-contamination.

The EEEV real-time assay described here is a rapid, accurate method for performing high-throughput vector surveillance and has the added advantage of targeting two independent regions of the EEEV genome, thus minimizing false-negative results due to strain variations [109].

29.2.2.2 Real-Time RT-PCR for Detection of WEEV

Lambert et al. [105] described a TaqMan real-time RT-PCR assay for the detection of WEEV; they used a primer/probe set that targets the E1 region of WEEV (Table 29.1). The WEEV probe was labeled at the 5′ end with the 6-FAM reporter dye and at the 3′ end with BHQ1 quencher molecule.

29.2.2.2.1 Procedure

1. Prepare RT-PCR mix (50 μL) using TaqMan One-Step RT-PCR master mix (Life Technologies) with 1 μM of each primer, 200 nM of probe, and 5 μL of extracted RNA [105]. The negative control consists of water in place of extracted RNA.
2. Incubate the mix at 48°C for 30 min for RT, 95°C for 10 min, and 45 cycles of 95°C for 15 s and 60°C for 1 min on an ABI 7700 instrument in the original method (in our laboratory an ABI 7500 instrument is used).

Note: WEE standards, prepared from RNA extracted from WEE stock that was amplified in and titered on Vero cells, were divided into aliquots, stored at −80°C, and used in each assay at sequential tenfold dilutions equivalent to 1000–0.01 pfu. The WEEV real-time RT-PCR assay detected <0.1 pfu of virus and did not cross-react with any of the related alphaviral or unrelated arboviral RNA tested [105].

29.2.2.3 Standard RT-PCR

Laboratories that do not have the capability of performing real-time RT-PCR can conduct standard RT-PCR, although the assays may not be as sensitive [105]. Standard RT-PCR assays specifically for the detection of WEEV and EEEV have previously been reported and should be performed as documented [102,105,112]. Alternatively, group-specific RT-PCR assays for the detection of members of the *Alphavirus* genus, followed by sequence analysis for identification of members of the group, can be performed [96,97].

In the following, we present two nested PCR assays for the detection of EEEV and WEEV that were reported originally by Linssen et al. [102]. The primers for these assays were designed from the sequences of the structural polyprotein coding regions. For EEEV detection, the RT-PCR primers are EEE-4 and cEEE-7 and the nested PCR primers are EEE-5 and cEEE-6 (Table 29.2). For WEEV detection, the RT-PCR primers are WEE-1 and cWEE-3, and the nested PCR primers are WEE-2 and cWEE-3 (Table 29.2).

29.2.2.3.1 Procedure

1. Prepare the RT-PCR mix (100 μL) containing 5 mM dithiothreitol, 10 mM Tris-HCl (pH 8.3), 50 mM KCl, 0.01% gelatin, 2 mM $MgCl_2$, 200 μM dNTP, 2.5 U of TaqExtender PCR additive (Agilent Technologies, Santa Clara, CA), 2 U of RAV-2 reverse transcriptase (GE Healthcare Bio-sciences, Pittsburgh, PA), 2 U of AmpliTaq DNA polymerase (Life technologies), 0.1 μM each of EEE-4, and cEEE-7 primers (for EEEV detection); or 0.2 μM each of WEE-1 and cWEE-3 primers (for WEEV detection) and 5 μL of RNA template (extracted by Qiagen kit).
2. For EEEV detection, incubate the RT-PCR mix at 50°C for 30 min, 1 cycle of 94°C for 90 s, 64°C for 90 s, and 72°C for 90 s; 35 cycles of 94°C for 20 s, 64°C for 30 s, and 72°C for 20 s; and the final step, 72°C for 5 min. For WEEV detection, incubate the RT-PCR mix at 50°C for 30 min; 1 cycle of 94°C for 90 s, 68°C for 60 s, and 72°C for 90 s; 35 cycles of 94°C for 20 s, 68°C for 30 s, and 72°C for 17 s; and a final 72°C for 5 min.
3. Prepare the nested PCR (100 μL) containing 10 mM Tris-HCl (pH 8.3), 50 mM KCl, 0.01% gelatin, 5 mM dithiothreitol, 2 mM $MgCl_2$, 200 μM dNTP, 1.5 U of AmpliTaq DNA polymerase, 0.3 μM each of EEE-5 and cEEE-6 primers (for EEEV detection), or 0.3 μM each of WEE-2, cWEE-3 primers (for WEEV detection), and 2 μL of cDNA template from the previous RT-PCR.
4. For EEEV detection, carry out the nested PCR with 1 cycle of 94°C for 90 s; 25 cycles of 94°C for 20 s, 65°C for 35 s, and 72°C for 17 s; and a final 72°C for 4 min. For WEEV detection, carry out the nested PCR with 1 cycle of 94°C for 90 s; 25 cycles of 94°C for 20 s, 63°C for 35 s, and 72°C for 15 s; and a final 72°C for 4 min.
5. Electrophorese the nested PCR products on 2% agarose gel, and visualize with ethidium bromide stain.

Note: The expected nested PCR products for EEEV and WEEV are 262 and 195 bp, respectively. The sensitivity of the nested PCR assay is 30 (EEEV) or 20 (WEEV) RNA molecules [102].

29.3 CONCLUSION AND FUTURE PERSPECTIVES

EEE and WEE, although rare, are important arbovirus diseases affecting humans and animals in the United States. In recent years, cases of WEE have diminished. However, EEE, which has a greater mortality rate, continues to cause severe disease accompanied by long-term brain damage and death in humans and horses in the Atlantic and Gulf coast states. Many states in the United States have disease surveillance programs, which serve as early warning systems in the detection of mosquito-borne viruses that can infect animals and humans. Mosquito testing, baited traps, and wild bird and sentinel chicken testing all aid in the early detection of mosquito-transmitted diseases such as EEE and WEE. The control of mosquito populations is critical in protecting humans from infectious bites.

Several vaccines are under development for EEE and WEE although there are none currently available for humans. Equine vaccines are in use in some countries and help reduce infections in horses. Inactivated-virus vaccines derived from a North American strain of EEEV [113] and WEEV [114] are both available for veterinary use. Safety is a concern because inactivated-virus vaccines have the potential to cause disease if the virus used in the manufacture of the vaccine is not completely inactivated. Individuals such as laboratory workers, who are at high-risk of infection at work, can be immunized against both viruses, but the vaccines are not available for the general public [115]. Efforts are being made to develop recombinant vaccines, which are safer to use and which induce rapid and effective humoral and cellular immunity [116]. In addition, the potential use of recombinant, chimeric WEEV and EEEV as the basis for vaccines is under investigation [117].

There is an urgent need to develop rapid diagnostic methods for the detection of arboviruses in human and other

Downloaded From Vet-eBooks.com

animal hosts for testing of vector mosquito populations. Due to the small sample volume in some cases, multiplexed testing would be advantageous. Multiplexing would reduce hands-on time, the number of analytical instruments required, and reagent costs. The types of technology that allow multiplexing include multiplex real-time RT-PCR, microarrays, and xMAP technology [118,119]. More recently, massively parallel DNA-sequencing platforms, also termed next-generation sequencing technologies, are being used more frequently in diagnostic laboratories for pathogen discovery and diagnostic applications [120,121]. Whole genome sequencing and phylogenetic analysis have been used to detect HJV in the brain of a Mississippi sandhill crane (*Grus canadensis*) [122]. The feasibility of using pyrosequencing to detect DENV in *Aedes aegypti* mosquito pools was investigated and the method was found to be sufficiently sensitive to perform arbovirus surveillance [123]. Similarly, massively parallel sequencing using the Personal Genome Machine (PGM; Life Technologies) has demonstrated the potential for this technology in assessing arbovirus ecology and evaluating novel control strategies [124]. No doubt with the availability of these advanced molecular detection methodologies, the routine diagnostic testing for arboviruses such as EEEV and WEEV will be changing dramatically in the years to come.

30.1 INTRODUCTION

In recent decades, there has been a worldwide resurgence of viral pathogens transmitted by arthropods (arboviruses), particularly those transmitted by mosquitoes. Diseases caused by many of them (e.g., dengue, Venezuelan equine encephalitis virus, Chikungunya) constitute a major health problem of high impact in temperate and subtropical regions of the world [1,2]. The emergence of these viruses is usually associated with variants that have recently evolved, although the current knowledge shows that most are zoonotic arboviruses with specific ecological niches, residing naturally in wild animal species (hosts). Access to other host populations, such as domestic animals and humans, is a consequence of multiple factors, including environmental and ecological changes (relating to the structure of the soil, wildlife, animal migration, vector distribution, human migration, and trafficking of pets) as well as viral RNA genome plasticity.

Venezuelan equine encephalitis viruses (VEEV) are zoonotic pathogens of medical and veterinary importance circulating in the United States. Since its first isolation and identification in the 1930s [3], outbreaks of VEEV in human and equine populations have been periodically recognized in Venezuela, Colombia, Ecuador, Mexico, Trinidad, Panama, Guatemala, Peru, and the United States [2,4]. In humans, VEEV infections range from asymptomatic to encephalitis and death. In many cases, VEEV is clinically indistinguishable from dengue fever and other arboviral diseases (with symptoms like headache, chills, tachycardia, fever, myalgia, arthralgia, retro-orbital pain, rash, nausea, and vomiting), and confirmatory diagnosis requires the use of specialized laboratory tests [2,5]. In horses, depending on VEEV subtype and strain, infection may produce (1) unapparent infection followed by seroconversion; (2) systemic disease characterized by tachycardia, fever, depression, and anorexia; or (3) encephalitis [6–8]. Recent implementation of surveillance systems has allowed the detection of new human cases in countries and areas with unknown VEEV activity, showing endemic circulation of these viruses [2]. As part of viral control, molecular techniques represent a valuable tool. The potential emergence of epizootic viruses from enzootic progenitors further highlights the need to strengthen the control strategies against the disease [2].

30.1.1 Classification

VEEV form a complex of the same name within the *Alphavirus* genus of the *Togaviridae* family [9]. Due to their shared requirement for arthropods as transmission vectors, the genus *Alphavirus* and several genera of the families *Flaviviridae* and *Bunyaviridae* are collectively known as arthropod-borne viruses or "arboviruses." Members of the genus *Alphavirus* are often classified as either New World

Downloaded From Vet-eBooks.com

alphaviruses or Old World alphaviruses, depending on the geographic location from which they were originally isolated [10]. New World alphaviruses include Eastern equine encephalitis virus (EEEV), VEEV, Western equine encephalitis virus (WEEV), and Mayaro virus (MAYV), among others; and they generally cause encephalitis in humans and other mammals, with the exception of MAYV, which causes febrile illness, arthralgia, and rash. Old World alphaviruses such as Chikungunya virus, O'Nyong-Nyong virus, Ross River virus, Semliki Forest virus, and Sindbis virus can cause fever, rash, and arthralgia syndrome that is rarely fatal [11,12].

VEEV complex was originally formed by six serological subtypes (I–VI). VEEV was first isolated in 1938 during an outbreak of equine encephalitis in the Guajira region, Venezuela, from the brain of a sick horse. In the following years, VEE-related viruses were isolated and identified in many locations in South America, Central America, the Caribbean islands, and the southern regions of the United States [8]. Using a short incubation hemagglutination inhibition (HI) test, isolates of these viruses were distinguished into subtypes I–IV [13], which together form the VEEV complex. Subsequently, Cabassou virus (CABV) and Rio Negro virus (RNV) were isolated and showed to fall within the VEEV antigenic complex, forming subtypes V and VI, respectively [14,15]. Thus, the VEEV complex contains six serological subtypes, which are currently considered as viral species (Table 30.1).

30.1.2 Virion Structure and Genome Organization

Similar to other alphaviruses, VEEV is spherical and enveloped with an icosahedral symmetry of approximately 60–70 nm diameter. The virus possesses a positive-sense RNA genome, contained within a capsid formed by the protein C [8]. The nucleocapsid (RNA + capsid) is surrounded by a lipid envelope derived from the host cell membrane as well as the viral glycoproteins E1 and E2 [8,12]. In total, alphaviruses have five structural proteins, C, E3, E2, 6K, and E1, which are part of the viral particle structure, and four nonstructural proteins (nsP), nsP1–4, involved in RNA replication and production of subgenomic RNA from which structural proteins are synthesized [10].

The genome is composed of a single-stranded positive-sense RNA molecule of approximately 11,000 bp. It is organized with the nonstructural protein genes at the 5′ end (two-thirds of the genome) and the structural protein genes at the 3′ end (one-third left of the genome) [8,9] (Figure 30.1). Regions of glycoproteins E3-E2-E1 have been extensively used to compare divergence and construct phylogenetic trees for the genus *Alphavirus* since they are the most divergent [8,16]. In addition, the region encoding glycoprotein E2 may contain major determinants of equine virulence and amplification potential, which determine the strain phenotype [2].

30.1.3 Pathogenesis

Transmission to vertebrate hosts (including humans) occurs mainly through the bites of infected mosquitoes. During feeding, infected mosquitoes deposit virus-containing saliva extravascularly [17]. After subcutaneous inoculation, the virus infects skeletal muscle at the local site or Langerhans cells of the skin [18,19]. Langerhans cells, as well as dendritic cells, transport the virus to the regional lymph nodes, where replication takes place. The viral particles reach plasma circulation through which they infect other tissues [8]. Viremia is usually

TABLE 30.1
Members of the VEEV Complex: Origin and Current Distribution

Serologic Classification (Subtype)	Virus/Prototype Strain	Origin	Source	Current Distribution
IAB	VEEV—Trinidad donkey	Trinidad, 1943	Donkey	North, Central, and north of South America
IC	VEEV—P676	Venezuela, 1963	Mosquito	North of South America
ID	VEEV—3880	Panama, 1961	Human	South and Central America
IE	VEEV—Mena II, 68U201	Guatemala, 1968	Hamster	Central America and Mexico
IF	Mosso das Pedras virus—78V3531	Brazil, 1978	Mosquito	Brazil
II	Everglades virus (EVEV)—Fe3-7c	Florida, 1963	Mosquito	Florida (United States)
IIIA	Mucambo virus (MUCV)—BeAn8	Brazil, 1954	Monkey	North of South America and Trinidad
IIIB	Tonate virus—CaAn410d	French Guiana, 1973	Birds	French Guiana
	Bijou Bridge virus—Bijou Bridge	Colorado, 1974	Mosquito	West of the United States (Colorado)
IIIC	MUCV—71D1252	Peru, 1971	Mosquito	Peru
IIID	MUCV—V407660	Peru, 1998	Rodent, mosquito, and human	Peru
IV	Pixuna virus (PIXV)—BeAr35645	Brazil, 1961	Mosquito	Brazil
V	Cabassou virus (CABV)—CaAr508	French Guiana, 1968	Mosquito	French Guiana

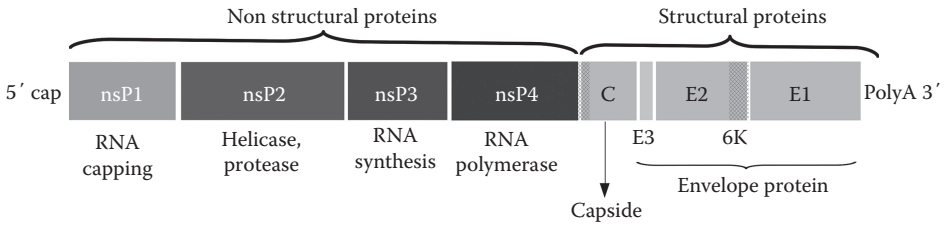

FIGURE 30.1 VEEV (and all alphaviruses) genome.

accompanied by interferon production, proinflammatory cytokines, and fever, and ends with the appearance of the humoral immune response approximately 5 days postinfection [8].

In humans, target tissues include the central nervous system (CNS) (producing encephalitis) [8]. The specific mechanism by which VEEV enters the CNS is not entirely clear. Recent studies demonstrate that VEEVs may enter through olfactory neurons and start replication in the brain, which induces opening the blood–brain barrier, allowing a second input of virus from the periphery to the CNS [20]. Neuroinvasiveness varies according to the virus and strain [21]. Once in the CNS, the virus spreads from cell to cell or through the cerebrospinal fluid (CSF). For most neurotropic alphaviruses, including VEEV, the target cell within the CNS is the neuron, and the damage can be severe and irreversible. VEEV can also cause persistent infection of the CNS including microglia and oligodendroglial cells, causing demyelization [8].

30.1.4 Epidemiology and Distribution

VEEV subtypes are divided into two epidemiological groups: epidemic/epizootic viruses and enzootic viruses.

30.1.4.1 Epidemic/Epizootic Viruses

Subtypes IAB and IC belong to the group of epidemic/epizootic viruses, which emerge periodically causing outbreaks in humans and equines [8,16], with high morbidity and mortality rates [22]. Transmission cycle for these subtypes involves equines, which act as highly efficient amplification hosts, developing high titers of the virus in the blood, and mosquito vectors [6]; humans are end hosts (Figure 30.2). The virulence in equines and the induction of viremia are the most important attributes of the epizootic phenotype. When horses become infected, humans living in close association with these animals in agricultural settings may also acquire the infection, resulting in epidemic disease [6]. Although infection by epidemic/epizootic strains has been observed in humans, sheep, dogs, bats, rodents, and some birds, there have never been any recorded major epidemics in the absence of horses [23]. Humans develop similar viral titers to equines, but do not usually act as amplifying hosts due to a limited exposure to mosquito bites [23]. Nevertheless, transmission by humans cannot be discounted completely. Infected people show high titers of virus with both epizootic and enzootic strains. Mosquito vectors with peridomestic urban habits,

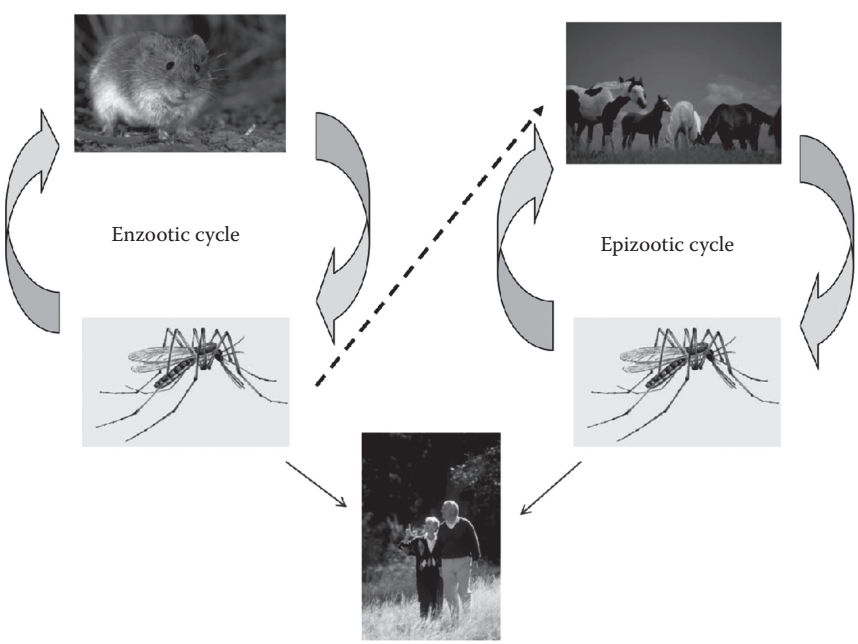

FIGURE 30.2 Transmission cycles of VEE complex viruses. The dotted line symbolizes the emergence of epidemic/epizootic strains from mutations of enzootic strains. For both cycles, humans are end hosts.

Downloaded From Vet-eBooks.com

such as *Stegomyia (Aedes) aegypti* and *Ae. albopictus* can transmit the virus after ingestion of oral doses of the virus similar to titers of viremia developed in human infections. Therefore, the occurrence of human–mosquito–human transmission is possible [24,25].

The epidemic/epizootic strains are opportunistic in the use of mosquito vectors during outbreaks. Field studies have indicated that more than one mosquito species can be involved in viral transmission during an outbreak [26]. Although susceptibility to infection is required for biological transmission of viruses and some species are almost completely refractory, ecological and behavioral traits such as longevity, food preference (host), survival, and population size are probably more important than the differences in susceptibility of vectorial capacity. Some species that appear to be moderately susceptible to viral infection have been implicated as major vectors for outbreaks of VEEV [23].

It has been described that the main species of mosquitoes involved in the transmission of these viruses would be *Aedes* spp. and *Psorophora* spp. [27]. *Ochlerotatus (Oc.) sollicitans* and *Oc. taeniorhynchus* also exhibit high infection rates, depending on the U.S. region [26]. *Oc. taeniorhynchus* is probably the most important epizootic vector in South America [23].

30.1.4.2 Enzootic Viruses

Subtypes ID, IE, IF, and II–VI have not been originally associated with epidemics or epizootics. They are called enzootic because they carry out their cycle in wild habitats, involving mosquito vectors and rodent reservoir hosts (Figure 30.2) [2]). These viruses are avirulent and unable to amplify in equines, but most of them can cause illness in humans. Only subtype IE has been related to an outbreak in horses in Mexico [28]. Interestingly, epizootic IE strains cause encephalitis in horses but with low titers of virus [29], and are unable to amplify in these animals [2]. For this reason, equines may represent an end host for these strains.

Enzootic strains are involved in active transmission cycles in tropical and subtropical areas of the United States: Everglades virus (EVEV) in Florida, VEEV ID in Central and South America, VEEV IE in Central America, and VEEV IF (Mosso das Pedras Virus), Mucambo virus (MUCV), Pixuna virus (PIXV), CABV, and RNV in South America [2,8]. In endemic areas, mosquito isolates mainly belong to *Culex* (*Melanoconion*) spp., which live in swampy areas and breed near aquatic plants [8]. These mosquitoes feed on a variety of rodents, birds, and other vertebrates. However, isolations have also been obtained from the genera *Aedes*, *Stegomyia*, *Mansonia*, *Psorophora*, *Haemagogus*, *Sabethes*, *Deinocerites*, and *Anopheles* [2,5]. Wild birds are susceptible to infection, but mammals (mainly rodents) are the most probable reservoirs as shown by viral isolations, levels of viremia, serology, and disease resistance [23,27,30–32]. Enzootic transmission cycles for VEEV ID, VEEV IE, EVEV, MUCV, and Tonate virus (Bijou Bridge virus) have been described; all of them (with the exception of Bijou Bridge) are maintained in cycles involving rodents and mosquitoes in the subgenus *Culex (Melanoconion)* [2]. Bijou Bridge virus is transmitted by the bedbug *Oeciacus vicarious* to the birds of western North America [33].

30.1.4.3 Origin of Epidemics

Venezuelan equine encephalitis epidemics or epizootics have occurred in intervals of approximately 10–20 years in livestock in many places of South America, when epizootic mosquito populations increase [34]. For several years, the main enigma regarding VEEV epidemiology was to detect the source of epidemic/epizootic virus and to uncover the mechanisms of persistence between outbreaks. To explain this, several hypotheses have been postulated: (1) the emergence of epizootic subpopulations within enzootic VEEV populations [35], (2) the initiation of outbreaks by the administration of improperly inactivated vaccines [16], (3) the emergence of subtypes IAB and IC from cryptic transmission cycles [6], (4) the maintenance of epizootic strains in latent infections in horses or other animals [23], and (5) the periodic emergence of epizootic IAB, IC, and IE strains from the evolution (mutations) of enzootic VEEV progenitors [16]. The last hypothesis has been supported by extensive phylogenetic analysis [2,9,16] and is the most accepted so far. It has been documented that remarkable similarities between epizootic IC and enzootic ID viruses exist. A total of 15 amino acid differences were identified between strains of both viruses isolated in Venezuela, and two of them were located within the E2 glycoprotein region, which is suspected to be the major determinant of equine virulence and amplification potential [2,6]. Some studies have reported that a single amino acid substitution in the position 213 of the glycoprotein E2 in ID Venezuelan strains (enzootic) resulted in a change in the equine viremia phenotype, generating high-titer viremia in horses, as occurred with epizootic strains [2,36].

30.1.5 Clinical Features

In horses, VEEV infection can result in (1) unapparent infection followed by seroconversion; (2) systemic disease characterized by tachycardia, fever, depression, and anorexia; or (3) encephalitis [6].

Enzootic strains can infect equines, but these infections are asymptomatic and with low titer of the virus, and may confer immunity in the animals against epizootic strains [37,38].

Epizootic strains produce illness in horses. The virus is found in nasal secretions, eyes, throat, urine, and milk and is transmitted by the respiratory route, as well as by mosquito bites [8]. The incubation period is short (1–5 days), then fever appears, along with viremia. After the disappearance of fever, some cases progress with neurological symptoms: hypersensitivity to noise and touch, incoordination, circular movement, disorientation, involuntary muscle movements, depression, drowsiness, paralysis, convulsions, and sometimes death [7,8]. Equine infections by these strains are associated to leukopenia and high-titered and prolonged viremia (sometimes $>10^8$ infectious particles/mL of blood, for 4–5 days) [8], which allows one horse to be the source of the virus for thousands of mosquitoes in only 1 day, facilitating the virus spread [7]. Encephalitis and death correlate to the magnitude of the viremia and the ability of the virus to replicate outside the CNS and then spread to the brain [23].

Downloaded From Vet-eBooks.com

In animals that recover, antibodies (Abs) appear approximately 7 days after infection [39].

In humans, infection occur mainly by mosquito bites, although it is also possible for an infection to occur through the respiratory tract, as has been demonstrated by the occurrence of infection in laboratory workers [7,8,40]. The incubation period is short (1–5 days). Most infections are asymptomatic or mild, and the individuals go through a short discomfort, with spontaneous recovery. Clinical manifestations that can occur are similar to those of dengue or influenza, with sudden onset of severe headache, chills, tachycardia, fever, myalgia, arthralgia, retro-orbital pain, nausea, and vomiting [5,40] accompanied by leukopenia [23]. Some cases may have a biphasic febrile course: after few days of fever, there may be signs of CNS involvement, ranging from somnolence, encephalitis, photophobia, disorientation, convulsions, paralysis, coma, to death [5,34]. Neurologic disease occurs in 4%–14% of the cases [16] and many of them may remain as sequelae [8].

30.1.6 Diagnosis

For the diagnosis of human and/or animal cases with clinical symptoms compatible with VEE, it is essential to know the epidemiological situation in the region. This is because in some parts of the United States, there is cocirculation of VEEVs and other arboviruses producing similar clinical manifestations. VEE can be misdiagnosed as diseases caused by dengue or Oropouche, group C bunyavirus, and/or Guaroa viruses, since they are clinically indistinguishable [2]. The differential diagnostic of neurological cases should be performed including other alphaviruses, such as WEEV and EEEV, as well as some neurotropic flaviviruses, like the Saint Louis encephalitis virus or the West Nile virus.

Laboratory diagnosis of VEEV is based on viral isolation, detection of the viral genome, and antigens, and/or detection of specific Abs (IgG or IgM).

30.1.6.1 Conventional Techniques

Since its first isolation in the 1930s, VEEV has been diagnosed through virus isolation or detection of specific immune response. Virus isolation is a very sensitive and specific technique, which can be performed using cell culture or suckling mice, and is the "gold standard" technique for virus detection [41,42]. Successful attempts of viral isolation from clinical specimens depend on the care taken for the collection, handling, and shipping of the sample to the laboratory. For virus isolation, the most adequate human samples are CSF and blood from the early days of symptom onset (viral load is very short) or autopsy materials (from the CNS). For equines, the sample of choice is blood and/or the brains of the fatal cases. Further identification of the isolations is performed using PCR, immunofluorescence (IF), and ELISA, among others. Although virus isolation presents many advantages, it is time consuming and requires sterile handling of tissue cultures under biosafety level 2 or 3 conditions (depending on the virus), or the use of experimental animals [41].

Serological diagnosis can be carried out through detection of IgG or IgM Abs. In the case of specific IgM detection, ELISA and indirect IF assays can be utilized using anti-IgM conjugates for both humans and horses from serum or CSF samples. Positive IgM results must be confirmed by seroconversion using plaque reduction neutralization test (PRNT), which detects total Abs and defines viral subtypes. For diagnosis or confirmation of infection using PRNT, it is necessary to use two paired samples, obtained at different times. The first sample must be obtained during the first days of the disease (this sample can be also used for isolation or amplification of the genome if it was taken under sterile conditions and maintained refrigerated); the other sample must be taken after the third week of the onset of symptoms. Seroconversion is defined by a titer difference of fourfold or greater between these samples or a negative result for the first sample and a positive result for the second one.

HI is another conventional technique for VEEV Ab detection based on the bind of VEEV specific Abs to viral particles, which inhibits agglutination of avian erythrocytes. This is a simple and accessible technique that can be used for quantification of specific Abs [8,43] but requires obtaining avian red blood cells periodically.

30.1.6.2 Molecular Techniques

Molecular techniques such as reverse transcription polymerase chain reaction (RT-PCR) and RT-nested PCR offer a valuable tool for rapid, sensitive, and reliable detection of VEEVs and can be used for both diagnostic application and epidemiological surveillance. Some of these techniques allow genus-specific amplification, followed by sequencing of the amplified fragments for specific identification of all alphaviruses [44]. These assays are useful in geographical regions with cocirculation of many alphaviruses that produce similar symptoms. Other techniques target several genome regions of VEEV complex, permitting specific discrimination of various subtypes [41,42]. Molecular techniques are particularly useful as a surveillance method in endemic and nonendemic areas, utilizing other biological samples such as mosquito homogenates or mammalian serum samples (rodent). These techniques provide a means to conduct phylogenetic analyses based on the amplification of the PE2 region, whose notable sequence variations help reveal details about the genetic variability of the strains [16,45].

With a higher sensitivity, nested PCR is clearly advantageous over single-round PCR. This is important for VEEV detection from clinical samples due to short viremia, as well as from mosquito samples in which the number of virus present is very low.

30.2 METHODS

30.2.1 Sample Collection and Preparation

For diagnosis, it is important to consider the time in which the sample is taken since the period of viremia (in humans and equines) is very short (3–5 days), so blood must be taken up to 5 days after the onset of the symptoms.

Downloaded From Vet-eBooks.com

After collection, the blood must be separated into serum, as this is what will be analyzed. It is also possible to analyze brain samples (biopsy or autopsy) if the infected equine dies. These samples must be refrigerated as soon as possible upon arrival at the laboratory to prevent the disintegration of the virus and the fall of viral titer. In cases when the sample could not be processed within 24 h, it must be frozen and stored at −80°C.

For brain sample, it is necessary to cut the sample in 2 or 3 parts, triturate in a cold mortar, homogenize with a sterile minimal essential medium supplemented with 10% fetal bovine serum and 1% gentamicin, and clarify by centrifugation at 10,000 rpm for 30 min. The supernatant is poured into individual screw-cap vials and frozen at −80°C until viral RNA detection.

For mosquito samples, pool the collected mosquitoes by species, date and place them in lots of 1–50 unengorged individuals, and store at −80°C until processing. Then, each mosquito pool is processed the same as described for brain sample, and the supernatant is used for virus detection.

Several methods are used for VEEV RNA extraction from clinical or field specimens. These include conventional RNA separation with the guanidine isothiocyanate method, as well as the use of commercial extraction kits, which are highly sensitive and reproducible. Commercial kits used for viral RNA extraction are mainly based on columns containing silica gel, which retain the nucleic acid. The RNA binds to the silica membrane, and contaminants are efficiently washed away using different wash buffers. High-quality RNA is eluted in a special RNase-free buffer, ready for direct use or safe storage. The purified RNA is generally free of protein, nucleases, and other contaminants and inhibitors.

Trizol® reagent (Invitrogen BRL, Life Technologies, Rockville, MD) is a complete, ready-to-use solution of phenol and guanidine isothiocyanate for isolation of total RNA. Using this procedure, 150 µL of the sample is mixed with 700 µL of Trizol reagent, 1 µL of glycogen, and 200 µL of chloroform. The mixture is vortexed for 2 min, incubated for 20 min at room temperature, and centrifuged at 13,000 rpm for 20 min. Total RNA is precipitated by isopropyl alcohol and ethanol, air-dried, and dissolved in 20 µL of sterile water. Once extracted, RNA should be stored at −80°C until RT-PCR.

30.2.2 Detection Procedures

30.2.2.1 Reverse Transcription

The passage of genome RNA to DNA copy (cDNA) can be performed using two kinds of primers. It is possible to use either reverse oligonucleotide, which is going to be used in the PCR amplification, or random hexamer primers, which are a mixture of six nucleotides primers of all possible combinations, with the capacity to generate cDNA of multiple lengths. The use of random primers has the advantage of converting any RNA that is present in the sample into cDNA, which can be then amplified by PCR. This is very useful for the diagnosis of VEE, which shares clinical symptoms with other arboviral diseases; a single RT reaction will provide templates for several specific PCR amplifications (for each arbovirus).

30.2.2.1.1 Procedure

Prepare the RT-mix as shown in Table 30.2. The volume of RT-mix for one sample is 10 µL, to which 10 µL of the extracted sample is added to obtain a final volume of cDNA, after the retrotranscription reaction of 20 µL.

First, the 10 µL of RNA is incubated at 65°C for 10 min, then 10 µL of RT-mix is added, and the mixture is incubated at 45°C for 60 min.

30.2.2.2 Nested-PCR Detection

All VEEV complex members are amplified by nested PCR using primers VEE45, VEE176, VEE83, and VEE138 (Table 30.3) [42].

30.2.2.2.1 Procedure

For the first amplification (PCR I), 5 µL of cDNA is added to 45.25 µL PCR I mix (50.25 µL final volume), prepared as shown in Table 30.4. The mix is subjected to an initial denaturation step at 94°C for 2 min, followed by 40 cycles of denaturation at 94°C for 30 s, primer annealing at 64°C for 1 min, extension at 72°C for 30 s, and a final extension at 72°C for 5 min.

For nested PCR (PCR II), 2 µL of each PCR I product is transferred to 48.25 µL nested PCR mixture (50.25 µL final volume), prepared as shown in Table 30.4. The second PCR is carried out with an initial denaturation at 94°C for 2 min, followed by 40 cycles of 94°C for 30 s, 61°C for 40 s, and 72°C for 30 s. A final extension at 72°C for 5 min is performed.

PCR products, of 80 bp (10 µL), are analyzed by electrophoresis using a 2% agarose gel containing 0.5 µg/mL of SYBR® Safe (Life Technologies) in TBE buffer gels and visualized under UV light. A molecular weight marker of 50 bp is included on each gel.

A negative control is concurrently included along with the test samples in order to monitor any possible contamination that might occur during the PCR procedure. Positive control is also included to test that reaction conditions are right.

GoTaq DNA polymerase	0.25	0.25
Total	45.25	48.25

It is important to note that this technique is not useful to identify VEEV subtype so that a positive result only indicates the presence of VEEV genome in the sample.

30.3 CONCLUSIONS

VEEVs cause human and equine diseases throughout the United States, with symptoms ranging from mild illness to encephalitis and death, in addition to a high proportion of subclinical cases. Clinically, VEE is indistinguishable from dengue fever and other arboviral diseases, and confirmatory diagnosis is required with the use of specialized laboratory tests. The disease burden of endemic VEE in developing countries remains largely unknown [2]. The potential emergence of epizootic viruses from enzootic progenitors highlights the need to strengthen surveillance activities, as well as employ fast and sensitive techniques for viral detection.

Diagnosis of acute VEEV infection can be done by detection of viral antigens or nucleic acids or by virus isolation. These techniques are only successful if the blood or CSF is collected during the viremic phase of infection, which lasts for 3–5 days. Detection of RNA by RT-nested PCR is a fast, sensitive, and specific alternative for diagnosis of VEE acute infection and can also be useful as a surveillance method.

Real-time PCR is another alternative for VEEV detection, using either SYBR Green reagent or specific probes. This technique has the advantages of requiring less processing time than a conventional PCR, and being highly sensitive and reproducible. Furthermore, it can be used for viral quantification, which is essential for determining the amount of virus in infected hosts and mosquitoes, with the goal to evaluate virus transmission.

31.1 INTRODUCTION

31.1.1 Classification

Equine arteritis virus (EAV), the causative agent of equine viral arteritis (EVA), was first isolated from the lung of an aborted fetus following an extensive outbreak of respiratory disease among horses on a Standardbred breeding farm in Bucyrus, Ohio, in 1953.[1,2] EAV is the prototype virus in the family *Arteriviridae* (genus *Arterivirus*), order *Nidovirales*, which also includes porcine reproductive and respiratory syndrome virus, simian hemorrhagic fever virus, lactate dehydrogenase–elevating virus of mice, and recently identified wobbly possum disease virus of free-ranging Australian brush-tail possums (*Trichosurus vulpecula*) in New Zealand.[3,4] All members of the order *Nidovirales* are enveloped viruses with linear, positive-sense, single-stranded ribonucleic acid (RNA) genomes. Furthermore, the genome organization and replication strategy of EAV strikingly resemble those of corona- and toroviruses, including the production of a 3′-coterminal nested set of subgenomic mRNAs (sg mRNAs), and key domains of the arterivirus replicase are homologs of domains found in corona- and torovirus replicases.[5] However, EAV and other arteriviruses differ considerably in their genetic complexity and virion architecture from the other nidoviruses.

31.1.2 Morphology, Biology, and Epidemiology

The EAV virion is an enveloped, spherical, 50–65 nm particle with an isometric core that contains a single-stranded, positive-sense RNA molecule.[5] The EAV genome length varies between 12,704 and 12,731 bp among different virus strains and includes a 5′ leader sequence (224 nucleotides) and at least ten open reading frames (ORFs).[6–11] The two most 5′-proximal ORFs (1a and 1b) occupy approximately three-fourths of the genome and encode two replicase polyproteins (pp1a and pp1ab). These two precursor proteins are extensively processed after translation into at least 13 nsps (nsp1–12, including nsp7 α/β) by three viral proteases (nsp1, nsp2, and nsp4).[5,12–13] The remaining ORFs are located in the 3′-proximal quarter of the genome and encode for the structural proteins of the virus, which include seven envelope proteins (E, GP2, GP3, GP4, ORF5a protein, GP5, and M) and a nucleocapsid protein (N), which are encoded by ORFs 2a, 2b, 3–4, 5a, 5b, and 6–7 that are located at the 3′-proximal quarter of the genome.[5,14,15] These structural proteins are expressed from six viral sg mRNAs that form a 3′-coterminal nested set and contain a common leader sequence encoded by the 5′-end of the genome.[16] The major envelope proteins of EAV are GP5 (glycosylated) and M (unglycosylated) and they form a disulfide-linked heterodimer in the mature virus particles.

Downloaded From Vet-eBooks.com

It has been shown that the GP5 is the principal target of neutralizing antibodies to EAV and four major neutralization sites (A, B, C, and D) are located in the amino terminal ectodomain of the protein. It has been demonstrated that GP5–M heterodimer formation is critical for the expression of the neutralization epitopes in their authentic form.[17–20] The M protein likely acts as an essential scaffold on which the GP5 protein folds to form the epitopes that induce neutralizing antibodies in horses. In addition, the EAV envelope contains a heterotrimer of three minor membrane glycoproteins (GP2, GP3, and GP4) and two unglycosylated envelope proteins (E and ORF5a protein).[14,15] It has been shown that the ectodomains of GP5 and M are not the major determinants of cellular tropism, but the minor envelope proteins are the critical proteins in mediating cellular tropism of EAV.[21–23] EAV is readily inactivated by lipid solvents (e.g., ether and chloroform) and by common disinfectants and detergents. The virus survives in cryopreserved semen samples and embryos for many years. EAV remains infectious for 75 days at 4°C, between 2 and 3 days at 37°C, and 20–30 min at 56°C. The virus is also highly stable and remains infectious for decades in organ samples and tissue culture fluid when stored frozen (−70°C to −80°C).

The advent of recombinant DNA technology and establishment of reverse genetics systems (e.g., infectious cDNA clone) has significantly advanced the knowledge on the molecular biology of EAV.[21] Specifically, these studies have lead to the identification of major viral determinants of virulence, neutralization, persistence, and protective host immunity.[24–27] Recently, the advances in EAV molecular biology and the disease EVA have been summarized in several review articles.[15,21,28]

EAV can infect horses, donkeys, mules, and zebras.[15] Based on serological surveys, EAV infection has been common among horses in North and South America, Europe, Australia, Africa, and Asia.[29,30] Other countries such as Iceland and Japan are apparently free of the virus.[15] Recent studies have shown that New Zealand is also free of EAV.[31] However, the seroprevalence of EAV infection of horses varies between countries and among horse breeds within a country. EAV infection is considered endemic in Standardbred but not in Thoroughbred horses in the United States, with 77.5%–84.3% of all Standardbreds but only up to 5.4% of Thoroughbreds being seropositive to the virus.[29,32–37] The seroprevalence of EAV infection of Warmblood stallions is also very high in a number of European countries, with some 55%–93% of Austrian Warmblood stallions being seropositive to EAV.[38] Similarly, there is high seroprevalence among mares and stallions of Hucul horses in Poland, 53.2% and 68.2%, respectively.[39] Seroprevalence to EAV increases with age, indicating that horses may be repeatedly exposed to the virus as they age.

It has been reported that 30%–70% of stallions that are exposed to EAV can become persistently infected carriers and continue to shed virus in their semen for variable time periods.[15] The duration of the EAV carrier state in the stallion can be short (2 months), intermediate (7 months), or long term (many years or sometimes lifelong). Persistently infected carrier stallions function as the natural reservoir of EAV and disseminate the virus to susceptible mares at breeding (Figure 31.1). Some 85%–100% of seronegative mares bred to long-term carrier stallions become infected with the virus and seroconvert within 28 days. Mares that become infected

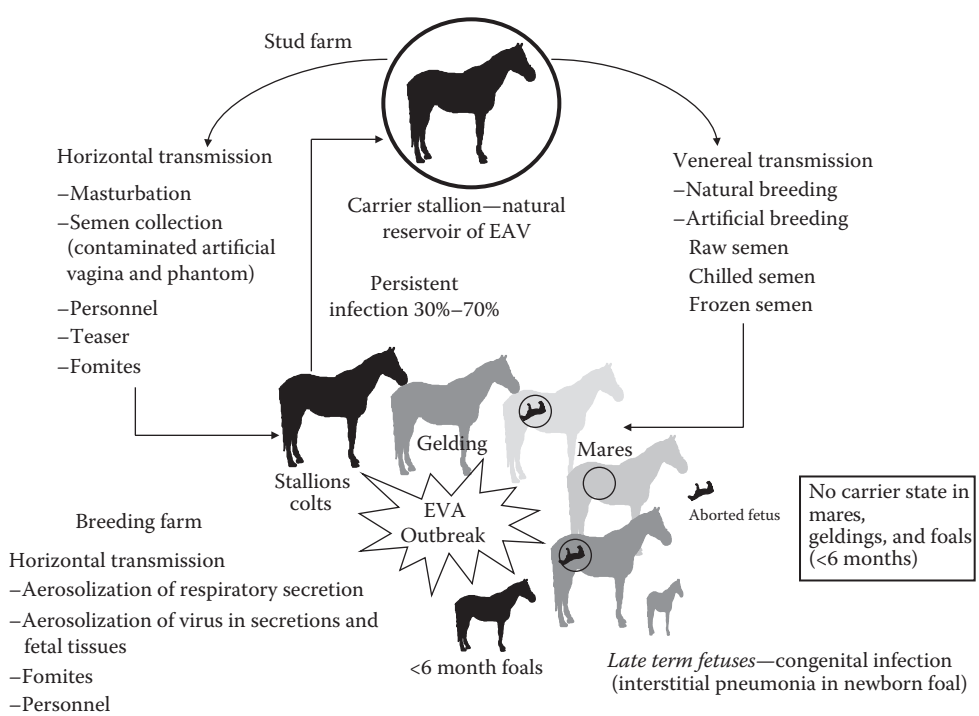

FIGURE 31.1 Transmission of equine arteritis virus.

Downloaded From Vet-eBooks.com

following natural or artificial breeding then can readily transmit the virus by nasal aerosol to susceptible cohorts in close proximity. Thus, the two principal modes of EAV transmission are horizontal transmission by aerosolization of infectious respiratory tract secretions from acutely infected horses and venereal transmission during natural or artificial insemination with infective semen from persistently infected stallions. However, direct and close contact is necessary for aerosol transmission of EAV between horses.[36,40] EAV can also be transmitted by aerosol from urine and other body secretions of acutely infected horses, aborted fetuses and their membranes, and the masturbates of acutely or chronically infected stallions.[38,41–46] Recently, it has been demonstrated that the virus can also be transmitted during embryo transfer from mares inseminated with infective semen.[15,28] EAV can also be transmitted through indirect contact with fomites or personnel. Congenital infection results from vertical transmission (transplacental transmission) of the virus when pregnant mares are infected late in gestation.

There is only one known serotype of EAV and field isolates from North America and Europe are genetically closely related and differ only by 15% at the nucleotide level. Phylogenetic analyses based on ORF5 sequence cluster EAV field strains into two distinct clades, reflecting their North American (NA) and European (EU) origin.[15,47–49] Recent phylogenetic analysis shows that EAV isolates in the EU group could be further divided into two subgroups, EU subgroup-1 (EU-1) and EU subgroup-2 (EU-2). Data from individual EU and NA isolates indicate movement of viruses between the two continents due to the transport of carrier stallions and/or their semen. The major nucleotide and amino acid differences between NA and EU EAV strains occur in the nsp2-encoding part of ORF1a, as well as in ORFs 3 and 5, which encode the GP3 and GP5 envelope proteins, respectively.[50] EAV tends to evolve during persistent infection in the reproductive tract of the carrier stallions that leads to the emergence of novel genetic and antigenic variants that could initiate new disease outbreaks.

31.1.3 Clinical Features and Pathogenesis

The vast majority of EAV infections are subclinical (or inapparent) in nature, and therefore, it is underdiagnosed and underreported in countries where the disease is endemic.[15,28] The clinical signs displayed by EAV-infected horses depend on a variety of factors including the genetics, age, and physical condition of the horse, challenge dose and route of infection, strain of virus, and environmental conditions. With the sole and notable exception of the experimentally derived and highly horse-adapted EAV VBS, other strains and field isolates of EAV very rarely cause fatal infection in adult horses.[49,51] The incubation period of 3–14 days (usually 6–8 days following venereal exposure) is followed by pyrexia of up to 41°C that may persist for 2–9 days. Acutely infected horses may develop a wide range of clinical signs including pyrexia, depression, anorexia, dependent edema (prepuce, scrotum, ventral trunk, and limbs), stiffness of gait, conjunctivitis, lacrimation and swelling around the eyes (periorbital and supraorbital edema), respiratory distress, urticaria, and leukopenia. The virus causes abortion in pregnant mares, and abortion rates during natural outbreaks of EVA can vary from 10% to 60% of infected mares. EAV-induced abortions can occur at any time between 3 and 10 months of gestation. The aborted fetuses are usually partially autolyzed at the time of expulsion. Aborted fetuses may exhibit interlobular pulmonary edema, pleural and pericardial effusion, and petechial and ecchymotic hemorrhages on the serosal and mucosal surfaces of the small intestine. EAV infection can cause a severe fulminating interstitial pneumonia and a progressive pneumoenteric syndrome in neonatal foals.

With the exception of persistently infected stallions, EAV is cleared from the tissues of infected horses by 28 days after the exposure. A significant number of acutely infected stallions (10%–70%) become persistently infected and shed the virus in semen; however, in contrast, there is no evidence of any analogous persistent infection in mares, geldings, or foals (<6 months of age). The virus persists in the ampulla and in the accessory sex glands of the male reproductive tract, and the establishment and maintenance of the carrier state in stallions are testosterone dependent.[29] Stallions may undergo a period of temporary subfertility associated with decreased libido and poor semen quality parameters (e.g., reduced sperm motility and concentration and an increased percentage of morphologically abnormal sperm in ejaculates) during the acute phase of EAV infection. The effect on semen quality is exerted by scrotal edema and fever during acute infection of the stallions and could be observed between 9 and 76 days postinfection (DPI).[29,52,53] However, semen quality is apparently normal in persistently infected stallions, despite high-titer virus shedding in the semen, which suggests that the virus seems to exert little to no direct effect after semen quality returned to normal.[53] Venereal infection of mares by persistently infected carrier stallions does not appear to result in subsequent fertility problems.[29]

Initial multiplication of EAV takes place in the upper respiratory tract epithelial cells and alveolar macrophages in the lung following respiratory exposure, and the virus soon appears in the regional lymph nodes, especially the bronchial nodes. Within 3 days, the virus is present in the blood (viremia lasts for 3–19 DPI) and in virtually all organs and tissues where it replicates in macrophages and endothelial cells. The pathogenesis of EVA is not clearly defined. *In vitro* and *in vivo* studies have demonstrated increased transcription of genes encoding proinflammatory mediators (IL-1β, Il-6, IL-8, and TNF-α) following EAV infection suggesting that these cytokine mediators are critical in determining the outcome of the infection and severity of the disease.[24,54] Furthermore, virulent and avirulent strains of EAV induced different quantities of TNF-α and other proinflammatory cytokines from both infected endothelial cells and macrophages. The clinical manifestations of EVA reflect endothelial cell injury in small arteries and consequently increased vascular permeability.[15] Recently, it has been shown that EAV can infect $CD3^+$ T cells from some horses *in vitro* but not from others.[55]

Downloaded From Vet-eBooks.com

Further studies have shown that based on this *in vitro* susceptibility of $CD3^+$ T cells to EAV infection, the horses could be divided into susceptible and resistant groups and the stallions with $CD3^+$ susceptible phenotype may represent those at higher risk of becoming carriers compared to those that lack this phenotype.[28] Subsequently, a genome-wide association study identified a common, genetically dominant haplotype associated with the *in vitro* $CD3^+$ susceptible phenotype, as well as EAV carrier state in the region of equine chromosome 11. Experimental inoculation with EAV into horses with *in vitro* $CD3^+$ susceptibility or resistance showed a significant difference between the two groups of horses in terms of proinflammatory and immunomodulatory cytokine mRNA expression and evidence of increased clinical signs in horses possessing the *in vitro* $CD3^+$ T cell–resistant phenotype.[24]

The characteristic histological feature of EVA is a severe necrotizing panvasculitis of small blood vessels.[56,57] Affected arteries show foci of intimal, subintimal, and medial necrosis with edema and infiltration of lymphocytes and neutrophils. Prominent vascular lesions are also seen in the placenta, brain, liver, and spleen of aborted fetuses. The lungs of affected neonatal foals have severe interstitial pneumonia. The characteristic vascular lesions of EVA do not appear to be the result of immune-mediated injury. Vascular injury in EVA is likely the result of direct virus-mediated injury to the lining (endothelium) and walls (media) of affected vessels. Increased vascular permeability and leukocyte infiltration resulting from generation of chemotactic factors lead to hemorrhage and edema around these vessels. However, the relative roles and importance of direct virus-induced injury versus virus-induced proinflammatory mediators have not yet been defined.

31.1.4 Diagnosis

Clinical signs of EVA resemble many other respiratory and reproductive diseases of horses, and therefore, diagnosis of EVA has to be further confirmed by laboratory diagnostic testing of appropriate clinical specimens. It is also important to identify EAV carrier stallions prior to breeding and/or international movement of their germplasm. During outbreaks, EAV can spread rapidly to susceptible horses and can result in very high morbidity. Therefore, rapid and accurate diagnosis of EVA is critical for implementation of prevention and control measures to avoid the spread of EAV and to reduce the economic impact of the disease. Various laboratory testing procedures based on both conventional and contemporary techniques have been described for the diagnosis of EVA in horses.[15]

31.1.4.1 Conventional Techniques

The confirmation of diagnosis of EVA is currently based on virus detection and/or serological demonstration of elevated neutralizing antibody titers (fourfold or greater) in paired serum samples taken at a 14–28-day interval. EAV can be isolated from nasal swabs or anticoagulated blood collected from horses with signs of EVA or the tissues (including placenta) of aborted equine fetuses. Putative carrier stallions are first identified by serology as they are always seropositive, and persistent infection is confirmed by virus isolation from semen in cell culture or by test-breeding using seronegative mares (and monitoring these for seroconversion to EAV after breeding).

Virus neutralization test (VNT) is the principal serological assay used to detect evidence of EAV infection by most laboratories around the world, and it continues to be the current World Organisation for Animal Health (Office International des Epizooties [OIE]) prescribed standard test for EVA (gold standard).[58] Several laboratories have developed and evaluated enzyme-linked immunosorbent assays (ELISAs) to detect antibodies to EAV using whole virus, synthetic peptides, or recombinant viral proteins (e.g., GP5, M, and N) as antigens. However, none of these ELISAs or recently described microsphere immunoassay (Luminex) has yet been shown to be of equivalent sensitivity and specificity to the VNT.[59] Interestingly, a recently developed commercial cELISA assay (VMRD, Pullman, WA) appears to have very high sensitivity and specificity compared to the VNT.[60,61,62] This new cELISA requires further validation before it can be used as a prescribed test for screening horses for international movement.

Virus isolation (VI) is currently the OIE-approved gold standard for the detection of EAV in semen and is the prescribed test for international trade. Isolates of EAV from clinical specimens, including semen, are often confirmed in a one-way neutralization assay using polyclonal equine sera raised against the prototype Bucyrus strain of EAV or by immunofluorescent assay using monoclonal antibodies to EAV.[58,59] These methods, although of proven reliability, are time-consuming, expensive, and cumbersome. The availability of modern nucleic acid–based assays has revolutionized diagnostic testing of clinical specimens for many infectious disease agents.[63–72] Compared to traditional VI, these assays are frequently more sensitive, less expensive, and less time-consuming.[64–66,71]

Histopathological examination utilizing indirect immunohistochemical staining is also useful for diagnosis of abortion in particular.[70] An avidin–biotin complex (ABC) for immunoperoxidase staining using monoclonal antibodies to individual EAV proteins has been successfully used to detect viral antigens in formalin-fixed, paraffin-embedded samples, as well as in frozen tissue sections.[56,57,74] Tissue samples should be fixed and saved in 10% neutral buffered formalin and submitted for histopathologic and immunohistochemical examination at an appropriate laboratory.

31.1.4.2 Molecular Techniques

Sensitive standard reverse transcription polymerase chain reaction (RT-PCR), RT-nested PCR (RT-nPCR), and real-time RT-PCR (rRT-PCR) assays for the detection of EAV nucleic acid in tissue culture supernatants and clinical specimens have been developed,[63,67,72,75–78] and these assays are being increasingly used for routine diagnostic purposes. These assays target different genes (ORFs 1b, 3, 4, 5, 6, and 7), and their sensitivity and specificity vary considerably. The sensitivity of RT-PCR-based assays is significantly increased by using either RT-nPCR that incorporate two primer pairs specific for ORF 1b or real-time

Downloaded From Vet-eBooks.com

TaqMan RT-PCR that uses primers and a probe specific for a highly conserved region of ORF7.[80,81] RT-PCR-based assays have several potential advantages over the current VI procedure including fast and reliable means of virus detection.

31.2 METHODS

31.2.1 Sample Collection and Preparation

31.2.1.1 Sample Collection

The most appropriate specimens for VI from horses with clinical signs include nasopharyngeal swabs or washings, conjunctival swabs, and citrated or ethylenediaminetetraacetic acid (EDTA) blood samples for separation of buffy coat cells. Heparinized blood is not suitable for virus isolation because of the inhibitory effect of heparin on the isolation of EAV in cell culture.[82] The sperm-rich fraction of the ejaculate is optimal for virus isolation from equine semen samples.[29] Placenta, fetal fluids, lung, spleen, and lymphoid tissues should be collected for virus isolation to confirm cases of EAV-induced abortion. A wide variety of organs and lymph nodes associated with the alimentary and respiratory tracts should be collected for virus isolation in suspected cases of "pneumoenteric" forms of EVA in young foals.

Specimens should be collected as soon as possible after the onset of clinical signs or suspected EAV infection. Nasopharyngeal and conjunctival swabs should be immediately placed in transport medium (any cell culture medium or balanced salt solution containing 2%–5% fetal bovine or calf serum) and either refrigerated or, preferably, frozen at −20°C or lower.[29] All other specimens for virus isolation should be packed in dry ice and dispatched by overnight delivery to an appropriate laboratory, except for blood samples that should be refrigerated.

For serologic diagnosis of acute EAV infection, acute and convalescent blood samples should be collected in tubes without anticoagulant. Serum is separated by centrifugation and either refrigerated or, preferably, frozen at −20°C or lower. Tissue samples should be fixed and saved in 10% neutral buffered formalin and submitted for histopathologic and immunohistochemical examination at an appropriate laboratory.

31.2.1.2 Processing of Clinical Samples for Virus Isolation

Nasal swabs and lacrimal swabs in virus transport medium are centrifuged at 500 × *g* for 10 min at 4°C to eliminate cellular debris and then filtered through 0.45 μm syringe filters. The filtrate is then used for inoculation of cell monolayers of susceptible cell lines or can be stored at −80°C until further use. Blood samples collected into EDTA anticoagulant tubes are centrifuged at 500 × *g* for 10 min. Plasma and buffy coat cells are aspirated and placed in 15 mL conical centrifuge tubes. Buffy coat cells are pelleted by centrifugation at 1500 × *g* for 10 min at 4°C. The plasma is aspirated and discarded, and the cell pellet is washed in Eagle's Minimum Essential Medium (EMEM; Mediatech, Herndon, VA) twice and resuspended in 2 mL of EMEM. The cell suspensions are aliquoted and frozen at −80°C until VI is performed. Tissue samples should be ground aseptically in EMEM to make 10% tissue homogenates for VI.

Cell culture isolation of EAV is usually done in the rabbit kidney-13 (RK-13) continuous cell line, and development of a cytopathic effect (CPE) in inoculated cells indicates the presence of virus. The identity of the virus isolate should always be confirmed by immunofluorescence or immunoperoxidase staining or by microneutralization assay with EAV-specific antiserum or monoclonal antibodies.

Isolation of EAV from equine semen samples is attempted in both high (passage level 399–409 [KY]) and low passage RK-13 (passage level 194–204; ATCC CCL-37, Manassas, VA) cell lines according to the OIE-described protocol.[58] It has been shown that the high passage RK-13 cell line is superior for the primary isolation of EAV particularly from semen as compared to the low passage RK-13 cell line. Briefly, semen samples are sonicated for 45 s (3 × 15 s), and sperm and cellular debris are sedimented by centrifugation (230 × *g*, 10 min) at 4°C. Serial 10-fold dilutions (10^{-1}–10^{-3}) of the seminal plasma of each sample are made in supplemented EMEM, and 1 mL of each dilution is inoculated into each of 2 × 25 cm^2 flasks containing confluent monolayers of RK-13 cells. Inoculated flasks are incubated at 37°C for 1 h before being overlaid with supplemented EMEM containing 0.75% CMC. Flasks are incubated at 37°C and checked for the appearance of CPE on days 3 and 4 post inoculation. If there is no detectable CPE, a second blind passage is performed on day 4. The RK-13 cell monolayers are fixed and stained with a 0.2% crystal violet solution containing 2% formaldehyde on day 5 post inoculation in the case of the first passage and on day 4 post inoculation in the case of the second passage in cell culture.[83]

31.2.1.3 Processing of Clinical Samples for Molecular Testing

Any of the clinical samples including semen samples can be tested for viral RNA by molecular diagnostic assays. A prerequisite for the performance of molecular diagnostic assays is an efficient method to isolate and purify viral RNA from clinical specimens from horses.[84–86] Viral RNA is extremely susceptible to degradation by endogenous RNases (ribonucleases) that are present in all living cells. Therefore, the key to successful isolation of high-quality RNA for laboratory diagnosis is to ensure that neither endogenous nor exogenous RNases are introduced prior to or during the nucleic acid extraction procedure. The extracted RNA should be aliquoted into multiple tubes and stored at −20°C (short-term) or −80°C (long-term) to avoid degradation prior to testing.

Currently, there are many methods to isolate and purify viral RNA from clinical specimens, but only a very few studies have been published that describe the comparison of various RNA extraction methods of samples from animal origin including equine.[81,87,88] Most of the commercial reagent kits for RNA extraction are based on fluid phase, solid phase, or magnetic separation techniques.[89–91] The traditional RNA

Downloaded From Vet-eBooks.com

extraction method using acid guanidinium thiocyanate–phenol–chloroform technique developed by Chomczynski and Sacchi in 1979 has been replaced by commercial reagent kits that use glass fiber filters, silica gel spin columns, and magnetic beads to trap RNA present in the clinical specimens.[89–92] Furthermore, the new commercial reagent kits have increased the yield, purity, and quality of extracted viral RNA by removing contaminating genomic DNA, other RNAs, and RT-PCR enzyme inhibitors present in the clinical specimens. However, these kits vary significantly in technological principles used for nucleic acid extraction. There are various pros and cons to each technological principle, and therefore, the quality and purity of RNA extracted from various reagent kits can vary significantly.

Several automated nucleic acid isolation kits using magnetic beads and magnetic particle processors are commercially available.[93] Unlike automated liquid handling systems that move reagents into and out of a single well of a multiwell plate to perform the different steps of an RNA isolation procedure, the magnetic particle processors use permanent magnetic rods to collect magnetic beads from the solution and release them into other wells containing reagents for the subsequent steps of the protocol. The effectiveness of bead collection and transfer leads to superior washing and elution efficiency, as well as rapid processing of a large number of samples (e.g., 24, 48, or 96 samples in a batch). Additionally, the magnetic bead–based method can also be used for manual RNA purification. Previous studies have demonstrated that viral nucleic acid extraction using the magnetic bead extraction method increases sensitivity of the rRT-PCR assay compared to the column-based extraction method for the detection of EAV nucleic acid.[81]

31.2.2 Detection Procedures

31.2.2.1 Standard RT-PCR and RT-nPCR

As indicated earlier, standard RT-PCR (two-step and one-step) and RT-nPCR assays for the detection of EAV in clinical samples have been previously described in the literature. RT-nPCR assay is more sensitive than the standard RT-PCR but prone to give false-positive results due to sample carry-over and cross-contamination.[67]

31.2.2.2 Real-Time RT-PCR

The rRT-PCR has the following important advantages over the standard two-step RT-PCR: (1) eliminating the possibility of cross-contamination between samples with previously amplified products since the sample tube is never opened and (2) reducing the chance of false-positive reactions because the rRT-PCR product is detected with a sequence-specific probe. Therefore, standard RT-PCR and RT-nPCR assays have now been replaced by rRT-PCR assays for diagnosis of EAV. It has been demonstrated that at least one of the rRT-PCR assays described in literature has equal to or higher sensitivity than VI for the detection of EAV nucleic acid in semen samples.[81]

31.2.2.3 Insulated Isothermal RT-PCR

Recently, GeneReach (GeneReach USA, Lexington, MA) has developed a TaqMan® probe-based insulated isothermal RT-PCR (iiRT-PCR) assay for the detection of EVA nucleic acid in semen and tissue samples.[94,95] The assay is based on iiRT-PCR for qualitative detection of EAV RNA in clinical samples. Fluorogenic probe hydrolysis chemistry is used to generate a fluorescent signal when a specific RNA sequence of EAV is amplified. This assay is specially designed to be used on a compatible iiRT-PCR instrument, POCKIT™ Nucleic Acid Analyzer (GeneReach USA, Lexington, MA).[92,93] The POCKIT Xpress™ Portable PCR Platform for on-site testing is suitable to be used in veterinary clinics, racetracks, breeding facilities, and diagnostic laboratories.[94]

31.3 CONCLUSION AND FUTURE PERSPECTIVES

EAV infection continues to pose a great threat to the equine industry in the United States and around the world. Over the years, the importation of carrier stallions and virus-contaminated semen into the United States unquestionably has been responsible for the introduction of new strains of EAV and precipitated outbreaks of EVA.[97–100] In 2006, a multistate occurrence of EVA was confirmed in Quarter horses for the first time, beginning in New Mexico and spreading to at least 10 other states (Utah, Alabama, Oklahoma, Kansas, Montana, Colorado, Texas, California, and Idaho).[9] This was the most extensive recorded occurrence of EVA in the United States and was primarily the result of interstate shipment of infective semen (fresh, cooled, or frozen) from virus-shedding stallions. Embryo transfer from mares bred to carrier stallions has increased the spread of EAV around the world. Therefore, the identification of persistently infected stallions and the institution of biosecurity and management practices to prevent the introduction of EAV-infected horses into new premises during acute outbreaks can prevent further outbreaks of EVA. Very clearly, rRT-PCR has significant advantages over VI in terms of reproducibility between laboratories, ease and speed of completion, and cost; thus, it is logical that the most accurate rRT-PCR assay would replace VI as the prescribed test for international trade. Furthermore, validation of the recently described cELISA could help to overcome the limitations associated with the VNT, which is the current "gold standard" for detection of serum antibodies to EAV.

There has been significant recent progress in understanding the molecular biology of EAV and mechanism of virus replication in cells. The application of cutting-edge molecular biology techniques along with development of reverse genetic systems to manipulate the viral genome has facilitated these advancements. However, neither the location of EAV persistence in the male reproductive tract nor the mechanisms of persistence have been examined in depth. Ongoing studies using contemporary molecular and genomic techniques will facilitate the identification of the cellular factors and pathways associated with the assembly of EAV particles in infected cells and the establishment of the carrier state in stallions. Such studies are prerequisite to the logical

Downloaded From Vet-eBooks.com

design and development of antiviral drugs to clear the virus from the reproductive tract of carrier stallions. Recent studies indicate that the existing vaccines may not induce complete protection against all field strains of EAV. Future development of efficacious vaccines that will engender broad heterotypic immunity to all strains of EAV will require ongoing comparative sequence analysis of the ORF5 of field isolates of the virus from around the world. Logically, future vaccines should be developed utilizing recombinant DNA technology, such as the use of infectious clones as a stable genetic background to develop marker (differentiating infected from vaccinated animals [DIVA]) vaccines that distinguish naturally infected horses from vaccinated ones.

32.1 INTRODUCTION

Porcine reproductive and respiratory syndrome (PRRS) is an economically important disease of swine resulting from the infection with a single-stranded, positive-sense RNA virus called porcine reproductive and respiratory syndrome virus (PRRSV). First recognized in the United States in 1987 and subsequently detected in Europe and other parts of the world, PRRS is characterized by late-term reproductive failure in sows (e.g., infertility, abortions, stillbirths, or the birth of weak piglets) and respiratory distress in piglets. With the capacity to induce severe clinical disease and maintain a life-long subclinical infection in swine population, PRRSV is a serious threat to the swine industry worldwide. In the United States, the estimated cost associated with PRRS amounts to >600 million U.S. dollars per year.

32.1.1 Classification

PRRSV is a single-stranded RNA virus classified in the genus *Arterivirus*, family *Arteriviridae*, order *Nidovirales*.

The order *Nidovirales* (nidus means nest in Latin, reflecting to the fact that members of this order produce a 3′-coterminal nested set of subgenomic mRNA during infection) covers RNA viruses that possess seven conserved domains (5′-TM2–3CLpro-TM3-RdRp-Zm-HEL1-NendoU-3′). Of these, TM2 and TM3 are transmembrane domains; 3CLpro is a 3C-like protease (a catalytic His-Cys dyad); RdRp is the RNA polymerase; Zm is a Zn cluster–binding domain fused with a helicase (HEL1); and NendoU is an uridylate-specific endonuclease. While the first three are encoded in open reading frame (ORF)1a, the remaining four are encoded in ORF1b.

Depending on the size of the genome, the order *Nidovirales* is conveniently arranged into two divisions: the large nidoviruses with genomes of 26.3–31.7 kb are found in the families *Coronaviridae* and *Roniviridae*, while the small nidoviruses with genomes of 12.7–15.7 kb are included in the families *Arteriviridae* and *Mesoniviridae* [1].

Currently, the family *Arteriviridae* consists of a single genus *Arterivirus*, in which five species are recognized: equine arteritis virus (EAV, the type species; see Chapter 31), lactate dehydrogenase elevating virus (LDV), PRRSV, simian hemorrhagic fever virus (SHFV), and wobbly possum disease virus (WPDV) [2]. Interestingly, EAV and PRRSV are associated with respiratory and reproductive disease in equids and swine, respectively. LDV is generally nonpathogenic and occurs in field and the laboratory mice. SHFV is found in colobus monkey (*Procolobus rufomitratus tephrosceles*)

Downloaded From Vet-eBooks.com

and in African red-tailed (guenon) monkeys (*Cercopithecus ascanius*). WPDV causes neurologic disease among free-ranging Australian brushtail possums (*Trichosurus vulpecula*) in New Zealand.

PRRSV is further distinguished into genotype 1 (European genotype or PRRSV-1) and genotype 2 (Northern American genotype or PRRSV-2). While PRRSV-1 mainly occurs in Europe, PRRSV-2 is present in North and South America as well as Asia, including a highly virulent type 2 PRRSV in Southeast Asia that harbors a discontinuous 30-amino-acid deletion in its nonstructural protein (nsP) 2 [3–5]. Although both genotypes 1 and 2 are infective to cells of the monocyte/macrophage lineage, they demonstrate differences at the protein and nucleic acid levels. For example, PRRSV-1 and PRRSV-2 share 75.2%–81.6% identity in the structural M protein, 73.2%–75.0% in nsP9, 50.5%–54.3% in nsP1, and 24.4%–28.0% in nsP2.

Recent examinations of ORF5 and ORF7 gene sequences and nucleocapsid protein from East European PRRSV isolates revealed the existence of three subtypes within PRRSV-1, that is, a pan-European subtype 1 and East European subtypes 2 and 3, whose nucleocapsid proteins are of 128, 125, and 124 amino acids (aa) in size, respectively [6]. Additionally, phylogenetic analysis of ORF5 gene sequence enabled the identification of 12 clades (A–L) within PRRSV-1 subtype 1 and 9 lineages within PRRSV-2 [7,8].

32.1.2 Morphology and Genome Organization

Like other arteriviruses, PRRSV possesses an enveloped, pleomorphic but roughly spherical virion of 45–60 nm in diameter. The virion displays surface patterns with no obvious spikes. Underneath the envelope is an icosahedral core (shell) measuring 25–35 nm in diameter, which encapsidates a monopartite, single-stranded RNA(+) of 15.1–15.4 kb in length.

The genome of PRRSV consists of a methyl-capped 5′ untranslated region (UTR; 156–224 nt long), 10 ORFs (ORF1a, ORF1b, ORF2a, ORF2b, ORF3, ORF4, ORF5, ORF5a, ORF6, ORF7), and a 3′ UTR (59–117 nt long) with a polyadenylated [poly(A)] tail [5].

Located at the 5′ end and accounting for 75% of the viral genome, ORF1a and ORF1b encode two long polyproteins (pp) (1727–2502 aa for pp1a and 3175–3959 aa for pp1ab), which, after enzymatic cleavage by four viral proteases (encoded in the nsP1α, nsP1β, nsP2, and nsP4 regions), produce 14 nsPs, including nsP1α, nsP1β, nsP2, and nsP3–6, nsP7α, nsP7β, nsP8–12, and two additional proteins, nsP2TF and nsP2N, which result from ribosomal frameshifting (Table 32.1) [9].

ORF2–ORF7 are located at the 3′ end and encode eight structural proteins designated as glycoprotein (GP) 2, E, GP3, GP4, GP5, ORF5a, M, and N (through an expression from a 3′-coterminal nested set of subgenomic RNAs) (Table 32.1). It is of interest that ORF5 (encoding the major

envelope glycoprotein) exhibits marked genetic variation and represents an ideal target for phylogenetic assessment of PRRSV isolates.

32.1.3 Biology and Epidemiology

The primary target cells of PRRSV infection in vivo are porcine pulmonary alveolar macrophages. PRRSV relies on the GP5 to attach to heparan sulfate on the cell surface and utilizes the GP2, GP3, and GP4 trimer to interact with host CD163 (cysteine-rich scavenger receptor, or SRCR). As the primary and core receptor for PRRSV, CD163 determines the susceptibility of cells to the virus. Sialoadhesin (CD169/Siglec-1) is an immunoglobulin-like lectin (carbohydrate-binding protein) that carries sialic acids and mediates endocytosis. Other cellular molecules with potential receptor role in PRRSV binding are vimentin, CD151, and dendritic cell–specific intercellular adhesion molecule-3-grabbing nonintegrin (CD209) [10].

Upon entry into the cell via clathrin-mediated endocytosis, the viral membrane fuses with the endomal membrane, and the viral ssRNA is released into the cytoplasm. After translation from the viral RNA, replicase pp1a and pp1ab interact with nsPs to form replication and transcription complex, which generates a full-length genome and a minus RNA strand. The synthesis of sgmRNA from the minus RNA strand facilitates the expression of structural proteins. Subsequently, the new genomes are assembled into the nucleocapsids at the host endoplasmic reticulum and then released via exocytosis [11].

In experimentally infected sows, PRRSV is detectable in the tonsils, heart, uterus, kidneys, and lymph nodes. In piglets from intranasally inoculated sows, PRRSV replicates primarily in lymphoid tissues and then spreads to the lungs, heart, liver, spleen, and kidneys. In boars, PRRSV persists in lymphoid tissues (such as the tonsils), although some infected macrophages may bring the virus to the tissues of the male reproductive tract and semen. Once contaminated semen appears in the uterus, PRRSV infection may begin from the endometrial tissues and regional lymph nodes following hematogenic or lymphogenic dissemination throughout the sow organism.

PRRS occurs only in pigs, and its horizontal transmission is made possible by close contacts between infected and naïve animals, through nasal secretions, saliva, feces, urine, and semen. Other factors that facilitate the virus spread include movement of carrier pigs, aerosols, droplets, dust, and contaminated boots, clothing, equipment, vehicles, as well as infected mallard duck.

Following its first report in the United States in 1987, type 1 (European genotype) and type 2 (North American genotype) PRRSV were isolated in Europe and North America in the early 1990s. Of the three subtypes within PRRSV-1 (European genotype), subtype 1 (Lelystad virus-like) is distributed throughout Europe and the world, while subtypes 2 and 3 are mainly present in Eastern Europe. Interestingly, PRRSV-1 isolates exhibit length differences in the nucleocapsid protein (ranging in size from 124, 128, to 132 aa) that are not observed in PRRSV-2. In addition to PRRSV-2 that occurs in North and South America and Asia, a type 2 highly pathogenic PRRSV (HP-PRRSV) strain was identified in swine farms in China in 2006 [3]. HP-PRRSV is characterized by a unique discontinuous deletion of 30 aa in the nsP2 and is responsible for causing high fever and severe morbidity and mortality in pigs of all ages. Subsequently, HP-PRRSV was also detected in other Asian countries such as Vietnam [3].

32.1.4 Clinical Features and Pathogenesis

PRRSV infection may result in a range of clinical presentations that are influenced by the host age and immune status, as well as the virulence of PRRSV strains involved. For example, PRRSV is commonly found in grower pigs in comparison with sows, possibly due to the fact that sows tend to be vaccinated while grower pigs are not.

32.1.4.1 Sows

Clinical signs of PRRS in dry sows during the first month of infection include inappetence (spreading over 7–14 days, affecting 10%–15% of sows), fever (39°C–40°C), abortions (often late term, affecting 1%–6% of sows), transient discoloration (bluing) of the ears (blue ear disease, affecting 2% of sows), early farrowings (10%–15% over the first 4 weeks), prolonged anestrus and delayed returns to heat postweaning, and coughing and respiratory signs [12].

Clinical signs of PRRS in farrowing sows in the first month of infection include inappetence over the farrowing period, reluctance to drink, no milk (agalactia) and mastitis, early farrowings, discoloration of the skin (including cyanosis or bluing of the vulva and ears) and pressure sores, lethargy, respiratory signs (coughing and pneumonia), mummified piglets (10%–15% death in the last 3–4 weeks of pregnancy), stillbirth (up to 30%), and very weak piglets at birth [12].

32.1.4.2 Piglets

Clinical signs of PRRS in piglets include diarrhea, increased respiratory infections (e.g., Glasser's disease), and decreased survival rate.

32.1.4.3 Boars

Clinical signs of PRRS in boars include inappetence, fever, lethargy, loss of libido, reduced fertility, poor litter sizes, and lowered sperm output.

32.1.4.4 Weaners and Growers

Clinical signs of PRRS in growing herd include slight inappetence, mild coughing, hairy wasting pigs, or no symptoms. In untreated herd, the disease may exacerbate, with acute extensive consolidating pneumonia, formation of multiple abscesses, loss of condition, diarrhea, pale skin, mild coughing, sneezing, discharges from the eyes, increased respiratory rates, and mortality (12%–15%) [12].

In 4–12-week-old pigs born from infected sows, clinical signs include inappetence, malabsorption, wasting, coughing, pneumonia, and mortality (12% or higher) in this

Downloaded From Vet-eBooks.com

postweaning period. Secondary bacterial infections in pigs from 12 to 16 weeks of age may lead to abscesses in the lungs and throughout the body, lameness with abscesses, and poor, stunted growth [12].

In grower pigs, lesions are mainly observed in cranioventral lung lobes that are characterized by consolidation, discoloration, and failure to collapse when the thorax is opened. Microscopically, the alveolar walls are thickened due to the infiltration of macrophages, lymphocytes, and neutrophils. Tonsillitis in the grower pigs is characterized by erosion of the crypt epithelia and dilated crypt lumina filled with macrophages, neutrophils, lymphocytes, and cryptal epithelial cells [12].

Histological examination of placenta from infected sows reveals local separation between the uterine epithelium and trophoblast, complete degradation of the fetal placental mesenchyme, and appearance of apoptotic (and necrotic) cells, which may be initiated by PRRSV damage of susceptible fetal placental macrophages and bystander cells. The deterioration of placental functions may contribute to fetal death and clinical representations of congenital PRRSV infection [13,14].

PRRSV nsPs have the ability to inhibit the production of type 1 interferons (particularly IFN-α and IFN-β), induce abnormal B cell proliferation and repertoire development (often lymphopenia and thymic atrophy), and suppress innate immunity, contributing to its survival in the host [15–19]. By damaging the mucociliary transport system, PRRSV impairs the function of porcine alveolar macrophages, induces apoptosis of immune cells, and thus increases susceptibility to secondary bacterial infections [20–23].

32.1.5 Diagnosis

Associated with severe weight loss (wasting), failure to thrive, and pneumonia, PRRS resemble to the postweaning multisystemic wasting syndrome caused by porcine circovirus type 2 (PCV2), which is a nonenveloped single-stranded DNA virus of the genus *Circovirus*, family *Circoviridae* [24]. Therefore, differential diagnosis for PRRS includes PCV2 infection, in addition to classical swine fever (caused by a positive-sense single-stranded RNA virus of the genus *Pestivirus*, family *Flaviviridae*), African swine fever (caused by a large enveloped, double-stranded DNA virus of the genus *Asfivirus*, family *Asfarviridae*), and Aujeszky's disease (pseudorabies, due to Suid herpesvirus 1, a member of the genus *Varicellovirus*, subfamily *Alphaherpesvirinae*, family *Herpesviridae*) [25–29].

Traditionally, diagnosis of PRRS is based on clinical signs, postmortem examinations, and detection of the virus in the herd by virus isolation and serological assays. Recent development of molecular techniques such as reverse-transcription polymerase chain reaction (RT-PCR) offers a rapid, sensitive, and specific alternative for identification and typing of PRRSV [30,31].

PRRSV is difficult to isolate using subcultured cells. Indeed, the initial isolation of PRRSV was achieved with primary porcine pulmonary macrophages [32]. Years later, Marc-145 cells and other cell lines are found to accommodate PRRSV growth in vitro [33].

The current serological assays for PRRSV detection include immunoperoxidase monolayer assay and enzyme-linked immunosorbent assay (ELISA). The commercially available ELISA (HerdChek® 2XR/3XR PRRS ELISA, IDEXX Laboratories, Inc.) provides a reliable approach for antibody detection with a rapid turnaround time.

Use of nucleic acid amplification technologies such as RT-PCR facilitates improved identification and genotyping of PRRSV [34–46]. Indeed, real time RT-PCR assays have been reported for specific determination of PRRSV-1 (European genotype), PRRSV-2 (North American genotype), and HP-PRRSV [47–50]. Several real-time RT-PCR assays are commercially available (e.g., VetMax, Applied Biosystems; VetAlert, Tetracore; and AcuPig, AnDiaTec) [51].

Using real-time RT-PCR, PRRSV may be detected in boar serum, blood swabs, and oral fluids as early as 24–48 h postinfection and in semen as early as 48–120 h postinfection. Sensitivity-wise, serum appears to be numerically superior to blood swabs > semen > oral fluid/frothy saliva for early detection of PRRSV infection in boars [52,53].

32.1.6 Treatment and Prevention

PRRSV is responsible for reproductive failure in sows, preweaning mortality in piglets, and reduced performance in growing pigs. Control and elimination of PRRS at the farm level are dependent on adopting several management procedures, including pig flow, gilt acclimation, and vaccination. The management of pig flow (or herd closure) is based on the delayed introduction of the new herd until the resident virus dies out. Vaccination of pigs with modified live virus vaccines (MLV vaccines or attenuated vaccines) and killed virus vaccines (KV vaccines or inactivated vaccines) provides full protection against homologous PRRSV challenges. Currently, MLV and KV vaccines for both European and North American PRRSV strains are available commercially (e.g., RespPRRS/Ingelvac PRRS MLV, Boehringer Ingelheim Animal Health) [9].

In general, attenuated vaccines are prepared by in vitro cell culture passaging of virulent virus until an attenuated phenotype appears, whereas inactivated vaccines are produced by chemical or physical inactivation of virulent viruses. With the capacity to induce virus neutralizing antibodies, attenuated vaccines prevent virus replication in target cells, viremia, and clinical symptoms. On the other hand, without inducing virus neutralizing antibodies, inactivated vaccines cannot prevent PRRSV infections. Nevertheless, MLV vaccines have an unwanted tendency to spread within the vaccinated herds as well as to neighboring nonvaccinated herds, and revert or recombinate genetically, leading to abortion and high mortality in pregnant sows. KV vaccines are safer but less efficacious in conferring protection [54].

To eliminate the possible side effects of MLV vaccines and improve the efficacy of KV vaccines, plasmid DNA and viral vector vaccines that contain PRRSV structural proteins (GP3, M, and/or GP5) are being developed [55]. This may also help overcome the drawback of current PRRSV vaccines relating to the difficulty to distinguish vaccinated animals from pigs

Downloaded From Vet-eBooks.com

that have recovered from a natural infection. However, the ability of the new generation vaccines to protect pigs against PRRS remains to be ascertained [9].

32.2 METHODS

32.2.1 Sample Preparation

Blood is collected from the anterior vena cava of pigs and placed in 5 mL centrifuge tubes without coagulant or anticoagulant. After centrifugation at 1000 × *g* for 10 min, serum is stored at −80°C until use.

Frothy saliva (from the submandibular salivary gland of aroused boars), oral fluid, and semen are collected from boars. Semen is centrifuged and semen supernatant and cell fractions are tested separately.

Tissues (from the tonsils, lungs, liver, spleens, and lymph nodes) are collected from pigs suspected of PRRSV infection. The tissues are first homogenized, 20% (w/v), in 10% (w/v) sterile phosphate-buffered saline and filtered through 0.22 mm membrane filters.

Viral RNA is extracted from serum, semen, or tissue filtrate by using QIAamp Viral RNA Mini Kit (Qiagen). Internal control RNA may be similarly processed. The extracted RNA is eluted in a 50 µL kit elution buffer.

32.2.2 Detection Procedures

32.2.2.1 Conventional RT-PCR

Xiao et al. [56] utilized primers nsP2-F (5′-AACA CCCAGGCGACTTCA-3′) and nsP2-R (5′-GCATGT CAACCCTATCCCAC-3′) from the nsP2 gene in RT-PCR for differential diagnosis of PRRSV and HP-PRRSV.

RT-PCR mixture (10 µL) is composed of 0.5 µL cDNA, 5.0 µL 2 × PCR reaction mix (TaKaRa), 0.4 µL nsP2-F (10 µM) primer, 0.4 µL nsP2-R (10 µM) primer, 0.1 µL Taq DNA polymerase (2.5 U/µL, TaKaRa), and 3.6 µL H_2O. amplification parameters that include the following: 95°C for 3 min; 30 cycles of 94°C for 30 s, 60°C for 30 s, and 72°C for 1 min; and a final extension at 72°C for 5 min. The resulting products are detected by 1.5% agarose gel electrophoresis in 1 × TAE.

Note: The presence of an 874 bp product is indicative of PRRSV, while the presence of a 787 bp product is indicative of HP-PRRSV.

32.2.2.2 Real-Time RT-PCR

Wernike et al. [57] developed a multiplex real-time quantitative reverse transcription polymerase chain reaction (RT-qPCR) for specific identification of PRRSV genotype 1 (European type 1), genotype 2 (North American type 2), and highly pathogenic North American strain (HP-PRRSV) (Table 32.2).

RT-PCR mixture (25 µL) is made up of 8.75 µL RNase-free water, 5.0 µL RNA UltraSense™ 5× Reaction Mix (RNA UltraSense One-Step Quantitative RT-PCR System, Invitrogen), 1.25 µL RNA UltraSense Enzyme Mix, 1.0 µL type 1 PRRSV–specific FAM-labeled primer–probe mix (20 pmol/µL PRRSV-EU-2.1F, 20 pmol/µL PRRSV-EU-2.1R, 6.25 pmol/µL PRRSV-EU-2.1FAM), 1.0 µL type 2 PRRSV–specific Texas Red-labeled primer–probe mix (10 pmol/µL PRRSV-US-1dF, 10 pmol/µL PRRSV-US-1R, 2.5 pmol/µL PRRSV-US-1TEX), 1.0 µL HP-PRRSV-specific Cy5-labeled primer–probe mix (10 pmol/µL PRRSV-HP-1F, 10 pmol/µL PRRSV-HP-1R, 2.5 pmol/µL PRRSV-HP-1Cy5aS), 2 µL IC-specific HEX-labeled primer–probe mix (2.5 pmol/µL EGFP-11-F, 2.5 pmol/µL EGFP-10R, 1.25 pmol/µL EGFP-HEX) (Table 32.2), and 5 µL RNA template.

Amplification and detection are carried out in a Bio-Rad CFX96 Real-Time Detection System (Bio-Rad) using the following thermal profile: RT at 50°C for 15 min, initial Taq activation at 95°C for 2 min; 45 cycles of denaturation at 95°C for 15 s, annealing at 56°C for 20 s, and extension at 72°C for 30 s.

Note: The multiplex PRRSV RT-qPCR allows rapid detection and differentiation of both genotypes 1 and 2 PRRSV as well

TABLE 32.2

as HP-PRRSV, with an analytical sensitivity of <200 copies per μL for PRRSV type 1 assay and 20 copies per μL for PRRSV type 2 and HP-PRRSV. The inclusion of EGF primers and probes as an internal control ensures the authenticity of test results.

32.3 CONCLUSION

PRRS is an economically significant disease of swine that is characterized by the appearance of severe clinical symptoms (e.g., embryonic death, late-term abortions, early farrowing, mummified fetuses, and weak-born piglets) and maintenance of a life-long subclinical infection, resulting in enormous production losses and increased control and prevention costs. The ability to rapidly and accurately identify PRRSV genotypes and subtypes is crucial for successful management of this disease. Although virus isolation and serological assays remain useful for diagnosis of PRRS, molecular techniques especially RT-PCR have become an indispensable tool for detecting and genotyping PRRSV and for selecting the most appropriate type-specific vaccines to control the disease.

Owing to the obvious shortcomings of current commercial PRRSV vaccines (MLV and KV vaccines), continuous efforts are necessary to develop a universal vaccine that provides broad protection against circulating PRRSV strains, without the risk of vaccine-introduced clinical signs. Clearly, this will require detailed knowledge as to how PRRSV suppresses and evades host innate and adaptive immune responses, what molecules are linked to such immune suppression and evasion, which PRRSV epitopes are able to confer broad protection, and how PRRSV nsPs and structural proteins influence virus replication, virulence, immunity, and protection [9,17].

33.1 INTRODUCTION

With a constantly increasing requirement for shrimp products, accompanied by an ever-advancing technology, penaeid culture has progressed from extensive subsistence farming to a major industry, with a worldwide production of over 4 million tons annually, valued at approximately US$19 billion in 2012.[1] The importance of shrimp disease has increased proportionally along with the growth of this new industry.

During the period of 1970s–1990s, shrimp aquaculture exhibited an astonishing expansion of approximately 24% per annum.[2] Since then, however, diseases such as yellow head disease (YHD) have had a devastating impact on the industry. An economic impact assessment from Fegan and Clifford[3] reported that in 1994, just over US$2 billion was lost due to disease, reducing the industry growth to approximately 8% per annum, the lowest in a 30-year period. More recently, Lightner[4] estimated that the costs, in 2001, of White Spot Syndrome Virus, Taura Syndrome Virus, Yellow Head Virus (YHV), and Infectious Hypodermal and Hematopoietic Necrosis Virus exceeded US$ 7 billion, and Briggs et al.[5] estimated that mortality due to shrimp viruses probably exceeded US$1 billion per year.

Recently, shrimp aquaculture has again shown rapid growth. The production period between 2000 and 2008 had an average annual increase of close to 15%, yielding approximately 3 million tons of shrimp products in 2008. This was reportedly due somewhat to the adoption of the white leg shrimp (*Litopenaeus vannamei*) within the Asian continent, after successful introduction from Latin America.[2] Disease outbreaks continue to cause major losses within the shrimp industry. Shrimp diseases have traditionally been a localized problem, but with the expansion and globalization of the industry, diseases that have been restricted to one region are now rapidly spreading cross geographic borders, placing a heavy reliance on sensitive detection methods to uphold biosecurity in the receiving region or country.

This chapter will focus on the yellow head complex nidoviruses, including gill-associated virus (GAV) with respect to the present literature, with a focus on the molecular detection of the closely related viruses.

YHV and GAV are considered to be genotypes within the yellow head complex, which includes four other closely related genotypes[6] with recombination between genotypes also being evident.[7] YHV emerged in 1990 in Thailand and its first description was published by Limsuwan in 1993.[8] The virus was reported to cause severe disease with 100% mortality within 3 days after signs of infection. While the disease-causing etiology was unknown, the syndrome was dubbed yellow head disease based on the yellow coloration of the dorsal cephalothorax due to the enlarged hepatopancreas and the

Downloaded From Vet-eBooks.com

generally pale appearance of affected shrimp. The etiological agent of the syndrome was identified as being viral in 1993.[8]

GAV is the junior synonym of lymphoid organ virus (LOV), which was reported in Australia in 1995[9] and was initially considered to be a nonpathogenic variant of GAV within wild and farmed black tiger shrimp, *Penaeus monodon*.[10] GAV was reported in 1997 as a pathogenic variant of LOV.[10] In 2000, a sequence analysis indicated that LOV had a 98.9% nucleotide identity to GAV, indicating they are the same virus presenting as either a chronic or an acute infection.[11]

33.1.1 Classification and Genome Organization

The yellow head viral complex consists of six recognized genetic lineages (Figure 33.1), which are distributed across most of the natural geographic range of penaeid shrimp. Of these, only genotype 1, which is the causative agent of YHD resulting in high mortalities, and genotype 2 (GAV), which is regarded as mildly pathogenic, have been associated with causing disease in penaeid shrimp.[8,10,12,13] Genotypes 3–6 were detected exclusively as low-level infections in apparently healthy shrimp.[6] The homologous genetic recombination of these genotypes has also been reported, both naturally and experimentally. Natural recombination was detected between YHV genotypes 2, 3, and 5, while experimental genetic recombination was demonstrated between pathogenic genotypes 1 and 2.[7] The high level of genetic exchange among genotypes indicates the expanding genetic diversity and has wider implications on detection methods, virulence, and international trade. Currently, YHD is considered to be an infection with YHV genotype 1 and is the only listed agent for YHD.[14] Trade barriers, disease definition, and obligatory reporting of viral detection have not yet been challenged with genome sequence containing a partial sequence of genotype 1, resulting in a mixed classification.

The collective groups of viruses in the yellow head complex are enveloped, rod-shaped, positive-sense RNA viruses that are classified as a single species in the genus *Okavirus*, family *Roniviridae*, order *Nidovirales*.[15] The 26,662 nucleotide (nt) genome of YHV (genotype 1) contains four long open reading frames (ORFs). ORF1a encodes a large polyprotein (pp1a) containing cis-acting papain-like protease (PLP) and 3C-like protease (3CLP) domains.[16] ORF1b overlaps ORF1a and is expressed only as a result of a (−1) ribosomal frame shift at a "slippery" sequence upstream of a predicted pseudoknot structure in the overlap region. The extended polyprotein (pp1ab) contains "SDD" RNA-dependent RNA polymerase, helicase, metal ion binding, exonuclease, uridylate-specific endoribonuclease, and ribose- 2′-O-methyl transferase domains of the replication complex.[16,17] ORF2 encodes the nucleoprotein (p20), which is the only polypeptide component of the helical nucleocapsid.[18,19] ORF3 encodes a polyprotein (pp3) that is processed at signal peptidase type 1 cleavage sites to generate the two virion envelope glycoproteins, gp116 and gp64, and an N-terminal triple-membrane-spanning fragment of unknown function.[20] The 26,235 nt YHV genotype 2 genome is slightly smaller than the YHV genotype 1, primarily due to significant deletions in intergenic regions (IGRs), but shares ~79% overall nucleotide sequence identity with YHV genotype 2.[16,21] The genome organization of genotype 2 is similar to genotype 1 and all identified functional domains are preserved, but YHV genotype 2 contains an additional small ORF near the 3′-terminus (ORF4, 83 aa) that may be expressed at low levels in infected cells.[11,21–23] Like other nidoviruses, the YHV complex transcribes a nested set of 3′-coterminal, polyadenylated, genomic, and subgenomic mRNAs.[16,21] Partial genome sequence analysis of YHV genotypes 3, 4, and 5 has indicated that they share a similar genome organization and transcription strategy and are more closely related in sequence to genotype 2 than to genotype 1.[6]

33.1.2 Morphology, Biology, and Epidemiology

YHV virions are rod-shaped, enveloped particles containing helical nucleocapsids that mature by the process of budding through intracytoplasmic membranes.[8,10] The nucleocapsids exhibit striations with a periodicity of approximately 7 nm and are often observed in association with the distended endoplasmic reticulum.[10]

The virions vary from 160 to 200 by 34–63 nm in size and are often packed densely into vesicles, resembling paracrystalline arrays. Free virions are also observed in intercellular spaces probably via release from disintegrating cells.[8,24] Within all stages of virally infected cells, virogenic stroma and filamentous viral nucleocapsids, 116–435 by 16–18 nm in size, are often observed scattered randomly within the cytoplasm.[24] The nucleocapsid of the YHV complex becomes enveloped by passage through the endoplasmic reticulum or the virions have occasionally been observed invading the interstitial spaces of the lymphoid organ and gain their envelope by passage through the plasma membrane.[24]

YHD outbreaks have been reported only in the black tiger prawn (*P. monodon*) and the white Pacific shrimp (*P. vannamei*).[8,25] Stentiford et al.[26] has produced a detailed review of hosts susceptible to YHV infection, according to scientific literature. About 18 potential host species were identified from the scientific literature. Stentiford et al.[26] used criteria to ascertain the validity of the reports, which included whether the exposure method was invasive or noninvasive, and scientific proof of the replication, viability, pathology, and location of the virus. From this review, Stentiford et al.[26] concluded that there are scientific data available to support susceptibility of *P. monodon*, *P. merguiensis*, *P. vannamei*, *P. setiferus*, *P. aztecus*, *P. duorarum*, *Metapenaeus brevicornis*, *M. affinis*, and *Palaemon styliferus*, and there are scientific data suggesting susceptibility of *P. esculentus*, *P. japonicus*, *P. stylirostris*, *M. ensis*, and *M. bennettae* with uncertainty of virus identification. Information on *P. esculentus*, *M. ensis*, *M. bennettae*, and *Macrobrachium lanchesteri* was considered insufficient to scientifically assess susceptibility with regard to criteria, and the scientific data suggesting susceptibility of *M. lanchesteri*, *M. sintangense*, and *Palaemon serrifer* were essentially experimental and invasive. Additional studies that surveyed 16 crab species collected from the vicinity of shrimp farms in

Thailand detected no evidence of either natural infection or experimental susceptibility[27] and, to date, infections by genotypes 2–6 in the YHV complex have been detected only in *P. monodon*.[6]

33.1.3 Clinical Features and Pathogenesis

33.1.3.1 Clinical Signs

Initially, infection of YHV (genotype 1) in *P. monodon* of cultured populations and experimental trials affected juvenile to subadult shrimp and often induced 100% mortality in shrimp within ponds within 3 days from the onset of disease.[8] However, natural disease outbreaks from YHV (genotype 2) have been reported in *P. monodon* up to 40 g,[10] showing genotypic variation in virulence.

The initial gross sign of infection is a rapid increase in feeding at an abnormally high rate for several days, followed by a sudden decline in appetite;[8] however, this is not seen in all cases. Within 1 day of the shrimp ceasing to feed, they begin either slowly or erratically swimming near the edge of the pond, and mortalities soon follow. Dead shrimp are found at the edge of the pond and scattered evenly over the entire bottom of the pond. The disease is often characterized by a pale to yellowish coloration of the cephalothorax and gills due to the underlying yellow hepatopancreas showing through the translucent carapace of the prawn and also a generally pale or bleached appearance of affected shrimp.[8,28] It has also been reported that YHV (genotype 2) from Australia causes the color of the prawn to change to a degree of pink to red, with primarily the appendages, tail fan, and mouth parts being most noticeable; however, this characteristic can often be attributed to general stress and is not necessarily caused only by YHV infection. Spann et al.[10] also reported that the gills changed from the normal clear/yellow to pink, and the shrimp exhibited fouling of the gills, shell, and tail rot.

33.1.3.2 Pathogenesis

Clinical signs of YHD occur in *P. monodon* within 7–10 days of exposure. YHV replicates in the cytoplasm of infected cells in which long filamentous prenucleocapsids are abundant, and virions bud into cytoplasmic vesicles in densely packed paracrystalline arrays for egress at the cytoplasmic membrane.[8] YHV infection can be transmitted horizontally by injection, by ingestion of infected tissue, by immersion in sea water containing tissue extracts filtered to be free of bacteria, or by cohabitation of naive shrimp with infected shrimp.[29,30] Infection of shrimp has also been established by injection of extracts of shrimp homogenate (*Acetes* sp.) collected from infected ponds.[31] Vertical transmission of genotype 2 has been shown to occur from both male and female parents, possibly by surface contamination or infection of tissue surrounding fertilized eggs.[21] The dynamics of how YHV infection spreads within aquaculture ponds is poorly understood. However, the rapid accumulation of mortalities during disease outbreaks suggests that horizontal transmission occurs very effectively. Low-level mortality on farms, throughout the production period, has also been associated with YHV (genotype 2) infection (Table 33.1), indicating that mortality attributed to YHV is often multifactorial.[13]

YHV (genotype 2) persists as a chronic infection for at least 50 days in *P. esculentus* that survive experimental challenge.[32] The high prevalence of subclinical or chronic infection often found in healthy *P. monodon* infected with YHV genotypes 2–6 from postlarval stages onward suggests that these infections can persist for life.[6,33] There is also evidence that genotype 1 can persist in survivors of experimental infection.[27,34]

The modes of infection of YHV have been placed into two general groups: horizontal transmission and vertical transmission. Horizontal transmission can occur when YHV-free susceptible shrimp feed on infected carcasses, experience bath exposure to membrane-filtered tissue extracts, either by

TABLE 33.1
Average Prevalence and Loading of GAV in Three Shrimp Farms Growing *Penaeus monodon* at 1-Month Poststocking and 1-Week Preharvest, Indicating the Percentage Increase between the Sampling Periods and Percentage of Daily Increase (*n* = 1800)

	Disease Outbreak, Low Production (*n* = 300[a])	Disease Outbreak, Emergency Harvest (*n* = 220[a])	No Disease Outbreak, Low Production (*n* = 200[a])	No Disease Outbreak, High Production (*n* = 180[a])

cohabitation with infected shrimp or by direct experimental injection of the viral inoculum.[33] Experimental infections with YHV (genotype 2) indicate that larger (~20 g) *P. japonicus* are less susceptible to disease than smaller (~6–13 g) shrimp of the same species.[35] However, experimental infection of *P. monodon* indicated an inverse relationship with shrimp size and mortality in the same study. This may have been due to the initial viral load of the chronically infected *P. monodon* compared to the uninfected *P. japonicus*, where the larger *P. monodon* may have had an elevated initial viral load compared to the smaller *P. monodon*. However, this was not discussed in the paper.

P. monodon are susceptible to YHV (genotype 1) infection beyond postlarvae (PL) 15.[36] However, this research was conducted under controlled environmental conditions and did not give a clear indication of susceptibility of postlarvae shrimp at stage PL15 or earlier, under suboptimal conditions. An experiment to determine the susceptibility of postlarvae *P. monodon* to YHV (genotype 2) by ingestion showed that PL20 shrimp died 7–10 days postinfection while PL_{15} survived the exposure;[33] these findings support the earlier research conducted by Khongpradit et al.[36] The available data suggests that the disease was associated with viral loading. Walker et al.[33] reported that YHV from a diseased *P. monodon* caused mortalities after ingestion or immersion exposure while extracts from YHV-infected healthy *P. monodon* caused infection without mortality. However, after the viral concentration of the healthy shrimp had an equivalent titer to the diseased shrimp, YHV extracts from chronically infected, healthy P. *monodon* also induced disease, indicating that the disease is associated with viral loading. However, in these studies, there was no referral to the possibility of multiple viral infections.

To determine whether vertical transmission of YHV contributes to the high prevalence of chronic infections in wild and farmed *P. monodon* in eastern Australia, Cowley et al.[21] tested gonads and lymphoid organs for signs of YHV (genotype 2) from healthy male and female *P. monodon* broodstock and in fertilized eggs in addition to nauplii spawned from wild-fertilized females, using reverse transcription (RT)-nPCR as the detection method. The results indicated that the level of YHV in wild *P. monodon* was generally low. However, high levels of YHV were detected in moribund male broodstock reared in captivity for more than 12 months. The RT-nPCR-nPCR products from spermatophores in these shrimp were also significantly greater than those amplified from the lymphoid organ, which had previously been identified as the primary site of YHV replication in chronically infected *P. monodon*.[9] It was also reported that one in three spermatophores examined by TEM had mature YHV virions in the seminal fluid but not in the sperm cells. The RT-nPCR for YHV in eggs were positive; however, nauplii and protozoa were generally negative. This implies that YHV is associated with the egg surface and the majority of the virus is lost when the nauplii hatch and that the infection levels in the protozoa remain low. Cowley et al.[21] reported that this could be due to the lack of development of the lymphoid organ in larval and early postlarval life stages, which is likely to limit potential infection levels. RT-nPCR has detected YHV in PL_5 to PL_{15} shrimp from hatcheries and experimental spawning's of *P. monodon*,[33] suggesting that viral replication in postlarvae is occurring at sufficient levels to be detected.[33] Cowley et al.[21] reported that the identification of lymphoid organ spheroid bodies and YHV particles in approximately 1.2 g juvenile *P. monodon* grown from hatchery stocks (PL_6 and PL_{20}), suggesting that at least some of the postlarvae were infected with YHV. However, as individual postlarvae were not grown in isolation, it strongly raises the distinct possibility that some juvenile infections occurred during the course of the grow-out through cannibalism or water-borne transmission. Clearly, this horizontal transmission could promote translocation of YHV and the potential infection of wild *P. monodon* in the vicinity of farms via water or through the escape of infected farmed shrimp. The authors concluded that the high prevalence of chronic YHV infection in *P. monodon* broodstock from Northeastern Australia and farmed shrimp produced from these broodstock promotes the idea that this is perpetuated primarily by vertical transmission both in the wild and in hatcheries.[21] Unfortunately, however, the paper failed to comment on the likely survival of the YHV-infected progeny. The study only tested eggs and nauplii for the presence of YHV (genotype 2). It is only a speculation that these postlarvae survive through adulthood.

The infection prevalence of yellow head complex viruses in healthy *P. monodon* (as detected by RT-nPCR) can be high (50%–100%) in farmed and wild populations in Australia, Asia, and East Africa as well as in *L. vannamei* farmed in Mexico.[6,13,33,37,38] The prevalence of individual genotypes varies according to the geographical origin of the shrimp. In contrast, except in situations of disease outbreaks in aquaculture ponds, the prevalence of genotype 1 is more commonly low (<1%) in healthy wild or farmed *P. monodon*. The use of detection methods less sensitive than PCR (e.g., histology, immunoblot, dot blot, *in situ* hybridization, etc.) is likely, in most cases, to result in the real infection prevalence among populations of shrimp being underestimated.

Tissue distribution of YHV: A study by Lu et al.[39] reported that YHV particles were detected in the gill, lymphoid organ, head soft tissue, heart, midgut, hepatopancreas, abdominal muscle, eyestalk, and nerve cord of an experimentally infected *Penaeus vannamei*. Lu et al.[39] reported that the lymphoid organ, gill, and head muscle had a 50% tissue culture infectious dose assay ($TCID_{50}$) titer (mL^{-1}) of 10^6, while the midgut, abdominal muscle, and heart had a $TCID_{50}$ titer (mL^{-1}) of 10^5, and the nerve cord, hepatopancreas, and eyestalk had a $TCID_{50}$ titer (mL^{-1}) of 10^4. These findings suggest that the lymphoid organ, gill, and head muscle contained the highest number of infectious virions compared with the other tested tissue/organs. Cowley et al.[21] tested gonads from *P. monodon* for signs of YHV (genotype 2) and reported that the RT-nPCR products had a greater intensity from the spermatophores than those amplified from the lymphoid organ. These results, combined, indicate that the viral infection is systemic. Virions with a morphological appearance similar to YHV have also been reported in the optic nerve fibers and in the nerve cord of *P. monodon*.[12,40]

33.1.4 Diagnosis

For diagnosis of YHV infection, several methods are available with varying sensitivity and specificity. These include histological and electron microscopy methods, antibody-based assays, and molecular techniques that involves traditional PCR, quantitative PCR, nucleic acid sequence analysis, and *in situ* hybridization. The PCR methods are considered the most sensitive and specific assays available and are regarded as the gold standard for the diagnosis of YHV, replacing the traditional transmission electron microscopy technique to visualize virions, which has a lower sensitivity and is unable to distinguish between specific genotypes. While the actual choice of assay is dependent on geographic location, cost, and the specificity and sensitivity required, all detection methods require a confirmation assay to confirm a positive result.

There are regular publications of detection methods for YHV, some of which will be discussed in this chapter. The World Organisation for Animal Health (OIE) publishes detection methods that are regarded as diagnostic procedures of choice when infection presence requires reporting. The molecular diagnostic methods discussed in the following will include the recommendations from the OIE as these specific techniques are regularly reviewed.

33.1.4.1 Conventional Techniques

33.1.4.1.1 Histopathology

Spann et al.[10] reported that diseased shrimp display disorganization and loss of a normal, defined tubule structure in the lymphoid organ, which could be seen on histological sections stained with hematoxylin and eosin (H&E). The gills of diseased shrimp displayed structural damage such as fusion of gill filament tips, general necrosis, and loss of cuticle from primary and secondary lamellae. However, this detection method and signs of disease only indicate a generic disease and, as mentioned previously, these symptoms are also characteristic of penaeid shrimp infected with other viruses.

Flegel et al.[41] reported that YHV can be diagnosed histologically in moribund shrimp by the presence of intensely basophilic inclusions in shrimp tissues and that these inclusions can be seen best with H&E staining of sectioned stomach and gill tissue. However, the cytoplasmic, virus-associated inclusions stain deeply basophilic in the same manner as pyknotic nuclei, and it can be difficult to differentiate between the two without using an electron microscope, suggesting that there is no clear way to characterize and diagnose YHV infection using standard histological examination with H&E-stained preparations alone.[8] The lymphoid organ is distinctly abnormal in YHV infections of acute levels, showing nuclear abnormalities, cytoplasmic abnormalities, and necrotic cells, which are also a characteristic of penaeid shrimp infected with other viruses.[8]

33.1.4.1.2 Electron Microscopy

Transmission electron microscopy, which gives an image of the virus, is the traditional gold standard test for the visualization and confirmation of viral infection, such from YHV. However, this method is not useful for detecting early stage infections, for on-farm applications or when high throughput is required. It is time consuming and requires expensive equipment, and therefore, it is not applicable for on-farm use or for screening hatchery broodstock.

33.1.4.1.3 Serology

Polyclonal antisera have been produced for the detection of YHV.[42] However, the assay (Western blot analysis) was not highly sensitive and was not applicable to on-farm field examinations.[43] Sithigorngul et al.[43,44] produced monoclonal antibodies (MAbs) specific to YHV-enveloped protein. Most of the YHV-specific MAbs were specific to the 67 kDa protein and only a few were specific to the 135 and 22 kDa protein. Several of these antibodies against YHV did bind to hemolymph and tissues from uninfected shrimp.[43] This would be expected to some degree; as the virus matures and protrudes through intracytoplasmic membranes, host material is incorporated into the viral envelope. Alternatively, the reported uninfected shrimp may have had an undetected low level of infection, resulting in elevated binding. Munro and Owens[45] developed chicken polyclonal antibodies (PAbs) and mice MAbs toward YHV (genotype 2) from Australia. The PAbs reacted with 63, 110, and 170 kDa proteins of YHV (genotype 2) while the MAbs reacted with the 20 kDa protein of YHV. These antibodies were used to develop an enzyme-linked immunosorbent assay (ELISA), which was capable of quantitative detection of YHV (genotype 2) in individual shrimp. However, the ability of the ELISA to detect other genotypes was not determined.

YHV has been reported to hemagglutinate chicken erythrocytes.[42] Hemagglutination (HA) activity was determined via a qualitative and quantitative detection method yielding an HA end-point titer of 1:256, and the virus was not eluted after 24 h, suggesting that the reaction was stable and that the virus lacked receptor-destroying enzymes. Munro and Owens[46] used this HA activity of YHV to develop a low-cost detection method, while they demonstrated that YHV-negative shrimp caused negligible HA. The method of Munro and Owens[46] was developed using genotype 2 of the yellow head complex, and it is only assumed that all the genotypes cause the same level of HA.

As previously mentioned, the decision on which detection method to use is dependent on many factors. Munro and Owens[47] compared the sensitivity, specificity, positive predictive value, negative predictive value, accuracy, and cost-effectiveness between RT-n PCR designed by Cowley et al.[11] and an ELISA designed by Munro and Owens,[45] with a subsequent comparison between the ELISA and an HA assay (Munro and Owens[46]) toward YHV (genotype 2).

Using the RT-nPCR as the gold standard, the ELISA had an accuracy of 91.7% when using a cut-off optical density >0.75 as a positive result. When compared with the ELISA, the HA had an accuracy of 73% when using an HA titer cut-off greater than 16 as a positive result. These results indicate that alternative tests for GAV (ELISA and HA) can be used to explore multiple questions about the disease status of *P. monodon* stocks in a cost-effective manner albeit less sensitive and specific.

Downloaded From Vet-eBooks.com

33.1.4.2 Molecular Techniques

33.1.4.2.1 In Situ Hybridization

In situ hybridization has been developed[48] for the detection of YHV infection in *P. vannamei* using a cDNA fragment labeled with digoxigenin that resulted in a highly sensitive test. This same probe was subsequently used to detect YHV from Australia (genotype 2).[49] Spann et al.[32] have also reported the development of an *in situ* hybridization probe for the detection of YHV in *P. monodon* and *P. esculentus* within Australia.

33.1.4.2.2 Polymerase Chain Reaction

Wongteerasupaya et al.[50] developed an RT-PCR for the detection of YHV (genotype 1) in Thailand. This test was specific and sensitive for the selected region of the YHV genome, with other nucleic acid templates (WSSV and HPV) commonly present in this region, giving no amplification signal. The RT-PCR was able to amplify as little as 0.01 pg of YHV-RNA and showed evidence of infection in *P. monodon* at 6–12 h after experimental exposure to the virus. However, it is more likely that the RT-PCR detected the YHV genome that was injected into the prawn and circulated in the hemolymph, than it was to be detecting infection at such an early time after injection. Cowley et al.[11] developed an RT-nPCR for the detection of YHV within Australia (genotype 2). The specific genome amplification with the one-step PCR is able to detect 0.01 pg cDNA, and while using the two-step PCR technique, 0.01 fg cDNA was detectable. The YHV genome could be detected within 6 h of experimental infection of *P. japonicus*. However, again it is probable that the test was detecting genome that was injected into the shrimp and does not necessarily indicate viral replication within cells. Gill biopsies can be used as a tissue sample[11] that offer a nonlethal sampling method; additionally, it has been reported that dried hemolymph can be used for the detection of YHV with RT-PCR,[51] resulting in the ability to sample broodstock. A multiplex RT-nPCR has been developed for the differentiation between genotype 1 and 2.[22] It can be used to differentiate the two genotypes in diseased shrimp or for screening for asymptomatic carriers. This test will not detect all six known genotypes, and genotype 3 may generate a PCR product indistinguishable in size from that generated with genotype 2.

The third assay is a multiplex RT-nested PCR protocol described by Wijegoonawardane et al.[52] This multiplex RT-nPCR is capable of detecting the six genotypes of the yellow head complex of viruses but will not discriminate between genotypes. Assignment and differentiation of genotype can be achieved by nucleotide sequence analysis of the RT-PCR product. Finally, Wijegoonawardane et al.[53] have reported a SYBR Green real-time quantitative RT-PCR for the detection of the six yellow head genotypes. The RT-nPCR has a sensitivity of approximately 1.25 RNA copies while the quantitative RT-PCR can detect down to approximately 2.5 RNA copies. All PCR products should be sequenced as a confirmation step when reporting the presence of positive samples.

33.2 METHODS

33.2.1 Sample Preparation

For juvenile or adult shrimp, gill tissue is easily accessible and may be taken with minimal damage to the individual and used to prepare total RNA. Alternatively, lymphoid organ, hemolymph, or pleopods may be used; however, viral loading may vary between organs and standardization must be prepared if quantitative methods are being used. Fresh tissue is preferred. Tissue preserved in 95% analytical grade ethanol or RNAlater, or stored frozen at –70°C, is also suitable for total RNA preparation. Homogenize 10–20 mg of tissue or dispense 50 µL hemolymph in 500 µL Trizol reagent and extract total RNA according to the manufacturer's instructions. Resuspend RNA in 25 µL of molecular grade water, heat at 55°C for 10 min, cool by semi-immersion in an ice slurry, and use immediately or store at –70°C until required. The quality and quantity of isolated RNA should be determined by testing against UV absorbance at 260 and 280 nm, with an optimal ratio of 1.8:1–2:1. RNA yield will vary with the type and freshness of tissues as well as the quality of the preservative used and the length of time tissue has been preserved. However, RNA yields from fresh tissues would be expected to vary from 0.2 to 2.0 µg/µL and about half these amounts from alcohol-preserved tissues.

Postlarval shrimp can be sampled by pooling individuals with positive selection of weak individuals increasing the likelihood of detection. Assumed infection prevalence must be taken into account when deciding on numbers to be pooled and processed for RNA extraction using Trizol.

Within each test group, a negative control of either molecular grade water or YHV-free RNA sample and a positive control of YHV-positive RNA should be used.

33.2.2 Detection Procedures

33.2.2.1 RT-PCR for Specific Detection of Genotype 1 in Diseased Shrimp

To synthesize cDNA, mix 2 µL RNA in 20 µL PCR buffer (10 mM Tris/HCl pH 8.3, 50 mM KCl) containing 2.5 U of M-MLV (Moloney murine leukemia virus) reverse transcriptase, 1.0 U ribonuclease inhibitor, 0.75 µM antisense primer 144R, 1 mM of dNTP stock mixture, and 5 mM $MgCl_2$, and incubate at 42°C for 15 min. Incubate the mixture at 100°C for 5 min and cool the mixture to 5°C. Add PCR mixture (10 mM Tris/HCl pH 8.3, 50 mM KCl) containing 2.5 U *Taq* DNA polymerase, 2 mM $MgCl_2$, and 0.75 µM of primer 10F to give a final volume of 100 µL. Conduct PCR amplification for 40 cycles at 94°C for 30 s, 58°C for 30 s, 72°C for 30 s, and finishing at 72°C for 10 min. Aliquot a portion of the product to a 2% agarose/TAE (Tris-acetate-EDTA [ethylenediamine tetra-acetic acid]) gel containing 0.5 µg/mL ethidium bromide and following electrophoresis, visualize the 135 bp DNA band expected for YHV with a suitable DNA ladder using a UV transilluminator.

Downloaded From Vet-eBooks.com

The sensitivity of the PCR is approximately 0.01 pg of purified YHV RNA (≈10^3 genomes).

PCR primer sequences: 10F: 5′-CCG-CTA-ATT-TCA-AAA-ACT-ACG-3′

144R: 5′-AAG-GTG-TTA-TGT-CGA-GGA-AGT-3′

33.2.2.2 Nested RT-PCR for Differential Detection of Genotype 1 and 2 in Healthy or Diseased Shrimp

For cDNA synthesis, 2 μL RNA (ideally 1.0 μg total RNA), 0.7 μL of 50 pmol/μL primer GY5, and molecular grade water are added to total 6 μL; the mixture is then incubated at 70°C for 10 min and chilled on ice. Add 2 μL Superscript III buffer × 5 (250 mM Tris/HCl pH 8.3, 375 mM KCl, 15 mM $MgCl_2$), 1 μL 100 mM DTT, and 0.5 μL 10 mM dNTP stock and mix gently. Preheat to 42°C for 2 min, add 0.5 μL 200 U/μL reverse transcriptase, and incubate at 42°C for 1 h. Heat the reaction at 70°C for 10 min, chill on ice, and spin briefly in a microcentrifuge to collect the contents of the tube.

For the first PCR step, prepare a 50 μL reaction mixture containing 1 × *Taq* buffer (10 mM Tris/HCl pH 8.3, 50 mM KCl, 0.1% Triton X-100), 1.5 mM $MgCl_2$, 35 pmol of each primer GY1 and GY4, 200 μM of stock dNTP, and 2.5 U *Taq* polymerase in a 0.5 mL thin-walled tube. Overlay the reaction mixture with 50 μL liquid paraffin, heat at 85°C for 2 min, and then add 1 μL of prepared cDNA. Conduct PCR amplification using 35 cycles at 95°C for 30 s, 66°C for 30 s, and 72°C for 45 s, followed by final extension at 72°C for 7 min. For the second (nested) PCR step, prepare a 50 μL reaction mixture containing 2 μL of the first step PCR product, 1 × *Taq* buffer, 1.5 mM $MgCl_2$, 35 pmol of each primer GY2, Y3, and G6, 200 μM of stock dNTP, and 2.5 U *Taq* polymerase in a 0.5 mL thin-walled tube. Conduct PCR using amplification conditions as described earlier. Visualize the final PCR product using the same procedures as previously described.

If the viral load is sufficiently high, a 794 bp DNA will be amplified from either genotype 1 or 2 in the first PCR step. In the second PCR step, a 277 bp product indicates detection of genotype 1 and a 406 bp product indicates detection of genotype 2. The presence of both 406 and 277 bp products indicates a dual infection with both genotype 1 and 2. The detection sensitivity of the second-step PCR is ~1000-fold greater than the first-step PCR, and genotype 1 or 2 can be detected to a limit of 10 fg lymphoid organ total RNA.

The sequences of RT-PCR primers generic for genotype 1 and 2 (GY) or specific for genotype 1 (Y) or genotype 2 (G) are as follows:

GY1: 5′-GAC-ATC-ACT-CCA-GAC-AAC-ATC-TG-3′
GY2: 5′-CAT-CTG-TCC-AGA-AGG-CGT-CTA-TGA-3′
GY4: 5′-GTG-AAG-TCC-ATG-TGT-GTG-AGA-CG-3′
GY5: 5′-GAG-CTG-GAA-TTC-AGT-GAG-AGA-ACA-3′
Y3: 5′-ACG-CTC-TGT-GAC-AAG-CAT-GAA-GTT-3′
G6: 5′-GTA-GTA-GAG-ACG-AGT-GAC-ACC-TAT-3′

33.2.2.3 RT-nPCR for Detection of All Currently Known Genotypes in the Yellow Head Complex

For cDNA synthesis, mix 2 μL RNA (ideally 1.0 μg total RNA), 50 ng random hexamer primers, and 1.0 μL 10 mM dNTP and make up to a total volume of 14 μL in sterile molecular grade water, incubate at 65°C for 5 min, and chill on ice. Add 4.0 μL Superscript III buffer × 5, 1.0 μL 100 mM DTT, 1.0 μL 40 U/μL RNaseOUT™, and 1.0 μL 200 U/μL reverse transcriptase and mix gently. Incubate at 25°C for 5 min and then at 42°C for 55 min, stop the reaction by heating at 70°C for 15 min, chill on ice, and spin briefly in a microcentrifuge to collect the contents of the tube. For the first PCR step, add 1 μL cDNA to a total 25 μL reaction mixture containing 1 × *Taq* buffer (10 mM Tris/HCl, pH 9.0, 50 mM KCl, 0.1% Triton X-100), 1.5 μL 25 mM $MgCl_2$, 0.35 μL primer mix containing 25 pmol/μL of each primer pool YC-F1ab and YC-R1ab, 0.5 μL 10 mM dNTP mix and 0.25 μL 5 U/μL *Taq* DNA polymerase. Conduct PCR amplification by denaturation at 95°C for 1 min followed by 35 cycles at 95°C for 30 s, 60°C for 30 s, and 72°C for 40 s, followed by a final extension at 72°C for 7 min. For the second PCR step, use 1 μL of the first PCR product in the reaction mixture as prepared previously but substituting primer pools YC-F2ab and YC-R2ab. Conduct PCR amplification using denaturation at 95°C for 1 min followed by 35 cycles at 95°C for 30 s, 60°C for 30 s, and 72°C for 30 s, followed by a final extension at 72°C for 7 min. Visualize the final PCR product using the same procedures as previously described.

If the viral load is sufficiently high, a 358 bp DNA is amplified in the first PCR step. The second (nested) PCR step amplifies a 146 bp product. The detection of these products indicates detection of at least one of the six genotypes in the yellow head complex. Further assignment of genotype is possible by nucleotide sequence analysis of the PCR product followed by comparison with sequences of the known genotypes by multiple sequence alignment and phylogenetic analysis. The detection sensitivity limits of the first PCR step and nested PCR step are 2500 and 2.5 RNA templates, respectively.

PCR primer sequences are as follows (each primer comprises a pool of equal quantities of two related oligonucleotide sequences):

YC-F1ab pool: 5′-ATC-GTC-GTC-AGC-TAC-CGC-AAT-ACT-GC-3′
5′-ATC-GTC-GTC-AGY-TAY-CGT-AAC-ACC-GC-3′
YC-R1ab pool: 5′-TCT-TCR-CGT-GTG-AAC-ACY-TTC-TTR-GC-3′
5′-TCT-GCG-TGG-GTG-AAC-ACC-TTC-TTG-GC-3′
YC-F2ab pool: 5′-CGC-TTC-CAA-TGT-ATC-TGY-ATG-CAC-CA-3′
5′-CGC-TTY-CAR-TGT-ATC-TGC-ATG-CAC-CA-3′
YC-R2ab pool: 5′-RTC-DGT-GTA-CAT-GTT-TGA-GAG-TTT-GTT-3′
5′-GTC-AGT-GTA-CAT-ATT-GGA-GAG-TTT-RTT-3′

Mixed base codes: R(AG), Y(CT), M(AC), K(GT), S(GC), W(AT), H(ACT), B(GCT), V(AGC), D(AGT), N(AGCT).

33.2.2.4 Qualitative RT-PCR for Detection of All Currently Known Genotypes in the Yellow Head Complex

cDNA synthesis is achieved by using the same method as for the multiplex nRT-PCR (see previous texts). The primers are eightfold degenerate and target the same ORF1b gene sequences as the nested RT-PCR primers used earlier.

The qRT-PCR is performed by diluting 2 μL of cDNA into 8 μL of molecular grade water and adding this to an 18 μL reaction mixture containing 7 μL of 2× SYBR Green Master mix and 5 pmol/μL each primers, YHc-F2 and YHc-R2. Dispense 5 μL aliquots as 3 replicates into a 384-well real-time PCR plate. PCR cycling conditions are 50°C for 2 min and 95°C for 10 min and 40 cycles of 95°C for 15 s and 60°C for 1 min, followed by incubation at 95°C for 15 s, 60°C for 15 s, and 95°C for 15 s to generate a DNA dissociation curve.

PCR primer sequences are as follows:

YHc-F2: 5′-CGCTTYCARTGTATCTGYATGCACCA-3′
YHc-R2: 5′-RTCAGTGTACATGTTKGAGAGTTTRTT-3′

33.3 CONCLUSIONS AND FUTURE PERSPECTIVES

YHV was discovered as the etiological agent of shrimp mortalities in Thailand over 10 years ago. Since its discovery, YHV is now present in most shrimp-producing countries and is a major concern to the shrimp industry causing mortalities in endemic areas and placing biosecurity limitations on YHV naïve or specific genome naive shrimp farming areas. The relatively poor understanding of the mechanisms of viral infection and replication[54] and the limited understanding of the shrimp immune system limit the control of the virus.

The risk of homologous recombination within the YHV complex stands to be a future problem not only for prescribed detection methods that rely on a specific molecular sequence but also for further trade and biosecurity measures. Currently, border biosecurity refers to specific genotypes within the complex, which does not address the risk of a hybridized genotype that could potentially harbor highly virulent genes while presenting molecularly as a nonpathogenic genotype.

The molecular detection of YHV is extremely specific and sensitive with the capabilities of high-throughput automated screening of samples. The application of the available assays has contributed to driving our current knowledge and therapeutics for the industry, ultimately being a major contributor to controlling the health and economic impact of the virus. While the available molecular assays are extremely beneficial to the shrimp industry, the high cost involved in molecular testing can be a limitation for use in developing countries, where the virus is often prevalent. When combined with the limited availability of alternative, low-cost detection methods, the viral and disease spread will continue until effective treatment is developed. Treatment methods for the virus, and shrimp viruses in general, are still within the research realm. Some methods such as RNA interference,[55–59] which is driven by our molecular understanding of the viral and host complex, show promising results if effective delivery methods for application at a farm level and effective sequence targets can be optimized.

34.1 INTRODUCTION

Viral respiratory diseases are important causes of economic losses to the poultry industry worldwide. They are responsible for impaired growth of the flocks, reduced egg production, and quality, mortality, and slaughter downgrading. In addition, they may be associated with intercurrent bacterial infections, contributing to increased economic losses (including costs for diagnoses, vaccines, antimicrobials, and treatment). Two viral respiratory diseases (the very virulent Newcastle and the highly pathogenic avian influenza) have the potential to devastate poultry industry, but biosecurity efforts have kept the world's main poultry-producing regions free of these pathogens. Three other viral respiratory diseases (infectious laryngotracheitis, swollen head syndrome, and infectious bronchitis [IB]) are highly prevalent and frequent in industrial poultry flocks worldwide. Of these, IB has been considered the most economically important [1].

IB is an acute and highly contagious disease that affects only domestic fowl (*Gallus gallus*). The disease occurs in birds of all ages and any type of chicken (broiler, breeder, layers). Young birds are particularly susceptible and mortality is usually high when opportunistic pathogens complicate the disease. IB virus (IBV) is prevalent in chicken flocks, and it has also been found in peafowl (*Galliforme*). Furthermore, IBV-like viruses have been isolated from pigeon (*Columbiforme*), turkey (*Galliforme*), teal, duck, and goose (*Anseriforme*) [2].

IBV initially infects the upper respiratory tract (mainly trachea) and may later spread to the kidney, oviduct, and other organs and tissues. Clinical signs include cough, nasal discharge, and watery eyes in birds with respiratory manifestation. When young pullets are affected, damage to the reproductive tract can result in layers and breeders failing to come into production. Reduced egg quality can also be observed in IBV-infected layers and breeders. Decreased feed conversion efficiency and increased carcass condemnations are common in broiler, reducing the overall performance of the flocks. Morbidity is typically 100%, and mortality is variable according to the IBV strain and characteristics of the flock (age, type of chicken, breed, immune status, etc.). In flocks with nephritis, mortality can be higher than 50%. All these losses determine the economic impact of this disease in the different levels of the poultry industry chain [2,3].

34.1.1 Classification, Morphology, and Genome Organization

Avian IBV is a member of the genus *Gammacoronavirus* (formerly group 3), subfamily *Coronavirinae*, family *Coronaviridae,* order *Nidovirales*. The genus *Gammacoronavirus* currently consists of two species: avian coronavirus (type species) and Beluga whale coronavirus SW1. IBV and other previously existing coronaviruses of birds, such as turkey, duck, goose, pheasant, and pigeon, represent strains of avian coronavirus [4].

IBV is round to pleomorphic, with a mean diameter of 120 nm. It possesses an envelope and club-shaped surface projections (the glycosylated spike protein) of about 20 nm in length. Virions form by budding at internal cell membranes and their characteristic appearance under electron microscopy is a fringe of bulbous surface projections forming an image reminiscent of the solar corona. This morphology is created by the viral spike (S) peplomers, proteins of the viral surface. After spontaneous

Downloaded From Vet-eBooks.com

disruption of IBV particles, the core structure could be observed as strands of only 1–2 nm in diameter [2].

In addition to the S protein, there are three other proteins that contribute to the overall IBV structure: membrane (M), envelope (E), and nucleocapsid (N). S protein is a dimer or trimer in coronaviruses and has two basic functions: (1) to attach the virus to receptor molecules on host cells and (2) to activate fusion of the viral envelope with cellular membranes, releasing the viral RNA into the host cell's cytoplasm to be replicated [5]. IBV has the S protein in a cleaved form, with amino-terminal S1 (535 amino acids) and carboxy-terminal S2 (625 amino acids) subunits. The bulbous head of the S protein is formed largely by the S1 subunit, and it is anchored in the membrane by the carboxy-terminal portion of S2. S proteins interact with the transmembrane regions of a large copy number of a small integral M glycoprotein and with low amounts of the very small, membrane-associated, and nonglycosylated E protein. Both of these proteins are required for virus particle formation [2,5]. The genome is packaged into a helical nucleocapsid with the N phosphoprotein, creating the ribonucleoprotein [2].

The single-stranded, positive-sense RNA genome contains a 5′ cap structure and a 3′ poly-A tail and has about 27.6 kb in length in classical IBV (Figure 34.1). It includes several open reading frames (ORFs) that encode both the structural and nonstructural viral proteins. The whole genome is predominantly arranged in the order 5′ untranslated region (UTR)–replicase gene–structural protein genes (S, E, M, and N)–3′ UTR. Both UTR have around 500 nucleotides essential to viral RNA transcription and replication [6]. There are further nonstructural accessory protein genes interspersed between the structural protein genes that can vary in number among the IBV groups [2,7].

The replicase segment is also called Gene 1 and encodes the RNA-dependent RNA polymerase (RdRp), which is responsible for replicating the IBV genome. Gene 1 has a length of 20 kb and consists of two independent ORFs (ORF1a and ORF1b). These ORFs are translated into two polyproteins that are further cleaved into 15 products, among which the first two N-terminal ones are separated by a papain-like proteinase (PL^{pro}) and the remaining of the C-terminal products by a 3C-like proteinase ($3CL^{pro}$) [8]. The RNA genome also encodes the four structural proteins S (Gene 2), E (Gene 3c), M (Gene 4), and N (Gene 6), as well as the small nonstructural accessory proteins 3a, 3b, 5a, and 5b [2]. S is the most highly variable gene in the genome, mainly the S1 fragment, and responsible for the high diversity of IBV serotypes/genotypes. It also plays a key role in determining the species and tissue–cell tropism of all avian coronavirus [2,9–11].

The complex and large positive-sense RNA genome can have different sizes and organization in some variant IBV as well as in avian coronavirus that infects other bird species (turkey, pigeon, duck, etc.). For example, genomes that lack either all or most of the genes coding for nonstructural proteins at the 3′ end were observed in Australian types of IBV subgroup 2. These viruses had a unique ORF called X1 instead of the Genes 3 and 5, presenting two possible organizations: 5′ UTR–replicase gene–S–X1–E–M–N–3′ UTR or 5′ UTR–replicase gene–S–X1–E–M–5b–N–3′ UTR [12].

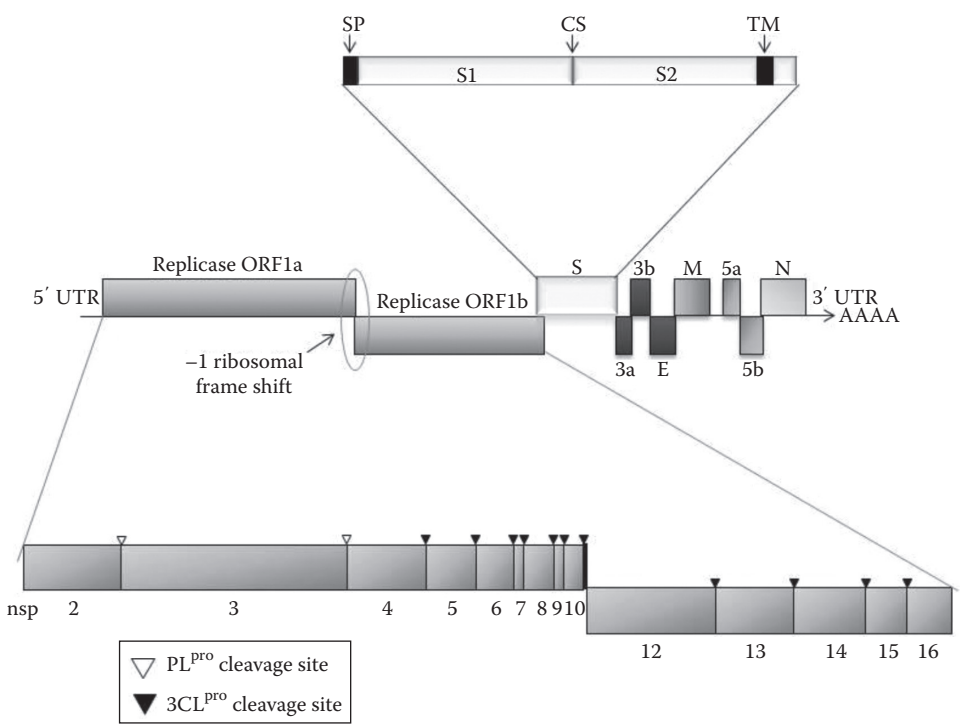

FIGURE 34.1 Classical genome organization of IBV. The genome is 27,620 nt long, excluding poly (A) tract. Middle: 10 genes and ORFs. Ribosomal frame shift is indicated. Top: details of spike protein, signal peptide (SP), spike protein cleavage (CS), transmembrane domain of spike protein (TM). Bottom: putative domains of ORF1a/1b polyprotein: nonstructural protein (nsp).

A recent study demonstrated that Korean variant strains are defective in segments of the Genes 3a and 3b [13]. On the other hand, turkey coronavirus (TCoV) has a genome very similar to IBV (>80%), and the main difference is in the S1 sequence (<40% of similarity) [7,14]. The quite common emergence of IBV variants as well as other avian coronaviruses in the field seems to be a result of mutation events in the S gene [13,15–18].

34.1.2 Biology

Initially, IBV replicates in the avian respiratory tract, but it has also tropism to epithelial cells from the kidney, oviduct, and gut. Viral entry relies on the interplay between the virion and the host cell, and it is initiated by the interaction of the S1 viral protein with specific receptor domains on the cell surface. Experimental data demonstrate that tropism to different cells (trachea, kidney, oviduct, cecal tonsils, etc.) is also determined by the S protein [10,19–21]. After initial binding, the coronavirus fuses the envelope with the host cell membrane to deliver the nucleocapsid into the target cell. The fusion involves large conformational changes of the S protein [5].

In order to infect cells, IBV enters by endocytosis. Inhibitory drugs of the clathrin-mediated pathway (such as chlorpromazine) abolished IBV infection. IBV virions harbor cleaved S glycoproteins between the S1 and S2 domains, proteolytically matured during infection in the host. This processing is carried out by the cellular proprotein convertase furin. IBV Beaudette strain has the peculiar feature to contain a second furin cleavage site in the S2 domain of the spike. Infection was inhibited by the presence of a furin inhibitor or amino acid substitutions in the S1–S2 cleavage site in Beaudette strain. Mutants containing a minimal cleavage site are still infectious, but they are dependent on serine proteases for productive infection [22].

After entrance, IBV replicates in the cytoplasm. Translation of the plus-stranded genome is initiated at the Gene 1 to produce the RdRp. The replicase–transcriptase proteins are encoded in the ORF1a and ORF1b and are synthesized initially as two large polyproteins: pp1a and pp1ab. The synthesis of pp1ab involves programmed ribosomal frame shifting during translation of ORF1a, resulting in the C-terminal extension of a relatively small fraction of ORF1a-encoded polypeptide (pp1a) with the ORF1b-encoded polypeptide. During or after synthesis, these polyproteins are co- and posttranslationally processed by the autoproteinases (PL^{pro} and $3CL^{pro}$) that reside in pp1a. Among the 15 nonstructural proteins (nsp) produced, nsp2–nsp11 are encoded in ORF1a, and nsp12–nsp16 are encoded in ORF1b (Figure 34.1) [23,24]. RdRp replicates the genome through a continuous process that starts with the synthesis of an intermediate full-length minus-strand RNA, which then serves as the template for the asymmetric synthesis of progeny plus-strand genomes. A process of discontinuous transcription during negative-strand synthesis, regulated by short AU-rich sequences known as transcription regulatory sequences (TRSs), leads to the production of a nested set of subgenomic mRNAs (sgmRNAs) sequences and expression of the structural and accessory proteins. Three of the sgmRNAs (from the Genes 2, 4, and 6) are responsible for production of the S, M, and N proteins, respectively. Two sgmRNAs (3 and 5) encode three (3a, 3b, and E) and two (5a and 5b) nonstructural proteins. However, the precise mechanisms of sgmRNA synthesis are yet not fully understood, and probably, more transcripts are produced [23–25].

With the synthesis of structural proteins, N binds genomic RNA and the M and S proteins are integrated into the membrane of the endoplasmic reticulum (ER). Assembled nucleocapsids with helical twisted RNAs bud into the ER lumen and are encased with the membrane. The viral progeny is transported by Golgi vesicles to the cell membranes, and the viral release is by exocytose into the extracellular space. New virus starts to appear 3–4 h after infection, with maximum output per cell being reached within 12 h at 37°C [3,23].

Rapid replication, high mutation rate, and genomic recombination result in extensive IBV genetic diversity [26]. The precise mechanism behind the emergence of this high diversity is still largely unknown, but it is well known that RdRp has low fidelity and limited ability to correct mistakes, although it has an associated exoribonuclease. High mutation rates are attributed to this low proofreading capability that generates around 10^{-3}–10^{-5} substitutions per site per year [5,7]. Point mutations, insertions, and deletions are observed along the genome of different IBV strains, especially in the gene encoding the S glycoprotein. In the most conserved parts of the genome, synonymous replacements also accumulate significantly [25]. Further, avian coronaviruses exchange genetic material (recombination) when different viral genotypes cocirculate in the same host [5]. Recent studies have also shown that recombination is the main mechanism behind the emergence of the novel *Gammacoronavirus* of turkey (TCoV) [14,27]. It is suggested that TCoV is a recombination between the classical IBV genome with the S fragment of another coronavirus from a still unknown source [14]. Similar studies have demonstrated that these two phenomenons (mutation and recombination) are also associated to the emergence of new IBV variants in the field worldwide [12,15,16,18,28].

34.1.3 Epidemiology

IBV is ubiquitous in most poultry-producing regions of the world and able to spread very rapidly in nonprotected birds. The virus is highly infectious, and it spreads by aerosol as well as by mechanical means. It is shed via both the respiratory tract and the feces and persists in the flocks for several weeks or months. Furthermore, one or more serotype/genotype can circulate in a specific geographic region [3].

An overview of the IBV history is essential to understand the current epidemiological situation. IB was first reported in the United States as a respiratory disease of young birds by Schalk and Hawn in 1931. Viral etiology was established some years after by Beach and Schalm in 1936. The first vaccine against IBV, strain M41 of the serotype Massachusetts (Mass), was developed in 1941. Other clinical manifestations,

Downloaded From Vet-eBooks.com

such as decline in egg production and more typical clinical respiratory signs, were demonstrated in 1950. A different serotype named Connecticut (Conn) was isolated in 1956 and considered the first IBV variant strain [29,30]. In the following decade, H52 and H120 vaccines (both of Mass serotype) were developed by serial passages in eggs and have been widely used in poultry flocks until today [31].

Injuries in kidney tissue were associated with IBV in the 1960s [32]. Other variant serotypes (Florida, Clark 333, and Arkansas) were described in the United States in the following years. Arkansas was one of the most important IBV variant strains found in the United States, and it is still associated to economic losses [26]. The emergence of viral field variants required the development of new vaccines (against variant serotypes), since Mass did not provide adequate immune protection [30].

The involvement of the enteric system (mainly the intestine) with IBV infection was demonstrated only in the 1970s, with several reports of viral excretion in feces but no apparent effect on the gut function [29].

Several variants (such as D274 and D1466) were reported in Europe in the 1980s. The control of these variants was performed with the use of attenuated live and inactivated vaccines against these specific strains. With the development of new diagnostic tools using molecular biology techniques, other variants (such as California, DE072, Vic S, N2/75, QX, and BR) were reported worldwide [29]. Despite this great diversity of variants, a small number of them (Mass, 4/91, QX-like) spread globally and are currently found in different regions of the world [33–36]. The main example of a globally distributed strain is the Mass, probably due to the intensive vaccination of the poultry industrial flocks with strains of this serotype. Other strains, as for example 4/91 and QX, disseminated naturally and are now present in important poultry-producing regions and backyard chickens [37,38].

34.1.4 Transmission, Pathogenesis, and Clinical Features

The main mode of IBV transmission is believed to be airborne, but the frequency of the air spread between flocks is unknown. Infection can also occur with the ingestion of water and contaminated food with fecal material, since IBV can survive for days in the environment, especially at low temperatures [39]. There are reports of survival for up to 20 weeks in the feces, a potential source of infection for birds [40]. It is also suggested that other species of birds can act as vectors, since IBV was demonstrated to infect more species [3,41].

IBV is highly contagious and has a very short incubation period up to the colonization of the trachea and appearance of the first respiratory signs (24–48 h after infection). Most IBV strains are isolated from the trachea with high concentrations during the first 3–5 days postinfection (PI) [42]. The viral titer drops rapidly in the second week and virus isolation is not always possible [43]. The progression of tracheal lesions can be classified into three stages: (1) degeneration, with deciliation and shedding of the epithelium (first 2 days PI); (2) hyperplasy, with the formation of new epithelial cells (3–10 days); and (3) regeneration, with the repair of the injured tissue (10–20 days) [44]. When secondary pathogens like avian mycoplasmas, *Escherichia coli*, *Ornithobacterium rhinotracheale*, and/or *Bordetella* complicate the disease, pneumonia, airsacculitis, and peritonitis can also occur [3,7].

After respiratory tract infection, IBV spreads to various tissues. The urinary (mainly kidneys), reproductive, and digestive (mainly cecal tonsil) systems are the preferential places for viral replication [2,29]. In the kidney, viral replication occurs in the proximal convoluted tubules and distal and collecting tubules. IBV can cause granular degeneration, vacuolization, and desquamation of the tubular epithelium [3]. The injury of the epithelial cells may result in changes in the transport of liquids and acute renal failure [45]. Poultry infected with nephropathogenic strains (e.g., T strain, Holte, Gray, SAIBK, and B1648) may show exclusively these renal damages, without any respiratory lesion [3].

In the digestive tract, the virus replicates in different tissues, such as esophageal, proventricular, duodenal, jejunal, cecal tonsil, rectal, and cloacal [2]. In the intestine, IBV replication has been reported in histiocyte-like and lymphoid cells of the cecal tonsils [45]. IBV was detected in the digestive tract and cloacal swabs from chickens infected with an IBV enterotropic variant strain (named G) for a period of up to 28 days. This strain has also been associated with the presence of lesions in the intestine and beyond the trachea, kidney, and reproductive tract [46,47].

Viral excretion occurs intermittently during the IBV persistence in chicken bodies. In a classic experiment, it was demonstrated that the onset of lay is preceded or coincided with a period of IBV excretion [48]. The intermittent excretion is the main way to spread among birds of the same flock by horizontal transmission (with direct and indirect contact) and even to new flocks [3,49].

Clinical presentation in the field includes respiratory, renal, reproductive, and digestive typical signs. The main affected tissue and/or organ depends on the tropism of the infecting strain, but respiratory signs are quite common for all strains and include cough, sneezing, depression, catarrhal inflammation in the airways and sinuses with nasal discharge, and watery eyes. The consequence is a decrease in food consumption and weight loss. Adult birds usually do not show respiratory signs or they are discrete [45].

Renal manifestation is observed in some cases and can be confused with other diseases. Signs of this manifestation are depression, ruffled feathers, wet droppings, watery stools, and increased water consumption. Mortality can be high (>50%) when renal injury is accompanied by urolithiasis [3].

Reproductive signs are mainly observed in layer and breeder flocks. IBV infection of 1-day-old chicks and even pullets can cause permanent damage to developing organs of the reproductive system. In adult hens, a decrease in egg production, and reduced internal quality (low albumen protein synthesis) and shell quality (soft-shelled or rough-shelled)

Downloaded From Vet-eBooks.com

are observed [45]. The severity of the production decline may vary with the period of lay and infecting virus strain [3].

Chickens with the digestive form of the disease may have watery stools and/or severe diarrhea. Some lesions can be found along the gastrointestinal tract and cecal tonsils [2,3]. However, enteric IBV infection is usually asymptomatic in chickens. Interestingly, the main clinical signs of turkeys infected with TCoV are enteric. Birds exhibit depression, anorexia, decreased water consumption, watery diarrhea, dehydration, hypothermia, and weight loss [50].

34.1.5 Diagnosis

Diagnosis of IB is initially based on the clinical history of the flock and gross lesions of the affected birds. Infected chickens have serous, catarrhal, or caseous exudates in the trachea, nasal passages, sinuses, and air sacs. Pneumonia signs may be observed around the large bronchi. Swollen and pale kidneys occur in the nephropathogenic infections, while oviducts and ovaries with reduced length and weight are eventually present in layers and breeders [3]. However, all of these clinical signs and lesions are also seen with other diseases, and confirmation of the IBV infection must be carried out by laboratory testing.

34.1.5.1 Conventional Techniques

The most classical methodology is virus isolation by inoculation into embryonating chicken eggs. IBV isolates usually replicate well in 10–11-day-old embryonating chicken eggs following inoculation of the allantoic cavity [51]. Field isolates often require adaptation via several (three or more) passages to achieve high viral titers. Characteristic IBV-infected chicken embryos (stunting, dwarfing, curling of the embryo) and increasing mortality rates are observed with more passages. A common lesion of the IBV-infected embryo is the presence of urates in the mesonephros of the embryonic kidney [3].

IBV can also be isolated in an organ (mainly trachea) or cell cultures. Twenty-day-old embryos' tracheal rings are usually prepared and maintained in roller tubes. After IBV infection, ciliostasis occurs within 3–4 days; and it is easily observed by microscopy. However, some strains with affinity to other tissues cannot cause visible ciliostasis [52]. Further, IBV can also be propagated in chicken kidney cell cultures. This cell type forms syncytia, which quickly round up and detach from the culture surface and has been largely used with several IBV isolates. However, some strains (e.g., Beaudette) cannot form syncytia and the cells remain attached to the culture surface. These strains should be maintained in other cell type, such as Vero [53].

In any system, virus isolation is generally a sensitive and useful procedure for the diagnosis of viral infection when clinical specimens are of good quality and have been collected ideally within 3–5 days PI. The main biological samples for virus isolation are trachea (especially with the first week of infection) and cloacal swabs or cecal tonsils collected during postmortem examination (mainly when more than 1 week has elapsed since the start of the infection). IBV is preferably isolated from a specific-pathogen-free (SPF) source (embryonating eggs or cells). The whole process is lengthy and laborious because field isolates usually require more passages [3,42].

Observations in embryonating eggs, organ, and cell cultures are not in themselves enough to detect IBV. Virus isolates must be tested with serological or molecular assays to confirm IBV presence and determine the identity of a field strain. Virus neutralization (VN) and enzyme-linked immunosorbent assay (ELISA) are considered type specific, although some cross-reactions between serotypes can occur. VN is based on the reaction of the IBV isolate with serotype-specific antibodies raised in chickens. Chicken embryos are most often employed, but antibodies can be measured using tracheal organ cultures or cell culture systems [54]. Two strains (A and B) are considered to be of the same serotype when two-way heterologous reactions (antiserum A with virus B, and antiserum B with virus A) differ less than 20-fold from the homologous reaction titer (antiserum A with virus A, antiserum B with virus B) in both directions [42]. ELISA is also widely used, and there are several commercial kits available. IBV antigen can be captured by anti-IBV antibodies that are coated on a microtiter plate. Subsequent incubations with anti-IBV conjugate and substrate will show positive optical densities when IBV is present in the sample. Samples have been previously inoculated in eggs since high amounts of virus are needed for antigen detection [42]. However, ELISA has many advantages for routine virus testing, being cost effective, robust, easy to use, and scalable to testing large numbers of samples [55].

34.1.5.2 Molecular Techniques

Molecular nucleic acid amplification techniques have been increasingly used for IBV detection and genotyping [3]. The main technique, reverse transcription polymerase chain reaction (RT-PCR), has been applied worldwide to detect IBV directly in clinical samples, after passages in embryonating eggs or in organ and cell cultures. Further, other molecular assays such as restriction fragment length polymorphism (RFLP) and nucleotide sequencing are able to genotype or even indirectly serotype the IBV sample, determining the identity of the strain. There is a good agreement between data represented by the VN serotype and S1 nucleotide sequence [3,56].

IBV molecular detection methods have highly conserved genomic regions as targets, such as the nucleocapsid gene [57,58] and 5′ UTR [59]. On the other hand, only S1 gene is currently used as a target in the genotyping assays [3,60]. Previous studies also developed RT-PCR genotype-specific assays, targeted on S1 gene, to detect only specific variant strains [61–63].

34.2 METHODS

Molecular methods to detect and genotype IBV require an adequate sample collection, transport, and storage as well as an efficient RNA extraction. In general, these first steps are laborious and time-consuming but essential to obtain a

Downloaded From Vet-eBooks.com

conclusive result in the analysis. Afterward, the main molecular biology technique used is RT-PCR either to detect or to genotype IBV. IBV can be detected by traditional RT-PCR and gel electrophoresis [64,65] or more recently by real-time RT-PCR procedures [57,59]. Some methods include a nested amplification step to improve the sensitivity and specificity of the assay. In contrast, the main methods to genotype IBV require an additional nucleotide sequence characterization step: RFLP or sequencing [66,67].

34.2.1 Sample Collection and Preparation

The main clinical specimen for this analysis is traditionally the trachea, considered the first replication site in the beginning of the infection, especially within the first week of infection. However, the cloaca and cecal tonsils are also recommended because IBV can replicate in the digestive tract in later stages of the infection. Other organs and tissues (lung, kidney, and oviduct) should also be considered to detect IBV according to the clinical history of the disease [3,42]. The samples for analysis could be either trachea/cloacal swabs or any organ/tissue collected during postmortem examination. Procedures for sample collection and processing have been previously described in detail [42]. The recommendations should be implemented on the farm. In addition, specimens should be transported to the laboratory from the collection site with a coolant to maintain a refrigerated temperature of approximately 2°C–8°C or preferably frozen [54,68].

Clinical samples are usually prepared in pools (set of organs collected from three to five birds) prior to the RNA extraction. Each pool should be composed of organs from a specific physiological system (lung, trachea, or tracheal swabs for respiratory; cecal tonsils, intestine, and cloacal swabs for digestive; kidney, ovary, and oviduct for urinary/reproductive), but it is also common to mix organs from different systems. Afterward, the extraction and purification of nucleic acids are prerequisites for nucleic acid–based molecular diagnostics. The main steps in all nucleic acid extractions are as follows: cell lysis, inactivation of cellular nucleases, and extraction of the RNA [69]. The main methods to extract RNA include the use of phenol and chloroform organic solvents, silica beads, and magnetism.

Phenol–chloroform alkaline extraction involves the lysis of the biological sample by a detergent or chaotropic substance with or without protein-degrading enzymes, followed by several processing steps applying organic solvents such as phenol and/or chloroform or ethanol and nucleic acid precipitation [70]. Silica particle extraction is a solid-phase method for isolating nucleic acid from biological samples. Silica beads are used to bind to nucleic acids in the presence of a chaotropic substance. This is one of the most widespread method for isolating nucleic acids from biological samples and is known as simple, rapid, and reliable [71]. Finally, magnetic separation of nucleic acids is an emerging technology that uses magnetism for the efficient separation of nucleic acids in solution. Magnetic carriers with immobilized affinity ligands or prepared from a biopolymer exhibiting affinity to the target nucleic acid are used to isolate nucleic acid [72]. Despite the method used, extracted RNA should be stored between −20°C and −80°C until tested. It is advised to keep RNA at −80°C for long-term storage [54].

34.2.2 Detection Procedures

Molecular assays used to detect IBV RNA include RT-PCR and its variations (nested RT-PCR and real-time RT-PCR). In traditional RT-PCR, IBV RNA is first reverse transcribed to a complementary DNA (cDNA) by a reverse transcriptase. Subsequently, the cDNA is submitted to PCR. Amplification products are then submitted to electrophoresis in polyacrylamide or agarose gel and stained with silver nitrate or ethidium bromide, respectively [73,74].

An additional amplification step ("nested" to the first amplicon) can improve the sensitivity [75]. However, nested PCR should be used carefully in routine diagnosis because of the high risk of contamination ("carryover"), leading to false-positive results. Another very important topic to the development of a molecular technique for IBV is the target RNA region. Genome fragments commonly used in detection tests are the highly conserved N gene, 5′ UTR, and 3′ UTR [57–59]. However, these assays may be unable to distinguish between IBV and other avian coronaviruses.

Several studies describe RT-PCR for IBV detection, but two methods have been widely used [57,59]. The assay described by Callison et al. is a real-time RT-PCR that uses a primer pair and a TaqMan® dual-labeled probe to amplify a 143-bp fragment of the 5′ UTR of IBV genome [59]. Meir et al. chose a primer pair and a TaqMan probe to amplify a 130-bp fragment of nucleocapsid gene [57] (Table 34.1).

Genotyping techniques are usually performed after an RT-PCR of the S1 gene. RFLP includes restriction digestion with selected enzymes followed by gel electrophoresis. The banding patterns are observed after gel staining and then compared with expected patterns of known genotypes [3,66].

However, nucleotide sequencing of the hypervariable fragment of the S1 gene is the most useful technique for IBV genotyping. RT-PCR product cycle sequencing may be used diagnostically to identify previously characterized strains and also unrecognized field isolates and variants [3,33]. One important step in all sequencing methods is the careful preparation of the template with adequate concentration and purity of the RT-PCR products. Prior to sequencing reaction, the unincorporated nucleotide and primers remaining after the PCR amplification must be removed using commercial kits [76]. S1 gene sequences should then be comparatively analyzed with reference data to determine the relatedness among the IBV strains [3].

S1 genotype-specific RT-PCR may be used to identify IBV field isolates as well as vaccine strains in avian flock samples. S1 gene primers specific for several genotypes have been described in previous studies [61–63,67,77]. More recently, real-time PCR assays have been developed for the detection of Mass, Conn, Arkansas, and Delaware genotypes, and specific primers and probes are described in Table 34.1 [63].

[a] IBV detection.
[b] IBV genotyping.

34.3 CONCLUSION

IBV has been controlled by the extensive use of vaccines, but this virus remains as a major economic problem. The constant emergence of variant strains has challenged vaccination strategies. The advent of molecular techniques greatly improved the detection of this important pathogen in industrial poultry flocks. Further, the availability of molecular techniques to amplify and sequence viruses provides tools for the characterization of IBV classical and variant strains. In previous years, the application of these methods in veterinary laboratories contributed to improve the health status of domestic fowl flocks and to determine the vaccination strategies for this virus in the main chicken-producing regions of the world. The continuous use of these methodologies will certainly help in the detection of new outbreaks as well as allow the surveillance of the emergence of new genetic variants, displaying different biological and antigenic properties, which may require a revision of the current vaccination program in a specific region or country.

35.1 INTRODUCTION

Bovine coronavirus (BCoV) is a single-stranded, positive-sense RNA virus implicated in three distinct clinical syndromes in cattle: (1) calf diarrhea (CD), (2) winter dysentery (WD) with hemorrhagic diarrhea in adults, and (3) bovine respiratory disease complex (BRDC) or shipping fever of feedlot cattle. Given its common occurrence in dairy and beef cattle farms worldwide and its negative impact on milk production in dairy herds and weight gain in calves and adult cattle, considerable efforts have been made in recent years toward the elucidation of BCoV's genetic characteristics, epidemiology, transmission, clinical features, pathogenesis, diagnosis, treatment, and prevention.

35.1.1 Classification

Coronaviruses are enveloped, single-stranded, positive-sense RNA viruses classified in the family *Coronaviridae*, order *Nidovirales*. Of the two subfamilies within the family *Coronaviridae*, the subfamily *Coronavirinae* is separated into four genera, *Alphacoronavirus* and *Betacoronavirus* naturally occurring in bats and *Deltacoronavirus* and *Gammacoronavirus* residing primarily in birds and pigs, while the subfamily *Torovirinae* is divided into two genera, *Bafinivirus* and *Torovirus*, being present in fish and mammals (causing gastroenteritis in mammals such as cattle, horses, and pigs, but rarely humans), respectively [1].

Currently, the genus *Alphacoronavirus* consists of at least 16 species: transmissible gastroenteritis virus, porcine respiratory CoV, canine CoV, feline infectious peritonitis virus, mink CoV, rhinolophus bat CoV HKU2, miniopterus bat CoV 1A, miniopterus bat CoV 1B, miniopterus bat CoV HKU8, human CoV 229E (HCoV-229E), human CoV NL63 (HCoV-NL63), porcine epidemic diarrhea virus (see Chapter 37), scotophilus bat CoV 512, hipposideros bat CoV HKU10, rousettus bat CoV HKU10, and mystacina tuberculata bat CoV [2].

The genus *Betacoronavirus* is divided into four lineages (A–D). *Lineage A* includes rabbit CoV HKU14, human CoV-OC43 (HCoV-OC43), porcine hemagglutinating encephalomyelitis virus (PHEV), dromedary camel coronavirus HKU23, canine respiratory CoV, bovine CoV, giraffe CoV, sable antelope CoV, equine CoV (ECoV), human CoV-HKU1 (HCoV-HKU1), murine hepatitis virus, rat CoV, and China Rattus coronavirus HKU24. *Lineage B* contains severe acute respiratory syndrome (SARS)-related palm civet CoV, SARS-associated human CoV, SARS-related Chinese ferret badger CoV, and SARS-related rhinolophus bat CoV HKU3. *Lineage C* comprises Middle East respiratory syndrome CoV (MERS-CoV), pipistrellus bat CoV HKU5, and tylonycteris bat CoV HKU4. *Lineage D* consists of rousettus bat coronavirus HKU9 [2–5].

The genus *Deltacoronavirus* contains wigeon CoV HKU20, common moorhen CoV HKU21, night heron CoV HKU19, bulbul CoV HKU11 (type species), munia CoV HKU13, magpie–robin CoV HKU18, thrush CoV HKU12, white-eye CoV HKU16, porcine CoV HKU15, and sparrow CoV HKU17 [2].

The genus *Gammacoronavirus* consists of infectious bronchitis virus (IBV), partridge CoV (IBV-partridge), turkey CoV, peafowl CoV (IBV-peafowl), beluga whale CoV SW1, and bottlenose dolphin CoV HKU22 [2].

Downloaded From Vet-eBooks.com

The genus *Bafinivirus* contains a single species white bream virus and the genus *Torovirus* consists of equine torovirus (type species; formerly Berne virus), human torovirus, porcine torovirus, and bovine torovirus (BoTV; formerly Breda virus, BRV). Of particular relevance, BoTV is a kidney-shaped virus associated with diarrhea in calves worldwide (see Chapter 38) [1].

Interestingly, although coronaviruses in the subfamily *Coronavirinae* do not usually produce clinical symptoms in their natural hosts (bats and birds), accidental transmission of these viruses to humans and other animals may result in respiratory, enteric, hepatic, or neurologic diseases of variable severity. Coronaviruses that have been shown to cause diseases in humans include HCoV-229E (alphacoronavirus 1b), HCoV-NL63 (alphacoronavirus 1b), HCoV-OC43 (betacoronavirus 2a), HCoV-HKU1 (betacoronavirus 2a), SARS-HCoV (betacoronavirus 2b), and MERS-CoV (betacoronavirus 2c) [2].

Belonging to Lineage A, genus *Betacoronavirus*, subfamily *Coronavirinae*, and family *Coronaviridae*, BCoV consists of a single serotype that encompasses a diversity of strains/isolates (e.g., BCoV Bubalus, BCoV cow, BCoV alpaca, bovine enteric coronavirus, bovine respiratory coronavirus, human enteric coronavirus 4408, sambar deer coronavirus, waterbuck coronavirus, and white-tailed deer coronavirus) that demonstrate genetic and antigenic proximities to HCoV-OC43, PHEV, and ECoV. Besides inducing diarrhea in newborn calves, WD with hemorrhagic diarrhea in adult cattle, and respiratory tract infections in calves and feedlot cattle, BCoV has the capacity to cause transboundary infection/disease in buffalos, lamas, alpacas, deer, and giraffes [6].

Phylogenetic examination of BoCV isolates reveals the existence of two genomic clades (1 and 2). While reference enteric BoCV strains and a vaccine strain belong to clade 1, BCoV from respiratory tract, nasal swab, and bronchoalveolar washing fluids belongs to clade 2. In addition, the respiratory isolates from Oklahoma are further separated into three subclades, 2a, 2b, and 2c [7,8].

35.1.2 Morphology and Genome Organization

BCoV possesses an enveloped, pleomorphic/spherical virion of 65–210 nm in diameter, with a double layer of short (hemagglutinin) and long (spike) surface projections, the latter of which appear club-shaped and measure about 20 nm in length. The lipoprotein envelope carries four structural proteins: membrane (M) glycoprotein, spike (S) glycoprotein, hemagglutinin–esterase (HE) glycoprotein, and small envelope (E) protein. Beneath the envelope is a flexible and helical nucleocapsid formed by nucleoprotein (N) in association with the viral genome.

The genome of BCoV is a linear, nonsegmented, single-stranded, positive-sense RNA of 31,028 nt and includes 13 open reading frames (ORFs) flanked by 5′- (nt 1–210) and 3′- (nt 30,740–31,028) untranslated regions (UTRs). Its 5′-UTR is capped, and its 3′-UTR contains a polyadenylated tail. Some overlappings are observed in ORF1a (nt 211–13,362, including stop codon) and ORF1b (13,332–21,494); ORF4 (S, 23,641–27,732) and ORF5 (N_s "4.9 kDa", 27,722–27,811); ORF7 (N_s "12.7 kDa", 28,106–28,435) and ORF8 (E, 28,422–28,676); and ORF10 (N, 29,393–30,739) and ORF11 (I, 29,454–30,077). Intergenic sequences are identified in ORF1b and ORF2 (N_s 32 kDa, 21,504–22,340); ORF2 and ORF3 (HE, 22,352–23,626); ORF3 and ORF4; ORF5 and ORF6 (N_s "4.8 kDa", 27,889–28,026); ORF6 and ORF7; ORF8 and ORF9 (M, 28,691–29,383); and ORF9 and ORF10] [9].

Comparison of genome sequences of two field isolates of BCoV, representing respiratory (BCoV-R) and enteric (BCoV-E) strains, respectively, revealed differences in 107 out of 31,028 positions, scattered throughout the genome except the 5′-UTR. Differences in 25 positions are nonsynonymous, leading to 24 amino acid changes in all proteins except pp1b. The remaining 82 nucleotide differences do not cause amino acid changes, although they might modulate phenotypic properties by affecting the RNA structure and/or RNA interaction(s). Six replicase mutations are identified within or immediately downstream of the predicted largest pp1a-derived protein, p195/p210. It is possible that single amino acid changes within p195/p210 as well as within the S glycoprotein may have contributed to the different phenotypes of the BCoV isolates [9].

Of the five structural proteins (nucleocapsid [N], transmembrane, small envelope [E], hemagglutinin–esterase [HE], and spike [S] proteins) encoded by the BCoV genome, the N protein (50 kDa) is highly conserved and offers an ideal target for molecular diagnostic application; the surface HE glycoprotein (120–140 kDa) acts a receptor destroying enzyme (esterase) to reverse hemagglutination; and the outer surface S glycoprotein (190 kDa, 1363 aa) forms large club (petal)-shaped spikes on the surface of the virion. Cleavage of the S protein by an intracellular protease between aa 768 and 769 results in a variable S1 N-terminal domain (subunit) and a more conserved S2 C-terminal domain (subunit). The S1 subunit is involved in virus binding to host–cell receptors, induction of neutralizing antibody expression, and hemagglutinin activity. With a highly variable/mutable sequence, the S1 is associated with changes in antigenicity, tissue tropism, viral pathogenicity, and host range [10]. Indeed, a single amino acid change (A528V) within the BCoV S1 subunit has been shown to confer resistance to VN [11]. The S2 is the transmembrane subunit with a critical role in the mediation of fusion between viral and cellular membranes. Interestingly, no consistent differences are observed in the full-length S gene between BCoV strains causing respiratory and enteric diseases [12].

35.1.3 Biology and Epidemiology

BCoV has a predilection for intestinal and pulmonary epithelial cells. First recognized as enteric pathogens (BCoV-E) in association with CD and WD in adult cattle, BCoV was also identified as respiratory pathogens (BCoV-R) in association with BRDC or shipping fever of feedlot cattle. Although BCoV strains causing enteric (BCoV-E) or respiratory (BCoV-R) infection may show distinct biological properties and host cell tropism, they are closely related antigenically

Downloaded From Vet-eBooks.com

and genetically [13–17]. In fact, some BCoV strain may cause simultaneous enteric and respiratory tract infections.

Transmission of BCoV is mainly through fecal–oral and respiratory (aerosol) routes. As in the case of BRDC, BCoV may enter the host via aerosol and undergo initial and extensive replication in the nasal mucosa. Following ingestion of mucus secretions containing large quantities of infectious virus with protective coating, cattle with respiratory infection may develop gastrointestinal symptoms such as diarrhea. Clinically or subclinically infected calves and young adult cattle function as reservoirs for BCoV in the herd, with sporadical shedding of the virus in feces and nasal secretions [18].

BCoV has a widespread presence in both dairy and beef cattle. WD has been described in Europe, North America, and East Asia, with a peak incidence in winter, while CD and shipping fever are found in various regions of the world [19–21]. Although BCoV outbreaks typically occur in autumn and winter, severe cases of infection in adult cattle may also emerge in warmer seasons. Economic losses due to BCoV infection are attributable to dramatic reduction in milk yield in dairy herds and loss of body condition in both calves and adults, with death being a not uncommon outcome for affected calves.

Unlike many other coronaviruses that have restricted host ranges, BCoV has the ability to cause transboundary infections. This is evidenced by the findings that bovine-like CoV is present in sambar deer (*Cervus unicolor*), white-tailed deer (*Odocoileus virginianus*), waterbuck (*Kobus ellipsiprymnus*), elk (*Cervus elephus*), caribou (*Rangifer tarandus*), giraffe, water buffalo calves, alpacas, and dogs [22–27], and that bovine-like CoV is implicated in deer and waterbuck with bloody diarrhea resembling WD in cattle. Furthermore, isolation of a BCoV-like human enteric coronavirus-4408/US/94 from a child with acute diarrhea highlights the public health impact of BCoV.

As an enveloped virus, BCoV is sensitive to detergents and lipid solvents such as ether and chloroform. It is also inactivated by conventional disinfectants, formalin, and heat [28].

35.1.4 Clinical Features and Pathogenesis

With an incubation of 3–8 days, BCoV is implicated in enteric disease in newly born calves (CD) and adult cattle (WD) as well as respiratory tract infections of growing calves and shipping fever pneumonia in feedlot cattle. Although BCoV infection rarely causes death, its morbidity can be as high as 100%, contributing to sudden and dramatic reduction in milk production and loss of body weight.

35.1.4.1 CD (calf scours)

BCoV infection in calves between the ages of 1 and 3 weeks often produces gastrointestinal signs such as profuse diarrhea (watery yellow, gray, or greenish containing blood or mucus), dehydration, depression, weakness, weight loss, anorexia, convulsions, and sometimes death. Notable lesions include colon villous atrophy. Some calves (2–6 months of age) may develop respiratory infection with a serous to purulent nasal discharge, coughing, rhinitis, pneumonia, fever, and inappetence, often with concurrent diarrhea. Sporadic shedding of virus in nasal secretions and feces may begin 5 days after infection. Secondary bacterial infections with other common respiratory viruses (e.g., bovine rotavirus A), bacteria, and mycoplasms may exacerbate clinical signs [2,29].

WD with hemorrhagic diarrhea in adults: BCoV infection in adults is normally subclinical, although it may cause WD outbreaks in housed cattle over the winter months, with a sudden onset of semiliquid, often hemorrhagic diarrhea, leading to severe anemia, marked drop in milk production in dairy herds, and death. Histopathologically, loss of surface epithelial cells and necrosis of crypt epithelial cells in the large intestine containing detectable virus particles are noted [30–32].

BRDC or shipping fever: BCoV infection in young adult feedlot cattle (6–10 months of age) may develop fever, coughing, dyspnea, rhinitis, bronchopneumonia, anorexia, diarrhea, and weight loss, accompanied by necrotizing lung lesions (e.g., interstitial emphysema, bronchiolitis, and alveolitis). Death of infected cattle may occur as a result of necrotizing pneumonia. Shedding of respiratory BCoV in nasal secretions and feces begins 4–10 days after infection, with nasal shedding consistently preceding fecal shedding. Interestingly, cattle with relatively high respiratory BCoV antibody ELISA titers or neutralizing antibodies in serum are less likely to shed respiratory BCoV [33,34].

The pathogenesis of BCoV-induced diarrhea lies in its ability to destroy surface epithelial cells of the intestinal villi in both the small and large intestines, with remarkable loss of absorptive capacity, increase in the gut fluid volume, and osmotic imbalance. This contributes to rapid loss of water and electrolytes, hypoglycemia, lactic acidosis, hypervolemia, acute shock, cardiac failure, and death. The severity of the disease is influenced by the host age, nutritional and immune status, virus load, stresses, and copresence of other pathogenic organisms. For example, the onset of BRDC may be linked to coinfection with bovine respiratory syncytial virus, parainfluenza-3 virus, bovine herpesvirus, and bovine viral diarrhea virus that have the capacity to sabotage host's immune mechanisms. In addition, long-distance shipping with cattle from multiple feedlots may create physical stresses that compromise host's immune defense against BCoV and other pathogens, and also increase exposure of cattle to high concentrations of new pathogens not previously encountered. Chemotherapy (e.g., corticosteroids and dexamethasone) may reduce the numbers of cells (CD4 and CD8 T cells) and levels of cytokines that directly impact on host immune fitness.

35.1.5 Diagnosis

BCoV is associated with CD, WD in adults, and BRDC (shipping fever). Diagnosis of BCoV infection requires differentiation from other diseases with similar symptoms. For example, bovine rotavirus A (BRV), *Escherichia coli*, *Salmonella enterica*, *Giardia intestinalis*, and *Cryptosporidium parvum* are known to cause diarrhea in calves, while *Mannheimia haemolytica*, *Pasteurella multocida*, *Histophilus somni*,

Downloaded From Vet-eBooks.com

Arcanobacterium pyogenes, and *Mycoplasma* are often involved in bovine respiratory disease [35,36].

Although a presumptive diagnosis can be made on the basis of history and clinical signs, definitive diagnosis of BCoV infection relies on laboratory confirmation of the presence of virus particles/antigens and antiviral antibodies in nasal secretions, feces, and tissues.

Virus isolation using the G clone of human rectal tumor (HRT)-18 cells, or Vero cells, provides a useful way to diagnose BCoV infection [37].

Electron microscopy allows direct observation of BCoV particles in feces and other samples. Typically, 5 g of feces is resuspended in 25 mL of phosphate buffered saline (PBS) and centrifuged at 5000 × *g* for 20 min. The clarified supernatant (12 mL) is centrifuged again at 100,000 × *g* for 1 h, and the resultant pellet is resuspended in 1 mL of water. Then, 5 μL of sample is mixed with 5 μL of 2% phosphotungstic acid (pH 6.9), and 1 μL of the mixture is applied to the center of a 300-mesh grid. The sample is side blotted with a piece of torn filter paper to remove the majority of the sample, thus leaving a fine layer to air dry. Samples are examined under a microscope at 30,000× magnification [10].

Serological assays such as direct fluorescent antibody test, virus neutralization (VN), hemagglutination inhibition, and enzyme-linked immunosorbent assay (ELISA) enable detection of viral antigens and antiviral antibodies in nasal secretions, feces, serum, and frozen or paraffin-embedded tissues (trachea, lung, ileum, and colon) [10].

Nucleic acid amplification techniques such as PCR allow sensitive detection of viral nucleic acids directly from clinical specimens [38–46]. In particular, real-time reverse transcription (RT)-PCR targeting conserved regions of the BCoV genome (polymerase or N protein) facilitates rapid detection of divergent strains [47,48]. In addition, sequence analysis of the S gene facilitates subtyping of BCoV strains causing intestinal and respiratory infections [49–53].

35.1.6 Treatment and Prevention

Treatments of animals with BCoV infections are largely aimed at alleviation of clinical symptoms, including intravenous fluid therapy and provision of adequate colostrum intake in newborn calves. In addition, isolation of calves with diarrhea and ventilation of housing are helpful in reducing disease incidence.

Control of BCoV-related diarrhea is possible by vaccinating calves on farm prior to shipping to auction barns or feedlots with a live vaccine (ATCvet code QI02). Although no vaccines are currently available to prevent BCoV-associated pneumonia in young calves or in the BRDC of feedlot cattle, there is evidence that intranasal (IN) vaccination of feedlot calves with a modified live BCoV calf vaccine on entry to a feedlot reduces the risk of treatment for BRDC in calves. In addition, IN administration of a BCoV CD strain induces cross-protection against field exposure to a respiratory BCoV [54,55]. Future research on the combined use of strains representing CD, WD, and respiratory isolates may open a way for a single broad-spectrum BCoV vaccine against BCoV infections [10].

35.2 METHODS

35.2.1 Sample Preparation

Samples (feces, fecal swabs, and nasal swabs) are collected from suspected cases of gastrointestinal and/or respiratory tract infections. Swabs are placed immediately after collection in 2 mL minimum essential media (MEM) containing 1000 U penicillin and 1 mg streptomycin. After transportation on dry ice, samples are mixed by pulse-vortexing for 15 s, and swabs are discarded. Sample suspensions are diluted 1:10 in MEM and centrifuged at 5000 rpm for 15 min at 4°C. The clarified supernatants are transferred to sterile vials, and aliquots of 140 μL are separated for RNA extraction using QIAamp Viral RNA Extraction Kit (Qiagen).

Fecal suspensions (approximately 0.1 g of feces or 100 μL in 1 mL 1× PBS, pH 7.5–8.0) are mixed for 1 min at 15 Hz on a tissue lyser. Fecal suspension of 50 μL is mixed with 400 μL of lysis solution, 1 μL of carrier RNA (1 μg/μL), and 1 μL of exogenous internal positive control (XIPC) RNA (at 10,000 copies/μL) for 5 min at 15 Hz and centrifuged at 20,000 × *g* for 3 min to generate the clarified lysate. The clarified lysate (350 μL) is transferred to a 96-well, deep-well plate containing 20 μL of magnetic bead mix (10 μL of lysis/binding enhancer and 10 μL of RNA binding beads), and 200 μL of isopropanol is added. The plate is loaded onto an automated magnetic particle processor for nucleic acid purification: lysis/binding for 5 min, one 2 min wash 1, one 2 min wash 2, 1 min dry step, and a 3 min heated elution step at 70°C. Purified nucleic acid is then denatured at 95°C for 5 min in a thermal cycler to denature the double-stranded BRV RNA for RT-PCR.

Alternatively, feces are diluted in nuclease-free water (Promega) at a ratio of 3:1 (v/v), and suspensions are centrifuged at 5000 × *g* for 10 min at 4°C. RNA is extracted from 250 μL of supernatant recovered using the TRIzol Reagent (Invitrogen), and the RNA pellet is diluted in 30 μL of nuclease-free water (Promega).

Tissues from the upper respiratory tract (nasal, pharyngeal tissues, trachea) and lung, and tissues from the distal small intestine and colon may be collected from suspect necropsied disease cases. RNA is extracted from these tissues by using Qiagen RNeasy Kit.

35.2.2 Detection Procedures

35.2.2.1 Conventional RT-PCR

Erles et al. [56] reported a gel-based RT-PCR for the detection of BCoV RNA in clinical samples with primers from the spike-protein gene (Sp1: 5′-CTTATAAGT GCCCCCAAACTAAA-3′, nt 25,277–25,300 and Sp2: 5′-CC TACTGTGAGATCACATGTTTG-3′, nt 25,876–25,898), which generate a specific product of 622 bp.

RT-PCR is conducted with SuperScript™ One-Step RT-PCR Kit (Invitrogen) using the following cycling program: RT at 50°C for 30 min, inactivation of Superscript II RT at 94°C for 2 min, and 45 cycles of 94°C for 30 s, 55°C for 30 s, and 68°C for 30 s, with a final extension at 68°C

Downloaded From Vet-eBooks.com

TABLE 35.1
Identity of Primers and Probe for Real-Time RT-PCR Detection of BCoV

Primer/Probe	Sequence (5′–3′)
BCVF[c]	GCTACATCAATCTCAAGGACATTGGT
BCVR[c]	CTTAAAACAACTAGTCCCACATCCTGT
BCVPb[c]	FAM-TAAAAGCCATACATACCAAGGCCA-BHQ1

for 10 min. PCR products are separated by electrophoresis in 1.5% agarose gels and visualized under UV light after ethidium bromide staining [56,57].

35.2.2.2 Real-Time RT-PCR

Cho et al. [58] utilized primers BCVF and BCVR from the spike (S) gene sequence for specific detection of BCoV. The TaqMan probe BCVPb is labeled with 6-carboxyfluorescein (FAM) at the 5′ end and with a nonfluorescent quencher 1 (NFQ1) at the 3′ end (Table 35.1).

RT-PCR mixture (25 μL) is prepared with AgPath-ID™ Multiplex RT-PCR Kit (Applied Biosystems), containing 5 μL extracted template, 500 nM each of BCVF and BCVR, and 150 nM BCVPb.

Amplification and detection are carried out on an automated real-time PCR system (Smart Cycler® II, Cepheid, Inc.) with the following cycling parameters: 50°C for 30 min, 95°C for 15 min, and 35 cycles of 94°C for 15 s and 60°C for 60 s.

Samples with a Ct of 35 cycles or less are considered positive.

35.3 CONCLUSION

With a specific tropism for intestinal and pulmonary epithelial cells, BcoV is associated with CD, WD in adult cattle, and respiratory distresses in cattle of all ages. Economical losses due to BCoV outbreaks are not limited by animal mortalities (which can be as high as 80% in complicated cases), as dramatic reduction in milk yield in dairy herds and poor growth in calves and cattle together with cost of veterinary care and medications can add a significant burden on the affected farms. Due to the fact that a number of other microbial pathogens cause similar clinical signs, laboratory identification of BCoV antigen, antibodies, and nucleic acids is essential for correct diagnosis. In particular, the application of real-time RT-PCR has made it possible to detect and identify BCoV with unprecedented sensitivity, specificity, and speed [59].

36.1 INTRODUCTION

Feline infectious peritonitis (FIP) was recognized as a new and emerging disease entity in the late 1950s [1]. It has been subsequently identified worldwide and in virtually all species of *Felidae*, with domestic cats being the major target host [2]. The disease occurs primarily in an enzootic form [2] and epizootics are noteworthy because of their rarity [3]. The incidence of FIP was reported at 1:300 cats seen in North American veterinary institutions [4] and from <1% to >5% of kittens and younger cats from shelters, catteries, and other such high-density environments [2]. Once clinical signs appear, the mortality is extremely high; and there is currently no effective way to prevent or treat the disease.

The viral etiology of FIP was not established until 1966 when viral particles were observed in diseased tissues of experimentally infected cats [5]. The feline infectious peritonitis virus (FIPV) was linked to a coronavirus in 1970 [6]. The causative agent was subsequently found to be closely related to transmissible gastroenteritis virus of pigs, canine coronavirus (CCoV), and human coronavirus 229E [7]. Genetic comparisons and phylogenetic analysis of feline coronavirus (FCoV), CCoV, and porcine coronavirus were not carried out until almost two decades later [8,9].

There was initial confusion about the exact coronavirus responsible for FIP. Coronavirus seropositivity was found to be widespread among both diseased and healthy cats in the same environments, although cats with FIP tended to have higher antibody titers than healthy cats [10]. Since the incidence of FIP was only a fraction of the incidence of seropositivity, it was initially hypothesized that FIP was an infrequent clinical manifestation of a common and largely innocuous coronavirus infection. However, cell culture–propagated FIPV was subsequently found to cause FIP in virtually all experimentally infected cats [11]. In contrast, fecal extracts from healthy seropositive cats in environments where FIP occurred caused a transient mild to unapparent enteritis and not FIP [12]. The fecal virus from healthy cats was then given the name feline enteric coronavirus (FECV), while the virus from FIP diseased tissues retained the name feline infectious peritonitis virus (FIPV). It was subsequently postulated that FIPVs evolved by internal mutation from FECVs, a theory that was ultimately proven correct [13]. The precise incidence of this transformation is unknown, but one study using cats infected with feline immunodeficiency virus suggests that FIPV mutants may arise in as high as 20% of FECV infections [14]. No particular strain of FECV is more likely to mutate to become an FIPV than another [13,15].

FECVs have a highly specific tropism for the mature apical epithelium of the villi in the lower intestine, while FIPVs have lost their tropism for the intestine and have gained a specific tropism for peritoneal macrophages [13]. Three specific types of mutations have been currently associated with the FECV-to-FIPV transformation: (1) the accumulation of mutations in the 3′ portion of the accessory 3c gene that leads either to truncations of the 3c gene product or to significant amino changes [15]; (2) the single nucleotide polymorphism (SNP) mutations in the S1/S2 cleavage site of the structural spike (S) gene that can have a negative, positive, or neutral effect on the

Downloaded From Vet-eBooks.com

rate of furin cleavage [16]; and (3) an SNP mutation in the fusion domain of the S gene [17]. The first two mutations are highly variable and unique to each FIPV and absent from the infecting FECV strain, while the third mutations in the fusion region of the S gene are common to all FIPVs and absent from all FECVs. It is yet to be determined how these various mutations affect enterocyte vs. macrophage tropism and host/virus interactions.

FECV and FIPV, although different in cell tropism and disease potential, are virtually identical and do not meet the definition for distinct species or even strains. Therefore, they are designated as biotypes or, in some instances, pathotypes. The biotype designations of FECV and FIPV are analogous to that of mouse hepatitis virus (MHV), and there are interesting analogies between the cat and mouse viruses in a biotype-associated disease. MHV, biotype enteric, is a common enteric and largely inconsequential pathogen of wild mice but a bane for experimental mouse colonies [18]. In contrast, MHV, biotype systemic, causes a range of systemic diseases not seen in nature but characteristic of each laboratory where they have been cell cultured and animal passaged for decades.

36.1.1 Classification, Morphology, and Genome Organization

FECV and FIPV are positive-sense, single-stranded RNA viruses (Group IV) belonging to the family *Coronaviridae*, subfamily *Alphacoronavirus*. They are about 120 nm in diameter with an envelope displaying numerous large petal or spikelike progressions. The genomic structure and replication strategy of FIPV is similar to other coronaviruses [19]. The genome of FCoVs consists of >29,000 nucleotides and 11 open reading frames (ORFs) encoding structural, nonstructural, and accessory genes. Two-thirds of the 5′ end of the genome is made up of ORF1ab, which is translated into polyproteins pp1a and pp1ab and processed into the viral polymerase and other nonstructural proteins involved in proteolytic cleavage and RNA synthesis. One-third of the 3′ end of the genome encodes for structural (S, M, M, N) and accessory (3abc, 7ab) genes. Structural and accessory genes are expressed as genomic and subgenomic RNAs, and each is translated to yield only a protein encoded by the 5′-most ORF.

FIPVs are virtually identical to the FECVs from which they arise, a concept that is sometimes difficult to articulate. This has led many researchers to use the collective nomenclature of FCoV for FIPVs and FECVs. However, this often leads to greater confusion, as it is often difficult to ascertain which biotype is being researched [2]. Moreover, the use of the term FCoV does not take precedence into account. FIPV was the name originally given to the causative agent of FIP found in diseased tissues or effusions, while FECV was the name originally given to the enteric form of the virus isolated from feces of groups of cats that suffer periodic loses to FIP. If the term FCoV is to be used, it should be prefaced to indicate the biotype, that is, FCoV biotype enteric or biotype FIP.

FECVs, and their FIPV biotypes, exist as a myriad of strains with 70%–98%+ relatedness [2]. Although there is considerable genetic differences between FECVs and FIPVs based on geography and population isolation, strains in cohoused groups of cats tend to remain the same between cats over time [20]. These facts make it possible to trace many isolates back to their geographic or colony origins.

In addition to the two biotypes, all FECVs (and, therefore, all FIPVs) occur in two serotypes, 1 and 2 (types 1 and 2 or types I and II) [21]. These serotypes are determined by the makeup of the 3′ region of the S and adjacent 3a genes [15,22]. Serotype 1 FECVs and FIPVs have characteristic catlike S genes, while serotype 2 viruses arise by recombination with CCoV. The exact extent of the recombination varies from one serotype 2 isolate to another [23]. Serotype 1 viruses make up from 70% to 90%+ of isolates around the world [24,25], with serotype 2 strains being somewhat more common in Asia than North America and Europe [26].

Serotypes 1 and 2 FECVs, and, to a lesser extent, serotype 1 FIPVs, have been extremely difficult to culture *in vitro* [27]. Serotype 2 FIPVs appear to be more easily cultivated and on a wider range of cat cell lines. FECV appears to be highly tropic for mature intestinal epithelium, and only recently have intestinal cell lines been developed that appear to support viral growth [28]. Likewise, macrophage cultures that can be readily infected and can replicate serotype 1 FIPVs have not been available. An occasional serotype 1 isolate of FIPV has been adapted to grow on continuous macrophage-like cells [11].

36.1.2 Transmission, Clinical Features, and Pathogenesis

36.1.2.1 FECV

FECV is the most common in the large and diverse group of enteropathogens detected at similar prevalence in feces from diarrheic and healthy cats [29]. The major site for virus replication in healthy shedders is in enterocytes of the colon and cecum [30]. FECV is enzootic in cat populations throughout the world and is most prevalent in dense multicat environments where kittens are present, such as shelters, catteries, and large urban/suburban feral cat colonies. The infection is less common among rural cats where population densities are low, and opportunity for cat-to-cat transmission through the fecal–oral route is lower. It is absent from the isolated Falkland Islands [31]. The virus is present in very high levels in feces, especially during the acute stage of infection, and to a greater level in kittens than adults [32,33].

FECV transmission is by the fecal–oral route and facilitated by the shared use of litter pans and other communal defecation sites. The virus can survive for up to 2 weeks in dried feces and fomites and can be easily transferred on clothes and body by people [12]. Kittens are usually not infected before 9 weeks of age, suggesting some degree of maternal immunity [32]. Clinical signs of infection are usually inapparent or mild, consisting of a transient diarrhea lasting for only several days. Therefore, there is only a slightly greater prevalence of

Downloaded From Vet-eBooks.com

fecal FECV shedding between diarrheic and healthy cats [29]. FECV-infected cats will continue to shed virus for weeks, months, and sometimes indefinitely following initial infection [32]. A weak immunity is eventually achieved and virus shedding ceases. However, the loss of infection is also associated with a loss of immunity and secondary infections are not unusual.

FECV is not an important enteropathogen of cats in its own right [29]. Rather, it is significant for two other reasons: (1) FECVs mutate within the cat's body to become FIPVs, and FIP is a highly fatal disease that is one of the leading infectious causes of death in cats, and (2) the extreme genotypic and phenotypic similarities of FECVs and FIPVs confound many diagnostic procedures for FIPV infection [27].

36.1.2.2 FIPV

FIPVs reflect the strain and clade diversity of FECVs within the same environments [2,34]. FIP is not considered to be an infectious disease in the classic sense, because infectious virus is not shed in the feces [2,13]. Therefore, cat-to-cat transmission of FIPVs does not occur to any degree. FIPVs are highly macrophage associated and are usually infectious only when diseased tissues or fluids are directly inoculated into susceptible cats. There are rare exceptions, however, where horizontal transmission has been documented [3].

The name "feline infectious peritonitis" is derived from the most common clinical manifestation of the disease, a diffuse subacute to chronic inflammation of the omentum, serosal surfaces, and mesenteries of the abdomen, and less commonly the pleura and pericardium [1,2] (Figure 36.1). This inflammation leads to an outpouring of a characteristic exudate that is yellowish in color, mucinous in character, high in proteins, often containing fibrinous tags, and with macrophages, neutrophils, and lymphocytes being the prominent cell types. The same virus was later found to be the cause of a second form of FIP characterized by larger, focal, and more typically granulomatous lesions resembling tumors [2,9]. The two forms of FIP are referred to as wet/effusive/nonparenchymatous and dry/noneffusive/parenchymatous. Noneffusive FIP appears to evolve from an initial bout of effusive disease, and terminally, some cats with noneffusive FIP may retrogress into a more effusive disease and *vice versa*.

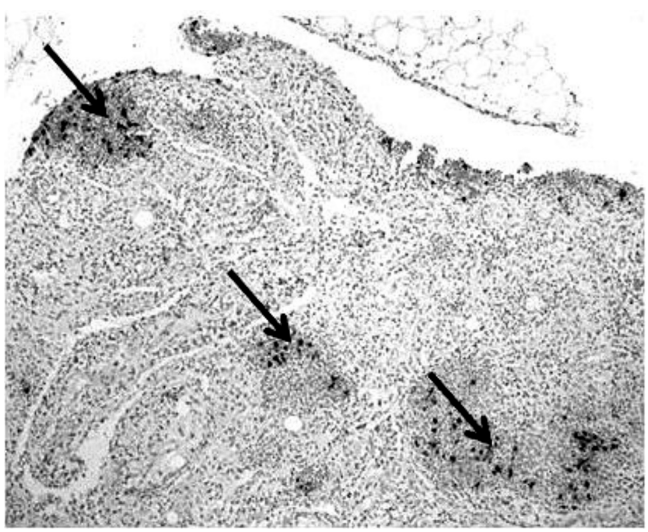

FIGURE 36.1 Photomicrograph of inflamed omentum from a cat with the effusive form of FIP. Arrows indicate pyogranulomas that contain macrophages staining positive by immunoperoxidase for FIPV antigen.

The classical lesion of the effusive form of FIP is the pyogranuloma, an accumulation of macrophages and neutrophils, appearing grossly as numerous small whitish plaques surrounding small venules in target tissues [2] (Figure 36.1). Venous congestion, microhemorrhage, edema, and inflammatory effusion are prominent features of effusive FIP. The lesions of noneffusive FIP are much less diffuse and tend to target selective areas of the abdomen (kidney, mesenteric lymph node), chest (pericardium), eyes (uveal tract), brain (ependyma and meninges), and spinal cord (meninges). Granulomatous lesions contain small foci of infected macrophages that appear to be remnants of surface pyogranulomas that have followed blood vessels deeper into the parenchyma. The mass of the lesion consists of a dense lymphocytic/plasmacytic infiltrate that extends some distance into the surrounding parenchyma. Inflammatory effusions are either absent or comparatively minor.

The consequence of FECV-to-FIPV mutations depends on the nature of the host's immune response. Ample evidence suggests that only cell-mediated immunity is effective in eliminating the virus once it enters the peritoneal macrophages [13]. Humoral immunity appears to actually be harmful in that it enhances the uptake of virus by macrophages and participates along with the viral antigen and complement in an Arthus-type vasculitis [2,13]. Most cats, in nature, are apparently able to mount a protective immune response. Those that fail to do so will develop FIP, which has an extremely high mortality. The form of disease following FIPV infection is also dependent on the balance between humoral and cellular immunity. Effusive FIP indicates a failure of cellular immunity, thus allowing the virus to replicate to a high level and spread rapidly from macrophage to macrophage within the peritoneal cavity and to distant sites. Noneffusive FIP is a product of a partially effective cellular immune response. Cellular immunity is sufficient to localize the virus to specific tissues but insufficient to eliminate it from the body.

36.2 METHODS

36.2.1 Sample Collection and Preparation

Proper sample collection is essential for successful identification of FECV or FIPV infections. First and foremost, samples for the detection of FECV or FIPV by reverse transcription PCR (RT-PCR) or RT-quantitative PCR (RT-qPCR) must contain sufficient levels of viral RNA. This is not a problem with FECV, because FECV shedding is extremely high and even very small amounts of feces will yield a positive result. However, attention should be paid to eliminating fecal

Downloaded From Vet-eBooks.com

inhibitors of PCR [35]. The greater, and more significant, problem lies with diagnosing FIPV infection. FIPV is highly macrophage associated (Figure 36.1), and infected macrophages are found only within diseased tissues. There is not a significant viremia at any stage of the infection, making blood an unsuitable tissue to sample. The levels of FIPV are high in diseased tissues and abdominal or pleural exudates from cats with effusive FIP, while virus levels are much lower in diseased tissues of cats with noneffusive FIP [2]. Abdominal or thoracic exudate from cats with effusive FIP is usually rich with virus, but over 90% of the virus is cell associated. Therefore, testing should be concentrated on the cellular fraction and not cell-free supernatant. Biopsies of diseased tissues, such as would be taken in cats with noneffusive FIP in organs such as the kidney or mesenteric lymph nodes, should be tested by immunohistochemistry to make sure that the diseased tissue was present in the biopsy. Samples taken at necropsy should contain mainly diseased tissues and not normally appearing tissues from a grossly diseased organ. This puts the onus on the veterinarian or veterinary pathologist to provide the proper type of sample.

36.2.2 Detection Procedures

The diagnosis of FECV and FIPV infections, and the pitfalls of indirect and direct diagnostic procedures, has been amply reviewed [27]. The definitive diagnosis of FIPV as a cause of disease requires identification of the virus within typical lesions or effusions by an RT-PCR-based test or immunohistochemistry. The question is whether it is necessary to confirm the FIP biotype of this virus. It can be argued that this is not necessary, because it would be extremely unlikely to find the FECV biotype in a typical FIP lesion.

36.2.2.1 Serologic Testing

Misinformation still exists over the use and interpretation of FCoV antibody titers in serum or plasma [2]. The main problem with antibody tests is that both FECVs and FIPVs, being virtually identical to each other, evoke the same antibody responses. Titers also tend to be high among healthy cats in the same environments that foster FIP. FCoV antibody titers, if accurately done, are nonetheless of some value. Although many healthy FECV-exposed cats have titers by indirect immunofluorescence assay from 1:100 to 1:400 [32], as do many cats with FIP, the likelihood of a titer being associated with FIP increases with its magnitude. Few healthy cats have titers of 1:1600, and titers of 1:3200 and above are highly indicative of FIP [27]. Healthy cats with titers below 1:100 infrequently shed FECV in their feces, while cats with titers of 1:400 are usually positive shedders [32].

36.2.2.2 RT-PCR

Tests based on RT-PCR have been used to help diagnose FIP for almost two decades [36]. Nested PCR is a method used to amplify very small amounts of FCoV cDNA and, therefore, increase sensitivity. A nested PCR was reportedly over 90% sensitive and specific in detecting FIPV in ascites from cats with effusive FIP [37]. However, nested PCRs are extremely sensitive to contamination of the laboratory with PCR products, causing false-positive reactions. The problem of laboratory contamination with PCR products is greatly reduced with RT-qPCR.

A detailed description of a diagnostic RT-qPCR for identifying FECV/FIPV genomic RNA was described by Gut and colleagues [38]. RT-qPCR was reportedly 10–100 times more sensitive in detecting FIPV mRNA than nested RT-PCR [30]. Primers used by Gut and colleagues [38] were from the accessory 7b gene, which is more conserved than the 3c, S, and M genes and less conserved than the 7a, 3a, and 3b genes [39]. As a result of its 5′ location in the genome, it is also the most plentiful subgenomic mRNA. However, it is difficult to design a single primer pair that is truly universal, so several sets of primers that are based on the researches of known FECV and FIPV genomes have been used in combination. It is also common to incorporate a recombinant FCoV plasmid (pT7-StFCoV) produced in *E. coli* with a test sample to assure the integrity of the test procedure and to quantify viral genomic copies [38]. Commercial tests often include a standard negative control and a negative extraction control. PCR product carryover as a source of false-positive reactions can be virtually eliminated by incorporating the AmpErase UNG system (Applied Biosystems) [40] to ensure that PCR products cannot be amplified in subsequent PCR reactions. The laboratory should also be routinely monitored for random positive PCR signals due to cDNA contamination. Test procedures should also take into account PCR inhibitors, especially in fecal samples [35].

Differentiating FECVs from FIPVs is a problem with any PCR-based test, because FECV and FIPV sequences are virtually identical [41]. However, it was assumed at the time that FECV replicates only in the intestine, while FIPV replicates only in macrophages within extraintestinal tissues. Based on this premise, Simons and colleagues [42] developed primers to the highly conserved M gene that would only detect subgenomic mRNA. This test was found to identify 46% of FIPV in the blood of cats suspected of having FIP, but only 5% of healthy cats. Positivity increased to 93% in cats with confirmed FIP, while none of the non-FIP cats tested positive. However, a second study using the same procedure found that 54% of healthy cats, especially in the 6–12-month-old range also tested positive [43]. This was explained subsequently by experimental infection studies of FECV by Kipar et al. [30] and Vogel et al. [33], who identified replicating forms of FECV in blood monocyte/macrophages.

Different methodologies have been used to increase the sensitivity and spectrum of FECV and FIPV detection. Hornyák et al. [44] developed an RT-qPCR using the principle of primer-probe energy transfer that combined the detection of the M gene subgenomic messenger, genome copy quantitation, and a broad range of genetic variants. They claimed that this procedure was 10–50,000 times more sensitive in detecting subgenomic mRNA in tissues of cats with FIP than in the feces of healthy FECV shedders. Although such procedure may increase the sensitivity and limit the

Downloaded From Vet-eBooks.com

detection to only replicating virus, it would still not differentiate FIPVs from FECVs.

Present attempts to differentiate FIPVs from FECVs have centered on FIP-associated mutations. Mutations in the 3c and S1/S2 furin cleavage peptide are unique to each FIPV and are therefore not good candidates. The most FIPV-specific mutations are two alternative single-nucleotide changes within the fusion protein region of the S protein [17]. One or the other of these mutations occurs in over 95% of FIPVs detected in diseased tissues.

It is generally assumed that current RT-qPCR is highly accurate in detecting FCoV RNA in feces and diseased tissues/effusions. Although a positive result is highly specific, the sensitivity of RT-qPCR is dependent on obtaining samples with sufficient levels of coronavirus RNA. Insufficient viral genomic RNA would lead to false-negative tests. This is usually not a problem with the detection of FECV in feces, which contain high levels of virus. It can be a significant problem with inadequate sampling of tissues or effusions of cats with FIP. FIPV is highly macrophage bound, so effusions must include the cellular fraction. Blood and nondiseased tissues contain extremely low levels of virus and are therefore not reliable substrates for testing. Finally, no test with this complexity and sampling limitations is expected to be 100% sensitive and specific. Indeed, PCR-based testing was found to be only 80%–90% accurate in confirming the presence of FIPV in diseased tissues in one field study [45].

36.2.2.3 Immunohistochemistry

Immunostaining of diseased tissues (immunohistochemistry) of fluids by either immunofluorescence or immunoperoxidase can be as reliable a method as RT-PCR, but the accuracy is also limited by the quality of the reagents used, the presence of infected macrophages within the tissues sampled, and the expertise of the microscopist in discerning true-positive staining within macrophages in tissue lesions or from effusions. Staining is either by immunofluorescence or immunoperoxidase, with the former being more sensitive. However, immunofluorescence requires frozen sections either fresh or in glycerol/resin protection, while immunoperoxidase can be done on formalin-fixed tissues. Formalin fixation and wax embedding should be done as rapidly as possible following tissue collection. Although immunohistochemistry is considered to be an accurate way to make a definitive diagnosis of FIP [46], there are cases of FIP that will test negative depending on the quality of the tissues, the presence of adequate lesions within the material examined, and the quality of reagents and test performance. Nonspecific-positive staining of macrophages may also be a problem. Litster et al. [47] compared results from direct immunofluorescence on antemortem feline effusions with necropsy results in 17 cats with abdominal or thoracic effusions. Histopathologic examination of tissues collected at necropsy confirmed FIP in 10/17 cases and ruled out FIP in 7/17 cases. Antemortem direct immunofluorescence testing was positive in all 10 cases confirmed as FIP at necropsy. In the seven cats where FIP was ruled out at necropsy, direct immunofluorescence was negative in five cases and positive in the remaining two cases. The calculated sensitivity of immunohistochemistry testing was 100% and the specificity was 71.4%.

Immunohistochemistry should be used much more often with effusions or fluids from cats suspected of having FIP. Effusions often contain numerous virus-filled macrophages that can be concentrated onto slides. This technique has also been used successfully to detect FIPV-infected macrophages within the cerebrospinal fluid of a cat with neurologic disease [48]. Immunoperoxidase was used to diagnose FIPV in macrophages in the skin of two cats and atypical skin lesions (multiple papular lesions) [49,50].

36.2.2.4 Sequence Analysis and Genotype Comparison

All known FCoVs belong to a single species with numerous genotypes and at least two serotypes and two biotypes. Genotypic differences are a result of the inherent mutability of RNA viruses [13]. The S, 3a–c, E, M, N, and 7a/b structural and accessory genes are the most common regions for genotyping [39] (Figure 36.2). The large ORF1ab is highly conserved between isolates and more difficult to amplify. The S gene, while less conserved, is very large and, therefore, difficult to amplify without creating progressive primer sets. Therefore, it is common to sequence fragments B (3a–c, E, M) or C (N, 7a, 7b). The 3c is the most polymorphic, followed by the S and M genes [39]. The 3a, 3b, 7a, and 7b accessory genes are the most conserved. The 7b gene is often used for diagnostic RT-qPCR, because 7b subgenomic mRNA is transcribed at the highest concentration and the 7b sequence is the most conserved between isolates.

Genotypic differences vary according to the relative geographic isolation of a given cat population. FECV isolates

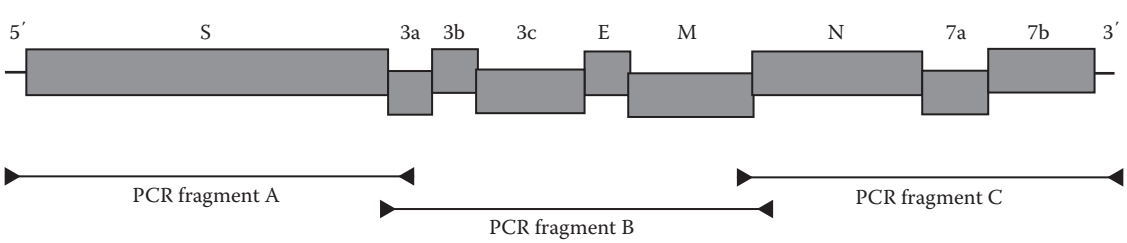

FIGURE 36.2 Structural and accessory genes of FECV/FIPV. Fragment B is commonly used for genotyping. The 3′ region of S or the 5′ region of 3a can be used for identifying serotype 1 and 2 strains.

Downloaded From Vet-eBooks.com

within isolated groups of cats tend to remain virtually identical over time [20]. As expected, FIPV isolates usually differ by less than 1%–2% from FECVs in the same environments [14,15]. Strains differing by just a few SNPs can be frequently found within the same infected cat [39]. FECV and FIPV isolates from different geographic regions of the Western United States can differ by as much as 6%–16% [39]. Variation up to 30% or so can occur between more disparate regions.

Serotype 2 FECVs and FIPVs occur as a result of recombination between FCoV and CCoV. This recombination always involves the 3′ region of S and the 5′ region of 3a (Figure 36.2) [39]. The segments that recombine vary in size and genotype, thus making each serotype 2 isolate unique. Although sequencing of the large S gene is often used to identify CCoV sequence, sequencing of the smaller 3a gene is simpler and just as accurate [39]. Serotype 1 and 2 isolates can also be differentiated by virus neutralization, as the recombination involves the virus neutralization epitopes of either FCoV or CCoV.

Biotype conversion has been one of the most intriguing and often debated topics related to FIP pathogenesis. The concept of FECV-to-FIPV internal mutation was first confirmed from animal studies conducted by Poland et al. [14], but based on sequencing of FIPV/FECV pairs subsequently published by Vennema et al. [51]. The original mutation was found in deletions, insertions, or premature stop codons that involved the accessory 3c gene. Subsequent studies confirmed the presence of functional 3c gene mutations in FIPVs and the role of an intact 3c gene in intestinal tropism [15]. However, further studies indicated that only about two-thirds to three-fourths of FIPVs had mutations in 3c leading to a truncated protein [39,52]. The conclusion of one study was that 3c gene mutations played no role in FIP because functional mutations were not universal in all FIPVs [52]. However, the second study found that the 3′ region of nonfunctionally mutated 3c gene was also highly mutated in FIPVs due to the accumulation of nonsynonymous SNPs causing major amino acid substitutions. This led to the conclusion that different types of mutations in the 3′ region of 3c could be involved in FIPVs. Based on the conclusion that 3c mutations were not important for the FIP biotype, Chang and colleagues [17] sequenced whole genomes of 11 FECV/FIPV pairs searching for other possible mutations. Other than functional mutations in about two-thirds of 3c genes, they found only two mutations that were consistently found in FIPVs and not in their parental FECVs. These two mutations were SNPs in the fusion domain of the S gene, the first at position 23,531 and the second two residues downstream. The first mutation was present in 108/118 FIPVs sequenced and none in 183 FECVs, while the second mutation was present in 5/118 FIPVs and none in FECVs. The first mutation caused a methionine-to-leucine change, while the second mutation caused a serine-to-alanine substitution. Chang and colleagues [17] postulated that these particular mutations, which were present in at least 95% of all FIPVs, might affect virus/cell fusion and were solely responsible for the change in cell tropism and virulence of FECVs. However, a recent study by Porter et al. [53] demonstrated the presence of the methionine-to-leucine-associated SNP in tissues of healthy cats, leading them to conclude that this mutation is associated with spread of the virus from the intestine but not in the pathogenesis of FIP disease. Studies conducted at around this same period identified an additional highly mutable region in the S1/S2 furin cleavage peptide [16]. SNP mutations in this short region were unique to each FIPV and caused a number of amino acid changes, some enhancing furin cleavage, some inhibiting furin cleavage, and some without effect. This suggests that furin cleavage peptide mutations, like mutations in the fusion domain, are related to changes in cell tropism and not to the interaction of infected virus with the host immune system.

36.3 CONCLUSION

The diagnosis of FIP is tantamount to a death sentence and owners of affected cats often require a definitive diagnosis before conceding to euthanasia. A diagnosis of FIP can be made with a very high degree of certainty based on the age, breed, and origin of the cat; clinical signs; and identifying certain abnormalities in complete blood counts, blood proteins (albumin, globulin, A:G ratio), urine, blood chemistry, analysis of fluid, histopathology on biopsies, and serology [27]. However, classical changes are not always present in these various tests and a diagnosis is frequently based on indirect rather than direct evidence. A definitive diagnosis requires the identification of viral proteins or RNA in diseased tissues or effusions [27]. These substances are found only within macrophages within diseased tissues and rarely in the blood. Moreover, they are not always found at levels that are measureable, especially in cases of noneffusive FIP where there may be a paucity of virus relative to the degree of damaged tissue. Tests such as RT-qPCR and immunochemistry remain the mainstay in making a definitive diagnosis of FIP, and even these tests and published reports indicate that they may only confirm a diagnosis in around 80% of cases. This is not a problem with the tests, but rather with the type and condition of samples that are submitted. Samples to be tested must contain adequate numbers of infected macrophages and be properly stored, transported, and tested.

37.1 INTRODUCTION

Porcine epidemic diarrhea (PED), also known as PED syndrome, is a serious disease of pigs due to a coronavirus named porcine epidemic diarrhea virus (PEDV). Clinically, the disease is characterized by acute diarrhea, vomiting, dehydration, and high mortality, especially in suckling piglets. First identified in Europe in the 1970s, PED has been reported in Asia and North America. In view of its serious disease outcome, widespread distribution, and clinical resemblance to diarrheal illness associated with transmissible gastroenteritis coronavirus (TGEV), rotavirus, and other pathogens, prompt and accurate diagnosis is vital to reduce the economical impact of PED on swine farming industry worldwide.

37.1.1 Classification

PEDV is a member of the genus *Alphacoronavirus*, subfamily *Coronavirinae*, family *Coronaviridae*. The family *Coronaviridae* (order *Nidovirales*) covers an expanding group of enveloped, single-stranded, positive-sense RNA viruses that are organized into two subfamilies. The subfamily *Coronavirinae* consists of four genera: *Alphacoronavirus* and *Betacoronavirus* naturally occurring in bats, and *Deltacoronavirus* and *Gammacoronavirus* residing primarily in birds and pigs; the subfamily *Torovirinae* includes two genera: *Bafinivirus* and *Torovirus*, which are present in fish and mammals (causing gastroenteritis in mammals such as cattle, horses, and pigs, but rarely humans), respectively.

Currently, the genus *Alphacoronavirus* contains at least 16 species: transmissible gastroenteritis virus (TGEV), porcine respiratory coronavirus (PRCV), canine coronavirus, feline infectious peritonitis virus, mink coronavirus, *Rhinolophus* bat coronavirus HKU2, *Miniopterus* bat coronavirus 1A, *Miniopterus* bat coronavirus 1B, *Miniopterus* bat coronavirus HKU8, human coronavirus 229E, human coronavirus NL63, PEDV, *Scotophilus* bat coronavirus 512, *Hipposideros* bat coronavirus HKU10, *Rousettus* bat coronavirus HKU10, and *Mystacina tuberculata* bat coronavirus [1].

Phylogenetic analysis of the full-length genomic sequences of PEDV classifies PEDV strains into two distinct genogroups, with the genogroup 1 (G1) consisting of PEDV field strains isolated before 2010 and the derived vaccine strains while the genogroup 2 (G2) including PEDV strains isolated since 2011 in China and the United States (U.S. PEDV) [2,3].

G1 can be further separated into at least three clusters (subgroups 1a, 1b, and R). The subgroup 1a includes strains with the same SL2 and SL4 sequences at the 5′-untranslated region (UTR) (e.g., the prototype CV777 strain as well as strains LZC and SM98). The subgroup 1b consists of strains with the 8-aa deletion in nsp3 and the large open reading frame 3

Downloaded From Vet-eBooks.com

(ORF3) deletion at the C-terminus (e.g., the DR13-attenuated vaccine strain as well as strains JS2008 and SD-M). The subgroup R comprises strains that may represent recombinants of other genogroups (e.g., the virulent DR13 strain from South Korea and the oldest Chinese PEDV strain, CH/S) [2].

G2 is distinguished into two subgroups (2a and 2b). The subgroup 2a contains strains that share several unique nucleotides (e.g., the U.S. strains MN, IA2, CO/13, IA2013, and IN2013 and a Chinese strain, AH2012), which may be further divided into two sublineages: MN-IA2 and IA1-CO/13-IA2013-IN2013. The subgroup 2b includes strains mainly from southeastern China [2,4,5].

The classification of PEDV strains into two distinct genogroups (G1 and G2) based on whole genome sequences is supported by data generated from comparison of the spike (S), ORF3, envelope (E), membrane (M), and nucleocapsid (N) gene sequences of PEDV strains [6].

Besides PEDV, other swine-infecting coronaviruses include TGEV and PRCV (both belonging to the genus *Alphacoronavirus*) as well as porcine deltacoronavirus (PdCV) (belonging to the genus *Deltacoronavirus*).

TGEV was identified in 1946 as the cause of a life-threatening acute enteric disease of pigs in the United States. Similar to PEDV, TGEV replicates in the differentiated enterocytes covering the villi of the porcine small intestine and induces profuse watery diarrhea, vomiting, emesis, and dehydration in suckling piglets, with morbidity rates of 80%–100% and mortality rates of 50%–90% [7].

First noted in the United States in 1984, PRCV is a naturally occurring deletion mutant of TGEV, with a 224-aa deletion at positions 21–244 in the S gene. This alters viral tropism from intestinal to respiratory epithelia. By replicating almost exclusively in the respiratory tract of swine, PRCV infection closely resembles other porcine viral pneumonias.

PdCV emerged in early 2014 as the culprit for fatal cases of PEDV-negative diarrhea in Ohio piglets and quickly spread to >20 states in the United States and Canada. Typical of TGEV and PEDV infections, clinical presentation of PdCV-related illness includes vomiting, diarrhea, and dehydration, with high rates of morbidity and mortality [8].

37.1.2 Morphology and Genome Organization

Similar to other coronaviruses, PEDV has an enveloped, pleomorphic/spherical virion of 80–120 nm in diameter, with a double layer of short (hemagglutinin) and long (S, club-shaped, 20 nm long) surface projections. The lipoprotein envelope is composed of four structural proteins: M glycoprotein, S glycoprotein, hemagglutinin–esterase (HE) glycoprotein, and small E protein. Underneath the envelope is a flexible and helical nucleocapsid that is formed by nucleoprotein (N) in association with the viral genome.

The genome of PEDV is composed of a linear, positive-sense, single-stranded RNA. Analysis of the genome sequences of a virulent PEDV strain (CH/ZMDZY/11) from a suckling piglet with severe diarrhea in China revealed a genome of 28,038 nucleotides (nt) in length, excluding the poly(A) tail, with the typical gene order 5′ UTR-ORF1a/1b–S–ORF3–E–M–N-3′ UTR. The 5′ and 3′ ends of the genome contain 292 and 334 nt UTRs, respectively, which flank seven ORFs within the genome. The ORF1a/1b gene (nt 293–20,637) encodes two large nonstructural precursor polyproteins: replicase 1a (nt 293–12,601) and replicase 1b (nt 12,601–20,637). The S gene consists of 4161 nt (nt 20,634–24,794), ORF3 of 675 nt (nt 24,794–25,468), the E gene of 231 nt (nt 25,449–25,679), the M gene of 681 nt (nt 25,687–26,368), and the N gene of 1326 nt (nt 26,379–27,704) [9].

Interestingly, the complete genome sequence of CH/ZMDZY/11 exhibits varied nucleotide sequence identities with those of other Chinese PEDV strains: 99.1% with BJ-2011-1 and GD-B; 98.9% with CH-FIND-3-2011; 98.8% with AJ1102 and LC; 98.2% with GD-A, CH-GD-1, and ZJCZ4; and 97.3% with CH–S. In addition, the S gene of CH/ZMDZY/11 displays 92.5%–99.1% amino acid homology to those of other reported Chinese strains. These genetic variations might have contributed to antigenic changes in the strains under investigation, and thus decreased efficiency of the CV777-based vaccines against these strains [9–11].

The S glycoprotein (1365 aa, 180–220 kDa, encoded by ORF2; also known as E2, peplomer protein) consists of S1 domain (718 aa) at the N-terminal and S2 domain (649 aa) at the C-terminal. S1 domain interacts with cell receptors and induces conformational changes in the S protein unmasking the fusion peptide of S2 domain to facilitate fusion of viral and host cell membranes [12–14].

The M protein (226 aa, 27–32 kDa, encoded by ORF5; also known as E1 glycoprotein, matrix glycoprotein, M glycoprotein) is a component of the viral envelope (which also includes E and S proteins) that interacts with E protein in the budding compartment of the host cell, located between the endoplasmic reticulum (ER) and the Golgi complex. Through its interaction with N protein, the M protein participates in RNA packaging into the virus. Besides its involvement in the virus assembly process, the M protein induces antibodies that neutralize virus in the presence of complement [15].

The nucleoprotein N (441 aa, 58 kDa; also known as Nucleocapsid protein) is a major structural component of virion that associates with genomic RNA to form a long, flexible, helical nucleocapsid. Localized in the ER, the PEDV N protein induces cell cycle prolongation at the S-phase, ER stress, and upregulation interleukin-8 expression. The N protein may be also involved in viral transcription and translation and/or replication [16,17].

The envelope small membrane protein E (76 aa, 7 kDa encoded by ORF4; also known as sM protein) is localized in the ER, with small quantities localized in the nucleus. Through its interaction with the M protein, the PEDV E protein induces ER stress, activates NF-κB, and thus upregulates IL-8 and Bcl-2 expression [18].

37.1.3 Biology and Epidemiology

PEDV targets the epithelial cells of small and large intestines of pigs for replication and is not known to infect hosts other than pigs. Therefore, it is not considered a zoonotic pathogen and poses no risk to human health or to food safety.

Downloaded From Vet-eBooks.com

As PEDV is discharged in feces, its transmission is mainly through oral–fecal route, although aerosols may play an accessory role in its transmission [19]. Feces-contaminated feed, service vehicles, equipment, and personnel represent additional risk factors for disease spread [20].

The virus can survive at least 28 days in slurry at 4°C, 7 days in feces-contaminated dry feed at 25°C, up to 14 days at 25°C in wet feed, and at least 28 days in wet feed mixture at 25°C but loses infectivity above 60°C. In addition, it is stable at pH 6.5–7.5 at 37°C but susceptible to formalin (1%), anhydrous sodium carbonate (4%), lipid solvents, iodophors in phosphoric acid (1%), and sodium hydroxide (2%) [21,22].

First emerged in the United Kingdom in 1971 as the cause of a swine disease resembling transmissible gastroenteritis, PEDV prototype strain CV777 was identified in Belgium in 1978. In the subsequent years, PEDV was reported in other European countries (including Hungary, Italy, Germany, France, Switzerland, and the Czech Republic), Asia, and Americas [23–25]. Currently, PEDV causes gastroenteritis in pigs of all ages with high morbidity but low mortality in Europe and is responsible for high mortality in suckling piglets in Asia, especially China, South Korea, Japan, Thailand, the Philippines, and Vietnam [26–32]. In 2010, massive outbreaks of PED in China resulted in near 100% illness among infected swine herds and 80%–100% mortality among infected suckling piglets (<10 days of age) [33,34]. In April 2013, a highly virulent PEDV variant was behind explosive epidemics on swine farms in the United States, leading to mortality rates of up to 95% among suckling pigs [35,36]. By December 2014, PEDV has been reported in 41 U.S. states and Canada [37]. In addition, a less virulent PEDV variant (strain OH851) that causes mild disease in sows instead of younger animals was also identified in the United States [38,39]. In Canada, PEDV was first noted in January 2014 on a pig farm in Ontario Province and has since appeared on farms in Manitoba, Prince Edward Island, and Quebec Provinces [40]. Furthermore, PEDV was detected in swine samples from Mexico in 2013.

37.1.4 Clinical Features and Pathogenesis

With an incubation period of 1–4 days, PED is a highly contagious, acute enteric disease of swine characterized by vomiting, watery diarrhea (which may appear as early as 2 days postinfection and subside by 10 days postinfection), dehydration, and death, particularly in neonates. The severity of PED is dependent on age and immunological status of the pigs, previous exposure and presence of secondary infection, etc. [41].

In adult swine, the primary signs are watery diarrhea, pyrexia, anorexia, and lethargy, with a mortality rate of <5%.

In suckling piglets, clinical signs may range from watery diarrhea, dehydration, metabolic acidosis, to death (as high as 90% in pigs less than 7 days of age but very low in pigs older than 2 weeks).

In weanlings/feeders, clinical signs include watery diarrhea, vomiting, high morbidity (almost all animals are sick), and reduced weight gain, with a mortality rate of <10% [42].

PEDV is detectable in feces by PCR from 1 day to 24 days postinfection. Microscopic lesions consist of severe diffuse atrophic enteritis with significantly reduced villous length (this thinning of the intestines is notably seen in the small intestines).

Being enteropathogenic, PEDV enters the host via oral ingestion and replicates in the villous epithelial cells of the entire small and large intestines, especially the jejunum and ileum [43,44]. This results in degeneration of enterocytes and shortening of the villi, which are typical of acute, severe atrophic enteritis, with profound watery diarrhea, viremia, vomiting, extensive dehydration, and death as main clinical manifestations.

A 204-aa deletion at positions 713–916 in the C-terminus of S1 and N-terminus of S2 in the PEDV variant destroys four N-linked glycosylation sites at positions 728, 745, 783, and 875, as well as two neutralizing epitopes, SS2 (753–760) and SS6 (769–776), leading to conformational change of S protein and subsequent alteration in antigenicity/immunogenicity [45,46].

37.1.5 Diagnosis

PEDV induces acute diarrhea, dehydration, and other nonspecific symptoms in pigs, which are clinically indistinguishable from those caused by TGEV, rotavirus, bacteria, (e.g., *Clostridium*, *E. coli*, *Salmonella*, *Brachyspira*, *Lawsonia intracellularis*, etc.) or parasites (*Isospora suis*, *Cryptosporidium*, *nematodes*, etc.). Therefore, laboratory confirmatory tests are necessary to make a final and definitive diagnosis.

Laboratory diagnostic methods for PED are essentially reliant on the detection of virus particles, antigens (by virus isolation, electron microscopy, immunohistochemistry, antigen enzyme-linked immunosorbent assays [ELISA], nucleic acid detection, etc.), or antibodies (ELISA, immunofluorescence, serum neutralization, etc.).

37.1.5.1 Virus Isolation

PEDV can be isolated by using Vero (African green monkey kidney cell line ATCC® CCL-81™), Vero 76 (ATCC® CRL-1586™), MARC-145 (M145), ST (pig testis cell line), IPEC-J2, or MK-DIEC (duck intestinal epithelial cell) cells [47].

Prior to inoculation, intestines from infected pigs are homogenized in phosphate-buffered saline, and the debris is removed by centrifugation at 10,000 × *g* for 10 min followed by filtration through a 0.2 μm filter. Alternatively, intestinal swabs and intestinal tissue emulsions are treated with a 100× antibiotic cocktail (10× final concentration) containing 10,000 IU/mL penicillin G, 10 mg/mL streptomycin, 10 mg/mL kanamycin, 5000 U/mL nystatin, and 1500 U/mL polymyxin B sulfate at 1:10 for 30 min at room temperature. The 10× antibiotic cocktail treated swabs and emulsions are then clarified by centrifugation.

Downloaded From Vet-eBooks.com

Vero cells (or other cells) are cultured and maintained in minimum essential medium supplemented with 10% fetal bovine serum, 2 mM l-glutamine, 0.05 mg/mL gentamicin, 10 unit/mL penicillin, 10 μg/mL streptomycin, and 0.25 μg/mL amphotericin. Confluent Vero cells in 6-well plates are washed twice with the postinoculation medium and inoculated with 300 μL of sample and 100 μL of postinoculation medium. The postinoculation medium is MEM supplemented with tryptose phosphate broth (0.3%), yeast extract (0.02%), and trypsin 250 (5 μg/mL). After 2 h incubation at 37°C with 5% CO_2, 3.6 mL postinoculation medium is added to each well. Inoculated cells (passage 0 [P0]) are incubated at 37°C with 5% CO_2. When a 70% cytopathic effect (CPE) develops, the plates are subjected to freeze-thaw once. The mixtures are centrifuged at 3000 × *g* for 10 min at 4°C. The supernatants are harvested for further propagation or saved at −80°C. If no CPE was observed at 7 days postinoculation, the plates are frozen and thawed once and the supernatants are inoculated on new Vero cells for a second passage. Inoculated cells at each passage may be tested by an immunofluorescence assay (IFA). If CPE and IFA staining are negative after four passages, the virus isolation result is considered negative.

37.1.5.2 Electron Microscopy

The small intestine homogenate is centrifuged at 4,200 × *g* for 10 min, and the supernatants are subjected to ultracentrifugation at 30,000 × *g* for 30 min to pellet the virus particles, which are then negatively stained with 2% phosphotungstic acid (pH 7.0) and examined with electron microscope.

Vero cells infected with PEDV are trypsinized at 24 h postinfection and centrifuged at 800 × *g* for 5 min. The cell pellets are resuspended in 0.01 M PBS (pH 7.2–7.4) and centrifuged again at 800 × *g* for 5 min. The cell pellets are fixed with 2.5% glutaraldehyde-0.1 M sodium cacodylate. The cell pellets are postfixed in 1% osmium tetroxide for 90 min. The samples are dehydrated in an ascending ethanol series followed by propylene oxide and embedded in Eponate 12 resin (Ted Pella Inc). Ultrathin sections are stained with uranyl acetate and lead citrate and examined with electron microscope.

37.1.5.3 Immunohistochemistry

Five micrometer sections are cut from embedded tissues (jejunum, ileum, colon), air-dried overnight, and placed into a 60°C oven for 1 h. The deparaffinized and rehydrated sections are quenched for 10 min in aqueous 3% hydrogen peroxide and rinsed in MilliQ water. Epitopes are retrieved using Dako Target Retrieval Solution in Biocare Medical Decloaking Chamber. Once slides are cooled, they are placed into Tris-buffered saline plus Tween (TBST; MediMabs) for 5 min. The slides are incubated with mouse monoclonal antibody directed against the PEDV S protein at a dilution of 1:1500 for overnight incubation at 4°C. Slides are rinsed with TBST and incubated for 30 min with an Envision + antimouse kit (horseradish peroxidase labeled) (Dako) and a TBST rinse. Diaminobenzidine (DAB; Dako) is used as the substrate chromogen, and the slides are counterstained with Gill's hematoxylin [48,49].

37.1.5.4 Indirect Fluorescent Antibody Test

PEDV-infected and mock-infected cells grown on glass cover slips in 24-well tissue culture plates are fixed with 3.7% polyoxymethylene, washed three times with 0.1 M PBS, and permeabilized for 5 min with 0.1% Triton X-100. The cells are incubated with a 1% solution of bovine serum albumin (BSA) (30 min, room temperature, reverse transcription [RT]), then stained with fluorescein isothiocyanate (FITC)-conjugated TGEV polyclonal antibody (VMRD) and monoclonal mouse anti-PEDV M protein, respectively (overnight, 4°C in dark conditions). After washing five times with 0.1 M PBS, a Cy3-conjugated sheep antimouse IgG (A0521, Beyotime) is added to the cells (1:400, 1 h, RT). The negative control slices are treated in an identical manner except the primary antibodies that are omitted. Cells are washed 3 times with 0.01 M PBS, and images are acquired using a fluorescence microscope (Zeiss).

Alternatively, infected Vero monolayers are fixed in cold ethyl alcohol, and polyclonal rabbit anti-PEDV nucleoprotein (NP) antiserum is added at 1:500. Cells are rinsed and then incubated with FITC-labeled goat antirabbit IgG (Jackson Immunoresearch) at a dilution of 1:50, and then read using a fluorescent microscope.

37.1.5.5 ELISA

PEDV S protein antibodies are detected with a complex-trapping-blocking ELISA using monoclonal antibodies and PEDV grown on Vero cells as antigen. Samples with a blocking percentage >50% are considered positive, samples with <40% blocking are considered negative, and samples between 40% and 50% blocking as dubious or suspicious. Samples with initial results in the dubious/suspicious range are retested in the ELISA and also tested by an IFA using PEDV BR1/87-infected Vero cells fixed with ice-cold methanol [50–52].

37.1.5.6 Nucleic Acid Detection

Nucleic acid amplification techniques such as RT polymerase chain reaction (RT-PCR) and its derivatives offer a rapid and sensitive approach for PEDV identification and phylogenetic analysis [53–59]. The common targets for RT-PCR include the S and N genes [60–63]. Exploiting the fact that classically attenuated cell culture passaged PEDV shows mutations in ORF3, which changes to restriction fragment length polymorphism (RFLP) patterns, an RT-PCR-based RFLP assay was developed to detect PEDV in clinical specimens and differentiate between field PEDV isolates and a vaccine strain. Furthermore, genotyping and phylogenetic analysis on the S gene enabled differentiation of pandemic (PX) and classical (CX) groups of PEDV.

37.1.6 Treatment and Prevention

Other than symptomatic relief of diarrheal and control of secondary infections, no specific treatment is available for PED. The use of electrolyte and energy supplements may prevent dehydration in young pigs. Colostrum from immune sows can protect neonates against infection. Unless secondary

Downloaded From Vet-eBooks.com

infections occur, most growing pigs recover in 7–10 days without treatment. Adequate quarantine, isolation of cases, disinfection of transportation and equipment vehicles, appropriate disposal of dead pigs, and slurry are helpful to prevent the disease spread in the herd [41].

Modified live vaccines (MLV) have proven valuable for the control of PEDV [64]. The cell culture attenuated, subgroup I strain 83P-5 with 14 amino acid changes in the immunodominant S protein is available as an attenuated live PEDV vaccine. The J-vac (Nisseiken) attenuated live vaccine derived from the 83P-5 strain can be also utilized. In addition, the live attenuated, subgroup II DR13 vaccine strain with 13 mutations in the S protein was developed. MLV is able to stimulate a more robust and protective immune response than inactivated virus vaccines [65]. However, due to viral mutations and accompanying antigenic changes, long-term protection is often lacking. Furthermore, attenuated, live vaccine may have a risk for reversion to virulence [66]. For these reasons, continuing effort is required to develop safer vaccines based on protective viral protein subunits [41,67].

37.2 METHODS

37.2.1 Sample Preparation

Total RNA is extracted from 500 μL of the clarified supernatant of the 10% tissue emulsion using Qiagen RNeasy® Mini Kit and eluted in 50 μL of nuclease-free water. Alternatively, total RNA is purified by Trizol reagent (Invitrogen). Briefly, 100 μL of unclarified emulsion is added to 900 μL of Trizol reagent and vortexed thoroughly. After adding 200 μL of chloroform, the mixture is vortexed thoroughly for ~30 s and incubated for 10 min. The aqueous and organic phases are separated by centrifugation, and the aqueous phase is transferred to an equal volume of isopropanol. The RNA precipitate is then pelleted, dried, and dissolved in 20 μL of nuclease-free water.

37.2.2 Detection Procedures

37.2.2.1 Conventional RT-PCR

Song et al. [68] described a multiplex RT-PCR for simultaneous detection of PEDV and TGEV. While primers P1 and P2 generate a specific fragment of 651 bp from the PEDV S gene, primers T1 and T2 produce a specific fragment of 859 bp from the TGEV S gene (Table 37.1).

TABLE 37.1
Primers for Identification of Porcine Epidemic Diarrhea Virus and Transmissible Gastroenteritis Coronavirus

Primer	Sequence (5′–3′)	Position on the S Gene	Product (bp)
P1	TTCTGAGTCACGAACAGCCA	1466–1485	651
P2	CATATGCAGCCTGCTCTGAA	2097–2116	
T1	GTGGTTTTGGTYRTAAATGC	16–35	859
T2	CACTAACCAACGTGGARCTA	855–874	

For RT, 10 μL of extracted RNA and 1 μL (1 μg/μL) of random primer (hexadeoxyribonucleotide mixture) are mixed. The mixture is heated at 95°C for 3 min and immediately placed on ice. The remaining reagents, which consisted of 10 μL of 53 first strand buffer (50 mM Tris-HCl, 75 mM KCl, 3 mM $MgCl_2$), 10 mM DL-Dithiothreitol, 0.3 μM of each deoxyribonucleotide triphosphate (dNTP), and 100 units of M-MLV reverse transcriptase in a final volume of 50 μL, are added. The mixture is incubated at 37°C for 60 min, and the reaction is stopped by heating to 95°C for 2–3 min. The cDNA is either stored at 22°C or amplified immediately.

For PCR amplification, 2 μL of cDNA is mixed with a reaction mixture containing 2.5 μL of 10× Taq DNA polymerase buffer, 3 mM of $MgCl_2$, 2.0 μL of dNTPs (2.5 μM/μL), 0.5 μL of each primer (10 pmol each), and 1 μL of Taq DNA polymerase. MilliQ water is added to make up a total volume of 25 μL.

Amplification is performed at 94°C for 5 min; 30 cycles of 94°C for 30 s, 53°C for 60 s, 72°C for 60 s; and a final extension at 72°C for 5 min.

The RT-PCR products are analyzed by electrophoresis in 1.5% agarose gel containing ethidium bromide. The presence of a 651 bp band is indicative of PEDV, while the presence of an 859 bp band is indicative of TGEV.

Note: This multiplex RT-PCR provides a rapid, sensitive, and cost-effective tool for the identification of PEDV and TGEV. If desired, SuperScript II RT/Platinum Taq One-Step RT-PCR Kit (Invitrogen) may be utilized for RT and amplification in a single step [69].

37.2.2.2 Real-Time RT-PCR

Yu et al. [70] utilized primers PED-NF (5′-CGCAAAG ACTGAACCCACTAATTT-3′) and PED-NR (5′-TTGCC TCTGTTGTTACTTGGAGAT-3′) and probe PED-Cy5 (Cy5-TGTTGCCATTGCCACGACTCCTGC-BHQ3) from the N gene for quantitative detection of PEDV by RT-PCR [71].

RT-PCR mixture (20 μL) is made up of 0.8 μL of ThermoScript™ Plus/Platinum® Taq Enzyme Mix (Invitrogen), 10 μL of 2× ThermoScript Reaction Mix (a final concentration of 3 mM $MgCl_2$), 0.5 μL of both PEDV forward and reverse primers, 0.5 μL of PEDV-Cy5 probe, 2 μL of RNA, and 5.7 μL of water.

Amplification is conducted in an ABI7500 (Applied Bio systems) under the following conditions: initial reverse transcription at 58°C for 30 min, followed by initial denaturation at 95°C for 5 min, 40 cycles of denaturation at 95°C for 30 s, and annealing and extension at 60°C for 1 min.

The intensities of the fluorescent dyes in each reaction are read automatically during PCR cycling and optical data are analyzed with 7500 software v2.0.6.

37.3 CONCLUSION

PEDV is implicated in acute, severe atrophic enteritis of swine that presents diarrhea, vomiting, dehydration, and death as main symptoms. With a widespread distribution and a propensity to form mutational variants that escape the reign

Downloaded From Vet-eBooks.com

of host immune systems, PEDV is responsible for devastating economic losses in pig farming industry throughout Europe, Asia, and North America. Owing to the clinical similarity between PED and diseases caused by other microbial pathogens, PEDV has proven to be a challenge for laboratories engaged in its diagnosis and relevant authorities in its control. Fortunately, with serological assays as a backup and through its intrinsic sensitivity, specificity, and speed, RT-PCR provides an assurance on our technical capability to reliably diagnose and track PEDV [72–74]. This will greatly enhance our decision-making as to the most appropriate management and intervention strategies against this important pathogen in the event of an outbreak.

38.1 INTRODUCTION

Toroviruses are a distinct group of positive single-stranded RNA viruses belonging to the genus *Torovirus*, family *Coronaviridae*. Of the four torovirus species recognized to date, equine torovirus (EToV), bovine torovirus (BToV), and porcine torovirus (PToV) are associated with enteric infections and diarrhea in horses, cattle, and pigs, respectively, while human torovirus (HToV) is implicated in nosocomial gastroenteritis, especially in individuals with suppressed immune functions. Although toroviruses generally cause subclinical infection or mild diarrheal disease in adults, they can be deadly when naïve young animals and children are involved. Given their widespread distribution and their ability to cross species boundary, toroviruses certainly deserve more attention in the areas of rapid diagnostic methodologies and effective control measures than they are currently receiving.

38.1.1 Classification

Toroviruses are classified in the genus *Torovirus*, subfamily *Torovirinae*, family *Coronaviridae*, order *Nidovirales*.

The family *Coronaviridae* covers an expanding group of enveloped, nonsegmented, single-stranded, positive-sense RNA viruses that are separated into two subfamilies: *Coronavirinae* and *Torovirinae*. The subfamily *Coronavirinae* consists of four genera, including bat-infecting *Alphacoronavirus* and *Betacoronavirus* and bird-/pig-infecting *Deltacoronavirus* and *Gammacoronavirus*; the subfamily *Torovirinae* contains two genera: fish-infecting *Bafinivirus* and mammal-infecting *Torovirus* [1–3].

Currently, the genus *Torovirus* is divided into four species: EToV (type species; formerly Berne virus, or BEV), BToV (formerly Breda virus, or BRV), PToV, and HToV [2].

EToV was identified from a diarrheic fecal sample of a horse with diarrhea in Berne, Switzerland, in 1972, and thus named Berne virus (BEV). It is also the first torovirus successfully cultured in vitro [4].

BToV was isolated from a case of neonatal calf diarrhea in Breda, Iowa, in 1979 [5–7]. Morphologically and antigenically related to EToV, BToV (also known as Breda virus, or BRV) was shown to cause calf diarrhea in experimentally infected gnotobiotic calves and under field conditions. Various BToV strains have been propagated in the human rectal adenocarcinoma cell line (HRT-18) and other cells. Besides its link to neonatal calf diarrhea, BToV-like particles have been described in children with gastrointestinal and respiratory symptoms.

PToV was identified and characterized in the feces of swine in the Netherlands in 1998 [8]. Analysis of the amino acid sequence of PToV HE protein led to the separation of two HE lineages, represented by strains Markelo and P4, respectively, which share amino acid sequence homology of 80% and are antigenically distinct [9].

Downloaded From Vet-eBooks.com

HToV was identified from fecal samples of humans with enteric disease in the 1980s [10–13]. A recent study showed that persons infected with torovirus are frequently immunocompromised and nosocomially infected and tend to have bloody diarrhea [14].

38.1.2 Morphology and Genome Organization

Morphologically, toroviruses are spherical, oval, elongated, kidney shaped, enveloped particles of 100–140 nm (average 120 nm) in diameter, covered with two sets of surface projections. The longer projections (made of S protein) are drumstick or petal shaped, extending for approximately 19 nm in length, while the short projections (made of HE protein) are club shaped, measuring about 6 nm in length. Underneath the envelope is an elongated, tubular (or torus) nucleocapsid of helical symmetry (from which the virus gets its name) that encases a monopartite, linear, positive-sense, single-stranded RNA of approximately 28,000 nucleotides (e.g., BToV Breda-1 strain is 28,475 nt, PToV SH1 strain is 28,301 nt, and PToV-NPL/2013 strain is 28,305 nt in length) [15–17].

Besides a capped 5′ untranslated region (UTR) and a polyadenylated 3′ UTR, the torovirus genome encompasses two large, overlapping open reading frames, ORF1a and ORF1b, coding for nonstructural proteins with replicase/transcriptase activity, as well as four small ORFs, ORFs 2–5, coding for spike (S), membrane (M), hemagglutinin–esterase (HE), and nucleocapsid (N) structural proteins, respectively. In culture-adapted EToV (BEV) and some BToV strains, the HE gene is partially deleted although the corresponding mRNA is produced.

Analysis of the complete genome sequence of PToV-NPL/2013 strain revealed a 28,305 nt genome, which shares a 92% identity to that of PToV-SH1 strain. The 5′ UTR and 3′ UTR are 792 and 196 nt in length, respectively. The polyprotein-encoding ORF (ORF1ab) is located between nt 794 and 20,910 and encodes a polyprotein of 6,706 aa. ORF1a is located between nt 794 and 14,047 and encodes a replicase of 4,418 aa. Genes encoding S, M, HE, and N proteins are 4722, 702, 1284, and 492 nt in length, respectively, and predicted proteins share 94%, 99%, 92%, and 96% identity to those of PToV-SH1, respectively [16,17].

The S protein is a major glycoprotein forming the large spikes that protrude from the viral particles. Upon entry to the host, the S protein binds to host cell receptors, induces virus-mediated cell fusion, and elicits neutralizing antibodies.

The HE protein is a class I membrane glycoprotein (65 kDa) belonging to the receptor destroying enzyme protein family. It forms homodimers, which make up the smaller spikes, and has the ability to bind sialic acids and catalyze the disruption of that binding by means of its acetyl-esterase activity. Torovirus HE protein is thought to function as a viral coreceptor, an enzyme that digests mucus layers to allow virus access to the target cells in the respiratory and/or enteric tracts, and a molecule that influences host/cell tropism. Interestingly, culture-adapted EToV and BToV strains harbor deletions or mutations in the HE gene, which are acquired during in vitro growth, leading to a malfunctioned HE protein. The fact that the HE protein is intact in a vast majority of PToV and BToV field strains highlights its indispensible role during in vivo infection [9].

38.1.3 Biology and Epidemiology

Similar to other coronaviruses, torovirus employs the viral S protein (also HE protein if present) to attach to host receptors and mediate its entry via endocytosis into the host cell. Subsequent fusion of virus membrane with the endosomal membrane facilitates the release of ssRNA(+) genome into the cytoplasm, from which the replicase polyprotein is translated and proteolytically cleaved into the viral polymerase (RdRp). Transcription of genomic ssRNA(+) into ssRNA(−) enables formation of a dsRNA genome, whose transcription/replication generates viral mRNAs/new ssRNA(+) genomes. Following synthesis of structural proteins from subgenomic mRNAs, virus assembly takes place at membranes of the endoplasmic reticulum and/or the Golgi complex. New virions are then released after budding or cell lysis.

Although EToV is the first torovirus identified and represents the type species of the genus, BToV and PToV have attracted much attention lately due to their common occurrence and association with diarrheal diseases in cattle and pigs.

Since its first observation from a case of neonatal calf diarrhea in Iowa, United States, in 1979, BToV has been detected in the Netherlands, Switzerland, Germany, Belgium, Hungry, United Kingdom, France, Spain, Italy, Japan, South Korea, India, Turkey, New Zealand, South Africa, and Brazil [18–25].

BToV is sensitive to lipid solvent (10% chloroform) and heat at 56°C for 30 min, but is somewhat resistant to acid (pH 3.0 at 22°C for 3 h) and 5-iodo-2′-deoxyuridine (IUdR). In addition, BToV does not pass through 50-nm-pore-size (or less) filter.

After initial identification in the feces of swine in the Netherlands in 1998, PToV has been reported in many other countries, including Hungary, Italy, Spain, United Kingdom, United States, Canada, South Korea, China, and South Africa [18,26–28].

In addition to horses, cattle, pigs, and humans, toroviruses have been detected in sheep, goats, lagomorphs, rodents, and domestic cats. In cats, torovirus infection is associated with diarrhea and protrusion of nictitating membranes. This highlights the promiscuous nature of toroviruses and the need to clarify the roles of these additional animal hosts in the epidemiology of toroviruses.

38.1.4 Clinical Features and Pathogenesis

Toroviruses are implicated in enteric diseases in both animals and humans, with BToV and PToV being recognized as infectious gastrointestinal agent in cattle and as a predominant cause of acute enteric infections in piglets.

Clinical signs of BToV infection in cattle include diarrhea, dehydration, pyrexia, lethargy, depression, and anorexia,

Downloaded From Vet-eBooks.com

together with mucoid feces, trembling, paralysis, and sudden death in calves [29,30]. Experimental infection of gnotobiotic calves or colostrum-deprived calves results in mild to moderate diarrhea, depression, and anorexia. Histopathologically, BToV infection is evident in villous and crypt enterocytes of the mid-jejunum, ileum, colon, and cecum, leading to severe vacuolar degeneration, necrosis and exfoliation of enterocytes, villous atrophy, crypt hyperplasia, and, in some cases, fused villi [31].

Although most pigs with PToV infection appear to be subclinical, they shed virus in feces that represent a constant source of infection to susceptible, naïve piglets. This was demonstrated by PToV-related epidemic outbreaks of diarrhea in piglets that occurred in China in 2011. With high morbidity and mortality, these outbreaks resulted in devastating losses to pig farming industry [28].

EToV (BEV) was shown to cause cytopathic effect (CPE) (e.g., cell rounding and detachment) in E. Derm cells 24 h postinfection (hpi) (at 5 pfu/cell), with some cells displaying characteristic signs of apoptosis, including disorganized nucleus, chromatin condensation, membrane blebbing, altered mitochondria, and cell disassembly in vesicles. At 48 hpi, extensive CPE causes many cells to float in the medium [32].

38.1.5 Diagnosis

A number of microbial pathogens may induce diarrhea in cattle and pigs. For example, in pigs, potential diarrhea-causing viruses include PToV, porcine epidemic diarrhea coronavirus, porcine kobuvirus, porcine group A–C rotaviruses, transmissible gastroenteritis coronavirus, astroviruses, mammalian orthoreovirus, porcine sapovirus, and porcine norovirus [28]. Therefore, definitive diagnosis of torovirus infections are dependent on the detection of viral particles, antigens, antibodies, and nucleic acids using various laboratory procedures such as virus isolation, electron microscopy, serological assays, and nucleic acid detection.

38.1.5.1 Virus Isolation

EToV (BEV) has been shown to grow in E. Derm and embryonic mule skin cells, while BToV is able to replicate in human rectal adenocarcinoma HRT-18 cells [33]. Typically, confluent HRT-18 cell monolayers in 24-well plates are washed with Eagle minimal essential medium (EMEM) and inoculated with 0.1 mL of the intestinal-content suspensions. After adsorption for 60 min at 37°C, the cells are washed with EMEM and added 0.5 mL of EMEM. The cells are incubated for 7 days at 37°C and examined for CPEs. After incubation, the cells and supernatant were frozen and thawed once to harvest cell lysates, and subsequent passages are carried out in the same manner with 0.1 mL of cell lysates.

38.1.5.2 Electron Microscopy

Fecal specimens are diluted with an equal volume of 1% (wt/vol) ammonium acetate and clarified by centrifugation at 9000 × *g* for 15 min at 4°C. The supernatant is transferred to a new tube and centrifuged at 12,000 × *g* for 15 min at 4°C. Each sample is applied to a 400-mesh grid precoated with polyvinyl formal and carbon. The grids are stained for 1 min with 2% phosphotungstic acid (pH 7.0) and examined by negative-contrast electron microscope with a Philips EM 300 microscope, at a magnification of ×50,000.

For infected cell culture supernatants, partial purification is carried out by ultracentrifugation through a 20% (wt/wt) sucrose cushion. The cells are negatively stained with 2% ammonium molybdate and examined under electron microscope. For ultrastructural observation, infected cells are fixed with 2% glutaraldehyde, postfixed with 1% osmium tetroxide, dehydrated in graded ethanol solutions, and embedded in an Epon mixture. Ultrathin sections are stained with a lead citrate-uranyl acetate solution and observed under electron microscope.

38.1.5.3 Serological Assays

A variety of serological procedures are useful for detection of torovirus antigens and antibodies. These include indirect fluorescent antibody test, hemagglutination inhibition, serum neutralization, and enzyme-linked immunosorbent assay (ELISA). Serum neutralization (plaque reduction) test allows detection of serum neutralizing antibodies against torovirus. The presence of specific IgG antibodies against PToV in the sera may be tested with an indirect ELISA using the highly conserved, recombinant viral N protein as antigen [34].

38.1.5.4 Nucleic Acid Detection

Recent development of nucleic acid amplification techniques such as reverse transcription-polymerase chain reaction (RT-PCR) has enabled rapid, sensitive, and precise detection of toroviruses [35–38]. In particular, the use of SYBR Green chemistry and/or the TaqMan probes in real-time RT-PCR allows quantitative detection of toroviruses.

Comparative phylogenetic analysis of the genes encoding the structural proteins S, M, HE, and N of BToV and PToV from European swine and cattle herds showed that all newly characterized BToV variants might have arisen from a genetic exchange, during which the 3′ end of the HE gene, the N gene, and the 3′ UTR of a BToV Breda virus-like parent had been swapped for those of PToV. In addition, some BToV and PToV variants with chimeric HE genes may have resulted from recombination events involving unknown toroviruses [39,40].

38.1.6 Treatment and Prevention

No specific treatment is currently available for torovirus infection. Symptomatic treatments such as fluid therapy (to prevent dehydration), colostrum containing antibodies (to strengthen the immune response), and antibiotics (to control secondary bacterial infections) may be applied to animals suffering from torovirus disease.

Other control and prevention measures include isolation of affected animals from apparently healthy animals, wearing gloves and boots when handling affected animals, composting of fecal matters, proper disposal of bedding material, and disinfection of floor and walls [41].

Downloaded From Vet-eBooks.com

38.2 METHODS

38.2.1 Sample Preparation

Samples (feces, rectal swabs, intestinal contents from the ileum and rectum, blood) are collected from animals. Fecal samples are diluted 1:1 in sterile phosphate buffered saline (PBS), homogenized by vortexing, and centrifuged at 3000 × *g* for 10 min at 4°C. The supernatant is aliquoted and kept at −80°C. Rectal swabs are embedded in 900 μL of sterile PBS solution and stored at −80°C. Prior to RNA isolation, tubes containing rectal swab samples embedded in PBS are vortexed, and 250 μL of the fecal suspension is transferred to a new tube. Fecal debris is discarded by centrifugation at 9000 rpm, 10 min at 4°C. Intestinal contents are diluted 1:10 in 0.01 M PBS (pH 7.4) and clarified by low-speed centrifugation at 3000 × *g* for 10 min.

Total RNA is extracted from 200 μL of supernatant or clarified rectal swab homogenate using TRIzol reagent (Invitrogen) or High Pure RNA isolation kit (Roche Applied Science), resuspended in 50 μL of RNase-free water, and stored at −80°C until analysis.

38.2.2 Detection Procedures

38.2.2.1 Conventional RT-PCR

38.2.2.1.1 BToV Detection

Hoet et al. [42] reported an RT-PCR for detection of BToV with forward primer (5′-GTG TTA AGT TTG TGC AAA AAT G-3′, nt 37–57) and reverse primer (5′-TGC ATG AAC TCT ATA TGG TGT-3′, nt 758–777). The predicted RT-PCR product is 741 bp from the 5′ end region of the spike gene.

RT-PCR is performed by pretreating 4 μL of the extracted RNA with 1 μL of dimethyl sulfoxide for 10 min at 70°C–75°C. Then, 5 μL of the pretreated RNA sample is mixed with the RT-PCR mixture (5 μL of 10× buffer, 5 mL $MgCl_2$ [25 mM], 1 mL dNTPs [10 mM], 1 μL of forward primer [200 ng/μL], 1 μL reverse primer [200 ng/μL], 0.5 μL of Avian myeloblastosis virus (AMV)-RT [10 U/μL], 0.5 mL of RNasin [40 U/mL], 0.5 μL of Taq DNA polymerase [5 U/μL], and 31.5 μL of dH_2O, in a total of 50 μL). The mixture is subjected to 1 RT phase of 90 min at 42°C, an initial denaturation step of 5 min at 94°C, and 30 cycles of 1 min at 94°C, 2 min at 55°C, and 2 min at 72°C. The final extension step is 10 min at 72°C. The RT-PCR products are visualized on 1.5% agarose gels stained with ethidium bromide, and their size is determined by comparison against DNA molecular weight markers.

38.2.2.1.2 PToV Detection

Zhou et al. [43] developed an RT-PCR for PToV detection with forward primer (5′-ACCCCTGCCTGAGGTTTCYTT-3′) and reverse primer (5′-AGCACGACGTTGTCTRCGTGT-3′), which amplifies a 451 bp fragment from the conserved region of the S gene.

Reverse transcription is conducted with TaKaRa RT system. PCR amplification is carried out with 200 μM of each dNTP, 10 pmol of each primer, 1.0 U Taq DNA polymerase (Promega), and 1.5 mM $MgCl_2$, in a total volume of 40 μL.

PCR cycling parameters include denaturation at 94°C for 2 min, 30 cycles of amplification (94°C for 30 s, 57°C for 30 s, and 72°C for 30 s), and a final extension of 72°C for 7 min.

The PCR product is resolved using 1% agarose gel electrophoresis, stained with ethidium bromide, and visualized under ultraviolet light (Bio-Rad gel imaging system, Hercules).

38.2.2.2 Real-Time RT-PCR

38.2.2.2.1 BToV and PToV Detection

Hosmillo et al. [44] described a SYBR Green real-time RT-PCR assay with a universal primer pair (F: 5′-TTACTGGYTATTGGGCMYT-3′, nt 26029–26047; R: 5′-AAAGGRGTGCAGTGWAGCTT-3′ nt 26196–26215) for the detection and quantitation of both BToV and PToV in bovine and porcine stool samples. These primers come from the membrane (M) gene of bovine and porcine torovirus strains and generate a 187 bp product from BToV and PToV. Subsequent melting curve analysis permits differentiation between BToV and PToV.

RT-PCR mixture (25 μL) is composed of 5 μL of RNA template, 12.5 μL of SensiMix one-step mixture (Quantace), 1 μL each of 0.5 μM forward and reverse primers (final concentration of each primer: 20 nM), 0.5 μL of 50× SYBR Green solution (final concentration: 1×), 0.5 μL of RNase inhibitor (final concentration: 10 units), 0.5 μL of $MgCl_2$ (final concentration: 4.0 mM), and 4 μL of RNase-free water.

Amplification and detection are carried out in Corbett Research Rotor-Gene 6000 series Real-Time Amplification system (Corbett Research), with the following conditions: RT at 42°C for 30 min, activation of the hot-start DNA polymerase at 95°C for 10 min, and 45 cycles of 94°C for 15 s, 50°C for 45 s, and 72°C for 20 s.

The melting curve analysis is performed after 45 reaction cycles; the temperature ramp is programmed from 72°C to 95°C in increments of 1°C, waiting 5 s before each acquisition. Samples are considered positive if both an exponential increase of fluorescence and a BToV- or PToV-specific melting peak are observed.

38.2.2.2.2 PToV Detection

Pignatelli et al. [45] employed forward primer rtNII5′ (5′-CCCTGGTTTTAGACCTATGTTTCA-3′) and reverse primer rtNII3′ (5′-GCAGCACTCTTAGCAATCT-TCACTA-3′) flanking a 279 bp conserved region of PToV N gene for PCR detection of PToV.

RT reaction is carried out with SuperScript III reverse transcriptase (Invitrogen). Briefly, 9 μL of viral RNA purified from field samples is mixed with 0.5 mM of dNTPs mix (Roche Diagnostic) and 0.5 μM of random hexamers mix (Roche Diagnostic S), incubated for 10 min at 65°C and kept on ice for 1 min. Then, a mixture containing 4 μL of 5× reaction buffer, 1 μL of 0.1 M DTT, 2 μL of 50 mM $MgCl_2$, and 1 μL of SuperScript III reverse transcriptase (1 U/μL) are added to the mixture. The reaction mix is incubated for 5 min at 25°C,

Downloaded From Vet-eBooks.com

followed by 45 min at 50°C, and finally 15 min at 75°C to inactivate reverse transcriptase. The cDNA preparations are aliquoted and stored at −20°C until use.

Real-time PCR is conducted with Power PCR SYBR Green kit (Applied Biosystems). The PCR mixture (20 μL) is made up of 2 μL of RT reaction, 10 μL of Power PCR SYBR Green mastermix (including hot-start DNA polymerase, reaction buffer, dNTP mix, and SYBR Green dye; Applied Biosystems), 0.5 μM of each primer, and 12.8 μL of PCR grade water.

PCR amplification is performed on an ABI 7000 sequence detector (Applied Biosystems) using universal thermal conditions: 10 min at 95°C and 40 cycles of 15 s at 95°C and 1 min at 60°C. A denaturation step is added at the end of amplification reaction for Tm analysis.

The results are analyzed using SDS v1.2 software (Applied Biosystems). The baseline, threshold, Ct (Ct indicates the cycle in which a target sequence is first detected), and Tm values of amplified products are automatically determined.

38.3 CONCLUSION

Toroviruses are causal agents of enteric infections and diarrhea in various mammal hosts including cattle, pig, horses, and humans. Due to the fact that many other viruses, bacteria, and parasites may induce similar clinical symptoms in these hosts, use of laboratory methods is essential for definitive diagnosis of torovirus infection. With the rapid advances in nucleic acid detection technologies, especially the development of real-time RT-PCR, precise and speedy identification of toroviruses has never been so straightforward. In comparison with the increasing sophistication of diagnostic methodologies, however, our understanding of torovirus pathogenesis and our available tools for torovirus control are far from adequate. Unquestionably, the ability of toroviruses to undergo constant mutations in response to changing external environments and the absence of a reliable in vitro culture system that does not lead to mutated toroviruses may have hampered the progress of our research efforts. Plugging such knowledge gaps will help us keep an upper hand over these opportunistic pathogens.

39.1 INTRODUCTION

39.1.1 Classification

Proventricular dilatation disease (PDD) is a common progressive and often fatal neurologic disease of captive psittacine birds worldwide, affecting more than 70 species, and has been reported in several captive and free-ranging birds representing at least five additional orders, including toucans, honey creepers, weaver finches, water fowl, raptors, and passerines. PDD has long been considered an infectious disease, with multiple viruses having been involved as possible etiological agents. In 2008, two independent research groups in Israel and the United States, using pyrosequencing of cDNA from the brain tissue of parrots with PDD, identified two strains of a novel, nonsegmented, negative-sense, single-stranded RNA viruses, which were classified as distinct genotypes of a new genus of the *Bornaviridae* family denominated as avian bornavirus (ABV).[1,2] ABV RNA was detected by real-time polymerase chain reaction (PCR) in the brain, proventriculus, and adrenal gland of three parrots that died from PDD but not in four unaffected birds.[2] Kistler and colleagues identified by microarray a bornavirus hybridization signature in five of eight PDD cases and none of the controls. High-throughput pyrosequencing in combination with conventional PCR cloning and sequencing allowed to define a complete viral genome sequence. Gray et al.[3] succeeded in culturing ABV by inoculating primary mallard embryo fibroblasts with a fresh brain suspension from the brain of psittacines diagnosed with PDD. Based on ABV isolates, seven distinct genotypes were identified, each sharing only approximately 65% nucleotide sequence identity with previously known members of the *Bornaviridae* family, all of which originated from mammalian hosts, and approximately 85%–95% with other ABV genotypes. The presence of different genotypes can be explained by the wide diversity of species affected by PDD.

In short, ABVs are classified as distinct serotypes/genotypes within the species Borna disease virus (BDV), genus *Bornavirus*, family *Bornaviridae*, order *Mononegavirales* on the basis of several unique features of the genome and mechanism of replication (in particular, nuclear replication rather than cytoplasmic replication). As the only species in the *Bornaviridae* family, BDV is a neurotropic virus responsible for an encephalitic disease in horses, sheep, and occasionally other domesticated mammalians as well as birds. There is also correlative evidence suggesting a possible link between BDV infection and neuropsychiatric disorders (e.g., bipolar disorder) in humans.

39.1.2 Morphology, Genome Structure, and Epidemiology

ABVs are spherical and enveloped particles with a diameter ranging from 40 to 190 nm. While particles of 90–150 nm with electron-dense core presumably represent infectious virions, smaller particles are proposed to be defective. Morphologically, ABV particles are characterized by spikes

Downloaded From Vet-eBooks.com

with lengths of about 7 nm, observable by electronic microscope, that represent viral glycoproteins.[4]

The genome of ABVs is a linear, negative-stranded, nonsegmented RNA comprising approximately 8900 nt that encodes 6 viral proteins. In particular, the first monocistronic mRNA (1.2 kb) encodes for the viral structural protein corresponding to the nucleoprotein N (p40). The second transcription unit is bicistronic and encodes the X protein (p10) and the phosphoprotein P (p23). The third tricistronic mRNA (2.8 or 7.1 kb) encodes matrix protein M (p16), glycoprotein G (p57), and L-polymerase (p190). Expression of these viral proteins is regulated by alternative splicing. In contrast to the other members of the *Mononegavirales* order, ABV replicates and transcribes in the cell nucleus.[5] The glycoprotein G plays an essential role in initiation of infection. In particular, this structural protein has been implicated in binding to one or more still unidentified cellular surface receptors.[6] Subsequently, ABV requires a low pH to initiate fusion and is therefore internalized by endocytic compartments. Clathrin-mediated endocytosis represents the model for virus entry; after binding to the cell surface and endocytosis, the low pH of the endosome activates fusion of the viral membrane with that of the endosome by leading the release of the ribonucleoprotein (RNP) complex (genomic RNA packaged by the nucleoprotein N and assembled with the phosphoprotein P) into the cytosol.[7] The release of the RNP complex is also mediated by the matrix protein M; in particular, this protein is associated with infectious particles and it functions in early events of viral infection by causing the release of RNP complex into the cytoplasm.[8] Subsequently, viral RNP complex is imported into the nucleus where viral RNA synthesis occurs. The X protein mediates nuclear shuttling of viral gene products such as RNP particles, and it is also involved in the regulation of the viral polymerase.[9] Nuclear replication and transcription of the ABV genome are catalyzed by the same viral polymerase complex; the genomic RNA packaged by the nucleoprotein N constitutes the ribonucleocapsid that serves as template for the associated polymerase complex components L and P. The six major open reading frames (ORFs) (N, X, P, M, G, and L) are expressed from three 5′-capped and 3′-polyadenylated RNAs. Replication of negative-strand RNA genome is facilitated by the synthesis of a full-length positive-strand copy of the viral genome (antigenome) that serves as a template for new negative-strand progeny genomes.

The recent discovery of sequences distantly related to L, M, and N genes in the ABV genome belonging to the same phylogenetic group indicates the presence of several genotypes globally distributed that infect a wide range of vertebrate species. Initially, particularly in 2008, ABVs were identified in parrots and related species (order *Psittaciformes*) suffering from PDD.[2] To date, 7 ABV genotypes (ABV-1 to ABV-7), located to 2 different phylogenetic groups, have been detected in about 30 psittacine species from four different continents. ABV-2 and ABV-4 represent the predominant genotypes in Europe, whereas ABV-6 sequences were detected in birds from Austria and Switzerland.[1] Additional ABV genotypes were discovered in 2 other host orders, passerines (*Passeriformes*) (genotypes ABV-C1 to ABV-C3 and genotype ABV-EF) and waterfowl (*Anseriformes*) (genotype ABV-CG). In particular, genotypes ABV-C1, ABV-C2, ABV-C3 were described in common canaries, whereas genotype ABV-EF was isolated from estrildid finches.[10–12] ABV-CG was isolated from geese and swans and is widely distributed across North America. Recently, a new ABV genotype has been characterized and isolated from the brains of wild ducks.[13] This new genotype, provisionally designated as ABV genotype MALL, was detected in 12 of 83 mallards, and 1 of 8 wood ducks collected at a single location in central Oklahoma. It has 72% nucleotide identity and 83% amino acid identity with the ABV-CG genotype previously shown to be present in geese and swans. ABV strains of the same genotype usually exhibit at least 95% nucleotide identity with each other. For genotypes belonging to the same phylogenetic group, sequence identity is approximately 80%–85%, whereas viruses from different phylogenetic groups are only 65%–75% identical. So far, only infections with a single genotype of ABV have been attributed to PDD cases in psittacine birds. However, a recent study described cases of double infection with two different ABV genotypes indicating the need for a more systematic search for mixed infections. Two cases showed a mixed infection with ABV-2 and ABV-4 genotypes, and one case showed a mixed infection with ABV-2 and ABV-6.[14] Issues that remain to be resolved are whether psittacine birds constitute, also, the natural reservoir of ABVs or whether other species, in which disease probably does not develop upon infection, will be identified in the future. Many important questions regarding the biology and epidemiology of ABV remain to be answered.

39.1.3 Clinical Features and Pathogenesis

PDD (synonyms: proventricular dilatation syndrome, macaw wasting/fading syndrome, neuropathic gastric dilatation of psittaciformes, psittacine encephalomyelitis, myenteric ganglioneuritis, and infiltrative splanchnic neuropathy) is a progressive fatal inflammatory disease that affects mainly, but not exclusively, psittacine birds (order: *Psittaciformes*). PDD was first recognized in the 1970s in imported macaws (*Ara* sp.) in Europe and North America and subsequently has been reported in Australia, Middle East, South America, and South Africa.[15] PDD has been termed after the predominant feature of the disease in parrots, consisting in a dilatation of the proventriculus by ingested food resulting from defects in intestinal motility. It seems that intestinal abnormalities derive from virus-induced damage to the enteric nervous system, in that birds are unable to empty their digestive tract or digest the food, with consequent weight loss, crop stasis, proventricular and intestinal dilatation, vomiting/regurgitation, maldigestion with passing of undigested seeds in their feces, starvation, and eventually death. As relevant damage in the central nervous system is also present, neurological signs are typical, with encephalitis and myelitis resulting in depression, seizures, ataxia, blindness, and tremors. Both gastrointestinal and neurological signs can be observed in affected birds. At physical examination, birds suffering from PDD can be dehydrated and mildly to severely emaciated, with atrophied

Downloaded From Vet-eBooks.com

pectoral muscles. The proventriculus may or may not be dilated in all affected birds, but in nearly 70% of the cases it appears distended with seeds and thin walled. Sometimes, the proventriculus may rupture with spillage of food into the coelomic cavity, with consequent peritonitis. Also duodenum may appear distended, as well as the adrenal glands. Occasionally, signs are almost unapparent and birds die suddenly. Definitive diagnosis is based on histopathological examination on crop biopsy or necropsy findings, with pathognomonic lesions being the occurrence of a lymphoplasmacytic infiltration in the ganglia and myenteric plexus of the gastrointestinal tract or central nervous system. Microscopic lesions can be found in several organs including the gastrointestinal tract; central, peripheral, and autonomic nervous system; heart; adrenal glands; and occasionally in the nerves and ganglia of various visceral organs. Infiltrate consists of a few to large number of lymphocytes mixed with some plasma cells occurring in the proventriculus and/or gizzard, duodenum, and other parts of the intestine. In the proventriculus, it can be observed an attenuation of glands and fibrosis of the mucosa. In other parts of the gastrointestinal tract and other organs, lesions tend to be less consistent.

The incubation period of PDD is extremely variable, from a minimum of 11 days reported in one study to approximately 1 month or more, up to years in some cases.[16] Clinical presentation is not peculiar and none of the signs should be considered pathognomonic; moreover, the severity of both gastrointestinal and neurologic symptoms may vary. Other differential diagnoses should always be considered. Among laboratory abnormalities, aplastic anemia is the most commonly seen and is likely related to malabsorption. Some birds present leukocytosis. Moreover, catabolic condition may account for reduction in total protein and albumin levels, increase in muscular enzymes such as lactate dehydrogenase, creatine kinase, and aspartate aminotransferase. No other significant abnormalities are present, as well as no fecal or cytologic findings are specific for PDD. However, these investigations are usually performed for the differential diagnosis process. Diagnostic imaging is useful for making the diagnosis, although in the absence of specific signs, usually a moderately to markedly distended proventriculus is found with ingesta and gas. The gold standard for diagnosing PDD is the histologic examination on a bioptic specimen from a relevant anatomic site of the proventriculus or the crop. This is a simpler and less invasive approach; the sensitivity of crop biopsy for PDD may vary and can be increased by proper selection of the biopsy site and utilization of multiple biopsy sections. The recent discovery of ABV has had a great impact on diagnostic process of PDD, with the development of specific molecular and serologic assays for its detection.

39.1.4 Diagnosis

Although PDD clinical symptoms are not pathognomonic and vary greatly between patients, a marked weight loss, vomiting/regurgitation, and the presence of undigested food in feces should be considered as an alert for the gastrointestinal PDD form, mostly if they are concomitant. The central nervous system form has a wider range of nonspecific clinical symptoms from slight to deep neurologic disorders such as seizures and ataxia, with the most severe cases reaching status epilepticus.[15] In the clinical diagnosis, a differential diagnosis has always to be considered for the nonspecific nature of symptoms; and it should be noted that mixed gastrointestinal and central nervous system PDD forms may commonly affect birds.[17]

Fecal and crop cytology are necessary in differential diagnosis for ruling in or out avian yeasts and helminth, causing gastrointestinal signs similar to PDD. Diagnostic imaging techniques such as survey radiography, contrast radiography, contrast fluoroscopy, and ultrasonography are helpful diagnostic tools, but not appropriate for PDD confirmation or exclusion. It has to be noticed that while the presence of classical clinical signs represents a strong indication for PDD, in the absence of clinical signs, freedom from disease and/or infection could not be assumed. Although this variety of clinical techniques has been used for tentative antemortem diagnosis, histopathologic examination of tissues remains the gold standard for a definitive PDD diagnosis. Therefore, considering the uneven distribution of lesions in biopsy material, false-negative results may occur.[18]

The significant genetic variation within the *Bornaviridae* family and, particularly, the higher genetic variability of strains recognized within *Avian Bornavirus* genus, represent a challenge for veterinary laboratory diagnosticians. Since 1980, different diagnostic assays have been developed for both indirect and direct diagnosis of ABV by employing different type of samples from dead or live birds belonging to different avian species. It has to be taken into account that ABV RNA detection is not indicative of PDD. Moreover, seropositive birds may shed the virus in their urofeces and past exposure to one ABV strain does not provide protection against a different one. Thereby, diagnostic tools should be used carefully, due to the fragmentary knowledge on ABV and the inherent limitations of the techniques.

39.1.4.1 Conventional Techniques: Indirect/Direct Diagnosis

As concerns indirect diagnosis, the detection of specific anti-ABV antibodies is performed by serological tests. Over the last two decades, indirect fluorescent antibody tests (IFAT), enzyme-linked immunosorbent assays (ELISA), and Western blot have been the most used tests.[19,20] Direct diagnosis is mainly based on identification and characterization of viral antigens by using IFAT, immunohistochemistry (IHC), in situ hybridization, and virus isolation (VI) on dead birds and crop biopsies. As a consequence of bornavirus infection, animals develop a detectable antibody response that seems to correlate positively with the onset of PDD.[21] Serology provides a much superior diagnostic procedure compared to crop biopsy although apparently healthy normal birds may possess detectable antibodies to ABV.[22] However, Heffels-Redmann and colleagues demonstrated that virus shedding and antibody production coincided in only one-fifth of the positive psittacine birds.[23] Therefore, they recommended to use swabs from crop and cloaca along with serum for a reliable diagnosis of

Downloaded From Vet-eBooks.com

ABV infections in live birds. Besides, the same authors in a later study outlined that birds with high ABV RNA load in crop and cloaca together with high anti-ABV antibodies demonstrate a high risk of PDD onset, indicating that humoral antibodies do not protect against the disease. To date, as outlined by Gancz and colleagues, the definitive diagnosis of PDD continues to be based on histology by using serology, PCR, and IHC as confirmatory tests.[15,24]

39.1.4.1.1 Serology

As indication of a previous exposure to the virus, serological tests are used to detect the presence of specific antibodies to ABV in the bloodstream. The two major ABV immunogenic proteins are the nucleoprotein N and the phosphoprotein P.[15] Detection of bornavirus-specific antibodies is routinely performed by serological assays, such as IFAT, Western blot, or ELISA assays, even though serologic tests appear to be of limited usefulness in disease diagnosis. IFAT and Western blot assays are the most sensitive and specific tests, with 90%–95% sensitivity and specificity.[21,25]

Considering that ABV strains do not replicate equally well in all cell types, numerous ABV/BDV persistently infected cells lines of avian and mammalian origin have been tested as target cells for ABV antibody detection by IFAT.[3,26–28] Recently, the effect of antigenic variability on the sensitivity of antibody detection was assessed by IFAT on sera from naturally or experimentally infected animals by using various cell lines infected with different ABV/BDV genotypes. The principal outcome of the study is that antibody titers are highest when the homologous target virus is used. Furthermore, a good cross-reactivity between closely related genotypes belonging to a common phylogenetic group exists, but detection sensitivity is reduced when target viruses are not closely related. It is therefore suggested that antibodies detected with any target bornavirus should be considered as bornavirus-reactive rather than genotype-specific.[20]

A homemade ELISA assay using ABV recombinant P40, P24, and P16 proteins produced in *Escherichia coli* demonstrated a considerable variation in the nature and titer of antibodies in ABV naturally infected psittacine birds. Hence, variability in the presence of anti-ABV P24 phosphoprotein and P16 matrix protein antibodies makes these antibodies less useful for the diagnosis of ABV infection. Conversely, the constant identification of anti-P40 protein antibodies allows to identify past/present infection in many birds.[29] Recently, an indirect ELISA for the detection of anti-ABV antibodies in captive canary birds has been set up.[28] Plates were coated with recombinant ABV N protein and serum antibodies were detected by rabbit anti-canary IgG serum. As evidenced in the study, seroconversion did not correlate with virus tissue distribution or viral shedding, in accordance with previous observations from naturally infected psittacines.[24]

The assessment of the specificity and sensitivity of serologic tests is difficult due to different assays, poor understanding of disease epidemiology, absence of gold standard to identify infection in live birds, difficulty in identifying a true control group of uninfected birds, variability among species, and relatively poor correlation between viral shedding, pathology, and presence of antibodies.

39.1.4.1.2 Virus Isolation

Viral propagation on cell lines remains a very sensitive tool for the detection of new ABV genotypes, even though time consuming. Therefore VI, rarely used for routine diagnosis, finds application in research as a source of virus for genome sequencing, in vivo experimental inoculation, development of new molecular techniques, and serologic assays.[12,27]

Quail cell line CEC-32 and primary duck embryo fibroblasts have been the most commonly cell lines used for ABV isolation.[27,28] In particular, CEC and QM7 quail cells have shown best results for ABV isolation from canary birds, while, as concerns psittacine, significant results have been obtained by using exclusively quail cell line CEC-32.

Bornaviruses establish persistent infections in cell culture, without causing an evident cytopathic effect. Hence, the virus identification is usually performed by immunofluorescence staining for viral antigen. Bornavirus-specific antigens could be detected by using IFATs with polyclonal anti-ABV-2 or anti-BDV-1 rabbit sera on organ samples of various psittacine birds.[10,12,26–28,30]

In particular, in a recent study a panel of different polyclonal rabbit sera and monoclonal mouse antibodies for antigen was systematically tested for the detection of 4 bornavirus genotypes (ABV-2, ABV-C2, ABV-EF, and BDV-1) from different phylogenetic groups.[20] Polyclonal rabbit sera directed against N, X, P, and M proteins showed good cross-reactivity with all 4 genotypes tested. Although these recent data confirm previous evidences of a high degree of cross-reactivity between different ABV and BDV genotypes, more distantly related virus strains that are able to escape detection by such antibodies may exist.[10,11,26,30] Nevertheless, VI might complement ABV diagnosis when the presence of a new or uncommon virus genotype is suspected.[27]

Swabs or blood samples are commonly collected from live birds. In particular, swabs, placed in transport medium containing antibiotics, are considered a good sample to investigate the shedding of infectious virus.[27] Any prolonged storage of infected materials should be at –70°C or below to minimize loss of virus titer, avoiding repeated freezing and thawing.

39.1.4.1.3 Immunohistochemistry

Histopathological diagnosis is still considered the gold standard test for PDD diagnosis; nevertheless, histopathology might also show false-negative results, due to the not constant distribution of PDD lesions.[18] Anyway, a recent study demonstrated an excellent statistical association between histopathologic diagnosis of the disease and results obtained by ABV-specific reverse transcription polymerase chain reaction (RT-PCR) and IHC.[18] IHC has been applied directly on paraffin-embedded organ samples to the identified cell and organ distribution of viral antigens in psittacine birds, using polyclonal antisera raised against purified recombinant ABV nucleoprotein N and ABV phosphoprotein P.[18,30,31] In live birds, IHC on crop biopsy is a simple and less invasive diagnostic approach, although its

Downloaded From Vet-eBooks.com

sensitivity is controversial, with a prevalence of ganglioneuritis in crops of patients with PDD ranging from 22% to 76%.[15,16,32] It has to be noted that proper selection of the site and the setting up of multiple sections have been suggested to increase the sensitivity of the method.

The brain, spinal cord, adrenal gland, pancreas, and kidney are considered the best samples for IHC, in the presence of postmortem diagnosis, due to the clear ABV antigen localization and to the minimal unspecific background staining. Unspecific background staining might be also influenced by samples autolysis, making the use of fresh samples essential for IHC test.[23] ABV was also detected in multiple other organs, including the anterior gastrointestinal tract (crop, proventriculus, ventriculus, and duodenum) as well as the heart, testes, ovary, and thyroid. The broad tissue distribution of viral antigens has been confirmed also in canary birds.[10,15,28]

39.1.4.2 Molecular Techniques

Specific molecular techniques for ABV RNA identification represent an efficient tool to verify the infection of a bird in suspected cases of PDD.[33] Nonetheless, the selection of samples for PCR testing is crucial to obtain a reliable result. However, due to the limited knowledge gained on this virus, molecular tools should be used with caution. At the moment, RT-PCR is routinely used for the detection of RNA ABV. RT-PCR on feather calami, a relatively noninvasive sample collection, may be a reliable method for the diagnosis of a current ABV infection in live birds. Although single feathers may be sufficient for the detection of viral RNA, processing feathers in pool is advisable for a meaningful result.[29]

The presence of PCR inhibitors should be taken into account when performing PCR on feather and fecal materials. In these cases, the use of inhibitors removal procedures, such as bovine serum albumin added to PCR mix or simply sample dilution, would help to avoid false negative.[34] As noticed by some authors,[27] RT-PCR assays may fail to detect distantly related or yet unknown genotypes, so classical viral isolation and serology could represent valid alternatives. Moreover, given that birds shed the virus intermittently in their droppings, diagnosis requires multiple PCR tests to confirm results.[35] However, RT-PCR for the identification of ABV infections represents, actually, the better assay to use for screening of psittacine birds at risk for PDD, especially in early infections.[18] Moreover, gene sequencing and comparison with the available ABV sequences present in public databases allow the characterization of genotype and the phylogenetic reconstruction.

39.2 METHODS

39.2.1 Sample Preparation

Crop biopsy and cloacal, choanal, pharyngeal, and crop swabs, as well as urofeces, white blood cells, and feather calami are recommended samples for ABV PCR testing in case of intravitam diagnosis.[23] Fresh urofecal droppings or cloacal swab collection are simple methods to evaluate ABV infection, because birds excrete the greatest amount of virus in the urine.[36] Nonetheless, shedding appears to be intermittent in healthy infected subjects, consequently the test of a single dropping from a single bird is of limited usefulness. A pool of multiple droppings from single or different birds over a week of collection period may improve sensitivity.[35] Feather sampling is relatively noninvasive approach and gives the advantage that ABV RNA remains stable for at least 4 weeks when the feather is stored at room temperature.[29] Based on results from Delnatte and colleagues, bone marrow is to be considered as an accessible antemortem sample for the diagnosis of ABV infection.[37] In the same study, a tissue ranking obtained by threshold cycle (Ct) values of the real-time PCR has been applied to determine the viral load of each organ suggesting proventriculus, kidney, colon, cerebrum, and cerebellum as the best samples for the diagnosis by RT-PCR from dead birds. On the other hand, ABV RNA was reported in the nervous system, in the gastrointestinal tract, and in nearly all other tissues in PDD-affected dead psittacine birds.[1–3,18,21,26,31,38] For a meaningful diagnostic result, collection of samples should be made from freshly dead or euthanized birds and organs transported to the laboratory at 4°C within 48 h. In case of long-range delivery, tissue samples should be transported in an RNA stabilization reagent or at least frozen.[23]

39.2.2 Detection Procedures

Due to the marked genetic variability of ABV, several primer sets have been designed able to identify nucleic acid of different avian orders. Degenerated primer sets targeting ABV/BDV consensus sequences of the N (Ncon), M (Mcon), or L (Lcon) gene have been widely and successfully applied for the detection of 7 ABV genotypes isolated in psittacine birds.[1,26,27,31] RT-PCR assays targeting the highly expressed N gene and the conserved M gene regions demonstrate a comparable sensitivity, higher than L gene assays. Specific primers set, targeting consensus sequences of the N (Ccon) and P (Fcon) genes of ABV genotypes isolated from canary birds, have been used in combination with the Ncon and Mcon pairs to identify ABV strains in canary birds belonging to the *Passeriformes* order.[28] This study highlighted remarkable variations in sensitivity between different primer sets used in the detection of ABV strains from canary bird.

Two real-time RT-PCR protocols designed on the P and M genes have been applied successfully on different psittacine and anserine bird tissues.[2,37] In particular, real-time RT-PCR targeting M gene appeared more sensitive than conventional M gene RT-PCR and IHC in tissues with low viral load, reducing also the number of false-negative results.[37,38]

39.2.2.1 Detection of Avian Bornavirus in Psittacine Birds by RT-PCR

Weissenbock and colleagues described two RT-PCR assays for conserved genes of ABV and nucleotide sequence analysis used to examine paraffin wax-embedded or frozen tissue samples of 31 psittacine birds with PDD.[30]

Downloaded From Vet-eBooks.com

Name	Sequence (5′–3′)	Nucleotide Position	Product Size (bp)
N632-F	CATGAGGCTATWGATTGGATTA	632–653	389
N1020-R	TAGCCNGCCMKTGTWGGRTTYT	1020–999	
M1908-F	CAAGGTAATYGTYCCTGGATGG	1908–1929	352
M2259-R	ACCAATGTTCCGAAGMCGAWAY	2259–2238	

39.2.2.1.1 Procedure

1. Design bornavirus-specific universal oligonucleotide primer pairs targeting putative N protein and M protein gene fragments. Align BDV-specific nucleic acid sequences deposited in GenBank, including representative sequences of the 5 ABV genotypes described by Kistler and colleagues, and search for conserved genomic regions.[1]
2. Extract viral RNA from 10 µm sections of paraffin wax-embedded psittacine tissue samples. Process samples in pools of 3–5 sections of each block. Remove paraffin from the tissue section by incubation with 1mL xylene for 20 min at 37°C, followed by pelleting tissues by centrifugation at 16,000 × *g* for 5 min at room temperature. Remove xylene and resuspend the pellets in 1 mL RNase-free ethanol for 5 min at room temperature. Samples were centrifuged again at 16,000 × *g* for 5 min at room temperature, and repeat the ethanol treatment. After centrifugation, remove the ethanol, and let the pellets air-dry. After 10 min, resuspend the tissue samples in 250 µL ATL tissue lysis buffer (QIAGEN, Hilden, Germany) and 25 µL Proteinase K (QIAGEN) was added. Samples were digested with proteinase for 16 h at 55°C, followed by an enzyme inactivation step for 8 min at 95°C. Use 140 µL of tissue lysates to extract viral RNA using the QIAamp Viral RNA Mini Kit (QIAGEN) according to the manufacturer's recommendations.
3. Carry on one-step RT and amplification using a One-Step RT-PCR Kit (QIAGEN) according to the manufacturer's instructions and with a final primers concentration of 0.8 µmol/L. Perform amplification reaction in a GeneAmp PCR System 2700 Thermocycler (Applied Biosystems, Foster City, CA) with the following thermal profile: 30 min at 50°C, 15 min at 95°C, 45 cycles × (30 s at 94°C, 30 s at 50°C, and 30 s at 72°C), and 7 min at 72°C. Use RNA extracts from psittacine organs without indication of PDD as negative controls.
4. Run PCR products by electrophoresis in 1.5% Tris-acetate–EDTA agarose gel and stained with ethidium bromide.
5. For sequencing, purify PCR products with the Quantum Prep PCR Kleen Spin Columns (Bio-Rad, Hercules, CA) according to the manufacturer's protocol. Perform a fluorescence-based direct sequencing of amplicons in both directions by using the ABI PRISM Big Dye Terminator Cycle Sequencing Ready Reaction Kit (Applied Biosystems).
6. Identify nucleotide sequences by the Basic Local Alignment Search Tool performing the alignment with the Align Plus program, version 4.1 (Scientific and educational Software, Cary, NC). Create multiple alignments for phylogenetic analyses using the Clustal X program and conduct phylogenetic analyses by the neighbor-joining algorithm. Perform bootstrap resampling analyses of phylogenetic trees on 1000 replicates. Draw phylogenetic trees with the help of the TreeView 1.6.6 software.

Note: Due to the nature of sample material (paraffin wax–embedded tissues), primers for the amplification of relatively short PCR products were designed to reduce the chance of false-negative reactions due to the RNA fragmentation effect of the formaldehyde fixation.

39.2.2.2 Detection of Avian Bornavirus in Canary Birds

Rubbenstroth and colleagues applied four different RT-PCR protocols to investigate the presence of ABV in captive canary birds and to analyze the genetic variability.[28] In the initial detection of ABV RNA from canary swabs and organs, the widely used RT-PCR assays Ncon and Mcon were applied.[1] Following the detection of two ABV strains, two new PCR assays specific for passerine birds were designed: the Ccon primer pair targeting the N gene consensus sequence of two canary isolates and the Fcon targeting the P gene consensus sequence of same isolates plus an ABV sequence derived from a Bengalese finch.

Name	Sequence (5′–3′)	Nucleotide Position	Product Size (bp)
Ncon F	CCHCATGAGGCTATWGATTGGA TTAACG	629–656	426
Ncon R	GCMCGGTAGCCNGCCATTGTDGG	1026–1004	
Mcon F	GGRCAAGGTAATYGTYCCTGGA TGGCC	1905–1931	359
Mcon R	CCAACACCAATGTTCCGAAGMCG	2264–2242	
Ccon_F	GGTGTGGTGATTGGKTCTTC	490–509	219
Ccon_R	SGGYGAYTCAAAGTCTGTAG	708–689	
Fcon_F	CCGCAGACAGYACGTCGC	1323–1340	167
Fcon_R	TCATCATTCGAYARCTGCTCCCTTCC	1489–1465	

39.2.2.2.1 Procedure

1. Extract RNA from swab samples using the QIAamp Viral RNA Mini Kit (Qiagen, Hilden, Germany) and organ samples using phenol–chloroform extraction with Trifast (Peqlab, Erlangen, Germany).

Downloaded From Vet-eBooks.com

2. Perform RT of approximately 2 µg RNA per sample using the Revertaid Reverse Transcription Kit (Fermentas, St. Leon-Rot, Germany).
3. Carry out the initial detection of ABV RNA from canary samples by two RT-PCRs with Ncon and Mcon degenerated primer sets. Prepare PCR mix with $MgCl_2$ 3 mM, dNTPs 0.2 mM each, primers 0.2 µM each, and 0.625 units of Taq Polymerase (Fermentas) in a 25 µL reaction. Set up the cycling condition for both assays with a denaturation step (2 min at 94°C), followed by 40 cycles of denaturation (94°C, 20 s), primer annealing (30 s, 48.5°C), and elongation (72°C, 25 s) with a final elongation step (72°C, 5 min).
4. Design Ccon and Fcon primers, specific for the N and P genes of canary birds, using complete genome sequence of canary isolates obtained in the study and a putative ABV sequence originating from a Bengalese finch (GenBank DC290659).
5. Apply four PCR assays to screen samples derived from canary birds for the presence of ABV. Perform the Ncon and Mcon assays as described in procedure 4 and for the Ccon and Fcon methods prepare the PCR mix with $MgCl_2$ 2 mM, dNTPs 0.2 mM each, primers 0.2 µM each, and 0.625 units of Taq Polymerase (Fermentas) in a 25 µL reaction. Set up cycling conditions respecting time and temperatures indicated for each of the following primer set: denaturation step (2 min at 94°C), followed by 40 cycles of denaturation (94°C, 20 s), primer annealing (30 s, 48.5°C for Fcon, 50.5°C for Ccon), elongation (72°C, 15 s for Ccon and Fcon), and a final elongation step (72°C, 5 min).
6. Perform the Sanger sequencing of PCR products of the Ncon PCR and a phylogenetic analysis together with ABV and BDV sequences derived from GenBank, including two ABV sequences from canary birds.

Note: Ccon and Ncon appeared to be the most sensitive assays for the detection of ABV strains from canary birds and related finches.

39.2.2.3 Detection of Avian Bornavirus in Wild Canada Geese and Swans by Real-Time RT-PCR

Delnatte and colleagues described a duplex real-time RT-PCR assay targeting both psittacine ABV (ABV_M set) and geese ABV (ABVG_M set) matrix gene sequences to identify ABV in frozen and fixed paraffin-embedded tissues from free-ranging waterfowls.[37]

Name	Sequence (5′–3′)
ABV_M_F_120201	CAAGGTAATYGTYCCTGGATGGCC
ABV_M_R_120201	TCACTGAAAGAAANGGTATRTTGAT
ABV_M_Pr_120201	TAATGTTGGARATAGACTTTGTTGG
ABVG_M_F_111029	CGAGGGAGAAGAGACTGGTTGATT
ABVG_R_111029	ACTGCCAAAGAGTTGAGCGT
ABVG_M_Pr_111029	ATGTGGAACCTGCTGGTCACTCA

39.2.2.3.1 Procedure

1. Perform RNA extraction on FFPE sections of tissues using the RNeasy FFPE Kit (Qiagen Inc., Mississauga, Ontario, Canada) according to the manufacturer's instructions.
2. Set up the duplex amplification mixture in a 25 µL final volume using the AgPath-ID One-Step RT-PCR Kit (Applied Biosystems, Inc.), according to the manufacturer's recommendations.
3. Carry out amplification reactions in a LightCycler 480 Real-Time PCR System (Roche, Laval, Quebec, Canada) with the following thermal profile: 10 min at 45°C, 10 min at 95°C, 45 cycles × (5 s at 94°C, 60 s at 60°C).

Note: In the interpretation of the results, a Ct value <37.00 was considered positive, Ct from 37.00 to 39.99 inconclusive, and Ct ≥ 40.00 negative.

39.3 FUTURE PERSPECTIVES

A huge collection of data has been accumulated through research all over the world from the first description of ABV in 2008 in psittacine birds. Despite all this considerable work, several questions about avian bornaviruses are still looking for an answer. In the next future, research efforts should be dedicated at elucidating the factors that induce the development of disease in infected subjects, since many aspects in the pathogenesis of PDD remain unclear.[37]

Moreover, the great genetic heterogeneity as well as the supposed existence of novel genotypes in other avian and nonavian species poses a major challenge for the near future in the diagnosis of ABV infections.[27] Robust and reliable tools for the molecular characterization of ABV genotypes are necessary and would be of great value to understand the antigenic and evolutionary relationships within the virus family.

40.1 INTRODUCTION

Bovine ephemeral fever (BEF; also known as 3-day sickness) is a vector-borne, viral disease of cattle and water buffaloes that leads to dramatic loss in milk production. The disease in cattle is characterized by acute febrile reaction, stiffness, lameness, and spontaneous recovery within 3 days [1]. The mortality rate was reported as 1%–3% in the past outbreaks, but about 20% was noted in some herd of the recent outbreaks [2]. The most important vector of the causal agent bovine ephemeral fever virus (BEFV) is *Culicoides* flies. Although the disease has been reported in the tropical and subtropical regions of Australia, Africa, and Asia, considering that *Culicoides* flies are transported to long distances especially by wind, BEFV may spread to wider geographies or continents in recent years [1–3]. Given the increased number of epidemics and high mortality rates observed in recent outbreaks of BEF, with devastating economic consequences, it is critical that rapid, sensitive, and specific diagnostic methods are available and applied for improved detection and monitoring of BEFV.

40.1.1 Classification

BEFV is classified as a member of the genus *Ephemerovirus* in the family *Rhabdoviridae*. Besides BEFV, the genus *Ephemerovirus* also includes Berrimah virus, Adelaide River virus, Kotonkan virus, Malakal virus, Kimberley virus (KIMV), and Obodhiang virus. As Berrimah, Kimberley, and Malakal viruses are morphologically similar to BEFV and react with BEFV serologically, they are collectively called BEFV serogroup. Some of the more recent phylogenetic studies have shown that BEFV serogroup viruses may have evolved as a geographic variant of BEFV due to high percentage of the genome and amino acid sequence similarity. Additionally, BEFV serogroup viruses showed cross-reactions with rabies-related viruses of the *Lyssavirus* genus. For this reason, it was suggested by some researchers that BEFV serogroup viruses and rabies-related viruses may combine to form a large complex new group. As BEFV genome and amino acid organization demonstrate significant differences from other rhabdoviruses, it is accepted as the most realistic approach that BEFV should remain a distinct genus within the family *Rhabdoviridae* [4,5].

40.1.2 Morphology, Biology, and Epidemiology

BEFV virions are enveloped, bullet- or cone-shaped, with a negative-sense single-stranded RNA of approximately 14.9 kb in size. The BEFV genome contains 10 long open reading frames, arranged in the order 3′-N-P-M-G-G_{NS}-α1-α2-β-γ-L-5′, encoding the five common rhabdovirus structural proteins—nucleoprotein (N), phosphoprotein (P), matrix (M), glycoprotein (G), and large (L)—and several additional proteins of unknown functions [5–7].

The N protein (52 kDa) is a phosphorylated protein associated with nucleocapsid structure. N protein plays a canonical role in the transcription and translation complex and is also involved in the virus assembly. BEFV is similar to KIMV, both having a group-reactive antigen region in the N protein [6].

G protein is an 81 kDa transmembrane glycoprotein that contains type-specific, neutralizing antigenic sites. It can be

Downloaded From Vet-eBooks.com

removed from the virion by treatment with nonionic detergents. G protein is considered as the main discriminative antigen of BEFV with four distinct antigenic sites (G_1, G_2, G_3, and G_4) on its surface. Although BEFV G_1 region is a linear antigenic structure that can react with only anti-BEFV antibody, G_2, G_3, and G_4 regions are able to react with BEFV and BEFV-related viruses. BEFV expresses a 90 kDa nonstructural glycoprotein (GNS), which also has the characteristics of a rhabdovirus glycoprotein identified in BEFV-infected cells, including putative signals and transmembrane domains. The role of GNS is still obscure. However, antibodies against this protein do not have any neutralization activity [7–10].

The other small BEFV accessory genes (α1, α2, β, and γ) encode proteins of unknown functions that have not previously been detected in infected cells or in virions. All other ephemeroviruses (Berrimah virus, KIMV, Malakal virus, Adelaide River virus, Obodhiang virus, and Kotonkan virus) encode α1 protein in the long G–L intergenic region, directly downstream of the GNS gene. BEFV α1 proteins play a role as a viroporin and promote release of viral particles from cells [7,11].

BEFV entry is through a clathrin-mediated and dynamin 2-dependent endocytic pathway. BEFV enters host cells after receptor-mediated endocytosis and depends on acidic cellular compartments for productive infection [5–7]. BEFV-induced apoptosis is reported in BHK-21, Vero, HeLa, NS-1, and MDCK cell lines. Indeed, replication of BEFV has higher efficiency and apoptosis induction is greater in Vero cell line [12–14]. Viral gene expression is required for apoptosis induction in BEFV-infected cells. BEFV induces apoptosis through Fas signaling and mitochondrial pathway and causes caspase-3, caspase-8, and caspase-9 activation [13]. Further investigations revealed that Src-dependent JNK signaling pathway has a key role on apoptosis triggered by BEFV [14].

Although the virus has one serotype, in recent years, virological studies and field observations showed that isolated virus from several outbreaks might have different phenotypes (virulence, transmission, etc.) or antigenic variations. Mutations on BEFV genome, especially the G gene, result in different phenotypes or antigenic variants. The nucleotide sequences of G gene showed three different clusters or genotypes. For this reason, it is suggested that different phenotypes isolated may have been responsible for various morbidity and mortality rates observed in the same country in different years [2,15–18].

The first scientific account of ephemeral fever was documented under the title "Epizootic dengue fever of cattle." It is then estimated that the infection spread in East African countries and others [1]. BEFV is reported in tropical regions of Asia and Australia in the following years. BEF endemic or epidemic mainly occurs in summer or rainy seasons in some regions of Africa, Asia, and Australia [1–3,15–18]. As *Culicoides* midges are abundant in the emerging region of BEFV, they form an important link in the BEFV epidemiology. Although countries with outbreaks or high prevalence of BEFV employ a wide variety of measures to reduce *Culicoides* biting attacks on cattle or other animals, this control approach is neither effective nor practical. During the past few years, a number of articles investigating how the virus is spread over continents and vast distances have been published. The findings revealed that the mosquitoes can be dispersed overnight up to distances of 650 km compared to only 50 km during the day [2,16,19]. The epizootic swept 1000 km westward into the Kimberley region of Western Australia and eastward into Queensland and then progressively moved 3000 km southward on a wide front through eastern states to reach Victoria in February 1937 [17].

Vaccination is recommended in countries where BEFV is prevalent and outbreaks occur often [1,3,8]. BEFV-free countries with neighbors where the disease is present and has the appropriate environmental conditions for insect vectors should be carefully monitored for the epidemic. BEFV-free countries should take the necessary precautions and plan for emergency vaccination. Attenuated and inactivated vaccines have been used in Japan, Australia, and South African countries [1,3,20,21]. Although natural infection provides long-lasting protective antibodies against BEFV for years, attenuated vaccine may protect cattle for approximately 1 year. It is clear that the attenuation may reduce the immunogenicity of the virus. Additionally, attenuated vaccines may cause clinical disease because attenuated BEFV vaccines, like other RNA virus vaccines, have a much higher mutation rate. Thus, there is a possibility of the vaccine reverting to a more virulent strain in the cattle. Furthermore, the vaccines may be contaminated with other viruses, mainly pestiviruses. However, inactive vaccines that include a high amount of viruses should be used to achieve the desired level of protective immune response, at least twice [21]. Although BEFV has one serotype, there are many genotypes and different strains [17,22]. The preferred vaccine strains that provide optimal immune responses are those isolated from BEF outbreak seen in the country. As animals that recover from natural infection develop lifelong immune protection, they do not show any clinical symptoms following new outbreaks [21]. In the new outbreaks, young animals (born after the previous epidemic) living in a herd that has naturally infected are affected severely. Therefore, young animals should be vaccinated.

40.1.3 Clinical Features and Pathogenesis

While BEF-affected cattle and water buffalo show clinical symptoms, other ruminants have subclinical symptoms [1,3]. Clinical symptoms of the infection range from asymptomatic infection to death. It is thought that BEFV may cause distinct clinical symptoms based on animal factors such as age, reinfection, and genetic background. However, compared to host (animal) factors, virus-related factors may be less significant. Cattle with BEFV infection develop sudden onset of fever (41°C–42°C), usually biphasic or triphasic. During the first fever, milk production in lactating cows often drops dramatically. Animals may have tachypnea, depression, anorexia, ruminal atony, serous or mucoid discharges from the nose and eyes, waves of shivering, joint pain, stiffness,

Downloaded From Vet-eBooks.com

and shifting lameness. Many animals become recumbent for 8 h to several days. During the second fever, the symptoms are more severe. Level of milk production will never go back as it was before the disease. One of the major clinical signs is paralyses in the limbs. Recumbence may be seen progressing from sternal to lateral. These paralyses are temporary and the affected animals may promptly recover following the fever stage. Symptoms in severe cases can include significantly increased salivation, dyspnea, progressive loss of reflexes, and finally death. Other complications may include pneumonia, mastitis, temporary infertility in later pregnancy, and abortion in the cow. Clinical symptoms and death rate are lower in young cattle than in the older ones, with the former having higher average daily weight gain and higher milk production. Mild and uncomplicated cases recover in a short period of time and recovery rate is 95%–97%. Although there are some preliminary data about which genotype and phenotype of the virus exerts a notable influence on the severity of the disease and clinical observations, further studies are required to support this conclusion [1–3,23].

The pathogenesis of the disease is complex and remains obscure [1,2]. Injury of the endothelial lining of small blood vessel is central to expression of BEFV, but there is no evidence that the virus causes widespread tissue destruction. The primary effect of the inflammation is an increased permeability of small blood vessels, which has been demonstrated in BEFV infection. The first main signs of BEF are depression and cessation of milk secretion. Animals have fever, depression, anorexia, tachycardia, permeability of blood vessels, joint swelling, subcutaneous edema, ocular and nasal discharges, and neutrophilia with many immature forms that represents one of the most important hematological changes. Hypocalcemia is caused by the development of immature neutrophilia. Hematological and biochemical changes caused by BEFV are similar to periparturient hypocalcemia symptoms. These changes may lead to subcutaneous emphysema in a small percentage of cases especially in hot weather. And finally, another sign of BEFV-affected animals is the prolonged paralysis that remains after the fever terminates. Significant hematological and biochemical changes have been reported in cattle suffering from BEFV disease. In short, the clinical disease of BEF is accompanied by a marked neutrophilia, lymphopenia, increased plasma fibrinogen levels, and decreased serum calcium levels. The clinical signs of BEFV infection can be ameliorated without preventing viremia by treatment with anti-inflammatory and with calcium influx due to these parameters. Polyserositis and synovitis are recorded in lymph nodes; focal necrosis and edema of the lungs are also seen in certain muscle groups as a result of pathophysiological effects [1,3,24].

40.1.4 Diagnosis

40.1.4.1 Conventional Techniques

Although BEF demonstrates characteristic epidemiological and clinical signs, laboratory diagnosis should be mandatory for definitive diagnosis [1,3]. Virus isolation in cell culture and suckling mice are used as a gold standard. For these purposes, whole blood with EDTA should be collected from sick animals that have fever. It is known that the gold standard workflow for BEFV identification is time consuming and labor intensive. As an alternative diagnostic approach, sera from cattle should be taken again 2 weeks later and increased virus titer might be determined in this second sample by microneutralization test. The microneutralization test is very sensitive but expensive and technically demanding. Therefore, application of ELISA for BEFV diagnosis is more popular in recent years than neutralization test. Among numerous ELISA systems available, a blocking ELISA is preferable. The most important problem in the serological diagnosis of BEFV is KIMV because of their close antigenic relationships. KIMV causes subclinical infection in cattle and induces low titer neutralization antibody that does not provide any protection against BEFV. This situation creates difficulty for the evaluation of serological testing. To overcome this problem, G1-ELISA can be used to detect BEFV only. Given that sera positive to KIMV did not cross-react in the blocking ELISA or virus neutralization test, it is possible that sera from animals with KIMV infection would not test positive with indirect ELISA as recently reported [18,25].

40.1.4.2 Molecular Techniques

BEFV may spread very fast following the infection focus to impede infect broad geographical region. Therefore, at the beginning of the BEF-suspected outbreak, it is mandatory to use a reliable and rapid diagnostic method. Due to the fact that virus isolation and microneutralization are time consuming, molecular diagnostic methods are increasingly used in recent years [1–3]. Reverse transcription-polymerase chain reaction (RT-PCR) is the most preferable method for diagnosis of BEFV [1–3,15–17,22]. RT and PCR stages may be carried out separately but also performed in a single tube known as one-step. One-step RT-PCR is a commonly used system because it is rapid, inexpensive, and non-labor intensive. To help choose a particular molecular test for adoption, it is desirable to consider various elements of primer design requirements into one process such that users can simply input the template and obtain the desired target-specific primers. Primers specific for BEFV G region are used commonly for diagnosis [2,15–17,22]. Some of the positive RT-PCR products are chosen for sequencing confirmation of RT-PCR. Evolutionary analysis conducted on nucleotide sequences of the G gene is important to find genotypes and to better understand the molecular epidemiology of BEFV. Phylogenetic analysis of the BEFV G gene sequences from field isolates or clinical samples showed that BEFV isolates are grouped into distinct genotypes or clusters. To date, these genotypes are mainly based on the comparison of the different geographical regions. These genotype analyses are sometimes differently interpreted because each researcher chooses different parts and various lengths of the G gene for phylogenetic analysis. Based on phylogenetic analysis of the BEFV G gene sequences, a genogroup or cluster (genotype I-3 virus strains) includes Far East Asian countries such as Taiwan, China, and Japan. Virus strains isolated from Turkey, Egypt, and Israel are assigned in

Downloaded From Vet-eBooks.com

a different cluster [2,15,16,22]. Australian strains are placed in an independent cluster [17]. As a result, phylogenetic studies showed that, although BEFV is serologically monotypic, it displays significant antigenic variations among its genotypes.

Real-time PCR and the novel RT-loop-mediated isothermal amplification (RT-LAMP) methods are later developments in the molecular diagnosis and genotype determination of BEFV [26,27]. RT-LAMP appears to be more sensitive and allows earlier detection of BEFV in clinical samples compared with conventional RT-PCR and the virus isolation method [27]. However, the use of RT-LAMP method is not as widespread as conventional RT-PCR.

40.2 METHODS

40.2.1 Sample Preparation

Whole blood samples containing EDTA as anticoagulant that have been taken from the acute phase of the disease should be used for RT-PCR. It is suggested that blood samples should be taken from the recumbent cattle or those with high fever. Samples for virus isolation must be transported to the laboratory immediately on ice and may be stored at 4°C in the laboratory for a few days if needed. If a portion of the samples is stored at −70°C, these samples may be used for virus isolation in future. Although both conventional procedures and commercial kits may be used for BEFV RNA isolation, commercial extraction kits are generally preferred because these kits provide larger quantity and higher quality of RNA than conventional isolation procedures.

Before RNA extraction, 2 mL of blood cells should be suspended in 4 volumes of sterile 0.2% NaCl to lyse erythrocytes, and 7.2% NaCl should be added to reconstitute and washed with PBS. While many commercial kits (e.g., QIAamp Viral RNA Mini Kit, Qiagen, and ZR Viral RNA Mini Kit, Zymo Research Corp.) are available for RNA isolation from blood samples with EDTA, the following protocol is based on ZR Viral RNA Mini Kit. Briefly, the pelleted cell is mixed with 400 µL of RNA lysis buffer. The mixture is incubated at room temperature for 15 min. Then, the lysate is transferred to Zymo-Spin IC Column in a collection tube and centrifuged at 16,000 × *g* for 2 min. The flow-through is discarded and the Zymo-Spin IC Column is placed back into the collection tube. Next, 500 µL of viral RNA wash buffer is added to the column. Centrifugation is repeated at 16,000 × *g* for 2 min and the column is transferred into the emptied RNase-free collection tube. Then, 25 µL of DNase/RNase-free water is added to the column and incubated at room temperature for 1 min. The RNA is eluted from column with centrifugation at 16,000 × *g* for 30 s. The RNA samples can be used immediately or stored at −70°C.

40.2.2 Detection Procedures

In this section, a one-step RT-PCR protocol is presented for the detection of BEFV from clinical blood samples. Subsequent phylogenic analysis reveals additional details on the genotypes of BEFV strains.

40.2.2.1 One-Step RT-PCR

The following one-step RT-PCR assay utilizes the QIAGEN OneStep RT-PCR Kit (Qiagen, Valencia, CA). The assay is carried out with 50 µL total volume containing 10 µL of 5× RT-PCR buffer, 400 µM of each dNTPs, 2 µL of RT-PCR enzyme, 400 nM of each forward (bef19F; 5′-ATTTACAATGTTCCGGTGAA-3′) and reverse (bef523R 5′-GGTATCCATGTTCCGGTTAT-3′) primers, 1 µL of 1.5 mM $MgCl_2$, 3 µL of template RNA, and 30 µL of RNase-free water. Amplification is performed with the conditions involving an RT step at 53°C for 30 min followed by denaturation at 95°C for 15 min, 35 cycles of denaturation at 94°C for 1 min, annealing at 52°C for 1 min and extension at 72°C for 1 min, and a final step of extension at 72°C for 10 min. The PCR products are electrophoresed on 1.5% agarose gel. With the RT-PCR procedure, the nucleotide sequences (520 bp) of the partial gene region of G gene of BEFV are amplified. But, for amplification of the full G gene of BEFV, BEF-GF, 5′-ATGTTCAAGGTCCTMATAATTACC-3′, and BEF-GR, 5′-TTAATGATCAAAGAACCTATC-3′, primers can be used from RT-PCR.

40.2.2.2 Sequencing and Phylogenetic Analysis

The RT-PCR products may be sequenced for confirmation of amplification and phylogenetic analysis. For this purpose, positive RT-PCR products are purified using gel purification kits (e.g., QIAquick Gel Extraction Kit**,** Qiagen, Valencia, CA). Then, 2 µL of purified product is visualized using agarose gel before sequencing and DNA concentration and purity of DNA are measured by the spectrometer (Thermo Scientific NanoDrop 2000 Spectrophotometer). The product is sequenced in both directions with the forward and reverse primers by using the ABI 310 Genetic Analysis System (Iontec Co., Istanbul, Turkey). The gene sequences are aligned using ClustalW program and then compared to the other sequences of BEFV obtained from the GenBank database. The position of the sequences in the phylogenetic tree may be checked by a neighbor-joining method from the PHYLIP software. In addition to nucleotide sequence analysis, converting gene sequences into amino acid sequences is suggested for the determination of amino acid variations in the antigenic region that induces neutralizing antibodies.

40.3 FUTURE PERSPECTIVES

Vaccine provides an important advantage fighting against BEFV because of one serotype. Additionally, current epidemiological studies that determine virus circulation in countries or continents are a useful tool. Given the possibility that new BEFV serotypes may emerge due to high mutation rate and that BEFV vector, *Culicoides* species, may find new life zone due to changing ecological balance, BEF will spread to countries or regions more than expected. Therefore, continuing efforts in BEFV vaccine developments are warranted to provide sustained, lifelong immunity to animal hosts against existing as well as newly emerged BEFV serotypes.

While the application of molecular techniques has uncovered valuable insights on the molecular epidemiology of BEFV, there are still controversial issues and some problems that remain unsolved. It is known that appropriate vectors and susceptible hosts are crucial elements for a vector-borne disease to emerge. One unsolved issue concerning BEF is that BEFV cases may disappear after an outbreak in a region but continue for many years in other regions. In addition, it is not fully elucidated whether there is any relationship between distinct mortality and morbidity rates according to the different epidemic years, virus genotypic, and phenotypic variations. To address these questions, we need further investigations on molecular evolution and epidemiology of BEFV, contributing to our fight against BEF.

Given our incomplete knowledge about the functions of BEFV proteins especially accessory proteins to date, it is essential that further studies are conducted in these areas. The full elucidation of the functions of the BEFV protein will not only improve our understanding of rhabdovirus biology but also open potential new avenues for effective control of BEF in the future.

41.1 INTRODUCTION

Rabies virus is the causative agent of a zoonotic disease called rabies (a term derived from Latin word rabies, meaning "fury" or "madness"), which has been known since antiquity. The disease is easily recognizable when a dog infected with rabies virus loses its usual temperament and attacks/bites people without provocation. Considered a scourge for its prevalence in the nineteenth century, rabies has created irrational fear among people due to the absence of efficacious treatment. Following the discovery of the causative agent and the development of postexposure prophylaxis (PEP), this once ferocious disease has been largely brought under control. As a consequence, rabies has become a neglected disease in modern times, in spite of its stubbornly high prevalence and its association with around 50,000 deaths each year worldwide. In this chapter, we redraw readers' attention to rabies virus, with a concise overview on its classification, morphology, genome organization, epidemiology, clinical features, pathogenesis, diagnosis, treatment, and prevention. This is followed by the presentation of streamlined molecular protocols for its detection and identification, and a discussion of future research needs that will help us keeping an upper hand over this deadly pathogen.

41.1.1 Classification

Rabies virus (RABV) is negative-sense, single-stranded (ss) RNA virus classified in the genus *Lyssavirus*, family *Rhabdoviridae*, order *Mononegavirales*. Consisting of over 200 viruses, the family *Rhabdoviridae* is separated into 11 cleared defined genera (*Cytorhabdovirus*, *Ephemerovirus*, *Lyssavirus*, *Novirhabdovirus*, *Nucleorhabdovirus*, *Perhabdovirus*, *Sigmavirus*, *Sprivivirus*, *Tibrovirus*, *Tupavirus*, and *Vesiculovirus*) as well as nine proposed genera (*Almendravirus*, *Bahiavirus*, *Bracorhabdovirus*, *Curiovirus*, *Dichorhabdovirus*, *Hapavirus*, *Ledantevirus*, *Sawgravirus*, and *Sripuvirus*).

In turn, the genus *Lyssavirus* (lyssa, derived from Greek word "lud" or "violent") is divided into 12 recognized species (RABV [type species], Lagos bat virus [LBV], Mokola virus [MOKV], Duvenhage virus [DUVV], European bat lyssavirus types 1 and 2 [EBLV-1 and EBLV-2], Australian bat lyssavirus [ABLV], Aravan virus [ARAV], Khujand virus [KHUV], Irkut virus [IRKV], West Caucasian bat virus [WCBV], and Shimoni bat virus [SHIBV]) as well as two recently discovered species (Bokeloh bat lyssavirus [BBLV] and Ikoma virus [IKOV]) [1].

Based on phylogenetic analyses, lyssaviruses have been differentiated into seven genotypes: RABV (genotype 1), LBV (genotype 2), MOKV (genotype 3), DUVV (genotype 4), EBLV type 1 (EBLV-1; genotype 5), EBLV type 2 (EBLV-2; genotype 6), and ABLV (genotype 7). The five recently identified lyssaviruses (ARAV, KHUV, IRKV, WCBV, and SHIBV) may represent distinct genotypes in accordance with current approaches for genotype definition (amount of nucleotide identity of the N gene and bootstrap support of joining to certain

phylogenetic groups). Nevertheless, experimental data suggest that KHUV demonstrates relatedness to genotype 6; ARAV shows moderate similarity to genotypes 4, 5, and to a lesser extent 6; IRKV may be related to genotypes 4 and 5; WCBV has limited relationship to genotypes 2 and 3; and SHIBV is most similar to genotype 2 [1].

Through serological examination, members of the genus *Lyssavirus* have been distinguished into 2 phylogroups, with phylogroup 1 covering RABV, DUVV, EBLV-1, EBLV-2, ABLV, ARAV, KHUV, and IRKV and phylogroup 2 containing LBV, MOKV, and SHIBV. WCBV and IKOV are non-cross-reactive serologically with any of the two phylogroups, with WCBV possibly forming a separate phylogroup 3, while IKOV being part of phylogroup 3 or constituting a fourth phylogroup [1].

Furthermore, the classic RABV may be divided into the following two major phylogenetic groups: one associated with carnivores (typically dogs) in an "urban" cycle, and another associated with bats, raccoons, and skunks in a rural or "sylvatic" cycle. The former is distributed widely and contains six clusters (clades): the Africa 2, Africa 3, Arctic-related, Asian, cosmopolitan, and Indian subcontinent clades. The other lyssavirus species are largely maintained in bats with a more restricted distribution: DUVV, LBV, MOKV, SHIBV, and IKOV are present in Africa; EBLV-1, EBLV-2, and BBLV in Europe; ABLV in Australia; and ARAV, KHUV, IRKV, and WCBV in Asia [1,2].

41.1.2 Morphology and Genome Structure

As its family name (*Rhabdoviridae*, rhabdo is Greek for rod) suggests, lyssavirus is an enveloped, bullet-shaped (or elongated, rod-like) virus of about 75 nm in diameter and about 180 nm in length. The lipid envelope is decorated with spikes of 9–11 nm (made of glycoprotein [G] trimers), which interact with the matrix protein M. The matrix protein M forms a protective coating for the nucleocapsid underneath, which is composed of the nucleoprotein (N), large protein (L), and phosphoprotein (P). Coiling symmetrically to form a cylindrical structure with a striated appearance, the nucleocapsid encapsidates a linear, nonsegmented, negative-sense, ssRNA genome of 11,924 nucleotides [3–5].

The genome of RABV comprises five protein-coding genes arranged in the order of 3′ N-P-M-G-L 5′, encoding nucleoprotein (N), phosphoprotein (P), matrix protein (M), glycoprotein (G), and large protein (L), respectively [3–5]. Of these, the glycoprotein (G) is the only viral protein exposed on the virion surface and is involved in viral attachment and cell entry. Not surprisingly, as the primary surface antigen, the trimeric G protein is the main target of host neutralizing antibodies. The nucleoprotein (N), the phosphoprotein (P), and the large protein (L) interact with each other to form the nucleocapsid (also referred to as ribonucleoprotein complex, for which the matrix protein (M) provides a protective coating). The phosphoprotein (P) and the large protein (L) function as viral RNA polymerase, which is involved in the transcription from the original negative-strand RNA into five mRNA strands and a positive strand of RNA [6]. After sufficient proteins (P, L, N, G, and M) are translated from five mRNA strands, new negative strands of RNA are synthesized from the template of the positive-strand RNA. These negative strands form complexes with N, P, L, and M proteins and then interact with the G protein to generate new viruses [1].

41.1.3 Biology and Epidemiology

RABV infection usually begins with the transdermal inoculation of infected saliva in the bite of a rabid dog or bat. On rare occasions, rabies can be transmitted via routes other than bites (e.g., aerosols, corneal, and organ transplants as in the case of human rabies). The virus initially enters into muscle cells close to the biting site, with the assistance of its G protein (trimeric spikes) that binds to acetylcholine receptors (p75NR) on the cell surface [7]. After replication in muscle cells without disturbing the host's immune system, the virus utilizes its P protein to interact with dynein, a protein present in the cytoplasm of nerve cells, facilitating its travel to the central nervous system (CNS). After undergoing further replication in motor neurons of the brain, the virus migrates centrifugally to the peripheral and autonomic nervous systems and then the salivary glands (as well as nasal and oral cavities, adrenal glands, kidney, cardiac muscle, and hair follicles), where the virus is ready to be transmitted to the next host [8].

Many warm-blooded species are susceptible to RABV. These include humans, monkeys, raccoons, cattle, groundhogs, weasels, bears, wolves, coyotes, dogs, cats, foxes, mongooses, skunks, and bats [9–12]. While birds infected with RABV are often asymptomatic, squirrels, hamsters, guinea pigs, gerbils, chipmunks, rats, mice, rabbits, and hares are apparently refractory to RABV.

The main reservoir hosts and transmission vectors for RABV are carnivores (order Carnivora) and bats (order Chiroptera), although other animals (e.g., kudu antelope in Namibia and nonhuman primates in Brazil) may be potential reservoir hosts [13–16].

Dogs (and to a lesser extent cats) are involved in the urban cycle of rabies infection and represent the primary RABV vector in Asia and in parts of the United States and Africa [17–24]. Human mortality from urban canine rabies is estimated to be 55,000 deaths per year, with 56% of the deaths occurring in Asia (especially India and Vietnam) and 44% in Africa. The majority of the western European countries are free of urban canine rabies (RABV) [25].

Bats appear to be the original reservoir for lyssaviruses. Bats (red fox, raccoon dog, raccoon, and skunks) are associated with the sylvatic (wildlife) cycle of rabies infection, which remains widespread throughout parts of Europe, Africa, and North America [26]. In Europe, fox rabies is common, while the raccoon dog is often implicated in the epidemiology of rabies in the Baltic countries. In addition, rabies cases in Europe are mostly attributable to Lyssavirus genotypes 1 (RABV, classical rabies), 5, and 6 (EBLV types 1 and 2) [27].

41.1.4 Clinical Features and Pathogenesis

RABV infections in mammals involves three stages: prodromal, excitement (furious), and paralytic (dumb), although in atypical cases, not all stages are necessarily observed [1].

The first (prodromal) stage lasts 1–3 days and is characterized by behavioral changes and nonspecific signs typical of a viral encephalitis. In addition, due to viral replication in dorsal root ganglia and ganglionitis, there is neuropathic pain at the site of infection (bite wound).

The second (excitative) stage (often known as "furious rabies") lasts 3–4 days and is characterized by the tendency of the affected animal to be hyperreactive to external stimuli and bite at anything near.

The third (paralytic) stage is caused by damage to motor neurons and characterized by rear limb paralysis, drooling, and swallowing difficulty (paralysis of facial and throat muscles). Death is usually an outcome of respiratory arrest.

Interestingly, different animal species tend to exhibit varying times of virus excretion before the onset of clinical signs (cats <24 h, dogs <13 days, and foxes <29 days postinfection).

Postmortem examination of nonspecific lesions in the cervical spinal cord, hypothalamus, and pons may reveal ganglioneuritis in nerve centers, histolymphocytic cuffs, and gliosis. The only specific lesions may be oval-shaped intracytoplasmic eosinophil inclusions (Negri bodies) of 4–5 μm in size located in Ammon's horn, which correlate to the aggregation of developing RABV particles and which have provided a basis for diagnosing rabies for many years prior to the availability of specific and sensitive diagnostic methodologies.

In humans, although the period between infection and the first flu-like symptoms (e.g., fever) is typically 2–12 weeks, incubation periods as short as 4 days and longer than 6 years have nevertheless been observed. Clearly, a deep bite near the head of the victim may entail a short incubation period. With progression toward acute encephalitis, clinical signs may expand to hypersalivation, paresthesia (itching) around biting site, progressive cranial nerve paralysis, leg weakness, anxiety, insomnia, confusion, agitation, abnormal behavior, paranoia, terror, hydrophobiasis, and hallucinations, progressing to delirium, coma, and death (which almost always occurs 2–10 days after first symptoms) [28].

As the historic name for rabies, hydrophobia ("fear of water," which is commonly associated with furious rabies that affects 80% of infected people) refers to a set of symptoms (including difficulty swallowing, panicking when presented with liquids to drink, and thirst due to increased saliva production) that appear in the later stages of an infection. As the multiplication and assimilation of rabies are concentrated in the salivary glands, there is an urge to further transmit the virus through biting. The remaining 20% may experience a paralytic form of rabies marked by muscle weakness, loss of sensation, and paralysis, without usual fear of water [1].

41.1.5 Diagnosis

Animals infected with rabies generally show nonspecific symptoms such as frenzy, extreme tremors, salivation, and paresis that are indistinguishable to encephalitic conditions caused by canine distemper virus or acute trauma. Other differential diagnoses include herpes simplex virus type one, varicella zoster virus, echoviruses, polioviruses, human enteroviruses 68–71, West Nile virus, Nipah virus, transmissible spongiform encephalopathies, tetanus, listeriosis, poisoning, and Aujeszky's disease. Paralytic rabies may be sometimes mistaken for Guillain–Barré syndrome. Secondary infections such as malaria may also complicate rabies diagnosis.

For many years, histopathological detection of Negri bodies in the CNS has provided a basis for diagnosing of rabies. However, this postmortem diagnostic approach is largely irrelevant or unsuitable for guiding PEP. Therefore, alternative laboratory methods (e.g., virus isolation, serological tests, and nucleic acid detection) have been developed and applied for confirmation of rabies [29–32].

41.1.5.1 Virus Isolation

Virus isolation involves the inoculation of brain homogenates suspected to harbor RABV onto neuroblastoma cells (whose cell membranes contain acetylcholine receptors and neurotransmitter synthetic enzymes that render them susceptible to wild RABV infection). Positive results are often available within 2–4 days.

Another useful way to isolate and detect RABV is the mouse inoculation test (MIT), which involves the intracerebral inoculation of mice with a clarified supernatant of a homogenate of brain material (cortex, Ammon's horn, cerebellum, medulla oblongata) and observation for up to 28 days. Clinical signs suggestive of rabies may appear as early as 6–8 days.

41.1.5.2 Histopathology

Observation of specific histologic changes (e.g., Negri bodies) in CNS tissues has been commonly applied for rabies diagnosis before sensitive and specific diagnostic tests became available. This procedure is no longer routinely performed in clinical diagnostic laboratories, due to its poor reliability, particularly for decomposed material.

41.1.5.3 Serological Tests

One of the most widely applied serological tests for rabies diagnosis is the fluorescent antibody test (FAT). This technique utilizes fluorescently labeled antirabies antibodies to detect RABV nucleocapsid protein in smears prepared from the hippocampus, cerebellum, medulla oblongata, or spinal cord tissue as well as cell monolayers. The FAT takes a few hours to complete and has a sensitivity of 95%–99%. For the antemortem diagnosis of rabies using nonneural material (e.g., saliva, cerebrospinal fluid, skin biopsies) or decomposed tissues, the performance of FAT may be less optimal, although in tissue sections of skin biopsies, especially in the nerve endings surrounding the hair follicles, viral antigens may be detected with the FAT [1].

Other serological tests for RABV include rapid immunodiagnostic assay, histochemical test, enzyme-linked immunosorbent assay (ELISA), rapid rabies enzyme immunodiagnosis, and rapid fluorescent focus inhibition test.

41.1.5.4 Nucleic Acid Detection

Methods for detecting rabies nucleic acids range from in situ hybridization, reverse transcription polymerase chain reaction (RT-PCR), nucleic acid sequence-based amplification, to microarray [33–35].

Among these, RT-PCR (and its various derivatives, such as standard, nested, multiplex, and real time) is widely adopted in clinical laboratories for qualitative and quantitative detection of rabies from a variety of samples (saliva, urine, and cerebrospinal fluid, as well as decomposed or paraffin-fixed archival specimens) [36–42]. Many of these assays target the highly conserved N and L genes of RABV and lyssaviruses. To date, a large number of RT-PCR procedures for RABV detection have been reported [36–42]. Further advances in real-time RT-PCR technologies allow instant result readout and eliminate potential cross-contamination between samples [43]. Real-time RT-PCR for ARAV, KHUV, IRKV, and ABLV are also available [44,45]. Recently, a one-step quantitative real-time PCR assay utilizing a single primer–probe set for detecting four African lyssaviruses (RABV, MOKV, LBV, and DUVV) was described [46]. However, species-specific assays for individual African lyssaviruses (MOKV, LBV, DUVV, SHIBV, and IKOV) and WCBV have not been published. Fortunately, the use of pan-lyssavirus real-time RT-PCR will help cover this limitation (particularly, a recent study indicates that the sensitivity of RT-PCR is similar to that of virus isolation concerning SHIBV and WCBV) [1].

41.1.6 Treatment and Prevention

Treatments for rabies are largely based on the use of PEP. In humans, following exposure to an animal with suspected rabies, the biting/scratch wound should be carefully cleaned and washed for 5–15 min, with running water, soap/detergent, then povidone-iodine, alcohol, or other antiseptic; and a vaccine produced on cell culture (e.g., a vaccine prepared through the chemical inactivation of rabies-infected tissue culture human diploid cells HDCV) administered. Injection of rabies immunoglobulins (RIGs, especially immunoglobulins of human origin and fragments $F(ab')_2$ of equine origin) is advisable in case of high-risk exposure (e.g., transdermal bites/scratches, licks on broken skin, contamination of mucous membrane with saliva from licks, and exposure of bites/scratches and wound or mucous membrane to bat saliva). For humans, the Centers for Disease Control and Prevention in the United States recommends one dose of human RIG (<20 units per kg body weight, injected around the bite, as well as by deep intramuscular injection away from vaccination site) and four doses of rabies vaccine (at days 0, 3, 7, and 14) at the deltoid area or lateral thigh in infants. PEP may be stopped if laboratory examination rules out the suspected animal of rabies. In general, PEP is not effective after onset of neurological signs (generally after 10 days of infection) [47–49].

The control measures for rabies should center on notification, isolation, disinfection, and immunization. Vaccination of dogs and improved access to PEP represent effective approach for the prevention of rabies. Several vaccine preparations (e.g., SAG2 [RABIGEN® SAG2], Street Alabama Dufferin B19 [SAD B19, and SAD Bern]) have proven to be safe and potent for animals and are used in Europe. SAG2 vaccine is a modified live attenuated RABV vaccine, selected from the SAD Bern strain. This attenuated strain does not spread in vivo or induce a persistent infection [50–53]. Recombinant vaccines based on vaccinia virus and human adenovirus vector, both expressing the rabies glycoprotein of the ERA strain (V-RG and ONRAB, respectively), are in use in the United States and Canada to prevent outbreaks of rabies in wildlife.

The annual World Rabies Day on September 28 provides the general public with information about rabies, its prevention, and elimination.

41.2 METHODS

41.2.1 Sample Preparation

Tissues from the thalamus, pons, and medulla are recommended for rabies diagnosis in animals. The hippocampus (Ammon's horn), cerebellum, and cerebrum have been shown to give negative results in up to 11% of positive brains, while the thalamus gives 100% positive results. Therefore, a pool of brain tissues including the brain stem may be collected for testing. Brain tissue collected via transorbital or transforamen magnum route is also usable. If large numbers of animal carcasses are involved, the brain material may be collected by passing a plastic straw through the occipital foramen, the so-called "straw technique." The use of glycerine preservation (temperature: +4°C or −20°C) or dried smears of brain tissue on filter paper (temperature: +30°C) may facilitate safe transportation of infected material.

If brain tissue is not available, other types of specimens (e.g., saliva, spinal fluid, tears, oral and fecal swabs, skin biopsies from wound site or nape of neck, and corneal impression) may be tested [54].

For virus isolation, 1 g of brain sample may be homogenized with sand (Sigma) in 10 mL of alpha-minimum essential medium (α-MEM; Gibco BRL), or using the MagnaNA lyser tissue homogenizer tubes containing 1.4 mm (diameter) ceramic beads (Roche Applied Science) and 1.0 mL of MEM-10 as a diluent. The homogenized sample is centrifuged at 8000 × *g* for 5 min, and the supernatant filtered through a 0.45 μm membrane (Millipore). Briefly, 100 μL of filtrate is inoculated onto a monolayer of murine NG108–15 neuroblastoma cells (ATCC HB-12317) in a 24-well plate. The cells are maintained in α-MEM supplemented with antibiotics (100 IU/mL penicillin, 10 μg/mL streptomycin, and 0.25 μg/mL amphotericin B) and 10% heat-inactivated fetal bovine serum (Gibco BRL) at 37°C in a 5% CO_2 incubator for 1 h. Afterward, the inoculation

medium is removed and replaced with fresh α-MEM. Cells are observed for cytopathic effects for 5 days.

For FAT, frozen thin sections of brain tissue (e.g., Ammon's horn tissue) on slides are fixed in 80% chilled acetone (–20°C) for 20 min. After three washes with phosphate buffer saline (PBS; pH 7.2), the slides are incubated with a monoclonal antibody (Jeno Biotech) against rabies for 45 min at 37°C, and then stained with fluorescein isothiocyanate–conjugated goat anti-mouse IgA, IgG, and IgM (KPL). After rinsing with PBS, the slides are air dried and mounting buffered glycerin (Southern Biotechnology Associate, Birmingham, AL) is applied. The slides are examined under cover slips at magnification of 400 using a fluorescent microscope (Nikon). Positive and negative controls are run together with the test samples. The slide showing specific fluorescence is confirmed as positive.

Viral RNA may be extracted from brain samples using the Qiagen RNeasy Mini Kit (for brain and cell culture medium) or Qiagen QIAamp Viral RNA Mini Kit (for serum and CSF). Briefly, brain samples (400 mg) are first homogenized in 1 mL of PBS with a Potter homogenator. Then, 85 μL of the brain homogenate is mixed with 265 μL of lysis buffer (RLT) and used for RNA extraction. For RNA extractions from infected cell culture supernatants, a volume of 150 μL is homogenized in 200 μL of RLT buffer, as starting material for the RNA extraction. Starting from serum or CSF, a volume of 140 μL is used for RNA extraction with the Qiagen QIAamp Viral RNA Mini Kit. The extracted RNA is eluted in 50 μL of RNase- and DNase-free water.

41.2.2 Detection Procedures

41.2.2.1 RT-PCR for Rabies Virus Detection

Yang et al. [29] utilized primer sets (RVNDF: 5′-GRAA TTGGGCTTTGACTGGA-3′ and RVNDR: 5′-AAAGGG GCTGTCTCGAAAAT-3′) for amplification of 181 bp product from the N gene for specific detection of RABV.

RT-PCR mixture is composed of 5 μL of denatured RNA, 1 μL of each primer (50 pmol), 5 μL of 5 × buffer (12.5 mM $MgCl_2$), 1 μL of dNTP mix, 1 μL of an enzyme mix (reverse transcriptase and Taq DNA polymerase), and 11 μL of distilled water (Qiagen).

The cycling program includes cDNA synthesis at 42°C for 30 min, 45 cycles of 95°C for 15 s, 55°C for 15 s, and 72°C for 15 s, and a final extension at 72°C for 5 min.

RT-PCR products are separated and visualized on 1.8% agarose gels containing ethidium bromide. Samples showing a 181 bp band are considered positive.

41.2.2.2 RT-PCR for Pan-Lyssavirus Detection

Fischer et al. [43] described the use of pan-lyssavirus and RABV-specific real-time RT-PCR for the detection of lyssaviruses and RABV, with primers and probes designed from the N gene (Table 41.1).

RT-PCR mixture is prepared by using AgPath-ID™ One-Step RT-PCR Kit (Applied Biosystems), with each 12.5 μL reaction containing 2.75 μL (R13 MP) or 1.25 μL (R14 MP) RNase-free water, 6.25 μL 2 × RT-PCR buffer, 0.5 μL 25 × RT-PCR enzyme mix, 2.5 μL RNA template or RNase-free water for the no template control, and 0.5 μL of primer–probe mixes (Table 41.1).

Amplification and detection are performed in duplicates in Bio-Rad 96-well PCR plates using a CFX96 quantitative PCR system (Bio-Rad Laboratories), with the following thermal program: 1 cycle of 45°C for 10 min and 95°C for 10 min, followed by 45 cycles of 95°C for 15 s, 56°C for 20 s, and 72°C for 30 s.

For each RT-qPCR, a quantification cycle number (C_q) is determined according to the PCR cycle number at which the fluorescence of the reaction crosses a value that is statistically higher than the background. Finally, mean C_q values are calculated from duplicates. A cutoff >42 is defined for negative results.

41.3 CONCLUSION

As a zoonotic pathogen with a worldwide distribution, RABV is maintained in two lifecycles: while urban rabies involves dogs and cats as the primary transmission vector, sylvatic rabies utilizes bats and other wildlife species as the

transmission vector. Rabies usually begins following a bite from an infected animal and quickly develops clinical signs typical of encephalitis. In humans, rabies is fatal if PEP is not administered before severe symptoms emerge (about 10 days after infection). Therefore, the ability to rapidly and accurately detect and diagnose rabies plays a crucial role in the decision to implement PEP (which is costly). For this reason, WHO and OIE recommend the FAT, the rabies tissue culture infection test, and the MIT for the diagnosis of rabies. With the recent development in nucleic acid amplification technologies such as RT-PCR, rapid, sensitive, and specific detection and typing of rabies are no longer unreachable [55–57].

42.1 INTRODUCTION

Vesicular stomatitis (VS; also known as vesicular stomatitis virus disease, vesicular stomatitis fever, and Indiana fever) is an arthropod-borne, zoonotic vesicular disease caused by vesicular stomatitis viruses (VSV) in the genus *Vesiculovirus*, family *Rhabdoviridae*. Clinically, VS is characterized by the formation of vesicles, erosions, and ulcers on the tongue, oral tissues, feet, and teats, along with pain, anorexia, and secondary mastitis, leading to substantial loss of productivity in all affected species (primarily horses and cattle and occasionally swine, sheep, goats, llamas, and alpacas) and death in swine. With the exception of its appearance in horses, VS resembles other vesicular diseases in animals, that is, foot-and-mouth disease (FMD), swine vesicular disease (SVD), and vesicular exanthema of swine (VES), which all display vesicular lesions on the mouth and/or feet, and some (e.g., FMD) of which have significant impact on international trade. Therefore, differentiation of VS from other vesicular diseases is vital to contain the spread of these diseases and reduce their drain on agriculture industry.

42.1.1 Classification

VSV are negative-sense single-stranded (ss) RNA viruses classified in the genus *Vesiculovirus*, family *Rhabdoviridae*, order *Mononegavirales.* Encompassing >200 different viruses that are present in a broad range of hosts (including insects, fish, mammals, and plants), the family *Rhabdoviridae* (*rhabdo* is Greek for "rod") is organized into 11 genera (*Cytorhabdovirus*, *Ephemerovirus*, *Lyssavirus*, *Novirhabdovirus*, *Nucleorhabdovirus*, *Perhabdovirus*, *Sigmavirus*, *Sprivivirus*, *Tibrovirus*, *Tupavirus*, and *Vesiculovirus*) together with nine proposed genera (*Almendravirus*, *Bahiavirus*, *Bracorhabdovirus*, *Curiovirus*, *Dichorhabdovirus*, *Hapavirus*, *Ledantevirus*, *Sawgravirus,* and *Sripuvirus*) [1].

Interestingly, while members of the genus *Lyssavirus* (e.g., rabies virus) replicate exclusively in mammals, viruses belonging to the genera *Vesiculovirus* and *Ephemerovirus* (e.g., bovine ephemeral fever virus) occur in both vertebrate and invertebrate hosts. The agents of the genus *Novirhabdovirus* are present in fish and other aquatic animals, including

invertebrates, and those of the genera *Cytorhabdovirus* and *Nucleorhabdovirus* are plant pathogens.

Currently, the genus *Vesiculovirus* consists of nine recognized species: Carajas virus, Chandipura virus (CHPV), Cocal virus (COCV; formerly the Indiana 2 subtype of VSV), Isfahan virus (ISFV), Maraba virus, Piry virus (PIRYV), vesicular stomatitis Alagoas virus (VSV-AV; formerly the Indiana 3 subtype of VSV), vesicular stomatitis Indiana virus (VSV-IN, the type species; formerly the Indiana 1 subtype of VSV, often still referred to as VSV), and vesicular stomatitis New Jersey virus (VSV-NJ). An additional 19 viruses are also tentatively assigned to this genus.

It is notable that Chandipura, Piry, and Isfahan viruses cause acute febrile illness and meningoencephalitis in humans, with CHPV and ISFV being identified in Asia and PIRYV in South America. VSV-IN, VSV-NJ, VSV-AV, and COCV are responsible for VS in animals (particularly horses, cattle, and pigs) and are collectively known as VSV [2,3]. VSV are endemic in North, Central, and South America, with VSV-IN and VSV-NJ being of importance to animal health [4]. Except for COCV, VSV may occasionally infect humans [5].

42.1.2 Morphology and Genome Organization

Similar to other members of the genus *Vesicuovirus*, VSV are enveloped, bullet-shaped (or elongated, rodlike) particles of approximately 75 nm in diameter and 185 nm in length. The envelope is made up of glycoprotein (G) and matrix (M) protein, with a trimer of the G protein forming spikes of 9–11 nm on surface and M protein lying underneath. Within the envelope is the helical nucleocapsid that is coiled symmetrically into a cylindrical structure with a striated appearance [6]. Composed of the nucleoprotein (N) and large (L) protein, the nucleocapsid wraps around a linear, nonsegmented, negative-sense, single-stranded RNA of 11,161 nucleotides (as exemplified by the prototype VSV-IN), protecting the RNA from ribonuclease digestion and maintaining the RNA in a configuration suitable for transcription [7].

Structurally, the VSV genome is organized in the order 3′ N-P-M-G-L 5′, encoding (via five monocistronic mRNAs) five multifunctional proteins: nucleocapsid (N) protein, phosphoprotein (P, a component of the viral RNA polymerase), M protein, G protein, and L protein (a component of the viral RNA polymerase). There is evidence that the gene transcripts are synthesized both in sequential order and quantity according to the same order of the genes in the genome (i.e., N > P > M > G > L) [8].

The nucleoprotein (N) is a 52 kDa molecule that forms a complex with the P protein, thus preventing the concentration-dependent aggregation (oligomerization) of N and keeping the N protein in a monomeric, encapsidation-competent form. The N protein encapsidates nascent genome RNA (through binding to the ribose-phosphate backbone of the RNA) into an RNase resistant form (which functions as the active template for transcription and replication) to protect from cellular RNAse activity in the absence of polynucleotide synthesis.

Binding to the nascent leader RNA in its unphosphorylated form, the P protein promotes read-through of the transcription termination signals and initiates nucleocapsid assembly on the nascent RNA chain. Together with L protein, P protein forms viral RNA-dependent RNA polymerase required for replication of the mRNA, while L protein maintains catalytic functions for RNA polymerization, capping, and Poly-A polymerase.

M protein is a 229 amino acid protein of 25 kDa in size that forms a layer between the G protein containing outer membrane and the nucleocapsid core (consisting of nucleoprotein [N], polymerase [L], P protein, and RNA genome), condensing the nucleocapsid core into the "skeletons" seen in mature virions. The N terminus of M possesses several positively charged amino acid residues that interact directly with negatively charged membranes.

G protein is a 67 kDa (495 amino acid) molecule with N-linked glycan. Spiking out of the membrane, G protein mediates viral attachment to an LDL receptor (LDLR) or an LDLR family member present on the host cell and contains major antigenic determinant [9]. Indeed, the VSV G protein has been shown to be a determinant of higher virulence of VSV-NJ than of VSV-IN in swine [10].

42.1.3 Replication and Epidemiology

In general, the replication of vesiculoviruses involves three distinct phases: uncoating, transcription/replication, and viral assembly. First, G protein binds to LDL receptor on the surface of host cells and mediates the viral entry via endocytosis and fusion of the viral envelope with the endosomal membrane. The virus then enters the cell cytoplasm through partially clathrin-coated vesicles, which recruit components of the actin machinery to induce its own uptake. Once inside the cytoplasm, the L + P polymerase complex (i.e., the viral RNA-dependent RNA polymerase) attaches to the encapsidated genome at the leader region and initiates sequential transcription of the open reading frames (ORFs) in the virus genome to generate five monocistronic mRNAs, with the intergenic sequence directing termination and reinitiation of transcription by the polymerase between genes. The mRNA is capped and polyadenylated by the L protein during synthesis, and progeny vRNA is made from a positive-sense intermediate. Virions are then assembled around the nucleoprotein core and subsequently bud from cytoplasmic membranes and the outer membrane of the cell, acquiring the M + G proteins during the process, which are responsible for the characteristic bullet-shaped morphology of the virus [11].

VSV mainly infect insects, horses, cattle, swine, sheep, goats, llamas, alpacas, donkeys, and mules. Other susceptible animals include deer, pronghorn antelope, South American camelids, raccoons, lynx, bobcats, bears, coyotes, foxes, dogs, deer, rabbits, skunk, armadillo, opossum, rodents, bats, turkeys, and ducks, which may function as potential reservoir host for VSV. In addition, guinea pigs, hamsters, mice, ferrets, and chickens have been infected experimentally. Humans are also susceptible [12].

The most important vectors for VSV transmission are sand flies (*Lutzomyia* sp. especially *Lutzomyia shannoni*). Other potential biological vectors include blackfly (*Simulium*), horsefly (*Tabanus*), deerfly (*Chrysops*), stablefly (*Stomoxys*), biting midges (*Culicoides*), and mosquitoes (*Aedes* and *Culex*). Flies in the genus *Musca* and eye gnats (*Chloropidae*) may act as mechanical vectors for VSV. In addition, cattle that ingest experimentally infected grasshoppers (*Melanoplus sanguinipes*) develop clinical signs [13].

Natural VSV infections involve cytolytic infections of mammalian hosts and subsequent transmission by insects. Within insects, infections are noncytolytic persistent. Once introduced into a herd, VS may spread from animal to animal by direct contact with broken skin or mucous membranes, vesicular material, saliva and nasal secretions, and exposure to contaminated fomites including food, water, and milking machines. Animals may acquire infection by aerosols, but most species do not develop skin lesions via this route. In addition, VSV do not seem to cross the placenta or cause fetal seroconversion [14].

VSV in saliva can remain viable for 3–4 days on fomites but do not survive for long periods in the environment except in cool, dark places. The virus is inactivated by sunlight, formaldehyde, ether, 1% sodium hypochlorite, 70% ethanol, 2% glutaraldehyde, 2% sodium carbonate, 4% sodium hydroxide, 2% iodophore, 1% cresylic acid, 2.5% phenol, 0.4% HCl, 2% sodium orthophenylphenate, and 4% sodium hypochlorite [15]. Insect vectors may acquire the virus by feeding on lesion material or contaminated secretions, as domesticated or wild animals generally have insufficient viremia for insect vectors to become infected. Humans may acquire the infection by contact with vesicular fluid and saliva from infected animals, or through insect bites [16].

VS was first described in 1916 on horses showing the clinical signs typical of VSV infection in Denver, Colorado stockyards. In the same year, the disease was also reported in Illinois, Iowa, Kansas, Missouri Montana, Nebraska, South Dakota, Utah, and Wyoming. In 1925, the causal agent for VS was detected from healthy cattle arrived in Indiana from Kansas City and named vesicular stomatitis Indiana strain. In 1926, investigation of a VS outbreak in cattle in New Jersey led to the identification of vesicular stomatitis New Jersey strain, which appears distinct from vesicular stomatitis Indiana strain. In the subsequent years, sporadic VS cases have been described throughout the United States, with the exception of New England [4]. The most recent VS outbreak in the United States occurred in 2012, when two horses on an equine property in Otero County, New Mexico, had clinical signs consistent with VS and positive VS virus serology. The causal agent was identified as VSV-NJ, and a total of 51 horses on 36 premises in 2 states (including 34 in New Mexico and 2 in Colorado) were confirmed positive. Phylogenetic analysis of the virus indicated its close relationship to viruses detected in the state of Veracruz, Mexico, in 2000 [17].

At the moment, VS is endemic in Mexico, Central America, and South America (particularly Brazil), with seasonal outbreaks emerging at the end of the rainy season or early in the dry season. Sporadic VS may appear in other parts of the Western Hemisphere, both north and south of the endemic area. While VSV-NJ and VSV-IN are present in North, Central, and South America, VSV-AV (Indiana–3) and cocal virus (Indiana–2) are mainly found in parts of South America such as Argentina and Southern Brazil. Besides the Western Hemisphere, VS has been recorded in France and South Africa.

42.1.4 Clinical Features and Pathogenesis

With an incubation period of 2–8 days, the initial symptoms of VS are fever (24–48 h after infection) and excessive salivation (due to rupture of the oral vesicles). This is followed by the appearance of vesicles (blisters, of varied sizes), papules, erosions, and ulcers (which result from rupture of vesicles) around the mouth and on the feet, udder, and prepuce. Due to the pain associated with these lesions, animals may show inappetance, anorexia, lethargy, and pyrexia and refuse to drink and walk. Other clinical signs may include sloughing off in the epithelium of the tongue or muzzle, swollen nostrils and muzzle, catarrhal nasal discharge, bleeding from ulcers, and fetid odor in the mouth. Although most (80%–95%) of the animals (especially those of under a year of age) in a herd may have subclinical infections, the morbidity rate in the symptomatic animals (particularly pigs) ranges from 5% to 90%. If no secondary bacterial infections or other complications develop, affected animals often recover in approximately 2–3 weeks [8].

In humans, infections with Indiana and New Jersey VSV serotypes may show biphasic high fever and other flulike symptoms such as severe malaise, headaches, myalgia, arthralgia, retrosternal pain, eye aches, and nausea. Occasionally, vesicles may form on the oral mucosa, lips, nose, and hands, with a rare occurrence of cervical lymphadenopathy. In human cases of Alagoas virus infections reported in Brazil, flulike symptoms resolve within 3–4 days of appearance. Due to its zoonotic nature, human VS is only transmitted from animals, not from other humans.

VSV have been shown to induce intercellular edema in the Malphigian layer of the epithelium, leading to the separation of the epithelial cells by vacuolar cavities. Subsequent infiltration of inflammatory cells, such as granulocytes and monocytes, contributes to cellular lysis and necrosis. As the necrotic, edematous mucosa breaks free from underlying tissue, cellular exudates fill the cavity and form the vesicles. The whole process of vesicle formation (involving intercellular edema, cellular necrosis, and inflammatory cell infiltration) takes about 48 h upon infection and vesicles may begin to disappear with seepage of edematous fluid afterward [8].

VSV M protein has the capacity to interrupt cellular transcription pathways and to block mRNA export from the nucleus, both of which contribute to its aversion of the host type I interferon response and its disease process in mammalian hosts [18].

42.1.5 Diagnosis

With the exception of horses, VS in most animal species is indistinguishable on the basis of clinical manifestations from other vesicular diseases including FMD, vesicular exanthema, and SVD. Other differential diagnoses consist of footrot, rinderpest, infectious bovine rhinopneumonitis, bovine viral diarrhea, malignant catarrhal fever, epizootic hemorrhagic disease, bluetongue, contagious ecthyma, lip and leg ulceration, and chemical or thermal burns. Therefore, laboratory tests are required for accurate diagnosis of vesicular stomatitis. The current recommendations from World Organization for Animal Health (Office International des Epizooties) for the laboratory diagnosis of VS include virus isolation, serological detection of viral antigens and antibodies, and RNA detection [15].

42.1.5.1 Virus Isolation

African green monkey kidney (Vero), baby hamster kidney (BHK-21), and IB-RS-2 cells are useful for VSV isolation and detection, as VSV, FMDV, and SVDV cause different cytopathic effects on these cells. Therefore, inoculation of all three cell lines with the test sample enhances the diagnosis. In addition, embryonated eggs, or infant mice may be employed for VSV cultivation.

42.1.5.2 Serological Detection of Viral Antigens and Antibodies

Although electron microscopy can help differentiate vesicle-causing viruses, detection of viral antigens and antibodies provides a cost-effective approach for confirmation of the virus identity. The widely used serological assays include serum neutralization test (SNT), complement fixation test (CFT), and enzyme-linked immunosorbent assays (ELISA). SNT, CFT, and competitive ELISA (cELISA) have been recognized as prescribed tests by the OIE for international trade purposes. In addition, immunochromatographic (ICT) assay based on colloidal gold label has proven useful for identification of VSV in comparison with reverse transcription (RT)-PCR (which employs forward primer: 5′-CGGATCCGTCAAAATGCCCAAGAGTCACA-3′ and reverse primer: 5′-CCTCGAGTGGGTTTTTAGGAGCA AGATAGC-3′) [19].

42.1.5.3 RNA Detection

VSV RNA may be amplified and detected by (RT-PCR on a variety of formats (heminested, multiplex, and real-time assays) [20–28]. Recently, a multiplex RT-PCR with an accompanying microarray assay was reported for simultaneous detection and typing of FMDV and VSV and for the detection of SVDV and VESV [28].

Other useful molecular technologies for detection and identification of VSV RNA and related pathogens include isothermal amplification, nucleic acid hybridization-based procedures (e.g., macroarray, microarray, and proximity ligation assay), metagenomic analysis, next generation sequencing, microfluidic analysis systems, and nanotechnology [29–32]. The recent description of padlock probes and microarrays highlights the power of these alternative technologies for simultaneous detection and differentiation of FMDV, SVDV, and VSV and for uncovering serotype details in cases of VSV infection. In contrast to other array methods, the padlock probe/microarray assay requires conserved target sequences only for the padlock probes and thus is sensitive to genomic variations only during the probe hybridization. Furthermore, the intramolecular hybridization and ligation of padlock probes makes it easy to include additional probes in the pool without affecting the protocol, in order to cater for new emerging strains that are not recognized by the current padlock probe set. Therefore, this multiplex detection platform based on padlock probes and microarrays provides an effective screening tool for viruses causing similar vesicular symptoms and facilitates rapid counteractions, especially in case of FMD outbreaks [33].

42.1.6 Treatment and Prevention

As no specific treatment or cure is currently available for vesicular stomatitis, symptomatic treatments, such as cleansing the lesions with a mild antiseptic solution to eliminate secondary bacterial infections and provision of softened feed, will help reduce the impact of the infection.

Good sanitation, disinfection, and quarantine practice will facilitate the containment of the disease. Feed and water troughs should be cleaned regularly. Milking equipment should be disinfected between uses using 1% sodium hypochlorite, 70% ethanol, 2% glutaraldehyde, 2% sodium carbonate, 4% sodium hydroxide, iodophore disinfectants, formaldehyde, or chlorine dioxide. VSV may be also inactivated by UV light, lipid solvents, or heat. Uninfected livestock should be kept away by stabling from any infected/symptomatic animals during outbreaks to prevent the spread of VSV between animals by direct contact. Unless the animals are going directly to slaughter, no movement of animals from an infected property should be allowed for at least 21 days after all lesions are healed. Insect breeding areas should be sprayed with insecticides, and treated eartags are used on animals [15].

Human infection with VSV often results from handling affected animals, contaminated fomites, tissues, blood, or virus cultures. To prevent VSV infection in humans, protective clothing and gloves should be used when handling infected animals, and biological safety precautions should be taken in the laboratory.

It is of interest to note that while only a limited number of vaccine preparations are available for use in animals, but not in humans, against VSV infection, many vaccine candidates based on recombinant VSV have been developed for treatment/control of cancers and certain viral diseases (e.g., diseases caused by filoviruses, HCV, HIV, etc.) [34,35]. Given that most cancer cells have impaired antiviral responses related to type I interferon pathways, they are more susceptible to VSV than normal cells. In addition, with an easily manipulated genome, relative independence of a receptor or cell cycle, cytoplasmic replication without risk of host cell transformation, and lack of preexisting immunity in humans, VSV offer a promising candidate for clinical use [35].

42.2 METHODS

42.2.1 Sample Preparation

42.2.1.1 Sample Collection

As VS is a zoonotic disease, samples (serum, blister fluid, the epithelium covering unruptured vesicles, epithelial flaps from freshly ruptured vesicles, swabs of the ruptured vesicles, esophageal/pharyngeal fluid collected with a probang cup from cattle, or throat swabs from pigs) should be collected and handled with all appropriate precautions, and sent frozen with dry ice within 2 days of collection to authorized laboratories to prevent the spread of the disease [36].

42.2.1.2 Virus Isolation

Clinical specimens are inoculated onto African green monkey kidney (Vero), baby hamster kidney (BHK-21), and IB-RS-2 cells maintained in minimum essential medium supplemented with 10% fetal bovine serum (FBS) or the sand fly cell line maintained in Grace's insect cell culture medium supplemented with 15% FBS. The inoculated cultures are checked under an inverted microscope regularly for cytopathic effects and stained after 48 h postinfection with amido black. Tissue culture fluids from cultures showing cytopathic effects are stained with 1% sodium phosphotungstic acid pH 6·0 and examined with a transmission electron microscope.

42.2.1.3 RNA Isolation

Total RNA is extracted from 100 to 200 µL amounts of samples (cell cultures, serum, EDTA-blood, nasal and pharyngeal swabs, and feces or tissue homogenates 10% in PBS) with a commercial reagent (e.g., Tripure Isolation Reagent or High Pure PCR Template Preparation Kit, Roche Diagnostics; QIAamp viral RNA minikit, Qiagen). RNA is resuspended in 10–50 µL of Milli-Q water. Nasal and pharyngeal swabs are solubilized in 2 mL of PBS for 2 h prior to RNA extraction. Interestingly, a recent study by Arshed et al. [27] showed that a guanidine-thiocyanate-based RNA extraction (Qiagen RNeasy Mini Kit, Qiagen, Valencia, CA) followed by column-based purification is superior to triphasic extraction (Tri-reagent method) for preparation of VSV-IN and VSV-NJ RNA from cell lysate and spiked tissue samples as assessed by one-step RT-PCR.

42.2.2 Detection Procedures

42.2.2.1 Multiplex RT-PCR for the Detection of Vesicular Disease Viruses

Lung et al. [28] described a multiplex RT-PCR for detection of vesicular disease viruses with species-specific primers obtained from gene regions of FMDV, VSV, SVDV, and VESV (Table 42.1). The multiplex RT-PCR is highly specific as it does not react with genomic nucleic acids of eight nontarget livestock viruses tested: exotic malignant catarrhal fever virus, rinderpest virus, bluetongue virus, bovine herpesvirus 1, bovine viral diarrhea virus type I and type II, orf virus, and porcine reproductive and respiratory syndrome virus. In addition, nucleic acids from oral swabs collected from healthy cattle, sheep, and pigs are not recognized by the multiplex RT-PCR.

42.2.2.2 Real-Time RT-PCR for the Detection of VSV-IN and VSV-NJ

Rasmussen et al. [23] developed a quantitative RT-PCR assay for the detection and differentiation of the two main VSV serotypes based on primer–probe energy transfer (PriProET) detection system, which combines probe-based real-time monitoring of PCR amplification with confirmation of probe hybridization from the melting temperature (T_m) curve. A pair of primers (one of which was labeled with the donor fluorophore 6-carboxyfluorescein [FAM]) is designed from the most conserved regions of the L gene (encoding the RNA-dependent RNA polymerase) of the VSV genome, and two serotype-specific fluorescent probes are labeled with a reporter fluorophore, Texas Red (a serotype Ind-1-specific probe), or cyanine 5 (Cy5; a serotype NJ-specific probe), facilitating differentiation on the basis of the corresponding emission spectra (Texas Red, 610 nm;

Cy5, 660 nm) (Table 42.2). This RT-PCR method provides a sensitive, fast, and robust tool for the simultaneous detection, differentiation, and quantification of the two major VSV serotypes, Ind-1 and NJ.

42.2.2.3 RT-PCR and Enzyme Digestion for the Detection of VSV-IN and VSV-NJ

VSV specific primers (VSV-1/VSV-2) targeting the highly conserved L gene region enable amplification of a 110 bp fragment from VSV-IN and VSV-NJ (Table 42.3). Subsequent digestion of the PCR product with BsmA I restriction endonuclease generates two fragments of 86 and 24 bp for VSV-IN and two fragments of 102 and 8 bp for VSV-NJ [24].

42.2.2.3.1 Procedure

1. Prepare RT-PCR mixture (25 µL) containing 2 µL of RNA sample, 1× Buffer (Tris-Cl, KCl, $[NH_4]_2SO_4$), 2.5 mM $MgCl_2$, 1× Q solution, 0.2 mM dNTPs, 0.7 µM of each primer VSV-1/VSV-2, 5 U RNase Inhibitor (Applied Biosystems), and 1 µL Enzyme Mix (Omniscript and Sensiscript Reverse Transcriptases, HotStartTaq DNA polymerase).
2. Conduct RT amplification in a one step with the following conditions: 30 min at 50°C, 15 min at 95°C, 40 cycles at 94°C in 30 s, 60°C in 30 s, 72°C in 30 s, and finally 7 min at 72°C.
3. Digest 10 µL of VSV amplification products with 5 U of BsmA I in a volume of 20 µL for at least 1 h 30 min at 55°C.
4. Analyze the restriction pattern on a 3% agarose gel containing 0.5 µg/mL of ethidium bromide.

42.3 CONCLUSION

VSV are causative agents of an acute vesicular disease in animals (particularly cattle, horses, and pigs), with clinical manifestations ranging from vesicles, erosions, and ulcers on the tongue, oral tissues, feet, and teats. Although it is a nonlethal disease with geographical distribution largely limited to the West hemisphere (i.e., North, Central, and South America), VS is important in its resemblance to other viral vesicular diseases of livestock, FMDV in cattle, and SVDV and VESV in pigs. However, VSV are the only one of these vesicular disease viruses that infect horses. Indeed, inoculation of a horse's tongue was used historically to differentiate VSV from the other vesicular disease viruses. In addition, VSV is a zoonotic agent that may occasionally infect humans, while FMDV, SVDV, and VESV are in general, considered as noninfective to human hosts.

Laboratory differentiation of VS from FMD, SVD, and VES has traditionally relied on virus isolation and serological detection of viral antigens and antibodies. As these procedures are time consuming and pose significant health risk to laboratory personnel, nucleic acid amplification techniques such as RT-PCR have increasingly been adapted in clinical laboratories for improved identification and typing of VSV.

Considering the notable absence of effective vaccines, the increasing intercontinental travel, the insatiable demand for susceptible animals (cattle, pigs, and horses) as food source, and the remarkable plasticity of the VSV genome, there is a potential for VS outbreaks to occur more frequently in the future. Therefore, in addition to have an accurate and sensitive diagnostic tool at our disposal, further investigations on the pathogenic mechanisms of VSV will aid the development of novel control measures against vesicular stomatitis.

43.1 INTRODUCTION

Avian influenza virus (AIV) is type A influenza, which is adapted to an avian host. Although avian influenza has been isolated from numerous avian species, the primary natural hosts for the virus are dabbling ducks, shorebirds, and gulls.[1] The virus can be found worldwide in these species and in other wild bird species. In poultry (chickens, turkeys, and more rarely domestic ducks), AIV can cause substantial production losses. Therefore, it is among the most important diseases of animal production. AIV also gains notoriety because, although very uncommon, it can be transmitted to people so there is always awareness that the virus could constitute a public health threat.

Given the importance of AIV for agriculture, some strains (i.e., H5 and H7) are reportable to the World Organization for Animal Health (OIE). This adds a regulatory framework to the detection of the virus and necessitates the standardization of tests at the national and international level. In the past decade, molecular tests for AIV detection have been extensively validated by numerous animal health and veterinary diagnostic organizations (e.g., OIE, OFFLU, United States Department of Agriculture (USDA)). As AIV is a rapidly evolving virus, the validated tests are continually monitored for performance, and updates are made for new virus variants as appropriate. The current tests will be presented here. Finally, since AIV is a reportable disease, laboratories unfamiliar with working with AIV should check with local veterinary authorities on specific regulatory requirements.

43.1.1 Classification

Type A influenza, including AIV, is a member of the *Orthomyxoviridae* family and harbors a negative-sense RNA genome comprised of eight segments. Reassortment among the genomic segments and the high replication error rate typical of RNA viruses result in a high level of population diversity, which allows for rapid evolution of the virus, and may complicate detection. Therefore, among AIVs, there is tremendous biological and genetic diversity.

Of the eight genome segments, the segment encoding the two matrix proteins (M1 and M2), which are structural, and the segment encoding the nucleoprotein (NP) are the most conserved and, therefore, are the gene segments most frequently targeted for diagnostic tests. The shortest segment encodes two "nonstructural" genes (NS1 and NS2). The longest three segments each encode the three polymerase complex genes (PA, PB1, and PB2). Finally, the coat proteins, which determine the serological subtypes, are the hemagglutinin (HA), which binds the host cell receptor, and the neuraminidase (NA), which cleaves newly budded virus from the host cell. Identification of the HA and NA subtypes is diagnostically important but is difficult due to their high variability.

There are 16 HA subtypes and 9 NA subtypes of AIV. Of the 144 possible combinations, most have been isolated from the natural host species of the virus, where the greatest diversity of AIV is found. The subtypes vary in prevalence; H3, H4, and H6 are quite common while H14 and H15 are very rare. Importantly, the HA and NA subtype only denotes

the serological reactivity of a strain; there can be tremendous biological, host range, virulence, and genetic variation within a given subtype. For example, within the H7 subtype, sequences can vary close to 30% among lineages.[2–4] In addition, because of the segmented genome of AIV, the other six segments from two isolates of the same HA and NA subtype may be from different lineages. The practical benefit of this variation is that it provides valuable clues to molecular epidemiological studies.

43.1.2 Epidemiology

The natural host species of AIV are members of the Anatidae (dabbling ducks), Scolopacidae (shorebirds), and Laridae (gulls) families.[1] Some species from within these families have higher infection prevalence, for example, mallards (*Anas platyrhynchos*) tend to have higher prevalence among the Anatidae. AIV is essentially endemic in these populations and typically does not cause any clinical disease. Experimental infections and rare isolations from wild birds of other families demonstrate that other wild avian species may be infected, but data are limited or missing for a vast number of avian species. Domestic species (chickens and turkeys) are not natural host species; AIV strains have different levels of adaptation for different avian species, for example, the infectious dose for chickens can vary as much as 5 $\log_{10}$ among isolates.[5]

AIV ecology and epidemiology are best described in domestic poultry species, especially chickens and turkeys. In domestic birds, AIV is initially introduced from wild birds, although the specific exposure route is not always apparent unless the birds have outside access or their water source is untreated surface water.[6] AIV is highly contagious and host-adapted strains spread rapidly among susceptible birds. Movement of people (contaminated equipment, vaccination crews, vehicle movement) is likely the most important means of AIV spread. However, spread by wind up to about 1 km has been documented and birds on farms near roads on which infected birds were transported during outbreaks have become infected.[7] Therefore, biosecurity and increased surveillance are crucial elements of AIV control in domestic poultry.

43.1.3 Clinical Features

AIV is classified as low pathogenic (LP) or highly pathogenic (HP) in chickens and turkeys based on specific tests prescribed by the OIE. There is an *in vivo* test with a mortality end point and a molecular test that is based on the protein sequence at a known marker for virulence in chickens (the HA proteolytic cleavage site).[8] Only isolates of the H5 and H7 subtypes have ever been classified as HP so these two subtypes, even when LP, are frequently more highly controlled than other subtypes. It is important to understand that these criteria only apply to gallinaceous birds and are regulatory, not necessarily biological. The term "high pathogenicity" tends to be used as a relative term for other species which creates confusion.

Disease from AIV can vary widely depending on the infected species and virus strain. In natural host species (dabbling ducks), infection typically does not cause disease at all, even when ducks are exposed to forms that are HP for chickens.[9] The rare exceptions are some strains of the H5N1 HPAIV from Asia, which can cause severe disease and death. Clinical signs in young Pekin ducks are similar to HPAIV in chickens.[10]

In chickens and turkeys, HPAIV is characterized by rapid (can be as early as 24–48 h postexposure) and high mortality (as high as 100%).[9] Prior to death, birds will become severely lethargic and neurological signs may be present. Subcutaneous hemorrhages may be observed on the shanks and/or in the wattles and combs. Periorbital swelling and green diarrhea are also common. In contrast, infection with the LP form of the virus may be subclinical. Disease from the LP form is essentially respiratory; the birds present with congestion, periorbital swelling, and lethargy. Birds that lay eggs will often stop laying.

43.1.4 Diagnosis

43.1.4.1 Virus Isolation

Although the focus of this chapter is on molecular methods, virus isolation will be mentioned briefly. Virus isolation will always need to be conducted on some types of samples (e.g., index cases), both as a confirmatory test and to provide an isolate for characterization. Virus isolation for AIV is most commonly conducted with embryonated chickens eggs (ECE), which are free of maternal antibody to AIV. Virus isolation is highly sensitive but is nonspecific (numerous agents will replicate in ECE); it is expensive, requires a source of ECE, and demands more biosecurity and biosafety controls than molecular methods.[11] Positive samples may yield a result in a couple of days, but it can take up to 2 weeks to confirm a negative.

43.1.4.2 Clinical Sample Collection

The optimal specimens from avian species are oropharyngeal swabs (including swabbing the choanal cleft) or tracheal swabs and cloacal swabs. Oral/tracheal swabs are preferred from chickens and turkeys, and cloacal swabs are preferred from waterfowl. However, collecting both is optimal if resources allow. Lung, kidney, and spleen are among the best tissues for virus detection, but tissues are not necessarily better than swabs. Several recent reports have successfully utilized feather pulp for the detection of the highly pathogenic form of the virus.[12–14] Environmental swabs may be collected from any surface; however, in most cases, it is advised to perform virus isolation with environmental samples if they are being used to confirm cleaning and disinfection because molecular methods can detect inactivated virus.

Proper sample collection and transport are crucial to achieving the best accuracy of any diagnostic test. For AIV, the specifics of sample collection and transport have been empirically established. Also, most AIV clinical specimens will be tested by more than one type of assay (e.g., real-time reverse transcription polymerase chain reaction [RT-PCR] [rRT-PCR]

and virus isolation); therefore, the sample needs to be in a form that will work for most tests, and there needs to be in a sufficient volume for subsequent tests without diluting the sample.

Oral and cloacal swabs should be collected in a well-buffered, salt-balanced media, which contains protein such as brain–heart infusion broth.[15,16] Media that lack protein do not preserve live virus well. The media volume depends on whether swabs will be pooled; 3 mL is recommended for 1–5 swabs per vial and 5.5 mL is recommended for 6–11 swabs per vial. Specimens should never be transported dry as this will reduce detection by both virus isolation and molecular methods. Flocked nylon swabs have been shown to be optimal, but urethane foam and Dacron wound tip swabs are satisfactory.[16] Swabs with wooden shafts and calcium alginate swabs should be avoided as their use can inhibit RT-PCR and virus isolation. Finally, specimens should be maintained at refrigeration temperatures at all times, and freeze-thaw cycles and warm temperatures should be avoided.

43.1.4.3 Molecular Detection Assays

rRT-PCR is the most widely used format, and well-validated tests are available.[17,18] Conventional RT-PCR and isothermal nucleic acid detection assays have been reported,[17,19–23] but few have been adequately validated. When determining which test to use, it is best to start with validated tests and to consider what the goals are for testing. Most AIV tests will target a conserved gene therefore will have specificity for influenza A. Type-specific tests are much more reliable than subtype tests, although one should consider that false negatives still are a possibility due to sequence variation in the virus. Subtyping tests are best when used to confirm the presence of a specific virus lineage and are not suitable for screening samples for novel AIVs since they are prone to false negatives and even false positives because of the variability of the HA and NA genes. Gene sequencing is the most reliable method for subtype identification. It is also important to note that it is not possible to reliably identify the pathotype of an AIV isolate by RT-PCR.

Commercial kits for RT-PCR are widely available and one-step procedures are recommended. The procedures described here are presented with specific commercial kits; however, one may optimize most any kit for use with these tests. Note that for real-time RT-PCR using hydrolysis probes, the enzyme must have 5′ exonuclease activity.

43.2 METHODS

43.2.1 Sample Processing

Samples should be preserved on ice throughout processing to preserve the live virus if virus isolation will be attempted with the specimen after testing by RT-PCR. The RNA extraction methods utilized are another crucial element of the successful testing.[24] The sample type will dictate which RNA extraction method is used. Commercial kits and reagents are used frequently and provide good results. Oropharyngeal and tracheal swab samples may be extracted successfully with most any method as these samples are relatively clean. Cloacal and environmental swabs should be extracted with kits and methods that are designed for use with samples containing fecal material.[24] A 10% w/v homogenate of tissues should be prepared in a viral transport media, then the RNA may be extracted using a suitable method for tissues.

43.2.2 Conventional RT-PCR

Although rRT-PCR is more common than conventional RT-PCR for AIV detection, conventional assays are used when real-time PCR equipment is not available. The assay presented here targets the NS gene segment, the shortest influenza gene segment. The primers (Table 43.1) are directed to the conserved ends of the gene segment[25] and will detect most influenza A viruses. This procedure was optimized with the Qiagen OneStep RT-PCR kit (Qiagen Inc., Valencia, CA), and the volumes correspond to this kit. Positive controls and template-free negative controls (nuclease-free water in place of template) should be included in each set of reactions run.

1. Label the RT-PCR reaction tubes and place them on ice or in a cooling rack.
2. Prepare the master mix in a 1.5 mL microfuge tube as shown in Table 43.2. Prepare 10% extra to compensate for pipettor error.
3. Mix by vortexing and pulse spin the master mix.
4. Add 22 μL of reaction mix with primers to each tube.
5. Add 3 μL of template RNA to the appropriate tube.
6. Close the tubes and centrifuge for 3–5 s before loading the thermalcycler.
7. Run the thermalcycler with the conditions in Table 43.3.
8. Analyze the results by running the reaction on a 1% agarose gel. The expected size is approximately 890 bp.

TABLE 43.3
Cycling Conditions for Conventional Reverse Transcription Polymerase Chain Reaction for the AIV NS Gene

Phase	Number of Cycles	Time (min)	Temperature (°C)
RT	1 cycle	30	50
		15	95
PCR	35 cycles	1	94
		1	53
		1	72
Final extension	1 cycle	10	72
Soak	1 cycle	Infinity	4

Note: The RT phase is specific for the Qiagen OneStep kit.

43.2.3 Real-Time RT-PCR

The procedure described in the following is based on an rRT-PCR test that targets the M gene of influenza A[18], which is the basis of the U.S. Department of Agriculture AIV test, is referenced in the OIE manual and has been updated periodically to ensure optimal performance.[26] This test has been widely used with avian and mammalian specimens and extensive validation data have been generated that have demonstrated reliable performance with the detection of influenza A virus. As with any molecular test for an RNA virus, false negatives are still a possibility due to unpredictable sequence variation in novel isolates; therefore, results should be confirmed with virus isolation if necessary.

The procedure here is described with the AB7500 FAST real-time PCR instrument (Life technologies, Grand Island, NY) and Ambion AgPath-ID™ kit (Life technologies, Grand Island, NY). With optimization, other instruments and reagents may be used successfully. Positive controls and template-free negative controls (nuclease-free water in place of template) should be included in each set of reactions run.

1. Place a 96-well reaction plate in the manufacturer supplied rack, and prepare a key for the template positions in the plate.
2. Prepare the master mix in a 1.5 mL microfuge tube as shown in Table 43.4. Prepare 10% extra to compensate for pipettor error. Note that there are two reverse primers in the reaction; this is to provide the broadest reactivity.
3. Mix by vortexing and pulse spin the master mix.
4. Add 17 μL of reaction mix with primers and probes to the appropriate wells of the reaction plate.
5. Add 8 μL of template RNA to the appropriate well.
6. Seal the plate with the plate sealer provided by the manufacturer and centrifuge (pulse spin for 30 s) in a centrifuge equipped with cups for microtiter plates before loading the thermal cycler.
7. Run the thermalcycler with the conditions shown in Table 43.5.
8. Analyze the results: usually the automatic analysis setting will be accurate. First, ensure that the negative and positive controls are valid. Then examine each sample individually. With clinical samples, cycle threshold values over 35 are typically considered "suspect" and should be confirmed or additional samples should be collected from a flock if possible. With experimental samples, a standard curve may be used to establish an end point (be sure to prepare the standard curve with the same isolate, which will be in the samples being tested).

TABLE 43.4
Real-Time Reverse Transcription Polymerase Chain Reaction Master Mix Volumes per Reaction for the AI Matrix Assay Using the Ambion AgPath-ID™

	Volume per Reaction (μL)	Final Concentration
AgPath kit 2× buffer	12.5	1×
Nuclease-free water	0.33	
AgPath kit enzyme mix	1.0	
Forward primer M F25 (20 μmol/μL stock)	0.25	20 pmol
Reverse primer 1 M R124 2009 (20 μmol/μL stock)	0.25	20 pmol

AgPath kit detection enhancer	1.67	
RNase inhibitor	0.5	13 units
MM per reaction	17	
Template	8	
Total	25 μL	

Note that the ROX™ passive reference dye, dNTP's, and additional buffer components are included in the kit supplied 2× buffer.

TABLE 43.5
Amplification Parameters for the Ambion AgPath-ID™ Reverse Transcription Polymerase Chain Reaction Reagents and the ABI 7500 Fast Instrumentation for Avian Influenza Virus (M Gene)

Probe/ Primer Set		Step	Time	Temperature (°C)
Reverse transcription	1 Cycle	RT	10 min	45
		Heat activation of *Taq*	10 min	94
PCR	45 Cycles	Denaturation	1 s	94
		Annealing (acquire fluorescence)	30 s	60

Note that the RT step is specific for the enzyme supplied with this kit.

43.3 CONCLUSIONS AND FUTURE NEEDS

Detection of AIV by type-specific molecular methods is fast and accurate; however, a reliable method of rapidly identifying subtypes, which is robust to sequence changes, would be highly valuable. Microarray-based tests have been developed with this goal, but their performance: time, skills and equipment needed, cost, and poor sensitivity, have been barriers to validation and adoption.[27] RT-PCR, which utilizes mass spectroscopy to identify the product, is among the current up-and-coming technologies, and if validated and the cost were to be reduced to a reasonable level, it could provide an improvement to current methods.[28,29]

Finally, the technologies of viral diagnostics moves rapidly and influenza is a proof-of-concept agent for many new methods. New technologies will often be first validated for public health use but can often be validated for veterinary use for avian influenza if the fit for purpose for veterinary diagnosis is met.

44.1 INTRODUCTION

44.1.1 Classification

Equine influenza virus (EIV) that causes equine influenza (EI) is the most important equine respiratory viral pathogen and has the greatest economic impact internationally, because it has a very high morbidity rate during outbreaks leading to disruption of major equestrian events.[1–3] EIV can also infect other equids such as donkeys, mules, and zebras. EIV is a member of the family Orthomyxoviridae and belongs to the genus *Influenzavirus A* (influenza A type).[4] The first strain of EIV isolated in 1956 was of H7N7 configuration (subtype 1) and designated influenza virus A/equine/Prague/56, and it caused epidemics during the 1960s and 1970s.[5,6] The last confirmed outbreak caused by an H7N7 subtype in horses was recorded in 1979[5,7] and therefore, the H7N7 subtype is thought to be extinct or possibly still circulating at a very low level in nature.[8–11] A second EIV subtype (subtype 2), H3N8, emerged in 1963 and was designated as influenza virus A/equine/Miami/63.[7,12] This subtype has been associated with all confirmed outbreaks of EI since 1980. Extensive antigenic drift has been detected in this virus over the years (see later).[13–19]

44.1.2 Morphology, Biology, and Epidemiology

EIV is pleomorphic and has spherical or filamentous virions with a diameter of 80–120 nm. It is an enveloped virus with a segmented, single-stranded, negative-sense RNA genome. The entire EIV RNA genome is approximately 13.5 kb and contains 8 RNA segments that encode for 11 viral proteins: PB2 (encoded by segment 1), PB1 and PB1-F2 (segment 2), PA (segment 3), HA (segment 4), NP (segment 5), NA (segment 6), M1 and M2 (segment 7), and NS1 and NEP (segment 8). The viral proteins include three surface glycoproteins (hemagglutinin [H], neuraminidase [N], and ion channel protein [M2]) embedded in the host-cell-derived lipid envelope, five structural proteins (M1 matrix protein, nucleoprotein [NP], and polymerase complex proteins [PA, PB1, and PB2]), and three nonstructural proteins (NS1, NS2 [nuclear export protein—NEP], and PB1-F2). The RNA gene segments are closely associated with the NP and are surrounded by the M1 protein which is very closely associated with the lipid envelope containing the three surface glycoproteins. Both the HA and NA are major surface glycoproteins and horses mount a strong humoral antibody response to these two proteins following infection; the major neutralization epitopes of EIV are located in the HA protein. The HA protein has an important role in determining the binding to the host cell receptors that have α-2-6-linked or α-2-3-linked sialic acid moieties (α2-3 sialic acid in horses), as well as a cleavage site that must be cleaved by host cell proteases. HA protein also causes hemagglutination of red blood cells. The NA glycoprotein plays an important role in budding and release of progeny virus from the host cell surface by cleaving the glycosidic bonds of the mannosaccharide, neuraminic acid.

Both HA and NA genes (segments 4 and 6, respectively) play a very important role in the evolution of EIV and other type A influenzaviruses.[19,20] Point mutations in these two genes lead to antigenic drift whereas reassortment of HA and NA with other subtypes leads to antigenic shift (emergence of new subtypes). However, the antigenic drift in EIV H3N8 strains has been reported to be less than that reported for the human influenza A viruses. Since its emergence in 1963, EIV H3N8 subtype (represented by A/equine/Miami/63) evolved as a single lineage for two decades.[20] However, in the mid-1980s, the H3N8 subtype evolved into the Eurasian lineage and the American lineage due to natural selection of variants within equine hosts and reassortment between strains during outbreaks.[21,22] The viruses belonging to the American lineage (represented by A/equine/Newmarket/1/93 and A/equine/Kentucky/94) were predominantly isolated from horses on the North American continent, whereas the viruses belonging to the Eurasian lineage (represented by A/equine/Newmarket/2/93) were mainly isolated from horses in Europe and Asia. Recent sequence and phylogenetic analysis has shown that currently circulating H3N8 strains primarily belong to American lineage and over time, the American lineage viruses have further evolved into a Florida lineage with at least two distinct clades (Florida clade 1 and Florida clade 2).[23] The EIV strains belonging to the Florida sublineage have been spread across Europe, North America, South America, Japan, and Australia in the early part of the twenty-first century. A majority of the EIV H3N8 strains isolated in Europe since 2003 belong to the Florida sublineage. Two distinct clades of Florida sublineage have been identified; Florida clade 1 viruses isolated in North America in 2003 are distinct from Florida clade 2 viruses which spread to Europe in 2003. However, H3N8 strains belonging to both Florida clade 1 and 2 were isolated from horses in the United Kingdom from 2007 to 2010.[19,21,22] EIV H3N8 strains belonging to Florida clade 1 caused outbreaks in South Africa in 2003 and subsequently in Japan and Australia in 2007. EIV H3N8 strains belonging to Florida clade 2 were associated with the major outbreaks in China, Mongolia, and India from 2007 to 2009. Since 2005, the Eurasian lineage has been unimportant, although it may still circulate at low levels.

Interspecies transmission of EIV H3N8 has been reported both in the United States and United Kingdom.[4] A significant outbreak of canine influenza (CI) was reported in greyhound dogs in Florida in early 2004, which was shown to be due to cross-species transmission of H3N8 EIV.[58] Since the initial CI outbreak in Florida, evidence of virus activity has been reported in 30 states in the United States, reportedly affecting tens of thousands of dogs.[13] Sequence analysis of canine influenza virus (CIV) from the original outbreak (A/canine/FL/43/04) revealed that all eight gene segments of this virus shared ≥96% nucleotide sequence homology with that of the H3N8 EIV subtype, suggesting that CIV resulted from direct interspecies transmission of EIV to dogs without genetic reassortment.[13,58] The sequence changes in the hemagglutinin gene (H3 HA) are indicative of adaptive evolution of the virus in its new host.[25] Phylogenetic analysis of four greyhound isolates and two pet dog isolates revealed that these viruses were closely related to EIV strains recovered from horses since 2000, belonging to the Florida sublineage of the American lineage of H3N8 EIV.[24,58] The isolation of four closely related H3N8 EIV subtype strains from dogs that died in different locations over a 2-year period of time, together with serological evidence of widespread infection among greyhounds in different states, strongly confirmed sustained circulation of CIV involving dog-to-dog transmission of the virus.[2,13,24] Retrospective studies have also shown that transmission of EIV H3N8 from horses to foxhounds has occurred in the United Kingdom. Similarly, transmission of EIV to dogs has been also reported in the recent extensive outbreak of EI in Australia. Recent studies have shown that avian influenza viruses are capable of replicating in explanted equine tracheal epithelial cultures, but these viruses failed to establish productive infections in experimentally inoculated ponies.[27] EIV of the H3N8 subtype was isolated from pigs in China[28]; however, experimental infection of pigs with H3N8 EIV failed to demonstrate replication competence in that species.

Currently, equine H3N8 influenza virus continues to be the most important equine respiratory pathogen of horses in many countries around the world. EI is considered enzootic in the United States, United Kingdom, and many other European countries.[29] New Zealand and Iceland are the only countries that have remained continuously free of EI.[30] The epidemiology of EI is influenced by viral factors (e.g., emergence of variant strains), host factors (e.g., immune status of the horse), and environmental factors such as management practices and movement of horses. A major factor in the spread of EI in the last three decades has been the increase in long-distance international movement of horses by air. Horses incubating the disease, either clinically or subclinically infected, can introduce the infection into susceptible horses if they are not quarantined for an adequate amount of time. Such quarantine failures have led to major EI outbreaks in the United Kingdom, South Africa, Hong Kong, Dubai, Japan, and most recently Australia. Some of the horses vaccinated against EIV may be partially protected and such horses may not show any signs of clinical infection but continue to shed virus. Such horses may play an important role in maintenance and perpetuation of the virus in the equine population.

44.1.3 Clinical Features and Pathogenesis

Clinical presentation of EI disease was described by Landolt et al.[31] and is similar in its main aspects to typical influenza in humans.[32] The initial signs are pyrexia of up to 41°C and frequent dry hacking cough. Serous nasal discharge soon appears that changes to mucopurulent discharge within 1–2 days. Respiratory rate and heart rate become elevated and auscultation of the lungs often reveals an inspiratory wheeze. Horses may become lethargic and anorexic; donkeys less so—perhaps elevating their risk as they can be sicker than they appear. These signs vary in severity depending on the immune status of the horse from vaccination or prior

exposure, and EI-diseased horses can be sources of contagion without themselves being ill based on casual inspection. Mild uncomplicated cases often seem to resolve within a few days, although virus shedding may persist a few days beyond the cessation of overt disease signs, and cough may persist for weeks. However EI in horses, as with influenza in humans, predisposes the host to secondary infections owing to the loss of muco-ciliary escalator function, a key physical defense mechanism of the respiratory tract. Virus-mediated destruction by apoptosis of the ciliated respiratory epithelium denudes the trachea and bronchial tree of ciliated cells and ciliary fluid flow,[33,34] permitting bacterial pathogens, including *Streptococcus zooepidemicus*, to transit and colonize in the lungs resulting in bacterial bronchopneumonia that can be life threatening if untreated.[35,36] A secondary spike of pyrexia at 2–5 days after the initial spike is characteristic of secondary infections. Other complications of EI infection that have been observed include lower limb edema, myositis, and myocarditis.[32,37] Influenza-associated encephalopathy has been observed although rarely.[38] Given adequate veterinary care, EI is rarely fatal in otherwise healthy horses, even seronegative ones. However, in third world countries large outbreaks with significant mortality have been reported.[39] Neonatal foals are also at risk of lethal disease if they fail to ingest colostrum containing EI-specific maternal antibodies.[40,41]

44.1.4 Diagnosis

EI is the most important respiratory virus infection of horses and can disrupt major equestrian events and cause significant economic losses to the equine industry worldwide. Influenza H3N8 virus spreads rapidly in susceptible horses and can result in very high morbidity within 24–48 h after exposure to the virus. Therefore, rapid and accurate diagnosis of EI is critical for implementation of prevention and control measures to avoid the spread of EIV and to reduce the economic impact of the disease. Various laboratory testing procedures have been described for the diagnosis of EI in horses (Table 44.1). Traditionally, the gold standard laboratory test for the diagnosis of EI was attempted virus isolation (VI) from nasal swabs/washings in embryonated hens' eggs.[42] Following isolation, the virus is subtyped by means of the hemagglutination-inhibition (HI) test using sera specific for the H3N8 or H7N7 subtypes. These methods are time consuming and cumbersome. In the past decade, antigen detection immunoassays such as the Directigen™ Flu A test kit (Becton-Dickinson, Sparks, MD) and nucleic acid amplification-based assays (standard reverse transcription PCR [RT-PCR] or real-time RT-PCR [rRT-PCR]) were developed and evaluated by various groups.[43–53] The antigen detection immunoassay kits are designed to detect the NP of both influenza A and B viruses.[7,43] Of the commercially available antigen detection immunoassays, the Directigen Flu A test has been used to detect EIV in nasal swabs for a considerable time by certain laboratories.[43,49] While this assay has been found to be useful as an initial screening test to confirm a diagnosis of EI during an outbreak, its limited sensitivity does not make it an ideal method for the diagnosis of EIV infection on an individual animal basis.[50]

TABLE 44.1
Laboratory Techniques Used for Diagnosis of EIV

Laboratory Techniques
Detection of virus
1. Virus isolation (VI) in embryonated hens' eggs (10–11-day-old embryos inoculated via amnion or allantois) or cell culture (e.g., MDCK cells)
2. Electron microscopy (EM)
Detection of viral antigens
1. Immunofluorescence assay (IFA)
2. Antigen detection immune assays (rapid diagnostic assays)
Detection of viral nucleic acid using contemporary molecular biology methods
1. Standard PCR-based assays
2. Quantitative real-time PCR assays
3. Insulated isothermal RT-PCR (iiRT-PCR)
4. Loop-mediated isothermal amplification assay (LAMP)
Indirect demonstration of EIV infection (Serology)
1. Hemagglutination-inhibition (HI) assay
2. Single radial hemolysis (SRH) assay

44.1.4.1 Conventional Techniques

The longstanding method for diagnosis of influenza has been VI on culture of samples from respiratory secretions. In the horse, respiratory secretions of diagnostic utility include nasal or nasopharyngeal swab samples or transtracheal washes. Of these, nasopharyngeal swabs present the best combination of convenience and diagnostic sensitivity. Nasal swabs using, for example, applicator sticks (15 cm) are more convenient and more readily tolerated by the horse compared to nasopharyngeal swabs, which should be inserted 20–25 cm up the nasal meatus; but the amount of virus per sample and the duration of virus detectability postinfection are much superior with nasopharyngeal swabs.[54] The enhanced sensitivity is valuable since horses may not be sampled until after the peak of virus shedding has already passed. It is highly desirable that swab samples be collected as soon as possible after the first presentation of clinical signs.

In the laboratory, diagnostic specimens are usually cultured in 11-day-old embryonated eggs or alternatively in Madin-Darby canine kidney (MDCK) cells. Virus growth may be observed by various means such as hemagglutination assay or immunofluorescence assay using EIV-specific monoclonal antibodies. Once detected, the isolates are available for characterization of antigenic or genetic similarity to known EIV strains, an advantage not afforded by other detection methods. EIV readily mutates to adapt to replicate in embryonated hens' eggs or continuous cell lines,[55,56] but it is sometimes seen that virus replication to detectable levels requires one or more blind passages.

As a diagnostic tool, virus culture is disadvantageous because it requires a virological laboratory and availability of embryonated eggs of the right age, or MDCKs ready for use.

For field use a number of rapid influenza detection kits (IDK) have been developed. These are typically self-contained antigen-capture ELISA devices that most often detect the influenza NP protein and can produce a result within a few minutes. While designed for detection of human influenza infection, the NP of human influenza viruses and EIV are sufficiently antigenically similar that some of these kits also detect EIV. Their sensitivity, however, is less by some orders of magnitude compared to virus culture or alternatively to RT-PCR, so effectively a positive test result is useful but a negative result is not. A laboratory NP-ELISA has been developed, which has superior sensitivity albeit less convenience.[57]

Postmortem diagnosis of EI infection by immunofluorescence or immunohistochemistry analysis of lung tissue is useful for confirmation of EI as an etiologic agent of a disease outbreak causing fatalities, such as the first identification of CI.[58] Electron microscopy for EIV is rarely done today thanks to the availability of more convenient and agent-specific methods.

Retrospective diagnosis can also be done by using serological techniques, generally single radial hemolysis or HI assays, to detect EIV-specific antibodies. Paired acute and convalescent serum samples are required. This is of little use in the face of an ongoing outbreak.

44.1.4.2 Molecular Techniques

Following the introduction of EI into Australia in 2007, an rRT-PCR developed to detect the avian influenza virus matrix gene was used as the molecular diagnostic method of choice for EI.[51,59] Recently, an insulated isothermal RT-PCR (iiRT-PCR) for the detection of EIV H3N8 subtype has been described.[60]

44.2 METHODS

44.2.1 Sample Collection and Preparation

44.2.1.1 Nasopharyngeal Swabs

Nasopharyngeal swabs and transport medium for use by equine practitioners are available from vendors or obtained from the Maxwell H. Gluck Equine Research Center. Using care not to contaminate the gauze end of the swab, it is inserted into the nasal meatus angling inward and down to avoid the blind pouch of the nostril, then slid as far as possible up the meatus (about 25 cm in an adult horse) and, once fully inserted, rotated a few times to enhance contact with mucosal fluids. Upon removal the gauze end is inserted into transport medium (the formulation in the OIE Manual of Diagnostic Tests and Vaccines for Terrestrial Animals[61] is phosphate-buffered saline with either 40% glycerol or 2% tryptose phosphate broth, and antibiotic solution including penicillin [200 units], streptomycin [200 units], and fungizone [5 mg]). Sufficient transport medium must be used to completely immerse the gauze. Once collected, these samples must be kept cold (4°C) during transport to the laboratory. If they are not to be processed for testing within 1–2 days, they should be stored at −70°C. Processing is as described in the OIE Manual.[61] In brief, as much as possible of the liquid fraction of the sample is collected. It may be clarified of particulates by low-speed centrifugation if necessary, and further antibiotics may be added if the samples appear to be heavily contaminated. The authors do not recommend filtration to remove contaminants, as virus may stick to the filter. For injection into embryonated eggs, the sample may be used undiluted or with minimal dilution. For culture on MDCK cells, dilution to reduce the glycerol concentration below 5% is advisable.

44.2.1.2 Serum Samples

Equine sera for retrospective serology are obtained by standard blood collection from the jugular vein into sterile blood collection tubes without any clotting inhibitors (e.g., heparin, citrate, or EDTA). The whole blood is allowed to clot (this may be speeded by incubation at 37°C), then centrifuged at 1000 × *g* to pellet the clotted cells, and the clear serum fraction is removed with a pipette and stored at 4°C (for short periods) or −20°C (for long-term storage). Sodium azide (0.02%) may be added to inhibit growth of contaminants (but consider whether azide may interfere with subsequent assays such as ELISA).

44.2.2 Detection Procedures

44.2.2.1 Virus Isolation

Methods for VI have been published in the OIE Manual[61] and reviewed in Chambers and Reedy.[62] By either culture method, if virus is not detected upon first passage a sterile aliquot should be obtained for one or more subsequent blind passages. Virus isolates have to be further confirmed by hemagglutination assay or immunofluorescence assay using EIV-specific monoclonal antibodies.

44.2.2.1.1 Virus Isolation in Embryonated Eggs

Embryonated hens' eggs (such as SPAFAS eggs) are allowed to develop in a humidified, rotating egg incubator until 10–11 days of age. The injection site is determined by candling to identify the line of the air sac and a place along the circumference that is relatively free of major blood vessels. The surface of the egg is topically disinfected, for example, with 70% ethyl alcohol, and a small injection hole is drilled through the hard shell but not so deeply as to penetrate the inner shell membrane. Using a tuberculin syringe, 0.1–0.2 mL of the processed diagnostic sample is injected straight down into the allantoic cavity or alternatively the amniotic cavity. For diagnostic purposes, no dilution or minimal dilution of the sample is desirable (in contrast to amplification of high-titer virus stocks where a dilution of >1:100 is used to prevent production of defective interfering particles). Following inoculation, the injection site is resealed with paraffin wax or equivalent. Eggs are incubated at 35°C–37°C for 2–3 days, then chilled (e.g., overnight in a refrigerator). To harvest a small sample for virus analysis, the wax seal is melted, a sterile Pasteur pipet is inserted into the allantoic cavity, and a small amount of fluid is withdrawn taking care not to collect egg yolk. This sample can be analyzed without dilution by hemagglutination assay using 1% chicken erythrocytes

in U-bottom or V-bottom wells. If detectable virus growth in eggs has occurred, the allantoic fluid should yield a positive HA test result. The allantoic fluid may also be tested by RT-PCR or rapid IDK if desired.

44.2.2.1.2 Virus Isolation in MDCK Cell Culture

For virus culture in MDCK cells, the cells (ATCC CCL34) are grown to near confluency in tissue culture tubes or small flasks and then washed with PBS or with serum-free tissue culture medium. The inoculum, diluted with serum-free tissue culture medium containing antibiotics, is added and allowed to adsorb for 1 h. After washing and replacement of medium, exogenous trypsin protease activity must be supplied, and this is typically by addition of tosyl-phenylethyl-chloromethyl ketone (TPCK)-treated trypsin (1–2 μg/mL final concentration). It is sometimes useful also to pretreat the inoculum with TPCK-trypsin before inoculation of cells. Following infection, cells are incubated at 37°C and examined daily for cytopathic effects. If such effects are observed, the supernatant medium can be harvested and infection confirmed by, for example, HA or RT-PCR tests; supernatants should be so tested after 4–5 days regardless of appearance of cytopathic effect.

44.2.2.2 Rapid Antigen Detection Kits

These may be membrane or lateral-flow rapid ELISA modules and directions for use are manufacturer specific. The swab sample should be tested directly without any preprocessing or dilution other than as directed by the manufacturer. The test modules include positive controls, and these should be carefully observed to support a valid interpretation. As mentioned, these kits were not designed to detect EIV; where they do, it is a side feature and not every rapid IDK is effective or equally sensitive for the purpose of EIV detection. Positive results on EIV detection have been published for the Directigen Flu A and Flu A+B kits (Becton-Dickinson), Espline (Fujirebio), and Quick S-influ A•B (Denka Seiken),[43,49,63] and the author's lab has used the BinaxNOW Influenza A&B test (Inverness Medical) with success.

44.2.2.3 Retrospective Serology

Methods have been published in the OIE Manual[61] in detail.

44.2.2.3.1 Single Radial Hemolysis Test

The Single Radial Hemolysis (SRH) test measures the size of the zone of hemolysis created when EIV-specific antibodies diffuse radially through a matrix of complement-sensitized erythrocytes conjugated with virus. Paired acute and convalescent sera should be tested side by side, together with a subtype-specific positive control serum and if possible a known-negative serum. Sera should be heat inactivated by incubation at 56°C for 30 min.

44.2.2.3.1.1 Procedure

1. Obtain sheep whole blood in Alsever's solution and separate the red blood cells (RBCs) by low-speed centrifugation. Wash the RBCs 3× in saline/HEPES solution (0.85% NaCl, 0.05 M HEPES, and 0.02% sodium azide as preservative; adjust to pH 6.5). Resuspend the RBCs to make an 8% solution (v/v packed cells) in saline/HEPES, allowing a minimum of 1 mL of 8% RBCs for each 6 cm × 11 cm immunodiffusion plate.
2. Add a stock solution of clarified virus to the RBCs. The optimum ratio of virus to RBC volume is that which yields the largest and clearest zone of hemolysis and must be predetermined by titration for each virus strain; it typically lies within a range of 50–1500 HAU per mL of RBCs. Also, as negative control, prepare RBCs mixed with PBS-A only or mixed with a non-cross-reactive influenza virus strain such as influenza A/PR/8/34 (H1N1). Mix gently and incubate at 4°C for 10 min (PBS-A, aka PBS-London: 10 g NaCl, 0.25 g KCl, 1.45 g Na_2PO_4, 0.25 g KH_2PO_4, and 0.2 g Na azide per liter in distilled water).
3. Slowly stir in ½ volume of a freshly prepared 1:400 dilution (in normal saline) of $CrCl_3$ stock solution (6 g/10 mL distilled water). Incubate at room temperature for 5 min with occasional mixing and then centrifuge at 1500 × *g* for 5 min to pellet the RBCs. Discard the supernatant and resuspend the RBCs in saline/HEPES with 0.2% (w/v) bovine serum albumin. Repeat the centrifugation step and resuspend the RBCs to 8% (v/v) in PBS-A.
4. Add 0.9 mL of virus-sensitized 8% RBCs to 7.8 mL of 1% agarose that has been melted and tempered to 42°C. Mix gently, then immediately add 0.3 mL of undiluted guinea pig complement. Mix again and pour into 6 cm × 11 cm immunodiffusion plates (10 cm diameter Petri dishes made be used but will require more RBC-agarose mixture). Allow to set with the lid off for 5 min and then store the prepared plates at 4°C until use.
5. To perform the test, punch 3 mm wells in agarose about 12–15 mm apart, including a well on each plate for positive control serum. Add 10 μL of test or control serum to a well. Paired acute and convalescent sera should be tested side by side, in duplicate. Incubate at 34°C for 20 h in a humidified chamber. To read the result, illuminate the plate from beneath on a light box and measure the average diameter of each zone of hemolysis. Calculate the area of each zone of hemolysis in mm^2, subtracting the area of the well (expected to be about 7 mm^2).
6. An increase in area of hemolysis of 25 mm^2, or 50%, whichever is smaller, is considered a significant increase in antibody titer between paired acute and convalescent serum samples and is expected to represent a twofold increase in antibody titer. Positive and negative sera should give the expected results for the test to be valid. If sera also produce zones of hemolysis on the negative control plate (RBCs conjugated with an irrelevant virus or with no virus), the sera should be preadsorbed with fresh RBCs and retested.

44.2.2.3.2 Hemagglutination-Inhibition Assay

Methods have been published in the OIE Manual in detail.[61] The widely used HI assay is a quantal assay, meaning that the titers are expressed in successive stepwise multiples of (usually) 2 instead of continuous distributions as in SRH; thus, the difference between a titer of 512 and one of 1024 is a difference of only one well, which is within the accepted range of experimental error. A fourfold difference in titer is the minimum considered a significant difference. For data analysis, this quantal nature of the assay must be taken into account: geometric means (based on $\log_2$-transformed data) are used instead of arithmetic means.

44.2.2.3.2.1 Procedure

1. Removal of nonspecific inhibitors of hemagglutination
   Equine sera contain a natural inhibitor of hemagglutination, α-2 macroglobulin, which must be inactivated before the serum can be tested. There are several methods to do this, the most common being kaolin, receptor-destroying enzyme (RDE), and trypsin-periodate treatment. The kaolin method is adequate for HI against equine H3 HA but can yield false-positive HI reactions against equine H7 HA.[64]
2. Serum pretreatment with kaolin
   Mix 2 volumes of serum with 10 volumes of 10% kaolin (v/v in PBS) for 20 min followed by centrifugation at 1200 × *g* for 20 min. To the supernatant, add 1 volume of 5% chicken RBCs and 7 volumes of PBS. Centrifuge at 400 × *g* for 20 min. The supernatant, a 1:10 dilution of kaolin-treated serum, is ready for use.
3. Serum pretreatment with RDE
   Prepare an RDE working solution of 10–100 units/mL in calcium/saline solution (1.0 g $CaCl_2{\cdot}2H_2O$, 9.0 g NaCl, 1.203 g H_3BO_3, and 0.052 g $Na_2B_4O_7{\cdot}10H_2O$ per liter in H_2O). Mix 0.1 mL of serum with 0.4 mL of freshly prepared RDE working solution. Mix and incubate 12–18 h at 37°C. Add 0.3 mL of 2.5% (w/v in H_2O) sodium citrate solution. Mix, securely seal the tube, and incubate at 56°C for 30 min. Chill on ice and add 0.2 mL PBS. The serum, now at 1:10 dilution, is ready for use.
4. Serum pretreatment with trypsin-periodate
   Mix 0.1 mL of serum with 0.1 mL of 0.4% trypsin working solution (1.6 mL of 25 g porcine trypsin/L mixed with 8.4 mL of 0.1M sodium phosphate buffer, pH 7.2). Incubate at 56°C for 30 min and then cool to room temperature. Add 0.3 mL of 0.01 M $NaIO_4$ in PBS, mix and incubate 15 min at RT. Add 0.3 mL of 1% glycerol (v/v in normal saline) and incubate for 15 min at RT. The treated serum can then be tested as is (1:8 dilution) or 0.2 mL of normal saline may be added to achieve a 1:10 dilution.
5. Antigen pretreatment with Tween-80/ether
   Pretreatment of the virus antigen with Tween-80/ether is often done because it increases the sensitivity of the test to low levels of serum antibodies. Standardization of the resulting artificial antigen is, however, a problem and batch-to-batch variation can affect the reproducibility of the test result. For this antigen pretreatment, in a glass flask mix 39.5 mL of virus-containing allantoic fluid with 0.5 mL of 10% Tween-80 in PBS. Mix gently for 5 min at RT, chill on ice, transfer to a fume hood, and add 20 mL of fresh diethyl ether. Mix well for 15 min at 4°C, then let stand 1 h to allow the aqueous and organic layers to separate. Remove the aqueous layer into a new glass bottle and allow to stand overnight in the fume hood so that residual ether will evaporate. Aliquot and store the treated antigen at −70°C until use.
6. Performing the HI assay
   In a microtiter plate with U- or V-shaped wells, add 25 µL of PBS to all wells of a row (or column) except the first, for each serum sample to be tested, including a positive control serum. A negative control well contains 25 µL of PBS only. To the first well add 50 µL of the serum sample, then perform successive twofold serial dilutions by transferring 25 µL to the next well, mix and repeat down the row to the end, discarding the last 25 µL. Thus, if starting from a serum treated to 1:10 dilution by kaolin, RDE, and trypsin-periodate methods, the dilution series in reciprocal will be 10, 20, 40, 80, 160, and so on. To each well add 25 µL of virus antigen that has been diluted and carefully titrated to a concentration of 4 HAU/25 µL (or 8 HAU/50 µL). Mix gently and allow to stand for 30 min at room temperature. Add 50 µL of 0.5% chicken RBCs (v/v packed cells in PBS, freshly prepared) to each well, mix gently and incubate at room temperature for an additional 30 min, before reading the result. If insufficient hemagglutination-inhibiting antibodies are present at a given serum dilution, virus-mediated hemagglutination will occur and the RBCs will have settled into a fuzzy film across the bottom of the well, resembling the negative control well. Where antibodies have completely inhibited hemagglutination, RBCs will roll to the bottom of the well forming a compact button; and if the plate is tilted this button should form a tear-drop shape. The HI titer is the reciprocal of the greatest serum dilution that completely inhibits hemagglutination. If no inhibition is observed even in the first well, the titer is recorded as "<10," not as zero (assuming the starting dilution was 1:10). For purposes of computing means and variances, the authors' own arbitrary convention is to set "<10" as equal to 5.

44.2.2.4 Nucleic Acid Tests

44.2.2.4.1 Viral Nucleic Acid Extraction

The use of molecular diagnostic assays for the detection of viral agents in clinical specimens requires stringent methods to ensure the stability of the nucleic acids (RNA).[65–67] Sample collection and purification of RNA mark the initial step of every molecular diagnostic assay and therefore are the most important determinants of the reproducibility and biological relevance of subsequent RT-PCR results. Thus, it is prudent to start with proper sample collection, transport, and storage, followed by adherence to rigorous laboratory protocols when extracting nucleic acids and properly storing purified nucleic acids. Naked RNA is extremely susceptible to degradation by endogenous RNases (ribonucleases) that are present in all living cells. Therefore, the key to the successful isolation of high-quality RNA for laboratory diagnosis is to ensure that neither endogenous nor exogenous RNases are introduced prior to or during the nucleic acid extraction procedure. It is recommended to store the extracted RNA at −20°C (short term) or −80°C (long term) until further use. Care should be exercised every time the sample is taken out of storage for analysis. Repeated freeze–thaw cycles will degrade the RNA and therefore, it is recommended that the eluted RNA be aliquoted into multiple tubes for future use.

A prerequisite for the performance of molecular diagnostic assays is an efficient method to isolate and purify viral RNA from clinical specimens such as nasal swabs or nasal secretions from horses. Currently, there are many methods to isolate and purify viral RNA from clinical specimens, but there are only a very few studies that describe comparison of various RNA extraction methods of samples from animal origin including equine.[68–70] Most of the commercial reagent kits for RNA extraction are based on fluid phase, solid phase, or magnetic separation techniques.[71–73] The traditional RNA extraction method using acid guanidinium thiocyanate–phenol–chloroform technique developed by Chomczynski and Sacchi has been replaced by commercial reagent kits that use glass fiber filters, silica-gel spin columns, and magnetic beads to trap RNA present in the clinical specimens.[71–74] Furthermore, the new commercial reagent kits have increased the yield, purity, and quality of extracted viral RNA by removing contaminating genomic DNA, other RNAs, and RT-PCR enzyme inhibitors present in the clinical specimens. However, these kits vary widely in technological principles used for nucleic acid extraction. There are various pros and cons to each technological principle and therefore, the quality and purity of RNA extracted from various reagent kits can vary significantly.

Several automated nucleic acid isolation kits using magnetic beads and magnetic particle processors are commercially available.[75] Unlike automated liquid handling systems that move reagents into and out of a single well of a multiwell plate to perform the different steps of an RNA isolation procedure, the magnetic particle processors use permanent magnetic rods to collect magnetic beads from the solution and release them into other wells containing reagents for the subsequent steps of the protocol. The effectiveness of bead collection and transfer leads to superior washing and elution efficiency, as well as rapid processing of a large number of samples (e.g., 24, 48, or 96 samples in a batch). Additionally, the magnetic bead-based method can also be used for manual RNA purification.

44.2.2.4.2 Standard RT-PCR

Two-step and one-step standard RT-PCR assays for the detection of EIV in clinical samples have been previously described in the literature.[44,45,47] These include universal influenza A assays or assays that are specific for EIV. Quinlivan et al. described a nested RT-PCR assay targeting the nucleoprotein gene and a standard RT-PCR targeting the matrix gene of EIV.[50] However, most of these RT-PCR assays have now been replaced by rRT-PCR assays for routine diagnosis of EIV.

44.2.2.4.3 Real-Time RT-PCR

In the past decade, nucleic acid amplification-based assays (standard RT-PCR or rRT-PCR) were developed and evaluated by various groups.[43–51] However, such assays were not widely used for the routine diagnosis of this disease. This changed following the introduction of EI into Australia in 2007, when an rRT-PCR developed to detect the avian influenza virus matrix gene was used as the molecular diagnostic method of choice for EI.[51,52,59] A panel of rRT-PCR assays capable of detecting a wide range of EIV strains comprising both subtypes of EIV (H7N7 and H3N8) was developed.[76] These rRT-PCR assays use TaqMan® minor groove binding (MGB™) probes targeting the NP, M, H3, and H7 HA genes of the virus and they provide a fast and reliable means of virus detection and disease surveillance. Of this panel of assays, the NP-specific rRT-PCR assay has been routinely used for the detection of EIV clinical samples.

44.2.2.4.4 Insulated Isothermal RT-PCR

Recently, GeneReach (GeneReach USA, Lexington, MA) has developed a TaqMan probe-based iiRT-PCR assay for the detection of EIV H3N8 subtype, and this assay has a very high specificity and equal or higher sensitivity as compared to the NP-specific rRT-PCR.[53,60,77] The assay is based on iiRT-PCR for qualitative detection of influenza A virus subtype H3N8 in clinical samples. Fluorogenic probe hydrolysis chemistry is used to generate a fluorescent signal when a specific RNA sequence of influenza A virus subtype H3N8 is amplified. This assay is specially designed to be used on a compatible iiRT-PCR instrument, POCKIT™ Nucleic Acid Analyzer (GeneReach USA, Lexington, MA).[77,78] The POCKIT Xpress™ Portable PCR Platform for onsite testing is suitable for use in veterinary clinics, racetracks, breeding facilities, and diagnostic laboratories.[53]

44.2.2.4.5 Loop-Mediated Isothermal Amplification Assay

RT loop-mediated isothermal amplification (RT-LAMP) assay was developed to detect EIV H3N8 subtype. The RT-LAMP

primer set was designed to target the HA gene of this subtype. It was reported this assay was 10 times more sensitive than an RT-PCR assay and highly specific for EIV.

44.3 CONCLUSION AND FUTURE PERSPECTIVES

Timely diagnosis of EI depends critically upon prompt collection of appropriate specimens for testing. Once samples are in hand, there are various methods of greater or lesser utility available to perform that testing. The nasopharyngeal swab is the best sample and obtaining that swab is the weak link in the chain, as horses may be uncooperative. Horses are large and strong enough to be potentially dangerous and equine practitioners understandably may be reluctant to force the issue. Thus, a sampling method better tolerated by horses would be an important advance. Perhaps, with the development of highly sensitive field-capable diagnostic technologies, specimens such as saliva or visible discharges from the nares may be demonstrated to contain sufficient influenza virus for reliable diagnosis.

A further disincentive is that there is no disease-specific treatment for EI infection, other than management of clinical signs and control of secondary infections—which practitioners are likely to do with or without a laboratory diagnosis. Some anti-influenza drugs used in humans are indeed effective against EI[79–81]; but the prospect of viruses developing resistance to these drugs leads to their restriction to human use. Possibly once a drug becomes obsolete for human use, it may start a second life as a veterinary drug and be licensed for use in horses.

The benefit of timely diagnosis is both tactical and strategic disease control. Movements of affected horses can be curtailed, and at-risk horses can be freshly vaccinated. Characterization of virus isolates responsible for outbreaks is vital because influenza vaccines require periodic updating to match newly emerging variant strains. Improvement in diagnostic technologies, including sampling technologies, coupled with improvement in vaccine technologies that facilitate rapid updating, promises great benefits for control of influenza in horses.

45.1 INTRODUCTION

Infectious salmon anemia virus (ISAV) is a member of the family *Orthomyxoviridae*, responsible for causing infectious salmon anemia (ISA) in farmed Atlantic salmon (*Salmo salar*). Characterized by lethargy, anemia, hemorrhage of the internal organs, and death, ISA syndrome has been described in Norway, Scotland, Canada, the United States, the Faroe Islands, and Chile. Posing a serious threat to the economic sustainability of aquaculture industries worldwide, ISA is listed as a reportable disease by the OIE.

45.1.1 Classification

ISAV belongs to the genus *Isavirus*, family *Orthomyxoviridae*. The family *Orthomyxoviridae* (orthos, Greek for "straight"; myxa, Greek for "mucus") classifies a group of enveloped, segmented, negative-sense, single-stranded RNA viruses into six genera: *Influenza virus A*, *Influenza virus B*, *Influenza virus C*, *Isavirus*, *Thogotovirus*, and *Quaranjavirus*. Of these, *Influenza virus A*, *Influenza virus B*, and *Influenza virus C* contain one species (or type) each, with influenza A infecting birds, humans, pigs, horses; influenza B infecting humans and seal; and influenza C infecting humans, pigs, and dogs. *Isavirus* includes a single species that causes disease in Atlantic salmon. *Thogotovirus* consists of two species Thogoto virus (THOV, the type species) and Dhori virus (DHOV), the latter of which includes Batken virus and Bourbon virus, as well as tentative viruses Araguari virus, Aransas Bay virus, Jos virus, and Upolu virus as subtype/strains; these viruses infect ticks, mosquitoes, and mammals, including humans. *Quaranjavirus* (named from two of the constituent viruses *Quaran*fil virus and *J*ohnston *A*toll virus) comprises six species (Cygnet River virus, Johnston Atoll virus, Lake Chad virus, Quaranfil virus, Tyulek virus, and Wellfleet Bay virus) that are found in arthropods, birds, and occasionally humans (Quaranfil virus only); *Quaranjavirus* differs from other genera of the family in having insect (tick) vectors and 6 monocistronic genome segments, with distantly related tick-borne viruses containing 6 or 7 segments being classified in *Thogotovirus*.

The genus *Isavirus* consists of a single species, that is, ISAV, which is distinguished into two major genotypes (groups), genotype I (European) and genotype II (North American), on the basis of sequence variations within a small, highly polymorphic region (HPR) located in the 5′-end of the hemagglutinin-esterase (HE) gene (segment 6) in addition to changes in segments 2 and 8 sequences. Indeed, the presence of gaps rather than single nucleotide mutations in the HPR, together with single amino acid substitution or a sequence insertion near the putative cleavage site of the fusion (F) protein, has been implicated in ISAV virulence [1,2].

ISAV genotype I (European group) covers viruses originated from Norway, Scotland, and Chile, and genotype II (North American group) consists of isolates from Canada

and the United States. Typically, the homology shared between European and North American groups in the hemagglutinin nucleotide sequence is 79%, whereas that shared within each group is >90% [2,3].

In addition, focusing on the extracellular region of hemagglutinin, the European isolates may be further separated into three subgroups, with G1 containing isolates from Norway between 1996 in 2000, G2 comprising isolates from Norway, one from Scotland and one from the Faroe Islands, and G3 including isolates from Norway between 1987 and 2000 and Scotland [1].

As the name implies, ISAV induces severe anemia in sea-farmed Atlantic salmon (*Salmo salar*) as well as subclinical infections in sea-run Brown trout (*Salmo trutta*) and Rainbow trout (*Onchorhyncus mykiss*), which may act as important carriers and reservoirs of the virus.

45.1.2 Morphology and Genome Organization

ISAV is an enveloped, pleiomorphic (usually rounded but occasionally filamentous) particle of 100–130 nm in diameter, covered by surface projections of approximately 20 nm.

Encapsidated by nucleoprotein (N), the ISAV genome (13.5 kb in total) consists of eight linear, negative-sense, single-stranded RNA segments of 890–2341 nt, each of which contains the 3′ and 5′ noncoding sequences, and which together encode 11 proteins (Table 45.1) [1,2].

The HE protein is a glycoprotein involved in receptor-binding and receptor-destroying activities. The interaction between HE and host cell receptor [5-*N*-acetyl-4-*O*-acetyl neuraminic acid ($Neu4,5Ac_2$) residue] facilitates the fusion of the membranes and the entrance of the ribonucleoprotein complex. In pathogenic ISAV from diseased fish with clinical disease and pathological signs, a HPR containing gaps rather than single-nucleotide substitutions is identified before the transmembrane domain in the HE gene. Of the 28 different HPRs described to date, 26 are found in European group, 2 in North American group, and 28 in ISAV isolates from Chile, with HPR7b being the most prevalent. On the other hand, in nonpathogenic ISAV from both apparently healthy wild and farmed Atlantic salmon, the HPR in the HE gene contains all intact motifs (so-called HPR0). It is suggested that pathogenic ISAV arises from nonpathogenic ISAV through the deletions/alterations in HRP0 of the HE gene [3–5].

Segment 7 is capable of generating these proteins via alternative splicing mechanism. Located in the +1 reading frame, ORF-1 of segment 7 encodes a polypeptide (NS1) of 301 aa with an antagonist activity to signaling by type I interferon (Table 45.1). Retaining the first 66 nucleotides of ORF-1, ORF-2 of segment 7 eliminates an intron of 526 bases to continue with reading frame +2, and produces a polypeptide of 159 aa, which operates as nuclear export protein through exporting the ribonucleoprotein complex from the nucleus to the cytoplasm. Retaining the first 22 amino acids of ORF-1 (via splicing of an intron of 257) and inclusion of 81 amino acids from the +3 reading frame (ORF3), a protein (NS3) of 81 aa with unknown function is generated [3,6].

Similarly, segment 8 consists of two possible overlapping ORFs, with ORF-1 producing a 24 kDa protein (M1) in vitro, but a 22 kDa protein in vivo, that is related to the viral matrix (membrane), and ORF-2 generating a structural protein (M2) of 27 kDa, with RNA binding and type I interferon antagonistic properties [3].

The 3′ and 5′ untranslated regions (UTR) are highly conserved. The 5′-UTR may be involved in the process of replication and transcription, acting jointly with the 3′-UTR [7,8].

45.1.3 Biology and Epidemiology

The primary target cells for ISAV are endothelial cells lining blood vessels, indicating that virus replication may occur in any organ. Virus replication may also occur in leukocytes and sinusoidal macrophages in kidney tissue.

TABLE 45.1
ISAV Genome Segments and Encoded Proteins

Genome Segment	Segment Size (kb)	ORF (nt)	Encoded Protein	Protein Size (aa)	Protein Mass (kDa)
1	2.3–2.4	2166	PB2 (viral polymerase B2)	722	79.5
2	2.3–2.4	2127	PB1 (viral polymerase B1)	709	80.5
3	2.2	1851	N (nucleoprotein)	616	66
4	1.9–2.0	1737	PA (viral polymerase A)	579	65.3
5	1.6–1.7	1332	F (fusion protein)	444	50
6	1.5	1167	HE (hemagglutinin-esterase protein)	389	42
7	1.3	ORF1, 903	NS1 (nonstructural protein 1 with type I interferon antagonistic property)	301	35
		ORF2, 477	NEP (nuclear export protein)	159	18
		ORF3, 243	NS3 (putative nonstructural protein 3 with unknown function)	81	10.6
8	1.0	ORF1, 591	M1 (membrane protein 1)	197	22–24
		ORF2, 726	M2 (membrane protein 2, a RNA-binding structural protein with type I interferon antagonistic property)	242	26.4

Upon entry into the host via the gills, ISAV utilizes its HE protein to bind to host glycoprotein receptors containing 4-*O*-acetylated sialic acid residues, which also functions as a substrate for the receptor-destroying enzyme. This binding facilitates clathrin-mediated endocytosis of the virus, and subsequent fusion of virus membrane with the vesicle (endosome) membrane releases encapsidated RNA segments into cytoplasm. Migrating to the nucleus, genome segments are transcribed into genomic RNA of both negative and positive polarity and mRNA by viral polymerase (PB1, PB2, and PA). The viral transcripts then move out of the nucleus for translation. The translated proteins are transported from the cytoplasm to the nucleus, and ribonucleoprotein complex forms between genomic RNA, nucleoprotein, and RNA polymerase complex. In association with nuclear export protein (NEP), the ribonucleoprotein complex moves to the cytoplasm, and interacts with the plasma membrane region where virus assembly and budding of progeny virions take place [1].

ISA is primarily a disease of Atlantic salmon (*Salmo salar*). While it does not seem to occur at the embryo stage, ISA can affect the fish at any life stage after hatching. First coming to notice in Norway in 1984, when up to 80% of Atlantic salmon stock in some hatcheries died of a previously undocumented disease, the etiological agent for ISA was characterized as ISAV 10 years later using salmon head kidney (SHK-1) cell line. In 1996, a deadly disease tentatively named "hemorrhagic kidney syndrome" occurred in Atlantic salmon farm in Canada. Subsequent study confirmed that the culprit for both ISA and hemorrhagic kidney syndrome is ISAV. Since then, ISA has been reported in farmed Atlantic salmon in Scotland (1998), Faroe Islands (2000), USA (2001), and Chile (2007) [3,9,10].

Although Atlantic salmon does not appear to suffer lifelong infection, ISAV may persist in the population at the farm level by continuous infection of new individuals that may or may not develop clinical signs. Besides farmed Atlantic salmon, ISAV has been shown to cause subclinical infection in feral Atlantic salmon, brown trout, sea trout (*Salmo trutta*), cod (*Gadus morhua*), Coho salmon (*Oncorhynchus kisutch*), and pollock (*Pollachius virens*). In experimental infection, rainbow trout (*Oncorhynchus mykiss*), cod (*Gadus morhua*), Arctic char (*Salvelinus alpinus*), and Atlantic herring (*Clupea harengus*) are also susceptible to ISAV. These asymptomatically infected fish may shed ISAV through natural excretions/secretions and act as reservoir for this virus [11,12].

ISAV is largely transmitted by contact with infected fish, their secretions, or contaminated water. Contact with contaminated equipment or people who have handled infected fish may also facilitate its transmission. Another important factor is geographical proximity to infected marine sites or slaughterhouses/processing plants, which release unprocessed, contaminated water. ISA outbreaks tend to occur in late spring (rising water temperatures) and late autumn/early winter (falling water temperatures) [13].

The optimal temperature for replication of ISAV is between 10°C and 15°C. ISAV survives well at 15°C for 10 days or 4°C for 14 days, but lose infecting ability at 56°C for 30 min. In addition, the virus retains its infectivity in sea water for 20 h and in blood and liver for 6 days at 6°C. It is sensitive to UV irradiation and ozone, and inactivated by pH 4 or pH 12 for 24 h, or chlorine (100 mg/mL for 15 min).

45.1.4 Clinical Features and Pathogenesis

ISA is a multisystemic disease with high mortality rates in farmed Atlantic salmon (*Salmo salar*). Depending on infective dose, virus strain, temperature, age, and immune status of the host, ISAV infection often induces a variety of clinical signs, ranging from loss of appetite, lethargy, swimming slowly and gasping at the surface, pale gills, exophthalmia, scale pocket edema, swollen abdomen, bleeding along the belly and sides, blood in the anterior eye chamber, to death (average 30%, but as high as 100%). Some fish may maintain a normal appetite without displaying any external signs of illness and then suddenly die [3].

Postmortem examination often reveals dark and swollen kidney, liver, and spleen; pinpoint bleeding in the fatty tissue surrounding organs; pale heart; bloody fluid in the abdominal cavity and around the heart; swim bladder edema; intestinal congestion; circulatory system malfunction; and ascites. Histological findings include hemorrhages and/or hepatocyte necrosis in the liver, erythrocyte accumulation in spleen stroma, and diffuse interstitial hemorrhage with tubular necrosis [14,15].

At the genetic level, ISAV pathogenicity is associated with the existence of a high polymorphism region (HPR) in segment 6 and insertion in segment 5 sequence [16]. As ISAV targets vascular endothelial cells and macrophages, the underlying genetic variations in ISAV high and low pathogenic strains influence the expression of both innate and adaptive immune response relevant genes and outcome of the disease [17,18]. For example, ISAV high pathogenic strain induces hemagglutination that results in virus uptake and productive infection of Atlantic salmon erythrocytes whereas low pathogenic strain does not [17]. In addition, ISAV low pathogenic strain tends to cause the highest fold changes of most immune-relevant genes (including interferon-inducible protein Gig1, Mx1 protein, interferon-induced protein with tetratricopeptide repeats 5, Radical S-adenosyl methionine domain-containing protein [viperin], and several genes involved in the ISGylation pathway) in comparison with high pathogenic strain [18]. This suggests that ISAV high pathogenic strain is capable of evading and suppressing host immune responses for its own advantage.

45.1.5 Diagnosis

Diagnosis of ISA on the basis of clinical manifestations is difficult as several other diseases may also induce anemia, such as erythrocytic inclusion body syndrome, winter ulcer, and septicemia due to *Moritella viscosa*.

Laboratory methods that have been used for ISV diagnosis include virus culture, electron microscopy, serological assays, and nucleic acid detection, with the goal to detect virus particles, antigens, antibodies, and nucleic acids [19–21].

45.1.5.1 Virus Isolation

Atlantic salmon kidney (ASK) and Atlantic SHK-1 are recommended for in vitro isolation and growth of ISAV. Other cell lines such as TO (Atlantic salmon macrophage/dendritic-like cell), epithelioma papulosum cyprinid, and CHSE-214 (chinook salmon embryo) cells may support ISAV growth but do not always produce distinct cytopathic effect [18]. ASK cells are generally maintained at 20°C in Leibovitz's L-15 cell culture medium supplemented with fetal bovine serum (5% or 10%), L-glutamine (4 mM), and gentamicin (50 μg/mL) and 2-mercaptoethanol (40 μM) (optional) [22,23].

45.1.5.2 Electron Microscopy

Virus particles may be observed in endothelial cells and leukocytes from tissue preparations using electron microscopy.

45.1.5.3 Serological Assays

Indirect fluorescent antibody test using monoclonal antibodies (MAbs) against ISAV HE on kidney smears (imprints) or on frozen tissue sections of kidney, heart, and liver provides a useful way to detect ISAV. Immunohistochemistry based on polyclonal antibody against ISAV nucleoprotein allows detection of ISAV on paraffin sections from formalin-fixed tissue (of mid-kidney and heart). Hemagglutination assay may be applied to determine the level of hemagglutination that is induced by the highly pathogenic but not the low pathogenic ISAV strains. Enzyme-linked immunosorbent assays with either purified virus or lysates from ISAV-infected cell cultures permits detection of ISAV-specific antibodies [24,25].

45.1.5.4 Nucleic Acid Detection

Reverse transcription polymerase chain reaction (RT-PCR) and real-time RT-PCR enable detection of both European and North-American HPR-deleted ISAV, as well as HPR0 ISAV, with primer sets derived from genomic segment 8 and segment 7 [26–31]. Samples with positive PCR results by using segment 7 or 8 primer sets may be confirmed by sequencing the HPR of segment 6. This will help determine the ISAV HPR variant present (HPR-deleted or HPR0 or both) [32,33].

Given its high sensitivity and rapid turnaround time, RT-PCR is increasingly adopted in clinical laboratories for routine laboratory diagnosis of ISAV [34,35]. Using RT-PCR, ISAV is detected in the cephalic and middle kidney 8 days postinfection, and in the liver, heart, and gills 13 days postinfection [36].

45.1.6 Treatment and Prevention

Although no treatment is available for infected fish, recent research indicated that the broad-spectrum antiviral drug ribavirin (1-β-d-ribofuranosyl-1,2,4-triazole-3-carboxamide) is effective in inhibiting ISAV replication both in vitro and in vivo.

The current control and prevention approaches for ISA rely on early detection, eradication, and vaccination [37]. For example, implementation of husbandry practices has proven valuable to reduce the incidence of ISA. These include daily removal of dead/moribund fish, compulsory slaughter ("all in/all out"), disinfection of offal and wastewater in infected farms, strict movement controls on suspect farms, and surveillance of farms in the vicinity of an outbreak.

Despite being only partially effective, commercial vaccines have been employed for protection of Atlantic salmon against ISA in North America from 1999, the Faroe Islands from 2005, Norway from 2009, and Chile from 2010 [3,38,39]. In an attempt to further improve the efficacy of existing anti-ISAV vaccines, inactivated ISAV antigen was used to immunize against ISAV challenge, leading to a relative percent survival as high as 86 [40]. Moreover, intramuscular injection of plasmid expressing the type I interferons has been shown to confer strong immunity to Atlantic salmon against ISAV infection [41].

45.2 METHODS

45.2.1 Sample Preparation

Blood is collected from live fish in heparin or EDTA tubes. Heart (including valves and bulbus arteriosus), mid-kidney, liver, pancreas/intestine, spleen, and gills are collected from dead fish.

Fish tissue is weighed and macerated to a 10% suspension (w/v) in PBS with 10× antibiotics. The homogenates are then diluted 1:1 in sterile PBS and clarified by centrifugation at 3000 rpm for 15 min, and the supernatants are used for RNA extraction.

Total RNA is extracted from 375 μL of infected fish tissue supernatant, purified virus preparation, or virus-infected tissue culture suspensions using 1.25 mL of Trizol reagent (Invitrogen). The extracted RNA is eluted in 20–50 μL of nuclease-free water and treated with DNAse I (Roche). RNA is quantitated by UV spectrophotometry.

45.2.2 Detection Procedures

45.2.2.1 Conventional RT-PCR

Munir and Kibenge [42] described a one-tube RT-PCR for ISAV with primers F5 (5′-GAA GAG TCA GGA TGC CAA GAC G-3′)/R5 (5′-GAA GTC GAT GAT CTG CAG CGA-3′) for amplification of 211 bp product from ISAV RNA segment 8.

RT-PCR mixture (50 μL) is made up of 0.8 mM deoxynucleotide triphosphates, 0.8 μM of each primer, 5 mM dithiothreitol solution, 0.25 μL RNase inhibitor (40 U/μL), 2 μL template (>0.632 ng/μL), and 1.0 μL enzyme mix (AMV and Expand High Fidelity PCR-System, Titan One Tube RT–PCR System Kit, Roche Molecular Biochemicals) and 23.25 μL of PCR-grade water.

Amplification is carried out in a PTC-200 DNA Engine Peltier thermal cycler (MJ Research Inc.) with the following thermal profile: a single cycle of RT for 30 min at 55°C; a predenaturation step for 2 min at 94°C; 40 amplification cycles each consisting of denaturation for 30 s at 94°C, annealing for 45 s at 61°C, and extension for 90 s at 72°C; and a final extension step of 10 min at 72°C.

The amplified PCR products are resolved by 1% agarose gel electrophoresis in 0.5× TBE buffer and visualized by staining with ethidium bromide and photographed under 304 nm UV light.

45.2.2.2 Real-Time RT-PCR

McBeath et al. [43] utilized primers 404F_ISA8 (5′ tgg gca atg gtg tat ggt atg a-3′) and RA3 (583R)-ISA8 (5′ gaa gtc gat gaa ctg cag cga-3′) and FAM labeled probe (491_ISA8) (6-FAM cag gat gca gat gta tgc-MGB quencher) from segment 8 [44] for quantitative RT-PCR detection of ISAV.

RT-PCR mixture (20 μL) is composed of 8 μL of RNA and 12 μL of master mix containing 9.28 μL LC 480 RNA Master hydrolysis probe (one-step RT-PCR kit, Roche), 1.88 μL of activator $Mn(OAc)_2$ (50 mM), 1 μL of enhancer (20×), 1.13 μL of ISAV Segment 8 Forward primer and Reverse primer (20 μM each), and 1.04 μL of ISAV segment 8 probe (6 μM).

Amplification and detection are performed in 96-well plate using the LC 480 instrument (Roche) with absolute quantitation methods. The cycling conditions are 1 cycle of RT for 3 min at 63°C, denaturation at 95°C for 3 s, and 45 cycles of denaturation at 95°C for 15 s, annealing at 60°C for 1 min and amplification and detection at 72°C for 1 s.

For generation of the standard curve, the in vitro transcribed RNA standards are run in 5 replicates. The standard curve is constructed automatically with LC software version 4.0 (Roche) using the Ct values obtained when the serial 10-fold dilutions of the in vitro transcribed RNA samples with known numbers of RNA transcripts are used as templates. The standard curve obtained is then used as an external standard curve in all subsequent TaqMan® qRT-PCR assays on LC480.

For calculating ISAV RNA copy number equivalents per mL of unknown sample, the ISAV RNA copy number equivalents/20 μL RT-PCR reaction is multiplied by a factor of 20/8 × 1000/375 based on the use of 8 μL of the total 20 μL RNA eluted from 375 μL of virus lysate used for RT-PCR reaction.

45.3 CONCLUSION

ISAV is an orthomyxovirus implicated in ISA, which is a fatal disease of farmed Atlantic salmon, with symptoms ranging from severe anemia, exophthalmia, petechial hemorrhages in the visceral fat and skin, hemorrhagic hepatic necrosis and kidney tubular necrosis, interstitial hemorrhages, to death. Although ISA currently affects aquaculture in Norway, Scotland, Canada, the United States, the Faroe Islands, and Chile, it has potential to be transmitted to other Atlantic salmon farming regions in the world [45]. Considering its high sensitivity, specificity, and speed, RT-PCR has become a method of choice for routine identification and quantification of ISAV from clinical specimens and also for differentiation of high and low pathogenic ISAV strains [46].

46.1 INTRODUCTION

Influenza A virus (IAV) belongs to the family *Orthomyxoviridae*, and the genome is composed of eight single-stranded, negative-sense RNA segments. IAV can infect a wide range of host species such as birds (wild and domestic), bats, and mammals (including humans, pigs, horses, dogs, and cats) [1]. The epidemiology and ecology of IAVs are complicated due to the multihost and segmented genome. In swine, IAVs are one of the major pathogens that cause acute respiratory disease and result in substantial economic burden to swine producers. In addition to swine IAVs, human and avian IAVs can also infect swine. Swine have been thought to serve as an intermediate "mixing vessel" for the generation of diversified and novel influenza viruses [2]. There have been numerous reports of zoonotic human infections with swine IAVs and reverse zoonotic swine infections with human IAVs [3–7]. Therefore, swine hosts and swine IAVs are important components of the "one health" concept. Detection and characterization of swine IAVs are not only necessary for surveillance, control, and prevention of swine influenza but also critical for public health purposes. In this chapter, swine IAV classification, genome organization, epidemiology, clinical features and pathogenesis, and diagnosis are described.

46.1.1 Classification, Morphology, and Genome Organization

Influenza viruses belong to the family *Orthomyxoviridae* that includes six genera: *Influenzavirus A*, *Influenzavirus B*, *Influenzavirus C*, *Thogotovirus*, *Isavirus*, and *Quaranfilvirus* [8]. Influenza viruses are classified by type, and IAVs are further classified into subtypes. IAVs are named according to the following convention [8]: genus (type), species of origin (omitted if human), location of isolation, isolate number, year of isolation, and the subtype based on hemagglutinin (HA or H) and neuraminidase (NA or N), for example, A/swine/Iowa/A01477800/2014(H1N1). Currently, 18 HA subtypes (H1–H18) and 11 NA subtypes (N1–N11) have been identified for IAVs including two recently described subtypes of bat IAVs (H17N10 and H18N11) [9,10].

The genome of IAV possesses eight segments of negative-sense, single-stranded RNA: polymerase basic 2 (PB2), polymerase basic 1 (PB1), polymerase acid (PA), hemagglutinin (HA), nucleoprotein (NP), neuraminidase (NA), matrix (M), and nonstructural (NS) segments. Each of these segments encode one protein except the PB1, M, and NS segments where the PB1 segment encodes PB1 protein, PB1-F2 protein, and PB1-N40 protein; the M segment encodes M1 protein and M2 protein; the NS segment encodes NS1 protein

and nuclear export protein (NEP)/NS2 protein [8]. IAVs are enveloped viruses. The envelope is a lipid membrane derived from the host cell and harbors the HA, NA, and M2 proteins with abundances in the decreased order of HA, NA, and M2. In the virion, HA protein is present as a trimer, whereas NA and M2 proteins are present as tetramers [8]. The characteristic morphology of IAV particles is their distinctive spikelike projections on the virion surface formed by the HA and NA proteins [11]. The M1 protein lies beneath the lipid envelope of the virion, and M1 is the most abundant structural protein in the virion. The NEP/NS2 protein is also enclosed inside the virion. The core of the virus particle is the ribonucleoprotein complex that consists of eight RNA segments coated with multiple copies of the NP and bound by the polymerase proteins PB2, PB1, and PA [8]. The IAV virion particles are roughly spherical but could be pleomorphic and have a diameter of approximately 80–120 nm [11].

There are two main mechanisms for molecular evolution of IAVs: antigenic drift (natural mutation process due to the lack of viral RNA polymerase proofreading activity) and antigenic shift (reassortment process by which two or more different influenza viruses infect one cell or one host and exchange their genomic segments). Continuous antigenic drift and shift have resulted in growing diversity of IAVs. Understanding IAV epidemiology and evolution requires not only the type and subtype information but also genotype information. Genotyping involves determining the genetic sequences of each RNA segment of IAVs and performing phylogenetic analyses to define the evolutionary lineages. In recent years, genotyping has been increasingly used to understand the origins and evolutionary relationships of IAVs worldwide. Therefore, influenza viruses probably should be classified by type, subtype, and genotype (phylogenetic cluster).

46.1.2 Epidemiology and Ecology

IAVs are present throughout much of the world particularly where large numbers of pigs are raised. However, the viruses circulating in different geographic regions vary in their subtypes and genotypes. Here, a brief summary is provided with an emphasis on North American swine IAVs. Please refer to several published reviews for details [11–17].

46.1.2.1 North American Swine IAVs

In North America, swine influenza was first documented in pigs coincident with the 1918 human Spanish flu pandemic. The virus was isolated in 1930 and was referred to as classical swine H1N1 (cH1N1) [18]. The cH1N1 IAVs remained genetically and antigenically conserved in U.S. swine population until 1998 when a novel triple-reassortant H3N2 virus (HA, NA, and PB1 segments from human seasonal H3N2; PB2 and PA segments from North American avian IAV; NP, M, and NS segments from swine cH1N1) emerged and established itself in U.S. swine [19,20]. The unique composition of the internal genes (human PB1, avian PB2 and PA, and swine NP, M, and NS) of the triple-reassortant H3N2 virus was referred to as the triple-reassortant internal gene (TRIG) cassette [21]. Subsequently, the triple-reassortant H3N2 viruses reassorted with cH1N1, resulting in the emergence and spread of reassortant H1N2 and H1N1 IAVs that contained the TRIG cassette with the HA gene from cH1N1 [22,23]. From 2003 to 2005, two new swine H1N1 and H1N2 viruses emerged and spread in U.S. swine. These viruses contained either the HA or both HA and NA genes derived from human seasonal IAVs, but their internal gene constellation was similar to the TRIG genes of contemporary triple-reassortant viruses [24]. Further studies indicated that these swine IAVs emerging in 2003–2005 were likely from at least two separate introductions of human seasonal viruses [25] and the cross-species transmission from human to swine was estimated to occur during August 2002–March 2003 [26]. In 2009, pandemic H1N1 IAV (H1N1pdm09) emerged in humans and subsequently spread to swine. The H1N1pdm09 virus possesses PB2 and PA genes of North American avian virus origin, PB1 gene of human H3N2 virus origin, HA (H1), NP and NS genes of classical swine cH1N1 origin, NA (N1), and M genes of Eurasian avian virus origin [27]. This particular constellation of segments had not been previously detected in swine or other species prior to its emergence in humans in 2009 [27]. The H1N1pdm09 virus has further reassorted with contemporary North American swine IAVs and brought additional diversity to the genetic complexity of IAV [28–31].
