Due to increasing diversity of swine IAVs, a phylogenetic cluster classification system was established to help characterize the viruses [24]. Over the years, the HA gene of the classical swine H1N1 viruses have evolved into H1α, H1β, and H1γ clusters; the HA genes of two swine H1 viruses introduced in 2002–2003 from the human seasonal IAVs formed H1δ1 and H1δ2 clusters; the HA gene of the H1N1pdm09 formed the H1pdm09 cluster [13]. The HA genes of swine H3 viruses have evolved into H3I, II, III, and IV clusters with H3IV cluster being the most common [32]. The H3IV cluster viruses have further diversified into subclusters A–F [33]. Therefore, the IAVs currently circulating in the North American swine populations include at least 10 phylogenetically distinct HA clusters: H1α, H1β, H1γ, H1δ1, H1δ2, H1pdm09, H3I, H3II, H3III, and H3IV (H3IV A–F) [32,34]. The NA genes of swine IAVs in North America include classical swine lineage N1, human origin N2 lineage introduced in 1998, human origin N2 lineage introduced in 2002–2003, human origin N1 lineage introduced in 2002–2003, and N1pdm09 lineage although the prevalence of these NA lineages are variable [26,32].

IAVs with other subtypes (e.g., H2N3, H4N6, and H3N1) were also detected in the North American swine populations [35–38], but none of these viruses have become established in swine populations. Contemporary IAVs currently circulating in North American swine populations are still mainly H1N1, H1N2, and H3N2 subtypes in spite of the increasing diversity of these viruses.

46.1.2.2 European Swine IAVs

IAVs circulating in the European swine populations are predominantly H1N1, H1N2, and H3N2 subtypes. However, the genetic lineages of these swine IAVs are distinct from the

North American swine IAVs [11]. The classical swine H1N1 virus that previously circulated in European swine populations was replaced with an antigenically and genetically distinct European avian-like H1N1 virus around 1979 [14]. Subsequently, humanlike H3N2 and humanlike H1N2 viruses were introduced into and established infections in European swine [11–14]. Emergence of H1N1pdm09 and reassortment with endemic swine IAVs in Europe further diversified European swine IAV ecology [39–41]. Some unusual subtypes such as H3N1 and H1N7 viruses were detected in European swine but apparently failed to persist and spread in pigs [42,43].

46.1.2.3 Asian Swine IAVs

The epidemiology of swine IAVs in Asia is more complex than that in North America and Europe. Some swine IAVs from North America (e.g., classical swine H1N1 and triple-reassortant H3N2 and H1N2 viruses) and Europe (e.g., European avian-like H1N1 and European H3N2 reassortant viruses) and their reassortant descendants had been detected in Asia [15,16]. Some humanlike H3N2 viruses local to Asian countries were detected in Asian swine as well [15,16]. The H1N1pdm09 and its reassortants were also detected in Asia [44–47]. In addition, some avian-like IAVs such as H9N2, H5N1, H5N2, H4N8, and H6N6 and equine H3N8 IAV have been sporadically detected in pigs from some Asian countries [15,16,48–50]. Concurrent circulation of so many genetically diverse IAVs in swine has resulted in very complex swine IAV ecology in Asia.

46.1.2.4 Swine IAVs in South America and Africa

IAVs have also been detected in South American swine populations and African swine populations, as reviewed by Vincent et al. [12].

46.1.2.5 Role of Swine in IAV Ecology

Wild aquatic birds are the natural reservoir for IAV H1-H16 and N1-N9 subtypes [51]. H17-H18 and N10-N11 subtypes of IAV have recently been detected in bats [9,10]. However, it appears that only certain subtypes of IAV readily established their infections in mammalian species. For example, the IAV subtypes in global swine populations are predominantly H1N1, H1N2, and H3N2 although other subtypes can be sporadically detected. Swine tissues are found to express both α-2,6-linked sialic acid (receptor preferred by human/swine IAVs) and α-2,3-linked sialic acid (receptor preferred by avian IAVs), and swine were thought as a "mixing vessel" for genetic reassortment between avian and mammalian IAVs [2]. However, it has been argued whether swine are necessary intermediate hosts for avian-to-human infections because human and some land-based poultry were found to also express both types of sialic acids [11]. Nevertheless, swine play an important role in the ecology of IAV, and this is especially true at the human–swine interface. Zoonotic transmission of swine-adapted IAVs to humans has been documented. Searching PubMed database in April 2006 identified 50 cases of zoonotic swine IAV infections though the actual number could be higher [52]. From 2005 to 2014, there were a total of 372 cases of human infections with swine origin variant influenza viruses in the United States, including 351 H3N2v, 16 H1N1v, and 5 H1N2v [53]. Among which, an H3N2 variant (H3N2v) containing seven gene segments from the triple-reassortant swine H3N2 and one gene segment (M gene) from the H1N1pdm09 has caused 343 human infections between 2011 and 2014 in the United States [54]. Interestingly, reverse zoonotic transmission of IAVs from human to swine have occurred more frequently than the opposite [7]. Globally, there were at least 49 human-to-swine transmissions of the H1N1pdm09 during 2009–2011 and 23 separate introductions of human seasonal IAVs into swine during 1990–2011 [4].

46.1.3 Clinical Features and Pathogenesis

The transmission routes of IAV between pigs are thought to be through direct contact via nasal or oral secretions and through inhalation of aerosolized virus in droplets [11]. The clinical outcomes of swine IAV infection could be dependent on multiple factors including virus load, age of pigs, immune status, housing conditions, and concurrent infections. Typical clinical influenza in pigs is characterized as an acute, high-morbidity, low-mortality respiratory disease in uncomplicated infections [11]. At the first 1–2 days postinfection, pigs develop high fever (>40.5°C, 105°F) followed by lethargy, anorexia, and nasal discharge. Conjunctivitis, tachypnea, and dyspnea could occur. By days 3 and 4, pigs may develop a harsh deep barking cough considered as the hallmark clinical sign of swine influenza [55]. Pigs of all ages are susceptible to IAV infection, but clinical disease is often more mild in nursing pigs. In the absence of concurrent infections with other pathogens, pigs usually recover in 7–10 days but not all pigs in a population will get infected and recover simultaneously [55].

IAV infects the epithelial cells lining the surface of the respiratory tract of pigs (nasal mucosa, trachea, bronchi, bronchioles, and lung) with a preference for the lower instead of the upper respiratory tract [11,55]. Virus can be detected from the nasal or oropharyngeal swabs, bronchoalveolar lavage fluid, and respiratory tract tissues including lungs [11]. Virus shedding in nasal secretions begins by 1–3 days postinfection, and the duration of the shedding lasts approximately 4–7 days [55]. Swine IAV infection is generally limited to the respiratory tract and is occasionally detected from extra-respiratory sites. Low level and transient influenza viremia was only observed in one study [56]. In another study, virus was detected in intestines and spleen by reverse transcription polymerase chain reaction (RT-PCR) but not by virus isolation and in brainstem by both RT-PCR and virus isolation [57].

The most common gross lesions found in swine IAV-infected pigs are bronchopneumonia predominantly in the cranioventral lung lobes, but the consolidation level varies [11,55]. In cases involving concurrent bacterial bronchopneumonia, lesions could be more extensive [55].

The hallmark microscopic lesion of swine influenza is necrotizing bronchitis and bronchiolitis with variable severity of interstitial pneumonia [55,58]. Within the first 24 h postinfection (hpi), neutrophil infiltration and accumulation start to occur in the lumens of alveolar capillaries. Extensive necrosis and sloughing of epithelial cells into airway lumens accompanied by more evident neutrophil accumulation occur at 24–48 hpi, causing obstruction of the airways. From 48 to 72 hpi, some airways are in active necrosis accompanied by peribronchiolar and perivascular infiltration of lymphocytes. By 72–96 hpi and beyond, airways are in repair. During the recovery phase, the epithelial cells lining the airways proliferate and result in an irregular hyperplastic appearance; lymphocytic cuffs also become more prominent. Over the following days, the epithelial hyperplasia resolves and peribronchiolar lymphocytic cuffing may remain.

46.1.4 Diagnosis

Clinical signs of swine IAV infection are not pathognomonic and could be similar to symptoms caused by other respiratory pathogens. A definitive diagnosis needs swine IAV-specific laboratory tests. Numerous virological and serological assays are available for swine IAV detection and characterization, but in this chapter, only virological techniques are discussed. Here, we refer to the RT-PCR and sequencing as "molecular techniques" and all other virological methods as "conventional techniques." But it is noteworthy that some methods categorized under "conventional techniques" are still commonly used for swine IAV detection and diagnosis.

46.1.4.1 Conventional Techniques

Electron microscopy (EM) can directly visualize virus particles in examined specimens if sufficient amounts of virus are present. However, EM is not suitable for routine use due to the relatively lower analytical sensitivity and time-consuming procedures. The direct or indirect immunofluorescence assay (IFA) test using different swine IAV antibodies can detect viral antigen in fresh or frozen tissue sections. Immunohistochemistry (IHC) to detect viral antigen on formalin-fixed tissue sections is still frequently performed to confirm the histopathological observations. IHC can also facilitate comparison of virus distribution and cellular localization to determine whether viral antigen distribution coincides with lesions in the tissues. The NP is conserved among IAVs, and anti-NP antibodies can be used in IFA and IHC assays to detect multiple subtypes of IAVs. In contrast, the HA protein is subtype specific, and HA-specific antibodies can be used to detect specific subtypes of influenza virus. A number of commercial antigen capture enzyme-linked immunosorbent assay (ELISA) kits developed for detection of human and avian IAVs can be used to detect swine influenza virus antigen from clinical samples. These kits detect HA, NA, or NP of IAV [59]. The antigen ELISAs are a rapid assay and can be conducted in the field, but the sensitivity may not be satisfactory [59,60]. Swine influenza virus isolation can be conducted in embryonated chicken eggs and/or in a number of primary cells or continuous cell lines (the most commonly used cell line is Madin–Darby canine kidney) [61]. Virus isolation is an important technique to obtain a live and infectious virus for antigenic characterization, pathogenesis investigation, and vaccine production. Proper sample storage to maintain viable virus is critical for virus isolation success. IAV hemagglutinates chicken or turkey erythrocytes. Hemagglutination (HA) test is not often directly used on clinical samples but frequently used to test egg fluids or cell culture fluids for confirming virus isolation results.

46.1.4.2 Molecular Techniques

Since PCR technique became available, conventional gel-based PCR and RT-PCR have been widely used as a tool for diagnosis and research. Subsequent innovation and introduction of real-time PCR (rPCR) and real-time RT-PCR (rRT-PCR) provided a more powerful tool for diagnosis. Currently, rRT-PCR assays are the method of choice in many laboratories for the detection and subtyping of IAV in swine. Compared to other methods such as IFA, IHC, and virus isolation for swine IAV detection, rRT-PCR has a number of advantages: rapid turnaround time between sample receipt and obtaining results, high sensitivity, high specificity, high throughput, and capability for genomic quantitation. In addition, rRT-PCR can be used to test various specimen types, which can be problematic for other detection methods. Following detection and subtyping of IAV using rRT-PCR, sequencing technique can be used to further genetically characterize the virus.

46.1.4.2.1 rRT-PCR for Swine IAV Detection

rRT-PCR has been widely employed as a diagnostic and/or surveillance test for the detection of swine IAV. To detect a broad range of IAVs, swine IAV-screening rRT-PCR assays with primers and probes targeting the conserved M and/or NP gene are generally used. An avian influenza rRT-PCR targeting the M gene [62] was adapted for the detection of IAV in swine samples and has been validated by the USDA and is routinely used for swine IAV surveillance in the United States. Commercial swine influenza virus test kits are also available, some of which contain an internal control that provides an additional quality assurance measure and helps troubleshoot problems encountered during the rRT-PCR testing [63].

46.1.4.2.2 rRT-PCR for Swine IAV Subtype Identification

Traditionally, determination of the IAV HA and NA subtypes was performed on the cultured virus using hemagglutination inhibition test and neuraminidase inhibition test. However, both assays are time consuming and require standardized reference antigens and antisera for HA and NA, which are often difficult to obtain. Currently, RT-PCR is routinely used for IAV subtyping; in addition, subtyping RT-PCR can be conducted directly on clinical samples and not necessarily on the cultured viruses. A number of RT-PCR assays have been described [64–68]. In the United States, a multiplex swine IAV HA (H1 and H3) and NA (N1 and N2) subtyping PCR assay commercially available from Life Technologies™ has been used by the USDA National Animal Health

Laboratory Network laboratories for surveillance testing [63]. Contemporary IAVs circulating in the swine populations are predominantly H1N1, H1N2, and H3N2 subtypes although other subtypes can be sporadically detected. If any samples are strongly positive by the swine IAV screening PCR but negative for H1, H3, N1, and N2, the HA and NA genes from those samples can be sequenced to determine if any uncommon subtypes are present.

46.1.4.2.3 Determination of Swine IAV Genome Sequences

Detection of swine IAV by screening PCR followed by subtyping PCR is commonly performed for swine IAV diagnosis and surveillance. However, as mentioned in Section 46.1.3, continuous antigenic drift and shift have resulted in growing diversity of IAVs, and the type and subtype information is not sufficient to characterize the detected IAVs. Sequencing followed by comparative sequence analysis and phylogenetic analysis has been frequently conducted in recent years to further characterize IAVs and to enhance our understanding of the epidemiology and evolutionary relationships of the viruses. Many laboratories are still using the traditional Sanger methods to determine genetic sequences. However, more and more laboratories have started to employ next-generation sequencing technologies to obtain more extensive sequence data.

46.2 METHODS

46.2.1 Sample Collection and Preparation

Antemortem specimens such as nasal swabs and oral fluids and postmortem specimens such as nasal turbinates, tonsil, trachea, lung, and bronchoalveolar lavage can be used for swine IAV detection by RT-PCR. The most common specimens submitted to diagnostic laboratory for swine IAV testing are nasal swabs, oral fluids, and lung tissues. It is noteworthy that oral fluids are becoming more common for IAV prognostic profiling [60,69–71]. Oral fluids are collected by hanging absorbent cotton ropes above or on the sides of pens. Pigs interact with and chew on the rope. Usually within 30 min, the rope will be soaked with saliva and other oral secretions. Normally, oral fluids can be successfully collected from pigs older than 3 weeks of age but may be difficult to collect from suckling pigs [72]. Due to short periods of virus shedding, nasal swabs and oral fluids should be obtained from acutely ill animals.

During collection, samples should be kept on ice if at all possible. Following collection, samples should be transported to the laboratory as soon as possible. Samples can generally be stored at 4°C for up to 48 h. However, if testing cannot be initiated within 48 h, samples should be frozen either at −20°C (preferably in a non-frost-free freezer) for a month or less or at −70°C or below for long-term storage.

Numerous commercial kits for viral RNA extraction are available. Although manual RNA extraction is still being used in some laboratories, automated extraction of nucleic acid from specimens using 24-well, 96-well, or 384-well format is used in many laboratories for high-throughput extraction. The nucleic acid extraction procedures vary by specimen type. For example, in our laboratory, we use one procedure to extract viral RNA from nasal swabs, lung tissue homogenates, tracheal tissue homogenates, bronchoalveolar lavage, cell culture fluids, or embryonated chicken egg fluids and another procedure to extract viral RNA from oral fluids. Both extraction procedures are magnetic bead-based methods using the commercial 5× MagMAX™ Pathogen RNA/DNA Kit (4462359, Life Technologies). For nucleic acid extraction from nasal swab, lung, and other samples, the standard protocol from the manufacturer is followed. Briefly, 50 μL samples are mixed with 130 μL Lysis/Binding Solution and 20 μL Bead Mix for 5 min. RNA Binding Beads are captured and supernatants discarded. Two washes each with 150 μL Wash Solution 1 and 150 μL Wash Solution 2 follow. Beads are dried by shaking for 2 min. Viral RNA is eluted into 90 μL elution buffer. Compared to the nucleic acid extraction protocol from nasal swab and lung samples, the extraction protocol from oral fluids mainly differs in two aspects: (1) Sample preparation before extraction: Oral fluids are first vortexed, and 300 μL vortexed oral fluids are added to 450 μL Lysis/Binding Solution and shaken for 5 min. Lysate is clarified by centrifugation at 2500 × *g* for 5 min. Clarified lysate (600 μL) is used for nucleic acid extraction. (2) A 300 μL of Wash Solution 1 and 450 μL Wash Solution 2 are used for each respective wash step. Elution volume remains at 90 μL. The RNA sample should be tested by rRT-PCR as soon as possible after extraction. RNA samples can be stored at −70°C or colder for longer term storage.

46.2.2 Detection Procedures

In this section, the USDA-validated IAV M gene–based rRT-PCR is described for swine IAV detection, and a multiplex swine IAV HA (H1 and H3) and NA (N1 and N2) subtyping PCR assay from Life Technologies is described for swine IAV subtyping. Previously described sequencing approaches using the Sanger method [73] can be followed for determining the whole genome sequences of eight segments of IAV. In recent years, next-generation sequencing technology using different platforms such as Illumina® MiSeq® and Life Technologies Ion Torrent™ has been employed to determine the whole genome sequences of IAVs. It is beyond the scope of this chapter to describe the detailed sequencing procedures and sequence analysis methods. Thus, swine IAV whole genome sequencing and analysis procedures are not provided here.

46.2.2.1 rRT-PCR for Swine IAV Detection

The primers and probe of the USDA-validated swine IAV M gene–based rRT-PCR assay are M+25 forward primer (M+25F) 5′-AGATGAGTCTTCTAACCGAGGTCG-3′, M-124 reverse primer (M-124R) 5′-TGCAAAAACATCTTCAAGTCTCTG-3′, M-124 modified reverse primer (M-124R Mod) 5′-TGCAAAGACACTTTCCAGTCTCTG-3′, and M+64 probe (M+64P) 5′-FAM-TCAGGCCCCCTCAAAGCCGA-BHQ1-3′.

TABLE 46.1
USDA-Validated Influenza A Virus Real-Time RT-PCR (M Gene) Reaction Mix Volumes Using the AgPath-ID One-Step RT-PCR Kit (Life Technologies)

Component	Volume per Reaction (μL)	Final Concentration
AgPath-ID 2× master mix	12.5	1×
AgPath-ID 25× enzyme mix	1	
AgPath-ID detection enhancer	1.5	
M25F (20 μM)	0.5	0.4 μM
M124R (20 μM)	0.5	0.4 μM
M124R mod (20 μM)	0.5	0.4 μM
M64P (6 μM)	0.5	0.12 μM
RNA template	8	
Total volume	25	

The AgPath-ID™ One-step RT-PCR reagents from Life Technologies are used.

1. A 25 μL RT-PCR reaction is prepared as shown in Table 46.1 and is added to a 96-well reaction plate for the AB 7500 Fast. It is important to include a positive amplification control, a positive RNA extraction control, a negative RNA extraction control, and a negative amplification control (e.g., nuclease-free water).
2. Seal the plate tightly and centrifuge at 2000 × *g* for approximately 15 s.
3. Place the sealed reaction plate into the AB 7500 Fast instrument (Life Technologies) and run the rRT-PCR with the following conditions: 1 cycle of 45°C for 10 min, 1 cycle of 95°C for 10 min, and 45 cycles of 95°C for 15 s and 60°C for 45 s.
4. Analysis of results. Set the threshold to 0.2 and use the "autobaseline setting." Examine the positive and negative control to ensure that the reaction results are correct. The positive amplification control is expected to have a Ct value of 25, and the Ct value should be between 21 and 29 for the run to be valid. The positive extraction control should be positive. The negative extraction control and negative amplification control should each be clearly negative. Evaluate the raw data from each sample individually using the instrument analysis software. This swine IAV matrix gene rRT-PCR assay is run 45 cycles, and any Ct value less than 45 is reported.

46.2.2.2 rRT-PCR for Swine IAV Subtyping

The Swine Influenza Virus Subtyping RNA Reagents (primers and probes) (Life Technologies) and Path-ID™ Multiplex One-Step RT-PCR Kit (Life Technologies) include 2× Multiplex RT-PCR Buffer, 10× Multiplex RT-PCR Enzyme Mix, 25× H1H3 Primer Probe Mix, and 25× N1N2 Primer Probe Mix.

TABLE 46.2
Swine Influenza Virus Subtyping One-Step RT-PCR (Life Technologies) Reaction Mix Volumes

Component	Component	Volume per Reaction (μL)
H1H3 subtyping	2× multiplex RT-PCR buffer	12.5
	10× multiplex RT-PCR enzyme mix	2.5
	25× H1H3 primer probe mix	1
	Nuclease-free water	1
	RNA template	8
	Total volume	25
N1N2 subtyping	2× multiplex RT-PCR buffer	12.5
	10× multiplex RT-PCR enzyme mix	2.5
	25× N1N2 primer probe mix	1
	Nuclease-free water	1
	RNA template	8
	Total volume	25

1. RT-PCR reaction preparations are shown in Table 46.2. Set up two reactions for each sample in 96-well reaction plate for AB 7500: one reaction is for HA (H1 and H3) subtyping, and the other is for NA (N1 and N2) subtyping. It is important to include a positive amplification control (H1, H3, or N1, N2) and a negative amplification control (e.g., nuclease-free water).
2. Seal the plate tightly and centrifuge at 2000 × *g* for approximately 15 s.
3. Place the sealed reaction plate into the AB 7500 Fast instrument (Life Technologies) and run the rRT-PCR with the following conditions: 1 cycle of 48°C for 10 min, 1 cycle of 95°C for 10 min, and 40 cycles of 95°C for 15 s and 60°C for 45 s.
4. Analysis of results. Set the threshold to 0.2 and use the "autobaseline setting." Examine the positive and negative controls to ensure that the reaction results are correct. The positive H1 control should have a Ct 25–29 in the VIC channel (H1 probe), and the positive H3 control should have a Ct 25–29 in the FAM channel (H3 probe). Similarly, the N1 and N2 controls should have a Ct 25–29 in the VIC and FAM channels (N1 and N2 probes), respectively. The negative amplification control should be negative for H1, H3, N1, and N2. Evaluate the raw data from each sample individually using the instrument analysis software. If the sample has a Ct < 40 in a specific assay, the sample is positive for that subtype.

46.3 CONCLUSION AND FUTURE PERSPECTIVES

Swine influenza is a highly contagious, acute respiratory disease in pigs and can cause significant economic losses for pork producers. However, the multihost nature and interspecies transmission of IAV ensure that IAV in swine is not

only a viral pathogen for pigs but also has its unique niche in view of the whole IAV ecology. It was formerly believed that swine are intermediate hosts for avian IAV transmission to humans. However, recent advancement in IAV receptor studies suggests that swine are not more suitable hosts than humans for stable transmission of avian IAVs. Nonetheless, there is no doubt swine can receive and harbor a large number of IAVs with different lineages and then via reassortment generate novel viruses that can further transmit to other species including humans. In fact, numerous human-to-swine and swine-to-human transmissions of IAV have demonstrated the importance of the human–swine interface in influenza virus ecology.

Currently, there are no interventions that can effectively prevent influenza viruses from evolving through antigenic shift and antigenic drift. Efforts to better monitor IAV evolution through enhanced surveillance in both swine and human populations are warranted. Molecular techniques provide efficient tools to rapidly detect and characterize IAVs. Screening RT-PCR assays that can identify almost all IAVs are used for detection of IAV, and then subtyping RT-PCR and genetic sequencing can further characterize the detected viruses. In addition, antigenic evaluation of viruses should be performed in conjunction with genetic analysis. Together, these approaches can assist in understanding the epidemiology and evolutionary relationships of IAVs worldwide. The acquired information can be further used to update vaccine formulations to include contemporary circulating virus strains or to develop more effective vaccines for prevention and control of swine influenza.

47.1 INTRODUCTION

Avian metapneumovirus (aMPV), previously referred to as turkey rhinotracheitis,[1] is an emerging viral pathogen in poultry, responsible for a highly contagious disease particularly in chickens and turkeys.[2] Although aMPV infection often involves the respiratory tract, it can also affect the oviduct, contributing to reduced egg production.[3] Birds of any age are susceptible to aMPV infection, and secondary infection with bacteria such as *Escherichia coli*, *Bordetella*, and *Pasteurella* can complicate the situation, resulting in a condition known as swollen head syndrome (SHS), with adverse impact on infected animals.[3–5]

aMPV was first described in South Africa in 1978, but the disease rapidly spread to other regions in Europe and Asia[2,4] and more recently in the Americas (United States, Brazil, and Mexico).[6–10] The only countries reported as aMPV free are Australia and Canada.[11] aMPV belongs to the family *Paramyxoviridae* and is further divided into four subtypes. Subtypes A and B were identified in South Africa and Europe, subtype C in Asia and the United States, and subtype D was detected in France.[2,10,12–16] In Latin America, only subtypes A and B have been described, mainly in Brazil and Mexico.[6–8,17]

47.1.1 Classification, Genome Structure, and Function

aMPV is a member of the genus *Metapneumovirus*, subfamily *Pneumovirinae*, family *Paramyxoviridae*.[1] Apart from the subfamily *Pneumovirinae*, the family *Paramyxoviridae* contains a second subfamily *Paramyxovirinae*. While the subfamily *Pneumovirinae* comprises two genera (*Metapneumovirus* and *Pneumovirus*), the subfamily *Paramyxovirinae* encompasses seven genera (*Aquaparamyxovirus*, *Avulavirus*, *Ferlavirus*, *Henipavirus*, *Morbillivirus*, *Respirovirus*, and *Rubulavirus*).

Besides aMPV (which was isolated for the first time in South Africa in the late 1970s), the genus *Metapneumovirus* also includes *human metapneumovirus* (hMPV), which was described in the Netherlands in 2001. Whereas hMPV is separated into subtypes A and B,[18] aMPV is shown to contain four subtypes: A, B, C, and D.

aMPV is a pleomorphic, enveloped, unsegmented, single-stranded, negative-sense RNA virus of approximately 14,000 nucleotides, with helical symmetry and projections on its surface. The genome of aMPV encodes eight structural proteins: nucleoprotein (N), phosphoprotein (P), two matrix proteins (M1 and M2), fusion protein (F), small hydrophobic protein (SH), surface glycoprotein (G), and RNA-dependent polymerase (L).[1,2] The division of aMPV into subtypes (A–D) is based on the variations of the surface glycoprotein sequences as well as the antigenic differences among viral strains.[10,12,14,15]

As the best characterized structural proteins of aMPV, glycoprotein G is associated with viral coupling and pathogenesis.[19] Both the aMPV and hMPV differ from the genus *Pneumovirus* by their lack of genes required for the synthesis of nonstructural proteins NS1 and NS2 and structural protein M2, by the specific order of genes that code for other structural proteins in the viral genome, and by the order in which their protein-coding genes are located within the viral genome.[20] Part of the structural proteins is the polymerase complex, which includes protein N, which represents a key element of the nucleocapsid and an essential component of

the polymerase complex. Protein P is an important part of the replication and transcription complexes. Analysis of the interaction between protein P and protein N has shown that the carboxy-terminal domain of protein P contains most of the necessary elements to couple with protein N. Protein L is considered as the main component of the polymerase complex due to its role in the synthesis of viral RNA. Thus, proteins P, N, and L together with the viral RNA genome form the ribonucleoprotein of aMPV. In addition, gene M2 is composed of two open reading frames that code for proteins M2-1 (184–186 amino acids) and M2-2 (71–73 amino acids). It has been suggested that M2 is also linked to the nucleocapsid and that it is involved in the regulation of viral replication and transcription. Due to this feature, M2 has also been referred to as transcriptional elongation factor.[20] Protein M surrounds the nucleocapsid, and this facilitates its coupling to the virion's lipid envelope. Results from *in vitro* experiments suggest that protein M from hMPV influences the immune response, by promoting activation of macrophages and dendritic cells when shed as a soluble molecule. Another member of the *Paramyxoviridae* family, human respiratory syncytial virus (of the genus *Pneumovirus*), also has a protein M that can be shed during cell death or as an active process. It has also been proposed that protein M could have a role as part of the viral assembly, just like in other paramyxoviruses.[20–23]

aMPV contains three surface proteins. The first one, protein G, is a type II, highly glycosylated membrane protein, which is the most variable among MPVs and interacts with its receptors located on the target cell surface. It has been shown that protein G of hMPV has an important role as inhibitory factor for the immune response of the host by blockage IFN-α, IFN-β, and inducible chemokine production. Protein G was first thought to be the most important surface protein; however, studies have shown that some protein G–deficient, subtype C aMPV mutants are able to infect cells and replicate efficiently *in vitro.* Interestingly, the same aMPV mutant produced a milder disease in infected turkeys, as shown by lower clinical score and antibodies when compared with the wild-type virus. The results from these studies lead to the idea that *in vitro* replication of aMPV is protein G independent and that the presence of protein F is enough for viral coupling and fusion.[24,25]

The second surface protein, F, is a type I membrane protein, synthesized as an inactive precursor (F0), giving rise to subunits F1 and F2 after its cleavage by proteases in the host cell. Protein F promotes a pH-independent fusion between the viral envelope and the cell surface. It also induces the development of syncytia in infected cells and determines the viral host-specific tropism. This was experimentally shown by the inability of hMPV to infect turkey poults, even though aMPV can infect and replicate in mammal cell culture.[24,26]

Finally, protein SH is an integral type II membrane protein, which first allocates in the endoplasmic reticulum (ER), before being transported to the cell surface via ER–Golgi apparatus. It has been found that replication of hMPV can be SH independent, but it is involved in the modulation of immune responses by affecting nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB)-dependent gene transcription.[20,24,27–29] It is important to mention that the nature of the cell receptor for aMPV is yet to be elucidated, although it has been suggested that one or more glycosaminoglycans or heparin-like molecules could be involved.[20]

47.1.2 Epidemiology, Clinical Features, and Pathogenesis

Initial studies on glycoprotein G using molecular sequence analysis as well as neutralization with monoclonal antibodies suggested that two subtypes (A and B) of aMPV existed within the same serotype. These subtypes are the most frequent in Europe, Israel, Japan, and Brazil.[22,30] Later, in 1996, a third subtype (C) was reported in the United States, whose amino acid sequence was very similar to that of hMPV.[27] First emerged from the Colorado outbreak of turkey in 1996, aMPV subtype C was implicated in a subsequent, much bigger outbreak in Minnesota, the largest turkey producer in that country. The cost of aMPV subtype C to poultry industry in the United States has been estimated at US$15 million per year, from 1997 to 2002.[2,22,24,31] It was suggested that migratory birds could be involved in the dissemination of the virus because aMPV was detected in nasal turbinates of sparrows, geese, swallows, and starlings captured in the central region of the United States, showing a nucleotide identity of 90%–95% and an amino acid identity of 97%–99% when compared with the virus isolated from turkeys.[32–34] Moreover, aMPV outbreaks in the United States showed a seasonal pattern, with 80% of them happening during spring (April to May) and fall (October to December).[22,35] A retrospective study reported two aMPV isolates in France with low nucleotide identity to subtypes A, B, and C, therefore they were classified as part of subtype D.[12,15]

Subtypes A, B, and D mainly affect turkeys and chickens, although subtype A has also been detected in pheasants and guinea fowls.[2,36] Subtype C was first isolated from turkeys albeit reports of similar isolates from duck, sparrows, geese, swallows, and gulls also exist.[2,32,34] Migratory birds are a key in aMPV transmission due to the vast areas that they cover, although local wild birds have also been implicated in the viral dissemination, due to the source of food and shelter that a poultry farm represents. Turkeys are the main natural host for aMPV, followed by chickens and hens. Infection can occur from very early age in turkeys and chickens, although birds of any age can become infected. aMPV is transmitted by direct contact with infected birds, which usually disseminate the virus around 2–3 days after the first exposure and the viral shedding continues for up to 1 week. Airborne transmission is the least relevant form of transmission, and no vertical transmission has been demonstrated up to date.[2,3,5,20]

The severity of the disease is highly influenced by secondary bacterial infection together with poor husbandry standards. The pathogens involved in the complication of aMPV infection are *Bordetella avium*, *Pausterella*, *E. coli*, *Mycoplasma gallisepticum*, *Chlamydophila*, and *Ornithobacterium rhinotracheale.* The onset of clinical

signs and viral shedding usually begins as soon as 2–4 h postinfection. Different strains of aMPV show tropism for turkeys and chickens; however, other species such as sparrows, gulls, pheasants, wild ducks, and geese can get a subclinical form of infection by aMPV.

Clinical signs of the disease caused by aMPV infection are highly variable depending on species, age, environmental conditions, and secondary infections. However, in general terms, viral replication is limited to the trachea and lungs in both turkeys and chickens. In turkey poults, viral replication is limited to the upper respiratory tract, together with the onset of viremia. The clinical signs shown can be snicking, sneezing, crepitations, ocular and nasal discharge, conjunctivitis, foaming, swollen infraorbital sinuses, submandibular edema, and depression. When aMPV infection is not complicated by a secondary infection, recovery is rapid and can happen after approximately 14 days.[2,3,5,20] However, the risk of airsacculitis, pericarditis, pneumonia, perihepatitis, and increased morbidity and mortality increases significantly when a secondary bacterial infection complicates the initial aMPV infection. While morbidity can reach 100%, mortality of 80% of turkey poults is likely and only 0.5% of adults. In older animals, clinical signs include coughing and shaking head. Egg-laying hens can develop uterine prolapse due to the coughing, and egg production can drop down to 30%, affecting the quality of the egg shells and increase the risk of peritonitis. Mortality of laying hens ranges from 0% to 50%.

Clinical signs in broiler chickens are less characteristic than in turkeys and are often mistaken for infections of the upper respiratory system caused by different viral agents; however, just like in turkeys, a considerably more severe illness develops when a secondary agent, such as infectious bronchitis virus, influenza, *Mycoplasma*, or *E. coli*, complicates the disease. Evidence strongly suggests that aMPV is one of the main causes for SHS in broiler chickens. SHS is characterized by respiratory illness, depression, swollen infraorbital sinuses, unilateral or bilateral periorbital, and facial swelling, which in some cases can involve the whole head. These clinical signs can be followed by cerebral disorientation, torticollis, and opisthotonos. Even though normally the mortality does not exceed 1%–2%, morbidity can reach 10% and egg production is frequently affected. Similarly to turkeys, chicken mortality rate will increase in the presence of a secondary infection.

On histological analysis, macroscopic lesions in turkeys include loss of tracheal cilia, together with watery-to-mucous or purulent exudate. The reproductive tract can show regression of ovary and oviduct, abnormalities of the yolk and albumin, as well as peritonitis. Macroscopic lesions in chickens are less evident and only found in the head, although in cases of SHS, yellow jellylike or purulent edema and swollen periorbital sinuses can be observed. Histological analysis can show severe tracheal and pulmonary inflammation, loss of epithelial architecture, loss of cilia, and inflammatory cell infiltrates, sometimes combined with hemorrhage, lymphocytic infiltrates, and tracheal hyperplasia.[2–5,11,13,20,22,24,37,38]

47.1.3 Diagnosis

Several diseases can display similar signs to aMPV infection, such as Newcastle disease, avian paramyxovirus infection, infectious bronchitis, laryngotracheitis, and avian influenza. For the diagnosis of aMPV from live birds, it is recommended to collect blood samples or oropharyngeal swabs for antigen or antigen-specific antibody detection. aMPV infection is diagnosed by the presence of viral particles, viral nucleic acids from infected tissues, or detection of anti-aMPV antibodies from recovering birds. Sample collection should be done promptly, aiming for the acute phase of the disease, and samples should be collected also from birds without clinical signs, as long as they are part of the same flock. Postmortem examination samples from turbinates, trachea, and lungs should be collected, as well as swabs from infraorbital area and nasal sinuses.[2,3,11]

47.1.3.1 Conventional Techniques

Serology is the most common method for diagnosis of aMPV infection, particularly in nonvaccinated flocks, because aMPV can be difficult to isolate and identify. The most widely used method is enzyme-linked immunosorbent assay (ELISA) because it is a rapid test and its cost is lower than reverse transcription polymerase chain reaction (RT-PCR) or viral isolation.[2] When this test is used from chicken samples, the response is weaker than from turkeys.

The best method for viral isolation is the primary culture of tracheal tissue or embryonated eggs, followed by subsequent passages in cell culture.[2,11] Serial aMPV passages in tracheal and pulmonary primary cultures with further adaptation to Vero cell cultures have proved to be an adequate and sensitive method for aMPV isolation.[6] aMPV isolation using chicken or turkey embryonated eggs is done via the yolk sac. If during the first passage there is no evident infection, the yolk sac is processed and passed onto a second embryonated egg, and then the infection is evident usually after 7–9 days. Usually, several passages are required for aMPV to cause embryonic death; therefore, this method is considered as slow, expensive, and labor intensive.[2,11]

Neutralization assays with monoclonal anti–glycoprotein G antibodies are used to differentiate between subtypes A and B, whereas neutralization assays based on the use polyclonal antisera have shown that subtypes A and B belong within the same serotype.[13] aMPV subtype C is not neutralized by monoclonal antibodies that differentiates between subtypes A and B, and on top of that, it is poorly neutralized by polyclonal antibodies.[15]

47.1.3.2 Molecular Techniques

RT-PCR and real-time RT-PCR[14,39–41] are the most widely used assays for molecular detection of aMPV infection. Among the advantages of these methods are their high sensitivity and their speed. However, one important disadvantage is that viral RNA can be detected only in the initial phase of the disease; thus, 2–10 days postinfection, clinical signs have already appeared and viral detection will be difficult even from the affected birds. Therefore, it is recommended to make

sure that the samples are collected from birds without clinical signs but that are not in the recovery phase either. Usually, the RT-PCR is designed to amplify RNA fragments from the F, M, N, or G genes of aMPV.[11]

Moreover, due to the high similarities between subtypes and the inability of the first RT-PCR to discriminate subtype A from B, a nested RT-PCR is required to amplify a subtype-specific fragment of the gene G.[14,41] Once the target fragment has been amplified, it can be purified and used for sequencing analysis in order to compare different genotypes among subtypes A, B, C, or D.[6]

47.2 METHODS

47.2.1 Sample Collection and Preparation

The diagnosis protocol presented here is aimed to detect aMPV from respiratory tissue samples. This method is based on the amplification of a gene fraction coding for protein G and should be used to discriminate between aMPV subtypes A or B. It is important that tracheal tissue samples are collected at the earliest stages of infection. It is recommended to do postmortem analysis from 10 birds with clinical signs of the disease and 10 birds without signs but from the same flock. In case that the affected flock includes birds of different ages, samples representing each age group should be collected. Make sure that the tissue samples are collected individually with scissors and forceps, place the samples in cryotubes, and store in liquid nitrogen (this protocol is useful when viral isolation is required). Samples can also be stored in containers with dry ice or cooling packs, in case that only molecular analysis is required and the transit to the laboratory is shorter than 24 h. Once in the laboratory, use liquid nitrogen to macerate 0.2 g of sample with mortar and pestle. It is possible to pool tissues from up to five animals per sample (preferentially if the birds presented similar characteristics, age, or clinical signs). Once macerated, tissue samples should be rehydrated using minimum essential media or phosphate buffered saline (PBS) (pH7.4) at a 1:10 w/v ratio. Next, centrifuge the tissue suspension for 20 min at 2000 × *g* at 4°C and use the supernatant for total RNA extraction.

RNA extraction is based on cell lysis (guanidinium thiocyanate buffer), capture in a silica-gel membrane, RNAse inactivation, RNA washes with ethanol, and elution with diethylpyrocarbonate (DEPC) water. According to the RNeasy Mini kit (Qiagen), vortex 200 µL of 10% (w/v) tissue supernatant with 600 µL RLT buffer. Add 800 µL of 70% ethanol and mix well by pipetting. Transfer the sample to a column and centrifuge for 30 s at 8000 × *g* at 4°C. Next, samples are washed three times, first using 700 µL of RW1 buffer, followed by a second wash with 500 µL of RPE buffer, both washing steps include centrifugation for 30 s at 8000 × *g* at 4°C, and for the third wash, add 500 µL of RPE buffer to the column and centrifuge for 2 min at 8000 × *g* at 4°C. Finally, add 30–50 µL of DEPC water to the column for the elution step. This is followed by centrifugation for 1 min at 8000 × *g* at 4°C. The resulting RNA should be kept at −80°C until required. RNA quantification should be performed before starting the RT-PCR, using a spectrophotometer with a wavelength of 260 nm with the criterion of inclusion for the RNA being >1.8 OD_{260}/OD_{280} ratio.

47.2.2 Detection Procedures

As mentioned earlier, duplex nested RT-PCR allows discrimination between two of the most important aMPV subtypes for commercial aviculture (chickens and hens), and it is usually the first method of choice. Once the aMPV subtype has been identified, the following step is to sequence the amplified fragments for molecular epidemiology analysis. Alternatively, a subtype-specific quantitative RT-PCR can be used to determine the viral load from each sample. The following protocol has been modified from previous reports.[14,41]

47.2.2.1 cDNA Synthesis

47.2.2.1.1 Procedure

1. Add each of the components from the succeeding list into a sterile 0.2 mL PCR tube.

Component	Volume/Sample (µL)
Up to 500 ng total RNA	n
Primer G6– (10 pmol/µL)	4
5′-CTGACAAATTGGTCCTGATT-3′	
10 mM deoxynucleotide (dNTP) mix	1
DEPC-treated water	Up to 10

2. Mix gently by pipetting and briefly centrifuge.
3. Incubate the PCR reaction tube at 65°C for 5 min and immediately place on ice for 1 min.
4. Prepare a master mix reaction for cDNA synthesis adding each of the components in the order given.

Component	Volume/Sample (µL)
10× RT buffer	2
25 mM $MgCl_2$	4
0.1 M dithiothreitol (DTT)	2
RNase OUT™ (40 U/µL)	1
SuperScript® III RT (200 U/µL)	1

5. Incubate at 50°C for 50 min, then at 85°C for 5 min, and immediately place on ice.
6. Add 1 µL RNase H and incubate at 37°C for 20 min.
7. The cDNA obtained can be immediately used in PCR or stored at −20°C until required.

47.2.2.2 Duplex Nested Polymerase Chain Reaction Detection of Avian Metapneumovirus A and B Subtypes

Amplification of gene G from aMPV is done in two steps. The first step is to amplify the outer fragment (444 bp). Do not forget to include positive and negative controls (no template control) for each step of the PCR.

1. For the amplification of the outer fragment, add each of the following components into a sterile 0.2 mL PCR tube:

Component	Volume/Sample (μL)
5× Colorless GoTaq PCR buffer (Promega)	5
10 mM dNTP mix	2
Primer G6– (10 pmol/μL)	1.25
Primer G1+ (10 pmol/μL)	1.25
5′-GGGACAAGTATC T/C C/A T/G AT-3′	
GoTaq DNA polymerase	0.5
DEPC-treated water	10
cDNA	5

2. Place the mix tube in a thermocycler, using the following program: 3 min at 94°C; 30 cycles of 1 min at 94°C, 1.5 min at 50°C, 2 min at 72°C; and a final 10 min at 72°C.

Once the first amplification is completed, the second round of PCR will amplify the inner fragments (nested). The amplified fragments of gene G will be of 268 bp for aMPV subtype A and 361 bp for aMPV subtype B.

Prepare a master mix reaction for nested PCR adding each of the components in the order given.

Component	Volume/Sample (μL)
5× Colorless GoTaq PCR buffer (Promega)	5
10 mM dNTP mix	2
Primer G5– (10 pmol/μL)	1.25
5′-CAAAGA A/G CCAATAAGCCCA-3′	
Primer G8+A (10 pmol/μL)	1.25
5’-CACTCACTGTTAGCGTCATA-3’	
Primer G9+B (10 pmol/μL)	1.25
5′-TAGTCCTCAAGCAAGTCCTC-3′	
GoTaq DNA polymerase	0.5
DEPC-treated water	8.75
DNA from the first PCR	5

The program required for the thermocycler is the same as that used for the first PCR.

The amplified products should be analyzed using electrophoresis in 2% agarose gel in tris-acetate (TAE) buffer for 45 min at 80 V. Next, the gel should be stained using Midori Green and visualized using an UV transilluminator. Presence of a band size of approximate 268 bp indicates the presence of aMPV subtype A. Presence of a band size of approximate 361 bp indicates the presence of aMPV subtype B. The presence of two bands in the gel suggests a coinfection by both aMPV subtypes.

47.3 CONCLUSION AND FUTURE PERSPECTIVE

aMPV is an endemic agent in many zones with intensive poultry farming, affecting the most important regions for poultry meat type and egg production (United States, China, Brazil, and the European Union), therefore its economic impact is major. Measures to prevent aMPV infection include vaccination with attenuated and inactivated virus; however, it has been recently observed that some vaccine strains—derived mainly from subtypes A and B—have reverted their virulence, which has raised concerns about poor standards in the viral attenuation process.[42–44] Currently, molecular diagnosis of aMPV allows the detection of vaccine-derived virulent strains. This is done thanks to the partial sequencing of the G gene, which facilitates the detection of changes in nucleotide 6358, thus making possible to discriminate a vaccine derived from a wild-type virus.[44] In the current era of mass gene sequencing, it would be of great benefit if more studies focused on the complete analysis of the aMPV genome. This could facilitate the detection of new variants of the virus and assess any potentially detrimental effect of such variants on poultry industry. Similarly, the analysis of the whole aMPV genome will provide useful information for accurate selection of new vaccine candidates. This information would enhance the current control measures and possibly will lead to the eradication of this important avian disease.

48.1 INTRODUCTION

Bovine respiratory syncytial virus (BRSV) is a major pathogen involved in bovine respiratory disease (BRD), which is one of the disease complexes responsible for severe economic losses in cattle production [1]. Pure BRSV infections alone may cause acute and fatal illness, but coinfections with other respiratory viruses are often diagnosed simultaneously [2] and viral infections commonly precede bacterial colonization of the bovine lung [3]. The prevalence of BRSV is considered high worldwide, even based on direct detection by conventional techniques with moderate sensitivity, or indirect detection by serology, which is hampered by the inhibitory effect of preexisting immunity on humoral responses to infections [4]. However, novel, high-throughput molecular techniques with improved sensitivity provide new means to understand the real direct and indirect impact of this infection on agricultural profits, animal welfare, and the use of antibiotics.

48.1.1 Classification, Morphology, and Genome Organization

BRSV is an enveloped RNA virus classified in the genus *Pneumovirus*, family *Paramyxoviridae*, order *Mononegavirales* [5]. Virions are spherical to filamentous, with a diameter of 100 nm to 1 μm for spherical particles, and a width of 70–190 nm and a length of up to 2 μm for filamentous particles [6]. Its genomic RNA is single stranded, nonsegmented, negative sense, and approximately 15,000 nucleotides long and contains 10 genes that code for 11 proteins. The fusion glycoprotein (F), the membrane glycoprotein (G), and the small hydrophobic protein (SH) are incorporated in the host cell membrane–derived virus envelope, whereas the matrix protein (M) is present under this envelope. Within the virion, a helical nucleocapsid consisting of nucleoproteins (N) encapsidates a virus RNA and mediates interaction with the polymerase consisting of the large protein (L), the phosphoprotein (P), and the polymerase cofactor M2-1. Other proteins are M2-2, which mediates a switch from transcription to RNA replication, and the nonstructural proteins NS1 and NS2, which inhibit viral RNA transcription and replication, as well as host cell immune responses to virus infection through inhibition of and resistance to type 1 interferons [4].

48.1.2 Biology and Epidemiology

Virus assembly and spread occur by budding from the cell membrane, by cell fusion resulting in formation of multinucleated syncytia, and by lysis of cells [7]. The membrane glycoproteins F and G have essential functions in virus attachment and in cell membrane fusion of host cells. Virus–cell fusion likely occurs through an interaction between F and a cell surface receptor called nucleolin [8], and following virus entry into the cell, viral RNA transcription as well as replication takes place in the cytoplasm of the cell. The major target cells for replication are epithelial cells in the respiratory tract and pneumocytes [9,10], though replicating viruses have also been detected in B-lymphocytes within lymph nodes [11].

BRSV exists as a single serotype, and antibody cross reactivity occurs between BRSV, human RSV (HRSV), caprine RSV, and ovine RS virus (RSV) [12]. According to reactions with panels of monoclonal antibodies, BRSV can be divided into antigenic subgroups (A, AB, B, and untyped) [13–15] and sequence data on F, G, and N reveal 5, 6, and 5 distinct phylogenetic subgroups, respectively, with isolates from different time periods and geographical origin [16]. The average amino

acid homology between BRSV strains is 83.3% and 99% for the G and F protein, respectively [16], as compared with 53% and 89% for G and F between HRSV strains, respectively, of different subtypes (A and B) [17]. Bovine RSV and HRSV share 52% and 78% amino acid identity in G and F, respectively [16], and although these viruses do not seem to cross the species barrier naturally, probably due to differences in the F and NS proteins [4], infections have been reproduced experimentally with HRSV in cattle [18]. BRSV is most closely related to the caprine RSV [19], and high seroprevalence to ovine RSV has been reported in cattle, indicating transmission between different ruminants [20].

Clinical disease caused by BRSV is mainly diagnosed in autumn and winter in temperate climate zones [21]. It is unclear which factors favor disease during these periods and whether the virus continues to circulate between animals and herds when it is less frequently detected. It has been suggested that BRSV persistently infect animals between outbreaks, based on repeated outbreaks in herds, and antibody titer increases in the absence of reinfections [22]. Furthermore, viral messenger RNA has been detected in lymph nodes of animals 71 days after infection [11]. Although attempts to detect shedding of reactivated virus following provocation (with cortisol or other infections) have failed, BRSV-specific antibody titers increased also in serum of provoked animals, which suggested low-level virus activation [23]. However, this could presumably also be a result of polyclonal stimulation of BRSV-specific memory B cells through bystander T-cell activation or toll-like receptor engagement [24]. Indeed, sequence data from recurrent outbreaks in the same herds in different years have revealed considerable nucleotide variation, implying that new viral strains were introduced or that latent strains evolve dramatically [25] and consensus sequences of BRSV strains obtained in a herd during one outbreak are identical, even if obtained 2–3 weeks apart [16,25,26].

48.1.3 Clinical Features and Pathogenesis

Infections with BRSV cause clinical signs ranging from transient fever to acute respiratory distress with abdominal dyspnea [22,27]. In animal groups containing many naïve individuals, the morbidity is often close to 100%, whereas the mortality is usually low, but may reach 20%–30% [28,29]. Disease is generally observed in calves between 1 and 6 months of age in areas where the infection is endemic, probably because most older animals are immune and clinically protected [22], although these may shed virus following reinfection [30–32]. Furthermore, high levels of MDA provide at least partial protection in young calves [32–34].

When 13 groups of 1–15-month-old calves with serologically confirmed BRSV infection were investigated for clinical signs of disease, animals in 3 groups showed only mild clinical signs of BRD (increased coughing and nasal discharge), whereas 47% of animals in 10 groups showed abdominal dyspnea, 50% showed abnormal breathing sounds on auscultation, 59% had cough, and 62% had nasal discharge [35]. Pyrexia, lacrimation, tachypnea, and abdominal dyspnea are common clinical signs, whereas subcutaneous emphysema, anorexia, and reluctance to lie down are more occasionally observed—the latter is associated with poor prognosis. Death is generally preceded by strong depression, severe abdominal dyspnea, bradypnea, and cyanosis (unpublished observations including outbreaks described in [16]).

The clinical disease is partly caused by virus destruction of cells in the respiratory tract and partly by detrimental effects of inflammatory responses. Direct immunopathological mechanisms have also been suggested to be involved in the pathogenesis of BRSV, such as excessive immunoglobulin (Ig) complement binding and mast cell activation [36,37]. Bronchiolar obstruction by mucus and cell debris results in atelectasis and emphysema. In parallel, the mucociliary damage and virus-induced alterations of pulmonary immune responses lead to the predisposition of secondary bacterial or mycoplasma infections that can prolong and aggravate the disease [38]. Consequently, necropsy in late stages of respiratory disease often reveal bacterial infections when BRSV is no longer detectable, which illustrates the importance of early diagnosis in BRSV outbreaks [35,39].

48.1.4 Diagnosis

48.1.4.1 Conventional Techniques

48.1.4.1.1 Indirect Laboratory Diagnosis Based on Detection of BRSV-Specific Antibodies

BRSV-specific IgG antibody detection in serum or milk is commonly used for diagnosis of BRSV infection at a herd level, as well as for serosurveillance [40–42]. Since BRSV is endemic in most cattle populations and the seroprevalence consequently is high, the detection of increased antibody titers in paired samples from the same individual is necessary to diagnose a recent infection. When interpreting such data, it should be taken in consideration that animals with high levels of BRSV-specific IgG (actively or passively derived) at the time of infection commonly do not show an increase in antibody titer. In fact, although a weak IgM response is sometimes observed, both mucosal and serum IgG_1, IgG_2, and IgA responses may be completely suppressed [32,43,44]. For serological diagnosis of a recent BRSV infection at a herd level, paired samples for IgG analysis should therefore preferably be obtained from 6- to 7-month-old calves, which have lost their MDA but have likely not been repeatedly infected while being seronegative, which would result in persisting high titers of BRSV-specific IgG. If other animal age groups are targeted, results should be interpreted cautiously. Samples are preferably collected from three to five individuals during the first week after the onset of clinical signs in the herd and again 3–4 weeks later.

The kinetics of BRSV-specific antibodies can be used to date an infection. IgM and IgA antibodies are detected in serum from experimentally infected, previously naïve, colostrum-deprived calves, from day 8 to 14 and day 12 to 29, respectively, after infection [32]. Serum IgG becomes apparent from day 13 to 17 (IgG_1) or day 25 to 90 (IgG_2) and are

detectable for at least 4 months [32,43,45]. Following BRSV infection of calves that have previously been effectively primed with BRSV (by infection or vaccination), strong and rapid memory responses are observed already from day 6 to 8 in serum (IgA, IgG_1, and IgG_2, no IgM) and from day 4 to 11 in respiratory secretions (IgA) [32,44,46,47]. At least in some adult individuals, IgG antibodies may persist in serum and milk for more than 3 years after natural infection, without new reinfections [48]. The duration of humoral responses will depend on the magnitude of the initial antibody response (in turn influenced by preexisting antibodies, such as MDA) and the antibody half-life (26.6 days for IgG_1 [43]), as well as the possible induction of long-lived, antibody-producing plasma cells in the bone marrow and the persistence of antigen in lymph nodes [24].

The antibody kinetics will also depend on the sensitivity and specificity of the diagnostic assay utilized in different laboratories. Indirect antibody ELISAs, based on conventional or molecular techniques, have high sensitivity and specificity in general [49]. When the BRSV antigen in these assays derives from an infected cell lysate (or similarly a lysate of cells infected with a vector virus that expresses a BRSV protein [50]), samples should also be analyzed for antibody binding to antigens based on uninfected cell lysate so that a corrected optical density value ($COD = OD_{\text{BRSV-infected cell lysate}} - OD_{\text{uninfected cell lysate}}$) can be calculated to achieve specific results. Unspecific binding can be circumvented by molecular methods, for example, by using a highly purified RSV protein for coating [51]. However, in both the classic and molecular assays, the sensitivity may be impaired by antibody competition in which the dominating antibody isotype inhibits the detection of other isotypes, specific for the same epitope but present in minority [52]. This does not occur in BRSV capture ELISAs [43], but in such assays the sensitivity may decrease when analyzing samples containing much antibodies of the targeted antibody isotype, of other specificities.

Both the indirect and capture ELISAs detect a repertoire of antibodies with different BRSV epitope specificity, some of which are involved in the protection against BRSV disease. The contribution of different antibodies directed to various viral proteins or epitopes to protection against disease may vary considerably. The classic way to measure the protective efficacy of the total antibody response is to determine the titer of BRSV neutralizing (VN) antibodies, which are induced by both BRSV F and G [50]. However, the correlation between VN titers and the degree of protection against infection was not always consistent, probably because cytotoxic T lymphocytes and mucosal IgA are also important in controlling the viral infection [44,47,53]. Partly because of difficulties to standardize VN assays between laboratories, higher throughput blocking or competitive ELISAs (based on an RSV-neutralizing monoclonal antibody, palivizumab), are complementing, or even largely replacing, the classic HRSV-neutralizing assay in human medicine [54], and an equivalent assay was developed for BRSV [55]. While not being able to distinguish between antibody isotypes, this assay allows detection of BRSV-specific antibodies in samples from any animal species without changing assay components. However, unspecific antibody binding can block the particular epitope for which the assay is specific, by steric hindrance, which decreases specificity.

48.1.4.1.2 Direct Laboratory Diagnosis of BRSV

In contrast to indirect diagnosis, the conventional direct laboratory diagnosis of BRSV is disadvantaged by the short duration of shedding of high titers of the virus. The conventional direct detection of the virus is applicable only during a few days after the onset of clinical signs, whereas the most sensitive molecular techniques permit virus detection during a 2-week period [39,56,57].

Commonly used conventional techniques for direct detection of BRSV are isolation of the virus in tissue culture and immune-based detection of antigens in histological sections or body secretions (immunohistochemistry, antigen ELISAs, or pen-side antigen tests). Virus isolation, which is more used in research than in routine diagnostics today, is time consuming, cannot be automatized, requires expertise for result interpretation, and is dependent on virus viability. The previous extensive use of this technique for diagnosis of BRSV, which is a fragile virus, might have resulted in an underestimation of the frequency of infections in the past [58]. BRSV is preferably primary propagated on bovine embryonic turbinate [57], lung [59], or kidney cells [60] and is most easily isolated from infected respiratory cells obtained by nasopharyngeal brushing, transtracheal aspiration, or bronchoalveolar lavage (BAL) after removal of mucus (by filtering through a gauze) and centrifugation (at 200 × *g* for 10 min) of BAL and aspirate. The cell pellet rather than the supernatant is used for inoculation of tissue culture cells, after cell lysis by freezing in cell culture medium and thawing, since the virus is commonly present in high quantities in cells, or is attached to them, and since respiratory secretions may have a toxic effect on cells *in vitro*. If the sample, nevertheless, appears toxic to the cultured cells, the sample can be diluted or several virus passages can be performed. At first inoculation or after passage, multinucleated giant cells (syncytia) are usually observed in light microscope 3–5 days post infection and are thereafter lysed. Three passages are generally required to declare a sample negative. In addition to using immune staining of cells (e.g., by immunofluorescense), or staining for morphologic inspection of cytopathic effects (such as syncytia or lysed cells), live cultured cells can be imaged during the course of an infection by using dual-labeled hairpin oligonucleotide probes (molecular beacons) specific for BRSV and confocal microscopy [61]. Virus isolation always implies a risk of amplification of coinfections that are better gained by the culture conditions than the actual pathogen.

Immunohistochemistry and antigen ELISAs are widely used for BRSV antigen detection in tissue samples and body fluids [10], but the sensitivity and the specificity of these assays are not so high [62] or depend on the experience of the examiner. Several rapid pen-side antigen test kits for HRSV have been used for BRSV diagnosis in the field [57,63]. The BRSV-detection limit for three of these tests was reported to

be ~156 $TCID_{50}$, resulting in a sensitivity higher than that of a BRSV antigen ELISA but lower than that of a BRSV reverse transcription (RT)-PCR [63]. This is in agreement with previous findings for a similar test (88 PFU) [57]. However, the test accuracy for BRSV may vary considerably between trademarks [64].

48.1.4.2 Molecular Techniques

The introduction of RT-PCR for BRSV RNA detection during the 1990s resulted in dramatic diagnostic improvements [39,57,65]. The real-time RT-PCR, also called RT-quantitative PCR (RT-qPCR), is now probably the most commonly used direct diagnostic technique in routine laboratory diagnosis of this virus. In contrast to the classic, nested, and gel-based RT-PCR, which is labor intensive and consequently expensive, the RT-qPCR is rapid and user friendly, as well as easily standardized, automated, and scaled up to simultaneous analysis of up to 96 samples. The RT and PCR process is often made sequentially in the same reaction tube and only one round of amplification is performed, which decrease labor time and risks for sample cross-contamination. Moreover, no gel-based post-PCR processing is needed.

Several RT-qPCR assays were published for different target genes of BRSV such as F, G, and N [62,66–68]. Some of these assays are commercially available [68], and some are multiplexed for the detection of multiple respiratory viruses [69]. Since the RT-qPCR is based on a more objective detection of amplicons rather than the classic PCR, it can be used to quantify viral RNA in the original sample [46,66]. A range of different systems is available to detect amplicons in real time (e.g., TaqMan®, molecular beacon, CYBR Green, and Primer-Probe energy transfer), all of which generate a fluorogenic signal that can be measured in each cycle and quantified in "real time" by a computer. The TaqMan system is used in a high-speed droplet-real-time PCR, which enables the detection of BRSV in a few minutes, with maintained sensitivity compared to RT-qPCR [70].

48.2 METHODS

48.2.1 Sample Collection and Preparation

For optimal diagnosis of a BRSV outbreak, one or several (preferably three to five) animals with acute clinical signs of BRSV (e.g., fever, tachypnea, and serous nasal discharge for less than 3 days) are selected for sampling. When using direct detection techniques with moderate to high sensitivity, it is possible to make a herd diagnosis by pooling samples from several animals to lower laboratory costs.

Nasal swabs are easily collected from cattle (see Figure 48.1) and are minimally invasive, which limits stress of sick animals and allows repeated samplings on consecutive days for research purposes. When using RT-qPCR analysis on this type of sample, the diagnostic window is at least 4 days (between days 3 and 7 after infection [44]), but can reach 12 days (between days 7 and 19 after infection [56]). Swabs are immediately placed in a commercial virus transport medium (e.g., Virocult®) or 1 mL

FIGURE 48.1 Collection of nasal swab sample from calf for detection of BRSV by RT-qPCR. To avoid stress, which may aggravate hypoxia caused by respiratory disease, the calf is gently fixed by placing its hindquarters into a corner of the pen and by holding the base of its right ear with the sampler's left hand. The calf nozzle is directed upward and the sampler's right wrist is placed on the labial commissure of the calf while taking the sample so that any movement can easily be followed. A sterile, preferably flexible, nasal cotton swab is inserted approximately 5 cm into the nostril, swabbed against the nasal mucosa and then immediately placed in a virus transport medium.

Dulbecco's modified Eagle medium (Lonza, Belgium), supplemented with buffer and antibiotics as described in [46] in addition to 2% fetal calf serum, and stored at +4°C for analysis the same day or at −75°C for later RNA extraction and analysis by RT-qPCR. Though not suitable for animals with severe disease, transtracheal aspiration or BAL (obtained through a fiber-optic bronchoscope after sedation) can be performed with sterile saline as described earlier [71,72], and infected cells are recovered and stored at −75°C (in RNase inactivating solution or lysis buffer for PCR analysis, or in cell culture medium for virus isolation). Alternatively, postmortem samples can be collected by swabbing lung tissue from a densified lobe or by performing BAL through the trachea, with up to 500 mL PBS or cell culture medium. Besides virus isolation or PCR, antibody staining may be performed on such respiratory secretions after cytospin, on frozen cryosections of fresh lungs, or on sections of tissue fixed in 10% buffered formalin and after pretreatment, as described previously [11].

BRSV RNA may be extracted in different ways prior to RT-qPCR. The classic way, which is effective and which minimize any cross-contamination of samples, is to use phenol/guanidinium isothiocyanate and chloroform for cell solubilization, protein denaturation, and separation of RNA from proteins and DNA. Briefly, for each specimen, 250 µL sample material (e.g., nasal swab transport medium or lung tissue homogenate in equal amounts of PBS [w/v]) is mixed with

750 µL lysis buffer (e.g., TRIzol Reagent, Invitrogen/Life Technologies) and incubated for 5 min at room temperature (RT°C). Thereafter, 200 µL chloroform is added and then the sample is mixed, incubated for 2 min at RT°C, and centrifuged at 13,900 × *g* and 4°C for 15 min. The aqueous phase is then transferred to a new tube containing 500 µL isopropanol and incubated overnight at –20°C. After centrifugation at 9,070 × *g* and 4°C for 15 min, the isopropanol is removed and the RNA pellet washed with –20°C 1 mL of 80% ethanol. After an additional centrifugation at 13,900 × *g* and 4°C for 5 min, the ethanol is next removed and the RNA pellet is left to air-dry at RT°C for at least 1 h. The RNA is thereafter dissolved in 30 µL of diethylpyrocarbonate (DEPC)-treated water, preferably stored at –75°C and handled on wet ice. Another, quicker alternative is to use an RNA extraction kit, according to the manufacturer's instructions. It may then be suggested to discard fluids after centrifugation by pipetting, instead of pouring, and to open tubes with tube openers (e.g., USASI1400-1008, VWR, one tool per sample) instead of fingers. Extraction robots have also been used with success to study the kinetics of virus shedding after experimental challenge.

48.2.2 Detection Procedure

The RT-qPCR protocol detailed in the following has been modified from previous publications [44,46,47,62]:

1. Dilute primers and probes (designed as detailed in Table 48.1) in DEPC-treated water into stocks (100 µM for primers and probes) and working solutions (10 µM for primers and 5 µM for probes). Aliquot and store at –20°C.
2. Store Moloney murine leukemia virus reverse transcriptase enzyme at –75°C. Do not thaw this enzyme, but pipette it slowly when viscous and then immediately put it back at –75°C. Use a kit (e.g., iScript™ One-Step RT-PCR Kit for Probes, Bio-Rad Laboratories, or equivalent) and proceed as described in Table 48.2, or add separate ingredients to a reaction mix, as detailed previously [62].
3. Vortex all reagents, including RNA, and rapidly spin them in a microcentrifuge before pipetting into qPCR reaction tubes kept on wet ice. Protect the probe from light at all steps. When pipetting, avoid adding air bubbles in the reaction mix. Include several negative (in which RNA is replaced with DEPC-treated water) and positive (containing quantified plasmids or RNA extracted from different dilutions of BRSV infected cell lysate) control samples in each run. Use lids to close reaction tubes before analysis.
4. Place the reaction tubes in a thermal cycler, programmed as described in Table 48.3.

TABLE 48.1
TaqMan RT-qPCR System Specific for the BRSV F Gene, Generating Products of 85 Base Pairs

Type	Sequence (5′–3′)

48.3 CONCLUSION AND FUTURE PERSPECTIVES

A range of sensitive techniques are now available for BRSV diagnosis, *in vivo* or *postmortem*, and the key to successful detection remains the selection of animals to be sampled. An increasingly available and successively cheaper novel technology brings new perspectives: high-throughput sequencing and new generation vaccines will probably influence the way of controlling and understanding BRSV. Deep sequencing will enable virus tracing during epidemics to identify routes of transmission between herds and consequently to develop appropriate biosecurity measures.

Research on virus persistence will clarify whether some animals reexcrete BRSV following a primary infection, and research on virulence factors might come to explain the varying degree of disease severity in different BRSV outbreaks. Furthermore, high-throughput sequencing, proteomics, and the development of multiplex, broad diagnostic tests will aid in the detection of unknown respiratory pathogens and coinfections involved in BRD, as well as in the mapping of protective immune effectors. Such results will guide the development of new medical measures of pathogen control.

Currently, novel differentiation of infected from vaccinated animals (DIVA) vaccines, in which one or several virus proteins are omitted and used for serological diagnosis, are under development. These can potentially be used to protect naïve animals (e.g., in control programs currently discussed in Scandinavian countries) and allow serological monitoring of virus spread, vaccine safety, and efficacy (e.g., duration of protection) under field conditions. DIVA ELISAs will have to be developed and evaluated for the detection of antibodies directed against omitted virus proteins in vaccine preparations used to immunize animals. These tests will probably be used to indicate unsatisfactory virological protection at the population level, due to lack of vaccine efficacy, short duration of vaccine-induced protection, or antigenic drift due to evolution of circulating BRSV strains.

49.1 INTRODUCTION

49.1.1 Classification

Canine distemper virus (CDV) is a member of the order *Mononegavirales*, family *Paramyxoviridae*, subfamily *Paramyxovirinae*, and genus *Morbillivirus*. It is closely related to viruses responsible for measles in humans, rinderpest (now extinct) in cattle, peste des petits ruminants in small ruminants, phocine distemper in seals, and cetacean morbilliviruses in dolphins, porpoises, and whales.[1–3]

49.1.2 Genome Organization, Biology, and Epidemiology

CDV is an enveloped virus with a single-stranded, negative-sense RNA genome, 15,690 nucleotides long. The genomic RNA is enclosed by a helical nucleocapsid composed of the nucleocapsid (N) protein and is replicated by the viral polymerase (L) protein and its cofactor phosphoprotein (P). The P gene also encodes two nonstructural proteins (C and V). The N, P, and L proteins together with the viral RNA constitute the ribonucleoprotein (RNP) complex, which directs the synthesis of capped and polyadenylated mRNAs.[4] The viral envelope contains two glycoproteins, the fusion (F) and hemagglutinin (H) proteins, and a membrane-associated protein (matrix [M]), which links the envelope with the RNP. The H protein facilitates viral attachment to receptors on the host cell and is therefore the major determinant of viral tropism.[4] Neutralizing antibodies produced against H gene epitopes are important for protective immunity by preventing viral attachment to host cells. The F protein executes the fusion of the host cell plasma membrane and the viral envelope, resulting in entry of the viral RNP into the cytoplasm. The F protein also promotes fusion between host cell membranes[4,5]; however, experiments with recombinant viruses suggest that it is the H protein, not the F protein, that is actually the main determinant of fusion efficiency and, therefore, the cytopathogenicity determinant at least in vitro.[4]

Of all the proteins encoded by CDV, the H protein has the most variability.[4] In fact, compared to other morbilliviruses, the H protein of CDV has the greatest variability. This results in a very broad host range, which is not seen with other morbilliviruses. CDV infects several mammalian species in the order *Carnivora*, including members of the families *Canidae* (dog, fox, coyote, wolf), *Mustelidae* (ferret, badger, mink, weasel, otter, fisher), *Mephitidae* (skunk), *Procyonidae* (raccoon), Felidae (lion, tiger), *Ailuridae* (red panda), *Hyaenidae* (hyena), *Phocidae* (seal), *Ursidae* (bear), and *Viverridae* (palm civet, genets).[1,5–7] The virus also causes disease in noncarnivores, including collared peccaries (*Tayassu tajacu*)[8] and macaques (*Macaca*).[9,10]

Like other enveloped viruses, CDV is quickly inactivated in the environment, and routine disinfectants and cleaning readily abolish virus infectivity. Transmission mainly occurs by direct contact or via exposure to infectious aerosols. The virus is shed primarily by oronasal secretion, but the virus can be detected at high titers from all secretions and excretions, including urine.[1,5]

Transmission of CDV between different species has resulted in devastating epidemics. Domestic dogs have been implicated in the epidemic that led to the death of 20% of the Serengeti and Mara lions in the 1990s.[11] Terrestrial carnivores are thought to be the source of the CDV strain that killed thousands of Caspian seals (*Pusa caspica*) between 1997 and 2001,[12] and raccoons have been implicated in the transmission of CDV to animals in zoo collections and conservation parks.[7] CDV is considered a disease of global importance in both common and endangered carnivores.[13] CDV contributed to the endangerment of the North American black-footed ferret[14] and is an emerging disease in the endangered wild Amur tigers in the Russian Far East.[13]

Temporal fluctuations in disease prevalence have been observed, with increased frequency during the cold season. Dogs of any age are susceptible, but an age-related susceptibility to infection is evident because many adult dogs are protected by vaccine immunization. Disease tends to be more common in dogs 3–6 months old, correlating with the decline in maternally derived immunity during this period.[5] The infectious disease presents worldwide distribution and maintains a high incidence and high levels of lethality, with no specific treatment. Though intensive vaccination programs in developed countries have controlled the virus, there have been reports of increased activity of CDV worldwide.[6,15–20]

The use of molecular techniques facilitates in-depth study of CDV epidemiology and the dynamics of circulation of various CDV strains around the world in susceptible animals. The genetic diversity of the H gene allows identification of distinct genotypes, which cluster according to geographic patterns, irrespective of the species of origin.[5] These lineages have been defined based on the regions where they have been detected and include Asia-1, Asia-2, Europe, European Wildlife, Arctic-like, and Africa.[15,17–19,21] There have only been two (North) American lineages clearly defined, including America-1, which includes strains used in vaccine production in the 1950s and still in use today, and America-2. However, we recently sequenced CDV positive samples from the United States from 2010 to 2014, and based on our phylogenetic evaluation with previously identified strains from the United States, there appear to be at least four different "North American" genotypes currently circulating in the United States, including a new genotype of CDV we discovered circulating in the Southeast United States.[20] Recent reports suggest multiple genotypes are also circulating in South America, including two newly defined "South American" genotypes, designated South America-2[22] and South America-3.[19] The European lineage is also circulating in South America (including Brazil and Uruguay), resulting in a proposal to change the lineage name from Europe to Europe/South America-1.[19,22]

Some CDV strains seem to be more virulent or are associated with different tropism, but this relies on individual variations among the various strains rather than on peculiar properties inherent to a given CDV lineage.[5] Another research suggests that differences in neurovirulence are related to disease duration rather than strain variability.[23] Despite the presence of multiple genotypes, CDV is currently considered a single serotype, as defined by polyclonal antisera.[2,5] The greatest genetic and antigenic diversity is between the vaccine strains (America-1 lineage) and the other CDV lineages (approximately 10% amino acid variability for H protein). Sera raised against field CDV isolates may have neutralizing titers up to 10-fold higher against the homologous virus than against vaccine strains. Although it is unlikely that such antigenic variation may affect the protection induced by vaccine immunization, there have been several reports of vaccine failures in multiple countries, including Japan,[24] Mexico,[25] Argentina,[26] the United States,[16] and Spain.[27] Many have questioned the efficacy of the vaccines against currently circulating field strains. It is possible that critical amino acid substitutions in key epitopes of the H protein may allow escape, particularly from the limited antibody repertoire of maternal origin of young unvaccinated pups, increasing the risk for infection by field CDV strains.[5] However, there has been no research published to date that definitively proves that the currently available vaccines are not protective.

49.1.3 Clinical Features and Pathogenesis

CDV infection produces a systemic disease. The incubation period may range from 1 to 4 weeks or more. Following aerosol infection, the virus replicates in macrophages and lymphocytes of the upper respiratory tract, with subsequent infection of local lymphoid tissues, including the tonsils. This leads to the dissemination of the virus by the lymphatics and blood to distant hematopoietic tissues and the onset of lymphopenia. This initial viremia results in clinical signs that may include fever, lethargy, anorexia, ocular and nasal discharge, and tonsillitis. The virus then infects all the lymphoid tissues including lymph nodes, spleen, thymus, mucosa-associated lymphoid tissues (MALTs), and bone marrow, resulting in severe immunosuppression. A robust antiviral immune response, particularly production of detectable antibodies to the viral glycoproteins,[28] may enable the infected animal to eliminate the virus at this point in the infection, but in animals with a weak response, a secondary viremia follows and is associated with a high fever and infection of epithelial cells of multiple organs throughout the body. CDV can be detected in cells of the respiratory system, gastrointestinal and urinary tract, endocrine system, lymphoid tissues, central nervous system, and vasculature including thrombocytes and different lymphoid cell subsets, as well as keratinocytes of the skin. Morbilliviruses are highly cell associated, but massive amounts of virus are released as cells succumb to infection; this is particularly true of lung or bladder epithelia.[6,29,30] Clinical signs relate to areas of virus replication and can include gastrointestinal signs (vomiting and diarrhea) and/or respiratory signs that may be complicated by secondary bacterial infection (purulent nasal discharge, coughing, dyspnea, pneumonia). Secondary bacterial infections are common as a result of the immunosuppression caused by the virus. Dogs may also display ocular disease, enamel hypoplasia, or cutaneous lesions, such as a pustular dermatitis of the inner thighs, ventral abdomen, and inner surface of the ear

pinnae or hyperkeratosis of the foot pads and nose. The initial clinical signs disappear, but the virus persists for extended periods in the uvea, neurons, or urothelium and in some skin areas (foot pads).[5]

Disease may progress to neurologic signs. Some dogs develop acute demyelinating lesions with CNS involvement occurring parallel to systemic disease and succumb to encephalitis early (within 2–4 weeks of infection). Some have subacute to chronic demyelinating encephalitis, with CNS signs appearing weeks to months following systemic signs, or even occurring without any previous history of systemic signs.[28] Once in the CNS, CDV can invade multiple cells, resulting in acute or chronic demyelination. Perivascular cuffing with lymphocytes, plasma cells, and monocytes in the demyelinated areas may be present in chronic cases. Both white and gray matter may be affected. A rare outcome of CDV infection is chronic encephalomyelitis of older dogs, termed "old dog encephalitis,"[5] but this manifestation has not been well defined. Most infected dogs have CNS involvement, but only about 30% of dogs (those with low or no antibody response) exhibit neurological signs.[23,27] Typical signs include myoclonus of the temporal and forelimb muscles and chewing-gum movements of the mouth or may include circling, head tilt, nystagmus, paresis or paralysis, seizures, and dementia/behavioral changes. CNS disease is typically progressive (i.e., cerebellar or vestibular signs progressing to tetraparesis or paralysis) and many dogs die. Some dogs may recover but likely display lifelong persistent residual signs such as myoclonus.[5,27,30,31] There have also been recent reports of unusual acute neurological signs as a result of CDV infection in vaccinated adult dogs. Signs include acute or peracute onset of cerebellar and/or vestibular signs and tetraparesis/plegia in the absence of systemic signs, with progression to severe generalized seizures that were unresponsive to anticonvulsant therapy.[27] In a separate study, demyelinating lesions were a constant finding and chronic encephalomyelitis was predominant in mature dogs with distemper encephalomyelitis that presented exclusively with neurological disease.[31] CDV should always be considered as an important differential diagnosis in dogs with progressive and multifocal neurological disease, even when the typical CDV systemic signs are not present, particularly in areas where the virus is endemic.[31]

49.1.4 Diagnosis

49.1.4.1 Conventional Techniques

A practical diagnosis of distemper is based on multiple systemic clinical signs (respiratory, gastrointestinal, neurological, or dermatological); however, dogs may lack the classical clinical presentation and/or signs may be confounded with other respiratory or enteric diseases. Therefore, laboratory confirmation is required for suspected cases.[31,32] Some antemortem clinical information is useful, such as the presence of lymphopenia and viral inclusions in white blood cells. Predominant lymphocytic pleocytosis in the CSF (>5 cells/μL) may suggest the diagnosis of CDV infection, but not all dogs infected with CDV will have changes in CSF, and none of these clinical findings are definitive.[33,34] Conclusive diagnosis can be difficult due to the unpredictable and variable course of distemper, for example, length of viremia, organ manifestation, and a lack of or delayed humoral and cellular immune responses.[35] There are multiple methods for detection in addition to molecular methods, and understanding what the tests detect and how they can be used are important for appropriate application for CDV diagnosis. Summaries of serological tests (Table 49.1) and virus detection methods (Table 49.2) are provided.

TABLE 49.1
Serological Tests for Canine Distemper Virus

Test	Sample Type	Limitations	Significance	Comments
IgM titer	Serum	Low or absent very early in infection	Signifies recent exposure	Does not differentiate between recent vaccine exposure and infection
Serum neutralization (SN)	Serum	Low or absent early in infection	Measures functional antibodies, including maternally derived antibodies	Results may vary depending on strain used in testing; single test does not differentiate vaccine response from infection
CSF IgG	CSF and serum recommended	Testing CSF alone may misdiagnose CDV	Measures local production of IgG in CNS as a result of CDV encephalitis	Must insure intact BBB and no blood contamination of CSF sample
Indirect immunofluorescence antibody assay (IFA)	Serum	May be negative early in infection; subjectivity in assay variability between labs	Measures all CDV specific antibodies, not just neutralizing ones	May be more sensitive than SN, but as with SN, single test cannot differentiate vaccine response from infection
ELISA (TiterCHEK)	Serum	Commercially available test used mainly for detection of protective titers from vaccination	Promoted for detection of protective antibody titer; may be negative in acute infection	Protective titers not well defined in the literature

TABLE 49.2
Detection Methods for Canine Distemper Virus

Test	Sample Type	Limitations	Significance
Virus isolation	Whole blood (EDTA), tissues, and swabs	Vero/SLAM cells have made efficient isolation possible, but it is limited to research or some diagnostic labs; requires special sample handling to maintain virus viability	Isolated virus is viable; if virus detected in antemortem sample, suggests animal is contagious
Direct immunofluorescence antibody assay (IFA)	Slide made from swabs and tissues	Poor sensitivity, particularly with mucosal samples taken 3 weeks or more postinfection	Positive result is conclusive, but many false negatives occur; some subjectivity with test evaluation and variation between labs
Immunochromatography	Conjunctival swab	Commercially available; not as sensitive as molecular detection	Can be used patient side; false-negative results may occur
Immunohistochemistry	Formalin-fixed paraffin-embedded tissues	Mainly for postmortem testing	Confirms pathological lesions are associated with CDV
Molecular detection of CDV RNA	Whole blood (EDTA), swabs, tissues, urine, and feces	Limited to research and diagnostic labs but is the most sensitive method for virus detection	Detects RNA; virus does not have to be viable for detection

Detection of CDV IgM antibodies is reliable for the identification of recent CDV infection or exposure. It is important to note that an IgM response will also be detected within a week after vaccination and persists for at least a month, whereas IgM titers persist for at least 3 months following natural infection.[36]

The determination of CDV neutralizing antibodies (serum neutralization [SN] assay) in serum or CSF may be helpful in some animals, but the results are variable and depend on the stage of the disease. Titers will be low or absent during the acute phase of the infection. In addition, a positive titer may be the result of a vaccine-induced immune response or the presence of maternally derived antibodies. The neutralization assay measures only the functional antibodies that bind to CDV hemagglutinin or fusion protein and interfere with virus uptake[37]; however, neutralizing activity against the America-1 lineage Onderstepoort strain, which is commonly used in these assays, may not correspond to neutralizing activity against field isolates and, therefore, may not accurately reflect the titer or protection.[35]

Additional serological tests to detect CDV-specific antibodies include ELISA and indirect immunofluorescence antibody assay (IFA).[38] IFA and whole virus ELISA measure not only functional antibodies but all CDV-specific antibodies. The ELISA method has been shown to be more sensitive than the SN assay, but as with the SN assay, a single test cannot discriminate a vaccine titer from a titer resulting from infection.[5,38] Serologic methods, including a commercially available ELISA, are routinely used and marketed to detect "protective" antibody titers in previously vaccinated dogs.[39]

Detection of immunoglobulin G (IgG) in CSF is an additional serological method that is used to diagnose canine distemper encephalitis (CDE). Local antibody responses to CDV occur in the CNS in cases of persistent infection. Transfer of blood proteins, including IgG antibodies, is limited by the blood–brain barrier (BBB) to maintain homeostasis. Therefore, the amount of IgG in CSF is 1/256 to 1/2048 of that in serum in subjects with a normal BBB. CDV antibody titer in serum and CSF should be simultaneously examined for an accurate diagnosis of CDE by confirming local antibody production in the CNS. However, this ratio can be misleading if there is a nonspecific collapse of the BBB or an excess blood mixed with the CSF during sampling, which can result in misdiagnosis. Therefore, it is recommended that a reference antibody test (canine parvovirus or adenovirus) also be performed on the CSF sample to facilitate a more accurate diagnosis.[40] An increase in CDV IgG in the CSF, in the absence of IgG titers to parvovirus or adenovirus in the CSF, confirms a diagnosis of CDV encephalitis.

Other methods used to diagnose CDV involve detection of the virus itself. These methods include virus isolation, CDV antigen detection by an IFA, immunochromatography or immunohistochemistry, and molecular methods to detect CDV RNA. Virus isolation can best be made from buffy coat cells during the early phase of infection or from suspensions from macerated tissues (postmortem). This method involves cocultivation with mitogen-stimulated canine blood lymphocytes or the use of a marmoset lymphoid cell line, B95a.[1] Historically, this was an inefficient method because field strains do not replicate well in vitro and virus adaptation to cell culture is very time-consuming. However, with the engineering of Vero cells that express the canine signaling lymphocyte activation molecule (SLAM), which is the lymphotropic receptor (expressed on activated T and B cells, monocytes, and dendritic cells) used for viral attachment, efficient isolation of field strains is now possible.[41] CDV replication in cells usually induces formation of giant cells (syncytia) with intracytoplasmic and intranuclear eosinophilic inclusion bodies, both in vitro and in vivo (Figure 49.1).[5] Samples must be handled properly to maintain virus viability for isolation (kept cool and moist), and this can be difficult with an enveloped virus like CDV.

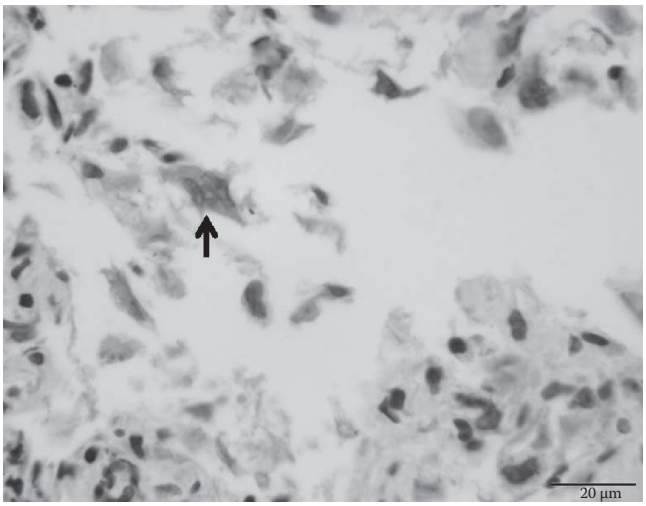

FIGURE 49.1 Raccoon, lung, H&E: multinucleated syncytial cell with eosinophilic intracytoplasmic inclusion body within alveoli (arrow). (Photo courtesy of Dr. Jenny Payette Pope, Department of Biomedical and Diagnostic Sciences, College of Veterinary Medicine, University of Tennessee, Knoxville, TN.)

IFA on conjunctival, nasal, and vaginal smears that are incubated with polyclonal or monoclonal anti-CDV antibodies marked with fluorescein has been widely used for virus detection. However, this method lacks sensitivity, particularly in subacute or chronic forms of the disease. For antemortem diagnosis, this method works best within the first 3 weeks after infection, when the virus is still present in epithelial cells associated with the mucous membranes.[5,38]

Immunohistochemistry represents a highly sensitive and specific method for the detection of CDV antigen in tissue obtained postmortem. In chronic CDV encephalomyelitis, viral antigen may disappear from the inflammatory demyelinating lesions due to the antiviral immune responses, and false-negative results have been reported.[31] This method is suitable only within limits for the diagnosis of distemper in living animals (i.e., from biopsy samples).[35]

In 2008, an immunochromatography rapid test was developed.[42] This commercially available test (Anigen Rapid CDV Ag Test Kit, Animal Genetics, Suwon, Korea) is fast and user-friendly but is not as sensitive for CDV diagnosis as molecular assays.[34]

49.1.4.2 Molecular Techniques

Use of a rapid detection method is desirable to properly manage CDV infection because of the contagious nature and the high mortality rates associated with this disease. The assay should not only be rapid, but it should be sensitive and specific as well to detect even small amounts of virus early in infection.[32] The sensitivity, specificity, and rapidity of molecular methods compared with conventional methods make molecular techniques preferable for CDV diagnosis.[32]

Molecular techniques are very sensitive, but sensitivity varies with sample source, viral nucleic acid extraction method, molecular platform (i.e., reverse transcription polymerase chain reaction [RT-PCR] vs. nested RT-PCR vs. real-time RT-PCR), and choice of primers. Additionally, endogenous RNases and lack of accessibility of partially degraded RNA may influence the sensitivity of RT-PCR.[35]

Multiple assay platforms have been developed for CDV RNA detection. Several RT-PCR protocols were originally developed.[26,35,43] Nested RT-PCR protocols followed and were developed to increase sensitivity because detection of CDV with the RT-PCR was not satisfactory during the first and end stages of the infection[16,38,44,45]; however, nested PCR is inherently prone to contamination and time-consuming. More recently, real-time RT-PCR protocols have been published.[32,34] Real-time assays are faster and less prone to contamination, while maintaining the sensitivity or even increasing the sensitivity obtainable by nested protocols. Another major advantage of real-time RT-PCR is the ability to quantitate the viral load in clinical specimens, whereas conventional RT-PCR allows only qualitative analysis. This makes the real-time assay useful for pathogenesis studies.[32] Various ways these molecular assays are used for CDV diagnosis are described in the following section.

49.2 METHODS

49.2.1 Sample Preparation

Suitable samples for the molecular detection of CDV RNA include serum, whole blood, CSF, urine, saliva, nasal samples, rectal swabs, and conjunctival swabs.[22,32,35,43] Some studies suggest that all these sample types are useful, irrespective of the clinical form of the disease.[35,43] Other studies suggest that this is not actually the case and relate stage of infection to variation in the best sample type.[34,45] Conjunctival swabs have been determined to be the best sample for diagnosis of acute CDV in experimentally infected dogs, compared to blood, CSF, nasal irrigation solution, and urine,[45] whereas urine samples have been found to be more sensitive than serum or leukocytes and at least as sensitive, if not more sensitive, as CSF for detection of CDV RNA in dogs with neurological signs.[31,45] In a recent report of CDV-induced acute onset of neurological signs in adult dogs, RT-PCR on CSF was negative in two out of four cases.[27] Lack of amplification of CDV in the CSF does not exclude distemper, because CDV is not always present in the CSF, even when distemper encephalitis is confirmed by immunohistochemistry.[35] Urine is much easier to collect than CSF and has been demonstrated to be a suitable sample type in our laboratory as well.

We suggest the most logical approach to best sample selection involves determination of the stage of infection. We recommend whole blood during febrile periods (presence of viremia), nasal and conjunctival (for conjunctivitis) swabs for acute infection in dogs displaying respiratory signs, and rectal swabs or feces for dogs showing gastrointestinal signs. Urine is our specimen of choice for dogs with neurologic signs. It is important to note that of these sample types, urine has been associated the most with PCR inhibition (second only to formalin-fixed paraffin-embedded tissue)[46] and an extraction procedure approved for urine should be used to ensure removal of inhibitors. We routinely use the QIAamp

Viral RNA Mini Kit (Qiagen). Extraction protocols specific for swabs are also available. Some protocols are marketed for the extraction of DNA from swabs, but we have found that one of these protocols works very well for the extraction of CDV RNA (buccal swab protocol, QIAamp DNA Mini Kit, Qiagen). Two swabs can be processed together in the same tube. Tissues useful for postmortem detection include lymphatic (i.e., lymph nodes, spleen, tonsil), renal pelvis, bladder, lung, and brain tissues. Minced tissues can be mixed 1:1 with phosphate-buffered saline and macerated. Supernatant can then be used for extraction with a protocol for blood. Additionally, extraction protocols for small pieces of tissue also exist. There are numerous extraction kits, protocols, and methods. The most important thing to do is to ensure that whatever method is used, it consistently produces efficient quality and quantities of RNA for amplification.

49.2.2 Detection Procedures

49.2.2.1 Methods for Detection

The preferable molecular method for rapid and sensitive detection of CDV is real-time RT-PCR, which targets a conserved region of the genome. Lineages, while identified most commonly in areas where they are originally detected, can also be detected in distant areas[47] as a result of trade and global movement of animals.[48] Therefore, the use of a conserved region of the genome is necessary for adequate detection of different strains from around the world. The N gene has been used for primer production for most published assays because it has areas of high conservation[49]; however, considering that CDV is an RNA virus (lacks proofreading during replication), silent mutations do commonly occur. These changes are not limited only to highly variable regions such as the H gene but occur in the N gene as well, including the middle region that is considered the most conserved area.[49]

We routinely use a published real-time RT-PCR assay that detects the N gene in our lab.[32] Primers and probe for this assay are included in Table 49.3. Briefly, the SuperScript III Platinum One-Step qRT-PCR Kit (Invitrogen, Life Technologies, Grand Island, NY, USA) is used with 300 nM of each primer and 200 nM of probe in a 25 μL total volume reaction with 5 μL RNA. Amplification is carried out with an initial RT step of 42°C for 30 min, followed by 95°C for 2 min and 45 cycles of 95°C for 15 s, 48°C for 1 min, and 60°C for 1 min. This assay successfully detected several strains that are currently circulating in the United States,[20] and the assay was originally validated with clinical samples from dogs in Italy, but the samples were not genotyped.[32] It is important to note that this assay failed to detect several Brazilian strains, which was thought to be the result of point mutations that were detected in the primer binding regions.[34]

Mutations in primer and probe binding regions may not necessarily inhibit detection (depending on where the mutations occur), but they will certainly affect the threshold cycle (Ct) value of a real-time RT-PCR assay. The Ct value is routinely used to correlate the significance of the positive result to clinical signs and also to distinguish modified live virus (MLV) vaccine shedding from true infection (see methods to determine vaccine shedding).

While real-time RT-PCR may be a preferred method, it does require expensive equipment and highly trained personnel, limiting the assay to diagnostic and research laboratories. Recently, we evaluated an RT-insulated isothermal (ii) PCR-based method to detect CDV. This platform is marketed for affordable, point-of-care molecular detection of CDV. The method uses a convective PCR platform, which uses natural thermal convection to drive PCR by providing a constant heat source at the bottom of the reaction tube. A temperature gradient is created through which the liquid is cycled, driving the PCR. This method provides natural flexibility in the annealing temperature and lessens the effect of base–pair mismatches on primer binding. RT-iiPCR is a useful technique for RNA viruses that commonly contain sequence variation between strains. However, due to concerns associated with specificity, this particular platform also incorporates a TaqMan-based probe in the reaction to increase test specificity. This specific assay was found to be just as sensitive and specific as a published real-time RT-PCR method for the detection of U.S. strains, while potentially having the added benefit of detecting a wider range of geographic lineages.[50] Additional testing with more lineages would confirm this.

An additional molecular method that has the benefit of use without the need for specialized equipment is RT loop-mediated

isothermal amplification (RT-LAMP). RT-LAMP is an autocycling strand displacement DNA synthesis carried out using a reverse transcriptase and a DNA polymerase (Bst DNA polymerase) with a high strand displacement activity. A set of specific primers that can recognize a total of six distinct sequences in the target cDNA are used; thus, the technique amplifies the target cDNA sequence with a high selectivity and the reaction can be performed with just a water bath. The method described for CDV in the literature was developed with primers based on the N gene sequence from the America-1 lineage Onderstepoort strain.[51] The assay was tested with clinical whole blood samples from dogs in Korea, but it is unknown how well the assay works with all the various genotypes.

49.2.2.2 Methods for Genetic Lineage Typing

While the N gene has been the target of choice for CDV detection, the variable H gene is commonly used to genotype CDV strains.[15,48,52–54] Another area that is useful for genotyping is the M-F intergenic region, which also contains high variability between strains.[20,55] Several different molecular methods have been published for genetic lineage typing for epidemiological studies, including RT-PCRs with sequencing,[15,54] heminested protocols with genotype specific probes,[48] and real-time RT-PCR with sequencing.[20] For our method,[20] 5 μL RNA samples are run in 25 μL total volume reactions using a commercially available master mix for real-time RT-PCR (SuperScript III Platinum One-Step qRT-PCR Kit, Invitrogen, Life Technologies, Grand Island, NY, USA). The optimized mix contains 200 μM deoxyribonucleotide triphosphates, 3 mM $MgCl_2$, 200 nM of the 6-carboxyfluorescein (FAM)-labeled probe, and 300 nM of each primer (Table 49.3). One unit of RNase inhibitor (RNaseOUT, Invitrogen, Life Technologies, Grand Island, NY, USA) is also added to the mix. Samples are amplified in a real-time PCR machine with an RT step at 50°C for 30 min and activation step for the Hot Start Taq Polymerase at 95°C for 10 s, followed by 45 cycles of denaturation at 95°C for 5 s, annealing at 48°C for 1 min, and elongation at 60°C for 1 min. The probe detects America-1 vaccine strains (additional methods described in Section 49.2.2.3); wild-type strains can be detected by running the sample on a gel. The real-time PCR products can be sequenced for genotyping.[20]

49.2.2.3 Methods to Distinguish Vaccine Shedding from True Infection

Many of the methods used for genotyping can also be used for differentiation of America-1 lineage vaccine strains from field strains. All the currently used MLV vaccines contain an America-1 strain except one,[52] which contains a Rockborn-like strain[56] and resembles the more contemporary field strains. False-positive results may occur with the molecular detection methods by amplification of MLV vaccine shedding.[20,38,43] Vaccine virus may be detected from day 2 post-vaccination up to day 14 in multiple sample types, including PBMCs, ocular discharge, nasal discharge, saliva, feces, and urine.[44] There is a recombinant pox-vectored vaccine containing H and F genes from an America-1 lineage strain that is available for CDV that is not shed by the vaccinate,[57] but it is more costly than MLV vaccines and not as widely used.[20] Differentiation tests are designed to take advantage of the sequence differences between the vaccine strains and wild-type strains.[58] Most of the assays used for differentiation are gel-based and use restriction fragment length polymorphism (RFLP).[26,53,59] Another assay uses separate primers for differentiation.[54] Most of these assays are a single RT-PCR and lack the necessary sensitivity for differentiation during acute stages of infection. This is particularly problematic for certain situations, such as outbreaks in shelter populations that are routinely vaccinated on intake.[20,60] A commercial laboratory has developed a quantitative RT-PCR (CDV Quant RealPCR™ Test, IDEXX) for differentiation. This quantitative information allows discrimination of vaccine interference from infection with a wild-type strain of distemper virus as the amount of virus present during infection is typically exponentially more than would be detected because of recent vaccination. This method cannot distinguish between the two when virus shedding is low (less than 1 million particles), which may occur during acute infection. Therefore, we developed a real-time RT-PCR with a probe that detects the America-1 lineage vaccines.[20] One of the other real-time PCR assays also has a method to differentiate between vaccine and field strains by using RFLP.[34] Differentiation of the Rockborn-like vaccine remains a problem and though one published assay has a way of distinguishing this vaccine from the Asia-1 lineage, the method will not work for all lineages.[55] Differentiation of this vaccine strain from field strains by sequencing works when all other methods fail.[20]

49.3 FUTURE PERSPECTIVES

Despite historically effective vaccination programs, CDV continues to be a worldwide problem for domestic dogs and wild carnivores. Several researchers have suggested the need for an updated vaccine for CDV. Vaccines strains have not changed since their development in the 1950s. However, there is currently no research to definitively substantiate the need for a new vaccine or to demonstrate what new strain or strains would be best if a new vaccine were made. Studies to determine how genetic differences influence antigenicity are warranted. It is important that any new vaccine developed be easily differentiated from field strains. Continual monitoring of field strains is needed to maintain assays with the ability to detect a broad range of genotypes. This is particularly important as global travel increases, with moving of animals and CDV strains into new areas.

Epidemiological evaluation has been made easier with the use of whole genome sequencing,[61] but full genome sequences are still needed for several genotypes. This molecular platform will likely provide data to produce improved primers and probes targeting different regions of the virus for CDV detection. As prices for whole genome sequencing continue to decrease, this method will potentially be used not only for research purposes but for diagnostics in the veterinary community as well.

50.1 INTRODUCTION

Hendra virus (HeV) is a zoonotic pathogen that was first identified in Hendra, a suburb of Brisbane, Queensland, Australia, in 1994. Commonly present in fruit bats (flying foxes) without overt clinical symptoms, HeV is capable of causing acute, rapidly progressive, and fatal disease in horses and humans. Since its initial description, HeV has continued to emerge in Queensland and northern New South Wales, Australia. By June 2014, a total of 50 sporadic HeV outbreaks have been recorded involving horses as the intermediate host, resulting in the death or euthanasia of 83 horses (with a mortality rate of 75%) and 7 human cases (including four casualties) after exposure to infected horses.

50.1.1 Classification

HeV is classified in the genus *Henipavirus*, subfamily *Paramyxovirinae*, family *Paramyxoviridae*, order *Mononegavirales*.

The order *Mononegavirales* covers viruses with linear, monopartite, single-stranded, negative-sense RNA genomes, which are organized into five families: *Bornaviridae* (containing spherical virions of 70–130 nm in diameter), *Filoviridae* (containing filamentous virions of 790–970 nm in length), *Nyamiviridae* (containing spherical virions of 100–130 nm in diameter), *Paramyxoviridae* (containing spherical virions of about 150 nm in diameter), and *Rhabdoviridae* (containing bullet-shaped virions of 180 nm in length and 75 nm in width). Some of the best-known or most deadly animal and human pathogens are found within the order *Mononegavirales*, including Ebolavirus, Marburgvirus (*Filoviridae*), measles virus, mumps virus, Newcastle disease virus, rinderpest virus, *Rubulavirus* (*Paramyxoviridae*), rabies virus, and vesicular stomatitis virus (*Rhabdoviridae*).

The family *Paramyxoviridae* is divided into two subfamilies: *Paramyxovirinae* and *Pneumovirinae*. Whereas the subfamily *Paramyxovirinae* consists of eight genera (*Aquaparamyxovirus*, *Avulavirus*, *Ferlavirus*, *Henipavirus*, *Morbillivirus*, *Respirovirus*, *Rubulavirus*, and type species Tupaia paramyxovirus (TPMV)-like viruses), the subfamily *Pneumovirinae* comprises of two genera (*Pneumovirus* and *Metapneumovirus*).

Representing a relatively new addition to the family *Paramyxoviridae*, the genus *Henipavirus* contains three recognized species, HeV (the type species), Nipah virus (NiV), and Cedar virus (CedPV), as well as a few tentative viruses [1].

HeV (originally referred to as equine morbillivirus) was discovered in September 1994 in Hendra, a suburb of Brisbane, Queensland, Australia, as the causal agent of a zoonotic disease that led to the deaths of 13 horses and a trainer at a training complex [2,3]. By June 2014, a total of 50 HeV outbreaks have occurred in Queensland and neighboring New South Wales, Australia, resulting in 83 horse deaths and 4 human casualties. Bats of the order *Chiroptera* appear to act as the natural host/reservoir for HeV, which may spread from fruit bats to horses and then from horses to humans in occasional "spillover" events [4,5].

NiV was found in April 1999 in the village of Sungai Nipah, Malaysia, as the cause of a neurological and respiratory disease of pigs and humans, involving 257 human cases (including 105 human deaths) and the culling of one million pigs.

FIGURE 50.1 Schematic presentation of Hendra virus genome. The 3′ leader (55 nucleotide [nt]) and 5′ trailer (33 nt) regions of *Henipavirus* genome serve as promoters for both transcription and replication. The coding sequence of each gene is flanked by untranslated regions that contain a gene-start sequence (12 nt) and a gene-end sequence (12 nt). Immediately following the gene-end sequence is a trinucleotide noncoding intergenic region (GAA) that precedes the gene-start sequence of the following gene. Besides the P, the *Henipavirus* P gene encodes at least three nonstructural proteins (C, V, and W). While the V and W proteins are generated by RNA editing, the C protein is encoded by a second open reading frame (ORF) that initiates 23 nt downstream of the translational initiation site for the P ORF. An additional accessible ORF within the P gene is identified as the small basic protein.

Since then, NiV outbreaks have been also reported in Bangladesh and India. It appears that NiV naturally occurs in bats of the order *Chiroptera*, domestic animals (pigs, cattle, and goats), and humans may acquire the virus after ingestion of date palm sap or other foods that are contaminated with bat saliva or urine. In addition, NiV transmissions from domestic animals to humans or from humans to humans are also possible [1].

CedPV was first observed in pteropid urine in 2009 in Queensland, Australia, while undertaking research on HeV. Despite its similarity to both HeV and NiV, CedPV does not induce disease in laboratory animals that are usually susceptible to paramyxoviruses. To date, CedPV has been largely detected in bats of the order *Chiroptera* [6].

Three tentative henipaviruses (BatPV/Eid.hel/GH10/2008, BatPV/Eid.hel/GH45/2008, and BatPV/Eid.hel/GH48/2008) were identified from feces of African straw-colored fruit bats (*Eidolon helvum*) roosting in zoological garden in the center of Kumasi, Ghana. Preliminary data suggest a limited risk of exposure to virus from bat feces, as virus RNA concentrations are low based on quantitative reverse transcription (RT)-PCR assessment [7]. In addition, molecular or serological evidence points out the possible existence of HeV-like RNA or proteins in bat bush meat from Congo, fruit bats *Pteropus rufus*, *Eidolon dupreanum*, *Rousettus madagascariensis*, and *Rousettus leschenatli* and *Myotis* spp. microbats in China [8].

50.1.2 Morphology and Genome Organization

Morphologically, HeV is an enveloped, pleomorphic (spherical or filamentous) particle of approximately 150–200 nm in diameter, which is covered by surface projections (spikes) of 10–18 nm. The spikes are composed of attachment glycoprotein (G) and fusion (F) protein. Beneath the envelope is the matrix (M) protein, which encases the nucleocapsid core (also referred to as the ribonucleoprotein [RNP] complex) consisting of the nucleocapsid (N) protein–encapsidated viral genome and the viral RNA-dependent RNA polymerase (RdRp) complex formed by the large (L) protein and phosphoprotein (P).

The genome of HeV is a nonsegmented, negative-sense, single-stranded RNA of 18,234 nucleotides (nt) in length, which contains six open reading frames (ORFs) in the order of 3′-N-P-M-F-G-L-5′. In all, the HeV genome encodes six major structural proteins (N protein, P, M protein, F protein, G, and L protein or RNA polymerase) and three nonstructural proteins (C, V, and W) as well as a small basic (SB) protein (Figure 50.1 and Table 50.1) [9–11].

The N protein (also known as nucleocapsid) homomultimerizes and binds to the P (via its carboxy terminal domain) and viral genomic RNA (via its amino terminal domain), forming the nucleocapsid core. This helps protects the viral RNA genome and position the polymerase on the template.

The P is produced from the unedited P gene and serves as a scaffold between the L protein and the encapsidated genome. RNA editing of the P gene consists of an insertion of one or two guanine nucleotides, with the +1G edited RNA giving rise to the V protein, and the +2G edited RNA giving rise to the W protein. The C protein is produced from leaky scanning of the P mRNA, via a second ORF that initiates 23 nt downstream of the translational initiation site for the P ORF, while an additional accessible ORF between the C and V proteins in the P gene generates the SB protein. The P and V proteins are localized in the cytoplasm, whereas the W protein is present in the nucleus. Functionally, the V and W proteins inhibit host immune response to infection by blocking the type I interferon (IFN) signaling pathway (through interaction with host STAT1 and STAT2 and thus inhibition of their

TABLE 50.1
Hendra Virus Genes and Encoded Proteins

Gene	mRNA (nt)	5′-UTR (nt)	3′-UTR (nt)	Protein	Protein (aa)	Protein Mass (kDa)

Note: aa, amino acid; kDa, kilodalton; nt, nucleotide; UTR, untranslated region.

phosphorylation and subsequent nuclear translocation) as well as by efficiently blocking the type II IFN signaling pathway. The C protein is also a weak antagonist of IFN and a regulator of viral RNA synthesis [12].

The M protein recruits cellular host factors for viral budding and provides rigidity and structure to the virion through interactions with the cytoplasmic tail of the F protein, the RNP complex, and the inner surface of the virion envelope. During bud formation, the M protein associates at the inner side of the plasma membrane of infected cells.

The F protein is a type I transmembrane protein that forms trimers on the cell surface and mediates the fusion of virus and host cell membranes during infection. The F protein is synthesized as an inactive precursor, F0, which is subsequently cleaved at amino acid K109 into the active subunits F1 and F2 by the host cellular protease cathepsin L after endocytosis of the virion. Both the F and G proteins are required for fusion [13].

The attachment G (also known as glycoprotein G) is a type II membrane protein that lacks hemagglutination and neuraminidase activities, forms tetramers upon cell surface expression, and binds to the protein-based receptor molecule EphrinB2 on neurons, smooth muscle, and endothelial cells surrounding small arteries [14]. The binding of glycoprotein G to the receptor induces a conformational change that allows the F protein to trigger virion/cell membrane fusion [15].

The L protein (also known as RNA-directed RNA polymerase L, large structural protein, replicase, transcriptase) displays RdRp, mRNA guanylyltransferase, mRNA (guanine-N(7)-)-methyltransferase, and poly(A) synthetase activities that are crucial for viral RNA synthesis (including initiation, elongation, and termination of both mRNA transcription and genome replication). The L protein interacts with the P to form the viral RdRp complex, which associates with the N protein–encapsidated genome to form the RNP complex [12].

50.1.3 Biology and Epidemiology

Upon entry into the host, HeV attaches to host cell surface receptors (such as EphrinB2) through glycoprotein G. This triggers F protein to undergo a conformational cascade, leading to membrane fusion between the virion and host cell and subsequent release of the nucleocapsid into the cytoplasm. The viral RdRp binds the encapsidated genome at the 3′ leader region and sequentially transcribes each gene by recognizing start and stop signals flanking viral genes, producing positive (+)-sense antigenomes and then negative (–)-sense genomes and capped and polyadenylated mRNA. Subsequent translation of viral genomes into nucleoprotein and other viral proteins facilitates the formation of newly formed RNP complex, which interacts with the M protein under the plasma membrane and initiates budding to release the virion.

HeV naturally occurs in fruit bats (or flying foxes) of *Pteropus* spp., which serve as the reservoir host and show no recognizable clinical symptoms despite having detectable virus in the blood, urine, feces, saliva, placental material, aborted fetuses, and birthing fluids. Of the four flying fox species found in Australia, that is, the spectacled flying fox (*Pteropus conspicillatus*), the little red flying fox (*Pteropus scapulatus*), the black flying fox (*Pteropus alecto*), and the gray-headed flying fox (*Pteropus poliocephalus*), all have neutralizing antibodies against HeV. Transmission among flying foxes likely takes place within the roost, where uninfected animals acquire the virus through exposure to urine or feces matter excreted by other infected animals [16].

As the spillover host for HeV, horses may become infected through contact with pasture or feed contaminated with flying fox urine, feces, and plant materials masticated by bats. Horse-to-horse transmission is possible when uninfected horses have direct contact with infectious bodily fluids such as blood, urine, saliva, or nasal discharge from an infected horse or surfaces or equipment contaminated with infectious material [17].

Human infection with HeV mostly results from exposure to mucous membranes and nonintact skin to nasal and respiratory secretions, blood, and urine from infected horses. Participation in autopsy of infected animals or direct close contact with infected horses creates opportunity for exposure via droplets, cuts, or abrasions. Human-to-human or bat-to-human transmission has yet to be described.

Besides horses and humans, HeV appears to be infective to a number of mammals including African green monkeys, pigs, cats, guinea pigs, hamsters, and ferrets. However, experimentally infected dogs, chickens, rabbits, rats, and mice are asymptomatic, in spite of the fact that HeV-infected dogs, rabbits, and rats may mount a neutralizing antibody response [18].

HeV is sensitive to desiccation, temperature, and pH, but can persist in the environment (such as nasal secretions) for several days under optimum conditions.

50.1.4 Clinical Features and Pathogenesis

With an incubation period (i.e., the time from exposure to the appearance of the first clinical signs) of 5–16 days, HeV infection may result in a range of clinical symptoms in infected hosts.

In horses, HeV tends to induce severe respiratory (e.g., increased respiratory and heart rate and labored breathing) and neurological (e.g., ataxia, head tilt, facial nerve paralysis, and encephalitis) signs along with high fever, facial swelling, depression, weakness, anorexia, and nasal discharge. Histological examination reveals interstitial pneumonia with alveolar edema associated with hemorrhage, alveolar thrombosis, and necrosis, in addition to necrosis of the walls of small blood vessels. Virus is present in the lung, spleen, kidney, brain, lymph nodes, blood, saliva, and urine. There is evidence that HeV may appear in nasopharyngeal secretions at least 2 days before the onset of clinical signs [19].

In pigs, oronasal or intranasal inoculation of HeV leads to respiratory symptoms and mild neurological disease. The virus is found in nasal, oral, and ocular swabs as well as in feces [20].

In cats, subcutaneous, oral, or intranasal administration of HeV results in acute febrile disease with pulmonary signs (e.g., severe dyspnea, open-mouth breathing, pulmonary

edema, necrosis of alveolar walls, and vascular lesions), similar to those observed in horses and humans. Virus is found in the lung, brain, spleen, kidney, rectum, trachea, bladder, heart muscle, liver lymph nodes, pleural fluid, urine, and blood, although the presence of virus in the brain is not accompanied by neurological signs. Cat-to-cat transmission may occur when housed in the same cage, and the cat's urine is infective to horses. However, no horse-to-cat transmission has been reported [21].

In pteropid bats, HeV infection is asymptomatic although specific antibodies are detectable. In some animals, histological lesions are present and immunostaining for HeV in endothelial cells of some animals is positive [16].

In African green monkeys (*Chlorocebus aethiops*), intratracheal inoculation of HeV results in a severe systemic disease, with resemblance to that observed in humans. Clinical signs range from decreased activity, depression, severe respiratory and neurological disease, generalized vasculitis, to death (nearly 100% in 8.5 days). Postmortem examination reveals pulmonary edema, meningeal hemorrhage and edema, endothelial syncytia, and vasculitis. Virus is detectable in the kidneys, heart, brain, gall bladder, stomach, sex organs, skeletal muscles, plasma, and whole blood [22]. Overall, the observed clinical signs observed in African green monkeys resemble those observed in human cases [23].

In humans, HeV infection begins with influenza-like illness (e.g., headache, high fever, and drowsiness) and progresses to interstitial pneumonia, encephalitis, seizures, segmental myoclonus, hypertension, tachycardia, areflexia, hypotonia, convulsion, coma, and death [36]. Histopathological examination reveals disseminated endothelial-cell involvement with vasculitis (in the brain, lung, heart, and kidneys), arterial thrombosis, ischemia, small necrotic or vacuolar plaques (in the cerebrum and cerebellum), and mild meningeal and brain parenchymal inflammation. Virus is detectable in CNS tissues (e.g., neurons, ependyma, and blood vessels), type II pneumocytes, pulmonary blood vessels, glomeruli and renal tubules, and blood vessels [24].

HeV demonstrates a predominantly respiratory or neurological tropism, with the ability to spread to other organs by the hematogenous route and form syncytia in vascular epithelial tissues. Assisted by its V and W as well as C proteins, HeV limits the induction of type I IFN in mammalian host cells and evades host immune surveillance, so that the virus can replicate inside the host cell and spread to other cells unhindered [25,26].

50.1.5 Diagnosis

Considering that HeV initially induces flulike symptoms followed by respiratory and neurological signs at the late stage, differential diagnosis should include a large number of viral and bacterial infections. Under the circumstance, use of laboratory methods (e.g., virus isolation, electron microscopy, immunohistochemistry, serological assays, and nucleic acid detection) is essential for achieving a precise and timely diagnosis [27].

Virus isolation: HeV is a Biosafety Level 4 (BSL 4) organism and a category C priority agent in the National Institute of Allergy and Infectious Diseases (NIAID) Biodefense Research Agenda. Isolation of HeV therefore requires the highest level of containment (BSL 4). Vero E6 (ATCC C1008) or Vero (ATCC CCL81) (African green monkey kidney), RK13 (rabbit kidney), MDBK (bovine kidney), LLC-MK2 (monkey kidney), BHK (baby hamster kidney), Hep-2 and HeLa cells, and embryonated chicken eggs may be utilized for HeV isolation from nasal swabs and throat swabs and the blood, urine, lung, liver, spleen, kidney, and lymph nodes of infected horses, from serum, urine, or nasopharyngeal aspirates (NPA), or from the kidney, spleen, lung, and brain of infected humans. Typically, 200–500 μL of serum, urine, or NPA (diluted in media) or tissue (kidney, spleen, lung, and brain) suspension (10% w/v, prepared in media) is clarified and filtered through a 0.2 μm filter and placed onto cell monolayers of Vero E6 (ATCC C1008) or Vero cells (ATCC CCL81) and incubated for 1 h at 37°C. Additional media is furbished and incubated at 37°C for 5 days. On Vero monolayer, HeV often produces large syncytia containing multiple nuclei. Two more passages are undertaken to ensure the success of isolation [27].

Electron microscopy: HeV particles can be observed by negative contrast electron microscopy. In addition, the location of HeV within tissues and cells can be pinpointed by immunoelectron microscopy.

Immunohistochemistry: Immunohistochemical detection of viral antigen in formalin-fixed tissues is useful for retrospective diagnosis of HeV.

Serological assays: Several serological assays have been used for detection of HeV antigens and antibodies [28,29]. These include neutralization test, indirect immunofluorescence assays (IFA), and enzyme-linked immunoassay (ELISA). Demonstration of a fourfold rise in antibody titer confirms a recent infection. In particular, ELISA allows efficient screening of large numbers of samples, especially during epidemiological and surveillance studies, while IFA is useful for testing small numbers of samples. Neutralization test is considered as the reference standard for definitive or confirmatory diagnosis.

Nucleic acid detection: A variety of molecular protocols has been developed for rapid and sensitive detection and quantitation of HeV RNA. These include conventional RT-PCR and real-time RT-PCR based on SYBR Green dye or TaqMan probe [30]. Additionally, loop-mediated isothermal amplification-lateral flow dipstick (LAMP–LFD) procedure offers a valuable approach for HeV identification [16].

50.1.6 Treatment and Prevention

Currently, no antiviral drugs are approved for animal or human infections with HeV. A recombinant human neutralizing monoclonal antibody targeting the ephrin receptor binding site has shown promise for HeV treatment and may be administered to humans following high-risk exposures to HeV. In addition, poly(I)-poly ($C_{12}U$)—a strong

inducer of IFN—heptad peptides corresponding to the C-terminal heptad repeat of the F protein, and RNA interference technology are being evaluated for the treatment of HeV infection [1].

Vaccination with a recombinant G surface antigen of HeV has resulted in the production of high levels of protective antibodies against HeV challenge in animals [31]. This vaccine (trade name Equivac HeV®) is available in Australia since November 2012 for horses.

Furthermore, HeV vaccine based on the soluble G-glycoproteins has been developed by NIAID-supported researchers. This vaccine is capable of inducing strong neutralizing antibodies in animals [32].

50.2 METHODS

50.2.1 Sample Preparation

Blood, nasal swabs, and urine from live animals and the brain, kidney, lung, and spleen from dead animals are suitable for HeV diagnosis. Fresh samples are sent chilled and not frozen to the laboratory.

QIAamp viral RNA mini extraction kit (Qiagen) is used to extract viral RNA from serum, nasopharyngeal aspirate (NPA), and cerebrospinal fluid (CSF), while QIAshredder and RNeasy mini kit (Qiagen) are employed for RNA extraction from tissues.

50.2.2 Detection Procedures

50.2.2.1 Conventional RT-PCR

Halpin et al. [33] described a RT-PCR with primers (forward, 5′ GGC TAC AAC GAG AAA TTT GTG 3′; reverse, 5′ TTC TAG CAT TGT CCT TGG GAT 3′) for specific amplification of a 200 bp fragment from the M protein gene of HeV.

For RT, 2.5 μL of template RNA is annealed with 10 pmol of reverse-sense primer in a total volume of 5 μL at 65°C for 10 min. The mixture is then chilled on ice. RT reagents are added to give a total volume of 20.5 μL containing synthesis buffer (250 mM Tris–HCl, 200 mM KCl, 2.5 mM $MgCl_2$, 2.5% Tween 20, v/v, pH 8.3), 100 mM dithiothreitol, 1 mM (each) deoxynucleoside triphosphates (dATP, dCTP, dGTP, dTTP), 20 U of RNase inhibitor and 50 U of expand reverse transcriptase (expand RT preamplification system, Boehringer Mannheim). This mixture is incubated at 42°C for 60 min and then chilled on ice.

PCR mixture (50 μL) is made up of synthesis buffer, 2.5 mM of $MgCl_2$, 10 pmol of each primer, 2 μL of the reverse-transcribed product, and 1.5 U *Tth* of DNA polymerase (Biotech International).

Amplification is performed in DNA Thermal Cycler 480 (Perkin Elmer) with the following programs: initial 94°C for 2 min and 30 cycles of denaturation (94°C, 1 min), primer annealing (45°C, 1 min), and extension (72°C, 1 min).

PCR product is separated by electrophoresis in 1.2% agarose gel prepared in 0.5× Tris/Borate/EDTA (TBE) buffer containing 0.5 μg/mL of ethidium bromide at 80 V for 60 min and visualized on a UV transilluminator.

50.2.2.2 Real-Time RT-PCR

Smith et al. [34] developed a TaqMan-based assay for real-time RT-PCR detection of HeV, with primers (forward, 5′-CTTCGACAAAGACGGAACCAA-3′, nt 5755-5775; reverse, 5′-CCAGCTCGTCGGACAAAATT-3′, nt 5823-5804) and probe [5′-(FAM) TGGCATCTTTCATGCTCCATCTCGG (TAMRA)-3′, nt 5778–5802] from a conserved region of the M gene.

RT-PCR mixture (50 μL) is composed of 1× TaqMan buffer A (50 mM KCl, 10 mM Tris–HCl, 0.01 mM EDTA, 60 nM ROX passive reference [pH 8.3], 5.5 mM $MgCl_2$, 300 μM of each of dATP, dCTP and dGTP, 600 μM dUTP), 150 nM of probe and 300 nM of each of forward and reverse primers, 12.5 U Multiscribe RT, 20 U RNase inhibitor and 1.25 U Taq Gold polymerase (Applied Biosystems), and 5 μL extracted RNA.

Amplification and detection are performed on Applied Biosystems 7700 machine with the following cycling parameters: 48°C for 30 min and 40 cycles of 95°C for 15 s and 60°C for 1 min.

50.3 CONCLUSION

HeV is an emerging zoonotic pathogen with the ability to evade host immune surveillance and replicate within and spread between the host cells undisturbed [35]. Not surprisingly, the outcome of HeV infection in horses and humans as well as other mammals is predictably grim [36]. Due to the noncharacteristic clinical symptoms caused by HeV, it is important to use laboratory means for its diagnosis. Negating the shortcomings of traditional procedures, RT-PCR has proven to be a powerful tool in the identification and quantification of HeV from various specimens. Given the mobility of its reservoir host (fruit bats), the abundance of its intermediate host (horses), and the breadth of its potential hosts, HeV is poised to extend its current geographic and species boundaries and pose increasing risk to human population and animal husbandry. Continuing efforts in anti-HeV drug and vaccine research and development together with refinement in diagnostic methodologies will be crucial to stop the spread of HeV outbreaks.

51.1 INTRODUCTION

Menangle virus, a recent addition to the family *Paramyxoviridae*, subfamily *Paramyxovirinae*, was isolated in 1997 from stillborn piglets at a large commercial piggery in New South Wales, Australia, during the investigation of an outbreak of severe reproductive disease, which persisted from April to September of that year.[1] The index piggery, which housed 2600 sows in four separate breeding units, was located approximately 60 km southwest of Sydney on a property that was adjacent to the Nepean River.[2,3] The disease was characterized by a reduction in both the farrowing rate and the number of live piglet births per litter, occasional abortions, and an increase in the proportion of mummified and stillborn piglets, some of which had deformities.[1,2,4] Although Menangle virus was only ever isolated from affected stillborn piglets, subsequent seroepidemiological investigations led to the implementation of a successful eradication program,[3] the identification of a likely natural host (fruit bats, also known as flying foxes, in the genus *Pteropus*),[1] and the unexpected realization that the virus had infected two piggery workers, causing severe influenza-like illness and a rash.[5]

51.1.1 Classification and Morphology

Paramyxoviruses are a diverse group of enveloped viruses that infect vertebrates, primarily mammals and birds, as well as reptiles and fish. The family *Paramyxoviridae* is divided into two subfamilies, *Paramyxovirinae* and *Pneumovirinae*, the member species of which can be distinguished on the basis of ultrastructure, genome organization, sequence relatedness of the encoded proteins, antigenic cross-reactivity, and biological properties of the attachment proteins (presence or absence of hemagglutinating and neuraminidase activities).[6,7] *Pneumovirinae* contains two genera, *Pneumovirus* and *Metapneumovirus*, whereas *Paramyxovirinae* is separated into seven genera, *Rubulavirus*, *Avulavirus*, *Respirovirus*, *Aquaparamyxovirus*, *Ferlavirus*, *Henipavirus*, and *Morbillivirus*, the type species of which are mumps virus, Newcastle disease virus, Sendai virus, Atlantic salmon paramyxovirus, Fer de Lance paramyxovirus, Hendra virus, and measles virus, respectively.

Following its original isolation and propagation in cell culture, Menangle virus was shown to be a member of the subfamily *Paramyxovirinae* by virtue of its ultrastructure as determined by electron microscopy (Figure 51.1).[1] Virions in this subfamily are typically 150–350 nm in diameter and are usually spherical in shape, although pleomorphic and filamentous forms are often observed.[6,7] Within each virion is the ribonucleoprotein core, a single strand of nonsegmented, negative-sense RNA, which is tightly bound along its entire length by nucleocapsid (N) proteins such that the genome is rendered insensitive to attack by nucleases.[8–10] The ribonucleoprotein complex, or nucleocapsid, is 19 ± 4 nm in diameter and has a helical symmetry with a pitch of 5.8 ± 0.4 nm,[1] thereby resulting in its characteristic "herringbone" appearance. Also associated with the nucleocapsid is the viral RNA-dependent RNA polymerase, which consists of two protein subunits: L and P. Surrounding the core is a lipid envelope containing two surface glycoproteins, which are visualized by electron

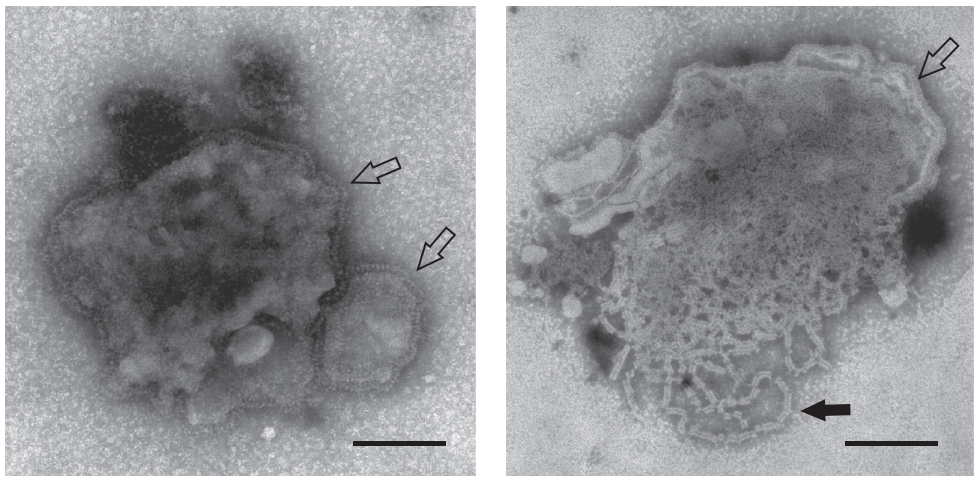

FIGURE 51.1 Transmission electron micrographs of Menangle virus negatively stained with 2% phosphotungstic acid (pH 6–8). (a) An intact virion with single fringe of surface projections (open arrows) extending from the viral envelope; bar, 100 nm. (b) A disrupted virion, viral envelope with surface projections (open arrow) and ribonucleoprotein complex or nucleocapsid (solid arrow); bar, 100 nm. (Adapted from Philbey, A.W. et al., *Emerg. Infect. Dis.*, 4, 269, 1998; Electron micrographs kindly provided by the AAHL Biosecurity Microscopy Facility, CSIRO, Australia.)

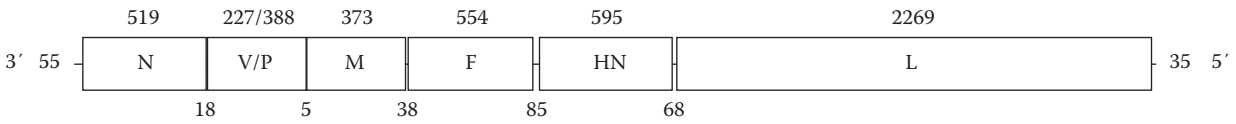

FIGURE 51.2 Genome organization of Menangle virus. The full-length genome (15,516 nucleotides) comprises six genes, each of which is drawn to scale. Numbers above each gene indicate the length, in amino acids, of the encoded proteins. Numbers below the gene boundaries indicate the length, in nucleotides, of the intergenic regions. Numbers immediately to the left and right of the genome indicate the length, in nucleotides, of the extragenic leader and trailer sequences, respectively. Note that unedited V/P gene transcripts encode the V protein, whereas insertion of two nontemplated G residues at the editing site (not shown) results in synthesis of the P gene mRNA. Note also that the negative-sense genome is depicted rather than the complementary antigenome, which is in the same sense as the viral mRNA molecules. GenBank accession number AF326114.

microscopy as an external fringe of projections 17 ± 4 nm long.[1] One glycoprotein, HN for rubulaviruses, avulaviruses, respiroviruses, aquaparamyxoviruses, and ferlaviruses, H for morbilliviruses, and G for henipaviruses, mediates attachment of the virion to the cellular receptor; the other glycoprotein, F, is responsible for mediating fusion between the virion envelope and the cell plasma membrane, a process that delivers the viral genome into the cell cytoplasm where viral transcription and replication occur.[7] Additionally, located on the inner surface of the viral envelope is a nonglycosylated matrix (M) protein, which is thought to play a central role in coordinating virion assembly and budding.[7]

Characterization and analysis of the complete genome sequence (15,516 nucleotides), and the encoded proteins, subsequently established that Menangle virus should be classified as a new member of the genus *Rubulavirus*.[11,12]

51.1.2 Biology and Epidemiology

As for most other members of the genus *Rubulavirus*, there are six transcriptional units, in the order 3′-N-V/P-M-F-HN-L-5′, which are separated by intergenic regions of variable length and sequence (Figure 51.2). Although believed to transcribe each gene sequentially from the 3′ end of the genome, the viral polymerase does not always reinitiate RNA synthesis at every gene junction following release of the newly synthesized mRNA. Instead, the polymerase detaches from the genome template, at which point it must reenter the genome at its 3′ terminus for further transcription to take place. Consequently, an mRNA gradient is produced such that genes located closest to the 3′ terminus of the genome are expressed at greater levels than their downstream neighbors.[7,13,14]

In contrast to the N, M, F, HN, and L genes, all of which encode single proteins using individual open reading frames, the V/P gene encodes at least two different proteins from two or more overlapping reading frames using a mechanism known as RNA editing, during which the polymerase adds one or more nontemplated G residues, cotranscriptionally, to a percentage of the newly synthesized mRNAs.[7] As such, two or more different transcripts are synthesized, which code for proteins that possess common N-termini but different C-termini, resulting from a translational shift downstream of the editing site. For Menangle virus, as for other rubulaviruses[7] and ferlaviruses,[15] faithful gene transcripts encode the V protein, whereas the

predominant editing event (the insertion of two nontemplated G residues at the editing site) yields the P mRNA, which codes for the P protein.[11] Significantly, many of the *Paramyxovirinae* accessory gene products, which are generated using a variety of distinct mechanisms, have important roles such as regulating viral RNA synthesis, mediating virulence *in vivo* and/or counteracting the induction of an interferon-mediated antiviral state by host cells following infection.[7]

Several novel findings were also apparent, the most significant of which would appear to be the limited sequence homology of the deduced Menangle virus HN protein when compared to attachment proteins of other *Paramyxovirinae*.[11] Although the predicted structure of Menangle virus HN was most similar to other rubulavirus HN proteins, it lacked the majority of the amino acids that are considered critical determinants of both sialic acid binding and hydrolysis. This unexpected finding is unique among all known rubulavirus, avulavirus, respirovirus, aquaparamyxovirus, and ferlavirus HN proteins, with the exception of that from the closely related Tioman virus,[16] another rubulavirus that was later isolated from fruit bats in Malaysia during the search for the natural reservoir of Nipah virus.[17] This lack of conservation in functional amino acids suggests that the Menangle and Tioman virus attachment proteins, in contrast to those from all other known members of the rubulavirus, avulavirus, respirovirus, aquaparamyxovirus, and ferlavirus genera, are unlikely to use sialic acid as a cellular receptor, a prediction that in part would explain the observation made at the time of its initial isolation that Menangle virus is nonhemadsorbing and nonhemagglutinating using erythrocytes from various species.[1] The uniqueness of the Menangle and Tioman virus HN proteins is further highlighted by the apparent marked divergence in their evolutionary development in comparison to the N, P, M, F, and L proteins, the significance of which is not yet understood.[11,12,16]

The isolation of Menangle virus in cell culture provided a means of detecting Menangle virus–specific neutralizing antibodies in sera, thus enabling seropositive animals to be identified. Sera from pigs that had been collected during and prior to 1996, as well as samples collected as late as February 1997, before the onset of clinical disease, were all seronegative for antibodies against the new virus. However, 58 of 59 samples collected from three of the four breeding units in late May, immediately preceding the onset of disease in these units, had high neutralizing antibody titers (256–4096) against Menangle virus.[3] Subsequent epidemiological investigations using archival sera collected during separate national surveys for unrelated infectious disease agents, trace forward and trace back piggeries, and pigs with and without reproductive disease elsewhere in Australia, revealed that infection with Menangle virus was confined to the index piggery and two associated piggeries, also within New South Wales, which were located several hundred kilometers away at Young and Trunkey Creek.[3] Neither of these piggeries was a breeding establishment. Instead, each was used for rearing batches of 12–14-week-old pigs, originating from the index piggery, until slaughter at 24 weeks of age.

Although the reproductive parameters had returned to normal by mid-September 1997, two separate cross-sectional studies, the first conducted during August and September 1997, the other in March 1998, subsequently revealed that the virus was being maintained in the affected piggeries by infection of successive batches of growing pigs as they lost their protective maternal antibody at about 12–14 weeks of age.[3] Whereas colostral antibodies had declined to almost undetectable levels by this age, 95% of pigs subsequently developed neutralizing antibody titers ≥128 by the time of slaughter, at 24–26 weeks of age, or by the time they entered the breeding herd as replacement gilts at 28 weeks of age.[3] Significantly, this immunity appeared to be protective because no further reproductive disease was seen after September 1997 and sows, which had produced affected litters during the outbreak, farrowed normal litters subsequently.[2,3]

Menangle virus was only ever isolated from the brain, heart, and lungs of affected stillborn piglets.[1,2] Thus, it was not determined how the virus was spread between pigs. However, serological monitoring of various groups of sentinel pigs provided circumstantial evidence regarding likely modes of transmission. Sentinel pigs placed into the grower and grower–finisher areas of one of the units during September and October 1997, respectively, when infection was known to be active, took up to 1 month to seroconvert, despite the fact that the sentinel pigs in the grower–finisher area were allowed free access to walkways, between pens, to maximize their exposure to other pigs.[3] This suggested that transmission between pigs was relatively slow and required close contact, and thus probably resulted from viral excretion in feces or urine rather than in respiratory aerosols.[3] Furthermore, 180 gilts and sows, which had been introduced into the breeding herd in November 1997, were seronegative to Menangle virus when tested in February 1999. This finding demonstrated that Menangle virus infection was not active in the breeding herd after the period of reproductive disease and that persistent shedding did not occur.[3] Finally, a large group of 8-week-old pigs that was moved into an uncleaned building, which, until 3 days earlier, was occupied by pigs known to be infected with Menangle virus, was seronegative at slaughter age suggesting that survival of the virus in the environment was not prolonged, and that maternally derived antibodies were protective in weaned pigs less than 8 weeks of age.[3] The realization that active Menangle virus infection was confined to the grower–finisher age group enabled a strategy for virus eradication to be developed. Implementation of this program, together with depopulation of the piggery at Young, resulted in successful elimination of the virus from the remaining two piggeries by February 1999.[3]

Determining the probable source of the outbreak was facilitated by the fact that fruit bats had previously been identified as the likely natural host of two newly described zoonotic viruses: Hendra virus,[18] a paramyxovirus that had caused the death of two humans in Queensland within the 3 years preceding the discovery of Menangle virus,[19–24] and Australian bat lyssavirus, a rhabdovirus that, although first identified in a sick fruit bat,[25–27] had subsequently caused the

death of a bat carer.[28,29] A large breeding colony of 20,000–30,000 fruit bats, which consisted primarily of grey-headed fruit bats (*Pteropus poliocephalus*), but also little red fruit bats (*Pteropus scapulatus*), roosted annually, from October to April, within 150–200 m of the nearest breeding unit, and had done so for at least 30 years.[1,3] Serum samples were initially collected from this colony, as well as from fruit bats elsewhere in New South Wales and Queensland. Forty-two of 125 samples were positive in a virus neutralization test with titers against Menangle virus ranging from 16 to 256.[1] Considering that antibodies were not detected in a range of wild and domestic species found within the vicinity of the piggery, including rodents, birds, cattle, sheep, cats, and a dog, fruit bats were implicated as the likely natural host of Menangle virus.[1] More comprehensive serological surveys have since demonstrated that antibodies to Menangle virus are widespread in at least three of the four pteropid species endemic to Australia.[3,30] However, despite finding paramyxovirus-like particles in fruit bat feces collected from the colony nearby the index piggery, attempts to isolate Menangle virus from these samples were unsuccessful.[3,30] Nevertheless, following the discovery of Menangle virus, two other paramyxoviruses were identified in Malaysia, Nipah and Tioman viruses, both of which were isolated from fruit bat urine.[17,31] Using similar sampling procedures and newly established primary cell lines of bat origin, Menangle virus was subsequently isolated from fruit bat (*Pteropus alecto*) urine samples that were collected in South East Queensland.[32] It would therefore seem probable that transmission of Menangle virus from fruit bats to pigs occurred indirectly, perhaps through ingestion of fruit bat excreta, and this may have been associated with the movement of pigs between buildings using uncovered walkways, a management practice that had only been implemented 2 years before the outbreak.[3]

Prior to the isolation of Menangle virus from pigs, only two paramyxoviruses were considered to be zoonotic: Newcastle disease virus, which in humans can cause conjunctivitis,[33,34] and Hendra virus, which was known to have infected three people, two of whom subsequently died.[19–24] Considering that the relationship between Hendra and Menangle viruses had not been clearly established, but that both were considered to have "jumped" from fruit bats to infect other species (horses and humans in the case of Hendra virus), a serological survey was conducted to assess the zoonotic potential of the new virus. A total of 251 people, all of whom were considered to have been exposed to potentially infected pigs, were tested. This included all staff at the index (n = 33) and grower (n = 5) piggeries, abattoir workers (n = 142), researchers and animal handlers (n = 41), veterinarians and pathology laboratory workers (n = 24), and others (n = 6).[5] Two piggery staff, one from the index piggery and the other from one of the two associated grower piggeries, were shown to be seropositive to Menangle virus with neutralizing antibody titers of 128 and 512, respectively.[5] Further investigations revealed that both workers had contracted very similar illnesses in early June 1997, during the period when reproductive disease in pigs was present. The first worker had regular prolonged contact with farrowing pigs, which resulted in splashing of amniotic fluid and blood to his face, and he also frequently received minor wounds to his hands and forearms.[5] Although the second worker had no exposure to birthing pigs, he performed necropsies on pigs without wearing protective eye wear or gloves and reported that exposure to pig secretions, including feces and urine, was common.[5] Neither worker had any contact with bats. Extensive testing of both men in September 1997 failed to identify an alternative cause for the illnesses, which were therefore considered to have resulted from infection with Menangle virus. Although the mode of transmission from pigs to humans was not established, the available evidence suggested that Menangle virus did not readily transmit to people, and that infection probably required parenteral or permucosal exposure to infectious materials.[5]

Experimental infection of weaned pigs, by intranasal inoculation, has since demonstrated that Menangle virus is shed in nasal and oral secretions, feces, and urine, typically for periods of less than 1 week, following an incubation period of only a few days.[35] Although the stability of Menangle virus in these samples was not evaluated, these findings suggested that transmission is possible not only by direct contact between pigs, by exposure to infectious nasal and oral secretions, but also by indirect means, following contamination of the environment, food, and water with virus. Furthermore, the presence of infectious virus in nasal and oral secretions indicates that spread by aerosol droplet might also play a role in transmission. Nevertheless, the low concentrations of virus shed in each sample type would appear to correlate with the slow rate of spread observed in the index piggery, which led to the hypothesis that Menangle virus was more likely to be spread by fecal or urinary excretion than by respiratory aerosols.[2,3]

51.1.3 Clinical Features and Pathogenesis

51.1.3.1 Pigs

In naive pigs, infection with Menangle virus causes a marked decline in reproductive performance, characterized by a reduction in both the farrowing rate and the number of live piglet births per litter, occasional abortions, and an increase in the proportion of mummified and stillborn piglets, some of which have deformities; there are otherwise no clinical signs attributable to infection with the virus in postnatal, growing, or adult pigs of any age.[1–4]

The first affected litter, detected during the week commencing April 21, 1997, consisted of one stillborn piglet and seven mummified fetuses.[2] The proportion of affected litters (those containing fewer than six live-born piglets) in this unit increased significantly in the following weeks and peaked at 64.3% 5 weeks later, at which time only 17 of 45 mated sows farrowed.[2] During the period of disease in this unit, which lasted for 15 weeks, the farrowing rate decreased from a pre-outbreak average of 80.2% to 63.2%, and the number of piglets born alive per litter decreased from an average of 9.6 ± 2.9 to 8.3 ± 3.9.[2] The disease occurred sequentially in the remaining three breeding units, commencing 7, 8, and 11 weeks after the

disease was initially recognized in the first affected unit, and continued for periods of 12, 12, and 11 weeks, respectively. The reproductive performance in all four units had returned to normal by mid-September 1997, 7 months after the virus was considered to have first entered the breeding herd.[2]

The composition of affected litters varied markedly throughout the Menangle virus outbreak. Some litters contained only one or two mummified or stillborn fetuses, suggesting that infection had occurred early during gestation, with subsequent death and resorption of the embryos.[2] In contrast, others contained a mixture of mummified and stillborn piglets in various stages of development, as well as apparently normal fetuses. Like porcine parvovirus,[36] this suggested that transplacental infection of fetuses was somewhat variable and that subsequent spread of the virus from infected to neighboring fetuses, *in utero*, was possible. The size of mummified fetuses, and the stage of development at which pathology was induced, also indicated that infection prior to day 70 of gestation was required for fetuses to be adversely affected,[2] which is consistent with other infectious causes of reproductive failure in swine.

Pathologic changes in affected stillborn piglets were characterized by severe degeneration, or even absence, of the brain and spinal cord (particularly the cerebral hemispheres, cerebellum, and brain stem), arthrogryposis, brachygnathia, and kyphosis,[1,2,4] although the pattern of central nervous system lesions observed within affected litters appeared to change over time.[4] Occasionally, marked pulmonary hypoplasia was observed, and in 41% of stillborn piglets examined, an excessive amount of straw-colored fluid, sometimes fibrinous, was present in body cavities.[1,4] Histologically, pathology was most marked in the central nervous system and was characterized by extensive degeneration and necrosis of grey and white matter, in association with infiltrates of macrophages and lymphocytes.[1,4] In some lesions within the brain and spinal cord, intranuclear and intracytoplasmic inclusion bodies were present in neurons and, occasionally, nonsuppurative myocarditis and leptomeningitis were also observed.[1,4]

Following experimental challenge of weaned pigs intranasally, a viremia of short duration (lasting only a matter of days) and low titer was detected.[35] Menangle virus was shed at low to moderate concentrations in nasal and oral secretions, feces, and urine, typically for periods of less than 1 week. Infectious virus and viral RNA were detected in a wide range of solid tissues, including tonsil, mandibular lymph node, jejunum, ileum, and mesenteric lymph node, indicating that secondary lymphoid organs and gastrointestinal tissues were major sites of viral replication and dissemination. This was subsequently confirmed by abundant immunolabeling of viral nucleocapsid protein in lymphoid tissues and throughout the intestinal epithelium, particularly within jejunum, which would explain the presence of virus in feces.[35]

51.1.3.2 Humans

Only two people are suspected to have been infected with Menangle virus, both of whom experienced a severe influenza-like illness with a rash. In each case, the diagnosis was made retrospectively after demonstrating that the men had high neutralizing antibody titers to the virus, with no other likely cause identified. The first patient experienced sudden onset of malaise and chills, followed by drenching sweats and fever, and was confined to bed with severe headaches and myalgia for 10 days.[5] By the fourth day, he had developed a spotty red rash and, on examination, exhibited upper abdominal tenderness, lymphadenopathy, and a rubelliform rash. He was absent from work for 14 days, tired easily on his return, and reported weight loss of 10 kg (~22 lb) due to this illness. The second patient experienced fever, chills, rigors, drenching sweats, marked malaise, back pain, severe frontal headache of 4–5-day duration, and photophobia.[5] A spotty, red, nonpruritic rash developed on his torso 4 days after the illness started and persisted for 7 days. He had essentially recovered after 10 days, having lost 3 kg (~6.6 lb).[5] Neither patient had cough, vomiting, or diarrhea.

51.1.3.3 Fruit Bats

Infection of pteropid bats with Menangle virus has not been associated with disease,[30] and this is consistent with the perceived role of bats as reservoir hosts of not only this and other paramyxoviruses that have emerged in the Australasian region since 1994, including Hendra, Nipah, Tioman, and Cedar viruses, but also many other viruses from a diverse spectrum of viral families.[32,37–41]

51.1.4 Diagnosis

Suspicion or confirmation of Menangle virus infection must be reported to relevant government authorities. In the United States, Menangle virus is listed as a U.S. Department of Agriculture Select Agent on the National Select Agent Register. Although the recommended sample types for confirming disease in humans will need to be guided by future characterization of the infection in people, should this opportunity arise, multiple laboratory tests have been developed and used, both during and since the outbreak, to increase understanding of the epidemiology and pathogenesis of Menangle virus, principally in pigs.

51.1.4.1 Conventional Techniques

51.1.4.1.1 Virus isolation

Menangle virus will grow in a wide range of cell types, including cells of porcine, human, and pteropid bat origin, and possesses neither hemadsorbing nor hemagglutinating activities using erythrocytes from several species.[1,32,35] The cytopathic effect is similar to that caused by other paramyxoviruses and is characterized by vacuolation of cells, formation of syncytia, and, eventually, lysis of the cell monolayer. During the outbreak, however, virus was only isolated from lung (n = 9), brain (n = 9), and heart (n = 5) of 10 affected, stillborn piglets, after 3–5 blind passages in baby hamster kidney (BHK_{21}) cells.[1,2] Considering that 170 tissues (including lung, brain, heart, kidney, and spleen from 57 affected piglets) were tested, virus was isolated from fewer than 1 in 7 samples. It has since been determined that virus is more likely to be isolated from piglets that exhibit gross or histological pathology of the central nervous system.[4]

51.1.4.1.2 Serology

Detection of Menangle virus–specific antibodies is undertaken using the virus neutralization test.[2,35] This test requires the use of live virus and cell culture, and routinely takes 5–7 days to complete. Neutralizing antibody titers >16 are considered positive in humans and pigs,[2,3] whereas titers ≥8 are considered positive in fruit bats.[3,30] The development of a prototype enzyme-linked immunosorbent assay, based on recombinant Menangle virus nucleocapsid proteins, offers the future prospect of a rapid and convenient serological test with no requirement for infectious reagents.[42]

51.1.4.1.3 Immunohistochemistry

In formalin-fixed pig tissues, demonstration of viral antigen in lesions can assist with diagnosis, either at the time of an outbreak investigation or retrospectively.[43] Following experimental infection of weaned pigs with Menangle virus, by intranasal inoculation, viral antigen was readily detected in lymphoid tissues and intestinal mucosa, and in limited amounts in other tissues, using a rabbit hyperimmune serum raised against purified recombinant viral nucleocapsid protein.[35]

51.1.4.1.4 Electron microscopy

Negative contrast[1] or ultrathin section[44] electron microscopical analysis of virus propagated in cell culture reveals the presence of pleomorphic enveloped virions and nucleocapsids, the ultrastructures of which are consistent with viruses in the family *Paramyxoviridae*, subfamily *Paramyxovirinae*.

51.1.4.2 Molecular Techniques

51.1.4.2.1 Real-Time Reverse Transcription Polymerase Chain Reaction

During the Menangle virus outbreak, molecular tests such as the reverse transcription polymerase chain reaction (RT-PCR) assay were not available to assist with disease investigation and control activities. Several attempts to amplify segments of the Menangle virus genome using primers based on conserved regions of other viruses in the subfamily *Paramyxovirinae* were unsuccessful. It was not until later, when a PCR-based cDNA subtraction strategy was used to isolate, clone, and sequence viral cDNAs from Menangle virus–infected cells, that the viral genome sequence was determined.[11,12] This led to the development of a multiplexed real-time RT-PCR TaqMan assay that, to date, has only been evaluated using clinical specimens (blood and solid tissues) collected from experimentally infected pigs.[35] Significantly, viral RNA was detectable in blood for a substantially longer period of time than infectious virus (at least 2 weeks), suggesting that blood might be a useful diagnostic indicator for confirming recent infection of pigs with Menangle virus. The assay clearly had both the specificity to distinguish Menangle virus from closely related viral genomes, including Tioman virus, with which it shares 72% nucleotide identity in the region corresponding to the target amplicon, and the analytical sensitivity to detect very low amounts of template in a wide range of cells and tissues. Simultaneous detection of 18S rRNA as an internal standard also provided a simple and effective means of excluding false-negative results.

In a diagnostic sense, several significant advantages of real-time PCR technologies are readily apparent, compared to conventional PCR: there is no requirement for any post-PCR processing, such as agarose gel electrophoresis or DNA sequencing, to confirm the identity of amplicons, and this greatly enhances the efficiency of sample testing; the sensitivity of the system is at least as good as conventional nested PCR tests; detection is performed in a closed-tube system, which greatly reduces the risk of carry-over contamination, either by previously amplified products or by samples containing high endogenous concentrations of target sequences; the methodologies are readily automated to increase sample throughput, if required; finally, because all TaqMan assays conform to universal cycling conditions, multiple assays targeting different pathogens can be run simultaneously in the same 96- or 384-well plate. Other improvements include hot start modifications to increase fidelity[45] and the inclusion of uracil N-glycosylase[46] for the prevention of carry-over contamination. Nevertheless, separation of work space into designated areas exclusively for reagent preparation, sample processing (nucleic acid extraction), PCR amplification, and post-PCR sample analysis, should this be required, is always recommended.[47]

51.2 METHODS

In experimentally infected pigs, viral RNA was detected in blood (for up to 21 days following challenge) and in solid tissues, including jejunum, ileum, nasal mucosa, lung, duodenum, colon, cecum, rectum, and spleen, all of which could conceivably be used to confirm recent infection with Menangle virus.[35] In a disease investigation scenario, however, brain, lung, and heart from affected stillborn piglets would be the samples of choice, since these are the tissues from which infectious virus was isolated during the outbreak in 1997.[1,2] Prior to the development of neutralizing antibodies in naive pigs, it is also likely that infectious virus would be present in nasal and oral secretions, as well as in feces and urine,[35] although the kinetics of viral RNA shedding in these samples has not been evaluated. The following two sections are therefore restricted to summarizing the extraction of Menangle virus RNA from blood and solid tissues, and its subsequent detection by real-time RT-PCR, since these are the sample categories that are likely to be of most relevance in the context of an outbreak investigation in pigs.

51.2.1 Sample Preparation

For whole blood, total RNA is isolated using the S.N.A.P. Total RNA Isolation Kit (Invitrogen) as recommended by the manufacturer. Briefly, 450 μL of Binding Buffer (7 M guanidine HCl, 2% Triton X-100) containing 2 mg/mL Proteinase K (Qiagen) is added to 150 μL of blood and vortexed vigorously for 1 min. Samples are subsequently incubated at 37°C for 20 min in a water bath and centrifuged for 3 min at 13,000 rpm (13,400–16,100 × *g*) in a benchtop microcentrifuge, after

which the supernatants are transferred to new 2 mL polypropylene tubes with O-ring caps (Sarstedt). To each supernatant is added 300 µL of isopropanol, which is mixed by pipetting. Each sample is passed several times through a 21 gauge needle attached to a sterile 1 mL plastic syringe, transferred to a S.N.A.P. Total RNA column and centrifuged for 1 min at 13,000 rpm (13,400–16,100 × *g*). Columns are washed once with 600 µL of Super Wash Solution (3.5 M guanidine HCl, 0.67% Triton X-100, 0.33% [v/v] isopropanol), twice with RNA Wash Solution (100 mM NaCl, 76% [v/v] ethanol), and are dried by centrifugation at 13,000 rpm (13,400–16,100 × *g*) for 2 min. Nucleic acid is eluted in 135 µL of RNase-free water, to which is added 15 µL of 10 × DNase buffer and 1 µL (2 U) of RNase-free DNase. After incubation at 37°C for 10 min, Binding Buffer (450 µL) and isopropanol (300 µL) are added to each reaction, which is mixed and transferred to a new column. Columns are centrifuged for 1 min at 13,000 rpm (13,400–16,100 × *g*), washed twice with RNA Wash Solution, and centrifuged for an additional 2 min to dry the resin. RNA is then eluted in 125 µL of RNAse-free water and stored at −80°C before use.

For fresh or RNAlater (Ambion) stabilized tissues, total RNA is extracted using the RNeasy Mini Kit (Qiagen) following the instructions of the manufacturer, with minor modifications as follows. Routinely, 10–20 mg of each tissue is cut into cubes of edge length 1–2 mm using a separate sterile pair of forceps, disposable scalpel, and tissue culture dish (as cutting surface) per sample. Cut tissues are transferred to 2 mL polypropylene tubes with O-ring caps (Sarstedt), to which have been added sterile 1.0 mm zirconia/silica beads (Biospec Products) to the 250 µL gradation, and 600 µL of lysis Buffer RLT. Samples are cooled on ice and homogenized in a Mini-BeadBeater-8 (Biospec Products) for two 1 min periods, which are separated by an additional incubation on ice. Samples are centrifuged for 3 min at 13,000 rpm (13,400–16,100 × *g*) in a benchtop microcentrifuge, after which supernatants are transferred to new 2 mL polypropylene tubes with O-ring caps (Sarstedt). To each lysate is added 600 µL of 70% (v/v) ethanol, which is mixed by pipetting. Successive aliquots (600 µL) of each sample are applied to an RNeasy column and centrifuged at 13,000 rpm (13,400–16,100 × *g*) for 1 min. Columns are washed once with 700 µL of Buffer RW1, twice with 500 µL of Buffer RPE, and are dried by centrifugation for 1 min at 13,000 rpm (13,400–16,100 × *g*). RNA is then eluted from each column with two successive 30 µL aliquots of RNase-free water, quantified by spectrophotometry, and stored at −80°C prior to use.

51.2.2 Detection Procedures

A two-step real-time RT-PCR assay has been developed for the quantitation of Menangle virus RNA in clinical samples from pigs.[35] The particular system used was the TaqMan assay (Applied Biosystems), a probe-based technology that provides a means of detecting only specific PCR products. The probe contains a fluorescent reporter dye, 6-carboxyfluorescein (FAM), at its 5′ end and a quencher dye, 6-carboxytetramethylrhodamine (TAMRA), at its 3′ end. The virus-specific primers and probe were designed to amplify and detect a short cDNA target of 66 nucleotides in length (corresponding to nucleotides 478–543 of the viral antigenome, within the N gene of Menangle virus). Their sequences are as follows: MP80F (5′-CGGATTTGAGCCTGGTACGT-3′), MP81R (5′-ACCTCTCCATTTGTCATCGGA-3′), and MT01-FAM (5′-FAM-TTCTCGCATTTGCCCTTAGCCGG-TAMRA-3′). Simultaneous detection and quantitation of an endogenous control (18S rRNA), in a multiplexed format, provides a means of excluding the presence of RT or PCR inhibitors in every sample tested, which provides a convenient and simple method of excluding false-negative results. The 18S rRNA primers and probe, the sequences of which are proprietary, are supplied in the TaqMan Ribosomal RNA Control Reagents Kit (Applied Biosystems).

51.2.2.1 Procedure

Synthesis of cDNA is performed using the TaqMan Reverse Transcription Reagents Kit (Applied Biosystems) according to the manufacturer's recommendations. Routinely, RT reactions are prepared in thin-walled 0.2 mL polypropylene capped tubes (Axygen Scientific Inc.) in 10 µL volumes: each reaction contains 1 × RT buffer, 5.5 mM $MgCl_2$, 500 µM of each dNTP, 2.5 µM of random hexamers, 0.4 U/µL of RNase inhibitor, 3.125 U/µL of MultiScribe Reverse Transcriptase, and either 2 µL (if extracted from whole blood) or 100 ng (if extracted from solid tissue) of RNA template.[35] Reaction mixtures without enzyme are also included as negative RT controls. Reaction tubes are capped, gently mixed, briefly centrifuged, and transferred to a GeneAmp PCR System 9700 Thermal Cycler (Applied Biosystems). RT is performed using the following cycling conditions: 25°C for 10 min (to maximize primer-RNA template binding), 37°C for 60 min (cDNA synthesis), and 95°C for 5 min (to inactivate the reverse transcriptase enzyme). Following RT, cDNA samples are generally stored at −20°C prior to use as template for real-time PCR.

Typically, real-time PCR assays are set up in polypropylene optical 96-well reaction plates (Applied Biosystems) in 25 µL volumes. Each reaction is set up in triplicate and comprises 12.5 µL of TaqMan Universal PCR Master Mix (Applied Biosystems) containing an internal reference dye (ROX) to normalize for non-PCR-related fluctuations in fluorescence occurring from well to well, 300 nM of each Menangle virus primer, 250 nM of Menangle virus probe, 50 nM of each 18S rRNA primer, 200 nM of 18S rRNA probe, 2 µL (if derived from whole blood) or 1 µL (if derived from solid tissue) of cDNA template, and nuclease-free water to 25 µL.[35] Plates are sealed with optical adhesive covers and transferred to an ABI Prism 7700 Sequence Detection System (Applied Biosystems) for amplification and detection of products using the following cycling conditions: 2 min at 50°C (to activate AmpErase uracil N-glycosylase), and 10 min at 95°C (to activate AmpliTaq Gold DNA Polymerase), and 50 cycles of 15 s at 95°C and 1 min at 60°C. Results are expressed in terms of the threshold cycle (C_T), the fractional cycle number at which the change in the reporter dye fluorescence (ΔR_n) passes an arbitrary, fixed

threshold set in the log (exponential) phase of amplification. Fixed threshold ΔR_n values are set at 0.25 for the Menangle virus–specific products and at 0.08 for the 18S rRNA-specific products (although these settings will need to be established for the specific real-time PCR platform in use).

Note: Using random hexamer primers to initiate cDNA synthesis enables viral genome, antigenome, and N mRNA (the most abundant viral transcript) to be amplified and detected simultaneously, thereby maximizing test sensitivity. For the Menangle virus assay, the amplification efficiency (98%) is constant for template copy numbers that vary by at least five orders of magnitude (corresponding to upper and lower C_T values of approximately 36 and 18, respectively). Notably, however, despite the N genes of the pig and bat isolates of Menangle virus sharing 95% nucleotide identity, two mutations in the 3′ terminal region of the reverse primer would prevent the bat variant from being detected by this assay. Development of additional virus-specific real-time RT-PCR assays will therefore be required to ensure that all currently known pig[11,12] and bat[32,41] isolates of Menangle virus are detectable.

51.3 CONCLUSIONS AND FUTURE PERSPECTIVES

Menangle virus is one of nine novel paramyxoviruses of fruit bat origin to be identified in the Australasian region within the last 2 decades. However, while it has caused disease in people, it is currently not in the same category as Hendra (Chapter 50) and Nipah (Chapter 53) viruses, which have caused serious illness and multiple fatalities in humans. Isolated in 1997 from stillborn piglets at a large commercial piggery in New South Wales, Australia, Menangle virus is a newly described cause of serious reproductive disease in pigs and may also cause severe influenza-like illness, with a rash, in humans. Although successfully eradicated from the affected piggeries within 2 years of entering the breeding herd of the index farm, many of the details relating to its pathogenesis and epidemiology, not only in pigs but also particularly in fruit bats and humans, remain unknown. Menangle virus probably remains endemic in fruit bats, the likely natural host of the virus, and therefore a continuing risk of reinfection exists.

Fortunately, it would appear that spillover of Menangle virus from the reservoir host to pigs is a rare event, with only one such occurrence documented to date.[1–5] In addition, it would seem that transmission to humans likely requires intense occupational exposure to recently infected pigs, including contamination of cuts and abrasions or mucosal surfaces, such as conjunctivae, with infectious materials.[5] Despite the lack of knowledge regarding the ecology of the virus, basic controls that restrict direct and indirect exposure of fruit bats to pigs should prevent future disease outbreaks in intensively managed piggeries that have effective biosecurity measures in place. An understanding of how and when the virus is shed from the natural host will help to define the risk factors associated with spillover to pigs, including extensively farmed and feral species, and real-time RT-PCR would be an ideal tool to facilitate screening of such samples prior to confirming their infectivity using cell culture. Increased awareness and recognition of Menangle virus as a potential cause of serious reproductive disease in swine, and influenza-like illness, with a rash, in humans, should also ensure its prompt consideration in the differential diagnosis of similar disease episodes in the future.

Also intriguing is the existence, in Malaysia, of Tioman virus, which cross-reacts with Menangle virus–specific antisera[17,48] and is closely related genetically.[11,12,16,17] Considering that antibodies to Tioman virus, or a Tioman-like virus, have since been detected in fruit bats in Madagascar,[49] novel rubulaviruses have been identified in, and isolated from, fruit bats in China,[50] Ghana,[51,52] and Australia,[41] and an estimated 66 new paramyxoviruses have been discovered in a worldwide surveillance study targeting 119 bat and rodent species,[39] it would appear that related viruses with an unknown propensity to cause disease in domestic animal species or humans are far more abundant and widespread than previously thought. Although Tioman virus has not been associated with disease in pigs or humans, a recent study has established that weaned pigs are susceptible to experimental infection.[53] Whether the virus is pathogenic in pregnant pigs, however, is not known. Furthermore, low neutralizing antibody titers to Tioman virus, or a closely related virus, have been detected in sera from 3 of 169 villagers on the island from which it was originally isolated, suggesting possible prior infection by this or a similar virus.[54] In the absence of any identifiable link to pigs, it was postulated that human infection might have occurred through consumption of fruit that had been partially eaten by bats, a potential risk factor common to 32 of the surveyed villagers, including two of the three who had detectable neutralizing antibodies to the virus.[54] It would not seem unreasonable to presume, therefore, that direct transmission of Menangle virus from fruit bats to people, such as wildlife carers, might be possible without prior amplification in pigs.

Many fundamental questions remain to be answered, such as how Menangle virus is maintained in fruit bats and over what geographic range it should be considered endemic, as well as which cellular receptor is used for viral attachment and how it relates to pathogenesis in each susceptible host species. Obtaining answers to complex questions such as these will be challenging and will require a multidisciplinary approach. However, until such time as Menangle virus infection in humans is better characterized, the true zoonotic potential of this recently emerged paramyxovirus will remain unclear.

52.1 INTRODUCTION

Newcastle disease (ND) is a highly contagious and often fatal disease of birds resulting from infection with the virulent strains of Newcastle disease virus (NDV). Since its first descriptions in the 1920s, ND has been responsible for drops in egg production and loss of stocks (up to 100%) in poultry farming industry through successive outbreaks. Given the nonspecific respiratory, gastrointestinal, and nervous symptoms it induces, the use of laboratory techniques such as reverse transcription polymerase chain reaction (RT-PCR) is crucial for rapid and accurate identification, virulence determination, and epidemiological tracking of this deadly pathogen.

52.1.1 Classification

NDV is a member of the genus *Avulavirus*, subfamily *Paramyxovirinae*, family *Paramyxoviridae*, order *Mononegavirales*.

Of the two subfamilies within the family *Paramyxoviridae*, the subfamily *Paramyxovirinae* comprises eight genera (*Aquaparamyxovirus*, *Avulavirus*, *Ferlavirus*, *Henipavirus*, *Morbillivirus*, *Respirovirus*, *Rubulavirus*, and *TPMV-like viruses*), whereas the subfamily *Pneumovirinae* includes two genera (*Pneumovirus* and *Metapneumovirus*).

The genus *Avulavirus* covers viruses that once belonged to the genus *Rubulavirus* and currently consists of 13 recognized species, namely, avian paramyxovirus serotype 1 (APMV-1, commonly known as NDV), APMV-2, APMV-3, APMV-4, APMV-5, APMV-6, APMV-7, APMV-8, APMV-9, APMV-10, APMV-11, APMV-12, and APMV-13, on the basis of hemagglutination inhibition (HI), neuraminidase inhibition, and phylogenetic assays (Table 52.1) [1–7].

Consisting of a single serotype, NDV, or APMV-1, can be separated into two classes (I and II) based on genome lengths and fusion (F) gene phylogenetic reconstruction.

Class I includes viruses that possess genomes of 15,198 nt, usually occur in waterfowl and shorebirds, and are of low virulence for chickens (except for one strain).

Class II encompasses pathogenic strains that have genomes of 15,186 nt (or 15,192 nt) and that are distinguished into 16 genotypes (I–XVI), with isolates from 1930 to 1960 belonging to I, II, III, IV, IX and those appearing after 1960 belonging to V, VI, VII, VIII, X, XI, XII, XIII, XIV, XV, XVI [8,9]. In addition, class II genotypes VI and VII are further subdivided into eight (a–h) and five (a–e) subgenotypes, respectively (Table 52.2). It is notable that of the 16 genotypes within class II, genotypes V–VIII harbor genomes of 15,192 nt, while others possess genomes of 15,186 nt. The increase in genome sizes (from 15,186 to 15,192 nt) results from insertion of 6 nucleotides in the 5′ noncoding region of the nucleoprotein (N) gene [10].

In accordance to their virulence in poultry, APMV-1 isolates can be differentiated into three pathotypes: lentogenic,

TABLE 52.1
Characteristics of Avian Paramyxovirus Serotypes 1–13

APMV	Genome (nt)	Host	Disease	F Protein Cleavage Site[a]
APMV-1 (velogenic)	15,186 (or 15,192)	>250 avian species; chickens most severely affected	High mortality	GRRQKR/F
APMV-1 (lentogenic)	15,198	Waterfowl, shorebirds	Asymptomatic or subclinical	GGRQGR/L
APMV-2	14,904	Turkey, chickens, psittacines, rails, passerines	Mild respiratory disease and drop in egg production; infertility in turkey	DKRAGR/F
APMV-3	16,272	Turkey, psittacines, passerines, flamingos	Encephalitis and high mortality in caged birds; respiratory disease in turkey and stunted growth in young chickens	PRPSGR/L ARRRGR/L
APMV-4	15,054	Ducks, geese, chickens	Mild interstitial pneumonia and catarrhal tracheitis	ADIQPR/F
APMV-5	17,262	Budgerigars, lorikeets	Depression, dyspnea, diarrhea, torticollis, and acute enteritis with high mortality in immature budgerigars	GKRKKR/F
APMV-6	16,236	Ducks, geese, turkey	Mild respiratory disease and drop in egg production in turkey; avirulent in chickens	PAREPR/L
APMV-7	15,480	Pigeons, doves, turkey	Mild multifocal nodular lymphocytic air sacculitis and decreased egg production in turkey	TLPSSR/F
APMV-8	15,342	Ducks, geese	Unknown	GYRQTR/L
APMV-9	15,438	Ducks	Unknown	RIREGR/I
APMV-10	15,226	Rockhopper penguins	Unknown	DKPSQR/I
APMV-11	17,412	Common snipe	Unknown	DSGTKR/F
APMV-12	15,312	Wigeon	Unknown	RGREPR/L
APMV-13	Incomplete	Geese	Unknown	QVRENR/L

[a] The amino acid sequence of the cleavage site of F protein precursor F0 to F1–F2 subunits is a primary determinant of avian paramyxovirus infectivity. NDV virulent strains contain at least three basic residues (lysine and arginine [K and R] between positions 113 and 116 at the C terminus of the F2 protein [cleavage site motif ^{111}GRRQKR/F^{117}] and phenylalanine [F] at the N terminus of the F1 protein [residue 117]).

mesogenic, or velogenic. The lentogenic pathotype is the least virulent and is associated with subclinical (mild respiratory or enteric) infections in both domestic poultry and wild bird populations. The mesogenic pathotype is moderately virulent and induces moderate respiratory and occasional nervous signs with low to moderate mortality. The velogenic pathotype is the most virulent and causes nervous signs or extensive hemorrhagic lesions in the gastrointestinal tract with high mortality (up to 100%). The velogenic pathotype may be further classified as neurotropic or viscerotropic depending on its predilection site [10].

52.1.2 Morphology and Genome Organization

NDV is an enveloped, pleomorphic (usually spherical, but sometimes filamentous) particle of about 200–300 nm in diameter. Derived from the plasma membrane of the host cell, the lipid bilayer envelope is covered with spike-like surface projections of 8 nm in length, which are made up of hemagglutinin–neuraminidase (HN) protein tetramers and F protein trimers. Beneath the envelope is the nonglycosylated matrix (M) protein, which encases the nucleocapsid core formed by the nucleocapsid (N) protein that encapsidates the viral genomic RNA. The phosphoprotein (P) and large (L) protein remain bound to the nucleocapsid core, forming the herringbone-like ribonucleoprotein complex.

Being a monopartite, negative-sense, single-stranded RNA of 15,186 nt (seen in isolates before 1960), 15,192 nt (seen in isolates from China), and 15,198 nt (seen in avirulent strain from Germany), which follows the "rule of six," the genome of NDV includes 55 nt leader at its 3′ end and 114 nt trailer at its 5′ end, flanking six open reading frames (ORF) in the order of 3′-N-P-M-F-HN-L-5′ [11–13].

The six ORFs (N, P, M, F, HN, L) are separated from each other by intergenic sequences, with each possessing its own gene start and gene end signal sequences, facilitating the production of the N protein, M protein, phosphoprotein (P), F protein, HN protein, and L-polymerase protein (Table 52.3). In addition, insertion of one G residue in the P ORF at consensus sequence "^{394}AAAAGGG^{401}" during RNA editing produces accessory protein V, which is present only in the virus-infected cells and is involved in anti-IFN activity (Table 52.3). Occasionally, insertion of two G residues at the RNA editing site in the P ORF generates W mRNA, which is present in NDV infected cells, but W protein has not been detected.

TABLE 52.2
Characteristics of Newcastle Disease Virus Classes and Genotypes

Class	Genotype	Subgenotype	Pathogenicity
I (between 1930 and 1960)			Avirulent
II (from 1960)	I		Mostly avirulent (including vaccine strain VG/GA)
	II		Avirulent (including vaccine strains B1, Clone30, LaSota, and MET95)
	III		Virulent
	IV		Virulent
	V		Virulent
	VI	a–h	Virulent
	VII	a–e	Virulent
	VIII		Virulent
	IX		Virulent
	X		Avirulent
	XI		Virulent
	XII		Virulent
	XIII		Virulent
	XIV		Virulent
	XV		Virulent
	XVI		Virulent

TABLE 52.3
Newcastle Disease Virus Genes and Encoded Proteins

Gene	Protein	Protein (aa)	Protein Mass (kDa)
N	Nucleocapsid (coat protein)	489	55
P	Phosphoprotein	395	42
	V	239	26
	W	179	19
M	Matrix protein	364	40
F	Fusion protein (glycosylated envelope protein)	553	59
H	Hemagglutinin–neuraminidase attachment protein	616	68
L	RNA polymerase	2204	248

52.1.3 Biology and Epidemiology

NDV has a tropism for avian respiratory epithelium cells. Upon entry to the respiratory tract, the virus attaches to host cell surface receptors through HN glycoprotein. This leads to fusion between virus and plasma membranes and release of ribonucleocapsid into the cytoplasm [14]. The viral RNA-dependent RNA polymerase sequentially transcribes each gene in the negative-sense RNA genome into viral mRNA, positive-sense antigenome, and then negative-sense genome. Following translation from mRNA and viral genome, the nucleoprotein encapsidates neosynthesized viral genomes to form the ribonucleocapsid. Then, the ribonucleocapsid binds to the M protein and the newly assembled virions bud at the plasma membrane or release after cell lysis.

NDV is an avian virus that is infective to over 250 species of birds of all age groups. As natural reservoir for the virus, wild birds tend to have asymptomatic infection. In susceptible hosts (such as domestic poultry), NDV infection causes severe illness, with high concentration of the virus in birds' bodily discharges. NDV is rarely isolated from naturally infected nonavian and nonhuman hosts except for one relating to cattle in 1952 and another relating to sheep in 2012 [15]. However, NDV is potentially pathogenic to humans and may cause conjunctivitis if exposed to the eyes.

NDV is relatively stable in nature and survives for several weeks in a warm and humid environment on birds' feathers, manure, and other materials, and indefinitely in frozen material. It also tolerates a wide range of pH (2–11). The virus is sensitive to heat at 56°C and is inactivated rapidly by dehydration and by the ultraviolet rays in sunlight. In addition, it is sensitive to detergents, lipid solvents, formaldehyde, and oxidizing agents.

NDV is spread primarily through direct contact between healthy birds and the bodily discharges of infected birds (including droppings and secretions from the nose, mouth, and eyes). Virus-bearing material picked up on shoes and clothing from infected flocks may spread the infection to healthy flocks [16].

Since its first descriptions in Java, Indonesia, in 1926 and Newcastle-upon-Tyne, England, in 1927, NDV has been responsible for causing devastating diseases in domestic poultry worldwide. Currently, NDV is endemic in Africa, Asia, and Americas. Between the years 2011 and 2014, NDV outbreaks have been reported in Israel (involving little owls and African penguins); Qatar; Cameroon, Central African Republic, Côte d'Ivoire, and Nigeria; China, Vietnam, Cambodia, Malaysia, and Indonesia; Dominican Republic; and Minnesota, Massachusetts, Maine, New Hampshire, and Maryland (involving cormorants and gulls) [17–23].

52.1.4 Clinical Features and Pathogenesis

With an incubation period of 2–15 days, ND is a highly contagious disease that affects a broad range of domestic and wild bird species and results in a spectrum of clinical diseases (from undetectable to rapidly fatal), the severity of which is dependent on the age and immune status of the host, pathogenic potential of NDV strains, and concurrent diseases [10].

Clinically, ND is characterized by sneezing, gasping, coughing, rales, anorexia, ruffled feathers, depression, listlessness, hyperthermia, hypothermia, greenish/watery diarrhea, edema of the eyes and neck, rough- or thin-shelled eggs, and reduced egg production. In some cases, neurological signs (e.g., circling, backward progression, convulsive somersaulting, head tremor, torticollis, ataxia, wing and leg paralysis) may be present. Death is a usual outcome, with sudden death occurring in acute cases [24].

Postmortem lesions include petechiae in the proventriculus and on the submucosae of the gizzard, and severe enteritis in the duodenum [25].

Differential diagnoses consist of highly pathogenic avian influenza, infectious laryngotracheitis, salmonellosis, spirochaetosis, mycoplasmosis, and hemorrhagic diseases.

NDV has the ability to undergo nucleotide change to enhance its pathogenic potential. One example relates to the F protein, which plays a critical role in virus entry into the cytoplasm. Highly pathogenic NDV strains have risen from changes in the glycosylation site or the cytoplasmic domain of F protein, leading to increased viral replication and pathogenesis in chickens. In addition, NDV virulent strains have a tendency to acquire at least three basic residues (lysine and arginine [K and R] between positions 113 and 116 at the C terminus of the F2 protein [cleavage site motif ^{111}GRRQKR/F^{117}] and phenylalanine [F] at the N terminus of the F1 protein [residue 117]). This renders the precursor protein F0 more susceptible to cleavage (into mature F1 and F2 subunits) by the ubiquitous proteases of the host, resulting in increased virulence. On the other hand, NDV strains of low virulence have fewer basic amino acid residues at the C terminus of the F2 protein and leucine (L) at position 117 (cleavage site motif ^{111}GGRQGR/L^{117}), which requires trypsin-like proteases to cleave the precursor [26].

Another example relates to the HN protein, whose receptor recognition and neuraminidase activities determine and also contribute to virulence of NDV. The HN protein from NDV virulent strains are less likely to have substitution of residues F220, S222, and L224 in the membrane proximal part of dimer interface of the HN globular domain, which weakens its association with receptors as well as its interaction with the F protein. Similarly, the HN protein of NDV virulent strains rarely has substitution of amino acid residue (L94) in the region intervening two heptad repeats in HN stalk structure, which affects fusion by hindering interaction with F protein [10].

Due to these nucleotide and amino acid changes, NDV virulent strains demonstrate enhanced ability to suppress or evade the host immune functions that are at harm's way to the invading virus [27].

52.1.5 Diagnosis

Laboratory methods for diagnosis of NDV infection rely on virus isolation, bioassays, serological tests, and nucleic acid detection.

52.1.5.1 Virus Isolation

NDV is often isolated in embryonated chicken eggs or African green monkey kidney (Vero) cell line. For virus isolation in embryonated chicken eggs, 0.2 mL of filtered sample is inoculated into 9–11-day-old specific pathogen free (SPF) embryonated chicken eggs via allantoic route, and the eggs are incubated at 37°C until death of embryos or a maximum period of 120 h, whichever is earlier. The embryos are candled every day, the dead embryos are chilled at 4°C overnight, and the harvested allantoic fluids are tested for hemagglutination (HA) activity and by bioassays. The allantoic fluids, which are negative for HA activity, are further passaged at least once more in embryonated chicken eggs. The presence of NDV in the allantoic fluids may be confirmed by HI test employing LaSota strain, specific serum, and RT-PCR.

For virus isolation on African green monkey kidney (Vero) cell line, the filtered sample is inoculated on cell monolayer in 25 cm^2 tissue culture flasks and incubated at 37°C for 1 h. Maintenance media (Eagle MEM) without fetal calf serum and with antibiotics (penicillin 10,000 IU/mL, streptomycin 100 μg/mL) is added. The flasks are incubated at 37°C and are observed daily for the appearance of cytopathic effects (CPE) for up to 7 days postinoculation. When 100% CPE is observed, the flasks are frozen at −20°C. The virus is harvested after two freeze–thaw cycles. At least three passages are carried out to confirm the isolation.

52.1.5.2 Bioassays

The pathogenicity of NDV isolates may be determined on the basis of the intracerebral pathogenicity index (ICPI) in day-old chicks, the intravenous pathogenicity index in 6-week-old chickens, or the mean death time (MDT) in chickens.

52.1.5.3 Serological Assays

HI and enzyme-linked immunosorbent assay (ELISA) including indirect, sandwich, and blocking or competitive ELISA are useful for screening and confirmation of NDV infection.

52.1.5.4 Nucleic Acid Detection

The virulence of NDV mesogenic or velogenic isolates is related to the basic amino acids at the cleavage site of the F protein, as lentogenic NDV isolates harbor fewer basic amino acids at that particular location. RT-PCR amplification and sequencing analysis of the gene segment underlying the F protein cleavage site provides a rapid and accurate approach for virulence determination of NDV strains [28,29]. The use of specific probes in real-time PCR makes pathotyping possible without sequencing analysis. In addition, various RT-PCR procedures have been developed for sensitive and specific identification and phylogenetic examination of NDV strains directly from clinical specimens [30–38].

ND is a list A disease by the Office Internationale des Epizooties (OIE). For NDV pathotyping, the OIE recommends the determination of ICPI with a value of 0.7 or higher and demonstration of amino acid motif in the F gene cleavage site after sequencing. According to the OIE guidelines, the presence of one basic amino acid at residues 116 and 115 of the F protein cleavage site and a phenylalanine at residue 117 along with a basic amino acid (R) at amino acid position 113 are considered markers of a virulent pathotype, and such isolates are notifiable to OIE [39].

52.1.6 Treatment and Prevention

As no specific treatment is available for NDV infection, the implementation of quarantine and sanitary measures and the use of prophylactic vaccines will help reduce the occurrence

or recurrence of ND outbreaks. These include immediate quarantine of any animals showing symptoms of ND, thorough cleaning and disinfection of facility, and vaccination of new birds before introduction to a flock [39].

Vaccines based on both live and killed NDV strains (including lentogenic vaccine strains Hitchner-B1, LaSota, V4, NDW, I2, and mesogenic vaccine strains Roakin, Mukteswar, and Komarov) are commercially marketed. Thermostable NDV vaccines have the advantages of easy preservation and transportation. Typically, broiler chickens are vaccinated via intraocular route on day one and boosted through drinking water on day 14. Layers are vaccinated first with live vaccine and then with inactivated vaccine via intramuscular or subcutaneous route [39,40].

NDV demonstrates a number of distinct features that make it a valuable vector for delivering antimicrobial and anticancer molecules in both animals and humans. These include its high growth efficiency in embryonated chicken eggs, cell culture, and the respiratory tract of avian and nonavian species; its predilection for the respiratory tract, which is ideal for delivering protective antigens from respiratory pathogens; its ability to elicit both humoral and cellular immune response; its relatively simple genome for easy manipulation; its tendency to replicate in host cytoplasm without integration into host genome; and its inherent ability to grow in IFN-deficient cells such as tumor cells.

Incorporating human influenza virus hemagglutinin (HA) protein, HIV and SIV Gag protein, HIV glycoproteins, human respiratory syncytial virus F glycoprotein, human parainfluenza virus 3 HN protein, or SARS-CoV spike glycoprotein, recombinant NDV strains have shown promise to confer protective immunity to respective pathogens in human recipients. In addition, recombinant NDV expressing VP2 or HA has been shown to protect chickens against infectious bursal disease, or H5N1 and H7N7 influenza virus, while that expressing gN and gG glycoproteins, gD glycoprotein, or G and F proteins protects mice against Rift Valley fever virus, bovine herpesvirus, or Nipah virus infection.

Furthermore, both NDV lytic (mesogenic and velogenic PV701, 73-T and MTH-68) and nonlytic (lentogenic Ulster) strains have proven to be potent anticancer agents. Recombinant NDV expressing immunostimulatory molecules (e.g., complement regulatory protein, IFNs, IL-2, GM-CSF, IgG antibody, and TNF-α) demonstrates enhanced oncolytic property.

52.2 METHODS

52.2.1 Sample Preparation

The trachea, liver, kidney, and brain as well as tracheal and cloacal swabs are collected from dead birds while blood samples are collected from alive but sick birds.

The mucosal layer of the trachea is scratched by a scalpel blade, and tissues of 0.5 cm^3 is removed from each liver and kidney. The specimen is then crushed in a sterile mortar with 1 mL sterile phosphate buffered saline (PBS) buffer. Brain tissue is triturated and homogenized in PBS with antibiotics (penicillin 1000 IU/mL and streptomycin 1000 μg/mL) making up a 10% (w/v) solution. The 10% suspension is clarified by centrifugation at 2500 × *g* for 15 min. The supernatant is collected and stored at −20°C until further use. Part of this suspension is used for RNA isolation for RT-PCR, and part is inoculated onto Vero cell culture after filtration through 0.22 μm filter for virus isolation. The samples may be also passaged in 10-day-old SPF embryonated eggs. The allantoic fluids are used for the assessment of pathogenicity (ICPI, MDT), a detection efficacy for validated real-time PCR and for sequence analysis [41].

Total RNA is extracted using RNeasy mini kit (Qiagen) or TRIzol reagent (Life Technologies) and stored at –70°C until use.

52.2.2 Detection Procedures

52.2.2.1 Conventional RT-PCR

Mase and Kanehira [42] described an RT-PCR-restriction enzyme analysis (REA) method for identification and differentiation of virulent and avirulent NDV isolates, with primers NDV-F2 (5′-TGGAGCCAAACCGCGCACCTGCGG-3′; nt 4235–4258) and NDV-R2 (5′-GGAGGATGTTGGCAGCAT-3′; nt 5000–4983), which covers the cleavage site of F protein and the region to construct a phylogenetic tree for genotyping the virus.

RT is performed with 9 mers random primers and SuperScript™ III (Invitrogen). PCR amplification is conducted with resulting cDNA and Takara Ex Taq PCR kit (Takara), using the following cycling parameters: 35 cycles of 94°C for 30 s, 50°C for 30 s, and 72°C for 30 s.

The expected PCR product is about 750 bp. Restriction enzyme *Hin*1 I digestion of this product from avirulent NDV strains yields several fragments, but not from virulent NDV strains, with the exception of the JP/Miyadera/51 strain (genotype II). However, the PCR product from the JP/Miyadera/51 strain is digested into 450 and 316 bp fragments with restriction enzyme *Apa* I, while those from other strains are not digested.

Note: This RT-PCR-REA method allows rapid differentiation of avirulent and virulent NDV strains. Further details on the cleavage site of F protein may be obtained by sequencing the 750 bp product.

52.2.2.2 Real-Time RT-PCR

Guo et al. [9] utilized degenerate primers (forward: 5′-GAGCTAATGAACATTCTTTC-3′; reverse: 5′-AAYAGGC GRACCACATCTG-3′; where R = A/G and Y = C/T) and probe (5′-FAM-TCATACACTATTATRGCRTCATTCTT-BHQ1-3′) from the L gene sequence for quantitative detection of NDV.

RT-PCR mixture (20 μL) is made up of 0.4 μL (10 μM) of primers and probe, 10 μL of 2× One-Step RT-PCR Buffer III (One-Step PrimeScript RT-PCR Kit, TaKaRa), 0.4 μL of TaKaRa Ex Taq HS (5 U/μL), 0.4 μL of PrimeScript RT Enzyme Mix II, 6 μL of RNase free dH_2O, and 2 μL of template RNA sample.

Amplification and detection are carried out in LightCycler 480 II Real-time PCR system (Roche), with the following parameters: 42°C for 5 min, 95°C for 10 s, 40 cycles of 95°C for 5 s, and 52°C for 30 s.

Note: To verify the results, RT-PCR products may be separated by electrophoresis on a 2.0% agarose gel and visualized using ethidium bromide.

52.3 CONCLUSION

Despite a history that spans for 90 odd years and our continuing efforts to put it under control during this time, ND has been far from being defeated or eradicated. This may be attributable to the fact that the etiologic agent of ND—NDV—naturally occurs in wild birds, which help spread and replenish the virus during seasonal migrations. Given the potential of NDV to cause serious economical damages, to the domestic poultry industry, it is vital that rapid, sensitive, and specific diagnostic methods are utilized for its identification, pathotyping, and monitoring. This will ensure the implementation of appropriate control and prevention measures including vaccination that will help limit the spread of this severe and often fatal disease of birds.

53.1 INTRODUCTION

Nipah virus (NiV) is a bat-borne paramyxovirus that causes disease in both humans and animals. The first recorded outbreak of NiV infection occurred in Malaysia from September 1998 to May 1999 [1]. The disease was named after Kampung Sungai Nipah (Nipah River Village), where the first viral isolate was obtained. Retrospective investigations suggested that NiV was responsible for sporadic diseases in pigs in Peninsular Malaysia since late 1996 but was not recognized as the clinical signs, morbidity, and mortality were not markedly different from those of several endemic pig diseases [2].

NiV is a highly pathogenic paramyxovirus and biosafety level (BSL)-4 containment is required to work with live virus in laboratories. The virus causes severe febrile encephalitis and respiratory distress syndrome with high mortality rate in humans. During the outbreaks in Malaysia and Singapore, most human infections occurred in workers in pig slaughterhouse who had direct contact with NiV-infected pigs. A relatively low mortality rate was noted in pigs. Approximately 1.1 million pigs were culled for a successful outbreak control [3]. Bats of the genus *Pteropus* were identified as the natural reservoir hosts of NiV.

NiV encephalitis was subsequently described in India in 2001 [4], and several NiV outbreaks were also reported in Bangladesh from 2001 to present. Drinking raw date palm sap contaminated with NiV from bat urine or saliva has been identified as a major route of transmission of NiV to humans in Bangladesh. There has been no intermediate animal host as in the outbreak in Malaysia [5]. Human-to-human transmission among family members, community care givers [6], and care workers has been documented in Bangladesh [7]. In 2014, there have been reports of 17 persons in the Philippines associated with NiV infection [8]. They had acute encephalitis, meningitis, or influenza-like illness. Almost all had participated in horse slaughtering and/or horse meat consumption.

53.1.1 Classification, Morphology, and Genome Organization

Classification: NiV is a single-stranded, negative-sense RNA virus belonging to the *Henipavirus* genus in the *Paramyxovirinae* subfamily, *Paramyxoviridae* family [9]. The *Paramyxoviridae* family is divided into two subfamilies: the *Paramyxovirinae* and the *Pneumovirinae* [10]. In turn, the subfamily *Paramyxovirinae* is separated into five genera: *Rubulavirus*, *Respirovirus*, *Avulavirus*, *Morbillivirus*, and *Henipavirus*, the latter of which has been added recently. Hendra virus (HeV), initially discovered in 1994, is the prototype of the genus *Henipavirus*, while NiV is the second species, which was first identified in Malaysia in 1999. Recently, a new paramyxovirus, Cedar virus, was isolated from Australian bats that share significant features with the known henipaviruses and has been classified as the third species within this genus [11].

Morphology: NiV shares common morphological characteristics with other members of the family *Paramyxoviridae*, including a herringbone-like nucleocapsid structure and nucleocapsid accumulation along plasma membranes during budding. Its RNA genome consists of helical nucleocapsids encased in an envelope forming relatively spherical, pleomorphic virus particle. However, some unique characteristics exist, including unusual cytoplasmic ringlike reticular inclusions in the proximity to the membranes of the endoplasmic reticulum and long cytoplasmic tubules in the periphery of NiV-infected cells. Nipah virions on average are larger in diameter than typical paramyxoviruses (150–400 nm) [1,12]. Extracellular virus particles are pleomorphic, with an average diameter of 500 nm.

Genome organization: The genome of NiV isolates from Malaysia is 18,246 nucleotides (nt) in size [13], 12 nt longer than the HeV. NiV isolates from Bangladesh contain 18,252 nt [14], one of the largest genomes among paramyxoviruses, with the exception of the rodent-borne J-virus and Beilong virus [15]. The genome size of Cedar virus, the new member of *Henipavirus* is 18,162 nt [11]. The *Henipavirus* genome consists of six genes encoded from 3′ to 5′, the nucleocapsid (N), phosphoprotein (P), matrix (M), fusion (F), attachment glycoprotein (G), and large (L) polymerase, respectively. The NiV N protein consists of 532 amino acids (aa) and is responsible for encapsidating the viral genome and its typical herringbone-like structures seen in electron micrographs [16]. The NiV M protein, 352 aa long, interacts with the cytoplasmic tail of the F protein, the ribonucleoprotein complex, and the inner surface of the virion envelope, to provide rigidity and structure to the virion [16]. The NiV F protein is a 546 aa long type I transmembrane protein, which forms trimers on the cell surface. It is responsible for mediating the fusion of virus and host cell membranes during infection [9]. The NiV G protein is a 604 aa long type II membrane protein that forms tetramers upon cell surface expression. It serves primarily in the cellular receptor binding [9]. The L gene of NiV is 6955 nt in length and contains an open reading frame (ORF) that is predicted to encode an L protein consisting of 2244 aa. It is the largest and the least abundant viral protein. There are many different enzymatic functions attributed to it, including initiation, elongation, and termination of both mRNA transcription (capping, methylation, and polyadenylation of mRNA) and genome replication [16]. The NiV P is 709 aa long and is the only essential gene product encoded by the P gene for genome replication [17]. In addition to coding for the P, the P gene of NiV encodes three other nonstructural proteins (C, V, and W). The V and W proteins are generated by RNA editing, while the C protein is encoded by a second ORF downstream of the translational initiation site for the P ORF [18].

Nucleotide homology in the ORFs of the various genes of HeV and NiV exceeds 70%, with more than 80% amino acid identity in most genes, but less than 49% nucleotide similarity compared with other members of the *Paramyxovirinae* family [18]. Sequence analyses of the N, P, M, F, and G genes of NiV isolated from human and pigs in Malaysia were nearly identical, while NiV isolated from *Pteropus hypomelanus* shortly after the outbreak had 5–6 nt differences when compared to the human isolates [19].

53.1.2 Epidemiology

53.1.2.1 Epidemiology of Nipah Virus Outbreak in Malaysia

The first incidence of human NiV infection was recognized in a large outbreak in Peninsular Malaysia from September 1998 to May 1999 [1]. The initial human cases were identified among pig farmers in the city of Ipoh, northwestern part of Peninsular Malaysia, in late September 1998. By December 1998, larger clusters of similar cases were reported 300 km south of Ipoh. A total of 283 cases were reported with 109 (39%) fatalities [20]. Between March 10 and 19, 1999, there was a subsequent outbreak in one of Singapore's abattoirs due to infected pigs imported from Malaysia. Eleven workers developed NiV-associated encephalitis or pneumonia, with one fatality [21]. The identical sequences of NiV isolates from humans and pigs, combined with the observation that humans with NiV infection had close contact with pigs' secretions and excretions, suggested that NiV was transmitted from infected pigs to humans through direct contact with pigs or fresh pig products [22]. There was no report of person-to-person transmission of NiV in Malaysia or Singapore.

Since 1999, NiV infection in human and animal has not been detected in Malaysia or Singapore but has been recurring in India and Bangladesh since 2001. The alarming one was an outbreak in the Philippines in 2014 [8].

53.1.2.2 Epidemiology of Nipah Virus Outbreak in Bangladesh

Nipah encephalitis/acute respiratory distress syndrome with very high case fatalities in humans have been recognized almost annually in Bangladesh since 2001. More than 70% of the NiV-infected patients have died [23]. As of January 2014,

304 human cases with NiV infection, leading to 232 (76%) fatalities, in Bangladesh have been reported, [24]. Drinking raw date palm sap contaminated with bat urine or saliva containing NiV has been demonstrated as a mode of transmission of NiV to humans in Bangladesh. There were no intermediate animal hosts [5]. Other mode of transmission is via human to human, usually nosocomial, or corpse to human [7]. A small number of NiV-infected cases in Bangladesh had history of contact with sick cows [25]. The retrospective study suggested that NiV patients were more likely than noninfected patients to have had contact with an ill cow (OR 7.9, CI 2.2–27.7). However, there was no definite proof due to unavailability of cow specimens for testing.

53.1.2.3 Infection in Bats

Bats of the genus *Pteropus* have been suggested as the potential natural reservoir hosts for NiV [19]. Table 53.1 shows a summary of testing for NiV in bats from outbreak and nonoutbreak countries. Successful virus isolation from bats has been reported from the urine of *Pteropus vampyrus* [38] and *P. hypomelanus* [19] in Malaysia and *P. lylei* in Cambodia [39]. NiV infection in non-*Pteropus* bat was evident by the response of antibody (Table 53.1). Viral RNA was detected in bats from India, Thailand, Indonesia, and East Timor. The seasonal prevalence of NiV in *P. lylei* was demonstrated by the presence of viral RNA from bat urine [40] whose sequences were similar to those found in several outbreaks in Bangladesh during the early part of the year. Nested reverse transcription polymerase chain reaction (RT-PCR) method has applied to detect NiV RNA in the urine, saliva, and serum of bats [41–43].

53.1.3 Clinical Features and Pathogenesis

53.1.3.1 In Humans

NiV outbreak in Malaysia caused severe, rapidly progressive encephalitis with a mortality rate of nearly 40%. The incubation period in humans ranged from 4 days to 2 months, where more than 90% of the cases had an incubation period of 2 weeks or less [20]. The main presenting features were fever, headache, dizziness, and vomiting. Distinctive clinical signs included segmental myoclonus, areflexia and hypotonia, hypertension, and tachycardia, suggesting brain stem and upper cervical cord involvement [44]. A few patients developed atypical pneumonia. Two unique features of encephalitis were observed in the cases in Malaysia as acute encephalitis with vasculitis and late onset or relapse with multifocal cortical gray matter involvement [45].

On the other hand, the case-fatality rate was higher in Bangladesh and India than in Malaysia. The clinical characteristics of NiV infection in Bangladesh other than encephalitis include a severe respiratory component, which was not reported in the outbreaks in Malaysia [46]. Other common clinical features include fever, altered mental status, headache,

TABLE 53.1
Summary of Bat Species Positive for Nipah Virus

Country	Bat Species	Testing Method	Year of Study (References)
Outbreak countries			
Malaysia	*Pteropus hypomelanus*, *Eonycteris spelaea*, *Cynopterus brachyotis*, *Scotophilus kuhlii*, *Pteropus vampyrus*	Antibodies	1999 [26]
	P. hypomelanus	Virus isolation	1999–2000 [19]
	P. vampyrus	Antibodies, virus isolation	2004–2005 [38]
	P. hypomelanus (antibodies only), *P. vampyrus*	Antibodies and RNA	2004 [27]
Bangladesh	*Pteropus giganteus*	Antibodies	2003, 2007 [25,28]
Nonoutbreak countries			
Africa	*Eidolon helvum*	Antibodies	1992, 2007–2011 [29,30]
Cambodia	*Pteropus lylei*	Antibodies, virus isolation	2000–2001 [39]
China	*Rousettus leschenaultia*, *Hipposideros armiger*, *H. pomona*, *Miniopterus* spp., *Myotis daubentonii*, *M. ricketti*, *Rhinolophus affinis*, *R. sinicus*	Antibodies	2004–2007 [31]
East Timor	*P. vampyrus*, *R. amplexicaudatus*	RNA	2004–2005 [32]
Ghana	*E. helvum*, *Epomophorus gambianus*, *Hypsignathus monstrosus*	Antibodies	2007 [76]
India	*P. giganteus*	Antibodies	2003 [33]
	P. giganteus	RNA, antibodies	2009–2010 [34]
Indonesia	*P. vampyrus*	RNA, antibodies	2009 [79]
Madagascar	*Eidolon dupreanum*, *Pteropus rufus*	Antibodies	2003–2005 [35]
Papua New Guinea	*Dobsonia magna*, *Pteropus alecto*, *P. conspicillatus*	Antibodies	1996–1997, 1999, 2008 [78,36]
Thailand	*P. hypomelanus*, *P. vampyrus*, *P. lylei*, *Hipposideros larvatus*	Antibodies	2002–2005 [41]
	P. lylei, *H. larvatus*	RNA	2002–2005 [41]
Vietnam	*Rousettus leschenaultia*, *Cynopterus sphinx*	Antibodies	2007–2008 [37]

cough, respiratory symptoms, vomiting, and convulsions. The median incubation period is 9 days (range 6–11 days). Cases with late-onset or relapsed encephalitis were not mentioned in Bangladesh and India.

Clinical features of patients in the Philippines include acute encephalitis, meningitis, and influenza-like illness where mortality was found only in the case of encephalitis (82%) [8]. There was also human-to-human transmission. One serum sample from patient was positive by real-time PCR for NiV, and one cerebrospinal fluid (CSF) sample from another of these patients was NiV positive by next-generation sequencing (single-sequence read with 71 bp of the P gene of NiV).

53.1.3.2 In Pigs

NiV infection in pigs was reported only from Malaysia during 1998–1999. The spread of NiV infection among pigs is easily spread through transport of pigs from farm to farm. The incubation period was estimated to be 7–14 days [47]. The clinical patterns of naturally infected pigs varied according to the age of the pigs. Sows were noted to primarily present the neurological symptoms, while porkers predominantly exhibited respiratory symptoms. However, many infected pigs appeared to be asymptomatic.

Infection in suckling pigs (piglets) presented with higher mortality rate (approximately 40%). The major symptoms include open-mouth breathing, leg weakness with muscle tremors, and neurological twitches.

Pigs from 4 weeks to 6 months of age (weaners and porkers) usually presented acute febrile illness (>39.9°C) with respiratory signs ranging from rapid and labored respiration to a harsh nonproductive cough (loud barking cough). The mortality rate is less than 5%, but the morbidity rate approaches 100%. In less severe cases, open-mouth breathing was presented, while hemoptysis was found in severe cases. One or more of neurological signs usually accompanied the respiratory signs, for example, trembling and neurological twitches, muscle spasms and myoclonus, rear leg weakness and varying degrees of spastic paresis or lameness, uncoordinated gait when driven and hurried, and generalized pain especially in the hindquarters.

Similar symptoms were presented in boars and sows. Sudden death could be observed. However, the usual presentations were acute febrile illness (>39.9°C), with labored breathing, increased salivation (drooling or frothy), nasal discharge (serous or mucopurulent or bloody), and possible early abortion for sows (first trimester). Some or all of the following neurological signs, such as agitation and head pressing, tetanus-like spasm and seizures, nystagmus, champing of the mouth, and apparent pharyngeal muscle paralysis, were also present.

53.1.3.3 In Bats

Fruit bats of the genus *Pteropus* are the natural hosts for NiV, but infection in bats causes no apparent disease. The longitudinal study of captive *P. vampyrus* bats strongly suggests that NiV circulates in wild bat populations and their antibodies can be maintained for long periods [48]. It was also found that maternal antibodies against NiV were transmitted passively. This study proposes that NiV was recrudesced and then transmitted horizontally between bats during the study period (1 year).

Experimental subcutaneous NiV infection in gray-headed fruit bats (*Pteropus poliocephalus*) resulted in the production of neutralizing antibodies in serum and histological changes in different tissues. However, these bats developed subclinical infection that was characterized by the transient presence of the virus within selected viscera, in episodic viral excretion, and in seroconversion, despite the inoculation of rather high viral doses [49]. The virus isolation was successful from the urine, kidney, and uterus.

53.1.3.4 In Other Animals

Other animals found to be infected with NiV during the initial outbreak in Malaysia were found to be naturally infected with NiV, such as cats, dogs, and horses [1,50]. Serological evidence of dogs in the areas in proximity with the farms during the outbreak in Malaysia revealed that dogs were susceptible to NiV infection [51]. Pulmonary vasculitis, alveolar edema, and inflammation were demonstrated in two naturally infected dogs [52]. A number of species of animals have been employed as animal models for NiV infection including fruit bats, pigs, horses, cats, ferrets, squirrel monkeys, African green monkeys, mice, hamsters, and guinea pigs [53]. Cats are susceptible to NiV infection under natural or experimental conditions. Severe pulmonary inflammation and bronchial epithelium involvement may be prominent. Vasculopathy was observed in many organs, except the brain parenchyma, but meninges were involved [52].

During 2014, *Henipavirus* infection caused severe illness and death in horses in southern Philippines [8]. Ten horses died with neurological symptoms (9/10), but no samples were available for testing. Four cats and one dog that ate horse meat died. Four serum samples from dogs were positive for neutralizing antibodies against NiV.

53.1.4 Diagnosis

A major challenge for NiV diagnosis is that the virus is listed as a BSL-4 agent. The first-class equipment for advanced diagnostic platforms are lacking in many developing countries identified as hot spots for NiV outbreaks. The diagnostic capability (exploiting both phenotypic and genotypic characteristics of NiV) has continually been developed and refined, but no commercial diagnostic kit for NiV is currently available.

53.1.4.1 Conventional Techniques

Conventional techniques useful for NiV detection range from virus isolation, electron microscopy (EM) examination, immunohistochemistry, to serological tests.

Virus isolation and EM are important for identification and characterization. NiV grows well in African green monkey kidney (Vero) cells, and the cytopathic effect (CPE) is usually seen within 3–5 days. CPE is not specific because many other viruses can cause similar syncytia formation;

thus, another test to identify the virus is required. Isolation of NiV requires laboratories with BSL-4 containment and has a very slow turnaround time in inoculation, with low viral titer sample. NiV was isolated from two bat species in Malaysia, *P. hypomelanus* (from urine and a partially eaten fruit swab) [19] and *P. vampyrus* (from urine) [38] and from the urine of *P. lylei* in Cambodia [39]. NiV from pigs was isolated after infecting Vero cells with lung tissue samples from NiV-infected pigs that died from acute respiratory distress syndrome and encephalitis [54]. It is recommended that tissue samples from the brains, lungs, kidneys, and spleens of suspected NiV-infected animals should be submitted for viral isolation [55]; otherwise, they can be tested by molecular assays. Samples should be transported at a temperature of 4°C to the designated laboratory within 48 h or should be sent frozen on dry ice, or nitrogen vapors should be used if shipping is over 48 h [56]. However, in the absence of BSL-4 containment, primary virus isolation from suspected samples can be conducted under strict BSL-3 conditions [57]. When CPE with syncytia is observed, the cell culture and manipulation of potentially infectious specimens should be stopped. Fixed cells should be confirmed using proper techniques: immunofluorescence assay or RT-PCR assay in supernatant fluids. In NiV-positive cases, the specimen should be transferred to an appropriate laboratory for further identification and analysis. Recently, different pteropid bat cell lines have been developed at Australian Animal Health Laboratory as a useful additional tool for virus isolation [58].

Immunohistochemistry proved to be one of the most useful tests in NiV investigation during the initial outbreak in Malaysia [59]. This technique is safe and can be performed using formalin-fixed tissue specimens. There is a wide range of tissues for NiV antigen detection. During the outbreak in Malaysia, the presence of NiV antigens were demonstrated by immunohistochemistry in syncytial cells in the lungs, in epithelial cells lining the upper airway passages, and in intraluminal necrotic debris in the upper and lower airways of infected pigs [1]. NiV antigen was also detected in the kidneys by focally staining the renal tubular epithelial cells. Ideal specimens for immunohistochemistry testing should include samples from various regions of the brain, lungs, mediastinal lymph nodes, spleen, and kidneys. In pregnant animals, the uterus, placenta, and fetal tissues should be included [55].

Initially, the immunostaining for NiV antigens was performed with rabbit HeV antiserum and later with convalescent pig and cat anti-NiV antisera [55]. At present, it has been replaced by hyperimmune mouse ascetic fluids [57] or rabbit polyclonal antibodies against NiV [60]. Monoclonal antibodies (MAbs) against NiV antigen were developed, and their abilities to detect NiV antigen in formalin-fixed tissues of naturally infected pig were tested [61]. The results were consistent with the previous assays using rabbit polyclonal antibody.

Several serological tests have been developed including serum neutralization test (SNT), enzyme-linked immunosorbent assay (ELISA), Luminex-based binding and inhibition antibody tests, and SNT based on pseudotyped viruses. Detection of antibodies by immunofluorescence assay, Western blotting, and immunoprecipitation assays is possible, but these methods are not routinely used [57].

SNT is the gold standard for serology and the confirmation test for ELISA results. It uses live virus to measure antibody function and requires BSL-4 containment [55]. A rapid immune plaque assay has been developed to detect neutralizing NiV antibodies [62]. The turnaround time is reduced from up to 3 days in the traditional microneutralization assay to 1 day in the immune plaque assay. Recently, several systems of SNT assays using pseudotyped viruses expressing F and G protein of NiV as targeted antigens have been developed, and the assay can be performed at BSL-2 laboratory [63]. The NiV recombinant vesicular stomatitis virus systems with luciferase [64] and green fluorescent protein (GFP) reporters [65] have been developed. Recently, the pseudovirus system using nonfluorescent reporter has been developed, where the GFP reporter gene was replaced by secreted alkaline phosphatase (SEAP). SEAP activity in culture supernatant can then be measured on an ELISA plate reader [66].

ELISA is convenient, rapid, and widely used as it can be safely performed at BSL-2 laboratory. Test serum is either inactivated by γ-irradiation or heated at 56°C. ELISA procedures for the detection of NiV-specific immunoglobulin (Ig) G and IgM have been developed at U.S. Centers for Disease Control and Prevention (CDC) [57]. They can be used for the detection of antibody in humans, livestock, and wildlife animals without a nonspecific reaction. NiV–Vero E6, which is prepared in a BSL-4 laboratory and inactivated by γ-irradiation, is used as an antigen, while a mock-infected Vero E6 is used as a control [57]. It has been found that CDC ELISA and SNT yield a relative sensitivity of 87% and specificity of 99% in bat sera testing [39]. The recombinant NiV G antigens expressed from baculoviruses or *Escherichia coli* [67,68], and NiV N antigen expressed from *E. coli* can be produced in a BSL-2 laboratory [69]. Results from the initial tests are promising. A MAb-based solid-phase blocking ELISA for the detection of NiV antibodies has been developed as a screening test for NiV infection and evaluated using samples from bats and pigs [70].

Anti-N and anti-P MAbs were used to develop two antigen capture ELISAs, one for virus detection and the other for differentiation between NiV and HeV. The lower limit of detection of the capture assay with both MAbs was 400 pfu [71]. The purified polyclonal antibodies derived from NiV G-encoding DNA-immunized rabbits were also developed for the detection of NiV antigen by ELISA [72]. The lowest detection limit against live Bangladesh strain viruses was 2.5×10^4 $TCID_{50}$ (50% tissue culture infectious doses). The applications of both capture ELISAs on natural biological specimens remain to be evaluated. In future, this system may provide a high-throughput format with simple and affordable methodology that could serve as an alternative rapid diagnostic assay.

Without the need for a BSL-4 facility, ELISA remains to be the most affordable serological test for the diagnosis of NiV infection, but it requires inactivated NiV–Vero E6 cell slurry antigen. During the past decade, novel serological technologies have been developed, increasing the surveillance capacity especially in developing countries. Examples of

new serological technologies include the new format of NiV antigens, which have been expressed by recombinant DNA technology, multiplex detection of multiple pathogen antibodies using microsphere technology, and the NiV–pseudovirus for the SNT where the test can be performed in a low-containment-level laboratory.

Luminex-based multiplexed microsphere assays have been developed specifically for the detection of *Henipavirus* (HeV and NiV) antibodies [73]. Two different test formats were developed, a total antibody-binding and a restricted receptor-blocking format designed as a surrogate for virus neutralization. The target antigen for both assays is recombinant-expressed surface G protein of HeV and NiV that are coated on two Luminex beads with distinctive fluorescent spectra. For binding assays, the bound antibodies were detected by biotinylated protein A/G, followed by streptavidin–phycoerythrin. On the other hand, in the blocking format, the cellular receptor, a recombinant ephrin-B2 labeled with biotin, will bind to the G protein on the beads in the absence of *Henipavirus*-specific antibodies. This supports the binding of streptavidin–phycoerythrin molecule, resulting in a positive binding signal. The Luminex blocking assay may be a substitute for SNT that can be performed in the absence of live virus at a standard laboratory without any high biocontainment need and requires very small amounts of sera while providing valuable data quickly (within 2–3 h) [73]. In addition, Luminex assays have significantly enhanced the capability and capacity to confirm HeV infection in humans [74], animal models [75], and international serosurveillance for henipaviruses in bats and other species including fruit bats and domestic pigs in West Africa [76,77], *Pteropid* bats in Papua New Guinea [78], and *P. vampyrus* bats in Indonesia [79].

53.1.4.2 Molecular Techniques

By targeting the nucleic acids, molecular techniques play an increasingly important role in the diagnosis of viral infection since they have high sensitivity and specificity and do not require a high-containment-level laboratory. The commonly applied molecular techniques include conventional PCR, real-time PCR, sequencing, and viral multiplex detection by microsphere suspension array system. Together with ELISA, PCR is indispensable during NiV surveillances in bats, the natural reservoir hosts for NiV. The conventional PCR system can be found in most laboratories in developing countries, and the positive control RNA or DNA can easily be constructed by direct synthesis or using in vitro transcription technology [80].

Genome sequence of NiV clearly places it in the *Paramyxoviridae* family and is closely related to HeV. NiV RNA was initially amplified using RT-PCR assay with primers designed to amplify 141 bp of the P gene, which has conserved sequences across many members of the *Paramyxoviridae* family [1]. The PCR primers used to amplify complete N, P, and M genes of NiV were designed from the initial short PCR products of these genes and sequence data from HeV in a stepwise fashion [1]. These three genes from NiV share 70% to 78% nucleotide homology with HeV [1]. NiV N-specific PCR used to amplify the 228 bp amplicon was developed to study NiV infection in tissues and serum specimens from infected humans and pigs during the outbreaks in Malaysia and Singapore and specimens from infected cats and dogs from Malaysia [1]. The sequences derived from isolates of human cases and pigs from both countries were identical.

Two conventional RT-PCR assays were developed during the recent NiV outbreaks in India and Bangladesh. The primer set NVNBF-4 (5′-GGAGTTATCAATCTAAGTTAG-3′) and NVNBR-4 (5′-CATAGAGATGAGTGTAAAAGC-3′) amplifies 159 bp of the N gene of NiV. The primer set NVBMFC1 (5′-CAATGGAGCCAGACATCAAGAG-3′) and NVBMFR2 (5′-CGGAGAGTAGGAGTTCTAGAAG-3′) amplifies 320 bp of the M gene [4,6]. NiV RNA in urine samples from 5 of 6 patients was detected by RT-PCR of N gene, while RNA from the M gene was detected in 3 of these 5 samples [4]. Sequence analysis of partial N and M gene sequences (159 and 320 bp, respectively) can be used to confirm NiV infection and differentiate between those in Bangladesh in 2004 and Malaysia in 1999 [4].

Another conventional PCR method, the duplex-nested RT-PCR, which was initially developed for surveillance study in bats [43], can be useful for NiV RNA detection in animals and humans. It has been shown to detect and differentiate NiV infection between that from Malaysia and that from Bangladesh. This method is based on the nested RT-PCR at N gene, yielding a high sensitivity; however, it requires standardization and stringent quality control to avoid false-positive result from cross contamination or false-negative result from PCR inhibitors. Using a positive control RNA construct of different sizes and nucleotide sequences can help differentiating the positive control from wild-type NiV [80]. Further, coamplification of extrinsic RNA with wild-type RNA, by adding a minimum amount of extrinsic RNA to the PCR reagents before starting the reaction, could monitor the PCR inhibitor contamination in the biological specimens [43]. The PCR product should be sequenced for confirmation. Sizes of first- and second-round PCR products are 398 and 227 bp, respectively. Two heminested PCRs can be performed from the same set of primers, and 357 bp sequences of NiV RNA can be obtained for further bioinformatics analysis. Details of the method can be found in the next section. Real-time RT-PCR methods for the detection and quantitation of NiV have been developed for the screening of a population of known negative pig samples [80], assessment of NiV infection in a feline model under the vaccine study [81], quantitation of NiV replication kinetics in Vero cells [82], and detection and characterization of NiV in cell culture and in biological samples [83]. All four PCR methods target the N gene for amplification, but at different positions. The array consensus PCR assays for the detection of henipaviruses at the N, P, M, and L genes by using the SYBR Green and TaqMan real-time PCRs and a conventional heminested PCR have been developed [84]. It has been found that N gene SYBR Green assay is the most useful assay for the investigation of unknown henipaviruses. The detection procedures of these five methods have been published [85].

Rather than serological assay, microsphere array system can be applied for simultaneous fluorescent identification of multiple separate nucleotide targets in a single reaction. Microsphere suspension array system (Luminex MagPlex-TAG) targets multiple sites within the N and P genes for the simultaneous detection and differentiation between HeV and NiV [86]. The analytical sensitivity of the microsphere array assays coordinated with the standard qPCR assay. The assays offer advantages over qPCR as it can multiplex; however, it requires more turnaround time. Two PCRs are required before hybridization followed by fluorescence detection using the Bio-Plex instrument.

53.2 METHODS

53.2.1 Sample Collection and Preparation

53.2.1.1 Sample Collection

Human antemortem specimens that can be used for NiV testing are CSF, saliva, urine, and nasal and pharyngeal secretions [3]. The specimens should be collected during the acute, febrile stages of the illness and frozen on dry ice or liquid nitrogen for further diagnosis by virus isolation or molecular techniques. NiV was isolated and identified using molecular techniques from porcine lung tissue, canine brain tissue, and feline brain tissue during the first outbreak in Malaysia [1]. Excretions and secretions such as urine, saliva, and pharyngeal and respiratory secretions of infected pigs were the source of transmission between pigs in the same farm during the outbreak in Malaysia and can be used for molecular testing [3]. In experimentally infected pigs, NiV could be detected in CSF, pharyngeal swabs and nasal washes, brain tissue, olfactory bulb, trigeminal ganglion, turbinate, trachea, submandibular lymph node, and bronchiolar lymph node using real-time RT-PCR [87].

Formalin-fixed tissue and paraffin-embedded blocks are suitable for immunohistochemistry assay and can be shipped at room temperature. Specimens for serology should be preserved and transported at a temperature of −20°C or below [57]. NiV isolation was successfully performed from bat urine and a swab from a partially eaten fruit [19]. NiV RNA has been detected in urine, blood, saliva, liver and bladder from naturally infected bats using PCR assay [34,41,42,79].

53.2.1.2 Sample Preparation

Excretions and secretions such as urine, saliva, and pharyngeal and respiratory secretions of pigs, porcine lung tissue, canine brain tissue, and feline brain tissue are sources of specimen for detection of NiV by molecular assays [1]. All types of specimens should be transported to the laboratory within 24 h and kept cool at 4°C during transportation. For long-term storage, specimens should be frozen at −80°C. Lysis buffer containing a chaotropic salt (guanidine isothiocyanate) can be used to collect the specimen for field sampling in order to preserve the nucleic acid and kill the virus at site [40].

Samples for NiV RNA testing can be collected directly from captured bats (saliva, urine, or blood) or from the environment using plastic sheets placed directly under bat roosts to collect their urine [40,41]. Oropharyngeal or urine swab is placed in a cryovial filled with 1 mL of NucliSENS Lysis Buffer (bioMérieux). Every 4–6 drops of urine swab collected from plastic sheet should be put immediately into 9 mL of NucliSENS Lysis Buffer [40]. Two cotton swabs containing approximately 1.2 mL of bat urine are pooled in each lysis buffer tube. The total nucleic acid is then extracted directly from these specimens using the Boom technology method according to the manufacturer's instructions (bioMérieux).

A dried blood spot (DBS) is an alternative type for sample collection for NiV surveillance in resource-limited settings. A blood sample of 50 μL is dropped onto the Flinders Technology Associates filter paper cards [FTA® cards] (Whatman), air-dried at room temperature, and kept in plastic bag containing a desiccator for further analysis or long-term storage (at −80°C). DBS filter paper containing 50 μL of bat blood is a source for NiV RNA PCR detection. NiV RNA extracted from DBS showed concordant results with RNA extracted from bat saliva [56].

Several commercially available methods can be used for extraction of viral RNA from biological specimens. Boom technology (bioMérieux) is a protocol for the extraction of RNA and DNA and is capable of simultaneously processing various sample types (serum, plasma, whole blood, urine, nasal washes, nasal swab, throat swab, bronchoalveolar lavages, sputum, feces, DBS, cells, or tissue specimens) and different volumes, using the same reagent kit. For specimens in the liquid form, place the secretion sample in the lysis buffer at an optimal ratio of 1 mL of specimen to 2 mL lysis buffer, except whole blood samples, where 0.1–2 mL ratio is allowed. The lysate is incubated at room temperature for 10 min before proceeding with the standard extraction steps according to the manufacturer's instructions (bioMérieux). Preextraction step is required for the extraction of nucleic acid from the DBS paper. Two blood spots (2 spots of 50 μL/extraction) are cut from the filter paper, using a pair of scissors, and added into a 2 mL NucliSENS Lysis Buffer tube (bioMérieux). Tubes are incubated horizontally on a roller mixer for 30 min at room temperature and centrifuged at 1500 × *g* for 15 s to spin down the fluid. The supernatant lysate is then transferred for nucleic acid extraction process.

Preextraction step is required to remove lipid component from fatty tissues, such as brain and adipose tissue. Recently, high yields and high quality of total RNA without phenol contamination kit has been introduced (RNeasy Lipid Tissue Mini Kit, Qiagen). The kit combines organic extraction and chaotropic disruption that contribute to the high lysis efficiency of QIAzol Lysis Reagent. Tissue sample (10–100 mg) is homogenized in QIAzol Lysis Reagent using a machine (TissueRuptor or TissueLyser, Qiagen) or manually gridded using a Micropestle (Eppendorf). After adding chloroform, the homogenate is separated into aqueous and organic phases by centrifugation. The upper, aqueous phase (RNA component) is extracted, and an equal volume of 70% ethanol is added to provide proper binding conditions. The sample is then applied to the RNeasy Mini spin column, as per the

manufacturer's instructions. Briefly, 700 µL of the mixture is transferred to an RNeasy Mini spin column, placed in a 2 mL collection tube, and centrifuged at 8000 × *g* for 15 s, after which 700 µL of RW1 buffer is added to wash the membrane. The column is centrifuged again at 8000 × *g* for 15 s and washed by adding 500 µL Buffer RPE twice. To elute the RNA, 30–50 µL of RNase-free water is added directly to the spin column membrane and centrifuged at 8000 × *g* for 1 min. Up to 100 µg of total RNA (mini kit) binds to the membrane, while other contaminants are efficiently washed away.

53.2.2 Detection Procedures

The molecular methods for the detection of NiV have been previously summarized; additional information not covered here can be found from a similar review [85]. The following RT-PCR protocol for the screening and sequencing characterization of NiV has been modified from previous report [43].

53.2.2.1 One-Step RT-PCR QIAGEN

53.2.2.1.1 Procedure

1. Thaw primer solutions, dNTP mix, 5× OneStep RT-PCR Buffer, and RNase-free water, and place them on ice.
2. Prepare a master mix according to Table 53.2.
3. Mix the master mix thoroughly, and dispense 43 µL into PCR tubes.
4. Add 2 µL of internal control (IC) RNA (2000 molecules of Kanamycin Positive Control RNA; Promega) to the individual PCR tubes.
5. Add 5 µL of individual RNA sample to each PCR tube.
6. Transfer the reaction tubes to thermal cycler with a heated lid.
7. Program the thermal cycler for RT and PCR as follows: 30 min at 50°C for RT followed by 15 min at 95°C for HotStarTaq DNA polymerase activation and reverse transcriptase inhibition and 30 repetitive cycles of 1 min of denaturation at 94°C, 1 min of annealing at 55°C, and 1 min of elongation at 72°C. Elongation is extended for 10 additional min in the last cycle.
8. Start the RT-PCR program while PCR tubes are still on ice. Wait until the thermal cycler has reached 50°C. Then place the PCR tubes in the thermal cycler.
9. Following amplification, pulse-spin the reaction tubes. Proceed to the next step of nested PCR or store at –20°C.

53.2.2.2 Nested PCR

53.2.2.2.1 Procedure

1. Prepare a master mix according to Table 53.3.
2. Mix the master mix thoroughly, and dispense 49 µL into PCR tubes.
3. Add 1 µL of individual first-round PCR sample to each PCR tube.
4. Transfer the reaction tubes to thermal cycler with a heated lid.

TABLE 53.2
Reaction Components for One-Step Reverse Transcription Polymerase Chain Reaction (First-Round Polymerase Chain Reaction)

Component (Volumes Indicated per Specimen)	Volume (µL)	Final Concentration
Master mix		
RNase-free water	23.75	—
5× OneStep RT-PCR Buffer containing 12.5 mM $MgCl_2$	10.0	1×
25 mM $MgCl_2$	1.0	0.5 mM
dNTP Mix (containing 10 mM of each dNTP)	2.0	400 µM of each dNTP
20 µM CONINT1F (IC forward primer) (5′-CTGGCCTGTTGAACAAGTCT-3′)	0.5	0.2 µM
20 µM CONINT1R (IC reverse primer) (5′-GATCTGATCCTTCAACTCAGC-3′)	0.5	0.2 µM

5 U/μL Taq DNA polymerase	0.5	2.5 U
Template (add at step 3)		
First-round PCR product	1.0	—
Total volume	50.0	—

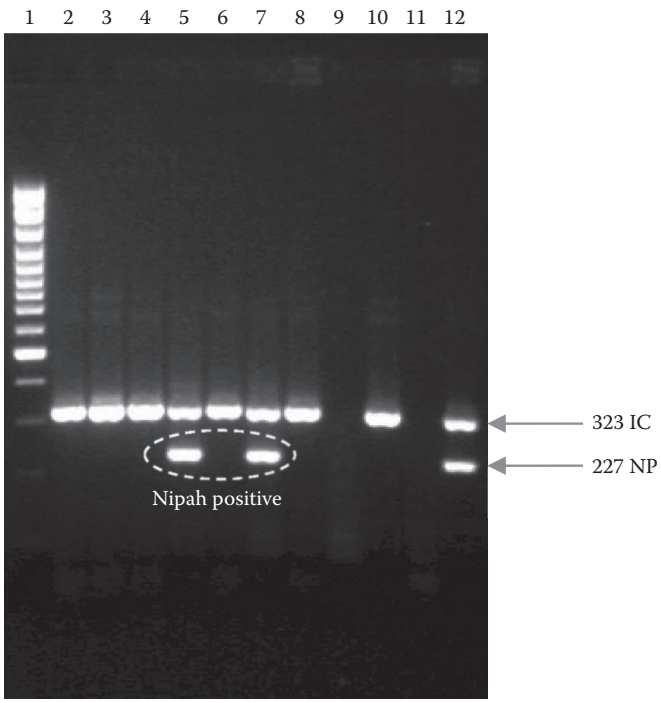

FIGURE 53.1 Duplex-nested polymerase chain reaction (PCR) detection of Nipah virus (NiV) RNA. The upper band (323 bp) is the internal control band. The lower band (227 bp) is the NiV-specific band. Lane 1 is the 100 bp DNA ladder markers (Fermentas), starting with 100 bp marker. NiV-positive samples are lanes 5 and 7. Lane 9 is a sample with PCR inhibitor. Lanes 10 and 12 are the negative and positive controls, respectively.

5. Program the thermal profile in the following order: 5 min denaturation at 94°C and 35 repetitive cycles of 30 s of denaturation at 94°C, 30 s of annealing at 55°C, and 1 min of elongation at 72°C. Elongation is extended for 5 additional min in the last cycle.
6. Analyze the PCR products (5–10 μL) by agarose gel electrophoresis through 2% agarose gel containing 0.5 μg/mL of ethidium bromide in Tris-borate-EDTA buffer for 45 min and visualized under UV light.
7. The presence of a 227 bp product is indicative of NiV positive, while the product size of IC is 323 bp (Figure 53.1).

53.2.2.3 Heminested PCR and Sequencing

The heminested PCR is prepared from the first-round positive PCR samples in the same manner as nested PCR, but without IC primers. The heminested primer pairs were NP1F/NP2R and NP1R/NP2F, which result in 342 bp and 283 bp PCR products, respectively. The 357 bp nt sequences at position 1197–1553 (according to GenBank accession no. NC 002728) can be obtained from these two PCR products.

53.2.2.3.1 Procedure

1. Prepare master mix as Table 53.3 of two separate PCRs from different 2 primer sets, NP1F/NP2R and NP1R/NP2F, but replace the IC primers from the reaction with 1 μL water.
2. Add 1 μL of product from the first round of PCR into each reaction tube.
3. Process all steps as stated in Section 53.2.2.2 (nested PCR). The resulting products of NP1F/NP2R and NP1R/NP2F are 342 bp and 283 bp, respectively (Figure 53.2).
4. Purify the PCR product by using a commercial spin column kit.
5. Add the primer NP2R to the sequencing reaction of NP1F/NP2R PCR product.

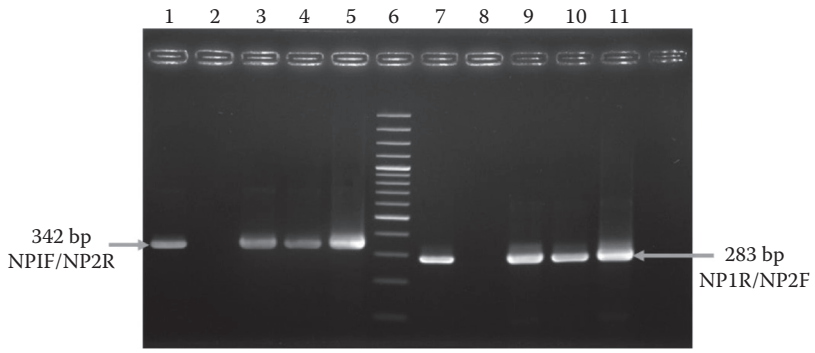

FIGURE 53.2 Heminested polymerase chain reaction detection of Nipah virus (NiV) RNA without internal control RNA. The left band (342 bp) is the NiV-specific band from the NP1F/NP2R primers. The right band (283) is the NiV-specific band from the NP1R/NP2F primers. Each pair of NiV-positive samples is shown in lanes 3 and 9, 4 and 10, and 5 and 11, respectively. Lane 6 is the 100 bp DNA ladder markers (Fermentas). Lanes 1 and 7 are the positive controls, while lanes 2 and 8 are the negative controls, respectively.

6. Add the primer NP2F to the sequencing reaction of NP1R/NP2F PCR product.
7. Perform the sequencing reaction according to the manufacturer's protocol (Applied Biosystems, Foster City, CA).
8. Analyze nucleotide sequence of the DNA product using an automated ABI PRISM 3730 sequencer.
9. Edit sequences using BioEdit program and assemble sequences from 2 PCR products; the nucleotide sequences are located at positions 1197–1553 (according to GenBank accession no. NC 002728).
10. Compare the 357 bp sequences with those of the reference strains available in databases such as the National Center for Biotechnology Information GenBank database.

53.3 CONCLUSION

NiV outbreaks have occurred in Malaysia, India, and Bangladesh and in the Philippines. The first outbreak in Malaysia (September 1998–May 1999) nearly collapsed the billion-dollar pig-farming industry. NiV continues to cause annual outbreaks of fatal human encephalitis/respiratory distress syndrome in Bangladesh due to spillover from its bat reservoir host. Recently, contact with NiV-infected horses and consumption of uncooked horse meat resulted in the outbreak in the Philippines. Currently, it lacks approved therapeutics and vaccines. Many countries are at risk of NiV infection outbreak due to the wide home range of NiV natural hosts, *Pteropus* bats.

The application of molecular methods allows the diagnosis in suspected human and animal cases. In addition, molecular methods have been used as a tool for NiV surveillance in bats in several countries such as Malaysia, India, Thailand, Indonesia, and East Timor. Although antibody screening assay is a powerful tool for NiV surveillance in many countries, it cannot characterize strain of viruses, and thus its use is limited compared to the PCR method.

There are many well-established PCR protocols with relatively low-cost methods. Transferring of these molecular protocols to the national or regional diagnostic laboratories in developing countries should enable a faster response and reduce the impact of future outbreaks. The surveillance of NiV infection should be conducted in natural hosts (bats), targeted livestock animals (pigs), and encephalitis/respiratory syndrome patients of unknown cause from at-risk countries. In order to have a complete understanding of the ecology and transmission of NiV, a comprehensive analysis of bats across their migratory routes in Africa, Southeast Asia, and Australia should be conducted. Knowledge of NiV molecular diversity and the presence of cross-species dissemination in bats and other animals will help in providing a clear assessment of the zoonotic potential of the bat-borne NiV.

ACKNOWLEDGMENTS

This work was supported by research grants from the Ratchadaphiseksomphot Endowment Fund of Chulalongkorn University (RES560530148-HR), Health and Biomedical Science Research Program by the National Research Council of Thailand and Health System Research Institute (P-13-50154), and the Research Chair Grant, the National Science and Technology Development Agency, Thailand. 54.1 INTRODUCTION

Peste des petits ruminants (PPR), caused by PPR virus (PPRV), is an acute and highly contagious disease of both domestic and wild small ruminants related to the eradicated rinderpest (RP) disease [1]. The disease is characterized by high fever, ocular and nasal discharges, pneumonia, necrosis and ulceration of the mucous membrane, and inflammation of the gastrointestinal tract leading to severe diarrhea and death [2,3]. PPR is now widely spread from the North, West, Central, and East Africa; Arabian Peninsula; Middle East; and Asian subcontinent [4].

First described in West Africa in 1942 [5] and later recognized to be endemic in West and Central Africa [6], PPR spreads into the Middle East and Asian subcontinent within a large area encompassing the developing world where subsistence small ruminants farming serves as a major source of food and trade. The high morbidity and mortality of PPR exerted a detrimental impact on food production and animal welfare in endemic areas [7].

PPRV belongs to the genus *Morbillivirus* and family *Paramyxoviridae*. It is genetically related to RP virus (RPV) of cattle, measles virus (MV) of humans, canine distemper virus (CDV), and the morbilliviruses of aquatic mammals [8]. All morbilliviruses are related serologically, and sequence data also reveal a high degree of homology at the nucleic acid level. The genome contains six tandemly arranged transcription units encoding six structural proteins: the nucleocapsid (N), phosphoprotein (P), matrix (M), surface glycoproteins F and H, and the polymerase or large (L) protein, as well as two nonstructural proteins C and V, respectively [9–11].

Clinically, PPR cannot be differentiated in sheep and goats from RPV or other similar diseases. Therefore, a laboratory confirmation is important for accurate diagnosis. Conventional serological tests like agar gel immunodiffusion (AGID) and counterimmunoelectrophoresis (CIEP) have been used in diagnosis but are not sensitive enough for reliability. Specific diagnosis can be made by virus neutralization test (VNT), competitive enzyme-linked immunosorbent assays (c-ELISA), and immunocapture ELISA [12], but the reverse

transcription polymerase chain reaction (RT-PCR) is a more sensitive test that has been developed and widely used for the detection of PPRV. Forsyth and Barrett [13] developed an RT-PCR using a set of primers to amplify the conserved region of fusion protein (F) gene, while Couacy-Hymann et al. [14] designed the nucleoprotein (N) gene primers. These techniques have become popular for specific diagnosis and molecular epidemiology of PPRV. Other techniques such as the real-time RT-PCR has also been developed to detect, quantify, and differentiate lineages [15,16]. Using molecular epidemiology tools, PPRV has been placed into four groups or lineages circulating in the world.

54.1.1 Classification

The classification of PPRV has been achieved by sequencing the F and N gene segments [13,14] into four distinct lineages. Out of the four phylogenetic lineages, three are located in Africa. The fourth lineage is the only one present in the Indian subcontinent but also coexists in the Middle East and some parts of Africa.

It is still not clear whether the apparent geographical spread of the disease in the last 50 years is real or reflects increased awareness, wider availability of diagnostic tools, or even a change in the virulence of the virus. It seems most likely that a combination of factors has been responsible for the current distribution of the disease [4]. It is also known that confusion of PPR with pneumonic pasteurellosis and other pneumonic diseases of small ruminants has precluded and delayed its recognition in some countries [17].

54.1.2 Virus Structure, Genome Organization, and Geographical Distribution

PPR is caused by a virus that was assumed for a long time to be a variant of RP adapted to small ruminants. However, virus cross neutralization studies and electron microscopy revealed that it was a morbillivirus that had the physicochemical characteristic of a distinct virus but biologically and antigenically related to RPV. It has also been demonstrated to be an immunologically distinct virus with a separate epizootiology in areas where both viruses were enzootic [18]. The development of specific nucleic acid probes for hybridization studies and nucleic acid sequencing has proved that PPRV is quite distinct from RPV [19].

54.1.2.1 Virus Structure and Genome Organization

When viewed through electron microscope, morbilliviruses display the typical structure of *Paramyxoviridae*: a pleomorphic particle with a lipid envelope that encloses a helical nucleocapsid [2,20]. The nucleocapsids have a characteristic herringbone appearance. The virus is equally very fragile and cannot survive for a very long time outside its host. Its half-life has been estimated to be 22 min at 6°C and 3.3 h at 37°C. Morbilliviruses have been described as linear, nonsegmented, single-stranded, negative-sense RNA with genomes approximately 15–16 kb in size [21] and organized into six contiguous, nonoverlapping transcription units corresponding to it six structural viral proteins in the order of 3′-N-P-M-F-H-L-5′ in the genome sense [11,22]. The virus has a variable diameter between 150 and 700 nm and mean of 500 nm [23]. This size variation is linked to the number of nucleocapsids incorporated into the virus particles. In the case of MV, this number might be more than 30 [24]. The full-length genome sequences of MV of humans [25], RPV [10], CDV of dogs and some wild carnivores [26], PPRV [9], and the dolphin morbilliviruses [27] have been generated and used in reverse genetics for the determination of gene function [28,29].

The nucleocapsid (N) protein is the major and most abundant viral protein both in the virion and in infected cells where it is directly associates with the RNA genome to form the typical herringbone structure of morbillivirus nucleocapsids [30]. It is located at the 3′ end of the genome adjacent to a 52–56 bases of the leader sequence in the genomic RNA [31,32]. Several roles have been proposed for the leader RNA, among which are its role as a binding site for the polymerase enzyme to initiate replication to generate positive strands and also in downregulating host cellular transcription [21,32,33].

Phosphoprotein (P), which is next to the N protein, is an essential subunit of the viral RNA-dependent RNA polymerase [34]. It encodes the nonstructural P, C, and V proteins. The P protein of morbilliviruses interacts with both the N and L proteins to form the viral polymerase. There is a great similarity between the N termini of V and P, which has been shown to play an important role in RPV replication [35]. C-minus mutants have been demonstrated to express growth defects in vitro, which were also evident by the level of mRNA transcripts generated. Contrarily, the V-minus mutants behave different from the C-minus mutants with an altered cytopathic effect (CPE) and increased genome/antigenome RNA production. The C and V proteins of paramyxoviruses also act as interferon antagonists, modifying the cellular immune response to infection [36,37].

The matrix (M) proteins are the most conserved protein within morbilliviruses and interact with surface glycoproteins (H and F) within the lipid envelope as well as the viral RNA. This was reflected in the conservation of the PPRV M protein when compared to that of other morbilliviruses with ranging identities from 91% between CDV and PDV to 76% between RPV and CDV, which PPRV and RPV share 84% identities [38]. This high conservation is probably due to the pivotal role the M protein plays in virion morphogenesis. The matrix protein is likely to be stable to variations giving its antigenic similarities within the family. M interacts with both the nucleocapsid and the cytoplasmic tails of the F and H glycoproteins [39].

The fusion (F) protein and hemagglutinin (H) protein are two surface glycoproteins produced by morbilliviruses that are buried into the viral envelope and project outward as spikes. Penetration of the host cell is made possible by the F protein, whereby it mediates the fusion of the viral and cellular membranes. Cooperation of the H protein is required to promote the activity of the F protein [40,41]. One of the

unique features of the morbillivirus F mRNA is the fact that it has a long 5′-untranslated region. When translated, F mRNA, which is named F0, undergoes cleaving by endoproteases into the active F protein [42]. Virus assembly can proceed without the F0 cleavage, but infectivity and pathogenesis are dependent on it for all paramyxoviruses [43].

The H protein is responsible for the attachment of the virus to the cell receptors [34,44], the main being the signaling lymphocyte activation molecule (which is also called CD 150) [45]. This biological activity of the H protein is one of the classification criteria for *Paramyxoviridae*. The H proteins are highly variable in their activity within members of the family [46], but for its activity to be elicited, the cooperation of F is required [47]. Near the N-terminus is a long hydrophobic domain, which acts as a signal peptide but does not require cleaving like the F protein. Structurally, the N-terminal is on the cytoplasmic side of the membrane, while the C-terminus projects outward. This particular arrangement classifies H as a type II glycoprotein, which is characterized by a disulfide-liked homodimer [48,49]. For a mature H protein to emerge at the cell surface, it has to go through glycosylation, folding, and oligomerization through the rough endoplasmic reticulum and Golgi apparatus [48,50,51].

The large (L) protein is the major component of viral transcriptases and replicase with several functions. The functions performed are polymerase activity, methylation, capping, and polyadenylation activities [34].

54.1.2.2 Geographical Distribution

PPR is known to be present in a broad belt of sub-Saharan Africa, Arabia, the Middle East, and Asia subcontinent. Major outbreaks in Turkey, Morocco, Algeria, and Tibet China in recent years have indicated a marked rise in the global incidence of PPR [4]. Although the virus was first isolated in Nigeria [52], serological evidences suggest its presence in many more countries. PPRV isolates have been grouped into four distinct lineages based on the partial sequence analysis of either nucleoprotein or fusion (F) protein genes. Genetic relationship between PPR isolates from different geographical regions has been studied by sequence comparison of the F and N protein genes. Using the two gene targets, four lineages were revealed [4,53]. Lineage 1 and 2 viruses have been found exclusively to West Africa from isolates of the 1970s to the 1980s. More so, viruses of the lineage 3 were found in East Africa, Arabia, and India; however, it was never found in India again since the first report in 1992 [54]. Lineage 4 has been distinct to Asia even though it has been reported in other parts of Africa [4,55].

54.1.3 Epidemiology

54.1.3.1 Transmission

PPRV transmission requires close contact between infected animals in the febrile stage and susceptible ones [56]. Discharges from the eyes, nose, and mouth, as well as loose feces, are a source of infection because they contain virus and when an infected animal coughs or sneezes, infective droplets are released into the environment [57,58]. Animals in close contact inhale the droplets and are likely to become infected. Besides, there has been no report of a carrier state for PPRV. Therefore, movement of infected animals and contact with susceptible herds usually is the major source in spread especially when infected animal cough and sneeze or share common drinking or grazing site [57]. Trades in small ruminants at markets where animals from different sources are brought into close contact with one another are at risk of infection. In addition, the extensive or semi-intensive farming system where animals move and interact with other herds freely increases the chances for PPR transmission.

54.1.3.2 Host Range and Pathogenicity

PPR is mainly a disease of goats and sheep where the virus exhibits different levels of virulence. The virulence varies from strain to strain with sheep generally undergoing a mild form of the disease, while goats are severely affected [17] but sometimes the reverse occurs with certain field strains [59]. Breed may also affect the outcome of PPRV infection and its epidemiology where certain breeds such as the West African dwarf, Iogoon, and Kindi are highly susceptible, while the Wall breeds only developed mild form of the disease [17,59–61].

Field outbreaks have also been reported from both zoological gardens, and the wild with wild animals such as gazelle, antelope, Nubian ibex (*Capra nubiana*), gemsbok (*Oryx gazella*), Laristan sheep (*Ovis orientalis laristani*), Nigale (Tragelaphinae) deer, and Asian lion (*Panthera leo persica*) have been confirmed with the virus [7,62,63].

Cattle are not affected with PPR, whether RP vaccinated or not, even if they are in contact with affected goats and sheep. Cattle and pigs are known to be a dead-end host, and all attempt to induce clinical disease in adult cattle experimentally failed; they undergo a silent or subclinical infection that protect them against subsequent challenge with virulent strain of RP [2,59]. Antibodies have been detected in camels and wild animals have been reported to be infected with the disease whether experimentally or under field condition [64]

54.1.3.3 Pattern of the Disease

Generally, morbidity is common, particularly in fully susceptible goat populations. Milder forms of the disease may occur in sheep and partially immune goat populations. There are considerable differences in the epidemiological pattern of the disease in the different ecological systems and geographical areas. Morbidity can be up to 80%–90% with accompanied mortality between 50% and 80% [17]. In arid and semiarid regions, PPR is rarely fatal but usually occurs as a subclinical or inapparent infection opening the door for other infections such as pasteurellosis [17]. At the same time, the disease can also be exacerbated and confused with other diseases such as pasteurellosis, contagious ecthyma, contagious caprine pleuropneumonia, bluetongue, heartwater, coccidiosis, mineral poisoning, and foot-and-mouth disease [64].

Serological data revealed that antibodies occur in all age groups from 4 to 24 months indicating a constant circulation

of the virus [65–67]. Therefore, an increase in incidence is a reflection of an increase in the number of susceptible young goats recruited into the flocks. Yearlings have been proved to be highly susceptible than the adults and unweaned animals compared to adults [68].

54.1.4 Clinical Features and Pathogenesis

54.1.4.1 Clinical Features and Pathogenesis

When an infection is introduced into a herd, the virus is incubated for 3–4 days within the lymph nodes draining the oropharynx before being disseminated to other parts of the animal via the circulatory system leading to pneumonia. The animal eventually begins to exhibit clinical signs that can be categories into three forms: peracute, acute, and mild forms. The acute form is the most common; it starts with a sudden rise in body temperature from 39.5°C to 41°C and may remain high for 5–8 days. These may return to normal prior to recovery or drops below normal before death. There is hyperpnea that may be characterized by rocking movements of the chest and abdominal walls as the animal breaths. Severely affected animals may show labored and noisy breathing characterized by extension of the head and neck, dilation of the nostrils, and protrusion of the tongue with painful coughs. A clear watery discharge starts to issue from the eyes, nose, and mouth, later becoming thick and yellow as a result of secondary bacterial infection. The appearance of a serous to mucopurulent nasal discharge may form crust and occlude the nostril and sneezing. There could be ocular discharge resulting in matting of the eyelids. The discharges wet the chin and the hair below the eye and tend to dry, causing matting together of the eyelids, obstruction of the nose, and difficulty in breathing [57,69].

One to two days after fever has set in, the mucous membranes of the mouth and eyes become reddened. The epithelial necrosis causes small pinpoint grayish areas on the gums, dental pad, palate, lips, inner aspects of the cheeks, and upper surface of the tongue. These areas increase in number and size and join together. The lining of the mouth changes in appearance. It becomes pale and coated with dying cells, and in some cases, the normal membrane may be completely obscured by a thick cheesy material. Underneath the dead surface cells, there are shallow erosions. Gentle rubbing across the gum and palate with a finger may yield a foul-smelling material containing shreds of epithelial tissue [56].

Following the onset of fever, diarrhea appears about 2–3 days after which may not be evident in either early or mild infections. The feces are initially soft and then watery, and foul-smelling and may contain blood streaks and pieces of dead gut tissues. Where diarrhea is not an obvious sign, inserting a cotton wool swab into the rectum may reveal evidence of soft feces, which may be stained with blood. Such victims may eventually become dehydrated with sunken eyeballs, and death often follows within 7–10 days from the onset of clinical reaction. Other animals may recover after a protracted convalescence [57].

54.1.4.2 Pathology

PPRV has affinity for lymphoid and epithelial tissues where it induces severe lesions in organs and systems rich in them [6]. The respiratory system is the most likely for viral entry. After viral entry through the respiratory tract, the virus first becomes localized and replicates in the pharyngeal and mandibular lymph nodes as well as tonsil. The virus buds and becomes available for systemic spread 2–3 days after infection to organs such as spleen, bone marrow, and mucosa of the gastrointestinal tract and respiratory system, and 1–2 days later, the first clinical signs begin to appear [6].

54.1.4.3 Postmortem Findings

Following the death of an affected animal, the carcass is usually emaciated, with the hindquarters soiled with feces and sunken eyeballs. The eyes and nose contain dried-up discharges with swollen lips with erosions and sometimes scabs or nodules in late cases. The nasal orifices are reddened and congested with clear or creamy yellow exudates and erosions. These erosions may be dry on the gums, on soft and hard palates, on tongue and cheeks, and into the esophagus. Grossly, the lung appears dark red or purple with some firm to touch areas mainly on the anterior and cardiac lobes, which is an indication of pneumonia. Associated lymph nodes become swollen and soft when touched in which the abomasum is congested and hemorrhagic [70].

The pathology caused by PPR may vary, but necrotic and ulcerative lesions within the oral cavity and gastrointestinal tract are predominant [71]. While oral erosions are a constant feature, there is rarely any lesion within the rumen and reticulum and omasum. Lesions within the small intestine are generally moderate. Comparatively, the large intestine is usually more severely affected, with congestion around the ileocecal valve, at the cecocolic junction, and in the rectum. The posterior part of the colon and the rectum are characterized by discontinuous streaks of congestion "zebra stripes" on the crests of the mucosal folds.

Erosion and petechiae may be obvious on the nasal mucosa, turbinates, larynx, and trachea of the respiratory systems sometimes accompanied with bronchopneumonia. Histopathologically, PPRV causes epithelial necrosis of the mucosa of the alimentary and respiratory tracts marked by the presence of eosinophilic intracytoplasmic and intranuclear inclusion bodies. Multinucleated giant cells (syncytia) can be observed in all affected epithelia as well as in the lymph nodes [69]. In the spleen, tonsil, and lymph nodes, the virus causes necrosis of lymphocytes evidenced by pyknotic nuclei and karyorrhexis. Brown and others [69] using immunohistochemical methods detected viral antigen in the cytoplasm and nuclei of tracheal, bronchial and bronchioepithelial cell, type II pneumocytes, syncytial cells, and alveolar macrophages. Small intestines are congested with lining hemorrhages and erosions. Large intestines (cecum, colon, and rectum) have small red hemorrhages along the folds of the lining, joining together as time passes and becoming darker, even green/black in stale carcasses.

54.1.4.4 Immunity

The surface glycoproteins hemagglutinin (H) and fusion protein (F) of morbilliviruses are highly immunogenic and confer protective immunity. PPRV is antigenically closely related to RPV, and antibodies against PPRV are both cross neutralizing and cross protective [18].

54.1.5 Diagnosis

For accurate and timely diagnosis of PPR to be possible, the appropriate samples need to be collected for the right control strategy to be implemented. Where PPR is suspected, samples can be collected from either live or dead animals for diagnosis. From live animals, ocular and nasal swabs and debris from oral lesions should be collected for diagnosis, while whole blood (in heparin or EDTA) should be taken for virus isolation especially at the acute phase of the disease. Biopsy samples of lymph nodes or spleen may also be useful. Samples for virus isolation should be collected during the acute stage of the disease, when clinical signs are present, whenever possible, these samples should be taken from animals with high fever and before the onset of diarrhea. At postmortem, samples can be collected from lymph nodes (particularly the mesenteric and mediastinal nodes), lungs, spleen, tonsils, and affected sections of the intestinal tract (e.g., ileum and large intestine). These samples should be taken from euthanized or freshly dead animals. Samples for virus isolation should be transported on ice. Similar samples should be collected in formalin for histopathology.

54.1.5.1 Conventional Techniques

Clinically, PPR suspected cases can be confirmed using a number of conventional laboratory tests. These conventional diagnostic tests include AGID test, CIEP, ELISA, VNT, and isolation of the virus in cell culture, which is time consuming and labor intensive [72]. But with the advent of molecular biology, RT-PCR techniques enable rapid and specific diagnosis of PPR possible [13–16].

AGID test: AGID is a very simple and inexpensive test that is widely used for the confirmation of PPR antigen [73]. The test can be ran within 2–4 h using standard positive or negative hyperimmune serum, respectively, to determine either antigen or antibodies in a suspected sample. AGID has a specificity of up to 92% and can be used on the field.

CIEP: This technique has been described as the most rapid test for viral antigen. It was described to utilize a glass slide, electrophoresis tank/buffer, and electric current to run through. Agarose is melted in 0.025 M barbitone acetate solution and poured onto the horizontal slide. Pair of wells is created on the agar, and the antigen and antiserum are poured site by site, and 10–12 mA current is allowed to pass through for 30–60 min in a 0.1 M barbitone acetate running buffer. The run is viewed under light for the formation of precipitation lines between a positive serum and tissue, respectively [73].

ELISA: Two ELISAs have been developed for the diagnosis of PPR: immunocapture and competitive ELISAs. The immunocapture (sandwich) ELISA is suitable for routine diagnosis of field samples such as ocular and nasal swabs [74]. The test utilizes monoclonal antibodies developed against the nucleocapsid protein in tissues or secretions of infected animals with high levels of sensitivity [72,75] and a quick result within 2 h that differentiates between PPR and RP.

The c-ELISA was developed to capture the hemagglutinin protein of PPR either in a blocking ELISA as developed by Saliki et al. [76] or in a c-ELISA as described by Anderson and McKay [77], all for the purpose of differentiating PPRV from RPV.

VNT: The VNT is a gold standard test for the diagnosis of PPRV and RPV. It is very reliable, sensitive, and specific but time consuming, laborious, and expensive [78].

Virus isolation: In addition to the rapid diagnostic techniques, virus isolation of field samples should be carried out to further understand the biology of the virus. Primary lamb kidney or African green monkey kidney (Vero) cell tissue cultures can be used to achieve this objective. Monolayer cultures are inoculated with suspect material (swab material, buffy coat, or 10% tissue suspensions) and examined daily for evidence of CPE. The CPE produced by PPRV can develop within 5 days and consists of cell rounding and aggregation culminating in syncytia formation in lamb kidney cells. In Vero cells, it is sometimes difficult to see the syncytia. However, in stained, infected Vero cells, small syncytia are always seen. Syncytia are recognized by a circular arrangement of nuclei giving a "clockface" appearance. Coverslip cultures may give a CPE earlier than day 5. There is also the presence of intracytoplasmic and intranuclear inclusions bodies [52]. After 5–6 days postinoculation, blind passages should always be carried out because CPE may take time to appear.

54.1.5.2 Molecular Techniques

RT-PCR: RT-PCR is applied to detect the PPRV genome in blood and ocular or nasal swab tissue samples. Small fragments of viral RNA are amplified by RT-PCR even when no infectious virus is detected by virus isolation. The RT-PCR provides a sensitive, specific, and rapid alternative to virus isolation for the detection of PPRV for appropriate control strategies to be implemented. However, the sensitivity of RT-PCR assays makes them prone to cross contamination, thereby giving a false result. The detection of genomic RNA by RT-PCR is the most sensitive technique for detecting the presence of the agent in persistently infected animals and is particularly useful if samples submitted are unsuitable for virus isolation and antigen detection because they have undergone degradation. PPRV can be detected by RT-PCR from a very early stage of infection in tissues and swabs.

Real-time RT-PCR: The real-time RT-PCR approach is widely preferred. The aim is to detect amplification of target product by fluorescence signals from target-specific "oligonucleotide probes," which has several advantages over gel-based conventional RT-PCR methods such as increased speed, sensitivity, reduced chances of cross contamination, and provision

of a quantitative result. A good number of real-time RT-PCR assays have been described for the detection, quantification, and lineage differentiation of PPRV [15,16]. The assay was found to be both sensitive and specific, with a higher analytical sensitivity.

Loop-mediated isothermal amplification (*LAMP*): LAMP is a faster and more sensitive method for amplifying viral RNA without having to use the thermal cycler. It follows the principle of strand displacement reaction and stem–loop structure allowing the amplification of the target with high specificity, selectivity, and rapidity under the isothermal conditions. Li et al. [79] described assay using six set of primers designed from the matrix gene to amplify PPRV RNA by incubated at 63°C for 60 min in a heating block or water bath. The sensitivity of LAMP was reported to be similar to real-time RT-PCR and 10-fold higher than conventional RT-PCR.

54.2 METHODS

54.2.1 Sample Preparation

Collection of samples: Both ocular and nasal swabs should be collected from the conjunctival and/or nasal discharges of live animals. Where there are buccal lesions, mucosal tissues should also be collected. During the peracute or early stage of the disease, whole blood is also to be collected in anticoagulant for virus isolation and PCR. Blood can equally be collected into sample bottles without anticoagulant for serum, which can be used for serum diagnosis. At necropsy, mesenteric and bronchial nodes, lungs, spleen, and intestinal mucosae should also be collected aseptically, chilled on ice, and transported under refrigeration to the laboratory. Fragments of organs collected for histopathology are to be placed in 10% formalin. During or after the outbreak, blood can be collected for serological diagnosis and monitoring [78].

Sample processing: Blood samples collected without anticoagulant are allowed to clot, and the serum is decanted into sterile tubes and kept at −20°C for antibody detection by c-ELISA, while blood collected in anticoagulant tubes are to be spun at 5000 rpm for 5 min and the plasma decanted and the buffy coat is collected and kept at −20°C for antigen detection. The ocular and nasal swabs, collected into a viral transport medium, are to be vortexed and centrifuged, and the supernatant is decanted into sterilized tubes and kept at −70°C for RNA extraction. From the tissues collected, 1 g is weighed and homogenized, and 9 mL of PBS is added and centrifuged in a refrigerated centrifuge at 10,000 rpm for 5 min to make 10% tissue suspension. The supernatant is to be decanted into a sterile tube and kept at 4°C for RNA extraction [78] and the pellet discarded into a disinfectant.

RNA extraction: The quality of RNA is important to the outcome or success of amplification. Over time, the procedure of isolating the RNA has evolved from the conventional method to the use of commercial kits. One of the kits used is QIAamp Viral RNA Mini Kit, Qiagen. Briefly, 560 µL of prepared Buffer AVL (viral lysis buffer) containing carrier RNA is mixed with 140 µL of the sample incubated for 10 min at room temperature. A 560 µL of ethanol (96%–100%) is added and mixed, and 630 µL of the solution is applied to QIAamp Mini spin column and spun at 6000 g for 1 min. After applying all the solution, the QIAamp Mini spin column is carefully opened and 500 µL of wash buffer 1 (AW1) was added and centrifuged and the flow through is discarded, and then wash buffer 2 (AW2) is applied and spun at high speed for 3 min and the flow through discarded. The QIAamp Mini spin column is placed in a 1.5 mL microcentrifuge and 60 µL of the elution buffer (AVE) was added and incubated for 1 min at room temperature and spun at 6000 × *g* for 1 min to elute the RNA and kept at −20°C for RT-PCR.

54.2.2 Detection Procedure

54.2.2.1 RT-PCR Amplification

Five microliters extracted RNA is reverse transcribed to cDNA using OmniScript™ Reverse Transcriptase Kit (Qiagen, Germany) using the following conditions: 1 µL of random hexamer, 0.125 mM each dNTPs, 10 units of ribonuclease inhibitor (MBI Fermentas), 2 units of OmniScript Reverse Transcriptase, and the buffer provided by the manufacturer. The reaction is carried out at 37°C for 60 min and stopped by incubation at 95°C for 10 min (Table 54.1).

Three microliters of the reverse transcribed (cDNA) product is used as template for the PCR. The reaction is carried out in 200 µL thin-walled PCR tubes, in a final volume of 25 µL containing the following reagents: 12.5 µL of DreamTaq PCR Master Mix (2×) containing ready-to-use DreamTaq DNA polymerase, buffer, $MgCl_2$, and dNTPs (MBI Fermentas), 1 µL of forward and reverse primers (10 pmoles of each primer) designed by Forsyth and Barrett [13] and Couacy-Hymann et al. [14], NP3/NP4, and 7.5 µL of nuclease-free water (Tables 54.2 and 54.3). Amplification using those primers (Table 54.1) was carried under the following conditions: initial denaturation step 95°C for 5 min followed by denaturation at 94°C for 30 min, annealing at 50°C at 60 s, extension at 72°C for 2 min for 35 cycles, and final extension at 72°C for 25 min to amplify a 372 bp product. The reaction conditions for NP3/NP4 primers targeting 351 bp product of the nucleoprotein gene are as follows: initial denaturation at 95°C at 5 min, followed by 35 cycles of denaturation at 94°C for 30 s, annealing at 55°C for 30 s and extension for 72°C for 1 min, and a final extension for 72°C for 25 min. The PCR products are analyzed on 1.5% agarose gel electrophoresis stain with ethidium bromide or gel red and viewed under ultraviolet light source.

54.2.2.2 Sequencing Analysis and Phylogeny

After amplifying a positive PPRV sample, characterization can be achieved by direct sequencing of the partial N or F protein genes segments. The products can be cleaned up using a commercial kit such as Wizard SV Gel and PCR Clean-Up System (Promega) or QIAquick PCR Purification

Kit (Qiagen). The purified product can be checked on an agarose gel before using it as a template for sequencing. Sequencing is performed using the BigDye Terminator v3.1 Cycle Sequencing Kit (Applied Biosystems, Foster City, CA) based on the manufacturer's protocol.

Sequences generated should be compared with other PPRV published or referenced sequences within either National Center for Biotechnology Information, GenBank databases, European Molecular Biology Laboratory, or DNA Data Bank of Japan. Phylogenetic analysis of quality sequences can be carried out using Molecular Evolutionary Genetics Analysis version 4 [82].

54.3 CONCLUSION AND FUTURE PERSPECTIVES

PPRV is a very important pathogen of sheep and goats that has continued to spread rapidly with high morbidity and mortality in spite of the availability of a protective vaccine. This spread has brought about attendant losses of livestock, thereby threatening PPR-free neighboring states. Since the virus has been identified to have a separate epizootiology from RP, it has been categorized as List A disease by the Office of International Des Epizooties. It has also received the attention of the international community toward a possible global eradication.

However, several factors and drivers have been implicated in the continuous spread and persistence of the disease to include population growth, trade, globalization, and

inadequate control strategy to combat the disease. Although the virus is a single strain with four lineages, inadequate control measures have allowed the virus to spread and persist within susceptible populations.

The advent of molecular techniques has made diagnosis highly sensitive, specific, and rapid. It also gives room for a thorough understanding of the molecular biology of the PPRV. However, there are still a lot of gabs in the understanding of the virus and its epidemiology in areas such as virus–host interaction, epidemiological factors, evolutionary mechanisms, and clinical outcome.

For a future global eradication campaigns to be successful, there is the need for coordination at national and regional levels among various stakeholders in the industry. However, there is the need to evaluate the effectiveness of the vaccination, and a new one should be developed to take care of the handling and storage factors. All this will enable the formulation of a comprehensive PPR control.

55.1 INTRODUCTION

The blue eye disease, affecting pigs of all ages, is caused by a virus of the *Rubulavirus* genus, *Paramyxoviridae* family [1]. The first cases were reported in 1980, in hog farms at La Piedad, Michoacán, Mexico. Clinical signs, mostly of nervous nature, were observed in piglets younger than 30 days. New outbursts were reported later on the same year in the nearby states of Jalisco and Guanajuato and in 1983 in Mexico City, Nuevo León, Hidalgo, Tlaxcala, Tamaulipas, Puebla, Campeche, and Querétaro. Since its emergence, the disease has been difficult to control, and by 1992, it had spread to 16 states in Mexico [2]. According to a seroprevalence survey of porcine rubulavirus (PRV) performed in 2004, a prevalence of 10%–30% was found in 18 Mexican states [3].

55.1.1 Classification

Based on its biologic and structural characteristics including the presence of hemagglutinating and neuraminidase activities, the blue eye virus is classified in the species *Porcine rubulavirus* (*Rubulavirus porcino*), genus *Rubulavirus*, subfamily *Paramyxovirinae*, family *Paramyxoviridae*, order *Mononegavirales* [4–6]. Other species within the genus *Rubulavirus* include *Achimota virus 1*, *Achimota virus 2*, *Mapuera virus*, *Menangle virus*, *Mumps virus*, *Parainfluenza type 2*, *Parainfluenza type 4*, *Parainfluenza type 5*, *Simian virus 41*, *Tioman virus*, *Tuhokovirus virus 1*, *Tuhokovirus virus 2*, and *Tuhokovirus virus 3*.

The *Paramyxoviridae* family comprises enveloped viruses that harbor a single-stranded RNA genome divided into six or seven genes. These genes code for an equal or greater number of proteins, including viral RNA polymerase. Paramyxoviruses are highly variable, showing one mutation in 10,000 bases on each replication [6–8].

The blue eye disease virus does not cross-react with antigens from parainfluenza 1, 2, 3, and 4 viruses, neither with Newcastle disease, measles, respiratory syncytial, or mumps viruses.

55.1.2 Morphology, Genome Organization, Biology, and Epidemiology

55.1.2.1 Morphology and Genome Organization

Besides sharing a tissular tropism and several pathological traits, PRV demonstrates significant structural and genetic similarity to human mumps virus [9].

Under electron microscope the virus appears as pleomorphic virions, most of which are spherical in shape, 180–300 nm in diameter. Its lipoprotein membrane shows 8–12 nm protrusions associated with HN and F glycoproteins, responsible for the hemagglutinating, hemolytic, neuraminidase, and syncytium-forming activities seen in PRV [4,9].

The genome of PRV consists of six genes, in the order of 3′-N-P/V-M-F-HN-L-5′. These genes encode ten proteins with structural, regulating, and enzymatic functions. The N, M, HN, and L genes code for one protein each; the F gene codes for a polypeptide called F_0, split by a cell protease into the F_1 and F_2 proteins; the P gene codes for several proteins, depending on the mRNA editing region [10–14].

Among the structural proteins, the HN is a multifunctional glycoprotein, consisting of 576 amino acids and having a molecular weight of 66 kDa. It is responsible for receptor recognition and for the adhesion to target cells during infection due to a specific recognition of the N-acetylneuraminic acid residues linked by α-2,3-glycosidic bonds to galactose (NeuAcα-2,3 Gal). Being the determinant in the susceptibility of hosts to PRV infection and the tissular tropism of the virus, the expression of NeuAcα-2,3 Gal is higher in the central nervous system of neonate pigs and also in the reproductive tract of adult hogs [15–17]. The HN protein exhibits hemagglutinating and neuraminidase activities. It has two functional domains: one is the ability of agglutinating erythrocytes and the other is the ability of deleting sialic acid groups. It agglutinates erythrocytes of a wide variety of animal species, including hogs, sheep, cows, dogs, rabbits, mice, rats, hamsters, guinea pigs, chickens, and humans with blood types A, B, and O due to a specific recognition of the NeuAcα-2,3 Gal expressed on the surface of all erythrocytes [5,17–19]. The neuraminidase or sialidase activity of HN allows for hydrolyzing the sialic acid residues of cell receptors; this activity has been proposed as a virulence factor [18,20]. This protein is regarded as immunodominant in PRV infections. Recent studies have reported changes in the nucleotide sequence of the gene coding for the HN protein, resulting in increased virulence and dissimilar clinical signs for each isolate [21,22].

The nucleoprotein (NP), an integral part of the nucleocapsid, is composed of 576 amino acids, with a molecular weight of 68 kDa. During replication/transcription, each NP molecule is linked to six high-affinity nucleotides, thus preventing the presence of uncoated PRV genome within the host cell and protecting the viral RNA against degradation in the cell [20,23–25].

The P protein, made up of 404 amino acids, has a molecular weight of 52 kDa. It is associated to the L protein and to NP. Additionally, it forms a complex with the L protein exhibiting polymerase activity, responsible for transcribing and replicating the viral genome [26].

The L protein, the largest protein in the virion, is made up of 2251 amino acids and has a molecular weight of 200 kDa. As the catalytic component of RNA polymerase, it plays a role in the initiation, elongation, methylation, edition, and polyadenylation processes. Its functions include catalytic activities in the synthesis of genomic and messenger RNA for transcribing and replicating viral particles without entering the host cell nucleus, since these events take place in the cytoplasm [14,20,23,27].

The matrix (M) protein is made up of 369 amino acids—with a high proportion of basic residues—and has a molecular weight of 41.7 kDa. It is located in the inner face of the viral envelope. Due to its net positive charge, it shows a great affinity for NP. This feature is crucial, since it allows the M protein to participate in the viral particle assembly with lower energy expenditure. It also plays a role in maintaining the virion structure and in the assembly of new virions [10,13,20,28].

The F glycoprotein is made up of 541 amino acids and has a molecular weight of 59 kDa. A highly hydrophobic domain in this protein takes part in the fusion of the viral envelope to the membrane of the host cell, allowing the virus to enter the cytoplasm and be transmitted cell-to-cell without being exposed to the extracellular medium [10,20,28]. This trait gives rise to the multinucleated giant cells (syncytia) visible in tissues and cell cultures infected by paramyxoviruses [29,30].

The nonstructural proteins V (249 amino acids and 26.1 kDa), I (174 amino acids and 18.1 kDa), P (404 amino acids and 42 kDa), and C (126 amino acids and 14.7 kDa) are all coded by the viral genome after editing the P gene. Apparently, these proteins are involved in transcriptional regulation and evasion of antiviral responses [4,20,29].

55.1.2.2 Biology

The replication cycle of rubulavirus comprises several phases: recognition, adsorption to cell surface, membrane fusion, cell penetration, uncoating, transcription, genome replication, virion assembly, and virion release.

A viral particle is adsorbed to the host cell membrane through the HN protein, which recognizes a specific receptor—usually glycosylated. Then, a conformational change in the HN protein activates the F protein, exposing a highly hydrophobic domain through which the cell membrane and the viral envelope are fused. This event takes place on the cell surface and at a neutral pH, and therefore it does not depend on lysosomal enzymes, as it is the case with other viruses.

The integration of the viral envelope to the cell membrane system results in the nucleocapsid being released into the cytoplasm. Since the virion generates its own polymerase, a complete copy in positive sense of the viral genome (which will serve as template for the new genomes) is synthesized once the viral RNA is released. In parallel, the synthesis of messenger RNA coding for viral proteins is started.

Translational products are directed to the assembly site. The NP, P, and L proteins are bound to the newly synthesized RNA, and the M protein accumulates in the inner region of the cell membrane. The HN and F proteins, synthesized in the endoplasmic reticulum, are glycosylated in the Golgi apparatus and then expressed in the outer face of the membrane, in sites with close contact to the M protein.

The affinity of NP to M protein and of the latter to glycoproteins is critical in the assembly of virions, which are subsequently released by exocytosis [28]. Since rubulavirus replication occurs entirely in the cytoplasm, nucleocapsid

agglomerations are produced and visible as large cytoplasmic inclusions within infected cells [26,27,31].

Viral genetic material could also pass directly from an infected cell to a neighboring cell, with no viral particle release. This is due to the fusion of cell membranes caused by HN and F proteins, giving rise to giant multinucleated cells (syncytia), the signature of paramyxovirus infections [28].

PRV is sensitive to lipid solvents, such as ether and chloroform, and also to formaldehyde and β-propiolactone. The virus is inactivated at 56°C after 4 h, while viral hemagglutinating activity is lost only after 48–60 h at 56°C [5]. PRV has been cultured in a wide array of cell lines such as PK-15, Vero, MDBK, ST, Pt, BT, Bt, BHK-21, GMK, CK, and BEK and in the primary cultures of cat kidney, bovine embryo, equine dermis, human fetal cells, porcine choroid plexus, bovine choroid plexus, and mink lung, causing a cytopathic effect (CPE) in all of them; it can also be replicated in chicken embryo [4,30,32–34].

55.1.2.3 Epidemiology

Hog is the only animal known to be clinically affected by PRV under natural conditions. PRV has been experimentally inoculated to mice, rats, chicken embryos, rabbits, cats, and dogs. None of these hosts showed infection-related signs. However, antibodies against the virus have been found in experimentally infected rats, rabbits, dogs, cats, and peccaries [4,35–37].

Blue eye disease has only been described in Mexico. Currently, the disease has set in and is occasionally reported in the states of Michoacán, Jalisco, Guanajuato, Tlaxcala, México, Hidalgo, Mexico City, and Querétaro [2,38,39].

55.1.3 Clinical Features and Pathogenesis

55.1.3.1 Clinical Features

In 1980, virtually all affected piglets were younger than 15 days. Clinical features included fever, bristly hair, and arched back, sometimes with constipation or diarrhea. Later, nervous signs like ataxia, weakness, rigidity (mainly in the hind legs), muscular tremor, and abnormal postures (such as the sitting dog posture) were observed [40,41].

After 1983, severe outbreaks of encephalitis and respiratory signs were observed, with mortality rates up to 30% in 15–45 kg pigs [34]. Reproductive failure became apparent on the same year with an increase in the rates of repeat breeding, stillborn pigs, and mummified fetuses, along with a small increase in abortions [42].

In 1988, reports of orchitis, epididymitis, and testicular atrophy with severe semen alterations were linked to the blue eye paramyxovirus. On that year, the morbidity rate for piglets born during an outbreak was 20%–50%, and mortality was 89%–90% [43].

In 1998, severe cases of the disease were reported in association to the porcine reproductive and respiratory syndrome virus (VPRRS). In these cases, reproductive parameters were further altered with respect to PRV and VPRRS alone. Pregnant sows exhibited anorexia and corneal opacity in some cases. Reproductive failure affected several parameters for 2–11 months, 4 months as an average. The number of piglets born alive decreased, while the number of mummified fetuses and piglet mortality increased, and therefore the number of weaned piglets dropped dramatically. A marked increase in the number of stillborn and mummified was also observed, and consequently a drop in the number of born alive and then in the total number of born piglets followed [40,44].

Some cases of animals showing respiratory signs such as dyspnea, cough, and sneeze were reported as associated to the blue eye disease, but they were found related to bacterial infective processes instead. Nevertheless, viral isolates were obtained from lungs and other organs from these animals [45].

55.1.3.2 Pathogenesis

The virus is transmitted by direct contact and by inhalation of virus-contaminated aerosol particles expelled by carrier animals through nasal discharges [2,26,40]. PRV spreads horizontally, from infected animals to susceptible animals; there is also evidence of vertical transmission since the virus is capable of crossing the placental barrier [46–48].

Under natural conditions, PRV enters the body through the oronasal cavity. When virus-contaminated particles are large, replication occurs first at the oronasal cavity, mainly at the nasopharyngeal mucosa and the associated lymphatic tissue (tonsils). When particles are small, the virus enters the lung with the inhaled air, settling on the upper airways, where it replicates profusely; the virus is then carried through the blood by erythrocytes and leucocytes, starting the systemic infection, propagation, and replication in a number of immunoprivileged sites in lymphatic and reproductive organs [1,49,50].

PRV may enter the central nervous system (CNS) through the olfactory nerve endings in the nasal mucosa, and then it can spread to the hippocampus, brain stem, and cerebellum [20,49,50].

Experimental PRV infections have been produced by intranasal, intratracheal, intraocular, intracranial, intraperitoneal, and intramuscular inoculation [51,52].

PRV distribution varies according to the age of infected pigs. In neonates, the main site for viral replication is tissues of the CNS (olfactory bulb, piriform cortex lobe, hippocampus, thalamus, brain stem, and cerebellum) and the respiratory tract; in weaned pigs, the infection occurs in the respiratory tract and in the CNS [4,53].

In adult boars, the virus replicates mainly in tissues from the respiratory and reproductive tract (testicle and epididymis). In experimentally infected pregnant sows, PRV was isolated mainly from the respiratory tract, tonsil, and ovaries [34,54].

The tissue distribution of PRV is determined by the expression of cell receptors, specifically of N-acetylneuraminic acid α-2,3 galactose (NeuAcα-2,3 Gal); this molecule is very abundant in the nervous, respiratory, and lymphatic systems of neonate piglets and in the respiratory and reproductive systems of adult pigs [17,49,51].

Studies reporting virulence changes in four isolates (PAC-6, PAC-7, PAC-8, and PAC-9) allowed subdividing PRV

strains into three groups: group 1 was formed by LPMV and PAC-4; group 2 was formed by PAC-2, PAC-3, and CI-IV; group 3 was formed by isolates PAC-6, PAC-7, PAC-8, and PAC-9. These changes resulted from sequence alterations of the gene coding for the HN protein, which confer virulence and cause nervous signs in adult animals and in the fattening line [54]. The humoral response against PRV starts with the presence of specific antibodies in titers of 4.6 $\log_2$ since days 9 and 10 postinfection (PI); maximum titers have been observed at weeks 7 and 9 PI, with values of 7.6 $\log_2$.

Studies on antibody levels in long-term experimental infections have detected hemagglutination-inhibiting antibodies since week 1 PI in a titer of 2.85 $\log_2$, reaching a peak at week 9 PI in a titer of 5.0 $\log_2$ and maintaining constant levels up to 19 weeks. These antibodies are directed against proteins HN, NP, and M [55–59].

55.1.4 Diagnosis

55.1.4.1 Conventional Techniques

Serological tests have proven valuable for PRV diagnosis. Hemagglutination inhibition (HI) is the most used test to assess PRV spread in Mexico, while seroneutralization (SN), ELISA, and immunoperoxidase assays are also applicable [57].

Several studies have been undertaken to establish the most reliable serological test for PRV diagnosis. In one study involving 46 animals after an acute outbreak, the sensitivity of SN, ELISA, and HI for PRV detection was 89.1%, 89.1%, and 84.7%, respectively. In 35 animals immunized with an experimental vaccine, SN sensitivity was 94.2%, ELISA sensitivity was 91.4%, and HI sensitivity was 80%. In 94 vaccinated animals at a farm during an outbreak, ELISA sensitivity was 91.5% and HI sensitivity was 98.9%. Thus, SN and ELISA represent the most sensitive assays, while HI can be used as a herd-testing tool. Since HI detects a small percentage of false positives, it is not appropriate for individual testing [57].

PRV diagnosis is also achievable by virus detection using viral isolation, indirect immunofluorescence, or electron microscopic observation in infected tissues. The most used cell lines for PRV isolation are Vero (African green monkey kidney), PK-15 (porcine kidney) [60], ST (swine testicle), and BHK-21 (baby hamster kidney). As a characteristic CPE in these cells, PRV promotes syncytium formation. Additionally, intracytoplasmic inclusion bodies have been observed in PK-15 cells [61].

55.1.4.2 Molecular Techniques

A reverse transcription polymerase chain reaction (RT-PCR) targeting the HN gene has been used for some years to detect PRV. Several modifications to the technique have been proposed [26,62,63]. A PCR assay amplifying the strains with genetic variations reported by Sánchez-Betancourt et al. [54] will be described in the Methods section, as the primers therein used are designed for conserved regions of the variants reported so far.

In 2013, a real-time RT-PCR (qRT-PCR) assay was first reported [64]. This test is more sensitive than and as specific as gel-based RT-PCR assay. In addition, this qRT-PCR has the capability of quantifying viral RNA, thus allowing stage-wise evaluation of a clinical infection. This technique should be considered when studies on viral infection dynamics with different viral isolates are to be performed. Since some of these strains are genetically and antigenically characterized, the qRT-PCR may also be used to establish strain virulence [62].

55.2 METHODS

55.2.1 Sample Preparation

Animals showing clinical signs suggestive of this disease can be diagnosed by obtaining a blood sample to perform HI or SN tests, as described in later text. It is advisable to obtain the highest possible amount of serum from blood samples; for this, an anticoagulant-free blood collection tube (e.g., Vacutainer®) should be kept horizontally immediately after collecting the sample. Once serum is obtained, complement proteins should be inactivated by incubating the tube in a water bath at 56°C for 30 min.

For antigen detection, viral isolation or RT-PCR can be performed (see Sections 55.2.2.3 and 55.2.2.4). The recommended swine samples are nasal swabs, tonsils, lung, and a brain sample in those cases with nervous signs. In any case, the sample should be taken within 1 h after the death of the suspect pig.

55.2.2 Detection Procedures

55.2.2.1 Hemagglutination Inhibition

To adsorb and eliminate nonspecific hemagglutination inhibitors, sera are treated as follows: 200 μL of serum is placed in a V-bottom 96-well culture plate, 100 μL of kaolin suspension and 100 μL of 5% bovine erythrocytes are added, and the plate is incubated at 4°C for 24 h.

Adsorbed sera are placed in U-bottom 96-well microplates and 50 μL of PBS (phosphate buffered saline, pH 7.2) is added to all wells. Then, 50 μL of the serum under investigation (supernatant) are placed in line A; double serial dilutions are made from lines A through H, and 50 μL is discarded at the end. It is advisable to reserve the last two rows as controls (positive and negative).

Then, 50 μL of viral antigen with 8 UHA is added to each well, from lines A through H. Plates are incubated for 30 min at room temperature, and 50 μL of 0.5% bovine erythrocytes is added to each well. Finally, plates are incubated at room temperature for 30–60 min.

As a positive control, one row per plate is added with a serum for which the titer of hemagglutination-inhibiter antibodies is known, along with PBS, viral antigen, and erythrocytes. In this case, a sample is regarded as positive when a button is formed by erythrocyte sedimentation.

As a negative control, a serum, known as not having antibodies against PRV, is added, along with PBS, viral antigen, and erythrocytes. Since no antibodies are present in this case, the antigen is bound to erythrocytes and hemagglutination is observed.

In HI tests, a serum is regarded as positive when its titer is equal to or greater than 1:16 [19].

55.2.2.2 Seroneutralization

Serum samples were inactivated at 56°C for 30 min. A sterile, flat bottom, 96-well microplate is used to make serum dilutions.

To all wells, 50 µL of serum-free medium is added from columns 1 through 10. Then, 50 µL of the serum under investigation is added to line A, and the plate is homogenized; then, 50 µL is passed to line B and so on until line H, and 50 µL is discarded at the end. Dilutions start at 1:2 up to 1:256. Positive and negative control sera are placed in the last columns.

At a dose of 300 $DICC_{50}$%, 50 µL of antigen (previously titered for virus) is added and is incubated for 60 min at room temperature. Then, 100 µL from each well line is transferred to a plate containing previously prepared Vero cells.

Plates are incubated for 72 h, and 50 µL of supernatant is transferred to a U-bottom plate. Then, 50 µL of 0.5% bovine erythrocytes is added to each well to read for agglutinating activity. The CPE caused by the virus is read after 120 h.

Positive result: The serum has antibodies, and when these antibodies bind to the antigen, no CPE is observed.

Negative result: Since no antibody is present, the virus causes CPE. A result is regarded as positive when it is higher than 1:32 [19].

55.2.2.3 Viral Isolation

Tissue samples should be macerated and filtered through a 0.22 µ filter under sterile conditions. Then, 1 mL of the suspect sample is placed on a monolayer of Vero cells (African green monkey kidney) with 24 h of growth in 25 cm^2 flasks, supplemented with Eagle's minimum essential medium (MEM) and 5% fetal bovine serum (FBS). Flasks are incubated at 37°C. Cultures are maintained with MEM, with no FBS. Flasks are checked daily, and the presence or absence of CPE is observed at days three and six postinoculation [64].

To observe the presence or absence of PRV-caused agglutination, 50 µL of cell culture supernatant are obtained and successively compared with 50 µL of 0.5% erythrocytes from bird, bovine, and guinea pig. Agglutination is reported as positive and classified as low, moderate, or high according to its intensity.

55.2.2.4 Titration of Isolated Virus

In all wells of a U-bottom 96-well microplate, 50 µL of PBS (phosphate buffer saline, pH 7.2) is placed. Then, 50 µL of clarified supernatant are placed in row 1, using two columns for each virus. Double serial dilutions are made, starting with 1:2 up to 1:4096. A positive and a negative control should be included in all cases, being the negative an erythrocyte sample and the positive a known virus.

Once dilutions are made, 50 µL of 0.5% bovine erythrocytes is added to all wells, from rows 1 through 12. The hemagglutination final titer is regarded as the wall prior to the one showing red cell sedimentation. Virus replication can be achieved until the third blind pass.

55.2.2.5 RT-PCR

55.2.2.5.1 Extraction of Viral RNA

If the suspect sample consists of tissue or nasal swab, it will be ground with liquid nitrogen in a mortar; 200 µL of MEM or PBS will be added, and the sample will be kept frozen until processed.

If the sample was taken from cell cultures, cells will be centrifuged at 4500 rpm for 15 min at 4°C. The cell button is then resuspended in 200 µL of sterile PBS, and 5 mL of glycogen is added, leaving it to stand for 4 min at 4°C.

Both sample types are processed as follows: 1 mL of TRIzol® reagent is added and the sample is incubated at 4°C for 10 min. Then, 200 µL of chloroform is added; the tube is vortexed for 15 s, incubated at 4°C for 10 min, and centrifuged at 12,000 rpm for 15 min at 4°C.

The phase containing RNA is separated in Eppendorf® tubes, and one volume of isopropanol is added. The tube is incubated for 15 min at 4°C and centrifuged at 12,000 rpm for 10 min at 4°C. Isopropanol is decanted, and the button (RNA) is washed with 200 µL of 70% ethanol. The tube is centrifuged at 12,000 rpm for 10 min at 4°C; ethanol is decanted and the button is left to dry. The button is resuspended in 50 µL of DEPC water (diethyl pyrocarbonate 0.1%).

55.2.2.5.2 Reverse Transcription

RNA from the previous step is used to obtain complementary DNA as follows: 7 µL of RNA, 1 µL of dNTPs, and 1.25 µL of the HNISBR1 primer are added to 5.8 µL of DEPC water. The tube is placed in a thermocycler at 65°C for 5 min and left to stand at 4°C for 5 min. Then, 5 µL of buffer (5×), 1 µL of DTT, and 1 µL of RNAseOut (40 unit/µL) are added, and the tube is incubated at 42°C for 2 min. Then, 1 µL of reverse transcriptase (200 units/µL) is added; the tube is incubated at 42°C for 50 min and finally at 70°C for 15 min.

55.2.2.5.3 PCR

Conditions for PCR are as follows: one initial denaturation cycle at 94°C for 4 min, 30 denaturation cycles at 94°C for 30 s, annealing at 54°C for 30 s, extension at 72°C for 1 min, and one final extension cycle at 72°C for 3 min. Amplifying reactions will include 4 ng/µL of template DNA, 0.5 pM of both primers, 0.2 mM of dNTPs, 0.15 mg/mL of BSA, Triton® 0.1%, buffer C 1X (1.5 mM $MgCl_2$), 0.125 U/µL of Taq polymerase, and H_2O in an amount enough to 20 µL.

55.2.2.5.4 Electrophoresis

PCR products are evaluated by electrophoresis on 2% agarose gel and ethidium bromide staining. BstEII-digested λ bacteriophage DNA (λ/BstEII 100 ng/µL) can be used as a molecular weight marker or any other marker containing DNA with 1000–2000 bp. PCR products are then viewed under ultraviolet light.

55.3 CONCLUSION

A number of vaccines have been developed to prevent the disease [65–70], with differing antigen concentrations and differing vaccination and evaluation schemes. However, the performed studies have consistently reported a viral evolution, evidenced in the genetic variants found; on the other hand, the reported viral clusters also indicate an antigenic change among the analyzed virus, as serological tests have shown [63,70].

The genetic and antigenic variants of PRV found to date help us to answer many questions about how to control the disease and about the failure of the marketed vaccines to prevent it. Also, it is now clear that the protection conferred by commercial vaccines will depend on the antigen they contain, since the deficient capacity of antibodies to protect against heterologous viruses, as commonly detected when evaluating commercial vaccines, is proved.

It is advisable to use the HI test as a diagnostic screening and the SN test to assess the protector capacity of postvaccine antigens. RT-PCR or qRT-PCR will be required for antigen detection, along with viral isolation, which remains as the gold standard to demonstrate the presence of viral antigen.

56.1 INTRODUCTION

One of the most devastating veterinary diseases in terms of economic and animal losses, rinderpest was declared globally eradicated in 2011,[1] an incredible feat considering the worldwide distribution of the disease, only matched by the global eradication of smallpox 31 years earlier.[2] Rinderpest was an ancient disease known to Romans and Egyptians alike, which accompanied humankind into the twenty-first century.[3] It has been estimated to have caused losses totaling $2 billion in, for example, Nigeria alone and brought huge suffering to communities depending on farming or meat production for their likelihood sweeping from Eastern Europe to Africa, where its devastating effects were especially felt.[4,5] The first major epidemic in Africa in the 1890s is believed to have killed more than 80% of the African livestock, and as a consequence, one-third of Ethiopians and two-thirds of the Maasai people starved to death.[6] The second African epidemic and outbreaks in many Asian regions in the 1980s led to the loss of an estimated 100 million animals.[6] The disease was devastating due to the mortality rates of up to 90% among susceptible animals.[7] Ultimately, the threat of rinderpest was so great that it led to the establishment of the first veterinary schools in Europe and the introduction of control measures such as slaughter policies and animal isolation when it became clear that close animal contact was the mode of virus transmission.[7–11] In the twentieth century, a concerted effort to bring the disease under control led to the announcement of the Global Rinderpest Eradication Program (GREP) by the UN's Food and Agricultural Organization (FAO), which aimed at an internationally coordinated collaboration to eradicate rinderpest worldwide.[12] The success of this program was, according to Professor John Anderson, "the development of the right technology for field use in Africa and Asia, successful transfer of that technology along with technical backup, and the provision of standardized diagnostic kits that everyone could use." In addition, the development of a live attenuated vaccine that gave lifelong immunity, rinderpest education programs, relevant training of staff involved in the eradication program, and the collaboration of people at national and international levels all contributed to the eradication.

Rinderpest is caused by one of the members of the morbilliviruses, a group of viruses that includes measles virus (MV) and distemper virus (DV). As such, the causative agent, the rinderpest virus (RPV), is an encapsidated virus characterized by the possession of a negative single-stranded RNA with a total genome of 15,200–15,900 nucleotides. It was prevalent in most parts of the world with the exception of the New World with several strains displaying different levels of virulence. The virus was spread by close animal contact through particularly ocular and nasal secretions and conquered new environments by animal movement and trade.

56.1.1 Classification and Genome Organization

According to the Baltimore classification, RPV belongs to group V and is a single-stranded, negative-sense RNA virus. The viruses in this group fall within the order of *Mononegavirales* and are part of the family *Paramyxoviridae* and the genus *Morbillivirus*. Other members of the genus *Morbillivirus* include peste des petits ruminants virus (PPRV), canine DV (CDV), human MV, and viruses that affect marine mammals including seals, porpoises, and dolphins[13,14] as well as Atlantic pinniped and cetacean species.[15,16] All morbilliviruses share similar physicochemical properties that are characterized by similar cytopathic effects in cell culture and common antigens.

The negative-stranded, nonsegmented RNA encodes eight viral proteins: nucleoprotein (N), phosphoprotein (P), matrix (M)-protein, fusion (F)-protein, hemagglutinin (H)-protein, polymerase (L), and two nonstructural proteins (C and V).[17] Gene expression is initiated when the RNA polymerase binds the encapsidated genome at the leader region followed by a sequential transcription of each gene after the recognition of start and stop signals of flanking viral genes. Capping and polyadenylation of mRNAs is regulated by the L-protein during synthesis. RNA editing generates the V-protein and the C-protein by leaky scanning of the P-protein mRNA.[17]

56.1.2 Morphology, Biology, and Epidemiology

The morphology of RPV was first described by Plowright et al.[18] in a study utilizing electron microscopy. Virus particles are measured to be between 1200 and 3000 Å in diameter with an internal helical component of about 175 Å. They are shown to be pleomorphic in appearance, and all possess an outer membrane and appear variable in shape and size, which are either spherical or filamentous. The hemagglutinin–neuraminidase and F-glycoproteins are located as spikes on the surface of the virus. The nucleocapsid appears hollow, coiled, and rod shaped with the herringbone pattern of subunits.[2] Over the years, more details have emerged, and we now know that there are clear functions for each protein. The H-glycoprotein is involved in the adsorption of the virus to the susceptible cells, whereas the F-protein plays a role in cell fusion. Made up of two polypeptides F1 and F2 via a disulfide bond, the F-protein is believed to contribute to the cytopathic effect of the virus. The L-, P-, and N-polypeptides are all parts of the nucleocapsid with the P-protein believed to be the viral RNA polymerase and the N-protein with a function in virus replication. The M-protein, or matrix protein, interacts strongly with the nucleocapsid and associates with the internal part of the virus envelope.[17] The replication of the RPV begins in the host cell cytoplasm after the attachment of the virus to the host cell surface receptors via the H-glycoprotein. Once fusion with the membrane has taken place, the ribonucleocapsid is released into the cytoplasm. Sequential gene transcription occurs, followed by the capping of viral mRNA and polyadenylation. Replication is completed with the encapsidation of newly synthesized viral genomes with nucleoprotein. The viruses exit the host cell after the interaction of the ribonucleocapsid with the M-proteins while still located close to the plasma membrane.[19]

Natural hosts for RPV are members of even-toed ungulates belonging to the order *Artiodactyla* including cattle, buffaloes and other bovines, goats, sheep, and pigs, but the virus can also affect wildlife such as giraffe, eland, kudu, various antelopes, and wildebeest. Although only one serotype of the virus exists, there are nevertheless differences in virulence with highly virulent strains such as RPV-Saudi and mild strains including RPV-Egypt.[20] The phylogenetic relationship of the RPVs revealed that there are three main lineages: the *African lineage 1* (Egypt/84, RBS/Rb-72, Nigeria/Buffalo/83, RBK/W.Pokot/86, RBK/Kiambu/88, RBS/Wakobu/92/1 and RBK/Marsabit/87/1), the *African lineage 2* (RBT/1, Nigeria/Sokoto/64, Nigeria/Sokoto/83, RGK/1 and RbuffaloK/95), and the *Asian lineage* (KAG, Sri Lanka/87, India Bison/89, India/Mukteshwar, Saudi/81 and Pakistan/84).[21] The disease is passed on to a susceptible animal through close contact with an infected animal, and its virus-laden nasal and ocular secretions. Spread through contaminated bedding, animal food and water are less common due to the instability of the virus particles outside its animal host. The virus is especially sensitive to high humidity (50%–60%), light, and high and low pHs. As an enveloped virus, it is also efficiently inactivated by lipid solvents.[22]

The disease is believed to have originated from Mongolia and then spread throughout Europe during the sixteenth century, leading to the devastating losses among the naïve cattle populations.[7] Rinderpest was introduced into Africa in the nineteenth century, resulting in the first great panzootic wave that hit Africa. Before the disease burnt itself out, it had affected the fauna and flora of Africa, leading to livestock losses in millions. A second epizootic occurred during the 1980s, culminating in the demise of again millions of animals.[7,23] Rinderpest also affected many regions in Asia.[24,25] Outbreaks were reported in China and Korea, which spread through military conflicts and eventually subsided possibly due to the interruption of host–host interactions.[26] Rinderpest was introduced from Korea to Japan in the seventeenth century, resulting in the loss of over 500,000 animals and continued to affect livestock into the twentieth century.[27,28] India and Pakistan were badly affected incessantly until the completion of GREP. Middle Eastern regions including Turkey, Kuwait, Saudi Arabia, Bahrain, Qatar, and the United Arab Emirates have been ceaselessly exposed to rinderpest invasion.[7] Only the New World appears to have been spared the devastation caused by the disease.[29–31]

The main driver in the spread of the disease is the import of the infected livestock into regions with naïve cattle populations, as once recovered from the disease, the animal requires lifelong immunity. This mechanism of disease establishment is believed to have been introduced with the invasion of Europe by the Mongol hordes, who brought infected yaks that had acquired innate resistance to the disease and was also responsible for the introduction of the virus into Africa through European soldiers and infected livestock taken

as food supply.[5,32] Thus, the changing status of the disease between an enzootic state and the epizootic state depends on the circulatory activity of the virus. Animals continuously exposed to the virus acquires an inherited innate resistance, resulting in a slow spread of the disease, reduced clinical response to the disease, and increased survival rates. Mainly young animals that has lost protection from maternal antibodies in the colostrum after weaning are susceptible in enzootic regions.[22] When newly introduced to a naïve host population, the virus is able to spread rapidly, causing a high number of losses among the whole population and resulting in epizootics as seen in the African continent.

56.1.3 Clinical Features

Historically, rinderpest clinical signs manifested themselves in the three Ds: discharge, diarrhea, and death.[22] The disease is characterized by an incubation period of 3–15 days, which is followed by a prodromal fever, anorexia, and the affected animal showing signs of depression. Mucopurolent discharge from the eye and nose precedes necrotic lesions on the gum and buccal mucosa. The final stages of disease are characterized by shooting diarrhea, which can be watery and bloody and may contain mucous. At this stage the animal may show extreme distress caused by abdominal pain and thirst. Its death is mainly due to severe dehydration.[7,22] Most recent cases of rinderpest manifested themselves in less severe clinical signs with slight transient fever caused by less virulent strains of rinderpest, which made a precise diagnosis difficult. The peracute, acute, or subacute status of infection is dependent on strain virulence and individual susceptibility of the animal. Upon the postmortem examination, the disease presents itself as pathological changes especially throughout the gastrointestinal and upper respiratory tract with pronounced necrotic regions and erosion. Congestion and hemorrhage are also seen leading to the characteristic zebra striping in the lower GI tract. Lesions are often found on the gums and associated regions of the oral tract. Other observations are the enlargement of lymph nodes with associated edema and the appearance of necrotic foci in Peyer's patches. Overall, the carcass appears dehydrated, emaciated, and soiled.[22]

56.1.4 Diagnosis

56.1.4.1 Conventional Technique

The diagnosis of rinderpest is either a direct diagnosis revealing the presence of the RPV or viral antigens or indirect diagnosis detecting the presence of antibodies to the virus. Once the causative agent of a rinderpest-like disease is suspected, various diagnostic techniques are available to confirm the presence of RPV. Classically, direct detection of RPV includes virus isolation, agar gel immunodiffusion (AGID), counterimmunoelectrophoresis, passive hemagglutination, immunofluorescence (IF), immunoperoxidase staining, and most recently immunocapture ELISA (IC-ELISA) and a chromatographic strip test. Here, virus isolation, ELISA, and chromatographic strip test technology will be discussed in more detail, as these are the more routinely used techniques for a large-scale testing or penside diagnosis during GREP. For information on the other techniques, there are several in-depth publications available.[7,22] For the detection of antibody, the virus neutralization assays and ELISA technologies were the most commonly developed assays.

Isolation of RPV involves the inoculation of a tissue suspension from a sample of a rinderpest suspect animal into the cell layers of susceptible cell lines such as bovine kidney or Vero cells, allowing the virus to infect the chosen recipient cell line. Virus infection is noted by microscopic examination of the recipient cells and manifested itself in early cytopathic changes, which eventually result in rinderpest-induced syncytia in the cell cultures. Once syncytia are observed, the addition of rinderpest immune serum and inhibition of cytopathic effects will confirm the presence of RPV and rinderpest infection. However, the fact that PPR infections can also produce similar cytopathic effects and are also inhibited by rinderpest immune serum activity due to cross-reactivity and the need for a sophisticated tissue culture laboratory setup with associated materials and equipment made this a cumbersome technique.

In contrast, AGID proves a simplistic and easy-to-use technology. Based on the interaction between viral antigen and antibodies, a soluble antigen (suspect sample) is placed in a clear medium, which precipitates out after the reaction with the rinderpest-specific antibody. The technique is improved by adding the sample in wells cut into agar contained within a Petri dish or on a microslide. Controls including a standard antigen and serum are also incorporated in the test, which is deemed positive for rinderpest if a precipitation line occurs between the sample and the standard serum in the agar.

AGID is easy to prepare and has been routinely used until it is replaced by an IC-ELISA for large-scale screening and, in the later stages of GREP, the chromatographic strip test for diagnosis at penside.[33,34] The IC-ELISA is an ELISA based on monoclonal antibodies (Mabs) specific for RPV N-protein. Here, suspect tissue is added to an ELISA plate precoated with an RPV-trapping antibody. Any antigen in the sample is trapped by the RPV-specific antibody on the plate, which is then detected after the addition of a biotinylated RPV-detecting secondary antibody. RPV's presence is visualized by color development, which is read and recorded using an ELISA reader. The advantages of the ELISA over the AGID are sensitivity as well as the ability to test several samples at once and reproducibility. It still requires access to laboratory equipment and an associated ELISA reader.

In the later stages of GREP, a rapid diagnostic chromatographic strip test was developed, which allows the fast diagnosis of rinderpest in the field or at penside.[34,35] This test relies like the other tests on the interaction of a rinderpest-specific antibody to antigen contained within a suspect sample. In the original test, an RPV H-protein-specific antibody labeled with blue colloidal dye is bound in a dehydrated state on a nitrocellulose strip encased in a plastic device. Upon rehydration by the addition of the sample, usually lachrymal fluid collected with a cotton swab, any antigen present is trapped by

the dye-labeled antibody and travels along the nitrocellulose strip by capillary action. This complex is then detected as a blue line in a result window, which contains another antibody line reacting with the rinderpest antibody. A control is also incorporated to confirm that the test has worked, so that a two-line result indicates the presence of RPV and a one-line result the absence of the virus. The test is easy to use, fast (in most cases a result will be obtained within 5 min), and robust enough for application in the field under even adverse conditions. It enables a rapid response to a suspect rinderpest outbreak. This technology is especially useful in the final stages of GREP when a differential diagnosis has to be made in the field. It led to the detection of remaining rinderpest foci in Africa and Pakistan.[36,37]

Indirect RPV detection relies on the detection of the presence of antibodies in RPV. The most commonly used technology is an assay in ELISA format. This format is ideal as antibody detection during the earlier stages of GREP, which is important for measuring the impact of mass vaccination on cattle populations and immunity status. Here, seroconversion of vaccinated animals is a valuable indicator of herd immunity, which needs to reach at least 80% in order to eradicate rinderpest. In this ELISA format initially, ELISA plates are coated with rinderpest antigen, and sera from suspect animals are added to the plates and then reacted with secondary antibodies to the species of animal to be tested. As for the IC-ELISA, colorimetric results are obtained with the ELISA. This test is fast (3 h) and highly sensitive; however, the need to produce secondary antibodies to a range of host species renders it cumbersome.[38] For this reason, a new format is adopted (competitive ELISA [C-ELISA]), which is based on rinderpest-specific Mabs.[39] In this assay, again, the first step is coating the ELISA plates with RPV antigen. The test serum is then added to the plate after which there is a further step with the addition of the rinderpest-specific Mab to the RPV H-protein. Any antibody present in the test serum competes with the mouse-derived Mab ELISA kit for antigenic sites in the samples leading to a reduced reaction between Mab and antigen. This competition event results in a colorimetric readout with reduced color development if antibody is present in the test sera. The percentage inhibition (PI) can then be calculated. The test is produced in a kit format by the World Reference Laboratory in Pirbright and is available through the FAO.[39] Reproducibility of results is consistently good, and associated training courses in this technique ensure that C-ELISA users are confident to carry out this test with high success rates.

56.1.4.2 Molecular Techniques

With the advent and advancement of detecting single copies of DNA by means of the polymerase chain reaction (PCR),[40,41] it becomes possible to detect RPV at the molecular level. Preceding PCR technology attempts have already made use of molecular probes such as single-stranded nucleic acid hybridization probes complementary to a single strand in the sample with an initially radioactive label, which is later replaced by a nonradioactive label.[42] For the rinderpest-specific assay, these are cDNA clones corresponding to the RPV N gene. Drawbacks of this technique are low sensitivity and the need for pure target RNA. However, the development of a PCR for the detection of RPV is an integral driver in the advancement of GREP. For the first time, whole virus genomes can be sequenced, which is especially important with regard to epidemiological studies to establish global geographical locations and movements of viral strains as well as to locate the origin of new outbreaks of rinderpest.

A rinderpest-specific reverse transcription (RT)-PCR was developed by Forsyth and Barrett.[43] In this assay, suspect sample is homogenized and then subjected to the phenol/chloroform extraction to purify the RNA. The RNA is used to make a complementary DNA (cDNA) by RT using random hexanucleotide primers. The generated cDNA is then amplified with the help of rinderpest-specific amplification primers, which are based on the virus F-protein gene of the virus. A universal primer set is generally used, which is based on sequences in the P gene of the morbilliviruses, allowing the amplification of copy DNA from all known morbilliviruses. This reaction is included to ensure that any morbillivirus is identified in the first reaction, which then can be used to make a precise diagnosis using the rinderpest-specific primer sets. The generated data can then also be utilized for sequencing allowing the identification of the RPV strain in question for epidemiological studies. Although these PCRs are routinely carried out during GREP at the World Reference Laboratory at Pirbright, other studies have aimed to improve upon the original assay.

Most recently, there have been publications on modified PCR assays for the detection of RPV. Carrillo et al.[44] reported a real-time RT-PCR system, which is highly specific recognizing virus strains belonging to the three lineages and also sensitive. Primer sets are designed to target the viral gene L10 as this probe detects all RPV tested and does not show cross-reactivity with PPRV or other viruses that cause diseases clinically similar to rinderpest. The assay detects RPV in samples from dead and live animals, and the authors suggested that the format, although lab based for the time being, can also be adapted for field use.

Differential diagnosis of RPV infections to distinguish RP infections from other viral infections are becoming increasingly important after considering that rinderpest is often concomitant with other diseases of veterinary importance with clinical signs similar to rinderpest. To address this, Yeh et al.[45] developed a specific and sensitive one-step multiplex RT-PCR assay for the simultaneous and differential detection of Rift Valley fever virus, bluetongue virus, RPV, and PPRV. This assay is based on novel dual-priming oligonucleotides that contain two separate priming regions joined by a polydeoxyinosine linker. Incorporation of the linker blocks extension of nonspecifically primed templates and allows the early diagnosis of the four viruses, when trialed using whole blood or oral mucosal tissue, as samples. Main events in rinderpest eradication and concomitant developments in diagnostic technologies are summarized in Figure 56.1.

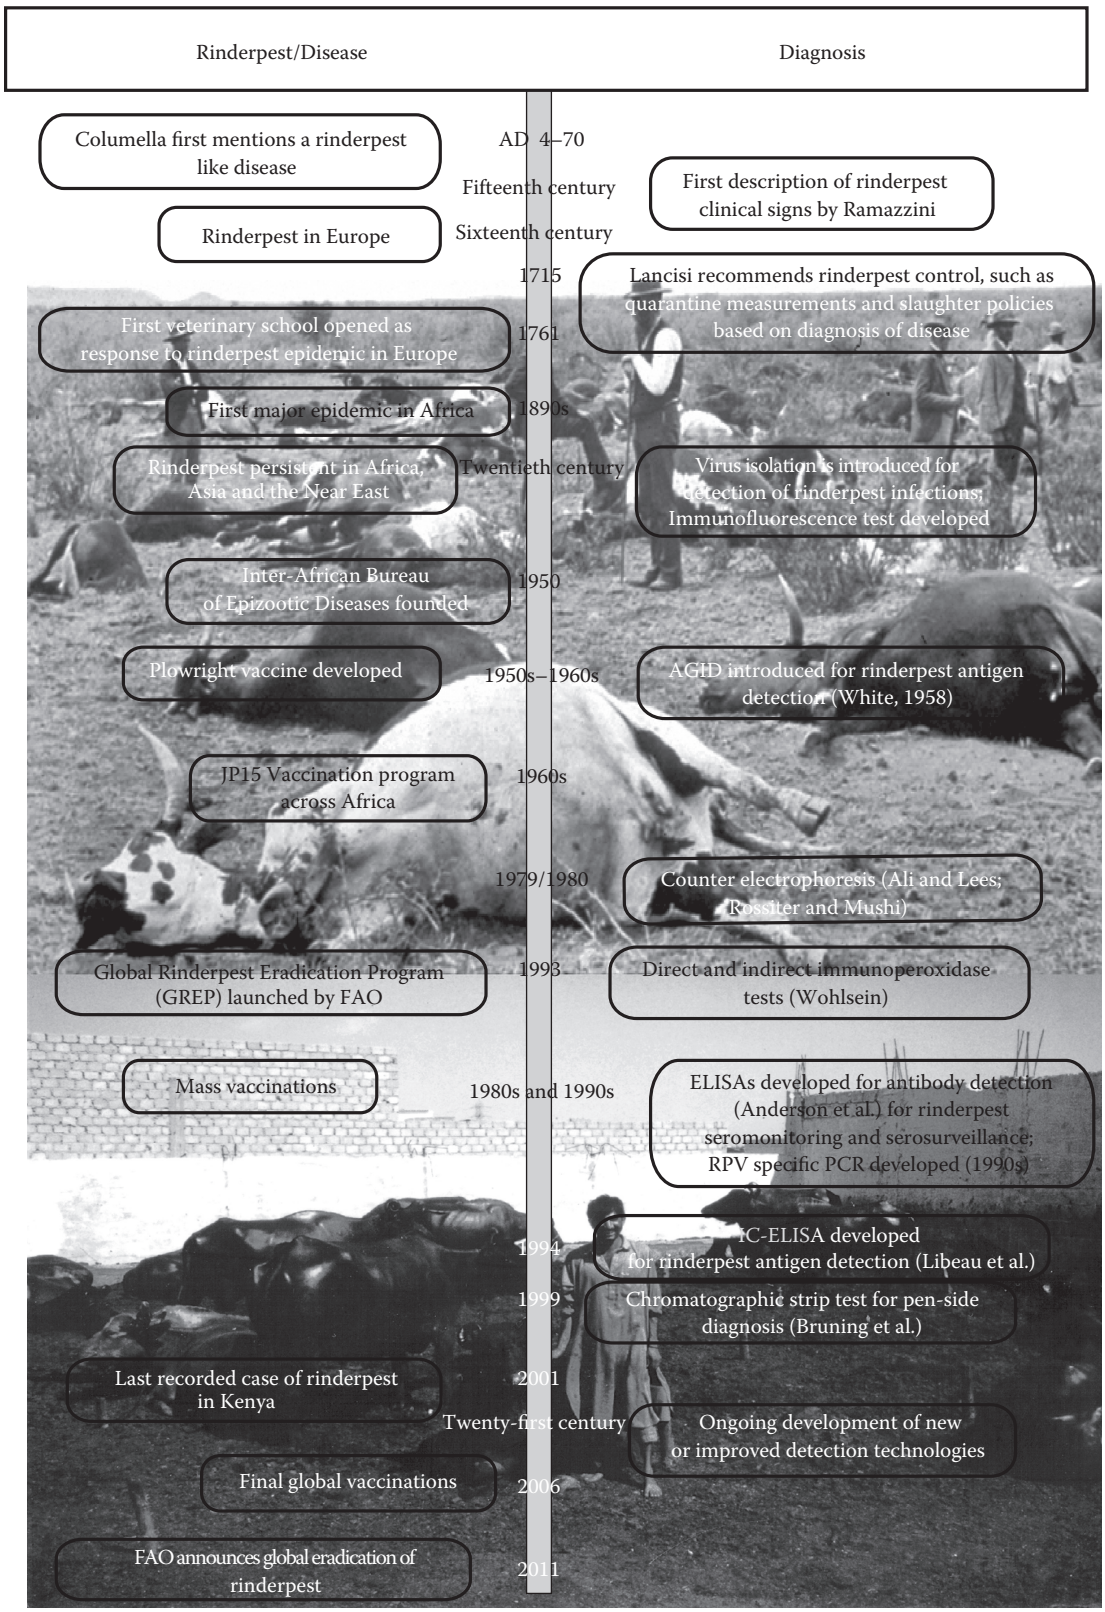

FIGURE 56.1 Simplified timeline of major events in the history of rinderpest disease and concomitant development of the diagnosis of rinderpest.

56.2 METHODS

56.2.1 Sample Preparation

Sample preparation is an important initial step for any of the diagnostic techniques discussed in this chapter. As RPV is particularly susceptible to humidity, light, and low and high pHs and is shed in great numbers only during the prodromal stage of infection, it is advantageous to sample efficiently and swiftly during the acute phase of the disease. Animals at the diarrheic stage of disease or recovering animals are less likely to yield enough detectable virus. For samples from carcasses, time is of essence due to autolysis and putrefaction. To maximize virus retrieval for analysis, it is advisable to sample as many animals as possible from an affected herd. Samples are taken from different sites (e.g., from the nose, eyes, and gums), placed into a cold box, and transported to the nearest reference laboratory for analysis. Lymph node and spleen biopsies, gum debris, and ocular and nasal discharges appear to harbor most viral particles. When using animal tissues, these are prepared for analysis by placing into a tissue grinder and working into a tissue suspension. Nasal and ocular secretions are collected with cotton swabs, which are then immersed in the appropriate extraction buffer to release the virus. Whole blood also contains virus. As RPV is associated with the leukocyte fraction, peripheral blood mononuclear cells (PBMCs) have to be isolated from the whole blood. To do this, Ficoll reagents or sequential centrifugation of whole blood are used to separate the buffy coat from the whole blood sample. All samples prepared in this way are then used in the direct or indirect conventional diagnostic techniques described previously. Sample preparation for PCR technologies requires the extraction of RNA from whole samples by phenol/chloroform extraction, but due to toxicity issues, this is replaced by commercially available RNA extraction kits based on column separation.

56.2.2 Detection Procedures

The procedures for the most commonly detection methods are described here and are the condensed version of protocols as they appear in the accompanying protocols of commercial kits or guidelines by the FAO.[22,46] An exhaustive literature exists on the lesser used technologies and can be found elsewhere.[7,22]

56.2.2.1 AGID Test

1. Prepare fresh samples (lymph node, spleen) as tissue suspensions or extract lachrymal/nasal secretion into phosphate-buffered saline (PBS buffer). Gum scrapings can also be used, which are added directly to the agar plate wells.
2. Prepare agar (4 g agar/400 mL distilled water) as previously described[22] and pour into Petri dishes or onto microslide to a depth of 4 and 3 mm, respectively.
3. Allow agar to solidify overnight. Use a template for well patterns to cut out wells in a hexagonal pattern in the solidified agar and remove agar plugs with dissecting needle.
4. Mark out the control antigen and sample position on the plate or slide.
5. Add the control antigen into the appropriate well and add the test antigen to the appropriate well using the Pasteur pipette.
6. Add prepared hyperimmune serum to the designated well.
7. Place plate/slide into a humidified chamber at room temperature less than 40°C. Remove suspect antigen preparation within 30 min to improve speed and accuracy of reaction.
8. Check plates at 2, 12, 24, and 36 h intervals. Record the lines of white precipitate indicating the presence of antigen in the sample. Ensure that the positive control lines are clearly visible.

Requirements for this technique are reagents such as agar, Petri dish/microslides, humidifying chamber, pastettes, control rinderpest antigen, and hyperimmune serum.

56.2.2.2 IC-ELISA[33]

1. Prepare samples as for the AGID test.
2. Add the trapping antibody to ELISA plate as per instruction and layout.
3. Incubate at 37°C with agitation.
4. Wash the plate 3× with a washing buffer and remove excess fluid.
5. Then add 50 µL of the sample in the supplied blocking buffer in duplicate, add 50 µL of reference antigen as per instruction, add negative controls (buffer only) to the wells as instructed, add 25 µL biotinylated RPV- and PPRV-specific Mabs to the assigned wells as instructed, and add 25 µL of supplied streptavidin–peroxidase conjugate in blocking buffer.
6. Incubate for 60 min at 37°C with agitation.
7. Wash the plate as in step 4.
8. Add 100 µL of substrate/chromogen as instructed and allow color development for 10 min.
9. Stop the color reaction by adding 100 µL of 1 M H_2SO_4.
10. Read the plate on ELISA reader at 492 nm.
11. Interpretation of results: A sample with an optical density (OD) value greater than twice the mean OD value of the blank controls is considered to be positive.

Requirements: Basic laboratory setup, washing facilities, buffer-making facilities, pipettes, shaking incubator, and ELISA reader.

56.2.2.3 Rapid Chromatographic Strip Test[34,35]

1. Collect lachrymal fluid with cotton swab; make sure to take a sample from both eyes.
2. Prepare lachrymal swab by immersing in the supplied extraction buffer (200 µL) and squeeze the swab gently to obtain as much fluid as possible.

3. Remove strip test from protective pouch. Lay on a flat surface.
4. Add 200 µL of lachrymal fluid in the extraction buffer to the sample window (blue pad at the bottom of the device).
5. Allow to react for 5–20 min.
6. Record the appearance of blue lines in the result window. Interpretation of test: Two blue lines mean positive, while one blue line means negative.

Requirements: All parts of the test are included in the test. It is advisable to keep samples on ice or at 4°C until tested so a cold box is desirable.

56.2.2.4 PCR[43]

Extract RNA from tissue or PBMCs using phenol/chloroform or RNA extraction kit according to the manufacturer's instructions.

1. RT of RNA
   For tissue-extracted RNA, dissolve RNA pellet in RNAse-free water at 1 mg/mL. For PBMC-derived RNA, allow ¼—1/10 of RNA/120 mL whole blood. Use 0.75 mL microcentrifuge tubes for thermocyclers.
   RNA—RT reaction:
   5 µL RNA solution
   2 µL random hexanucleotide primers (50 ng/µL)
   3 µL pure water to give 10 µL reaction mix
2. Incubate for 5 min at 70°C, and quickly spin to collect reaction mix in the bottom of the tube.
3. Prepare RT reaction mix: 4 µL of 5× RT buffer, 2 µL DTT (0.1 M), 2 µL BSA (acetylated, 0.1 mg/mL), 1 µL MoMuLV reverse transcriptase (200 units), and 1 µL deoxynucleotide triphosphates (dNTPs) (10 mM each). Then, add 10 µL of this to each RNA sample.
4. Mix carefully and centrifuge briefly for a few seconds to spin reaction to the bottom of the tube.
5. Incubate at room temperature (25°C) for 5 min and then at 37°C for 30 min; the RT products can be stored at −20°C until use.
6. For PCR, remove 5 µL of RT reaction and add 5 µL 10× PCR buffer, 36.5 µL pure water, 0.5 µL Taq polymerase (5 U/µL), 1 µL dNTPs (10 mM each), 1 µL forward primer, and 1 µL reverse primer.
7. Place the tubes in thermocycler and use appropriate cycling program such as the following:
   Step 1: 94°C 5 min
   Step 2: 50°C 1 min
   Step 3: 72°C 2 min
   Step 4: 94°C 1 min
   Step 5: Go to step 2 30 times
   Step 6: 50°C 1 min
   Step 7: 72°C 10 min
   Step 8: 4°C Hold

   Primer sequences:
   Universal primer set 1 for P gene conserved across the *Morbillivirus* genus:
   UPP1 5′ ATGTTTATGATCACAGCGGT 3′
   UPP2 5′ ATGGGTTGCACCACTTGCT 3′
   RPV-specific primer set 2 for the virus F gene conserved in each morbillivirus but different among RPV strains:
   RPVF3 5′ GGGACAGTGCTTCAGCCTATTAAGG 3′
   RPVF4 5′ CAGCCCTAGCTTCTGACCCACGATA 3′
   Nested PCR set 3 for RPV set within the amplified F gene fragment to confirm origin of DNA:
   RPVF3a 5′ GCTCTGAACGCTATTACTAAG 3′
   RPVF4a 5′ CTGCTTGTCGTATTTCCTCAA 3′
8. Analyze RT-PCR products by running samples on a 1.5% agarose gel; determine fragment size by comparing to reference ladder on gel, with the following expected product sizes: universal primers 429 bp, F-specific primer 372 bp, and nested PCR 235 bp.

Requirements: Standard RNA extraction kits or reagents, access to PCR-associated reagents, RNAse-free water, sterile tissue culture hood for reaction setup, pipettes, sterile and filtered pipette tips and plastics, thermocycler, running tanks for agarose gels, running buffer, agarose, and ethidium bromide.

Examples of the main detection techniques described here are illustrated in Figure 56.2.

56.2.2.5 Competitive ELISA[39]

1. Prepare serum from blood sample of suspect animal using standard techniques.
2. Prepare antigen as recommended by manufacturers. Add 50 µL of antigen to each well in ELISA plate. Incubate at 37°C for 1 h with agitation.
3. Wash the plate three times by immersing wells with PBS and expelling PBS.
4. Add 40 µL of blocking buffer to wells, add a further 10 µL to Mab control wells and 60 µL to conjugate control wells, add 10 µL test serum to appropriate wells, add 10 µL of strong positive control serum to appropriate wells, add 10 µL of weak positive control serum to appropriate wells, add 10 µL of negative serum to appropriate wells, and add 50 µL of Mab prepared in blocking buffer to all appropriate wells.
5. Incubate for 1 h at 37°C with agitation.
6. Wash the plate three times as under step 3.
7. Add 50 µL of the anti-mouse conjugate prepared in the blocking buffer to all wells at the predetermined concentration.
8. Incubate for 1 h at 37°C with agitation.
9. Wash the plate as before under step 3.

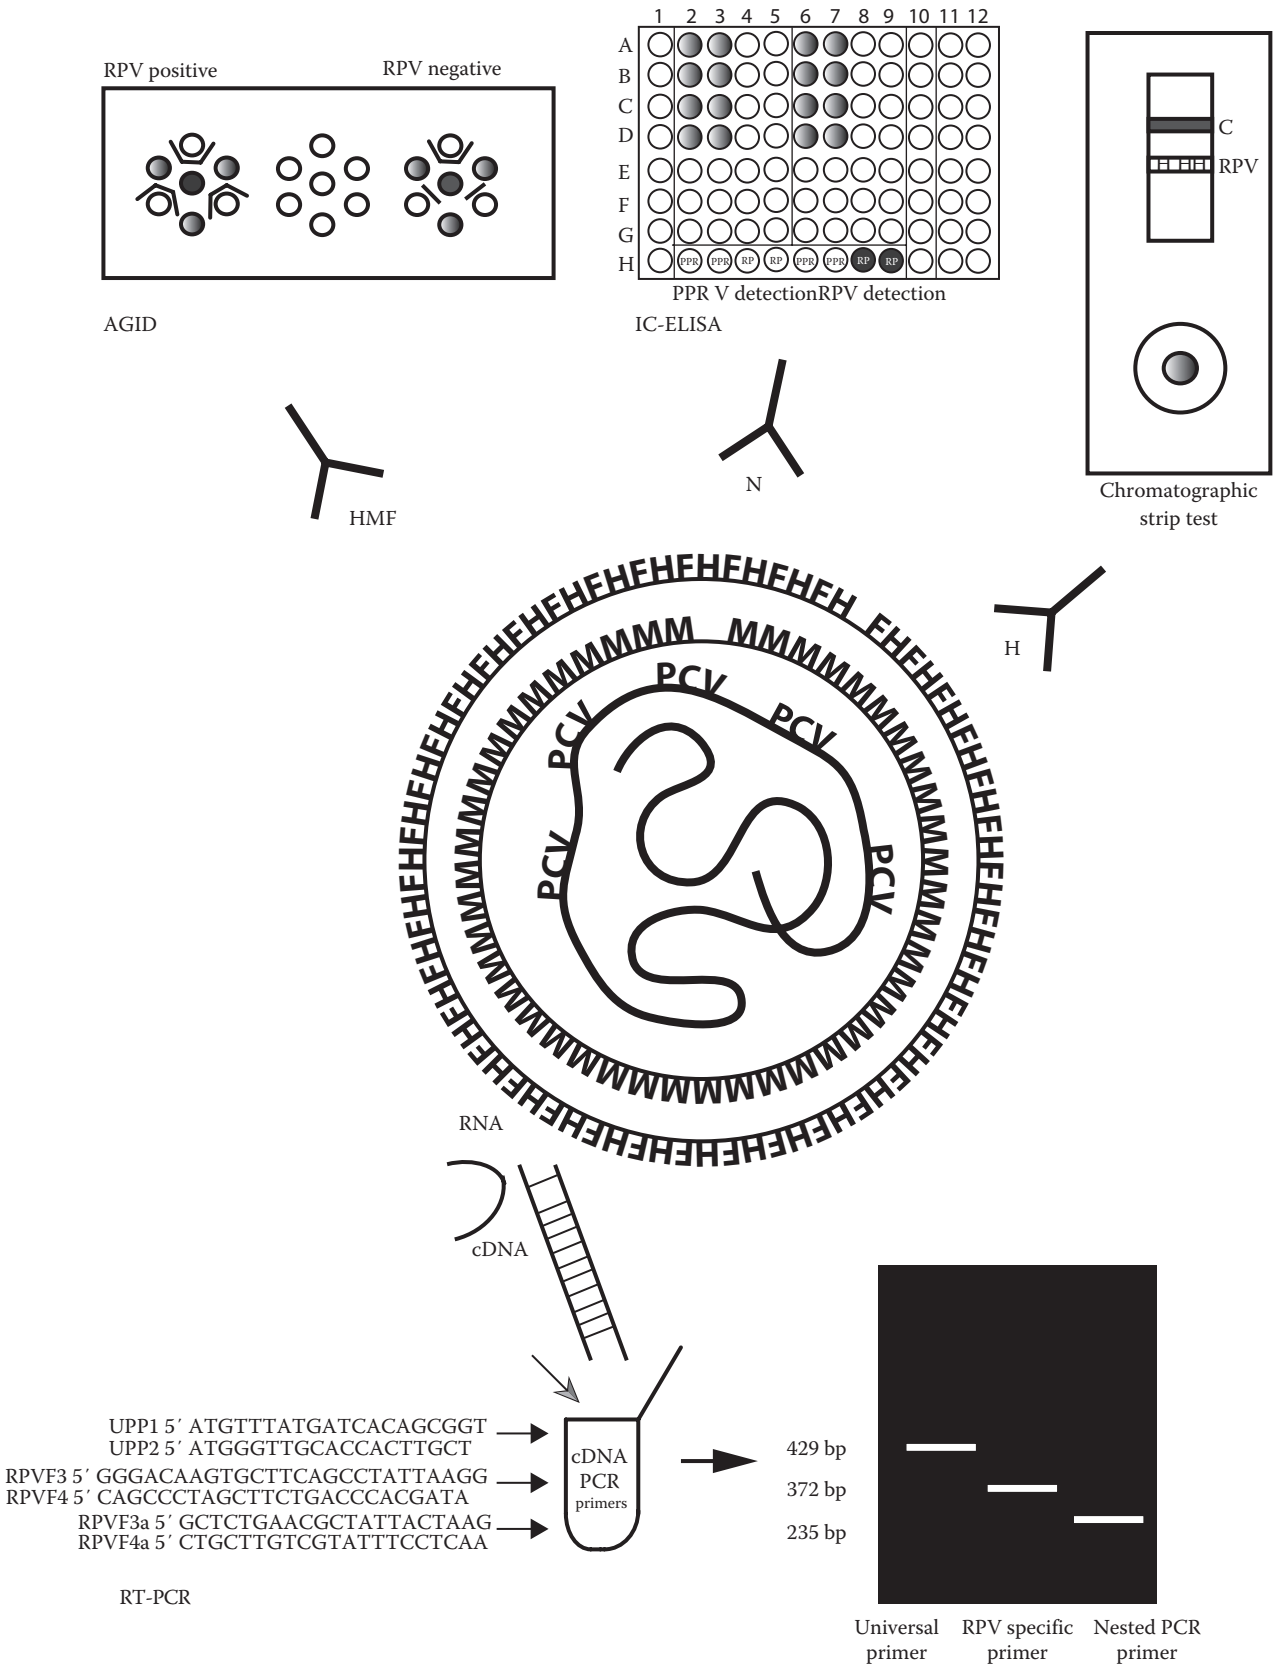

FIGURE 56.2 Diagram of four major diagnostic techniques for the detection of rinderpest antigen. The assays detect different rinderpest proteins as indicated by capital letters or RPV cDNA generated from RNA by RT. Dark shading indicates a control antigen and graduated shading indicates the suspect rinderpest sample. Y symbolizes antibodies used in the assays.

10. Make up OPD solution as per kit instruction and add hydrogen peroxidase solution just before use. Add 50 μL of substrate/chromogen/well; allow it to incubate for 10 min for color development.
11. Stop the reaction by adding 50 μL of 1 M H_2SO_4.
12. Read the plate on ELISA plate reader at 492 nm.

Interpretation of results is achieved by calculating the mean of the Mab control wells and determining the PI as follows:

PI = 100− [(Mean OD of test wells/Mean OD of Control Mab wells) × 100]

Inhibition values greater than 50% are RPV positive.

The kit also includes internal controls to ensure that the results are valid and not affected by external factors such as the quality of the water to rehydrate the supplied kit reagent with.

Requirements: Basic laboratory setup, water systems, shaking incubator and the like, pipettes, buffer-making facilities, and ELISA plate reader.

56.3 CONCLUSIONS AND FUTURE PERSPECTIVES

The success of GREP was multifactorial. The exploitation of virus biology has made eradication an achievable target as there is only one known serotype of the virus and infection conferred lifelong immunity if the animal has not succumbed to the disease, unlike diseases such as foot-and-mouse disease where several serotypes exist and vaccination only protects against infection with the virus in circulation at the time of infection.[47–50] When it became clear that a vaccine could protect animals from infection and that vaccination gave lifelong immunity to rinderpest, the possibility for global eradication of the virus became an attractive option. Through the collaboration of people at national and international levels, from herd farmer to clinical director of reference laboratories, an efficient global eradication program was conceived, which relied heavily on the mass vaccination of vulnerable animals. However, the rinderpest eradication success story was also made possible by the development of—in parallel—powerful diagnostic techniques, which reliably detected rinderpest infections or antibodies to rinderpest in vaccinated populations or in animals suspected to be infected with the virus. These started off as isolation of virus in cell cultures, detection of virus by visualization of antigen/antibody interactions in agar plugs, and other tests such as the IF test leading to more sophisticated technologies including ELISAs. For the first time, the mass screen and detection of present and past infections was possible, allowing the assessment of RPV infection status and the impact of vaccination programs on herd immunity. The development of a simple diagnostic chromatographic strip test facilitated the rapid diagnosis of the remaining rinderpest foci in the field leading to a swift implementation of emergency vaccinations. In addition, advances in the field of molecular biology resulted in the development of highly sensitive molecular probes for the detection of even low copy numbers of RPV RNA in samples supporting the diagnostic side of the rinderpest eradication program in addition to allowing the epidemiological study of virus origin, movement, and evolution in terms of virus virulence.

Even with the completion of GREP, new technologies are being developed or are being improved, perhaps reassuringly so bearing in mind that rinderpest viral stocks still exist in laboratories around the world and the threat of accidental or intended re-release of the virus into the environment remains.[51] Not only does the scientific interest in rinderpest and its biology remain, but it also extends beyond rinderpest related research into other fields. For example, the possibility to eradicate the close relative of RPV–PPRV has become a possibility through the lessons learned from GREP. Powerful diagnostic techniques similar to those developed for rinderpest eradication already exist for the fight against PPRV,[48,52–54] and the infrastructure left behind by GREP is still in place to be adopted by a similar eradication program for PPR.

57.1 INTRODUCTION

Viral hemorrhagic fever (VHF) is a general term for a severe illness characterized by fever and bleeding disorder caused by five families of RNA viruses, including *Arenaviridae* (Lassa fever, Junin, and Machupo), *Bunyaviridae* (Crimean-Congo hemorrhagic fever, Rift Valley fever, Hantaan hemorrhagic fevers), *Filoviridae* (Ebola and Marburg), *Flaviviridae* (yellow fever, dengue, Omsk hemorrhagic fever, Kyasanur forest disease), and *Rhabdoviridae* (Bas-Congo virus) [1–5]. Epidemic hemorrhagic fever caused by Ebola and Marburg viruses represents a major public health issue in Sub-Saharan Africa with the highest fatality rates of the VHFs and lack of any validated prophylaxis or treatment options. The current ongoing (largest known) outbreak of Ebola hemorrhagic fever (EHF) in West Africa (2014), including Guinea, Liberia, and Sierra Leone, brought the spotlight on Ebola virus and highlights the virulent nature of the pathogen [6].

Ebola viruses cause a severe, often fatal disease in humans and nonhuman primates (such as monkeys, gorillas, and chimpanzees). Since its discovery in 1976 in what is now the Democratic Republic of the Congo (DRC) near the Ebola River, Ebola viruses have caused small sporadic outbreaks except for the most recent one (Table 57.1) [3,7]. Before 2007, there were four identified species of Ebola viruses, *Zaire ebolavirus*, *Sudan ebolavirus*, *Taï Forest* (*Côte d'Ivoire*) *ebolavirus*, and *Reston ebolavirus.* Among these, *Z. ebolavirus* and *S. ebolavirus* have caused larger human outbreaks in Africa with high mortality rates (≈50%–90% and 40%–65%, respectively) [8]. *R. ebolavirus* was first reported in 1989 in association with an outbreak of VHF among monkeys imported from the Philippines to Reston, Virginia, United States. Subsequent outbreaks of *R. ebolavirus* were also associated with monkeys from the Philippines in 1990, 1992, and 1996 [9–13]. Although infection with this virus can be fatal in monkeys, the 13 infections confirmed in humans were asymptomatic [3,7]. Recently, *R. ebolavirus* was isolated from pigs coinfected with porcine reproductive and respiratory syndrome virus that were experiencing a severe respiratory disease syndrome in the Philippines in 2008. Phylogenetic analysis of these viruses suggested that *R. ebolavirus* has been circulating since, and possibly before, the initial identification of this virus in monkeys in 1989. These findings have raised concerns about the potential disease emergence in humans and other livestock animals in the future [14]. A fifth species of Ebola virus, *Bundibugyo ebolavirus*, was identified as a cause of EHF outbreak in Uganda from late 2007 to early 2008 with 25% fatality rate and a subsequent outbreak in the DRC in 2012 with 36.5% mortality rate [7,15–17].

57.1.1 Classification

Ebola viruses and its lesser known cousin, Marburg virus, constitute the *Filoviridae* family in the order of *Mononegavirales*. Based on genetic diversity and antigenic characterization, there are five designated specie, *Z. ebolavirus*, *S. ebolavirus*, *Taï Forest ebolavirus (*also known as *Ivory coast ebolavirus* or *Cote d'Ivoire ebolavirus*), *B. ebolavirus*, and *R. ebolavirus* [3,18]. The *Z. ebolavirus* is most pathogenic for human followed by *S. ebolavirus* and *B. ebolavirus*, while *Taï Forest ebolavirus* and *R. ebolavirus* cause lethal infections in nonhuman primates, but have not yet been associated with fatal human cases (Table 57.1). Genomic surveillance of current

TABLE 57.1
List of Ebola Outbreaks

Ebola Subtype	Year	Country	Reported Cases[a]	Mortality Rate[b]
Zaire	1976	DRC	318	88%
	1977	DRC	1	100%
	1994	Gabon	52	60%
	1995	DRC	315	81%
	1996 (Jan–Apr)	Gabon	37	57%
	Jul 1996–Jan 1997	Gabon	60	74%
	Oct 2001–Mar 2002	Gabon	65	82%
		RC	57	75%
	Dec 2002–Apr 2003	RC	143	89%
	2003 (Nov–Dec)	RC	35	83%
	2007	DRC	264	71%
	Dec 2008–Feb 2009	DRC	32	47%
	Mar 2014–present	Guinea, Liberia, Sierra Leone	745	Unknown
Sudan	1976	Sudan, England	284	53%
			1	0%
	1979	Sudan	34	65%
	2000–2001	Urganda	425	53%
	2004	Sudan	17	41%
	May 2011	Urganda	1	100%
	2012 (Jun–Oct)	Urganda	11	36.4%
	Nov 2012–Jan 2013	Urganda	6	50%
Taï Forest	1994	Ivory Coast	1	0%
Bundibugyo	Dec 2007–Jan 2008	Urganda	149	25%
	2012 (Jun–Nov)	DRC	36	36.1%

Note: DRC, Democratic Republic of Congo; RC, Republic of Congo.

[a] Number of human cases.

[b] Mortality rate is calculated based on reported number of deaths among reported number of human cases.

outbreak strains identified *Z. ebolavirus* as the causative agent and suggested an independent zoonotic transmission event since all strains diverged from a common ancestor followed by human-to-human transmission [6,19].

57.1.2 Morphology, Genome Organization, Biology, and Epidemiology

57.1.2.1 Morphology and Genome Organization

Ebola virus has a unique morphology: it appears as filamentous particles about 1.4 μm in length and 80 nm in diameter and forms twisted filaments (hence the name *filovirus*) (Figure 57.1). The filamentous, enveloped virus contains linear, nonsegmented, single-stranded negative-sense RNA. Along the central axis of the filamentous virion resides a nucleocapsid (NC), a right-handed double-layered helix with an outer diameter of 41 nm and a hollow inner channel 16 nm in diameter [20,21].

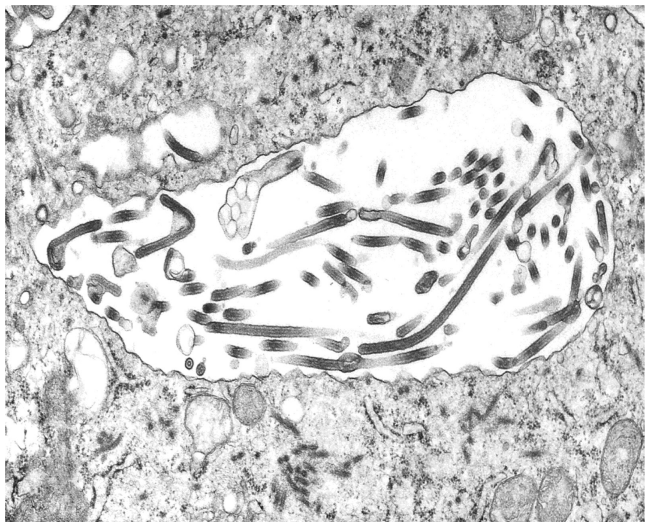

FIGURE 57.1 Ebola virus. Transmission electron micrograph of tissue samples infected with Ebola viruses showing the presence of numbers of Ebola virions. (Image downloaded from public health image library [ID #13218] of Centers for Disease Control and Prevention, Dekalb County, GA.)

The single-stranded, negative-sense RNA of the virus is ~18.9 kb long and encodes seven structural proteins and two nonstructural proteins. The genomes of all sequenced Ebola viruses share a conserved structure with a 3′ leader sequence (~55 bases long), followed by in sequence nucleoprotein (NP), P protein (VP35), matrix protein (VP40), glycoprotein (GP), second NP (VP30), envelop protein (VP24), RNA-dependent RNA polymerase (L), and finally trailer sequences (Figure 57.2) [18,22–25]. The genomes of Ebola viruses contain long 5′ trailer sequences and a conserved transcriptional start and stop (polyadenylation) signal, containing the sequence 3′-UAAUU, which are unique characteristics of *filovirus* genomes. Another distinct feature of the genomes of *filovirus* is the positioning of some of the genes that overlap one another without separating intergenic regions. For Ebola viruses, these overlaps, which are limited to the conserved transcriptional signals, were found between the VP35 and VP40, the GP and VP30, and the VP24 and L [23]. A final specific feature of Ebola virus is the organization of the GP gene that encodes two ORFs expressed through transcriptional editing [26]. It should be noted that the genome of *R. ebolavirus*, the less virulent strain in humans, showed similar sequences of proteins and 3′ leader to other Ebola viruses, but did not share any similarity in noncoding and intergenic regions as well as a much shorter 5′ trailer sequence (Figure 57.2) [25,27].

Five of the nine proteins encoded by Ebola viruses form a ribonucleoprotein (RNP) complex, including NP, VP35, VP30,

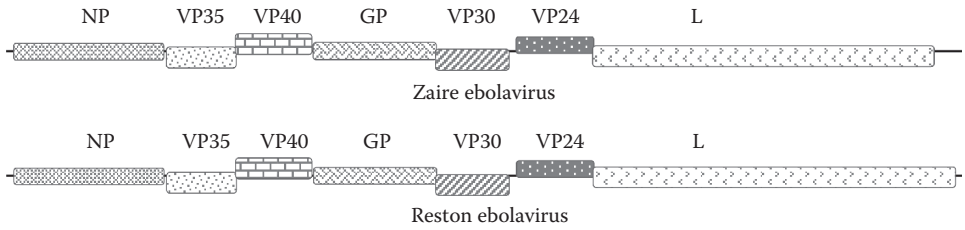

FIGURE 57.2 Genome structures of Ebola viruses indicating the proteins encoded by the viruses. NP, NP, VP35, VP4, GP, sGP, VP30, VP24, and L protein. The genome structures were constructed based on the sequences deposited in GenBank (*Zaire ebolavirus*, NC_002549; *Sudan ebolavirus*, NC_006432; *Cote d'Ivoire ebolavirus*, NC_014372; *Bundibugyo ebolavirus*, NC_014373; *Reston ebolavirus*, AB050936). The genome structure of *Z. ebolavirus* was used as a representative for *S. ebolavirus*, *Cote d'lvoire ebolavirus*, and *B. ebolavirus*.

VP24, and L protein, which is responsible for the transcription and replication of the viral genome [20,21,28–30]. NP functions in RNA encapsidation and consists of 739 amino acids (~104 kDa). The N-terminal 450 amino acids are required for the NP–NP interaction and formation of NP tube structure, while the region from amino acids 1 to 600 are essential for the formation of NC-like structure and for viral genome replication [31]. VP35 serves as RNA-dependent RNA polymerase cofactor and consists of 340 amino acids (~35 kDa) with a highly conserved C-terminal basic amino acid motif that displays remarkable similarity to the N-terminal RNA-binding domain of the NS1 protein of influenza A virus. Also similar to NS1 protein of influenza A virus, VP35 functions as antagonist of type 1 interferon (IFN) by preventing the activation of interferon regulatory factor (IRF)-3 and inhibiting IRF-3-dependent gene expression [32].

VP30 acts as an Ebola virus–specific transcription activator and is 288 amino acids in length (~30 kDa). It consists of a zinc-finger motif, two serine clusters (amino acids 29–31 and 42–46) each containing three serine residues, a stretch of hydrophobic amino acids (94–112), and C-terminal dimeric domain (amino acids 142–272). The functions of VP30 depend on homooligomerization through hydrophobic amino acids and C-terminal dimeric domain that leads to hexamerization as well as phosphorylation at the two serine clusters. Evidence suggests that the balance between hexamer and dimer forms of VP30 is fundamental to the regulation of transcription and replication activity. The phosphorylation of VP30 modulates the composition of the viral polymerase complex by dissociating from the VP35-L complex, thereby regulating transcription and replication activities of the polymerase [33–36].

VP24 is believed to be a secondary matrix protein, consists of 251 amino acids (~24 kDa) with a hydrophobic region (amino acids 90–130), and features commonly associated with a viral matrix protein that are crucial in virion assembly and budding. Similar to the matrix protein (VP40), the N-terminal region of VP24 is critical for self-oligomerization, preferentially tetramers. Evidences also suggested that VP24 possesses membrane binding capability potentially through a consensus motif of a functional L-domain (YxxL) (amino acids 172–175). However, the precise locations of these domains have yet to be defined [37]. VP24 is also essential for the formation of functional RNP complex by ensuring the correct assembly of a fully functional NC with NP and VP35; however, VP24 is not required for viral transcription and replication. Further evidence indicated that VP24 inhibits transcription and replication of the viral genome by hampering the functions of VP30 and L via binding to NP, and the association of VP24 with the RNP complex may serve as a converting signal from a transcription and replication-competent form to one that is ready for viral assembly [38,39]. In addition, VP24 functions as IFN antagonist by competing with tyrosine-phosphorylated signal transduction and transcription 1 (STAT1) protein to bind to karyopherin α1, blocking the nuclear accumulation of tyrosine-phosphorylated STAT1 and leading to the inhibition of IFN signaling and evade the antiviral effects of IFNs [40,41].

L (RNA-dependent RNA polymerase) protein, the largest and least abundant protein, is 2212 amino acids in length with a molecular weight of ~252 kDa. The L protein of Ebola virus, like most L proteins of nonsegmented negative-strand RNA viruses, consists of an RNA-binding element (amino acids 553–571), a putative RNA template recognition and/or phosphodiester bond formation domain (amino acids 738–744), and an ATP and/or purine ribonucleotide triphosphate–binding domain (amino acids 1815–1841), and highly conserved twin cysteine residues (amino acids 1351–1352) that potentially stabilize the secondary structure of the proteins for the proper conformation of the putative active sites [42].

The matrix protein (VP40, ~40 kDa) of Ebola virus, functionally similar to Gag protein of retroviruses and the M proteins of rhabdoviruses and paramyxoviruses, is the most abundant protein in mature filovirus virions and the key building block for virion maturation as well as budding. It is believed that VP40 consists of three functional domains, the M, I, and L, based on the working model of Gag protein. The M domain mediates the localization and binding to the plasma membrane, followed by self-interaction or oligomerization adjudicated by the I domain, and then the L domain, key C-terminal sequences of VP40, directed the interactions with host proteins Tsg101 and Nedd4 that lead to budding or "pinching off" from the cell surface. Evidence suggests that the N-terminal region of Ebola VP40 mediated the membrane binding and formation of hexamers; however, the precise locations of M and I domains have yet to be defined [43,44].

One distinct feature of Ebola viruses is the production of soluble and transmembrane glycoproteins (sGP and GP). The GP gene of Ebola virus encodes, through transcriptional editing events, four GPs, secreted GP (sGP), GP1, GP2, and small sGP (ssGP). The primary transcript (70%) is a single polypeptide at ~110 kDa, cleaved by furin to generate sGP that forms disulfide-linked homodimers and secreted Δ-peptide [45,46]. About 25% of transcripts generated experience transcriptional stutter resulting in another single polypeptide, the virion-attached or envelope spike GP. This polypeptide is cleaved by furin into GP1 and GP2 subunits that form disulfide-linked heterodimer and then assembled to trimers on the virus surface. The GP1 subunit, similar to the HA1 subunit of influenza virus, contains a receptor-binding site and mediates cellular attachment. The GP2 subunit contains a helical heptad-repeat region, transmembrane anchor, and a cytoplasmic tail. It is responsible for anchoring the GP into the viral membrane and the fusion of the viral and cellular membranes. Transcription stutter also results in the production of ssGP that forms disulfide-linked homodimers (5%) [45–48]. In addition to sGP, Ebola virus–infected cells also secrete shed GP that is produced by proteolytic cleavage of virion-attached GP by tumor necrosis factor (TNF)-α–converting enzyme that removes transmembrane anchor and releases the GP1-truncated GP2 heterodimers in the blood of infected animals. The functions of sGPs and shed GP is likely to facilitate immune evasion, acting as "antibody sinks" or decoys for host immunity, by competing with virion-attached GP for antibody binding that inhibits the neutralizing activity of Ebola virus antibodies [46,49].

57.1.2.2 Biology

Productive infection of Ebola viruses begins with the unique entry pathway into cells, which is complex and highly orchestrated requiring the binding of GP1 with adherence factors, including C-type lectins, β1 integrins, and Tyro3 (TAM) family tyrosine kinase receptors, as well as cell receptors, such as T-cell immunoglobulin (Ig) mucin domain-1 and various yet unidentified surface receptors [50]. Upon binding to the receptor, the virus is internalized into endosomes mainly through macropinocytosis, a mechanism that allows the uptake of large particle, where GP1 is cleaved to exposed receptor-binding site by cathepsin L and B and then interacts with endosomal/lysosomal membrane protein Niemann–Pick C1 (NPC1). The GP1/NPC1 interaction is important for *filovirus* entry events, viral escape, which occur in late endosomes and/or in lysosomes. Once the GP1/NPC1 interaction occurs, GP2 initiates viral/cellular membrane fusion via mechanisms similar to other enveloped viruses, releasing the NC into the cytoplasm and allowing the transcription and replication of the virions [51–54].

The newly entered encapsulated RNAs act as template for initial transcription of polyadenylated monocistronic mRNAs in a 3′–5′ direction via a polymerase complex consisting of NP, L, VP35, and nonphosphorylated VP30 proteins, which is critical to initiate transcription. Once initiated, the polymerase complex produces capped and polyadenylated mRNAs (Figure 57.3) [33]. Transcription is regulated by conserved start (RNA secondary structure) and stop signals at the viral gene border. Translation of these mRNAs is managed by cellular translation machinery at cellular ribosomes that leads

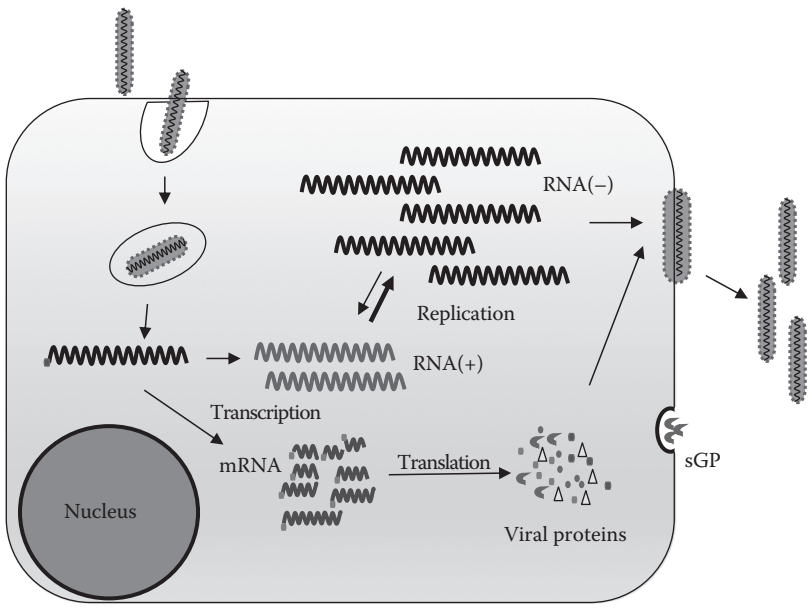

FIGURE 57.3 Life cycle of Ebola virus. Upon binding to the receptor, the virus is internalized into endosomes and release the nucleocapsid into the cytoplasm. The encapsulated RNAs act as template for transcription of mRNAs that were translated by cellular translation machinery and led to viral protein buildup. Phosphorylation of VP30 induces changes in the activity of the polymerase complex, triggering a transition between transcription and replication. In replication mode, copies of the viral genome are synthesized and serve as templates for replication of negative-strand viral RNAs that were assembled at the plasma membrane and bud from the cell surface. (Adapted from Takada, A., *Front. Microbiol.*, 3, 34, 2012.)

to viral protein buildup. Phosphorylation of VP30 by a still unidentified cellular kinase induces changes in the activity of the polymerase complex, triggering a transition between transcription and replication [18]. In replication mode, full-length positive-sense copies of the viral genome are synthesized and serve as templates for replication of negative-strand viral RNA. At the plasma membrane, NP-encapsidated full-length viral RNAs and the other viral structural proteins are assembled with VP40 and GP and incorporated into enveloped virus particles that bud from the cell surface (Figure 57.3) [20,30]. During replication, the phosphorylated VP30 dissociates from the polymerase complex, due to the impaired interaction with VP35 and possibly the viral RNA. The released phosphorylated VP30 remains bound to the NC via a strengthened interaction with NP. If VP30 becomes dephosphorylated by the cellular phosphatases PP1 or PP2A, the nonphosphorylated VP30 is again recruited to the polymerase complex to switch on the transcription mode [33].

57.1.2.3 Epidemiology

The first EHF outbreaks were described in 1976 in two neighboring locations, southern Sudan and northern Zaire (now the Democratic Republic of the Congo, DRC) [8]. The causative agents of these two epidemics were identified as two different strains of Ebola virus, *S.* and *Z. ebolavirus*. A small outbreak caused by *S. ebolavirus* was reported in 1979, and no further outbreak was further reported until 1994, which was followed by annual epidemics from 1995 to 1997, again from 2000 to 2004 and from 2007 to 2008 (Table 57.1). One case of EHF caused by a third strain of Ebola virus, *Taï Forest* (*Côte d'Ivoire*) *ebolavirus*, was reported in 1994. From late 2007 to early 2008, a new strain of Ebola virus, *B. ebolavirus*, was identified as a cause of EHF outbreak in Uganda and a subsequent epidemic in the DRC in 2012. With the current outbreak still raging in Guinea, Liberia, and Sierra Leone, EHF remains epidemic in equatorial Africa and a health threat for African populations [3,7,8].

It is suggested that fruit bats are the natural reservoir of filoviruses based on the successful isolation of Marburg virus from *Rousettus aegyptiacus* [55]. Experimental inoculation of *Z. ebolavirus* in 24 species of plants and 19 species of vertebrates and invertebrates indicated that fruit and insectivorous bats, *Epomophorus wahlbergi*, *Tadarida condylura* and *Tadarida pumila*, support the replication and circulation of high titers of Ebola virus without becoming ill [56]. Further studies detected seroprevalence of Ebola virus–specific IgG in serum from three different bat species, *Hypsignathus monstrosus*, *Epomops franqueti*, and *Myonycteris torquata*, which support the idea that bats are the reservoir for Ebola viruses; however, no viral RNAs were detected in these fruit bats [57,58].

Besides the fact that bats are probable natural reservoir, EHF is known to regularly infect primates living in Africa and the Philippines [59]. Epidemiologic studies show that almost all human EHF outbreaks in Gabon and in the Republic of Congo resulted from introductions of the virus from different infected animal sources, that is, gorilla, chimpanzee, or duiker. These studies also indicated that increased animal mortality always preceded the human outbreak. The index cases (mainly hunters) were all infected when handling dead animals, and subsequent transmission occurred by direct person-to-person contact [59,60]. While *R. ebolavirus* does not cause human illness, highly fatal infections in cynomolgus macaques (*Macaca fascicularis*) have occurred in the United States and Italy between 1990 and 1992 among monkeys imported from the Philippines [61–63]. Until recently, it was not known to infect domesticated animals, *R. ebolavirus* was identified in pigs in the Philippines in 2009 suggesting that *R. ebolavirus* has been circulating possibly before its initial discovery in monkeys that has raised concerns about the potential disease emergence in humans and other livestock animals in the future [14].

EHF is a classic zoonotic disease and is not persistent in the human population. Large outbreaks are caused by person-to-person transmission after the introduction of the virus into humans from a zoonotic reservoir. Human-to-human transmission occurs through direct physical contact with an infected person or contact through body fluids. The most important risk factor was direct repeated contact with a sick person's body fluids, and the risk was higher when the exposure took place during the late stage of the disease. Transmission through heavily contaminated fomites might also be a risk for transmission [64–66]. The examination of the presence of Ebola virus in various body fluids during the acute phase of illness found that Ebola viruses existed in a wide variety of bodily fluids, including saliva, breast milk, semen, stool, and tears [67].

57.1.3 Clinical Features and Pathogenesis

Illness can occur 2–21 days after infection, but most typically within 7–14 days, beginning with a sudden onset of malaise and fever, accompanied by headache, vomiting, and diarrhea. Three to four days after the onset of the initial symptoms, patients typically experienced progressively severe sore throat, abdominal pain, joint/muscle pain, and anorexia/weight loss. Hemorrhagic symptoms, such as internal (mainly the gastrointestinal tract) and subcutaneous bleeding, vomiting of blood, and reddening of the eyes, were experienced by 30%–50% of patients. Some patients also suffered from difficulty in swallowing/breathing, skin rash, red eyes, chest pain, and hiccups. In severe and fatal forms, patients suffered multiorgan dysfunction, including hepatic damage and renal failure, which leads to shock and death [16,68–70].

The characteristics of EHF are immune suppression and a systemic inflammatory response that result in the impairment of the vascular, coagulation, and immune systems that leads to multiple organ failure [8]. EHF generally occurs in resource-limited regions, where little data can be obtained from patients, and most of our current knowledge of pathogenesis comes from the studies in macaques. These studies indicated that the major early targets of Ebola viruses' infection are macrophages and dendritic cells (DCs). Macrophages

initiate antiviral defense by employing innate immune mechanisms resulting the release of proinflammatory cytokines, while DCs initiate adaptive immune response by presenting antigens to naïve T cells. Ebola virus infection partially impairs the functions of both macrophages and DC; however, both cells are still able to initiate an inflammation response that further attracts target cells into the infection site. The systemic spread of viruses occurs via release of newly made virions from infected macrophages and DCs that infect resident macrophages and DCs in tissues, while natural killer cells and T lymphocytes remain uninfected. This causes a further spike in proinflammatory mediators and vasoactive substances and results in multifocal tissue necrosis. The host immune response by macrophages and DC causes disseminated intravascular coagulation (DIC), which is a prominent characteristic of Ebola virus infection. DIC is similar to septic shock caused by endotoxin and other bacterial products and is a syndrome characterized by coagulation abnormalities including systemic intravascular activation of coagulation leading to widespread deposition of fibrin in the circulation, which contributes to the multiple organ failure and high mortality rates characteristic of Ebola virus infections [4,22,71,72].

A few studies have documented the serologic and cytokine profiles of Ebola virus infections that indicated abnormal innate immune response and suppression of adaptive immunity with characteristic low levels of proinflammatory cytokines, high levels of inflammatory cytokines, immunosuppressor, and antigen titers. The study on patients infected with *Z. ebolavirus* serological profiles indicated increased levels of numerous proinflammatory cytokines, such as interleukin (IL)-1β, IL-1RA, IL-6, IL-8, IL-15, IL-16, and TNF-α and chemokines and growth factors, including macrophage inflammatory protein (MIP)-1α, MIP-1β, monocyte chemotactic protein (MCP)-1, macrophage colony-stimulating factor, macrophage migration inhibitory factor, IFN-inducible protein 10, growth-regulated oncogene α, and eotaxin. In addition, very low levels of T lymphocytes' cytokines, that is, IL-2, IL-3, IL-4, IL-5, IL-9, and IL-13, along with significantly decreased CD4 and CD8 peripheral lymphocytes, were found in nonsurviving *Z. ebolavirus*–infected patients [73,74]. Similarly, patients infected with *S. ebolavirus* showed increased levels of IL-1β, IP-10, regulated-on-activation normal T cell expressed and secreted (RANTES), IFN-α, IL-6, IL-8, IL-10, and MIP-1β. It was implicated that higher levels of IL-6, IL-8, IL-10, and MIP-1β were observed in fatal *S. ebolavirus* infection, while surviving patients have higher level of IFN-α [75]. These results suggesting that cytokines produced by macrophages and other infected or activated cells, such as endothelial cells, may play a significant role in the hemorrhage and vascular shock seen in VHFs.

Similar results were obtained in the study of nonhuman primates with Ebola virus infection. Nonhuman primates with the highest antigen titers also had high levels of circulating inflammatory cytokines, such as TNF-α, IFN-γ, IL-2, IL-1β, and IL-6 that can induce vascular permeability changes *in vitro* and have been associated to some degree with vascular shock. In addition, two cytokines, MCP-1 and RANTES, can affect vascular permeability by inducing the release of superoxide radicals, and histamine also appeared to be higher in the same nonhuman primates. RANTES may also affect platelet function through the release of arachidonic acid [76,77]. However, a recent study on serological samples from patients with *B. ebolavirus* infection showed low levels of proinflammatory cytokines, such as IL-1α, IL-1β, IL-6, and TNF-α, as well as high levels of immunosuppressor cytokines like IFN-α2, IFN-γ, and IL-10 and viral antigen titers, which suggested that pathogenesis mechanism of *B. ebolavirus* is different from other *ebolavirus* infection [78].

57.1.4 Diagnosis

Clinical diagnosis of EHF is possible when patients present with severe and acute febrile diseases and with a history of travel to an endemic area if other prominent causes, in areas endemic for Ebola virus, such as malaria, typhoid fever, and shigellosis, can be ruled out. However, differential diagnosis of EHF is still difficult due to the fact that a wide range of causes in area endemic for Ebola viruses can result in similar clinical features. In addition to the aforementioned diseases, patients with meningococcal septicemia, plague, leptospirosis, anthrax, relapsing fever, typhus, murine typhus, yellow fever, Chikungunya fever, and fulminant viral hepatitis can all present similar symptoms [18]. Laboratory diagnosis is needed to confirm Ebola virus infection. Laboratory diagnosis is based on two principles, measurement of host-specific immune response or the presence of viral particles or particle components [8].

Conventional techniques: Due to its highly virulent nature, conventional virus isolation using tissue or organ culture and virus plaque assay are too dangerous for routine detection of the presence of Ebola virus in clinical samples. Virus isolation should only be attempted in high-level containment environment, that is, biosafety level 4 laboratory. Instead, serologic testing, such as antigen capture enzyme-linked immunosorbent assays (ELISA), is the most rapid means for diagnosing infection. The most common antibodies used in ELISA are against GP proteins as they are the antigenic determinants of Ebola virus [79–82]. ELISA using antibodies against NP protein also proved to be sensitive and specific [83–87]. Furthermore, ELISA detecting Ig antibodies, against Ebola virus, and IgM or IgG ELISA can be used to determine the seroprevalence of Ebola virus infection [88–90]. Other conventional techniques, including immunohistochemistry and indirect immunomicroscopy, were also used to identify viral particles in serum and tissue samples [12,63,91–94]

Molecular techniques: Molecular techniques, such as reverse transcription polymerase chain reaction (RT-PCR), nested RT-PCR, real-time RT-PCR, and RT loop-mediated isothermal amplification, were also developed for Ebola virus infection detection. For these molecular assays, L gene seems to be the main target, followed by NP and GP genes (Table 57.2) [63,94–103]. Although these molecular assays

provide higher detection sensitivity, common practice for outbreak investigation is to use both ELISA and RT-PCR to analyze clinical samples to confirm Ebola virus infections.

57.2 METHODS

Ebola virus is known to shed in a wide variety of bodily fluids; thus, various samples can be used for detecting Ebola virus infection, including tissue samples (liver, lung, and spleen), serum, blood, urine, saliva, breast milk, semen, sweat, and tear with serum as the most commonly used specimen. Due to its high infectivity, it is recommended that an inactivation treatment of specimens suspected of Ebola virus infection be applied using gamma irradiation from a cobalt-60 source before performing ELISA or molecular assays [18,67,104].

57.2.1 Sample Preparation

For ELISA, serum samples are used directly [105]. For molecular assays, samples can be purified with commercially available RNA extraction kits, such as Qiagen RNeasy or RNeasy Mini Kits and QIAamp Viral RNA kit [95,97]. Total RNA can also be extracted using the acid guanidine–phenol extraction procedure. Briefly, specimens are homogenized in 5 volumes of 4 M guanidine thiocyanate, 25 mM sodium citrate, 0.5% sodium sarkosyl, 100 mM b-mercaptoethanol, and 200 mM sodium acetate (pH 4.0) and then extracted with equal volume of phenol and 0.3 volume of chloroform–isoamyl alcohol (49:1) by incubating on ice for 20 min. After incubation, samples are centrifuged at 14,000 × *g* for 15 min at 4°C, and the aqueous phase containing RNA can be recovered by isopropanol precipitation and then resuspended in diethyl pyrocarbonate–treated water [98].

57.2.2 Detection Procedures

The two-step RT-PCR methods targeting L gene were developed by Sanchez et al. [63]. The RNA was first transcribed to cDNA in a 30 μL reaction volume containing 10 μL template, 2.5 μL each of primers EBO-GP1 and Filo-A (100 ng/mL, Table 57.2), 1 μL of RNase inhibitor, 1× RT buffer, 1 μM dNTPs, and 2 μL of murine leukemia virus RT, and the reaction was carried out at 42°C for at least 30 min. PCR was then performed in a 100 μL volume containing 15 μL cDNA, 1x PCR buffer, 2 mM $MgCl_2$, 200 mM dNTPs, 3 μL each of primers Filo-A and Filo-B (Table 57.2), and 0.5 U Taq DNA polymerase. The reaction was carried out for 3 cycles at 94°C for 30 s, 37°C for 30 s, and 72°C for 2 min followed by 30 cycles at 94°C for 30 s, 45°C for 30 s, and 72°C for 1 min [63]. This method is modified by Morvan et al. [102] using Filo-A and Filo-B primers (50 ng/μL each) for RT-PCR followed by nested PCR. The RT reaction was carried out in a 20 μL volume at 42°C for 60 min, and the PCR was carried out in a 50 μL volume with 5 μL cDNA for 3 cycles at 94°C for 1 m, 37°C for 30 s, and 74°C for 2 min followed by 35 cycles at 94°C for 1 min, 42°C for 30 s, and 74°C for 2 min. For nested PCR, Gabon subtype-specific primers (GAB-1 and GAB-2) were designed to amplify the L gene; the PCRs were carried out in a 50 μL volume containing 1 μL of RT-PCR product and 100 ng/μL each of primers for initial denaturation at 94°C for 1 min followed by 40 cycles at 94°C for 40 s, 55°C for 40 s, and 72°C for 1 min and then a final extension at 72°C for 2 min [102]. It was further modified by Leroy et al. [97] using 1 mM random hexamer in RT reaction that was carried out at 42°C for 90 min followed by heat inactivation of reverse transcriptase at 65°C for 5 min. PCR was then performed in a 50 μL volume containing 4 μL cDNA, 1× PCR buffer, 0.5 U Taq DNA polymerase, 200 mM each of dNTPs, and 400 nM each of primers 1 and 2 (Table 57.2). The reaction was carried out for 40 cycles at 94°C for 30 s, 55°C for 30 s, and 72°C for 90 s [97].

The RT-LAMP (loop mediated isothermal amplification) reaction by Kurosaki et al. [100] was performed with a Loopamp RNA Amplification Kit (Eiken Chemical Co. Ltd., Tokyo, Japan) in a 25 μL reaction mixture containing 1.6 μM each of primers FIP and BIP and 200 nM each of the outer primers F3 and B3 (Table 57.2) and 2.0 μL of RNA sample, and the reaction was incubated at 63°C for 60 min and then heated at 80°C for 2 min to terminate the reaction. For real-time RT-LAMP, the reaction mixtures were observed by spectrophotometric analysis using a real-time turbidimeter (LA-200, Teramecs, Kyoto, Japan). The time of positivity observed through real-time RT-LAMP assay was determined as the time at which the turbidity reached the threshold value fixed at 0.1, which doubles the average turbidity value of negative controls of several replicates [100].

RT-PCR for GP gene was developed by Sanchez et al. [63] using same PCR conditions as L gene with EBO-GP1 and EBO-GP2 primers (Table 57.2). This method is modified by Morvan et al. [102] using EBO-1 and EBO-2 primers at 100 ng/μL each for RT-PCR followed by nested PCR. The RT-PCR was carried out in a 100 μL volume at 41°C for 60 min and 94°C for 1 min followed by 40 cycles at 94°C for 40 s, 38°C for 40 s, and 74°C for 1 min with a final extension at 74°C for 2 min. For nested PCR, the PCRs were carried out in a 10 μL volume containing 3 μL of RT-PCR product and 100 ng/μL each of EBO-3 and EBO-4 primers (Table 57.2) for initial denaturation at 94°C for 1 min followed by 40 cycles at 94°C for 40 s, 43°C for 40 s, and 72°C for 1 min and then a final extension at 72°C for 2 min [102]. Rodriguez et al. [98] also developed a one-step RT-PCR using primers GPZA1201F and GPZAI1485R (Table 57.2) with cycling condition at 50°C for 30 min followed by 35 cycles at 94°C for 15 s and at 50°C for 60 s with a final extension at 60°C for 10 min. The real-time RT-PCR for GP genes was developed by Gibb et al. [103] using TaqMan EZ RT-PCR Kit (Life Technologies, New York, United States) with 0.5 μM each of EBOGP-1DF and EBOGP-1DR primers and 0.2 μM each of EBOGP-1DS and EBOGP-1DZ probes. The PCR was performed in a 50 μL reaction volume with cycling condition at 55°C for 45 min and 94°C for 1 min followed by 40 cycles at 94°C for 15 s and 60°C for 30 s [103].

A one-step RT-PCR for NP gene was developed by Sanchez et al. [63] using EZ rTth RNA PCR Kit (Roche, Indianapolis, IN) with RES-NP1 and RES-NP2 or ZAI-NP1 and ZAI-NP2 (Table 57.2) in a 50 μL reaction volume with 1–5 μL RNA template. The reaction was carried at 50°C for 30 min, followed by 35 cycles at 94°C for 15 s and 50°C for 30 s [63]. Nested PCR followed by RT-PCR for NP gene was developed by Towner et al. [101] using Access RT-PCR kits (Promega, Madison, WI) and 5 μL of RNA for RT-PCR in a 50 μL reaction volume containing SudZaiNP1(+) and SudZaiNP1(−) primers (Table 57.2). The reaction was carried out at 50°C for 30 min and 94°C for 2 min, followed by 38 cycles at 94°C for 30 s, 50°C for 30 s, and 68°C for 1 min. Nested PCR was performed using SudZaiNP2(+) and SudZaiNP2(−) primers (Table 57.2) with 38 cycles at 94°C for 30 s, 50°C for 30 s, and 72°C for 1 min [101]. In addition, Towner et al. [101] also developed a real-time RT-PCR assay for NP gene. The RNA was first transcribed to cDNA in a 10 μL RT reaction volume with 1 μM forward-1 primer (Table 58.2) and 1 μL RNA. The reaction was carried out at 55°C for 10 min, followed by heat inactivation at 95°C for 30 min. The real-time PCRs were performed in a 25 μL volume containing 5 μL of cDNA, 1× TaqMan Universal Master Mix (Life Technologies, New York), 1 μM each of forward-1 and reverse-1 primers, 200 nM of fluorogenic probe. The reaction was carried out at 50°C for 2 min and 95°C for 10 min, followed by 40 cycles at 95°C for 15 s and 60°C for 1 min [101]. The same group revised the real-time RT-PCR assay in 2007 using random hexamer to transcribe RNA into cDNA and then using cDNA in 50 μL PCR with 900 nM each of forward-2 and reverse-2 primers and 200 nM TaqMan probe (Table 57.2) utilizing the same PCR cycling conditions [94].

57.3 CONCLUSION AND FUTURE PERSPECTIVE

Ebola viruses represent a serious health threat to human and animal populations, and the historic frequency of outbreaks along with the increasing size of outbreaks suggests that the threat will only become greater in the future. The continuing

growth of human populations encroaching on wildlife habitats where bats (potential natural reservoir) and transmission vector animals, that is, primates, live ensures that the risks will increase. While only the *R. ebolavirus*, which so far has not proven fatal in humans, has been shown to have been transmitted to domesticated animals, such as pigs, this raises concern that a more lethal strain might make the same transition or that the *R. ebolavirus* might mutate in the domesticated animals to a more lethal version. This represents a serious concern as it would greatly increase the contact points and transmission vectors for the disease.

Detection methods for these viruses are unlikely to undergo modification unless a serious weakness is observed with the current tests. This has less to do with whether new methods might prove beneficial or not and more to do with the serious risks involved in handling the live pathogen. The risk is too great to warrant the testing required to validate new methods unless the payoff for the work is great enough.

The future research efforts on treatment and prevention of Ebola virus infection will be not only important, but also profitable. The identification of the proteins involved in the entry and initial transcription presents the possibility of study for chemicals that will interfere with one or the other mechanism. The recognition that many of the most severe consequences of the disease are due to runaway or over responses of the host immune system also presents many avenues of research for methods to mitigate this response and increase the survivability of the disease once it occurs.

58.1 INTRODUCTION

Marburg virus (MARV) is the causal agent of MARV disease (MVD) (formerly known as Marburg hemorrhagic fever) in human and nonhuman primates, which was first identified in 1967 during epidemics in Marburg and Frankfurt in Germany and Belgrade in the former Yugoslavia from importation of infected monkeys from Uganda [1,2]. Similar to the Ebola virus (EBOV) disease, MVD is a severe and highly fatal disease. Both MARV and EBOV are among the most virulent pathogens known to infect humans. Both diseases are rare, but have a capacity to cause dramatic outbreaks with high fatality. Despite significant progress in drug development for MVD [3], there are no approved vaccines or postexposure treatment drugs available yet. The predominant treatment is general supportive therapy.

MARV is transmitted by direct contact with blood, body fluids, and tissues of infected persons. Transmission of MARV may also occur by handling ill or dead infected wild animals (monkeys, fruit bats, etc.). Due to the fact that a number of viruses, such as Lassa virus, Hantavirus, and Yellow fever virus, could cause fever and bleeding disorders similar to MVD, laboratory diagnosis is absolutely necessary to identify MARV infections.

58.1.1 Classification

MARV belongs to the *Filoviridae* family. The genus *Marburgvirus* contains one species, *Marburg Marburgvirus*, formerly referred to as Lake Victoria marburgvirus [2,4,5], which has two lineages: Ravn virus (RAVV) (including isolates from 1987 outbreak, one isolate from the Democratic Republic of the Congo [DRC] outbreak in 1998–2000, and one human and several bat isolates from infections that took place in Uganda in 2007) and MARV (other isolates) [6]. Phylogenetic analysis of genomic sequence data divides the known members of the species into at least five different lineages, four of which are very close with the nucleotide sequences difference within 7%, while the fifth has a divergency of up to 21% [7–9].

58.1.2 Morphology, Biology, and Epidemiology

58.1.2.1 Morphology

Filoviruses have the shape of filament, so early electron microscopy (EM) of blood and tissues proposed that the causative agent of the disease might be related to rhabdoviruses or

spiral-shaped bacterium *Leptospira*, both of which resemble filoviruses to some extent [8,10]. Later, the distinct nature of filoviruses was recognized and the pathogen was identified as the newly discovered MARV [10]. Marburg virions are pleomorphic, with the appearance of rod- or ring-like, crook- or six-shaped, or branched structures [10]. Cryo-EM showed the morphological forms of purified MARV released from infected Vero cells: filamentous 30%, six-shaped 37%, and round 33% [11]. The MRAV filamentous particles have a mean length of 892 nm and a mean diameter of 91 nm, both of which are longer than the conventional EM (diameter 80 nm and length 795–828 nm [10,12,13]), ascribing to the less compression and shrinkage effects of cryo-EM [11]. MARV virions are similar to EBOV, since both belong to *Filoviridae*. However, although MARV genomes are slightly longer than EBOV genomes, morphologically MARV virions are apparently shorter than EBOV virions (EBOV with a length of around 1000 nm) [10].

58.1.2.2 Biology

Like EBOV, MARV is a single-stranded nonsegmented negative-sense (NNS) RNA virus. The genome of MARV is about 19.1 kb in size, containing seven genes in a linear order of *NP-VP35-VP40-GP-VP30-VP24-L* (Figure 58.1) [10,14]. Each MARV viral gene possesses a highly conserved transcription initiation site, a transcription termination site, an unusually long 3′ and 5′ untranslated regions, and an open reading frame [8,14]. Most of the genes are separated by short intergenic regions of 4–9 nucleotides (nts). There is only one long intergenic region of 97 nts located between the glycoprotein (GP) and the viral protein (VP) 30 gene. The transcription stop site of the *VP30* gene and the transcription start site of the *VP24* gene overlap, sharing a highly conserved sequence of 5 nts [15]. Gene overlap is found among all filoviruses and is unique among members of the order *Mononegavirales* (Figure 58.1) [15].

MARV particles are composed of seven structural proteins, five of which, nucleoprotein (NP), VP35 and VP40, GP, and RNA-dependent RNA polymerase (L), are counterparts of proteins found in all NNS RNA viruses [8]. The GP, the only surface protein, has the structural features of a type I transmembrane GP, mediating receptor binding and fusion during virus entry [16,17]. The nucleocapsid is surrounded by a layer of matrix protein VP40, which plays a key role in the budding of viral particles. The VP24, which is unique to the *Filoviridae* family, is a minor matrix protein, with a structural similarity to the NP and involvement in nucleocapsid formation and assembly. The four remaining proteins, NP, VP35, VP30, and L, associated with the viral RNA genome, form the MARV nucleocapsid [8,15]. The NP is not only a major structural component of the nucleocapsid but also playing a key role in viral replication and transcription. The VP35 can mask doubled-stranded RNA (dsRNA) to counter innate immunity through binding to dsRNA [18,19]. Once the nucleocapsid is released into the cytoplasm of infected cell, transcription and replication of the viral RNA genome start [8]. Replication of MARV begins with the synthesis of a positive-sense reverse complement of the genome, the antigenome. The antigenome, in turn, serves as a template for the synthesis of new genomes. The minimal protein requirement for replication is NP, VP35, and L. During transcription, the NNS genome is transcribed into seven monocistronic mRNA species. These mRNAs are capped and polyadenylated by the viral RNA-dependent RNA polymerase. NP, VP35, and L are sufficient to support the transcription of MARV minigenomes [8,15].

58.1.2.3 Epidemiology

MARV first emerged in August 1967 in Marburg and Frankfurt in Germany and Belgrade in Yugoslavia (now Serbia) among laboratory workers who handled African green monkeys (*Chlorocebus aethiops*) imported from Uganda. There were

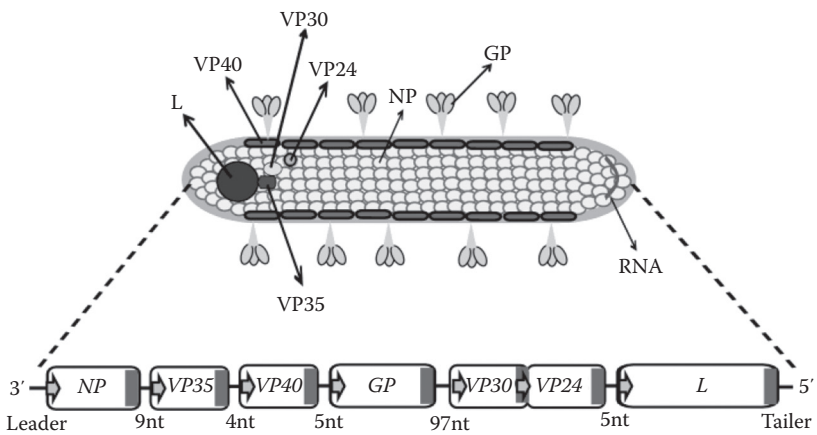

FIGURE 58.1 Marburg virus structure and genome organization. Top portion, schematic of Marburg virion. The RNA genome is encapsidated by nucleoprotein, viral protein (VP) 35, VP30, and L. VP40 and VP24 are matrix proteins. Glycoprotein trimers are inserted into the viral membrane. Bottom portion, structure of the MARV genome with transcription signals. The genes are illustrated as boxes and nontranscribed regions as black lines (leader, tailer, and intergenic regions). Transcription start signals are described as light gray arrows and stop signals as dark bars. A gene overlap appears between *VP30* and *VP24*. The lengths of the intergenic regions are shown in Table 58.1.

31 MVD cases (25 primary, 6 secondary infections) and 7 deaths. After 3 months, the unknown deadly infectious agent was isolated, characterized, and identified as MARV [1,20]. MVD had not been heard of for 8 years. In 1975, a young Australian who had traveled throughout Zimbabwe died in Johannesburg in South Africa [21]. The infection spread to his traveling companion and later also to a nurse. The latter two infected persons recovered and MARV was determined as the infectious agent [21]. During the period of 1975–1985, only sporadic outbreaks that affected small numbers of individuals were noted (Table 58.1). As the fatality rates of MVD were lower than those seen in the devastating outbreaks of EBOV (up to 90%), MARV had been thought to be less threatening until the outbreaks in the DRC in 1998–2000 and then in Angola in 2004–2005. A total number of 406 cases and the high fatality rates (83% in DRC and 90% in Angola) revealed that MARV is as threatening as EBOV [7,22].

MARV is a risk for travelers to sub-Saharan Africa, who, with their return home, may increase the chance of importing and spreading MVD to other countries. This is reflected by the two recent cases in 2008 of a Dutch and an American tourist who both presumably got infected during a visit to the Python Cave in Uganda (Table 58.1). In the nearby Kitaka mine in the Kamwenge District of Uganda, a gold mining activity resulted in four cases of MARV infection in June–September 2007 [23]. In the two more recent outbreaks in 2012 and 2014, while no epidemiologic data were available, sequence analysis of viral genomes in 2012 showed high similarity (~99.3%) to MARV isolates from *Rousettus aegyptiacus* bats [24]. So far, no genome information was obtained from the case confirmed on October 5, 2014. In addition, two laboratory infections have been reported and one of which had a fatal outcome [10,25]. Work with MARV is restricted to high-containment biosafety level 4 (BSL-4) laboratories owing to the lack of an approved vaccine or treatment, the high infectivity and fatality, and the potential of aerosol transmission [26]. Since MARV poses a severe threat to public health and safety, it has been classified as Select Agent by the Centers for Disease Control and Prevention, as Risk Group 4 Agent by the World Health Organization, and as Category A Priority Pathogen by the National Institute of Allergy and Infectious Diseases (Table 58.1).

58.1.3 Transmission, Clinical Features, and Pathogenesis

58.1.3.1 Transmission

Primary MARV infections are essentially acquired via exposure to an infected animal, either a reservoir host (several bat species) or a spillover host such as nonhuman primates. African green monkeys (*Cercopithecus aethiops*) imported from Uganda were the source of infection for humans during the first Marburg outbreak. Experimental inoculations in pigs with different EBOVs have showed that pigs are susceptible to filovirus infection and shed the virus. Therefore, pigs should be considered as a potential amplifier host during MVD outbreaks.

After transmission to humans, MARV can spread between individuals through direct contact with blood or other body fluids (e.g., saliva, tears, semen, sweat, urine, faces, and breast milk) from infected patients. Typical risks of exposure include administration of medical care to infected individuals as well as handling of corpses without the use of proper protection [31]. MARV disappears from blood and most tissues after the acute stage of the disease. However, it may persist for some time in certain anatomic sites, such as the testes or the anterior chamber of the eye [32].

58.1.3.2 Clinical Features

Much of what we know about MVD clinical data was obtained from the three main outbreaks: the first outbreak in 1967, the 1998–2000 DRC outbreak, and the 2004–2005 Angola outbreak. The incubation period in humans ranges from 2 to 21 days (with an average of 5–9 days) [8,33]. MVD course is divided largely into three distinct phases: a generalization phase (days 1–4), an early organ phase (days 5–13), and a late organ or convalescence phase (day 13 onward), depending on the outcome of infection [8]. The generalization phase starts abruptly with influenza-like symptoms including high fever (~40°C), severe headache, chills, myalgia, and malaise. Severe watery diarrhea, abdominal pain and cramping, rashes on face, nausea, and vomiting are also symptoms in this phase [32]. In the early organ phase, patients may have the symptoms of prostration, dyspnea, exanthema, and abnormal vascular permeability (including conjunctival injection and edema). Severe hemorrhagic manifestations appear in the later part of the early organ phase, such as petechiae, mucosal bleeding, uncontrolled leakage from venipuncture sites, visceral hemorrhagic effusions, melena, bloody diarrhea, hematemesis, and ecchymoses [33]. In fatal cases, death occurs most often between 8 and 9 days after symptom onset, usually preceded by severe blood loss and shock. In the late organ phase, the patients get into a critical state showing convulsions, severe metabolic disturbances, diffuse coagulopathy, multiorgan failure, and shock. Survivors do not normally have severe hemorrhagic manifestations and may not even reach the late organ phase [33].

58.1.3.3 Pathogenesis

The pathogenesis of MARV infections in humans is poorly understood. Several animal models have been developed for MARV infections using nonhuman primates and rodents, such as cynomolgus macaques and guinea pigs, which have contributed to understanding the pathogenesis of MVD [34]. MARV initially targets monocytes, macrophages, and dendritic cells in the lymphoid tissues as well as Kupffer cells and cells lining the sinusoids in the liver, progresses to infection of parenchymal cells in the liver and adrenal gland and high endothelial venules in lymphoid tissues, and finally spreads to endothelial cells in a variety of tissues [35]. The virus or viral antigen is detected in the liver, lymph nodes, spleen, adrenal grand, kidney, and blood in infected cynomolgus macaques [35]. Under experimental conditions, aerosol transmission of MARV is possible in macaque models, although such a transmission route has not been described in human outbreaks [36].

TABLE 58.1
Known Cases and Outbreaks of Marburg Virus Disease (in Chronological Order)

Year(s)	City/Country	Apparent or Suspected Origin/Mode of Infection	Reported Number (%) of Deaths among Cases	Isolate Designation (Abbreviation)	Reference
1967	Marburg and Frankfurt in Germany; Belgrade in Yugoslavia (now Serbia)	Uganda/handling of infected African green monkey tissues	7/31 (23%)	MARV Ci67, Flak (MARV Flak), Hartz (MARV Hartz), MARV "L," Porton (MARV Porton), Poppinga (MARV Pop), Ratayczak (MARV Rat), Voege (MARV Voe)	[20]
1975	Johannesburg in South Africa	Zimbabwe/unknown–most likely: sleeping in rooms inhabited by bats or visit to Sinoia caves (now Chinhoyi caves)	1/3 (33%)	Cruikshank (MARV Cru), Hogan (MARV Hogan), Ozolin (MARV Ozo)	[21]
1980	Nairobi in Kenya	Kenya/working close to Kitum Cave, Mount Elgon National Park	1/2 (50%)	Musoke (MARV Mus)	[27]
1987	Nairobi in Kenya	Kenya/visit to Kitum Cave/Mount Elgon National Park	1/1 (100%)	Ravn (RAVV Ravn), R1 (RAVV R1)	[28]
1988	Koltsovo in Soviet Union (now Russia)	Soviet Union (now Russia)/laboratory infection: needlestick injury	1/1 (100%)	"Variant U" (MARV "U")	[10]
1990	Koltsovo in Soviet Union (now Russia)	Soviet Union (now Russia)/laboratory infection: unspecified violation of safety requirements	1/1 (100%)	—	[25]
1998–2000	Durba, Watsa in Democratic Republic of Congo	Durba, DRC/gold mining in Goroumbwa cave	128/154 (83%)	MARV 01DRC99, MARV 02DRC99, MARV 03DRC99, MARV 04DRC99, MARV 05DRC99, MARV 06DRC99, MARV 08DRC, MARV 10DRC99, MARV 11DRC99, MARV 12DRC00, MARV 13DRC00, MARV 14DRC00, MARV15 DRC00, MARV 16DRC00, MARV17 DRC00, MARV 18DRC00, MARV 19DRC00, MARV 20DRC00, MARV 21DRC00, MARV 22DRC00, MARV 22DRC00, MARV 23DRC00, MARV 24DRC00, MARV 25DRC00, MARV 26DRC00, MARV 27DRC00, MARV 28DRC00, MARV 29DRC00, MARV 30DRC00, MARV 31DRC00, MARV 32DRC00, MARV 33DRC00, MARV 34DRC00, MARV DRC 5/99 Aru, MARV DRC 5/99 Dra, RAVV 09DRC99	[22]
2004–2005	Uíge Province, Angola	Uíge Province, Angola/unknown	227/252 (90%)	MARV Angola	[7]
2007	Kamwenge, Uganda	Lead and gold mine in Kamwenge District, Uganda/gold mining in Kitaka Cave	1/4 (25%)	MARV-01Uga 2007, RAVV-02Uga 2007	[23]

58.1.4 Diagnosis

Diagnostic tests for MARV need to have desired sensitivity, specificity, and reliability because any misdiagnosis will create havoc to the society. Therefore, MVD diagnosis should not rely on a single diagnostic method alone. Many of the signs and symptoms of MVD are similar to those of other more frequent infectious diseases, such as malaria or typhoid fever, making diagnosis of MVD difficult. This is especially true if only a single case is involved. However, if a person has the early symptoms of MVD and there is reason to suspect that MVD should be considered, the patient should be isolated and public health professionals notified. Samples from the patient can then be collected and tested to confirm infection. A BSL-3 laboratory with class II biosafety cabinet should be used to process clinical specimens and detect MARV, which general hospitals and health departments usually do not have. Therefore, clinical assessment is critical for initial diagnosis of a MARV infection.

MARV infections can be diagnosed definitively only in laboratories, by a number of different tests:

- Enzyme-linked immunosorbent assay (ELISA), IgM, and antigen detection
- Serum neutralization test
- Reverse transcription polymerase chain reaction (RT-PCR) assay
- Virus isolation by cell culture

Samples from suspected MVD patients should be handled minimally and with the utmost caution.

58.1.4.1 Conventional Techniques

Conventional diagnostic techniques include virus isolation, [37,38] followed by EM [13,39], serum neutralization test, and immunohistochemistry (IHC) [40].

Virus isolation and EM play pivotal roles to identify and diagnose MVD in the early years [41]. MARV grows well in cell lines MA-104, Vero E6, Vero 76, Hela-229, SW-1, and DBS-FRhL-2. Cell Vero E6 is used commonly for MARV isolation. However, the virus isolation can be laborious, time consuming, and costly, because high-level containment is warranted and a BSL-4 laboratory is required owning to the extreme hazard associated with handling this virus [37,42]. EM-based techniques can reveal the virions visually and have played a critical role in the discovery and recognition of MARV in 1967 [43]. As a simple and fast method, EM has proven valuable to assist MARV detection and provide insight into the pathogenesis of the agent. However, EM-based MARV diagnostic methods demand sophisticated instruments and require high virus titers (10^5–10^6/mL). Furthermore, some viruses with similar morphologies might complicate the EM observation.

After mixing a testing serum sample with neutralization antibodies specific to MARV, the neutralization test could be used to verify if the serum could stop the sample from causing cytopathic effects to Vero cells. If neutralization happens, it will confirm the presence of MARV in the sample. Similar to virus isolation, a BSL-4 laboratory is required for the serum neutralization test.

IHC is used to detect MARV in formalin-fixed biopsy/autopsy materials. An antibody specific to MARV is used to react with MARV first. Then an enzyme or fluorescent-labeled second antibody is used to react with the antibody attached to the MARV virions. Finally, the fluorescence or the signal generated by the enzyme is measured to test MARV. The significant advantage of IHC is that no need of high-level biocontainment is required during the test [40,44], but IHC usually needs experienced personnel to interpret the results.

58.1.4.2 Molecular Techniques

Molecular diagnostic methods for MARV mainly fall into two types: RT-PCR and ELISA.

As an important and widely used molecular method for detecting virus, RT-PCR has become increasingly popular, due to its speed, simplicity, sensitivity, and high-throughput capacity. MARV nucleic acid can be detected in the blood from day 3 up to 7–16 days after the onset of symptoms. RT-PCR is proven effective for detecting MARV RNA in body fluids and tissues of infected individuals and is capable of generating results in less than 2 h [44]. As summarized in Table 58.2, many nucleic acid amplification techniques, such as conventional RT-PCR [45,46], quantitative real-time RT-PCR (qRT-PCR) [46–54], and RT loop-mediated isothermal amplification methods (RT-LAMPs) as well as RT isothermal recombinase polymerase amplification assays (RT-RPAs) [55,56], have been developed for the detection of MARV RNA in clinical specimens. The fact that MARV is inactivated by a chaotropic agent guanidinium isothiocyanate, a common commercial component in RNA extraction buffers, facilitates safe handling of clinical materials [57]. In recent years, further improvements have been made on PCR-based techniques for MARV detection. Ogawa et al. [45] reported pan-MARV or pan-filovirus RT-PCR assays to detect all known MARV strains or even all known filovirus species using consensus PCR primer sets specific for the viral NP gene. Kurosaki et al. [55] described an RT-LAMP technique to effectively detect MARV, which is suitable for use as field diagnostics and is highly applicable to areas where MARV is endemic. Euler et al. [56] designed a panel of very rapid and highly sensitive isothermal real-time RPAs for the detection of category A bioterrorism agents including MARV and EBOV. This syndromic panel has the potential to be implemented onto microfluidic platforms (Table 58.2).

ELISA-based methods consist of two main varieties: antigen detection and antibody detection [37]. In deadly MARV infections with high mortality, patients usually die before specific antibody response is mounted. Fatal infections of MARV often end with high viremia and no evidence of an immune response. The presence of high titers of infectious MARV in the blood and tissues of patients at the early stage of illness suggests the appropriateness of antigen detection for diagnosis of the illness at this stage. Either hyperimmune serum or

virus protein-specific (e.g., NP) antibodies can be utilized to capture MARV antigen [37]. Generation of monoclonal antibodies to MARV protein (e.g., NP, GP) by immunizing mice or rabbits with native or recombinant proteins has increased the utility of antigen detection ELISA for diagnosis of MVD [58–61].

On the other hand, the host immune response can be effectively evaluated by using antibody detection ELISA. This method is particularly suitable for the diagnosis of MVD in patients who survive but not in those who succumb to the infection, given the high fatality and weak antibody response at an early stage of MVD. Direct IgM and IgG ELISAs, as well as IgM-capture ELISAs, are commonly used for the detection of virus-specific antibodies. MARV-specific IgM antibodies can appear as early as 2 days post-onset of symptoms and disappear from 30 to 168 days after infection, while IgG antibodies can persist for many years [33]. Accordingly, IgM-capture ELISAs are more frequently used for the diagnosis of acute illness, while IgG ELISAs are primarily used to identify individuals who have recovered from MARV infection or for conducting epidemiological (serosurveys) and epizoological studies. Since manipulation of live MARV is limited to a BSL-4, usually recombinant proteins of MARV are used as antigens to capture or detect the MARV antibodies. The usefulness of recombinant MARV proteins for detecting specific antibodies in IgG- and IgM-ELISAs has been confirmed. The carboxy-terminal half of MARV NP (341–695 amino acid residues), expressed as glutathione S-transferase-tagged recombinant proteins in an *Escherichia coli* system, was used to develop highly efficient and specific IgG-ELISA for MARV antibody detection [62]. His-tagged secreted form of MARV GP was also used as antigens for the detection of MARV-specific antibodies. The GP-based ELISA was evaluated by testing antisera collected from mice immunized with viruslike particles as well as from humans and nonhuman primates infected with MARV [63]. This GP-based ELISA allows detection of MARV-specific IgM antibodies in specimens collected from patients during the acute phase of infection, indicating its value for diagnosis as well as ecological and serosurvey studies [64]. Recently, a protein microarray comprised of NP, GP, and VP40 from all Ebola and MARV species was developed for detection of filovirus antibodies in sera. It not only permits detection of IgG responses to specific filovirus antigens resulting from vaccination or viral challenge but also provides a useful approach to measure the relative levels of other antibody isotypes (IgM) [65].

58.2 METHODS

58.2.1 Sample Collection and Preparation [47,48]

As blood and tissues from patients at the early stage of illness contain high titers of MARV particles, they represent an ideal source of specimen for MVD diagnosis. However, other specimens such as saliva (oral swab) and urine (less reliable), as well as breast milk, may serve as alternative source materials if blood is not available. Suspected MARV blood samples are collected with personal protective equipment (PPE), including surgical mask (N95), cap, goggles, gown or apron,

and two pairs of gloves and boots. Blood is collected using vacuumed blood tubes with clot activator and polymer gel for serum separation (3 mL in each tube). Then, the tubes are sealed by parafilm and put inside a plastic bag or a centrifuge tube to seal again. The surfaces of the tubes and the bags are disinfected with 1% hypochlorite solution before shipping to a laboratory for MARV detection.

Infectious specimens should be handled in the field laboratory by personnel wearing Tyvek suits and high-efficiency particulate arrestance (HEPA) filter-equipped air-purifying respirators in a class II biosafety cabinet inside a BSL-3 or BSL-4 laboratory.

58.2.2 Detection Procedures

RT-PCR and ELISA have been widely applied for rapid and sensitive detection of MARV. The conserved fragments of the NP, GP, L, or VP40 genes can be targeted for RT-PCR and antibodies to recombinant NP or GP can be used for ELISA. Two real-time RT-PCR-based methods (one-step and TaqMan™ real-time RT-PCR methods) and an antigen detection ELISA method are presented in the succeeding text.

58.2.2.1 RNA Extraction

Before RT-PCR, MARV RNA extraction should be completed in a BSL-3 laboratory with a class II biosafety cabinet. QIAamp Viral RNA Mini Kit is used for MARV RNA extraction from serum samples. (If other RNA extraction kits are used, please refer to the corresponding protocols.)

1. Pipette 560 μL of the Buffer AVL (to inactivate RNases and lyse viruses in the samples) into a 1.5 mL microcentrifuge tube.
2. Add 140 μL of serum to the aforementioned tube with Buffer AVL. Mix by pulse vortexing for 15 s.
3. Incubate at room temperature (15°C–25°C) for 10 min.
4. Briefly centrifuge the tube to remove drops from the inside of the lid.
5. Add 560 μL of ethanol (96%–100%) to the sample, and mix by pulse vortexing for 15 s. After mixing, briefly centrifuge the tube.
6. Carefully apply 630 μL of the solution from step 3 to the QIAamp Mini column (in a 2 mL collection tube) without wetting the rim. Close the cap, and centrifuge at 6000 × *g* (8000 rpm) for 1 min. Place the QIAamp Mini column into a clean 2 mL collection tube, and discard the tube containing the filtrate.
7. Carefully open the QIAamp Mini column, and repeat step 6.
8. Carefully open the QIAamp Mini column, and add 500 μL of Buffer AW1. Close the cap, and centrifuge at 6000 × *g* (8000 rpm) for 1 min. Place the QIAamp Mini column in a clean 2 mL collection tube (provided), and discard the tube containing the filtrate.
9. Carefully open the QIAamp Mini column, and add 500 μL of Buffer AW2. Close the cap and centrifuge at full speed (20,000 × *g*; 14,000 rpm) for 3 min. Continue directly to step 11 or to eliminate any chance of possible Buffer AW2 carryover, perform step 10, and then continue to step 11.
10. Recommended: Place the QIAamp Mini column in a new 2 mL collection tube (not provided), and discard the old collection tube with the filtrate. Centrifuge at full speed for 1 min.
11. Place the QIAamp Mini column in a clean 1.5 mL microcentrifuge tube (not provided). Discard the old collection tube containing the filtrate. Carefully open the QIAamp Mini column and add 60 μL of Buffer AVE equilibrated to room temperature. Close the cap, and incubate at room temperature for 1 min. Centrifuge at 6000 × *g* (8000 rpm) for 1 min.

The extracts are resuspended in 60 μL of AVE buffer, aliquoted, and stored at −70°C before RT-PCR amplification is carried out. All work should be performed with PPE as outlined earlier. All waste materials should be treated with disinfectant (e.g., 1% hypochlorite solution) for at least 10 min and incinerated on the same day.

58.2.2.2 One-Step Real-Time RT-PCR

Please refer to Table 58.2 for the primers and probes used for MARV real-time RT-PCR detection. The following procedure for one-step real-time RT-PCR has been described by previous reports [47,48]. SuperScript® III One-Step RT-PCR System with Platinum® Taq DNA Polymerase (Life Technologies, Karlsruhe, Germany) is used in SYBR Green Real-Time RT-PCR assays.

58.2.2.2.1 Procedure

1. Add the following to a 0.2 mL, nuclease-free, thin-walled PCR tube on ice. For multiple reactions, prepare a master mix to minimize reagent loss and enable accurate pipetting: 12.5 μL of 2× reaction mix provided with the kit (including 0.4 mM of each deoxy-ribonucleoside triphosphate (dNTP), 3.2 mM $MgSO_4$), 0.5 μL of 10 μM each primer, 2 μL of RNA, 1 μL of SuperScript® III RT/Platinum® Taq Mix, 1 μL of SYBR Green stock solution (Roche Molecular Biochemicals, Mannheim, Germany) diluted 1:5000 in dimethyl sulfoxide, and RNase-free water to 25 μL total volume.
2. Gently mix and make sure that all the components are at the bottom of the amplification tube. Centrifuge briefly if needed. Depending on the thermal cycler used, overlay with silicone oil if necessary.
3. RT-PCR detection involved the following steps: RT at 50°C for 20 min; initial denaturation at 94°C for 2 min; 40 cycles with 94°C for 15 s (denature), 60°C for 30 s (anneal), and 68°C for 1 min; and final extension of 68°C for 5 min. Collect the data and analyze the results.
4. Since SYBR Green intercalates nonspecifically into PCR products, a melting curve analysis is performed following PCR to identify the correct

amplification products by its specific melting temperature. Melting curve analysis included the following steps: 95°C for 5 s and 65°C for 15 s, with heating temperature of 95°C at a rate of 0.1°C/s with continuous reading of fluorescence. Samples were considered positive if they produced melting point–confirmed amplification products in two assays. Amplification products were later confirmed by sequencing.

Note: Negative control is concurrently included along with the test samples in order to monitor any possible contamination that might be occurred during the PCR procedure. The presence of a corresponding product is indicative of positive serum. All work should be performed with PPE as outlined earlier. All waste materials should be treated with disinfectant (1% hypochlorite solution suggested) for at least 10 min and incinerated on the same day.

58.2.2.3 TaqMan™ Real-Time RT-PCR

The primers and probes used for MARV real-time RT-PCR detection are shown in Table 58.2. The following procedure for one-step real-time RT-PCR has been reported previously [51,53,54]. One-step TaqMan™ real-time qRT-PCR is performed using AgPath-ID™ One-Step RT-PCR Kit (Applied Biosystems) according to the manufacturer's instructions. (If other RT-PCR kits are used, please refer to the corresponding protocols.)

58.2.2.3.1 Procedure

1. Remove all aliquots of PCR reagents (diethylpyrocarbonate [DEPC]-treated water, 5× Colorless GoTaq PCR buffer, 2.5 mM dNTP mix, primers, and GoTaq DNA polymerase) from the freezer. Vortex and spin down all reagents before opening the tubes.
2. Prepare the RT-PCR reaction mix as follows: 12.5 μL of 2 × RT-PCR buffer, 1 μL of 10 μM each primer, 1 μL 3 μM TaqMan™ probe, 5 μL of RNA, 1 μL of enzyme mix, and RNase-free water to 25 μL total volume.
3. Real-time RT-PCR cycling is performed on Bio-Rad CFX96 or ABI7500 system as follows: 50°C for 30 min, 95°C for 10 min, and then 40 cycles of 15 s at 95°C and 45 s at 60°C.

The threshold cycle (CT) value for a positive sample is adjustable according to a liner range of a typical standard curve for each virus detection assay, which was also a strict standard for positive determination. Negative control should be set along with the test samples in order to monitor any possible contamination that might occur during the test.

58.2.2.4 Antigen Detection ELISA

MARV NP and GP have been tested as the antigens to detect MARV in plasma or serum samples by ELISA. The following procedure is based on that described by previous reports [38,61].

58.2.2.4.1 Procedure

1. Before detection, inactivate the MARV samples at 60°C for 1 h in a BSL-3 laboratory with class II biosafety cabinet, and leave the samples on ice.
2. Coat the purified monoclonal antibody onto microwell immunoplates at >100 ng/well in 100 μL of phosphate-buffered saline solution (PBS) at 4°C overnight, followed by blocking with PBS containing 0.05% Tween-20 and 5% nonfat milk (PBST-M) for 1 h at room temperature.
3. Wash the plates with PBST, and add 100 μL of serially diluted MARV samples and incubate the plates at 37°C for 1 h.
4. Wash the plates with PBST, and add 100 μL of rabbit polyclonal antibody against MARV antigen (diluted 1:500 with PBST-M) to each well.
5. After 1 h incubation at 37°C, wash the plates with PBST. Then, add the horseradish peroxidase–conjugated goat antirabbit IgG. The plates are incubated for 1 h at RT.
6. After another extensive wash with PBST, add 100 μL of ABTS substrate solution [4 mM 2,2′-azino-di-(3-ethyl-benzthiazoline-6-sulphonic acid)], and add solution 2.5 mM hydrogen superoxygenphosphate (pH 4.2)] (Roche Diagnostics, Mannheim, Germany) to each well. Measure the optical density (OD) at a wavelength of 405 nm with a reference wavelength 490 nm after 30 min of incubation at 37°C.

Note: As a negative control, mock antigen-inoculated wells are tested. The adjusted OD values (OD_{405}nm) are calculated by subtracting the OD of the negative control well from the corresponding OD values.

58.3 CONCLUSION AND FUTURE PERSPECTIVE

Given the seriousness of MARV infection, it is important that sensitive, specific, and reliable tests are available and used at national and international reference laboratories for MVD diagnosis. While virus isolation is simple, its application is hampered by its time-consuming nature, and its requirement for high-level biocontainment and skilled operators. EM enables visualization of viral particles, but its usefulness is limited by its low sensitivity. Additionally, virus isolation and EM both involve handling live viruses in the highest laboratory BSL-4, restricting their use to well-resourced reference laboratories. ELISA and RT-PCR are sensitive and can detect viruses after inactivation of the viral particles. Therefore, these methods could be performed in a BSL-3 laboratory with class II biosafety cabinet and are thus more widely applied than virus isolation and EM for MARV detection.

Although the current methods are effective for detection of MARV, virus mutations should be monitored closely. RT-PCR and ELISA have shown their values for early detection of the viruses due to their high sensitivity and fast speed, but they might be ineffective dealing with mutated viruses.

Therefore, when new outbreaks emerge, the current molecular methods and reagents may need validation again to confirm their capability to detect mutated viruses. Traditional methods such as virus isolation and electron microscopy are less prone to miss mutated viruses, and they are invaluable for assisting the identification of filoviruses during disease outbreaks.

To date, MVD outbreaks have occurred mainly in underdeveloped Africa or originated from underdeveloped Africa (Table 58.1), such as Uganda and Congo. Due to limited power supply and refrigeration in these areas, field detection of MARV can be problematic using the current molecular techniques. Therefore, there is an urgent need to develop MARV test kits that do not depend on expensive instruments, have minimum sample handling and technical requirements, and generate the results within a short timeframe (preferably <30 min). Such devices would greatly aid the control of MARV infections in the future.

59.1 INTRODUCTION

Akabane virus (AKAV) causes reproductive and congenital problems in cattle, sheep, and goats, resulting in severe economic losses. AKAV is transmitted primarily by biting midges (*Culicoides* species). Although pregnant animals infected with AKAV exhibit no clinical signs, *in utero* fetal exposure to the virus results in abortion, premature birth, stillbirth, and congenital deformities such as arthrogryposis and hydranencephaly (AH) syndrome.[1]

Arthropod-borne diseases like Akabane disease, AH abnormalities of the calves, were first reported in Australia in 1951–1955,[2] but viral isolation was not attempted in that case. In 1959, the JaGAr39 strain, a reference strain of AKAV, was first isolated from mosquitoes (*Aedes vexans* and *Culex tritaeniorhynchus*) in Akabane village of the Gunma Prefecture, Japan, by the survey of *Aedes* arboviruses.[3,4] The first impact of the virus was reported in 1974 in Australia, in 1972–1975 in Japan, and in 1969–1970 in Israel,[1,5,6] and outbreaks of the disease have occurred in Japan, Israel, Turkey, and Australia.[6–8] In Japan, more than 42,000 congenital abnormalities, abortions, stillbirths, and premature births were caused in cattle.[1] Furthermore, AKAV has been detected in many tropical and subtropical regions,[9–13] and consequently, AKAV is widely distributed throughout Australia, Southeast Asia, East Asia, the Middle East, and Africa.

Vaccination has reduced the prevalence of Akabane disease; however, cases still occur in Japan and Korea.[14,15] Recently, antigenic and pathogenic variants of AKAV have been isolated.[16–19] For example, the Iriki strain caused nonsuppurative encephalitis and neurological symptoms to a calf in southern Japan in 1984.[20] Since the variants such as the Iriki strain showed low cross-reactivity with antiserum against the reference strain of AKAV by neutralization tests, those may be the reason for disease continuation in areas where vaccines are administered. Therefore, further investigation of both epidemiology and pathogenesis is required to elucidate the etiological agent. Besides, molecular studies will facilitate novel strategies for the control of Akabane disease in the future.

59.1.1 Classification

AKAV belongs to the genus *Orthobunyavirus* of the *Bunyaviridae* family. Based on serology, AKAV is a member of the Simbu serogroup, which consists of 25 viruses distributed globally. The viruses belonging to the serogroup cause disease in human and ruminants and are transmitted by biting midges and mosquitoes.[21] Although this group has been isolated from all continents except Europe,[21] Schmallenberg virus (SBV), which is likely a reassortant virus of Sathuperi virus and Shamonda virus[22] or an ancestor of Shamonda

virus,[23] was discovered in a vast region of Europe in 2011.[24–26] In the Simbu serogroup, Aino virus (AINOV) and SBV that affect Japan and Australia[27,28] and European countries, respectively, cause abortion and congenital abnormalities in cattle, sheep, and goats as well as AKAV, while *Oropouche virus* causes dengue-like febrile illness in human populations in South America.[29]

Currently, AKAV is divided into four clusters based on the S RNA segment sequences reflecting geographical origin such as Japan, Australia, Taiwan, Israel, and Kenya. Two clusters comprised the Japanese, Taiwanese, and Israeli isolates; hence, Asian strains seemed to have evolved in a common gene pool. The Australian and Kenyan isolates were each placed in the independent third (genotypes III) and fourth (genotypes IV) clusters, respectively. Phylogenetic analysis revealed that the Japanese field isolates could be divided into two major clusters (genotypes I and II), and genotype II was subdivided into two branches (IIa and IIb) (Figure 59.1). These data suggest that AKAV have evolved in multiple lineages, and the various genotypes might be introduced continuously from an exotic source. The geographic divergence is considered to drive AKAV variation.[17,30] In order to examine to what extent variation of the viral genome is reflected in the antigenic properties, monoclonal antibodies (MAbs) to AKAV were produced by immunization with OBE-1 strain and tested serologically.[16] There was no distinct correlation between the

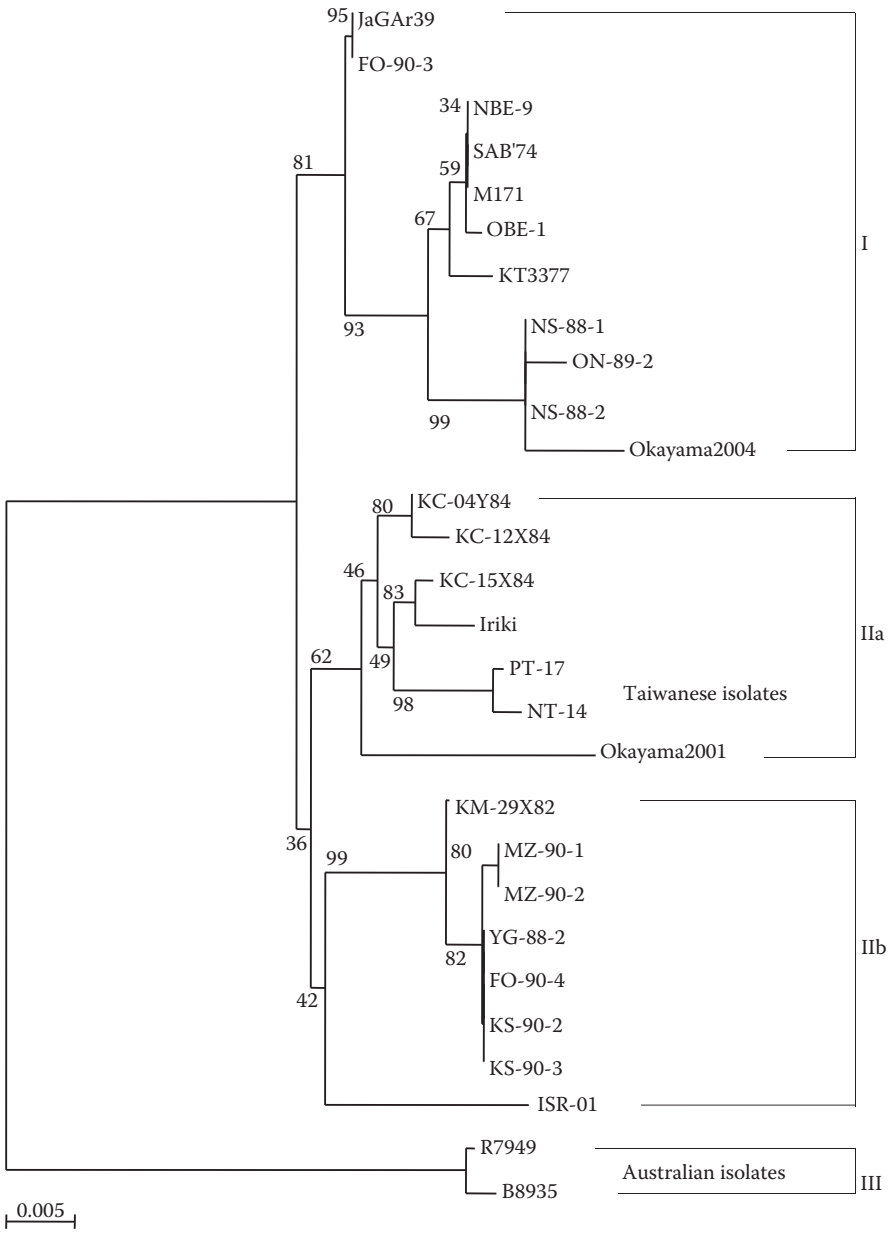

FIGURE 59.1 Phylogenetic relationship of the Akabane virus field isolates on the basis of their nucleocapsid (N) open reading frame (ORF) nucleotide sequences. Phylogenetic analyses of the N ORFs (between nucleotide positions −34 and −735, total 702 nucleotides) show that four groups are extant. Numbers indicate bootstrap percentages out of 1000 replicates. The scale bar represents 0.005% substitution per base.

phylogenic relationship and their reactivity to MAbs that recognized Gc and nucleocapsid (N) protein (Table 59.1). For example, only the OBE-1 strain responded with MAb 1B3 and showed high response to MAb 4F9 although NBE-9 and SAB′74 strain, which are phylogenetically close to the OBE-1 strain, showed no response to the MAbs. This suggests that the epitope is absent from those viruses, and therefore there is antigenic variation besides genomic diversity.

59.1.2 Morphology, Biology, and Epidemiology

AKAV is an enveloped virus and has a tripartite negative-sense, single-stranded RNA genome. The viral particle is roughly spherical, sometimes pleomorphic, and has a diameter of 70–130 nm (typically 90–100 nm). The virion surface consists of an envelope with a spikelike projection.[31] The envelope is a host cell–derived lipid layer, while spikes are comprised two viral glycoproteins (Gn and Gc). In the *Orthobunyavirus* genus, the virion has three genome segments: L, M, and S.[32] Each genome is encapsulated with N proteins and an RNA-dependent RNA polymerase (RdRp), referred to as the ribonucleoprotein (RNP) complex in a helical configuration. The large (L) segment encodes the large (L) protein, which acts as the RdRp. The medium (M) segment encodes a precursor polyprotein containing NH_2-Gn-NSm-Gc-COOH. Afterward, the polyprotein is cleaved into two glycoproteins, Gn and Gc, and a nonstructural protein (NSm). Gn and Gc are responsible for viral neutralization and attachment to cell receptors,[33] and analysis of AKAV antigenic properties using MAbs showed that Gc possessed hemagglutination activity (HA).[16] The function of NSm remains unknown, but it may be responsible for apoptosis signaling[34] and virus assembly.[35,36] The small (S) segment encodes N and a nonstructural protein (NSs) in an overlapping open reading frame (ORF). N plays a role in RNP formation, and NSs is responsible for interferon antagonism and regulation of host protein synthesis.[37,38] Additionally, the untranslated region (UTR) of each segment is suggested to play an essential role in RNA regulation and genome synthesis.[39]

Orthobunyaviruses enter cells by attaching to a cell surface receptor and penetrating through the endocytic pathway[40]; however, the complete details of viral entry remain unclear.

Most of the bunyaviruses utilize clathrin-dependent endocytosis,[40–43] although some viruses enter cells via another pathway such as caveolae-dependent endocytosis for Rift Valley phlebovirus to mammalian cell lines[44] and clathrin-independent endocytosis for Uukuniemi phlebovirus and Andes hantavirus.[45,46] Recently, it is suggested that AKAV enters bovine-derived cell lines in a manner of a nonclathrin, noncaveolae endocytic pathway that is dependent on

dynamin, while AKAV infection in nonbovine-derived cell lines is dependent on clathrin endocytosis.[47] After viral uptake into the cytosol, virus particles fuse with the endosome to gain acidity and release viral genome into cytoplasm. Subsequently, primary transcription and translation of viral proteins begin. The new virion assembles and buds into the Golgi compartment, followed by exocytosis from cells.[32,36,48]

The epidemiology of AKAV is consistent with the classification as arbovirus, that is, its appearance is seasonal, being restricted to period when insects are active, and it has a limited geographical distribution. The outbreaks of Akabane disease are associated with transmission by arthropod vectors in summer and autumn.[1,2] Since infected midges cannot survive during the winter, the outbreak gradually subsides.[49–51] In Australia, AKAV is transmitted by *Culicoides brevitarsis*,[52–54] which is a common biting pest of domestic ruminants. Due to suitable environmental conditions, the habitats of *C. brevitarsis* are widespread throughout the year in midnorthern and northern to southern coastal plains of New South Wales, Australia, and AKAV is an endemic disease in these areas.[55–57] AKAV-neutralizing antibodies have been found in other host species such as horse and camel, which are not common hosts of *C. brevitarsis* in the endemic areas, and therefore, it is suggested that these animals are accidental hosts of *C. brevitarsis* or that this virus has other vectors.[57] In the southern parts of Japan, *C. oxystoma* is the principle vector of AKAV.[58,59] On the other hand, *C. brevitarsis* has also been detected in the area, leading to concerns of arbovirus outbreaks involving AKAV and other orthobunyaviruses.[60] In Oman, *C. imicola* was reported as an AKAV vector.[61] In Israel, the definitive vector remains unknown. Furthermore, there is a report that AKAV can replicate in *C. variipennis* and *C. nubeculosus*, which are widespread in America and Europe, respectively. In the report, *C. variipennis* was susceptible to oral infection, and *C. nubeculosus* was susceptible to infection only when intrathoracic inoculation *in vitro*,[62] while there have been no reports of virus isolation from these midges in field surveys of these regions.

AKAV also have been isolated from mosquitoes, such as *A. vexans* and *C. tritaeniorhynchus* in Japan[3] or *Anopheles funestus* in Kenya.[63] However, experimental attempt to infect via the *Culex* and *Aedes* spp. have been unsuccessful although AKAV was isolated from the cephalothoraxes of *Aedes albopictus* fed blood meal in the laboratory.[64] Recently, AKAV was isolated from nonblood-fed *C. tritaeniorhynchus*, *Culex vishnui*, *Anopheles vagus*, and *Ochlerotatus* species in northern Vietnam.[9] Furthermore, AKAV was propagated and maintained in *Aedes albopictus* cell culture as a persistent infection.[65] Thus, it remains possible to AKAV transmission by mosquitoes.

59.1.3 Clinical Features and Pathogenesis

AKAV-associated congenital abnormalities have been reported in cattle, sheep, and goats.[1,53,66,67] In Taiwan, AKAV has been isolated in pigs, which showed convulsion and diarrhea.[68] Moreover, horse, donkey, camel, and wildlife animals have been found to be seropositive for AKAV, while pathogenic lesions have not been reported.[12,69]

The host immune system against AKAV infection has been suggested to be both humoral and cellular immunity, which decrease or eliminate AKAV from blood and infected tissues. Thus, animals with a mature immune system have the potential to resist AKAV infection,[70,71] whereas animals with an immature immune system, predominately the fetus, are susceptible to virus infection and exhibit pathogenic lesions.[72]

The well-known severe sign is delivery of fetus with congenital deformities, AH syndrome. Infected pregnant cattle, sheep, and goats show dystocia, abortion, stillbirth, and premature birth, while delayed labor can be observed with only pregnant goats.[73] Infected fetuses are generally dead during birth. The live newborns show neurological problems including the inability to stand, blindness, lack of a sucking reflex, nystagmus, and death within 3 days due to an inability to feed.[74,75] The fetuses with the nonpurulent encephalomyelitis and myositis are usually born with mild to moderate neurological and muscular problems such as ataxia, muscle atrophy, paralysis, and blindness.[75]

AKAV infection in newborn and adults generally results transient viremia without any clinical signs.[70,76] However, infection with the highly pathogenic Iriki strain, which was isolated from the cerebellum specimen of a calf, resulted in nonpurulent encephalitis.[20] Iriki-like strains also caused encephalomyelitis in young and adult animals.[11,77] Various clinical signs have been observed in those animals, including lassitude, anorexia, loss of milk yield, tremor, stretching of the legs, and ataxia. Since there is no typical therapy and symptomatic animals are suggestive of a poor prognosis, the animals should be euthanized.

Histopathological and immunohistochemical studies have shown that nervous system damage by AKAV is induced directly and indirectly. The direct effects are caused by virus infection into neurons, resulting in cytolysis,[78] and the indirect effects are caused by cytotoxic cytokine responses, resulting in inflammatory reactions such as vascular damage.[79] AKAV causes inflammation in all parts of the central nervous system (CNS), the cerebrum, cerebellum, brainstem, and spinal cord, and these inflammatory lesions typically develop into severe encephalitis such as necrotizing encephalitis.

Gross appearance of AH syndrome shows disorders in two major organs, the CNS and muscular systems. The lesions in the brain present hypoplasia in both sides of the cerebrum, such as hydranencephaly, microencephaly, and porencephaly, where the cranial cavity is replaced by a clear cerebrospinal fluid. These are produced by the circulating cerebrospinal fluid in necrosis areas. The midbrain, cerebellum, medulla oblongata, and spinal cord are reduced in size.[70,76] The cystic cavity and small subcortical cysts in brain tissue can also be observed.[80] Histopathological lesions in the CNS show nerve cell degeneration. "Perivascular cuffs" are prominent in perivascular layer, that is, cells including plasma cells, histiocytes, and lymphocytes infiltrate into perivascular layer.[79] The ventral horn of the spinal cord shows loss of motor neurons, gliosis, and perivascular cuffs.[81] Skeletal deformities present scoliosis,

kyphosis, torticollis, and brachygnathism.[70,79] Arthrogryposis is produced by the decrease in the number of ventral horn neurons that control muscle fiber. Skeletal muscle is atrophied and edematous, predominately in the limbs. Joints are fixed in flexion.[79] In case of polymyositis in skeletal muscle, the muscle system shows myotubule and myofiber degeneration and infiltration of inflammatory cells in skeletal muscle tissue.[82] Markedly, degenerative myotubules are broken into tissue fragments, and some disappear. Abnormal myotubules are swollen and their nuclei are pyknotic. Myofibers undergo degeneration, disruption, and fragmentation. Some of the fragmented fibers lose striation. With regard to encephalitis in newborns and adults, no macroscopic lesions are identified in the CNS. Histopathological signs of nonpurulent encephalomyelitis comprise perivascular cuffs and nerve cell degeneration in the midbrain, cerebellopontine, and medulla oblongata and rarely in the cerebrum and cerebellum.[83]

AKAV infection is initiated by intravenous route in the dermis by AKAV-infected arthropod vectors. After virus invasion, viremia typically occurs in 1–9 days, whereas the main cells responsible for viral multiplication remain unclear. AKAV-neutralizing antibody is detected 1–3 days after viremia and can be persistently detected for more than a year. During this period, the virus spreads to the brain, spinal cord, and skeletal muscle by a hematogenous route and also to the placenta, ovary, cornea, uvea, and lens fiber.[84,85] Transplacental vertical transmission is the route of AKAV infection into fetuses.[86] The pathological changes are closely related to the age at which the fetus is infected.

AKAV pathogenesis is divided into the following three phases: the nonpurulent encephalomyelitis phase, polymyositis phase, and AH phase. The nonpurulent encephalomyelitis phase is the primary pathological change in AKAV infectious stage. The fetus exposed to the virus after the middle stage of gestation produces only the pathological change.[70,77,80,87] Moreover, multifocal encephalitis but not the necrotizing one is produced during this stage. The polymyositis phase is the second pathological change. There is evidence that this lesion is produced by AKAV infection directly and indirectly only during the myotubule and myofiber development phases in muscular of the fetus, which correspond to first to middle stage of gestation, and results in abnormal myotubules and inflammation. Therefore, infection of AKAV at the late stages of gestation will not result in polymyositis.[82] The AH phase is the final stage of Akabane disease lesion development. These are sequential changes of nonpurulent encephalomyelitis and polymyositis, respectively.[79] The AH lesions are produced in the fetus exposed to AKAV during the early stage, that is, 62–96 days in cattle[76] and 26–69 days in goats and sheep[70,80,88] to middle stages of gestation.

59.1.4 Diagnosis

59.1.4.1 Conventional Techniques

Since Akabane disease spreads rapidly via arthropod-borne means, the diagnosis must be rapid and reliable in order to prevent transmission to noninfected animals. A field diagnosis is based on clinical manifestation and detection of arthropod vector activity. Postmortem changes are examined by autopsy or necropsy as well as histological examination. However, since other orthobunyaviruses including AINOV and Peaton virus (PEAV) have been associated with bovine congenital abnormalities in Japan, it is difficult to differentiate with clinical features alone. Serological analysis is a common and convenient method for AKAV detection due to its accuracy and high sensitivity. The analysis is generally used for epidemiological surveys and immunity levels in vaccinated animals. The neutralization test is the most commonly used for serological diagnosis of AKAV infection.[70,89–91] Detection of neutralizing antibody in precolostral or fetal serum is available. Since cattle, sheep, and goats cannot transfer maternal antibodies to the fetus through the placenta and newborn animals acquire antibodies from the dam via the colostrum, the presence of anti-AKAV antibodies in precolostral or fetal serum suggests that the fetus had been infected with the virus *in utero*. Additionally, the hemagglutination inhibition test,[92] complement fixation test (CFT),[93] hemolysis inhibition test,[94] and enzyme-linked immunosorbent assay (ELISA)[95,96] have also been used as serological diagnosis of AKAV infection, whereas the method such as CFT and ELISA detect cross-reactive antibodies against viruses of the same serogroup. Moreover, because these tests detect immunoglobulin (Ig) G, the antibody detection period after virus exposure can be prolonged. Whether observed animals were recently infected should be evaluated with paired serum samples taken at 1-week interval[1,74] or IgM (a recent infection indicator) assay simultaneously with IgG.[96]

Viral isolation using cell culture is a general technique that can be applied to virus identification and vaccine preparation. Generally, defibrinated blood from sentinel cattle and CNS and skeletal muscle tissues from aborted fetuses are used for virus isolation. The cell types for standard AKAV isolation involve HmLu-1 cells[66] derived from hamster lung, BHK-21 cells from hamster kidney,[19] and Vero cells from African green monkey kidney,[71,84] due to their sensitivity based on the cytopathic effect (CPE) and plaque formation.[97] Moreover, experimental animals such as suckling mice, hamsters,[4] or chicken embryos[98] are commonly used for AKAV isolation. However, this technique is not appropriate in routine diagnosis work because it takes a time to detect and fresh materials are required. Abnormally delivered animals cannot be also used due to the presence of antibody. In some cases, virus isolation is not successful but other tests show positive for AKAV.[18,81,99]

The establishment of anti-AKAV antibodies is the key factor for immunological tests including immunohistochemistry[18,77,83,87] and immunofluorescence[78] assays. Immunohistochemical detection of virus antigen has become an important tool for pathological studies and diagnosis of infectious diseases. Although brain and skeletal muscle tissues are typically subjected to histopathological examination, it is important to verify AKAV specificity of the antibody because of the cross-reactivity among Simbu serogroup viruses.

59.1.4.2 Molecular Techniques

With the advancements in molecular biology technologies, amplification of AKAV genetic materials has become one of the most valuable tools for the confirmation of AKAV infection. Reverse transcription polymerase chain reaction (RT-PCR), as well as nested RT-PCR,[100] has been proposed as the new standard method for AKAV detection due to the rapidity and sensitivity. Moreover, multiplex RT-PCR[101,102] and quantitative real-time RT-PCR[102] facilitate rapid identification of viruses to the serotype level with improved accuracy.

59.2 METHODS

59.2.1 Sample Preparation: Extraction of Viral RNA

59.2.1.1 Animal Tissue

Tissue samples collected from infected animals should be placed on dry ice or flash frozen in liquid nitrogen as soon as possible after autopsy. The samples can be stored at −80°C for many years. Viral RNA is extracted using TRIzol Reagent (Life Technologies), according to the manufacturer's instructions. Briefly, 50–100 mg of tissue sample is added with 1 mL of TRIzol Reagent and homogenized. The homogenized sample can be stored at −80°C for at least 1 month or proceeded sequentially to the following phase separation. After incubation at room temperature for 5 min to permit complete dissociation of the nucleoprotein complex, the homogenate is added with 0.2 mL of chloroform and incubated for 2–3 min at room temperature, and then, the mixture is centrifuged at 12,000 × *g* for 15 min. The mixture separates into a lower phenol–chloroform phase, an interphase, and an upper aqueous phase. The RNA remains exclusively in the aqueous phase. The aqueous phase is added with 0.5 mL of isopropanol and incubated at room temperature for 10 min and then centrifuged at 12,000 × *g* for 10 min to precipitate the RNA. The supernatant is removed and RNA pellet is washed with 1 mL of 75% ethanol. The RNA in ethanol is centrifuged at 7,500 × *g* for 5 min and the wash is discarded. The RNA pellet is dried for 5–10 min but not completely. The RNA pellet is added with 20–50 μL of RNase-free water or 0.5% sodium dodecyl sulfate (SDS) solution and incubated at 55°C–60°C for 10–15 min in order to resuspend completely. The RNA solution can be stored at −80°C until the following assay is performed.

Note: For liquid samples such as blood plasma or cerebrospinal fluid, TRIzol LS Reagent is used instead of TRIzol Reagent. A sample of 250 μL is added with 750 μL of TRIzol LS Reagent and homogenized by pipetting several times.

59.2.1.2 Cell Cultures

AKAV genomes are commonly isolated using cell culture techniques. Viral RNA is extracted from the supernatant of cells infected by viral solution or infected animal tissue homogenates in cold phosphate-buffered saline, using QIAamp Viral RNA Mini Kit (Qiagen), according to the manufacturer's instructions. Briefly, 140 μL of cell culture supernatant is mixed to 560 μL of AVL buffer containing carrier RNA. The mixture is incubated at room temperature for 10 min and 560 μL of ethanol is added. Then, the mixture is applied onto the spin column and centrifuge at 6000 × *g* for 1 min, and 500 μL of AW1 buffer is added. The column is centrifuged at 6000 × *g* for 1 min to remove unbound materials and washed by the addition of AW2 buffer. Then, the column is centrifuged at full speed for 3 min and placed into a new 1.5 mL microcentrifuge tube. Finally, 60 μL of AVE buffer is added directly onto the column to elute AKAV genomic RNA. After incubation at room temperature for 1 min, the column is centrifuged at 6000 × *g* for 1 min. The obtained RNA can be stored at −80°C until the following assay is performed. The RNA is used as a template for RT-PCR, nested PCR, or quantitative real-time RT-PCR amplification.

59.2.2 Detection Procedures

59.2.2.1 RT-PCR and Nested PCR

Since AKAV, AINOV, PEAV, and some other Simbu serogroup orthobunyaviruses have been isolated from bovine and insect specimens in Japan and AINOV causes similar congenital deformities such as AH syndrome, the differential diagnosis using molecular techniques is needed. Based on the high degree of sequence conservation among orthobunyavirus S RNA species, the following specific primer sets for AKAV and AINOV were developed to detect and differentiate these viruses by RT- and nested PCR.

Primers	Sequence (5′–3′)	Nucleotide Positions
First round for Aino virus		
AISF132	CCC AAC TCA ATT TCG ATA CC	132-151
AISR780	TTT GGA ACA CCA TAC TGG GG	780-761
First round for Akabane virus		
AKSF19	TAA CTA CGC ATT GCA ATG GC	19-38
AKSR740	TAA GCT TAG ATC TGG ATA CC	740-721
Nested for Aino virus		
AISF313	CCA TCG TCT CTC AGG ATA TC	313-332
AISR657	ACA GCA TTG AAG GCT GCA CG	657-638
Nested for Akabane virus		
AKSF177	GAA GGC CAA GAT GGT CTT AC	177-196
AKSR407	GGC ATC ACA ATT GTG GCA GC	407-388

These primer sets have been examined for their capacity to amplify PCR products using seven Simbu serogroup viruses (AKAV, AIVNOV, PEAV, Douglas virus, Tinaroo virus [(TINV]), *Thimiri virus*, and Facey's Paddock virus) isolated in Japan and Australia. RT- and nested PCR products with AKAV-specific primers are obtained for AKAV and TINV (Figure 59.2a). These results are expected on the basis of

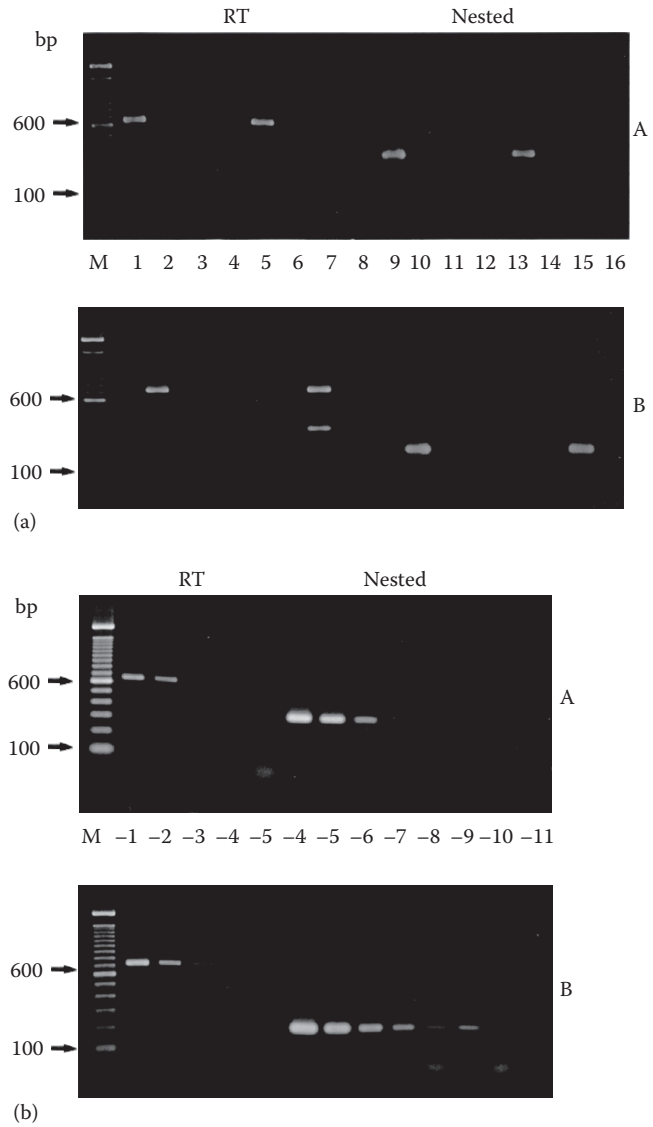

FIGURE 59.2 Agarose gel electrophoresis of the (A) Aino- and (B) Akabane-specific reverse transcription polymerase chain reaction (RT-PCR) and nested PCR products. (a) M, molecular weight marker; 1, 9 Aino virus; 2, 10 Akabane virus; 3, 11 Douglas virus; 4, 12 Facey's Paddock virus; 5, 13 Peaton virus; 6, 14 Thimiri virus; 7, 15 Tinaroo virus; 8, 16 cell culture fluid control. Numbers 1–8 show the result of RT-PCR; 9–16 show nested PCR. (b) Tenfold serial dilutions of RNA from 10^5 plaque-forming unit of each virus were amplified using the specific primers by RT-PCR and nested PCR. The figure shows from 10^{-1} to 10^{-5} dilutions for RT-PCR and from 10^{-4} to 10^{-11} for nested PCR.

their S RNA sequence similarity.[103] The nested PCR product of AKAV is digested only by *HphI*, and the TINV product can be cut only with *BstEII*. Similarly, PEAV yields RT-PCR and nested PCR products with AINOV-specific primers (Figure 59.2a). This nested PCR product of PEAV fails to be digested by three enzymes (*AvaII*, *EcoRI*, and *HaeII*), whereas that of AINOV is digested.

To determine the sensitivity of RT- and nested PCR, template RNA dilution was performed. RNAs extracted from approximately 100 plaque-forming units (PFU) of AINOV and 10 PFU of AKAV were detected by RT-PCR, whereas 10^{-3} PFU of AINOV and 10^{-5} PFU of AKAV were detected by nested PCR (Figure 59.2b). These results show that the nested PCR followed by restriction fragment length polymorphism analysis provides a simple, rapid, and reliable means for diagnosing AKAV and AINOV infection. Thus, these methods are currently being used in the field.

59.2.2.2 Cloning and Sequencing

A phylogenic analysis by N or M ORFs is carried out to characterize AKAV genotypes, and the identification of complete sequences of three genomes can clarify the presence of a mutant or unidentified strain. The following is the protocol of complete genome sequencing, which has been modified from previous reports[19,104]:

59.2.2.2.1 Procedure

AKAcon primer (sequence in the following table) used for cDNA synthesis is designed using the 3′- and 5′-end complementary sequences of each segment of the OBE-1 strain. The RT mix is present as follows. First-strand cDNA is synthesized using the SuperScript III Reverse Transcriptase (Life Technologies), according to the manufacturer's instructions.

Note: After the reaction, 1 µL of RNase H (Life Technologies) may be added and incubated at 37°C for 20 min to remove RNA complementary to the cDNA.

Component	Volume (µL)
RNA	7
AKAcon primer (1 pM)	2
dNTP (deoxyribonucleotide triphosphate) mix (2.5 mM each)	4
5× first-strand buffer	4
0.1 MDTT (M dithiothreitol)	1
RNaseOut	1
SuperScript III Reverse Transcriptase	1
Total	20

Subsequently, to prepare the PCR reaction mix of LA Taq (Takara Bio), 3 µL of cDNA is added to 22 µL of PCR mixture according to the manufacturer's instructions. Full-length S (856 bp: OBE-1), M (4309 bp: OBE-1), and L (6868 bp: OBE-1) RNA segments are amplified by PCR with the primer pairs, SF and SR, MF and MR, and LF and LR, respectively. The amplicon is ligated into the TOPO TA Cloning Kit (Life Technologies). Three clones are sequenced using the BigDye Terminator v3.1 Cycle Sequencing Kit (Applied Biosystems), according to the manufacturer's protocol. To confirm the 3′- and 5′-UTR sequences of the viral-sense RNA (vRNA), PCR is performed with AKAcon and S400-381 for the 3′-end of the S vRNA, S459-478 for the 5′-end of the S vRNA, M303-284 for the 3′-end of the M vRNA, M4059-4080 for the 5′-end of

the M vRNA, L-4R for the 3′-end of the L vRNA, or L5′RACE for the 5′-end of the L vRNA. The sequences of the UTRs are confirmed by direct sequences of the PCR products. The primer sequences are present as follows:

RNA Segment	Primer	Sequence (5′–3′)	Nucleotide Positions (OBE-1)
S, M, L	AKAcon	ggggctctagaAGTAGTG	
S	SF	AGTAGTGAACTCCACTA TTAACTACGC	1-28
	SR	AGTAGTGTTCTCCACTAA TTAACTATA	858-832
M	MF	AGTAGTGAACTACCAC AACAAAATG	1-25

59.2.2.3 Quantitative RT-PCR

Quantitative determination of viral genome provides information about viremia, and a quantitative PCR (qPCR) assay using AKAV-specific primers is useful to distinguish from infections of AINOV.[102]

59.2.2.3.1 Procedure: RT

1. cDNA for qPCR is synthesized briefly using the PrimeScript RT Reagent Kit (Takara Bio). Prepare the RT mix to each 0.5 mL tube as follows:

Component	Volume (μL)
RNA	2
5× PrimeScript Buffer (for real time)	2
PrimeScript RT Enzyme Mix I	0.5
Oligo dt primer (50 μM)	0.5
Random 6 mers (100 μM)	0.5
RNase-free water	4.5
Total	10

2. Transfer the reaction tubes to 37°C heat box for 15 min (RT reaction), and increase temperature to 85°C for 5 s (inactivity of enzyme), and then chill the tubes.
3. The cDNA can be used directly in the following qPCR step or stored at −20°C for future use.

59.2.2.3.2 Procedure: qPCR

1. Prepare the qPCR mix to 1.5 mL tubes as follows (volumes indicated per specimen) and place on ice. For qPCR, ak151f (5′-GCTAGAGTCTTCTT CCTCAACCAGAA-3′) and ak231r (5′-AAAAGTA AGATCGACACTTGGTTGTG-3′) primers[102] are used to amplify the AKAV cDNA (81 bp).

Component	Volume (μL)
Power SYBR Green PCR Master Mix	12.5
ak151f primer (10 μM)	0.5
ak231r primer (10 μM)	0.5
Sterilized water	9.5
Total	23

2. Put the mix into each well of 96-well plate, and add 2 μL of individual cDNA sample.
3. Spin the plate briefly to pull down the droplets at the inner wall of the wells.
4. Place the sample plate in a thermocycler with a real-time system. Perform the reaction under the following cycling conditions, 95°C for 10 min and 45 cycles of 95°C for 15 s and 60°C for 30 s.
5. Finally, analyze the results using a real-time PCR software.

Note: Especially, in case of animal tissues, an endogenous control gene such as GAPDH or 18S rRNA should be tested, using primers for those control genes.

For the purpose of absolute qPCR, the addition of external standard such as a plasmid coding AKAV target sequence is required in every reaction to determine the absolute amount of the target gene from each sample. The external standard should contain sequences that are the same as the target sequence.

59.2.3 Rescue of Virus by Reverse Genetics System

Reveres genetics systems for bunyaviruses have been developed based on the methodology originally established for the prototype of the genus *Orthobunyavirus*, *Bunyamwera virus* (BUNV).[105] The rescue systems using bacteriophage T7 RNA polymerase have been reported for BUNV, *La Crosse virus*, and *Rift Valley fever virus*,[105–107] and the system using RNA polymerase I has been established for AKAV.[108] The following is the protocol of virus rescue using RNA polymerase I–based reverse genetics, which has been modified from the previous report.

59.2.3.1 Plasmid Construction

The plasmids expressing the L and N protein of AKAV should be prepared for the supporting proteins. The pcDNA/*myc*-His A vector is used for cloning of the L or N coding region

using restriction enzyme sites *EcoRI* and *XhoI,* resulting in pcDNA/L and pcDNA/S, respectively. By change of ATG start codon to ACG of NSs, the mutated plasmid, pcDNA/SΔNSs, which is a mutant with a knockout of the nonstructural protein NSs and encodes N protein alone, is constructed. pcDNA/SΔNSs is recommended instead of pcDNA/S, since the NSs protein suggests to be a negative regulator of gene activity.[104]

The full-length L, M, and S segment should be inserted into the plasmid containing the murine RNA polymerase I promoter and terminator, such as pRF42 vector (Ramon Flick, University of Texas Medical Branch, and Ralf F. Pettersson, Karolinska Institutet, Sweden), and result in the pRF42/L, pRF42/M, and pRF42/S plasmids can exhibit RNA polymerase I–driven transcription of the respective genomic RNA.

59.2.3.2 Transfection

Procedure

The following manipulation should be conducted in a sterile environment:

1. Approximately 18–24 h before transfection, plate HmLu-1 cells in a 2 mL growth medium per well in a 6-well plate. Incubate the cells at 37°C overnight. Subconfluent cells should be used for transfection.
2. Prepare the plasmid mix as follows (volumes indicated per well):

	Component	6 Wells	12 Wells
Plasmid	pRF42/S	0.5 μg	0.25 μg
	pRF42/M	1.5 μg	0.75 μg
	RF42/L	2 μg	1 μg
	pcDNA/SΔNS	0.1 μg	0.05 μg
	pcDNA/L	0.4 μg	0.2 μg
	Total	4.5 μg	2.25 μg
	OPTI-MEM	100 μL	50 μL
	transIT-LT1	9 μL	4.5 μL

3. Add the plasmid mix into 100 μL of OPTI-MEM (Life Technologies) in a sterile tube, and mix gently.
4. Drop 9 μL transIT-LT1 (Mirus), warmed at room temperature before using, into the OPTI-MEM including the DNA mixture without contact with the sides of the tube, and mix gently.
5. Incubate at room temperature for 15–30 min.
6. Add the transIT-LT1 reagent: DNA complex dropwise to different areas of one well, and rock the culture vessel gently in order to evenly distribute the complex. Incubate the transfected cells at 37°C for approximately 2–5 days, and observe the occurrence of CPE.

Note: If the efficiency of the rescue of the virus is poor, two or more wells should be transfected with each aforementioned volume.

59.3 CONCLUSION AND PERSPECTIVES

Since there is no practical treatment for infected animals, Akabane disease is required to protect by vaccination and vector control. Inactivated vaccines have been used in Japan, South Korea, and Australia,[15,109,110] and live-attenuated vaccines have been used only in Japan and South Korea.[15,111] In case of inactivated vaccines developed in Japan, yearly booster immunizations were recommended for cows in terms of the safety and effectiveness.[109] The inactivated vaccine available to Australia is administrated by intramuscular injection on two occasions, 4 weeks apart, to heifers and cows prior to mating.[110] Recently, formalin-inactivated trivalent vaccines for AKAV, AINOV, and Kasba virus have been developed in Japan and South Korea. This vaccine exhibits improved safety and immunogenicity in pregnant cows.[15] The attenuated live vaccine has been established in Japan. The vaccine strain TS-C2[111] is a temperature-sensitive mutant derived from the OBE-1 strain, which was isolated from a naturally infected bovine fetus in 1974. The safety and immunogenicity of the strain have been showed in pregnant cows, but only the immunogenicity in pregnant ewes because the inoculation of the strain into pregnant ewes exhibited viremia.[111,112] Therefore, this vaccine should be used for only cows.

Although these vaccines have decreased the incidence of Akabane disease, sporadic cases still occur in Japan, South Korea, and Australia.[14] The extensive genetic and antigenic variants may be responsible for vaccine failure. While vaccine development is a long-term process, molecular biological approaches contribute to application to an emerging virus. Reverse genetics technology yielded a recombinant AKAV from cloned cDNA,[108] and the manipulation can be exploited in molecular analysis and vaccine development of AKAV.

Vector control is one of the most reliable methods of arbovirus disease prevention. This process includes the elimination of larvae and adult arthropods (biting midges and mosquitoes) using insecticides or the avoidance of exposure to arthropods by screening of animal sheds.[113] However, these vector control measures may be impractical and difficult to apply in the field due to a temporary effect and a negative impact on the environment.

60.1 INTRODUCTION

Hantaviruses are a group of segmented, negative-sense, single-stranded RNA viruses that commonly circulate in rodents without inducing overt clinical signs. However, accidental hantavirus infections in humans through inhalation of aerosolized rodent excretes may result in two serious clinical diseases namely hemorrhagic fever with renal syndrome (HFRS) and hantavirus pulmonary syndrome (HPS) or hantavirus cardiopulmonary syndrome (HCPS), depending on hantavirus species involved. Hantaviruses causing HFRS primarily occur in Europe and Asia (Old World) and employ rodents of the Murinae and Arvicolinae subfamilies for maintenance, while those causing HPS/HCPS are mostly found in the Americas (New World) and use rodents of the Sigmodontinae subfamily as reservoir. In order to implement effective control and prevention measures against HFRS and HPS/HCPS in human populations, it is vital to have the responsible agents correctly identified.

60.1.1 Classification

Hantaviruses are classified in the genus *Hantavirus*, family *Bunyaviridae*, which covers about 350 enveloped, tripartite, negative-sense, single-stranded RNA viruses, including 97 recognized species, 81 tentative species, and a large number of isolates with undefined taxonomic status. The family *Bunyaviridae* is divided into five genera (*Hantavirus*, *Nairovirus*, *Orthobunyavirus*, *Phlebovirus*, and *Tospovirus*), of which the genera *Orthobunyavirus* and *Phlebovirus* utilize mosquitoes and mammals for their life cycles, with humans becoming infected via mosquito bites; the genus *Nairovirus* circulates between ticks and mammals, with humans acquiring the viruses through tick bites; the genus *Hantavirus* is maintained by cyclical transmission between persistently infected small mammals (rodents and occasionally insectivorous shrews and bats), with incidental human infections arising primarily from inhalation of aerosolized rodent excreta; and the genus *Tospovirus* involves trips (commonly known as thunderflies and corn lice) and plants in its life cycle.

Consisting of more than 80 antigenically and genetically related viruses, the genus *Hantavirus* currently includes 24 recognized species (Andes virus [ANDV], Bayou virus [BAYV], Black Creek Canal virus [BCCV], Caño Delgadito virus [CADV], Dobrava-Belgrade virus [DOBV], El Moro Canyon virus [ELMCV], Hantaan virus [HTNV], Isla Vista virus [ISLAV], Khabarovsk virus [KHAV], Laguna Negra virus [LANV], Muleshoe virus [MULV], New York virus [NYV], Prospect Hill virus [PHV], Puumala virus [PUUV], Rio Mamore virus [RIOMV], Rio Segundo virus [RIOSV], Saaremaa virus [SAAV], Sangassou virus [SANGV], Seoul virus [SEOV], Sin Nombre virus [SNV], Thailand virus [THAIV], Thottapalayam virus [TMPV], Topografov virus [TOPV], and Tula virus [TULV]) as well as a number of less well known or unassigned viruses (Table 60.1). The criteria for the demarcation of hantavirus species reflect the recently updated rule of a 10% difference in small (S) segment similarity and a 12% difference in medium (M) segment similarity based on complete amino acid sequences [1–4].

HFRS, hemorrhagic fever with renal syndrome; HPS, hantavirus pulmonary syndrome; HCPS, hantavirus cardiopulmonary syndrome.

According to the types of rodent hosts involved in transmission, hantaviruses are separated into *Murinae group* (e.g., HTNV, SEOV, Amur virus [AMRV], DOBV, and SAAV, as they are transmitted by Murinae rodents [Old World mice and rats]), *Arvicolinae group* (e.g., PUUV and TULV, as they are transmitted by Arvicolinae rodents [voles]), and *Sigmodontinae group* (e.g., SNV, NYV, BCCV, BAYV, ANDV, and LANV, as they are transmitted by Sigmodontinae rodents [New World mice and rats]) (Table 60.1). For convenience, hantaviruses belonging to the Murinae and Arvicolinae groups are referred to as the Old World hantaviruses, whereas those belonging to the Sigmodontinae group are referred to as the New World hantaviruses.

Interestingly, DOBV, SAAV, HTNV, AMRV, SEOV, PUUV, and TULV (so-called Old World hantaviruses) are linked to HFRS in Europe and Asia, responsible for 150,000–200,000 cases per year and mortality rates of up to 12%. On the other hand, ANDV, BAYV, BCCV, LANV, NYV, and SNV (so-called New World hantaviruses) are implicated in HPS or HCPS in the Americas, involving >200 cases per year in South America and mortality rate of around 40% [5,6].

Phylogenetic analyses have shown that HTNV contains nine close-related clades (designated subtypes HTN 1–9); and SEOV from different geographic locations forms five clades (designated subtypes SEO 1–5) [7].

PUUV is differentiated into eight lineages in Eurasia: (1) the Central European lineage, (2) the Alpe-Adrian lineage, (3) the Latvian lineage, (4) the Danish lineage, (5) the South Scandinavian lineage, (6) the North Scandinavian lineage, (7) the Finland lineage, and (8) the Russian lineage [8].

ANDV consists of three clades: *Andes clade* includes 12 viruses, which are further differentiated into three well-supported groups: (1) Castelo dos Sonhos virus (CASV), CASV-2, and Tunari virus; (2) Pergamino virus, Maciel virus, Araraquara virus, and Paranoa virus; and (3) Oran virus, Bermejo virus (BMJV), BMJV-Neembucu virus, Lechiguanas virus, and Andes Central Plata virus. These viruses are found in Argentina, Bolivia, Brazil, Chile, Paraguay, and Uruguay and carried by rodents of genera *Akodon*, *Necromys*, and *Oligoryzomys*. *Laguna Negra clade* contains LANV (causing HPS in Paraguay, Bolivia, and Brazil and carried by *Calomys laucha*) and LANV-2 (causing HPS in Brazil); *Rio Mamore clade* consists of Alto Paraguay virus (Paraguay), Anajatuba virus (ANJV; Brazil), Maripa virus (MARV; French Guiana), Rio Mearim virus (Brazil), Rio Mamore virus (RIOMV; Bolivia and Peru), and RIOMV-3 and RIOMV-4 (Brazil). Of these, only ANJV and MARV are associated with HPS. Within the Rio Mamore clade, only RIOMV is currently recognized as a species by the International Committee on Taxonomy of Viruses. Other viruses within this clade may be unique genotypes of RIOMV. The reservoir of RIOMV in Peru, Bolivia, and Amazonas, Brazil (RIOMV-3), is *Oligoryzomys microtis*, while the host of RIOMV-4 is a related species similar to *Oligoryzomys* sp. RR-2010a [9–11].

60.1.2 Morphology and Genome Organization

Hantaviruses are enveloped, cytoplasmic viruses with a spherical to pleomorphic appearance and a diameter of 80–120 nm. Viewed by electron microscopy, negatively stained hantaviruses show a grid-like structure composed of surface projections (spikes) of 8 nm, which are surrounded by a prominent fringe embedded in a lipid bilayer envelope of 5 nm thickness. These spikes are made up of glycoprotein Gn and Gc heterodimers (encoded by the M segment).

Inside the envelope exist three filamentous, helical nucleocapsids, measuring 200–3000 nm in length and 2–2.5 nm in width. These nucleocapsids are made up of multicopies of nucleocapsid protein N encapsidating each of three segments of antisense (and sometimes ambisense), single-stranded RNA, designated S (small), M (medium), and L (large), amounting to about 12,000 nucleotides (nt) in total.

The S segment (1696–2083 nt in length) encodes the nucleocapsid (N) protein and possible a NSs protein in some isolates. The M segment (3613–3707 nt in length) encodes a polyprotein that is cotranslationally cleaved to yield the envelope glycoproteins Gn (formerly G1) and Gc (formerly G2). The L segment (6530–6550 nt in length) encodes the L protein, which is a RNA-dependent RNA polymerase with replicase and transcriptase activities.

Each of the three segments possesses short noncoding regions (NCR) at the 5′ and 3′ ends. The NCR at the 5′ end is 37–51 nt for all three segments, and the NCR at the 3′ end is 370–730 nt in S segment, 168–229 nt in M segment, and 38–43 nt in L segment. A consensus 3′-terminal nucleotide sequence (AUCAUCAUC) is found in the 3′ NCR, which is complementary to the 5′ terminal sequence. The 5′ and 3′ NCRs form panhandle structures and play a role in replication and encapsidation facilitated by binding with the viral nucleocapsid (N) protein [12].

60.1.3 Biology and Epidemiology

Hantaviruses commonly occur in rodents of subfamilies Arvicolinae, Murinae, and Sigmodontinae in the family Muridae (order Rodentia), which are widely distributed throughout the world [13–20]. In Europe and Asia (the Old World), hantaviruses are present in rodents of the Murinae and Arvicolinae subfamilies, while in the Americas (the New World), hantaviruses exist in rodents of the Sigmodontinae subfamily. Each hantavirus has one or possibly a few specific rodent hosts (Table 60.1). In addition, a hantavirus with unknown human pathogenic potential, Thottapalayam virus, appears in insectivore Asian house shrew (*Suncus murinus* of family Soricidae, order Insectivora), and several unassigned hantaviruses are found in insectivorous shrews and bats as well (Table 60.1) [21–28].

As reservoir hosts for hantaviruses, rodents may become infected for weeks to years without displaying overt clinical diseases, with viruses being concentrated and secreted via saliva, urine, and feces. Under experimental conditions, hantaviruses are generally eliminated during the first 2 months of the life of a rodent, but the elimination of viruses in the wild can take up about 8 months, as shown in bank voles.

Hantaviruses can survive for longer periods if protected by organic material. However, they are susceptible to drying in the environment and are vulnerable to disinfectants (e.g., 1% sodium hypochlorite, 2% glutaraldehyde, 70% ethanol, and detergents). Further, hantaviruses are susceptible to acid (pH 5) and heat (60°C for over 30 min).

Transmission of hantaviruses within rodents is facilitated by aerosols (particularly aerosolized urine), virus-containing saliva and feces, or bites during fighting. Humans generally acquire hantaviruses through inhalation of aerosolized excreta (urine, feces, and saliva) from infected rodents. From the respiratory tract, hantaviruses quickly move to the pulmonary epithelium and endothelium and then disseminate to other tissues and cell types (such as lungs).

Continuing expansion in agricultural or mining activities that disrupt predator–prey relationships has contributed to dramatic rise in rodent populations, and frequent leisure travel and excursions increase human exposure to hantaviruses. Together, these activities are reasons behind the re/emergence of hantavirus outbreaks in human populations [29,30].

Hantavirus infection tends to peak in spring and fall, and occupations at high risk of hantavirus infection include rodent control workers, farmers, forestry workers, hunters, military personnel, field biologists, and laboratory technicians during close contact with infected rodents in disease-endemic areas. In addition, camping or staying in rodent-infested cabins may also increase the risk. A few minutes of exposure to aerosolized virus is sufficient for the infection to establish. Furthermore, broken skin, the conjunctiva and other mucous membranes, rodent bites, and possibly ingestion may be other alternative route of hantavirus entry [31].

60.1.4 Clinical Features and Pathogenesis

In rodents, hantaviruses cause chronic, persistent, and sometimes lifelong infections with relatively few adverse signs, although viruses may be discharged through saliva, urine, and feces over a long period of time and are typically detected in lung and kidney tissue as well as the heart, spleen, liver, and nervous system during the acute phase of infection [32].

However, studies on wild rodents seropositive for the SNV and NYV revealed a high prevalence of pulmonary edema and periportal hepatitis, suggestive of an intermediate form of HPS. In addition, ANDV-infected hamsters showed the sudden and rapid onset of severe respiratory distress similar to HPS observed in humans [33]. In experimentally infected infant rats with SEOV, fatal meningoencephalitis was observed [34].

Overall, an ostensive proinflammatory response against hantaviruses is generally absent in rodent reservoir host. This may be attributable to the fact that (1) hantaviruses tend to cause a nonlytic infection, which does not attract as much attention from host immune surveillance network as in a lytic infection; (2) hantaviruses have the ability to replicate in immune cells such as macrophages, monocytes, and T lymphocytes; and (3) hantaviruses downregulate the cyclic phases of viral replication—the existence of a subtle balance between an efficient immune response to limit viral replication and a strong uncontrollable response that results in fatal illness [35].

In humans, hantaviruses are responsible for two major clinical syndromes: HFRS due to the Old World hantaviruses (such as HTNV, AMRV, SEOV, DOBV, SAAV, PUUV, and TULV), and HPS or HCPS due to the New World hantaviruses (such as ANDV, BAYV, BCCV, LANV, NYV, and SNV) [36].

HFRS, formerly known as Korean hemorrhagic fever, epidemic hemorrhagic fever, or nephropathia epidemica (a mild form of HFRS often caused by PUUV), was first noticed in Korea in 1950s and characterized in 1978. With an incubation period of 1–6 weeks, HFRS demonstrates several stages of progression (febrile, hypotensive/proteinuric, oliguric, diuretic, and convalescent). The initial clinical signs of HFRS are sudden and may include fever, chills, prostration, headache, backache, and blurred vision, along with gastrointestinal signs (e.g., nausea, vomiting, and abdominal pain) that

mimic appendicitis. Additionally, some patients may have a flushed face and conjunctivae, or a petechial rash on the palate or trunk, and photophobia (the febrile or prodromal stage). Later symptoms may include low blood pressure (hypotension), acute shock, vascular leakage, disseminated intravascular coagulation, and acute kidney failure, leading to severe fluid overload (the proteinuric stage) and death from acute shock. In general, HTNV, DOBV, and AMRV cause most severe symptoms (with mortality rates of 10%–15% for HTNV and 7%–12% for DOBV), SEOV results in more moderate disease (with mortality rate of 1%–5%), and PUUV induces typically mild disease (with mortality rate of 0.1%–0.4%). Complete recovery takes weeks or months [31,37].

HPS or HCPS came to prominence in 1993 when a novel hantavirus named Sin Nombre virus (SNV) was described from an outbreak of a respiratory distress syndrome with high case-fatality rate in Southwestern United States. This was followed by the identification of several other HCPS-causing hantaviruses (i.e., ANDV, BCCV, LANV, Juquitiba virus, and Araraquara virus) in North and South America in subsequent years. Since then, HPS/HCPS has been recognized as an emergent disease in the Americas and a significant public health problem in South America [31,38].

The clinical symptoms of HPS/HCPS range from a mild course disease without sequelae to fulminant respiratory distress with high lethality (up to 50% for SNV). At the early (prodrome) phase, the signs of HPS/HCPS may resemble those of other infectious diseases such as influenza and may include fever, myalgia, respiratory abnormality, and headache. However, a lack of rhinorrhea and sore throat may help differentiate HCPS from illness caused by influenza. Often, the patients develop acute noncardiac pulmonary edema and hypotension within 2–15 days, with bilateral infiltrates and occasionally pleural effusions. Marked conjunctival injections, facial flushing, and petechiae are also noted. Laboratory results such as thrombocytopenia, hemoconcentration, neutrophilic leukocytosis, and circulating immunoblasts in patients in living risk regions are additional indicator for HPS/HCPS. Patients often show signs of cardiopulmonary involvement by the time they are hospitalized due to the rapid disease progression; nearly 20% of the individuals may succumb to an acute respiratory distress syndrome before clinical and laboratory investigations are completed. Patients surviving the acute phase of the disease tend to recover normally within 5–7 days without any noticeable sequelae [31,39].

The clinical variability of hantavirus infections may be related to distinct factors, such as viral strain, size of inoculums inhaled, or genetic markers of the host. Hantaviruses appear to target endothelial cells, and viral entry is mediated by β_3-integrins [40]. Hantavirus infection of endothelial cells in the kidneys and lungs leads to increased vascular permeability and subsequent dysfunction mediated by immune responses underscores the distinct clinical manifestations of HFRS and HPS/HCPS [41,42]. As an immunopathologic disease with no evident cytopathic effects in hantavirus-infected human cells, patients with HPS/HCPS often show elevated levels of plasmatic IFN-γ, IL-2, IL-4, IL-6 and TNF-α, and presence of T lymphocyte (CD8+) and other cells producing proinflammatory cytokines in lung tissues [43,44].

60.1.5 Diagnosis

Hantaviruses are responsible for causing HFRS in Eurasia and hantavirus pulmonary syndrome (HPS)/hantavirus cardiopulmonary syndrome (HCPS) in the Americas. As clinical symptoms of these diseases are similar to those caused by influenza and other viral infections, laboratory methods (based on phenotypic and genotypic principles) are required for their correct diagnosis [37,45].

60.1.5.1 Phenotypic Techniques

Hantaviruses may be grown in Vero E6 cells (African green monkey kidney cell line) for initial identification by electron microscopy [46]. Subsequent examination by plaque-reduction neutralization tests provides a definitive diagnosis of hantavirus infection.

In case that in vitro recovery of relevant virus is unsuccessful, serological confirmation of specific IgM in acute phase sera or a rise in IgG titer is diagnostic. The commonly used serological tests include immunofluorescent antibody test, enzyme-linked immunosorbent assays, Western blot (immunoblotting), virus neutralization, and immunochromatographic tests. However, serological tests are only useful after seroconversion, and IgG response may take weeks to develop. In addition, these tests have limited specificity due to the high similarity of hantavirus proteins [47,48].

60.1.5.2 Genotypic Techniques

As an alternative to serological tests, nucleic acid–based procedures offer a more specific and sensitive approach for hantavirus detection, differentiation, and quantification in an early state of infection, before the onset of clinical symptoms [49]. Typically, total RNA is purified from whole blood or serum during the acute phase of infection or from autopsy tissue samples. Primers derived from the conserved regions of hantaviruses are applied in reverse transcription polymerase chain reaction (RT-PCR). The incorporation of SYBR Green dye or fluorescent probes into RT-PCR enables real-time quantification of hantavirus RNA from clinical specimens [48,50–54].

60.1.6 Treatment and Prevention

For patients with HFRS and HPS/HCPS, several treatment/prophylaxis approaches may be attempted. If used early, antiviral ribavirin (1-β-dribofuranosyl-1,2,4-triazole-3-carboxamide) may help reduce renal insufficiency. Administration of human neutralizing antibodies during the acute phase is another beneficial treatment and/or prophylaxis for hantaviral infections. In addition, provision of supportive treatment enhances natural recovery. Patients with suspected hantavirus infection may be given oxygen and mechanical ventilation support to relieve breathing difficulty during the acute pulmonary stage [55].

Prevention of hantavirus infection in humans should focus on (1) limiting exposure to rodent saliva, excreta, and bites;

(2) control of rats and mice in areas frequented by humans; (3) disposing of rodent nests, sealing any cracks and holes in homes where mice or rats may get in; and (4) setting up traps, laying down rodenticides or using natural predators such as cats at home [55].

When handling infected wild mice and rats, protective apparels (e.g., gloves, goggles, rubber boots or disposable shoe covers, coveralls or gown, and respirator masks equipped with N-100 filters) should be worn. Decontamination of infected areas is accomplished by soaking with a 10% (v/v) solution of household bleach [55].

A number of vaccines against hantavirus infections in humans are being developed or in early stages of clinical trials. For example, a vaccinia virus–vectored vaccine containing the M and S genes of HTNV was shown to elicit neutralizing antibodies. A vesicular stomatitis virus expressing hantavirus glycoproteins protects mice against HTNV infection. DNA vaccines containing HTNV, SEOV, PUUV, or ANDV M gene sequences stimulate high-titer neutralizing antibodies against hantavirus challenges [56–58].

60.2 METHODS

60.2.1 Sample Preparation

Considering the dangers posed by hantavirus-containing aerosols, tissues, and serum specimens, laboratory testing of hantaviruses needs extra caution, and all handlings should be preferably in biosafety cabinets with biosafety level 3 (BSL-3) or 4 (BSL-4) rating.

Total RNA is extracted from sera tissues and other specimens by using the TRIzol reagent (Invitrogen) or column-based kits (e.g., QIAamp Viral Mini Kit). The extracted RNA may be quantitated using spectrophotometer and stored at −80°C until used.

60.2.2 Detection Procedures

60.2.2.1 Conventional RT-PCR

Klempa et al. [21] developed a nested RT-PCR assay to detect currently known and possible novel members of the genus *Hantavirus*, with degenerated primers from the highly conserved L segment. Specifically, HAN-L-F1 and HAN-L-R1 are used for the first-round PCR, while primers HAN-L-F2 and HAN-L-R2 are used for the second-round PCR (Table 60.2).

Total RNA is extracted from rodent blood (preserved in liquid nitrogen) using Blood RNA Kit (Peqlab) and reverse transcribed with random hexamers.

The 412 nt sequence of the first PCR product is determined by amplification, cloning, and sequencing of overlapping fragments generated by two seminested PCR.

Note: To further verify the results, additional fragments of 837 nt and 694 nt are amplified from the S and M segments, respectively, by PCR and sequenced. The resulting sequences are subjected to maximum likelihood and neighbor-joining phylogenetic analyses.

TABLE 60.2
Primers for Nested Polymerase Chain Reaction Detection of Hantaviruses

PCR	Primer	Sequence (5′–3′)	Product (bp)
First round	HAN-L-F1	ATGTAYGTBAGTGCWGATGC′	412
	HAN-L-R1	AACCADTCWGTYCCRTCATC	
Second round	HAN-L-F2	TGCWGATGCHACIAARTGGTC	
	HAN-L-R2	GCRTCRTCWGARTGRTGDGCAA	

60.2.2.2 Real-Time RT-PCR

60.2.2.2.1 Pan-Hantavirus Detection

Mohamed et al. [59] described a SYBR Green–based RT-PCR for sensitive detection (<100 copies) of hantavirus RNA of different clades, with six degenerated PanHanta primers from highly conserved regions (2940 and 3481 nt) of the L segment (Table 60.3).

At nonconserved positions within the proposed primer sequences, where three or four different nucleotides are found, deoxyinosine are inserted to reduce the degeneracy of the PCR primers.

RT-PCR mixture (25 μL) is made up of 1 μL cDNA template, 25 μM of each primer, and 12.5 μL of KAPA master mix (KAPA SYBR® FAST qPCR Kit, KAPA Biosystems).

Amplification and detection are carried out in ABI Prism 7900HT Sequence Detection System 2.0 (Applied Biosystems), with the following cycling conditions: an initial denaturation step at 95°C for 3 min, 35 cycles of a denaturation step at 95°C for 15 s, and an annealing temperature of 56°C for 15 s.

60.2.2.2.2 Specific Detection of DOBV, HTNV, PUUV, and SEOV

Aitichou et al. [60] reported a one-step real-time RT-PCR for specific identification of DOBV, HTNV, PUUV, and SEOV, with primers from the S segment, which recognize all four viruses, and virus-specific TaqMan probes containing the fluorescent dyes fluorescein aminohexyl (FAM) at the 5′ terminus and tetramethyrhodamine (TAMRA) at the 3′ terminus (Table 60.4).

TABLE 60.3
Identity of Pan-Hantavirus Primers from Large Segment

Primer	Sequence (5′–3′)	T_m
PanHanta-F1	ATGTATGTIAGTGCWGATGC	54.3–56.4
PanHanta-R1	ACCAITCWGWICCATCAYC	53.0–59.5

PUU1P	FAM-TTC ACA ATT CCT ATC ATT TTG AAG GC-TAMRA	427-452
SEO1P	FAM-CCA TAA TTG TCT ATC TGA CAT CA-TAMRA	404-426

RT-PCR mixture (30 μL) is made up of 0.2 mM dNTP, 4 mM $MgSO_4$, 0.6 μL of RT/Platinum Taq mix (SuperScript™ III One-Step RT-PCR System with Platinum® Taq High Fidelity, Invitrogen), 0.4 μM of each primer, 0.25 μM of TaqMan probe, and various amounts of viral RNA. Separate RT-PCR mixture is prepared for each virus.

The RT and PCR amplification are carried out in a single tube on Smart Cycler (Cepheid) with 1× 50°C for 30 min, 1× 95°C for 2 min, and 45 cycles of 95°C for 15 s, 52°C for 30 s, and 72°C for 1 min.

Note: The RT-PCR assays have detection limits of 25, 25, 25, and 12.5 plaque-forming units for DOBV, HTNV, PUUV, and SEOV, respectively. The DOBV, HTNV, and SEOV assays demonstrate a specificity of 100%, while the PUUV assay shows a specificity of 98%. Therefore, these assays offer rapid, sensitive, and specific approaches for identification and differentiation of four Old World hantaviruses.

60.2.2.2.3 Specific Detection of SNY

Botten et al. [61] reported a real-time RT-PCR targeting the S segment for specific identification of SNV. Use of sense primer SNV S-179f (5′-GCAGACGGGC AGCTGTG-3′) and antisense primer SNV S-245r (5′-AGATCAGCCAGTTCCCGCT-3′) allows amplification of a 66 bp fragment from the SNV S segment, which is detected with a dual-labeled (FAM, TAMRA) fluorescent probe (positive-sense probe starting at nt 198, 5′-TGCATTGGAGACCAAACTCGGAGAACTT-3′).

RT-PCR mixture (50 μL) is made up of 45 μL of master mix (One-Step RT-PCR Master Mix Reagent Kit, Applied Biosystems) containing 0.2 μM of each primers and probe and 5 μL of extracted RNA.

Amplification and detection involve RT (50°C for 30 min), initial denaturation (95°C for 10 min), and 40 cycles of 95°C for 10 s, 50°C for 10 s, and 72°C for 30 s. Data acquisition occurs at the end of the annealing stage (50°C for 10 s) of each amplification cycle.

60.2.2.2.4 Specific Detection of ANDV

Rowe and Pekosz [46] employed a real-time RT-PCR for quantitative detection of ANDV. The primers (forward, 5′-GGAAAACATCACAGCACACGAA-3′, nt 66–87, and reverse, 5′-CTGCCTTCTCGGCATCCTT-3′, nt 118–136) and probe (5′-FAM-AACAGCTCGTGACTGCTCGGCAAAA-TAMRA-3′, nt 89–113) are derived from the ANDV S segment, with the probe containing FAM/TAMRA labels (FAM is 6-carboxyfluorescein; TAMRA is 6-carboxytetramethylrhodamine).

RT-PCR mix is prepared with the ABI TaqMan EZ RT-PCR kit according to the manufacturer's protocol (Applied Biosystems).

Amplification and detection are carried out on ABI 7000 Real-Time PCR System (Applied Biosystems) with the following conditions: RT at 60°C for 30 min, denaturation at 95°C for 2 min, and 40 cycles of denaturation at 95°C for 30 s and annealing and extension at 60°C for 1 min.

60.3 CONCLUSION

Commonly present in rodents of the Murinae, Arvicolinae, and Sigmodontinae subfamilies, hantaviruses are implicated in two clinical diseases in humans: hemorrhagic fever with renal syndrome (HFRS) in Europe and Asia and hantavirus pulmonary syndrome (HPS) or hantavirus cardiopulmonary syndrome (HCPS) in the Americas. Given the existence of a large number of hantavirus species and isolates and the severity of HFRS and HPS/HCPS, laboratory methods are indispensible for diagnosis of hantavirus infections.

Although phenotypic techniques such as virus isolation and serological assays are useful for hantavirus identification, they generally have low sensitivity, poor specificity, and slow result availability. The recent development and application of nucleic acid detection technologies such as RT-PCR have made rapid, sensitive, and specific detection and differentiation of hantaviruses a reality. It is envisaged that these high-performing molecular diagnostic methods will play a vital role in the epidemiological monitoring of hantavirus outbreaks and contribute to the improved control and prevention strategies against these deadly pathogens.

61.1 INTRODUCTION

Arthropod-borne viruses (arboviruses) constitute one of the largest groups of vertebrate viruses of which a majority have the potential to cause devastating epidemics of public health importance. The last few decades witnessed a spurt in the number and frequency of arboviral epidemics impeding socioeconomic development of many tropical countries, majority with a weaker health system. During these outbreaks, death rates were exceptionally high, and the survivors were left in a state of debilitating chronic arthralgia or with neurological complications for the rest of their lives. Introduction of the West Nile virus to the United States in 1999; explosive outbreaks of the Chikungunya virus in Indian Ocean islands, India, and Southeast Asian countries; outbreaks of the tick-borne encephalitis virus in Scandinavian countries; and geographic expansion of the Crimean–Congo hemorrhagic fever virus (CCHFV) in Europe, Africa, and Asia, including India, are some of the major arboviral outbreaks that caused high mortality and morbidity in recent years. Dengue, caused by four different serotypes of dengue virus, continued to be a major global threat with approximately 390 million cases and one million deaths annually. Global warming in association with rapid increase in population, urbanization, and advancements made in human transport and the changing agricultural practices are thought to be the major reasons for the spurt in arboviral outbreaks/epidemics. The changing environmental conditions favored the growth of vector populations, which showed a rapid increase in recent years thereby enhancing the transmission of arboviral infections. Recent decades have shown heavy migration of people across the nations and continents in search of opportunities either exposing themselves or exposing the naïve population to infections with an exotic agent. Despite considerable national and international efforts, arboviral infections continued to be a major public health issue, mainly due to the nonavailability of prophylactics and therapeutics.

Recent decades also witnessed a boom in the incidence of zoonotic viruses causing human outbreaks probably either due to the increased association with animals as part of animal husbandry or due to the explosive increase in vectors. Nairobi sheep disease virus (NSDV), an important member of the genus *Nairovirus* in the family *Bunyaviridae*, is highly pathogenic to sheep and goats in Africa causing acute hemorrhagic gastroenteritis with 70%–90% mortality in susceptible populations. The virus is viscerotropic in sheep and produces ecchymosis in the intestines and hyperplasia of the mesenteric nodes. Virus transmission is mainly through the bite of infected ticks.

Although the virus is deadly to sheep and goat, it is not a major health problem to humans so far as it causes only self-limiting febrile illness. Hybridization studies using RNA probes demonstrated that NSDV is closely related to Hazara virus (HAZV), a member of the CCHFV serogroup, which also includes the highly pathogenic agent CCHFV. NSDV exists in India as Ganjam virus (GANV), which is a milder virus that causes febrile illness and lumbar paralysis in native sheep and goats. This chapter is focused on NSDV biology with its association with other antigenically related viruses.

61.1.1 Classification and History

NSDV is the prototype virus of the genus *Nairovirus*, family *Bunyaviridae*. The genus *Nairovirus* comprises seven serogroups consisting of 34 predominantly tick-borne viruses, majority of which are associated with severe human and livestock diseases [1,2]. CCHFV, Dugbe virus (DUGV), Kupe virus, and GANV are some of the other economically important viruses in the genus. CCHFV is the most important human pathogen among nairoviruses, with a widespread geographical distribution covering Africa, Asia, the Middle East, and Eastern Europe with a case fatality rate ranging from 15% to 70%. This disease affects those people who work in close association with livestock such as agricultural workers, slaughterhouse workers, and veterinarians. Man acquires infection from direct contact with blood or other infected tissues from livestock or through the bite of infected tick. High mortality usually results when the transmission is through blood or respiratory secretions, which are most often intrafamilial or nosocomial in nature. A variant of NSDV is prevalent in the Indian subcontinent as GANV, causing febrile infections in humans and mild infections in sheep and goats [3].

Acute hemorrhagic gastroenteritis in sheep and goats with very high morbidity and mortality rates occurred in large scale in Nairobi, Kenya, and has led to the first isolation of NSDV in 1910 [2]. Inoculation of the blood of a sheep infected with NSDV in susceptible sheep induced acute gastroenteritis in the latter confirming NSDV as the causative agent of the disease [4,5]. The ixodid tick, *Rhipicephalus appendiculatus*, was identified as the transmitting agent of the virus subsequently [6]. Initially, it was thought that NSDV is only endemic in East Africa; however, recent data have shown that it is also prevalent in India and Sri Lanka [3]. Recent studies at the genetic and serologic levels have demonstrated GANV as an Asian variant of NSDV as the two viruses differed only by 10% and 3% at nucleotide and amino acid levels, respectively [3,7]. GANV was first isolated from *Haemaphysalis intermedia* ticks collected from goats suffering from lumbar paralysis in Orissa, India, during 1954–1955 and named after the place of isolation [8]. Subsequent studies have yielded several isolations mainly from *Haemaphysalis* ticks followed by a few from mosquitoes, sheep, and man [9].

61.1.2 Morphology, Genomic Organization, Biology, and Epidemiology

61.1.2.1 Morphology

NSDV virions are mostly spherical (elongated forms can also been seen) having a diameter in the range of 80–120 nm (Figure 61.1). It has a lipid bilayer envelope approximately 5–7 nm thick on which glycoprotein spikes or peplomers are embedded. Peplomers are 5–10 nm long projections from the surface of the envelope and are thought to be consisting of heterodimers of two viral glycoproteins, Gn and Gc. Electron microscopy and biochemical studies suggest that there may be 270–1400 GP peplomers per virion [10]. Being enveloped, the virions are very sensitive to heat, acid pH levels, lipid solvents, detergents, and disinfectants. The viral envelope gets removed after treatment with lipid solvents or nonionic detergents and results in the loss of infectivity [11].

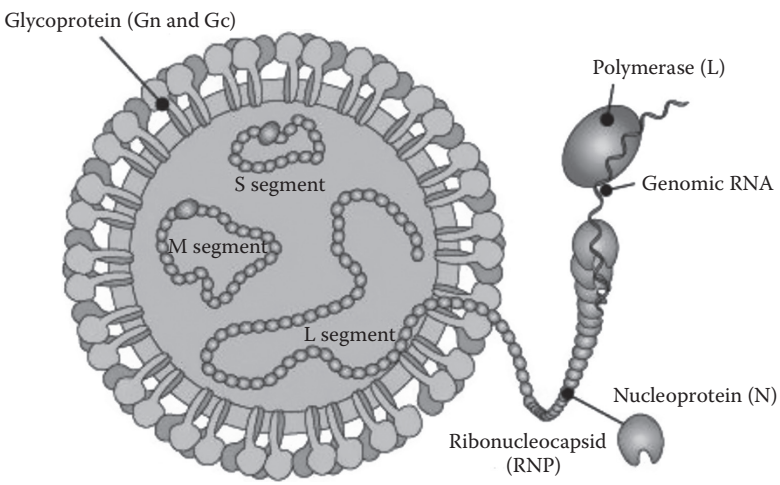

FIGURE 61.1 Structure of Nairobi sheep disease virus. (Courtesy of ExPASY Bioinformatics Resource Portal, SIB Swiss Institute of Bioinformatics, Lausanne, Switzerland.)

61.1.2.2 Genomic Organization

NSDV virion envelope comprises circular and helical nucleocapsid segments, which form the genomic structure. Panhandles, that is, noncovalent bonds between palindromic sequences on the 3′ and 5′ ends of each RNA genome segment, form the nucleocapsid circles [12]. The three RNA segments and the terminal sequences are identical for all the members of the genus *Nairovirus*. The genome consists of three segments of negative-sense, single-stranded RNA, namely, the small (S), medium (M), and large (L) segments (Figure 61.2). The S segment encodes the viral nucleocapsid (N) protein; the M segment encodes precursors to both Gn and Gc (preGn and preGc), which are generated by cotranslational cleavage. Posttranslational cleavage of preGn yields Gn and two other amino-terminal products of unknown function: a mucin-rich product (hypervariable mucin-like domain that is highly O-linked glycosylated) and an additional glycoprotein (GP38). Although a cleavage site at the carboxyl terminus of preGn is not yet identified, evidence of a polypeptide removal exists. The L segment encodes a large viral protein, namely the RNA–dependent RNA polymerase (transcriptase) protein [12]. The carboxyl-terminal half of this protein contains most of the polymerase motifs. The amino-terminal part is largely of unknown function. The L segment, being extremely long (>12 kb) and encoding a single protein of 450 kDa, is unusual among bunyaviruses [13]. Genomic segments can reassort between closely related viruses.

61.1.2.3 Virus Replication

After receptor-mediated endocytosis, virus replication takes place in the cytoplasm of the host cells. The first step after penetration of the host cell and uncoating is the activation of the virion RNA polymerase (transcriptase) and transcription of viral mRNAs from each of the three virion RNAs as genome of the single-stranded, negative-sense RNA viruses cannot be translated directly. The earlier procedure utilizes a cap-snatching mechanism (cleaving 5′-methylated caps from host mRNAs and adding these to viral mRNAs to prime transcription) mediated by the RNA polymerase as it also has endonuclease activity [14]. Translation of L, M, and S mRNAs takes place in the endoplasmic reticulum with cotranslational cleavage of M segment polyprotein and dimerization of Gn and Gc. Membrane-associated RNA replication of the virion RNA occurs after primary viral mRNA transcription. Structural proteins for virion synthesis are formed after a second round of transcription and translation. Morphogenesis requires localization of the N protein in budding compartments with transport of dimerized Gn and Gc to the Golgi where glycosylation takes place, and virions acquire envelopes by budding into the Golgi network in the final stages of assembly. They are then transported in the secretory vesicles through the cytoplasm and released by exocytosis at the cell surface [15]. In some particular cell types, viruses have been observed to bud directly from the host cell plasma membrane.

61.1.2.4 Phylogenetic Analysis

Molecular characterization of NSDV and GANV with respect to S, M, and L segments and its phylogenetic comparison with other members in the *Nairovirus* genus revealed antigenic relationship between the two [3]. Based on the sequence information available in GenBank, it appears that the S segment of GANV and NSDV is considerably shorter (1589 nt) than other characterized nairoviruses (1716, 1672, and 1677 nt for DUGV, CCHFV, and HAZV, respectively). The complete M segment generally encodes two structural glycoproteins for all nairoviruses, while an additional encoded nonstructural protein, NSm, has been described for members of the *Orthobunyavirus*, *Phlebovirus*, and *Tospovirus* genera. Mature glycoproteins encoded by the M segment are generally processed by cotranslational cleavage [16]. However, in DUGV, two surface glycoproteins have been reported: a 73 kDa G1 and a 35 kDa G2 protein [17], while in HAZV, a member of the CCHF serogroup has 3 surface glycoproteins [18]. Analysis of the glycoprotein precursor at amino acid sequence demonstrated the absence of RSKR, which is present in all CCHFV strains but not in DUGV or GANV.

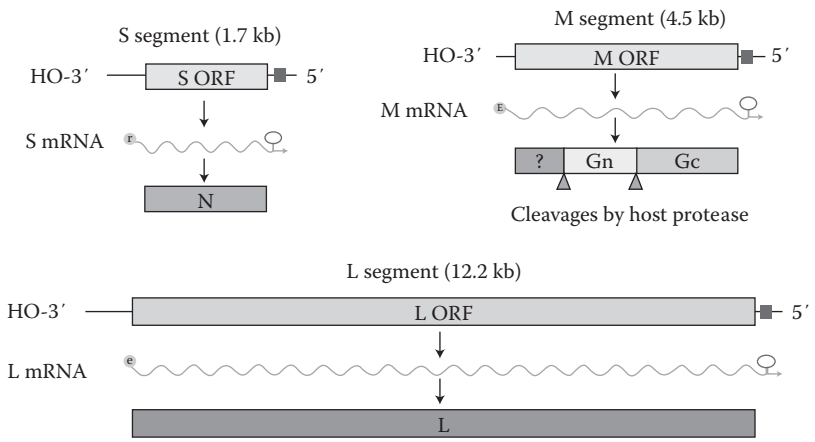

FIGURE 61.2 Genome organization of nairoviruses. (Courtesy of ExPASY Bioinformatics Resource Portal, SIB Swiss Institute of Bioinformatics, Lausanne, Switzerland.)

Phylogenetics of complete S, M, and L segment of Nairobi sheep disease virus and Ganjam virus: Amplification and sequencing of complete S segment of 1590 bp for eight strains of GANV predicted that open reading frame (ORF) encodes an N protein of 482 amino acids in length. The amplified products of M segment of GANV (strain G 619, 779, 6233) and NSDV (strain 708) were sequenced by different primers, and sequences were aligned for phylogenetic study. The complete nucleotide sequences of 5083 and 5063 nt of M gene of GANV and NSDV contained one long ORF of 1624 and 1627 amino acids and is predicted to encode a polyprotein of 180 and 181 kDa, respectively. The N-terminal 24 and 23 amino acids are likely to function as a signal peptide for the two viruses. Similar to CCHFV, topology predictions suggest that GANV and NSDV M polyprotein has the ability to traverse the membrane five times. Although the N-terminal with mucin-like domain characteristic of CCHFV is absent in GANV and NSDV, possibility of O-glycosylation at the N-terminal exists due to the presence of serines and threonines. Unlike CCHFV M genome, RSKR was not available in GANV and NSDV, which is conserved in all CCHFV strains. In CCHFV amino acid motif RRLL, in DUGV amino acid motif RRKL, and in GANV and NSDV amino acid motif RRLM has been found at same position. In CCHF amino acid motif RKPL, in DUGV amino acid motif RKLL, and in NSDV and GANV amino acid motif RRLL has been found at same position. In CCHFV M (IbAr10200) segment, motifs RRLL519 and RKPL1040 were the cleavage sites of Gn (mediated by SKI-1 protease) and Gc (mediated by unknown protease), respectively. Interestingly, in GANV and NSDV, potential SKI-1 or SKI-1-like cleavage sites are located at aa 449 and 453 (RRLM) and aa 972 and 976 (RRLL), respectively, raising the possibility for SKI-1-like proteases in the processing of glycoproteins. However, RKPL found at aa 137 in GANV is not represented in NSDV. A long fragment of amino acid is deleted in CCHFV in comparison to GANV, NSDV, and DUGV from position aa 781–872. An RSxR247 motif responsible for furin/PC-mediated cleavage in CCHFV M segment is absent in GANV and NSDV. Five N-linked glycosylation sites (NxT/S) are present in both viruses, and actual utilization will depend on their topological location and the presence of prolines in the motif. A highly conserved CPYC motif characteristically present in thioredoxin superfamily of proteins is found in two locations in both NSDV and GANV as well as in CCHFV. A hydropathy plot of the M-segment protein shows at least six highly hydrophobic potential membrane–spanning regions. N-terminal mucin-like domain, which is characteristic of CCHFV (aa 247), is comparatively smaller in GANV (aa 95) and DUGV (aa 47). Similarly, 14% of mucin-like domain of CCHF is O-glycosylated but in GANV it is only 10% according to the prediction. L genome of GANV (G 619 and 779) and NSDV is 12080 and 12064 nt, respectively, which is the second largest genome in *Nairovirus* group after DUGV. The ORF of GANV and NSDV starts from 42nd and 43rd positions to 12,015th and 12,016th positions, which encodes 3991 amino acids of 453 kDa for both viruses. GANV polymerase gene is having one ribosome-binding factor A situated at 3813–3835 positions, which is not found in NSDV and other nairoviruses. OTU-like cysteine protease and helicase are located at 29–158 and 35–157 positions, which are similar to that of CCHFV and DUGV. Catalytic sequence in OTU region of GANV differs from CCHFV as GDGNCFYHSIAX100 HFD is found in the latter, while ADGNCFYHSIAX HFD is found in GANV and NSDV. Zinc finger motif is present at same positions 604–627 in both viruses. RNA-dependent RNA polymerase is present at positions 2082–2823, while RNA-directed RNA polymerase is at positions 2378–2593 in both viruses. Sequence comparison showed that DUGV is the biggest genome in the genus *Nairovirus*. KTHIG is absent in NSDV, which is present in all CCHFV [7].

61.1.2.5 Epidemiology

R. appendiculatus (brown ear tick) is the principal vector of NSDV (Figure 61.3). The virus is maintained in the tick life cycle through transovarial and transstadial routes and can persist up to 2 years in adults. Transmission to goats and sheep occurs through the bite of larvae, nymphs, or adults. Transovarial transmission of NSDV was also demonstrated in *R. pulchellus* in Somalia [19]. *Amblyomma variegatum* (African bont tick) also plays an important role in virus transmission as it has been held responsible for an outbreak of Nairobi sheep disease (NSD) in Kenya [20]. However, NSDV was isolated only from *R. appendiculatus* out of eight species of ticks representing three genera (*Amblyomma*, *Hyalomma*, and *Rhipicephalus*) in Kenya [2,4]. A closer relationship exists between the presence of NSDV antibody in sheep and goats and infestations with *R. appendiculatus* rather than with *A. variegatum* [21]. In India, *H. intermedia* is the main vector of GANV, even though the virus has been isolated from *H. wellingtoni* and *Rhipicephalus haemaphysaloides* [22,23]. Perera et al. [24] reported isolation of a virus belonging to the NSD antigenic group from *H. intermedia* in Sri Lanka. NSDV infection should be suspected when there is movement of animals from endemic areas to nonendemic areas and vice versa.

Outbreaks also follow due to incursions of ticks, particularly following heavy rains [25]. Vertebrates develop high viremia, sufficient for virus transmission by ticks [26]. Domestic animals, namely, cattle, sheep, goats, and horses, as well as wild animals such as antelopes and bison are hosts for ticks. Virus spread from the pastoral communities, which exist near wildlife parks, and occasional mixing of wildlife and livestock allows transfer of ticks and possibly viruses between these animal groups. Livestock marketing practices allow movement of animals across the borders in the region, which allows the tick-borne virus to move between countries [27]. Poor husbandry and grazing practices put pressure on land resources resulting in continuous movement of herds of animals in search of pasture causing transmission of infected ticks. When susceptible herds were moved from northern districts to Nairobi area, which is endemic to NSDV, large epizootics of NSDV have been reported [2]. Maternal antibodies protect young animals in endemic areas while they acquire immune protection through active immunity when exposed to the virus. Apart from goats and sheep, no known vertebrate host is infected with the virus even in endemic areas. Human

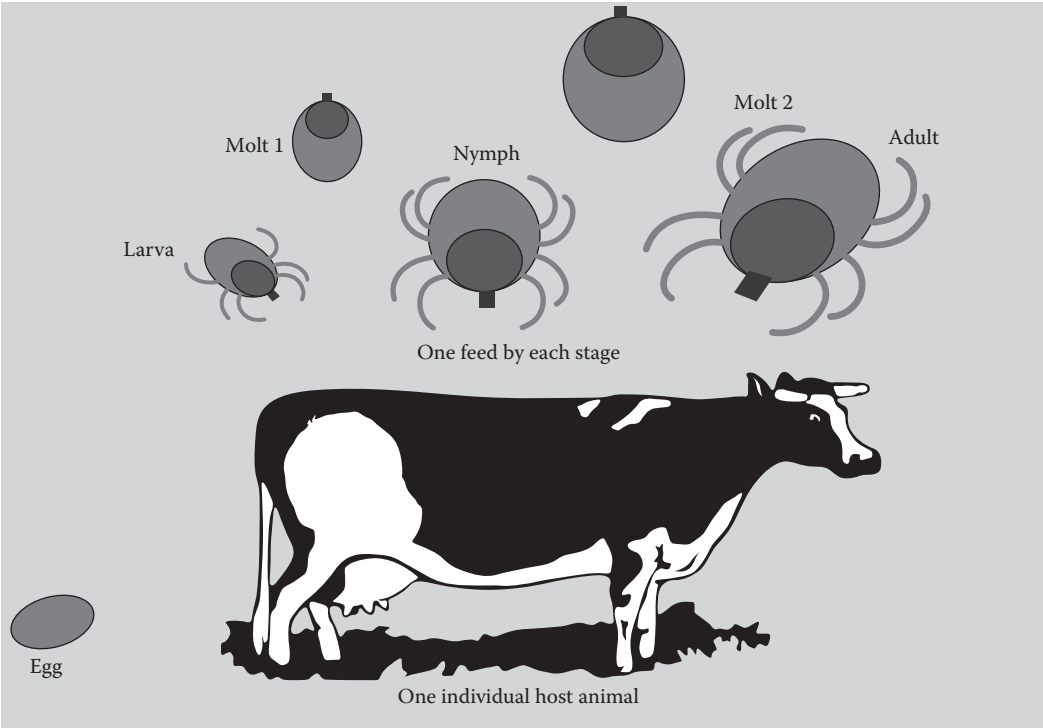

FIGURE 61.3 One host life cycle of *Rhipicephalus appendiculatus* (diagrammatic representation as cows do not get infected with Nairobi sheep disease virus/Ganjam virus). (From Walker, A.R., A one-host life-cycle of a hard tick such as Rhipicephalus (Boophilus) microplus feeding on one individual cow, author's own work, November 28, 2011. Ticks of Domestic Animals. Wikipedia. https://en.wikipedia.org/wiki/Ticks_of_domestic_animals. Last modified July 29, 2015.)

infections are common among pastoral communities in Nairobi as livestock are frequently maintained in enclosures close to human habitation or sometimes inside the houses due to security reasons. The close association increases the potential for virus transmission between animals and humans.

61.1.3 Pathogenesis and Clinical Features

61.1.3.1 Pathogenesis

There have been no detailed studies on the nature of the pathogenesis in NSDV/GANV infections as it was either ignored or misdiagnosed as peste des petits ruminants or Rift Valley fever virus. NSDV infection often results in severe disease in sheep and goats, which are implicated as being important vertebrate hosts [2]. In experimental NSDV infections of sheep, goats, and suckling mice, the virus is found replicating to high titers in the lung, liver, spleen, and other organs of the reticuloendothelial system [28]. Also, in India, GANV has not been taken seriously due to the mild nature of infection in native animals. However, the virus was found highly pathogenic to exotic and crossbred breeds inducing mortality [7,9]. Nevertheless, serology on NSDV/GANV cases has shown increase in IL-6, IL-10, and Tumour Necrosis Factor α (TNF-α) in clinically severe cases. Similarly, it was found that monocyte-derived dendritic cells infected with NSDV/GANV also release IL-6, IL-10, and TNF-α. Tarif et al. showed that pathogenicity of NSDV/GANV is associated with increase in all the aforementioned cytokines and IL-12 as well as due to a decrease in IL-4, all concordant with a Th1, proinflammatory response. Vascular endothelium appears to be the primary cell target. Virus replication in the endothelial cells and release of the aforementioned cytokines results in edema and necrosis of the capillary walls of the mucosal surfaces of the intestine, gall bladder, and female genital tract, leading to congestion, hemorrhage, and catarrhal inflammation. The highly pathogenic isolate leads to more prolonged pyrexia and profound leukopenia that has not previously been reported for NSDV infections, although it is a common clinical sign of viral hemorrhagic fever and may be caused by the large-scale apoptosis of leukocytes [29].

Although differences are observed among various breeds and strains of sheep and goats in the susceptibility to both viruses, clinical symptoms are almost identical. NSDV infection is characterized by acute hemorrhagic gastroenteritis [5]. Clinical signs begin with marked pyrexia and an increase in temperature to 40°C–41°C. This is followed by hyperventilation accompanied by a prominent clinical depression, anorexia, and a disinclination to move. Leukopenia is very prominent during this period of hyperthermia [28]. Diarrhea usually develops within 36–56 h postonset of the febrile reaction, which is profuse, watery, and fetid. Feces become hemorrhagic and mucoid (dysentery) followed by a temperature decline accompanied by colicky pains and tenesmus. Animals stand with lowered head and show conjunctivitis-like symptoms with mucopurulent or serosanguinous nasal discharge. Breathing becomes rapid and painful. Lymph nodes become enlarged and can be palpable. In hyperacute infections, a

sudden rise in body temperature occurs and abruptly declines on the third to sixth day followed by collapse and death, which is associated with severe diarrhea and dehydration. In less acute cases, the course of the disease is slower and death may occur up to 11 days after the onset of clinical signs or survive. It is the native breeds of sheep that show more severe disease than in Merinos with a mortality rate ranging from 40% to 90% [25,30]. East African hair sheep and Persian fat-tailed sheep are highly susceptible to NSD with case fatality rates exceeding 75%. Nonnative to Africa, Romney and Corriedale sheep show a low mortality rate ranging from 30% to 40%. Although mortality rates as high as 90% have been reported in some indigenous breeds of goats, NSDV is less virulent to goats than sheep. Contradictory to NSDV, GANV causes mild infections such as febrile illness and lumbar paralysis to native breeds of goat and sheep and causes high morbidity and mortality in exotic and crossbred sheep and goats [9].

61.1.3.2 Clinical Features in Animals

1. Gross lesions: Pathological lesions due to NSDV in sheep and goats can be misleading as many other febrile diseases of sheep reported from the NSDV endemic areas induce similar types of lesions. Generalized lesions include lymphadenitis with petechial and ecchymotic hemorrhages on the serous surfaces of the alimentary tract, spleen, heart, and other organs [5]. However, in infected animals, hemorrhages on the mucosa of the abomasum, especially along the folds in the ileocaecal valve and most commonly in the colon and rectum, where zebra striping (congestion or hemorrhages appearing as longitudinal striations in the mucosa) may be seen are characteristic of NSDV. Zebra striping of the rectum is more conspicuous than that of the colon. On occasions, enlarged and hemorrhagic gall bladder is also seen. Inflammatory lesions with hemorrhage may also be seen in the female genital tract in case of abortion.
2. Microscopic lesions: Most of the microscopic lesions are seen in the vascular endothelium, which appears to be the primary cell target as virus replication mainly takes place in the endothelial cells. Release of proinflammatory and other cytokines results in edema and necrosis of the capillary walls of the intestine, gall bladder, and female genital tract; leading to congestion, hemorrhage, and catarrhal inflammation. Other common histopathological/microscopic lesions observed are myocardial degeneration, nephritis, and necrosis of the gall bladder.

61.1.3.3 Clinical Features in Humans

Although highly pathogenic to sheep and goats, NSDV and GANV are apparently rare zoonotic agents that cause infections in humans. Natural infections are mostly subclinical or febrile illness with influenza-like symptoms. The clinical signs may include fever, headache, back and abdominal pain, joint pain, nausea, and vomiting as well as conjunctival infection. Laboratory infection has been associated with fever and joint pain in Africa [31], while laboratory-acquired infections with GANV have been reported in India [32].

Specific antibodies to these viruses have been detected in the general population, laboratory workers, and agricultural workers in Uganda, India, and Sri Lanka [8,33]. Even though NSDV and GANV are classified as Biosafety Level 3 agents, the diseases caused by these viruses are not considered to be of public health concern [34].

61.1.4 Diagnosis

NSDV infection should be suspected in sheep or goats, which exhibit hemorrhagic gastroenteritis and nasal discharge in or near an enzootic area. Tick infestation is also supportive. Diagnosis is particularly likely when native sheep/goats do not show clinical signs and only the recently imported sheep or goat shows clinical symptoms. Abortion is a common sequel to NSDV infection. A tentative diagnosis based on postmortem lesions can be sometimes difficult because many animals dying from NSDV do not show these lesions.

Therefore, the use of laboratory techniques is vital for confirmation of NSDV and GANV infections. Virus isolation in either infant mouse or invertebrate cell cultures can be carried out as these systems are susceptible to both NSDV and GANV.

Viral antigens and antibodies in infected or recovered animals can be detected by immunodiffusion, complement fixation (CF), indirect fluorescent antibody test (indirect IFA), hemagglutination, enzyme-linked immunosorbent assay (ELISA), neutralization test (NT), etc. Monoclonal antibodies have been developed against the antigens of NSDV strain I-34 and are being evaluated for their application as diagnostic reagents (OIE).

In particular, direct fluorescent antibody test is used for the identification of virus in tissue culture when no cytopathic effect (CPE) is evident [15]. Hyperimmune mouse ascitic fluids and immune serum prepared in rabbit or sheep conjugated with a fluorescent stain can be used for detection of antigen directly. While the method is simple, nonspecific fluorescence due to other members of the family may occur, which is a major drawback. Further confirmation tests will be required.

Indirect IFA is one of the most suitable tests recommended for detection of antigen/antibodies for the members of *Nairovirus* serogroup. Some drawbacks are associated with this test, including low specificity and erroneous visual reading of results. Since IFA is an indirect test where most of the nonspecific reactions can be avoided, it is one of the methods for screening large number of samples with high specificity. However, cross-reactions with closely associated viruses, namely, DUGV and CCHFV, could be observed [2,8].

ELISA is one of the best diagnostic tests used for detection of antigen and antibodies. With the standardization of techniques using partially purified antigen, diagnosis is specific and rapid [35].

Virus NT is one of the earliest techniques used for detecting antibody prevalence in human and animal sera. It is a

fundamental observation in virology that serum from an animal infected with a virus can neutralize the infectivity of the virus when allowed to react together. Hence, the test can be done virtually with every virus even if the titer of antibodies is low. The loss of infectivity is brought about by interference of the bound antibody with any one of the steps leading to the release of the viral genome into the host cells. The presence of unneutralized virus can be detected by CPE.

In recent years, a range of molecular techniques have been developed and applied for detection of NSDV and GANV nucleic acids. Molecular procedures such as single-step reverse transcription polymerase chain reaction (RT-PCR) and real-time RT-PCR have been standardized for rapid and specific diagnosis of both NSDV and GANV [27,36] (Table 61.1). RNA probes developed from S and M genome segments of DUGV have the potential to be applied as diagnostic tools for NSDV and GANV [17,37].

61.1.5 Prevention and Control

61.1.5.1 Management Practices

It has been shown by epidemiological investigations that outbreaks of NSDV do not occur in a state of enzootic stability. The disease spreads as a result of animal movements from endemic areas to disease-free areas and vice versa. The disease can be controlled by proper management of animals through strict vigilance. Since ticks are the vector of the disease, deticking is important and carried out with the supervision of veterinarians. Although it is largely a disease of sheep and goat, its potential to affect humans represents a serious health concern. People should be made aware of the transmission mechanism of the virus by posters/literature in the endemic areas. Professionals like slaughter house workers, sheep shearers, veterinarians, and others who are directly involved with livestock industry are at risk of contacting the infection. They should be educated to use personal protective

equipment while handling infected animals. Similarly, the use of tick repellents should also be considered while handling livestock as the immature stages and adult ticks are also infective and can transmit the virus by bite. Dead sheep should be buried or incinerated.

Vaccination: No licensed vaccine is available commercially to date either for humans or animals though several studies have been initiated. An attenuated vaccine has been developed by serial passaging; NSDV 35 passages in adult mice were found to cause severe reactions in some breeds of sheep and hence discontinued. A similar vaccine formulation by further mouse brain passages was developed in Entebbe but was found not applicable for vaccination due to its adverse effects. A tissue culture–based vaccine has been found to induce immune response and protection following two inoculations given at an interval of 14 days. However, this vaccine is not produced commercially [2,4].

Treatment: There is no specific treatment available for NSDV. Symptomatic treatment should be practiced against pyrexia, diarrhea, hemorrhages, depression, and other symptoms. Supportive treatment of patients is by means of fluid replacement therapy. Availability of a good-quality feed and protection from climatic adversities may reduce the mortality rate.

61.2 METHODS

61.2.1 Sample Preparation

61.2.1.1 Virus Isolation from Ticks

Virus isolation from ticks can be carried out as described by Joshi et al. [23]. In brief, ticks were allowed to digest blood, pooled according to species, sex, and locality, and triturated in chilled mortars and pestles in 1.5–2 mL minimum essential medium to fine suspension after washing the ticks thoroughly in water followed by surface sterilization with 70% ethanol. The suspension is centrifuged in a refrigerated centrifuge at 6000 × *g*; the supernatant is collected, Millipore filtered, aliquoted, and inoculated into the cell culture system or infant mice. High-speed homogenizers generate linear motion to disrupt samples thoroughly in just seconds. Specialized matrix beads can also be used for homogenization of ticks. An aliquot of the suspension can be used for RNA extraction using Qiagen (Valencia, CA, USA) RNA extraction kit as per manufacturer's instructions.

Virus isolation from animals: Samples such as blood, plasma mesenteric lymph nodes, and spleen tissue from febrile or dead animals can be used for virus isolation. Serum or plasma can be used directly as inoculums. Lymph nodes or spleen should be homogenized to make an approximate 10% (w/v) in growth medium or Bovine albumin in phosphate saline (BAPS) and inoculated in infant mice or cell culture for virus isolation as described earlier. Human serum can be used as inoculum for virus isolation.

Virus isolation in cell culture: Baby hamster kidney (BHK-21-C13) cells, Vero cell line, or any other susceptible cell line can be used for virus isolation [38]. Sample prepared as described earlier or mouse brain filtrate can be used as inoculum. Confluent monolayer cultures of BHK-21-C13 or Vero prepared in 24-well tissue culture plates (NUNC/Corning) were inoculated with the suspension at the rate of 100 μL per well, adsorbed for 1 h at 37°C with rocking at every 10 min and fed with maintenance medium [39]. Cultures were incubated in a 37°C incubator stationary and were observed daily for CPE. Cells were harvested when the cells show 50%–75% CPE. The cultures will undergo freeze–thaw cycle thrice followed by centrifugation in a refrigerated centrifuge as described earlier, and the supernatant will be aliquoted and stored at −80°C as stock virus. One aliquot will be used for confirmation of NSDV using molecular tools or immunofluorescent antibody technique (IFA) or any other confirmation technique (CF, indirect IFA, hemagglutination assay, ELISA, NT, etc.).

Virus isolation in animals: Suspected sample prepared as discussed earlier is inoculated in 2-day-old infant mice through the intracerebral route as described by Joshi et al. [23]. The mice are observed daily for sickness, and when acute sickness is observed, brains are harvested. Virus suspension is prepared in BAPS and confirmed by further passaging in mice followed by other diagnostic techniques such as RT-PCR and IFA.

Samples for agar gel immunodiffusion (AGID) test: AGID can be a valuable primary diagnostic tool for detection of NSDV antigen in tissues. This test has been used successfully with crude antigens prepared either from spleen and mesenteric lymph nodes of infected sheep or infected mouse brain. In brief, approximately 0.5–1 g of the aforementioned tissue is homogenized to give 10%–20% suspensions in phosphate-buffered saline (PBS). The suspension is centrifuged at 1000 g for 10–15 min and the supernatant is used for the test. Hyperimmune serum can be prepared in sheep, mice, or rabbits using isolated virus or tissues such as spleen or brain from an NSDV-infected sheep.

Samples for CF test: The infected tissue culture fluids can be used as antigens for CF tests for virus identification. However, with the standardization of ELISAs and molecular tools, CF test is rarely used as it is complicated by anticomplementary activity of sheep sera [40].

Samples for ELISA: Tissue culture or mouse brain antigen can be used for ELISA for virus identification. Uninfected cells can be used for the preparation of negative control. Positive antigen and negative controls are adsorbed directly onto the ELISA plates, and the test is carried out with NSD immune as well as normal serum [35].

Antigen preparation for IFA: Monolayer cultures of the Vero or BHK cells grown on cover slips either in Leighton tubes or in 24-well plates are infected with characterized strain of NSDV and incubated for 2–3 days at 37°C. At the commencement of infective foci, the cover slips are removed from the growth medium, washed once with PBS, and fixed in chilled acetone for 10 min at room temperature. The cover slips are air-dried and stored at –20°C until use for IFA.

Uninfected cover slips grown with Vero and BHK cells are also fixed and stored to be used as negative control in IFA.

For serodiagnosis of NSDV infection, paired acute and convalescent serum samples should be collected.

61.2.2 Detection Procedures

61.2.2.1 Virus Neutralization Test

Davies et al. described an NT protocol for NSDV detection [2,8]. In brief, serial twofold dilutions of heat-inactivated test serum are placed in 96-well tissue culture plates in quadruplicate and incubated with 2-log $TCID_{50}$ of the virus for 1 h at 37°C. After incubation, the serum–virus mixture is transferred onto susceptible cells (in this case, BHK cells) grown in 96-well plates as designed and incubated for a period of 4–5 days. The cultures are observed for CPE (if not neutralized) and scored under an inverted microscope, stained with Amido Black, and the antibody titer is determined. The disadvantage of this test is that it gives equivocal results with closely related viruses and hence unreliable in this disease.

61.2.2.2 Reverse Transcription Polymerase Chain Reaction

1. RT-PCR for detection of the family *Bunyaviridae*

   Lambert and Lanciotti developed an RT-PCR based on S segment, which is not specific for NSDV [41]. They evaluated numerous alternatives prior to the selection of primers and assay reaction, and then reaction conditions were selected based on the ability to detect the largest number of bunyaviruses with the highest relative sensitivity (Table 61.1).
2. RT-PCR for detection of NSDV

   S segment: Marczinke and Nichol [3] used nucleotide sequence data obtained from their initial PCR products to design additional primers specific for NSDV and GANV. This strategy resulted in the successful determination of the S RNA segment sequence of both viruses. Sang et al. [27] also reported RT-PCR-based diagnosis depending on S as the target gene segment, which encodes nucleoprotein regions (Table 61.1).

   L segment: Honig et al. [36] focused primer designing efforts on the highly conserved polymerase domains located within the L segment of *Nairovirus* genome. Primer targeting for the specific diagnosis of NSDV/GANV needs further testing and refinement (Table 61.1).

   S, M, and L gene segments: Full-length S, M, and L gene segments may also be amplified and sequenced to prove the relationship of NSDV to GANV [7] (Table 61.1).
3. Real-time RT-PCR for detection of NSDV/GANV

   NSDV-specific real-time RT-PCR has been described and is claimed to be more sensitive than other RT-PCRs [29]. They used primer sets from regions that were conserved in NSDV/GANV and not present in other nairoviruses, making it specific for NSDV/GANV. However, it has not yet been fully validated for diagnostic use (Table 61.1).

61.3 CONCLUSION

NSDV is an important disease of sheep and goats in northeast Africa with a mortality rate ranging from 50% to 90% impeding the economies of several countries. GANV, an Asian variant of NSDV, is widely prevalent in India although it causes mild infections in animals. Although GANV is less pathogenic to native animals, it was detrimental to crossbred and exotic varieties of sheep and goats causing huge economic loss in sheep/goat farmers in Tamil Nadu and Andhra Pradesh in India. While both viruses are not found to be pathogenic to humans, necessary preparedness to develop diagnostics and vaccines against them are warranted as they are closely related to the dreaded virus CCHFV, which has the potential to cause large outbreaks with case fatality rates exceeding 50%. Although many conventional techniques are available for the diagnosis of NSDV, such as CF, IFA, and AGID, tools for rapid diagnosis of the virus are the need of the hour. Although RT-PCR and real-time RT-PCR have been developed, more efforts are required to standardize these sensitive and specific procedures. There is also an urgent need for efficient vaccines for animals and humans for protecting humans and livestock in the endemic and nonendemic areas. A comprehensive approach from governments, scientists, and the local people is needed for the development of effective prophylactics/therapeutics to combat against diseases like NSDV.

62.1 INTRODUCTION

Rift Valley fever virus (RVFV) is a mosquito-transmitted virus (or arbovirus) that is endemic in sub-Saharan Africa. In the last decade, Rift Valley fever (RVF) outbreaks have resulted in the loss of human and animal life [1], with significant economic impact [2]. The disease in livestock is primarily associated with sheep, goats, and cattle, leading to abortions and hemorrhagic disease. Camel deaths were also reported in the 2010 RVF outbreak in Mauritania, which has raised concerns about the effects of the virus on these important domestic animals [3]. Severe disease outbreaks that involve human cases and mortality can be predicted by high rainfall and other measurable environmental conditions that contribute to the increased mosquito populations [4]. Similarly, prevalence of the disease in domestic and wild animals is associated with ideal environmental conditions [5]. Climate change and human activities (trade, irrigation, etc.) have increased concerns of arboviral disease outbreaks and movement of arboviruses into new ecosystems [6]. The potential of RVFV 1 day being introduced into new ecosystems such as Europe [7] or North America [8] has emphasized the need for the development and application of highly specific and sensitive diagnostic assays.

62.1.1 Classification, Morphology, and Genome Organization

Bunyaviridae is a large family of viruses with at least five genera: *Bunyavirus*, *Phlebovirus*, *Nairovirus*, *Hantavirus*, and *Tospovirus.* All of these except the tospoviruses infect vertebrates. Three of these genera, *Orthobunyavirus*, *Phlebovirus*, and *Nairovirus*, are associated with arthropod transmission, while the genus *Hantavirus* is typically spread by rodents. RVFV is the most common virus of the genus *Phlebovirus* [9]. Although RVFV has only one serological and immunological type, strains are generally classified into three genetic lineages: Egyptian, West African, and Central-East African. Still, the RVFV nucleotide and amino acid sequences are highly conserved [10].

RVFV particles are spherical, slightly pleomorphic, measure 80–120 nm in diameter and contain no matrix proteins. The virion consists of an envelope covering the genome; this envelope is composed of a lipid bilayer containing the Gn and Gc glycoproteins forming some 350–375 surface spikes, with spikes 10–18 nm in length and 5 nm in diameter [11,12]. The glycoproteins are organized as protruding hollow cylinders on the surface that cluster into distinct capsomers [13]. The surface is covered with 122 capsomers arranged in icosahedral symmetry with a triangulation number of 12 [14]. RVFV has a tripartite single-stranded ambisense RNA genome; the segments are designated according to their sizes as large (L), medium (M), and small (S) with a total length of approximately 11.9 kilobases (kb) [11]. The L segment (~6.4 kb) encodes for the viral RNA-dependent RNA polymerase. The M segment (~3.8 kb) encodes four proteins, two of which are envelope glycoproteins Gn/Gc and two are nonstructural proteins: the 14 kDa NSm and 78 kDa (NSm and Gn fusion peptides) [15,16]. The S segment (~1.6 kb) encodes the N nucleoprotein and the nonstructural protein (NSs) [17]. The viral ribonucleoproteins (RNPs) are composed of three genomic segments, associated with numerous copies of the N

nucleoprotein, and the RNA-dependent RNA polymerase L is packaged into the virion. The RNPs of RVFV have a string-like appearance, while other negative-sense RNA viruses have a structure with helical symmetry [18].

62.1.2 Epidemiology

RVFV was isolated in 1930 after the first outbreak near Lake Naivasha in the Great Rift Valley of Kenya. At that time, RVF was known as a disease of ruminants, particularly of cattle and sheep following sudden death of lambs and ewes [19]. In 1951, severe acute and fatal disease in cattle and sheep caused an estimated death of 100,000 sheep and 500,000 ewes due to abortions that reached 40%–100% among pregnant animals. This was the first epidemic where severe diseases in humans were also reported [20]. Within a short period, RVF was reported in the neighboring countries of Mozambique, Namibia [21], Zambia, and Zimbabwe [22,23].

In 1977, RVFV emerged from the north of the Sahara desert, where it was responsible for a massive epidemic with abortion rates estimated between 80% and 100% in pregnant animals along the Nile River and Delta in Egypt [24]. During the outbreak in Egypt from 1977 to 1978, there were an estimated 200,000 human infections and at least 594 deaths and an antibody prevalence of 29.6% among humans [25]. Common disease symptoms that were associated with RVFV infection in humans included hepatic necrosis with fatal hemorrhagic fever, delayed onset of encephalitis, permanent neurologic deficits, and severe retinitis with permanent blindness [26]. Transmission of the virus to humans was thought to have occurred primarily by direct contact with or exposure to aerosols from RVFV-infected animals or contaminated blood and tissues. The outbreaks in Egypt were possibly the result of windblown-infected mosquitoes, transport of infected animals from the neighboring countries, infected adult mosquitoes emerging from hibernation, or the return of the Egyptian troops from peacekeeping missions in Congo [27].

The introduction of RVFV outside of Africa was reported for the first time in 2000. The outbreaks in Saudi Arabia and Yemen were associated with severe RVFV infections that resulted in fatalities of both humans and livestock. There were an estimated 2000 human infections resulting in at least 245 human deaths and several thousands of sheep, goat, and camel deaths [28]. Phylogenetic analysis of six RVFV strains isolated from *Aedes* mosquitoes during the Saudi Arabia–Yemen outbreak showed no difference to viruses present during the 1997–1998 Kenyan outbreak, and thus the introduction was likely due to imported livestock or infected mosquitoes from Africa [29].

In Madagascar, RVFV was first isolated in 1979 from a pool of mosquitoes from the highlands; however, neither human nor animal cases were reported at that time [30]. The first epizootics occurred in 1990–1991 in humans and livestock in the highlands during two consecutive rainy seasons [31]. In 2008–2009, a large RVFV outbreak occurred, affecting livestock and humans throughout the country with 59 human cases, 19 of which were fatal [32]. A phylogenetic analysis of RVFV strains isolated in 1979, 1990–1991, and 2008–2009 revealed that strains were genetically different and that the virus was most likely introduced from the African mainland by cattle trade [33]. In West Africa, the first RVF outbreak occurred in Mauritania in 1987 and resulted in 220 human deaths [34]. In 1998, an RVF outbreak occurred in southeastern Mauritania, resulting in 300–400 human cases and 6 deaths [35]. In October 2003, nine human cases of hemorrhagic fever were reported in the three provinces of Mauritania as a result of acute RVFV infection. In this case, RVFV was isolated from the mosquito species *Culex poicilipes* and phylogenetic studies revealed little variation among the isolated strains [36]. In 1997, the largest RVFV outbreak was recorded in East Africa with an estimated 27,500 human infections in the Garissa District of Kenya alone [37]. In December 2006, an RVF outbreak was also identified in the Garissa District; however, virus activity was subsequently identified in other parts of Kenya as well as Somalia and Tanzania [38].

Historically, RVF outbreaks in Africa occur at irregular intervals of 5–15 years in the savannah grasslands and 25–35 years in the semiarid regions. Climate and weather are the factors that influence RVFV transmission patterns. In East Africa, outbreaks are significantly influenced by heavy rainfall, which causes natural depressions called "dambos," where RVFV-infected *Aedes* mosquito eggs are laid and hatched. More recently, many devastating outbreaks affecting both humans and domestic animals have occurred throughout a number of African countries including Kenya (2006) [10], Somalia (2006) [39], Sudan (2007) [40], Tanzania (2007) [41], Madagascar (2008) [42], Botswana (2010) [43], Mauritania (2010) [3], Namibia (2010) [44], and South Africa (2008–2011) [45].

62.1.3 Clinical Features and Pathogenesis

The clinical features and pathogenesis of RVFV have been reviewed recently [46–49] and thus will only be summarized here. The review by Davies and Martin [49] provides a thorough description of how to clinically recognize RVF disease. RVFV primarily causes disease in ruminant animals, including sheep, goats, cattle, and camels. The clinical signs of RVF are typically high fever, lymphadenitis, and nasal and ocular discharges in mature animals. Vomiting, abdominal colic, severe prostration, dysgalactia, and jaundice have also been noted. The disease is also associated with profuse hemorrhagic diarrhea. More specific to RVF is the sudden onset of abortion storms, with up to 100% mortality in newborn lambs. Disease outbreaks can affect as few as 15% of susceptible animals to as many as 90% [50]. The disease in other animals such as horses, dogs, cats, and rodents, which can become viremic, is usually subclinical or inapparent. The role of buffaloes, rodents, and other wild animals as potential reservoirs is still unclear [51–53]. Infection in humans can

be subclinical to fatal with disease symptoms including high fever, encephalitis with confusion and coma, ocular degeneration, and hemorrhage [54]. More recent case fatality rates as high as 20% to 50% have been reported [38,90]. Clinical features during this particular epidemic included retinal impairment or failure in 27.5% of human patients [56]. Many of the patients with ocular lesions (71%) remained legally blind for up to 5 years after initially acquiring the disease [57].

62.1.4 Diagnosis

Livestock abortions or sudden deaths during the rainy seasons are the first indicators of RVF. Standard diagnostic assays are available for RVF but availability can be limited. The international-approved protocols for these tests are described in the World Organization for Animal Health, Office International des Epizooties Terrestrial Manual [58]. Methods used include virus neutralization test, hemagglutination inhibition tests, immunofluorescence assay, and complement fixation test (CFT). The detection of immunoglobulin G or M (IgG or IgM) antibodies specific for RVFV in serum samples is widely used in laboratories to confirm the disease. A number of viral nucleic acid–based diagnostic tests have also been described [59].

62.1.4.1 Conventional Techniques

Virus neutralization test (*VNT*): VNTs including microneutralization, plaque reduction neutralization test (PRNT) [60], and neutralization in mice have been used to detect antibodies against RVFV in the serum of a variety of species. VNTs are highly specific and sensitive, but these tests require live viruses; thus, trained personnel can only do them in appropriate biosecurity facilities. Attenuated strains, such as the MP-12 vaccine strain, can be used for VNT assays providing a good estimation of wild-type virus VNT results.

Hemagglutination inhibition (*HI*): Sucrose/acetone-extracted hamster liver antigen and erythrocytes are used in the HI test, following well-established protocols [58]. The antigen is initially mixed with the RVFV serum sample and incubated overnight at 4°C; erythrocytes are then added to the antigen–serum mixtures. Results are read after 30 min at room temperature. A solid-phase immunosorbent technique can be developed to detect RVFV-specific IgM in human serum samples. Plates coated with goat antihuman IgM are incubated with serum samples, RVFV hemagglutinating antigen, and erythrocytes. The RVFV-specific IgM in the serum samples binds to the RVFV antigen and inhibits hemagglutination of erythrocytes. The advantages of HI assays are that results can be obtained within 5 h, reagents are inexpensive, and several hundred serum samples can be tested daily without the need for specialized equipment. However, there is the potential for false-positive results due to nonspecific agglutinins.

Indirect immunofluorescence assay (*IFA*): RVFV may be detected by immunofluorescence on impression smears of the liver, spleen, and brain. This is a method to detect viral infection in multiple types of host cells. This procedure can be modified for both high-throughput and low-throughput assays for any virus for which antibodies are available. In comparison with PRNT, IFA is less sensitive in detecting RVF viral antibodies than either HI or enzyme-linked immunosorbent assay (ELISA). Although reagents for IFA are relatively easy to obtain, IFA is very subjective and interpretation of results may vary between observers, thus resulting in false-positives (low specificity). In addition, IFA requires a fluorescence microscope, which may not be readily available to every diagnostic lab.

Complement fixation test (*CFT*): CFT is generally used for detecting RVF viral antibodies during acute infections. Although CFT is quite specific, the low sensitivity of this method in detecting RVF viral antibodies, even during acute infections, limits its usefulness [58].

62.1.4.2 Molecular Techniques

Molecular diagnostic methods allow the detection and identification of virus-specific nucleic acid, proteins, and antibodies with high specificity and sensitivity. Although they do require specialized reagents and equipment, they are faster than virus isolation or VNTs, which can take up to a week, and they are safer for the laboratory personnel performing the assays, because infectious samples can be inactivated prior to testing.

62.1.4.2.1 Reverse-Transcription Polymerase Chain Reaction

There are a number of sequence-based assays that have been developed with broad to very specific diagnostic capabilities. Reverse-transcription polymerase chain reaction (RT-PCR) assays enable rapid detection with high-throughput and multiplexing capabilities, are specific and sensitive, and can be performed by biosafety level (BSL)-2 laboratories after inactivation of infectious samples. This type of assay can be performed on blood, serum, and homogenized tissues. RT-PCR for the detection of RVFV nucleic acid (RNA) is important for early diagnosis and monitoring acute viremia. A detailed summary of published primers and probes designed for RT-PCR and real-time RT-PCR detection of RVFV from 1997 to 2011 has been reviewed previously [61]. These will be discussed here briefly with the addition of assays published in 2012 and 2013.

Early RT-PCR assays for RVFV were developed as single target assays to detect Gn-specific amplification of the M segment or NSs of the S segment of the RVFV genome [58]. These were effective as diagnostic tools for screening human and animal sera early in infection during the outbreaks of the disease [62]. Advancement to real-time RT-PCR assays allowed for not only detection of RVFV but also quantitation of the virus. Real-time RT-PCR assays were developed

to target the L, M, and S segments of the RVFV genome [63]. Highly sensitive and broadly reactive, these assays could detect 21 distinct strains representing all lineages of RVFV with as little as 5 RNA copies per reaction [64] or 37 different RVFV strains with a limit of 100 RNA copies per reaction [65]. To expedite the procedure for a more high-throughput format optimal for diagnostic laboratories, a one-step real-time RT-PCR assay for RVFV was developed [66] based on the primers published by [64]. A more economical real-time RT-PCR assay was published using the SYBR Green for the detection of RVFV with a limit of 300 RNA copies [67]. More recently, a real-time RT-PCR assay able to detect all three RVFV genome segments with differentiation of infected and vaccinated animals (DIVA) compatibility was developed [63]. This assay uses both L and M segments as confirmatory targets and the NSs as the DIVA-compatible marker, which is deleted in the commercially available clone 13 vaccine in South Africa as well as other candidate vaccines in development.

More broad-based and multiplexed assays have been developed as well, which allow detection of multiple viruses per test. A nested RT-PCR assay for the detection of phleboviruses in general was able to detect RVF, Toscana, sandfly fever, Aguacate, and Punta Toro viruses [68]. A multiplexed real-time RT-PCR assay to diagnose 8 different hemorrhagic fever viruses including RVFV was developed with a detection limit of 2.8×10^3 RVFV genome/mL plasma [69]. Another multiplex assay to detect RVFV and other RNA emerging viruses had a limit of 1.5×10^3 RNA copies per reaction for the detection of RVFV [70]. A more sensitive multiplex RT-PCR assay was able to detect and specifically identify RVFV, bluetongue virus, rinderpest virus, and peste des petits ruminants virus, with a limit of $10^{1.1}$ $TCID_{50}$/mL of an RVFV blood sample [71].

62.1.4.2.2 Reverse-Transcription Loop-Mediated Isothermal Amplification

RT loop-mediated isothermal amplification (RT-LAMP) assays that are faster than real-time RT-PCR, are highly sensitive, and have been successful for detecting a wide range of RVFV strains have also been developed. This type of assay uses multiple primer sets and can be performed at a constant temperature without the need for a thermocycler and is therefore advantageous for field diagnostic testing. RT-LAMP assays targeting the L segment are able to detect RVFV within 30 min, with as few as 10 RNA copies per reaction [72,73]. A more recent assay targeting the S segment demonstrated sensitivity of 19 RVFV molecules and was able to detect 20 different RVFV strains [74].

62.1.4.2.3 Enzyme-Linked Immunosorbent Assay

Although rapid and sensitive, RNA-based methods are most effective at an early time during the infection while the animal or individual is viremic, which may only last for a very short period of time. Reactions can also become easily contaminated, compromising the assay. Contamination may come from the environment where the specimen was collected or from within the lab where samples are prepared. Therefore, confirmatory tests based on the presence of viral antigen or antibodies are desirable. A number of ELISA formats for the detection of RVFV antigens or antibodies have been developed and have been reviewed previously by [48]. The disadvantages of many antigen-based assays include reagents that can be cumbersome and expensive to produce and, in many cases, require handling of live virus. The development of antigen for ELISAs using recombinant proteins has helped address safety concerns since they do not require infectious materials and samples can be inactivated prior to performing the procedure. Recombinant nucleocapsid proteins (rNPs) have been validated extensively and shown to be highly accurate for the detection of anti-RVFV antibody in humans and animals [75–78]. A sandwich ELISA for antigen detection using an RVFV rNP has proven to be effective at detecting a variety of RVFV strains from both human and animal samples at limits as low as $\log_{10}10^{2.2}$ $TCID_{50}$ per reaction and with a little cross-reactivity to other closely related phleboviruses [79]. An indirect ELISA based on RVFV recombinant glycoprotein Gn for the detection of IgG antibodies recently developed demonstrated sensitivity and specificity above 94% compared to viral neutralization [80]. The concurrent detection of IgG and IgM antibodies to RVFV has also been described [81]. Reactivity profiles of several baculovirus-expressed RVFV recombinant proteins against a panel of immune sera from natural hosts were recently evaluated and may be promising candidates for the development of improved diagnostic methods, which incorporate DIVA compatibility [82].

62.1.4.2.4 Antibodies for the Detection of Rift Valley Fever Virus–Specific Antigens

The generation of good monoclonal antibodies is also important for improving the specificity of ELISAs and other rapid antigen detection tests such as dipstick/strip tests or lateral flow devices [83,84]. Anti-RVFV antibodies are also important tools for the detection of RVFV antigen by immunohistochemistry (IHC) in fixed tissues [66]. The generation of monoclonal antibodies with a high specificity against recombinant RVFV proteins is needed for the development of safer diagnostic reagents and methods [84].

It is recommended that RVFV-specific antibody tests be run in parallel with nucleic acid–based and antigen-based detection methods because the short duration of RVFV viremia limits the effective time frame for use of these detection methods. Seroconversion can be determined early after infection, in subclinical or mild infections, and postviremia using RVFV-specific antibody assays [60].

62.1.4.2.5 Fluorescent Microsphere–Based Immunoassays

Fluorescent microsphere–based immunoassays (FMIAs) are promising for rapid, high-throughput, and multiplexed diagnostic tests based on nucleic acid, antigen, or antibody detection. FMIAs are simple to run, are cost-effective,

and have the potential to be highly sensitive and specific. Differential assays can be designed for the detection of multiple targets of a single pathogen or the detection of multiple pathogens using different color markers assigned to each target. The development of these types of multiplex assays enables the detection of RVFV and/or other pathogens in a single reaction with a minimal sample requirement. An assay for the simultaneous detection of RVFV antibodies against the virus nucleocapsid and the Gn glycoprotein was recently published [85]. To increase specificity and provide potential DIVA compatibility, additional RVFV antigens were added. The resulting test includes four recombinant antigens, N nucleoprotein, two nonstructural proteins (NSm and NSs), and two glycoproteins (Gn and Gc), which are produced in *E. coli* or baculovirus and affinity purified [86]. The advantage of FMIA is the ability to detect multiple targets in a single assay. Multiplex panels containing domestic pathogen targets in a nonendemic country that include RVFV targets as markers to reroute positive samples to national laboratories could result in early detection and rapid response.

62.2 METHODS

62.2.1 Sample Preparation

Handling and preparation of infected samples poses great health risk to personnel and often requires selecting BSL-3 or BSL-4 laboratories for processing suspected RVFV-infected specimens. Furthermore, there are few labs that are capable to handle such samples. Therefore, there is a critical need to safely inactivate infected tissues that would allow safe handling and expedite diagnostic confirmation by BSL-2 laboratories. For assays such as virus isolation or VNTs, inactivation is not an option; however, inactivation is permissible for most molecular diagnostic assays. The inactivation method used is dependent on the type of sample and the type of assay that will be used. Formalin fixation is usually suitable for tissues that are being prepared for histopathology and IHC analysis. For blood and serum samples tested by ELISA or FMIA, thermochemical inactivation is sufficient. For example, 1% Tween-20 added at an equal volume followed by incubation at 56°C for 1 h was demonstrated for the inactivation of RVFV up to $\log_{10}$ $10^{6.5}$ $TCDI_{50}$/mL [79]. For RNA-based assays, the virus is inactivated by the addition of guanidinium isothiocyanate and phenol-containing RNA extraction reagents that are available commercially, such as TriPure or TRIzol reagents [87]. The preferred method is to use phenol-containing RNA extraction, as that is the most effective means to inactivate the virus. Magnetic bead–based systems that can be automated are then used to provide cleaner template for amplification [88].

The serum, brain, spleen, and liver are the preferred tissues for diagnostic testing. The serum is ideal for diagnostic screening because sample preparation requires little manipulation and equipment, and it can be collected with minimal stress from the animal or individual. To improve detection by molecular diagnostic assays, one study found out that detection of RVFV was enhanced when whole-blood samples were used versus the serum only, likely due to the association of RVFV with monocytes and macrophages [88]. However, it may not be possible to acquire blood or serum samples especially if the animal is found deceased. Tissues are typically the first samples submitted to diagnostic labs during an outbreak. The condition of the tissues submitted, as well as which diagnostic tools are available to the reference laboratory, determines the type of assay used for diagnostic testing.

62.2.2 Detection Procedures

Nucleic acid amplification systems: Given the high sensitivity of nucleic acid amplification assays, the availability of a dedicated "clean," nucleic acid–free PCR hood and workspace is critical in helping reduce contamination risk and increase assay reliability. Gloves should be worn and changed often, and RNase-free reagents and materials should be used. Sample template should be prepared in a physically separated area if possible and added last to the reaction mix just prior to amplification. For RT-PCR, as well as for all other diagnostic tests, standardized positive and negative controls should be prepared and analyzed alongside test samples. Due to issues from potential contamination, closed systems such as real-time RT-PCR are recommended. Real-time RT-PCR samples with amplification occurring at cycle threshold (Ct) < 35.00 should be considered positive. If amplification occurs, but has a Ct value between 35 and 40, and/or the curve is low to the threshold, the real-time RT-PCR should be repeated and/or the RNA should be reextracted and tested again. If amplification does not occur, a Ct value must be obtained for the positive control to ensure the RNA extraction procedure was successful. At a minimum, an external amplification control should be used to monitor for inhibitors. Ideally, an internal or constitutively transcribed gene is also used to monitor for the quality of the RNA in the sample.

The multiplex RVF real-time RT-PCR assay was designed to have internal confirmation and be DIVA compatible with RVFV NSs-deleted vaccines [63]. This assay combines standard real-time RT-PCR assays [64,69] for detection and internal confirmation. The NSs target was specifically designed to be in the NSs coding region, thus DIVA compatible [63]. Finally, an external RNA amplification control was used to monitor amplification inhibitors [89]. The primer and probe designs are listed in Tables 62.1 and 62.2. The reaction mixture is described in Table 62.3. Interpretation of the results is described in Table 62.4. The primers and probe mixtures can be adjusted to meet the individual purposes. For example, if there is no need for a DIVA-compatible diagnostic test, the S primers and probe can be omitted. The amplification conditions consist of 45°C for 10 min and 95°C for 10 min, followed by 40 cycles of 45°C for 15 s and then 60°C for 60 s.

TABLE 62.1
Rift Valley Fever Virus Primers for Real-Time Reverse-Transcription Polymerase Chain Reaction

Primer	Final Conc. (μM)	Nucleotide Sequence 5′–3′

TABLE 62.4
Interpretation of the Rift Valley Fever Virus Multiplex Real-Time Reverse-Transcription Polymerase Chain Reaction Results

L Segment (CFR610) Status	M Segment (FAM) Status	S Segment (QUASAR670) Status	XIPC (Cy3) Internal Control RNA	Sample Interpretation
Negative	Negative	Negative	Positive	The sample is negative for RVFV.
Positive	Negative	Negative	Positive	The sample is positive for L segment and deemed positive for RVFV.
Negative	Positive	Negative	Positive	The sample is positive for M segment and deemed positive for RVFV.
Negative	Negative	Positive	Positive	The sample is positive for S segment and deemed positive for RVFV.
Positive	Positive	Negative	Positive	The RVFV sample is possibly NSs-deleted vaccinate.
Positive	Positive	Positive	Positive	L/M/S segments positive, the sample is positive for RVFV.
Positive/negative	Positive/negative	Positive/negative	Negative	Probable loss of RNA during extraction procedure. There is a new RNA extraction necessary to confirm results of assay.

62.3 CONCLUSION

There are numerous assays available for the detection of antibodies to RVFV, viral antigen, or RNA. The limitation of many of these assays is the requirement for high biosecurity to ensure the safety of diagnostic staff. Although there are ELISAs available for the detection of antibodies to RVFV, often the reagents have limited availability and are expensive to produce. Several research laboratories have developed recombinant protein–based RVFV serological tests that provide safer alternatives to assays that require production of RVFV-infected cell lysates. Two of these assays are commercially available (BDSL, Ayrshire, Scotland, and IdVet, Grabels, France). The molecular-based real-time assays such as the one described here provide rapid inactivation of this zoonotic viral pathogen and high sensitivity for the detection of RVFV RNA. Detection of viral RNA should not be considered as definitive confirmation of infectious virus, but it is a rapid and strong presumptive test. Data from several studies demonstrate the importance of combining assays (e.g., antigen capture, RT-PCR, or virus isolation) for the identification of viruses and diagnosis of the disease, as well as monitoring of virus-specific IgM to ensure that no acutely RVFV-infected animals or patients are missed [56].

63.1 INTRODUCTION

Schmallenberg virus (SBV) is an orthobunyavirus that was first identified using a metagenomic approach from dairy cattle near the town of Schmallenberg in Germany in October 2011. The virus causes fever, diarrhea, and a drop in milk yield in ruminants, as well as congenital malformations and stillbirths in calves, lambs, and goat kids. Since its initial description, SBV has been reported in thousands of cattle, sheep, and goat farms across Europe [1].

63.1.1 Classification

SBV is classified in the Simbu serogroup, genus *Orthobunyavirus*, family *Bunyaviridae*.

The family *Bunyaviridae* covers an expanding group of enveloped, tripartite, negative-sense, single-stranded RNA viruses, which in the latest estimate includes about 330 viruses that form five genera, 97 species, and 81 tentative species, as well as a large number of unassigned isolates. Of the five genera (*Hantavirus*, *Nairovirus*, *Orthobunyavirus*, *Phlebovirus*, and *Tospovirus*) recognized within the family *Bunyaviridae*, the genera *Orthobunyavirus* and *Phlebovirus* involve mosquitoes and mammals in their life cycles, with humans acquiring the viruses via mosquito bites; the genus *Nairovirus* circulates between ticks and mammals, and humans become infected through tick bites; the genus *Hantavirus* is perpetuated in persistently infected small mammals (rodents and occasionally insectivorous shrews and bats), with incidental human infections arising from inhalation of aerosolized rodent excreta; and the genus *Tospovirus* is maintained between trips (commonly known as thunder flies or corn lice) and plants.

Accounting for 170 of the 350 viruses within the family *Bunyaviridae*, the genus *Orthobunyavirus* is separated into 48 species: Acara virus, Akabane virus (AKAV), Alajuela virus, Anopheles A virus, Anopheles B virus, Bakau virus, Batama virus, Benevides virus, Bertioga virus, Bimiti virus, Botambi virus, Bunyamwera virus, Bushbush virus, Bwamba virus, California encephalitis virus, Capim virus, Caraparu virus, Catu virus, Estero Real virus, Gamboa virus, Guajara virus, Guama virus, Guaroa virus, Kaeng Khoi virus, Kairi virus, Koongol virus, M'Poko virus, Madrid virus, Main Drain virus, Manzanilla virus, Marituba virus, Minatitlan virus, Nyando virus, Olifantsvlei virus, Oriboca virus, Oropouche virus, Patois virus, Sathuperi virus (SATV), Shamonda virus (SHAV), Shuni virus, Simbu virus, Tacaiuma virus, Tete virus, Thimiri virus, Timboteua virus, Turlock virus, Wyeomyia virus, and Zegla virus, with Bunyamwera virus being the prototype virus for the genus as well as for the family [2].

Examination of antigenic relationships among members of the genus *Orthobunyavirus* by plaque reduction neutralization, hemagglutination inhibition, complement fixation, and radial immunodiffusion tests led to the differentiation of 19 serogroups: Anopheles, Bakau, Bunyamwera, Bwamba, California, Capim, Gamboa, Group C, Guama, Koongol, Mapputta, Minatitlan, Nyando, Olifantsvlei, Patois, Simbu, Tete, Turlock, and Wyeomyia [3].

As one of the largest serogroups within the genus *Orthobunyavirus*, the Simbu serogroup consists of at least 25 related viruses, including Iquitos virus, Jatobal virus, Leanyer virus, Oropouche virus, Oya virus, Thimiri virus, Akabane serocomplex (AKAV, Sabo virus, and Tinaroo virus), Sathuperi serocomplex (SATV, Douglas virus [DOUV],

and SBV), Shuni serocomplex (Aino virus and Shuni virus), Shamonda serocomplex (SHAV, Peaton virus, and Sango virus), and Simbu complex (Simbu virus). Members of the Simbu serogroup are arthropod-borne (or arboviruses), with transmission facilitated by *Culicoides* biting midges and mosquitoes. Some of the viruses in this serogroup produce a syndrome in ruminants referred to as arthrogryposis–hydranencephaly syndrome, presenting with abortions, stillbirths, and congenital defects in neonatal cattle, sheep, and goats, following infection during pregnancy.

First emerged in Europe in 2011, SMV shares 69% identity with AKAV in the L segment, 71% identity with Aino virus in the M segment, and 97% identity with SHAV in the S segment in the initial phylogenetic analysis [4]. Additional sequence comparisons revealed that the SBV shows the highest homology to SATV and DOUV in the M segment and has a close genetic relationship with SHAV in the S and L segments. Recent full-genome and serologic investigations indicate that SBV belongs to the SATV species and represents an ancestor of SHAV, which appears to be a reassortant containing the S and L genomic segments from SBV and the M segment from an unclassified virus [5–7].

The closest relatives to SBV appear to be Sathuperi, Douglas, Shamonda, Akabane, Aino, Peaton, or Sango viruses, but these viruses have not been identified in Europe to date.

Among these, SATV was initially isolated in India and Nigeria in the 1980s and appeared in Japan in 1999.

SHAV was identified from cattle and *Culicoides* biting midges in Nigeria in the 1960s and emerged in Japan in 2002. The fact that the nucleotide sequences of Japanese strains of SHAV isolated in 2005 differ by only 3% from those of strains isolated in Nigeria 30 years before highlights its relative genetic stability [8].

AKAV is a teratogenic virus closely related to SBV, with presence in Australia, Japan, Israel, Turkey, and Cyprus. Spread by *Culicoides imicola*, AKAV infection of dams between the third and sixth month of the 9-month gestation results in congenital defects (primarily in the central nervous system and skeletal muscle) in cattle (see Chapter 59).

63.1.2 Morphology and Genome Organization

Morphologically, SBV is similar to other members of the family *Bunyaviridae* and has an enveloped, spherical virion of 100 nm in diameter, with surface glycoproteins (Gn and Gc) projecting from an outer envelope. The lipid layer of the envelope is acquired during budding at the Golgi apparatus lumen.

Beneath the envelope are three filamentous, helical nucleocapsids (of 200–3000 nm in length and 2–2.5 nm in width), which are composed of multiple copies of nucleocapsid (N) protein encapsidating each of the three segments of antisense, single-stranded RNA, designated S (small, 830 nt), M (medium, 4,415 nt), and L (large, 6,865 nt) segments, with approximately 12,000 nt in total.

The L segment encodes the RNA-dependent RNA polymerase L (or L protein), which interacts with the nucleoprotein N to form the viral polymerase complex. Inside the virus particle, the viral genome associates with many copies of the nucleoprotein N and a few copies of the polymerase L forming ribonucleoprotein (RNP).

The M segment encodes a precursor polyprotein that is cleaved cotranslationally into the envelope glycoproteins Gn and Gc and the nonstructural protein NSm, which is situated between the glycoproteins Gn and Gc in the precursor polyprotein. Consisting of three hydrophobic and two nonhydrophobic domains, NSm may act as a scaffolding protein during viral assembly.

The S segment encodes the nucleoprotein N and the nonstructural protein NSs, which are encoded from the +1 open reading frame (ORF) within the N ORF. The NSs proteins are not essential for virus growth but contribute to viral pathogenesis.

63.1.3 Biology and Epidemiology

Similar to other bunyaviruses, SBV utilizes the Gn/Gc heterodimers on the viral surface to bind to cellular receptors and enters the host cell via endocytosis. This induces conformational changes in the viral glycoproteins and exposes the Gc fusion peptide. This facilitates fusion between viral envelope and endosomal membranes, and release of RNP inside the cytoplasm. Subsequent transcription produces viral mRNA, which is translated into viral proteins by host cell ribosomes. The L protein generates complementary copies of positive-sense antigenomes, from which negative-sense genomes are synthesized. The viral genome interacts with N proteins forming new genome RNP, which accumulates in the Golgi complex. The glycoproteins Gn and Gc form heterodimer complexes in the endoplasmic reticulum and are transported to the Golgi apparatus. The genome RNP interacts with the C-terminal domains of the glycoproteins Gn and Gc, and mature virus particles are then transported to the plasma membrane and then released in the extracellular compartment by exocytosis [9].

After its first description in dairy cattle in Germany in 2011, SBV was identified by reverse transcription polymerase chain reaction (RT-PCR) in sheep with the birth of malformed lambs displaying crooked neck, hydrocephalus, and stiff joints in the Netherlands the following month. By March 2012, the virus was shown to be present in cattle, sheep, or goats in Belgium, the United Kingdom, France, Luxembourg, Italy, and Spain [10,11]. The development of serological assays in early 2012 facilitated detection of anti-SBV antibodies in ruminants in Denmark, Switzerland, Austria, Poland, Sweden, Scotland, Finland, Ireland, Northern Ireland, Norway, Czech Republic, Estonia, Slovenia, Turkey, and Greece within a 2-year period [12–14]. Overall, SBV has been detected in 2062 cattle, 2482 sheep, and 77 goat farms by later 2012. However, relatively small percentages of sheep (up to 6.6%) and cattle (4%) in these farms were positive for SBV, suggesting the limited impact of SBV on animal health [15–17].

Members of the Simbu serogroup are known to be transmitted by *Culicoides* biting midges, and sometimes by

mosquitoes of the *Aedes* and *Culex* genera as well as by several tick species. The fact that SBV was detected by RT-PCR in several *Culicoides* species (*C. obsoletus complex*, *C. scoticus*, *C. chiopterus*, *C. dewulfii*, *C. pulicaris*, or *C. nubeculosus*) in Belgium, Denmark, the Netherlands, Norway, Poland, and Sweden, where animal infections with SBV were diagnosed, confirms the role of biting midges in the transmission of this virus [18–22]. However, the absence of SBV in hibernating mosquitoes during winter indicates a limited role of mosquitoes in the persistence of SBV in colder months [23].

Besides cattle, sheep, and goats, SBV is infective to bison, wild cervids, and llamas, in which the virus does not seem to induce clinical signs or macroscopic abnormalities. Similarly, experimental infection of pigs with SBV induces seroconversion, but virus replication and transmission are ineffective [24]. However, SBV infection in humans has not been reported so far [16].

63.1.4 Clinical Features and Pathogenesis

SBV induces various clinical signs in ruminants of different age groups and host species.

In adult cows, clinical symptoms due to SBV infection include loss of appetite, hyperthermia, diarrhea, and reduction (up to 50%) in milk production. Symptoms often abate within a few days, along with transient viremia (lasting for 2–6 days) [25]. In adult sheep and goats, SBV infection causes very mild symptoms for and for only a few days [9,26].

However, SBV infection in pregnant females may facilitate virus transmission to fetuses (ovine, caprine, and bovine), leading to atypical congenital malformations, intrauterine death, death immediately after birth, or premature birth. The aborted and stillborn animals may show a neuromusculoskeletal disorder called arthrogryposis, severe torticollis, ankylosis, kyphosis, lordosis, scoliosis, brachygnathia inferior, and neurological disorders (e.g., amaurosis, ataxia, and/or behavioral abnormalities). In twin gestation, arthrogryposis versus neurological disorders, or malformation versus delayed growth, may be seen in one but not the other [9].

Necropsy of stillborn and malformed newborn reveals hydranencephaly (lack of the brain cerebral hemispheres), hydrocephaly, cerebral and cerebellar hypoplasia, and porencephaly. Calf born at term may display severe central nervous system lesions, dysfunctions of the cerebral cortex, basal ganglia and mesencephalon, porencephaly, or hydranencephaly [9,27].

Histological examination uncovers lymphohistiocytic meningoencephalomyelitis with glial nodules in the mesencephalon and hippocampus in lambs and goats and neuronal degeneration and necrosis in the brain stem of calves. Astrogliosis, microgliosis, and sometimes myofibrillar hypoplasia of skeletal muscles are detected in both calves and lambs. In addition, calf may display evidence of poliomyelitis [9].

SBV RNA is detectable in brain, blood, or spleen samples in malformed aborted or stillborn ruminants [28].

The observation of various neurological signs and associated pathological changes suggests that neurons are the major target for SBV replication in naturally infected newborn lambs and calves. Although the underlying mechanisms of SBV pathogenicity are yet to be elucidated, they may be inferred from findings derived from other bunyaviruses. For example, NSs from Bunyamwera (Bunyamwera serogroup) antagonizes the expression of type I interferon, inhibits the transcription mediated by RNA polymerase II, blocks protein synthesis, and contributes to apoptosis mediated by IRF-3 (interferon regulatory transcription factor) [9,29].

63.1.5 Diagnosis

As SBV infections are usually subclinical and their reporting is not required by the veterinary regulations of most countries, the epizootic situation may be monitored by midge testing. The transovarial transmission of SBV in the midge population has been demonstrated to be possible, which may explain the overwintering of the virus in insects in the absence of acute infections detectable in ruminants. SBV spread into the colder and harsher climates of Europe may be related to the involvement of other vectors, such as that of *Culicoides punctatus* as described here.

Laboratory identification of SBV is possible by virus isolation, serology, and nucleic acid detection [30].

Viral isolation: Vero (African green monkey kidney epithelial), BHK21 (baby hamster kidney fibroblast), or KC (*Culicoides variipennis* larvae) cells may be used for SBV isolation from brain, serum, or blood samples. Typically, the homogenate sample is inoculated on KC cells (cell line L1062). After 5 days of incubation, cytopathic effects are visible. Following initial isolation on KC cells, the virus is passaged 3–5 times in baby hamster kidney (BHK21) cells (cell line L0164) (inoculum I: KC/BHK), alternatively once in BHK21 cells, again in KC cells and again in BHK cells (inoculum II: KC/BHK/KC/BHK) [4].

Serology: When SBV is isolated, virus neutralization tests and a plaque reduction neutralization test may be utilized to detect antibodies present in the serum of infected animals [31]. Indirect ELISA test is useful for serological diagnosis of SBV infection [32]. However, a positive serological result does not indicate that an animal is currently infected or that animal will give birth to an affected fetus [33,34].

Nucleic acid detection: SBV RNA is present in a variety of tissues from affected lambs and calves, particularly the cerebrum, spinal cord, external placental fluid, and umbilical cord. This provides an opportunity to diagnosis of SBV infection based on detection of the viral RNA using RT-PCR or other nucleic acid amplification techniques [35–38]. RT-PCR targeting the conserved regions of the S, M, and L segments of SBV has been developed. A real-time TaqMan assay with primers from the S segment enables detection of 1–10 genome copies of SBV [39,40]. A pan-Simbu real-time RT-PCR system targeting the L segment allows rapid and sensitive detection of members of the Simbu serogroup of SBV.

63.1.6 Treatment and Prevention

As no specific treatment is currently available for SBV infection, effective management of outbreaks and strategic deployment of vaccines are important for the control and prevention of SBV [41].

In the event of an SBV outbreak, thorough disinfection with viral disinfectants such as hypochlorite, chlorhexidine, alcohol, and phenols is beneficial. To prevent further SBV outbreak, management priorities should include sentinel monitoring of vectors and cattle, conducting mating in cattle and sheep to outside of the vector season, avoiding transportation of naïve animals to endemic areas for mating or during pregnancy, and application of a sensitive test to detect SBV RNA in semen [42,43].

Vaccination is a vital preventive measure against SBV infection [44]. Inactivated vaccines have been shown to provide complete protection of sheep against SBV infection [45]. Other vaccines for SBV are in the pipeline.

63.2 METHODS

63.2.1 Sample Preparation

Serum and fecal samples are collected from affected animals. For malformed lambs or calves, the cerebrum and the spinal cord are collected from areas with malformations. Other suitable samples include external placental fluid and umbilical cord.

For RNA extraction from serum, 200 μL serum is added to 400 μL working solution (High Pure Viral RNA Kit, Roche), vortexed, and incubated at room temperature for 10 min. Subsequently, the mixture is spiked with 5 μL of internal control (IC) RNA (8×10^5 copies/μL). After mixing, the solution is centrifuged through a high pure filter tube. In the next step, 500 μL inhibitor removal buffer is added to the filter tube and again centrifuged. After washing the column twice with the appropriate buffer, RNA is eluted with 50 μL elution buffer and stored at −20°C [39,46].

For RNA extraction from tissues, about 0.5 cm^3 of tissue is homogenized in 1 mL phosphate buffered saline (PBS) containing 10–15 1 mm silicon carbide beads (BioSpec Products, Inc.) via high-speed shaking (2 min, 25 Hz) in TissueLyser (Qiagen). The homogenate is then processed by using RNeasy Mini Kit (Qiagen) and RNA is eluted in 50 μL RNase-free water.

For RNA extraction from feces, 1 mL of PBS is added to approximately 100 mg of feces and homogenized in TissueLyser (3 min, 10 Hz). Next, 200 μL of the homogenate is added to 800 μL TRIzol and shaken in TissueLyser (5 min, 10 Hz). Then, 200 μL of chloroform is added, and phase separation is performed (Life Technologies). Total RNA present in the aqueous phase is extracted using Viral RNA Mini Kit (Qiagen) and eluted in 60 μL elution buffer.

For RNA extraction from insect pools, the insect pools are first homogenized in Lysing Matrix D tubes (MP Biomedicals) containing 1.4 mm ceramic beads and 1 mL of TRI Reagent (Sigma–Aldrich) and in FastPrep 120 ribolyzer (Thermo Electron Corp.) for 90 s at 6.5 m/s speed. Total RNA is extracted using 2-propanol, chloroform, and ethanol. Extracted RNA is suspended in 20 μL of nuclease-free water and stored at −70°C until testing [47].

63.2.2 Detection Procedures

63.2.2.1 RT-PCR for Schmallenberg Virus Detection

Bilk et al. [39] described a RT-PCR for rapid identification and quantitation of SBV with primers and probe designed from the S segment of SBV genome (Table 63.1). The inclusion of internal control primers and probe from epidermal growth factor (EGF) gene allows effective monitoring of sample preparation and amplification efficiency.

RT-PCR mixture (25 μL) is composed of 2.5 μL RNase-free water, 12.5 μL 2 × RT-PCR buffer, 1.0 μL 25 × RT-PCR enzyme mix (AgPath-ID One-Step RT-PCR Kit, Applied Biosystems), 2 μL SBV-specific primer–probe mix (10 μM SBV-specific primers +1.875 μM SBV-specific probes) and 2 μL IC-specific primer–probe mix (2.5 μM epidermal growth factor protein (EGFP)-specific primers +1.875 μM EGFP1-hexachlorofluoresceine (HEX) probe), and 5 μL RNA template.

Amplification and detection are conducted with the following temperature profile: 10 min at 45°C (RT), 10 min at 95°C (inactivation reverse transcriptase/activation Taq DNA polymerase), followed by 42 cycles of 15 s at 95°C (denaturation), 20 s at 55°C (annealing), and 30 s at 72°C (elongation).

Note: This real-time RT-PCR is highly sensitive with a detection limit of 1–10 copies of SBV genome per reaction. In addition, the assay is able to detect the highly related SATV species member DOUV as well as the reassortant SHAV [40].

TABLE 63.1
Identity of Schmallenberg Virus and Internal Control Primer and Probes

Primer/Probe	Sequence (5′→3′)	Genome Position	Amount per Reaction (μM)
SBV-S-382F	TCA GAT TGT CAT GCC CCT TGC	382–402	10
SBV-S-469R	TTC GGC CCC AGG TGC AAA TC	450–469	10
SBV-S-408FAM	FAM-TTA AGG GAT GCA CCT GGG CCG ATG GT-BHQ1	408–433	1.875
EGFP1-F	GAC CAC TAC CAG CAG AAC AC	637–656	2.5
EGFP2-R	GAA CTC CAG CAG GAC CAT G	768–750	2.5
EGFP1-HEX	HEX-AGC ACC CAG TCC GCC CTG AGC A-BHQ1	703–724	1.875

63.2.2.2 RT-PCR for Pan-Simbu Serogroup Detection

Fischer et al. [40] developed a pan-Simbu real-time RT-PCR with primers (panOBV-L-2959F: 5′-TTG GAG ART ATG ARG CTA ARA TGT G-3′, and panOBV-L-3274R: 5′-TGA GCA CTC CAT TTN GAC ATR TC-3′) targeting nt 2888–3167 of the L segment.

RT-PCR mixture (25 μL) is made up of 8 μL RNase-free water, 5 μL 5× One-Step RT-PCR Buffer, 1 μL One-Step RT-PCR Enzyme Mix (One-Step RT-PCR Kit Qiagen), 1 μL dNTP Mix (10 mM each), 1 μL ResoLight Dye (Roche), 2 μL of each primer (panOBV-L-2959F and panOBV-L-3274R; 10 μM each), and 5 μL RNA template (or RNase-free water for the no template control).

Amplification and detection is carried out with the following thermal program: 1 cycle of 50°C for 30 min and 95°C for 15 min, followed by 40 cycles of 95°C for 30 s, 55°C for 30 s, 72°C for 30 s, and 78°C for 15 s. The collection of the fluorescence data is performed during the 78°C elongation step.

Note: The pan-Simbu real-time RT-PCR system detects all members of the Simbu serogroup under investigation as well as three Bunyamwera serogroup viruses. Subsequent species classification is possible after sequencing the amplified product.

63.3 CONCLUSION

SBV is a newly emerged arthropod-borne virus of ruminants (e.g., cattle, sheep, and goats) that causes congenital deformities in young born to adults infected in their first trimester (sheep) or second trimester (cattle), and reduces milk production in dairy cows. First identified in Germany in the autumn of 2011, SBV has been since reported in various countries in Europe and Turkey. Given the significant economic impact of SBV on ruminant breeders and dairy farmers, use of rapid, sensitive, and specific laboratory tests such as RT-PCR is essential for its identification and control. The discovery of SBV highlights the power of molecular techniques in the studies of uncharacterized infectious agents that escape the attention of conventional diagnostic procedures. There is no doubt that continuing refinement and application of these state-of-art techniques will help unravel the molecular basis of SBV pathogenicity, leading to improved control and prevention strategies against SBV infection.

64.1 INTRODUCTION

The *Arenaviridae* family comprises of a diverse group of single-stranded RNA viruses. There are currently 25 confirmed members, most of which do not cause human disease. They have life cycles intimately associated with rodent reservoirs, a trait that imposes varied geographical limits on each member. Lymphocytic choriomeningitis virus (LCMV), the prototype virus, was first described in 1934 by Armstrong and Lily. It is the most widely distributed of the *Arenaviridae*, being found worldwide in the house mouse (*Mus musculus*). The study of LCMV and its host is to a large extent responsible for our understanding of immunology and virus–host interactions.

With the exception of LCMV, which causes viral encephalitis and meningitis in humans, all other arenaviruses associated with human disease cause viral hemorrhagic fevers. Five arenaviruses are known to consistently cause human diseases: LCMV causes lymphocytic choriomeningitis worldwide; Lassa virus (LASV) causes Lassa fever in West Africa; Junin virus (JUNV) causes Argentine hemorrhagic fever in Argentina; Machupo virus (MACV) causes Bolivian hemorrhagic fever in Bolivia; and Guanarito virus (GTOV) causes Venezuelan hemorrhagic fever in Venezuela. The viruses causing these diseases will be the subject of this chapter. Several other arenaviruses implicated in human illness are primarily involved in isolated cases of sporadic natural infections or accidental laboratory infections. These are Sabiá virus (SABV) in Brazil [1], Chapare virus (CHAV) in Bolivia [2], Whitewater Arroyo virus (WWAV) [3], Pichinde virus (PICV), Tacaribe virus (TCRV), Flexal virus (FLEV) [4], and Lujo virus (LUJV) [5].

64.1.1 Classification

The family *Arenaviridae* has a single unique genus, *Arenavirus*, which currently has 25 virus species and several tentative members, all with similar morphological, physiochemical, serological, and biological properties (Table 64.1). Traditionally, the arenaviruses are divided into two serocomplexes: the lymphocytic choriomeningitis–Lassa (Old World) complex and

TABLE 64.1
Arenaviruses

Virus Species	Acronym	Lineage	Human Pathogenicity	Geographic Distribution	Primary Natural Host Reservoir
Old World Arenaviruses					
Ippy virus	IPPYV		No evidence	Central African Republic	*Arvicanthis niloticus*
Lassa virus	LASV		HF[a], sore throat, nausea	West Africa (Sierra Leone, Guinea, Liberia, and Nigeria)	*Mastomys* spp.
Lujo virus	LUJV		HF, diarrhea, vomiting, sore throat	Zambia	Unknown
Luna virus	LUNV		No evidence	Zambia	*Mastomys natalensis*
Lymphocytic choriomeningitis virus	LCMV		Meningitis or encephalitis, biphasic fever, nausea, teratogenic	Worldwide	*Mus musculus*
Mobala virus	MOBV		No evidence	Central African Republic	*Praomys* spp.
Mopeia virus	MOPV		No evidence	Mozambique, Zimbabwe	*Mastomys natalensis*
New World Arenaviruses (North and Central America)					
Bear Canyon virus	BCNV	Rec/A	No evidence	United States	*Peromyscus californicus*
Tamiami virus	TAMV	Rec/A	No evidence	Florida, United States	*Sigmodon hispidus*
Whitewater Arroyo virus	WWAV	Rec/A	HF, respiratory distress, liver failure	New Mexico, United States	*Neotoma albigula*
New World Arenaviruses (South America)					
Allpahuayo virus	ALLV	A	No evidence	Peru	*Oecomys bicolor*
Amapari virus	AMAV	B	No evidence	Brazil	*Oryzomys capito*
Chapare virus	CHPV	B	HF, headache, body aches	Bolivia	Unknown
Cupixi virus	CPXV	B	No evidence	Brazil	*Oryzomys capito*
Flexal virus	FLEV	A	Fever	Brazil	*Oryzomys capito*
Guanarito virus	GTOV	B	HF	Venezuela	*Zygodontomys brevicauda*
Junín virus	JUNV	B	HF	Argentina	*Calomys musculinus*
Latino virus	LATV	C	No evidence	Bolivia	*Calomys callosus*
Machupo virus	MACV	B	HF	Bolivia	*Calomys callosus*
Oliveros virus	OLVV	C	No evidence	Argentina	*Bolomys obscurus*
Paraná virus	PARV	A	No evidence	Paraguay	*Oryzomys buccinatus*
Pichinde virus	PICV	A	Subclinical infection	Colombia	*Oryzomys albigularis*
Pirital virus	PARV	A	No evidence	Venezuela	*Sigmodon alstoni*
Sabiá virus	SABV	B	HF	Brazil	Unknown
Tacaribe virus	TCRV	B	Fever, mild neurological signs	Trinidad	*Artibeus* spp.

[a] Major clinical signs including HF—hemorrhagic fever clinical (petechial, fever, etc.) and biological (thrombocytopenia) signs.

the Tacaribe (New World) complex. Designations of viruses into Old World and New World groups are based on antigenic differences in immunological tests, disease etiology, reservoir host species, geographical range, and protein sequence [7,8]. The Old World viruses are represented by the prototype (LCMV) that is found worldwide and causes viral encephalitis and meningitis in humans. Among the Old World arenaviruses, LCMV causes acute aseptic meningoencephalitis and congenital malformations of the central nervous system (CNS) in humans worldwide. In Africa, two arenaviruses are highly pathogenic for humans and can cause viral hemorrhagic fever. These include LASV associated with Lassa fever in West Africa and LUJV that has caused disease in Southern Africa. Among the New World arenaviruses, three viruses are highly pathogenic for humans and consistently cause viral hemorrhagic fever. These include MACV causing Bolivian hemorrhagic fever, JUNV causing Argentine hemorrhagic fever, and GTOV causing Venezuelan hemorrhagic fever. Two other viruses, CHAV and SABV, have potential to cause significant human disease. Four other arenaviruses are associated with human disease, but the disease is less severe or occurs infrequently; these are PICV, TCRV, FLEV, and WWAV [4].

64.1.2 Morphology, Genome Organization, and Biology

The arenaviruses (from the Latin word *arenosus*, meaning "sandy") derive their name from the *sandy* appearance in electron micrographs that generally results from host-derived ribosomes (20–25 nm) incorporated into the virion [9]. Arenavirus virions are spherical to pleomorphic in shape with a diameter of 50–300 nm. They are surrounded by a dense host-derived lipid envelope covered with viral glycoproteins, appearing as long (8–10 nm) club-shaped projections.

The arenavirus genome consists of two single-stranded ambisense RNA segments. The large (L) genomic segment (7.2 kb) encodes the L polymerase protein and the Z matrix protein. The small (S) genomic segment (3.5 kb) encodes the nucleoprotein (NP) and the glycoprotein complex (GPC) that is posttranslationally cleaved into a stable signal peptide and two envelope glycoproteins (GP1 and GP2). The proteins are translated by a unique ambisense strategy. Each genome segment encodes two proteins from open reading frames of opposite sense (Figure 64.1). From each segment, one protein is encoded directly from the viral RNA (vRNA) genome sequence, while the second protein is encoded from opposite sense or viral complementary RNA (vcRNA). The genes are separated by noncoding intergenic regions that can form hairpin loops and may function in termination of transcription of mRNA from the vRNA and vcRNA [10]. The 5′ and 3′ untranslated region of each RNA segment have spans of 19 nucleotides of relatively conserved reverse complementarity and form a panhandle structure at the end of the virus genome [11]. The L and NP proteins are translated through an mRNA transcribed by the virus RNA polymerase from the vRNA sequence of the L and S genomic segments, respectively. These translated proteins are thought to take part in the full-length vcRNA synthesis, which then becomes the template for transcription of the Z and GPC mRNA for translation of the respective proteins and synthesis of full-length vRNA [12]. The mRNAs are not polyadenylated but are capped using a unique cap-snatching method where cellular mRNA caps serve as primers for mRNA synthesis [13].

The L protein is an RNA-dependent RNA polymerase and along with the NP is the minimum requirement for RNA replication and transcription [8,14]. The NP encapsidates the genome segments to form the nucleocapsid, making it the most abundant structural protein in the virion. The NP has a variety of functions. It interacts with the L polymerase protein for RNA replication and transcription and with the Z matrix protein for viral assembly. The NP also plays a role in suppression of the innate immune response and exhibits exonuclease and nucleotide binding activity. The GPC and its subsequent GP1 and GP2 forms are responsible for host cell tropism, mediating virus assembly and entry into the host cell and uncoating of the virion. The Z matrix protein is a small zinc-binding protein that interacts with all of the other viral proteins [15]. These interactions play roles in viral transcription and replication with the L polymerase protein, in virus assembly with the glycoproteins, in virus budding with the NP, and in proapoptotic activity.

Rodents are the natural hosts of arenaviruses. TCRV, the prototype of the New World serocomplex, is the only exception, being associated with fruit-eating bats (*Artibeus* species) [16]. Each arenavirus species is closely associated with a

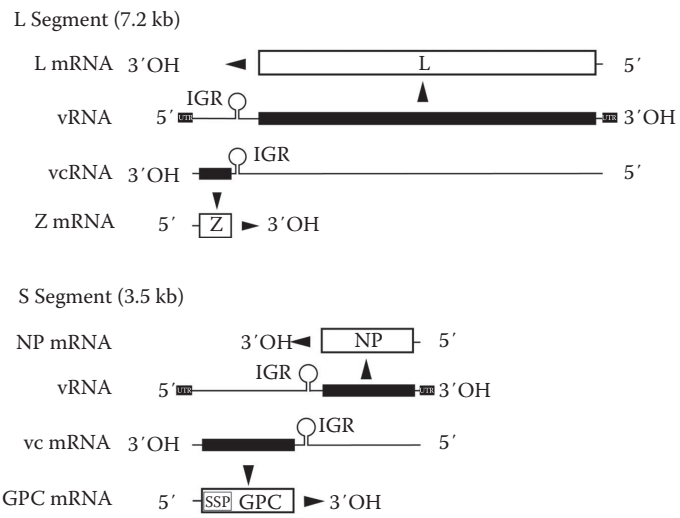

FIGURE 64.1 Organization, transcription, and replication of the arenavirus large and small genomic RNAs. Genomic regions encoding the polymerase (L), matrix (Z), nucleoprotein (NP), and glycoprotein complex (GPC) proteins are shown as solid bars, and the resulting proteins are shown as open boxes with arrowheads indicating the notional direction of translation. GPC is posttranslationally cleaved into a stable signal peptide and two envelope glycoproteins (GP1 and GP2). RNA transcription processes are indicated by vertical arrows. The intergenic regions (IGR) separate the open reading frames. Viral RNA segments have untranslated regions at their 5′ and 3′ termini. (Adapted from Zapata, J.C. and Salvato, M.S., *Viruses*, 5, 241, 2013; Salvato, M.S. et al., Arenaviridae, in *Virus Taxonomy*, *Ninth Report of the International Committee on Taxonomy of Viruses*, King, A.M.Q., Adams, M.J., Carstens, E.B., and Lefkowitz, E.J., Eds., Elsevier, San Diego, CA, 2012, 715pp.)

single rodent species or closely related group of species. This intimate association of rodent host and virus species has led to the speculation that the host and virus have coevolved over millennia. The coevolution is thought to have begun with the split of the rodent family *Muridae* into the subfamily *Murinae* that evolved into the Old World rodents and the subfamily *Sigmodontinae* that evolved into the New World rodents. The ancestral arenaviruses that infected each rodent subfamily codiverged and, through a long, shared evolutionary relationship, cospeciated. In many instances, the phylogeny of the arenavirus species matches the phylogeny of the rodent reservoir [17–19]. The hypothesis for rodent and arenavirus cospeciation is not universally accepted. Contradictions exist that are not explained by the model, such as the isolation of TCRV from bats rather than rodents, or New World viruses of different lineages that have the same rodent host [18,20,21]. Alternatively, a combination of virus transfers between rodent species with subsequent cospeciation would explain not only the virus–host pairings not explained by the coevolution hypothesis but also the bat host of TCRV [18,22]. Regardless, the pattern of geographical distribution of the arenaviruses coincides with their rodent hosts; however, the arenavirus distribution is patchy or discontinuous within the rodent geographical range [23]. Within the arenavirus host ranges, there are areas of greater rodent infection rates that correlate with increased human disease. Seasonal increases in rodent populations and/or greater rodent–human contacts are also associated with increase outbreaks.

Arenavirus infections are generally considered to be asymptomatic in the rodent reservoir host. This asymptomatic infection can lead to a chronic viremia and/or viruria, in which virus is continually shed in urine and feces throughout the life of the rodent host. This significant source of virus in the environment has ramifications for the epidemiology of the diseases they cause. Within the rodent populations, virus is transmitted through horizontal (direct contact), vertical (infected mother to offspring), and sexual transmission. Depending on the age an individual becomes infected, the rodents can be immunocompetent developing immunity and recovering or immunotolerant and not develop immunity and remain chronically infected. Chronic infections can be detrimental to the infected host and reduce their fitness or fertility. Arenaviruses are naturally transmitted to humans through contact with infected rodent hosts either directly, through bites, trapping, or meat preparation, or indirectly by ingesting food or inhalation of fomites contaminated with rodent urine or feces. Nosocomial infections can occur through infected bodily fluids during the care of the sick or preparation of the dead. Transmission has also resulted from tissue transplantation from infected donors.

64.1.2.1 Lymphocytic Choriomeningitis Virus

LCMV is more noted for its contributions as an experimental system for the understanding of viral immunology and pathogenesis than for the disease it causes in humans. The virus was discovered in 1933 by Armstrong and Lillie during an outbreak of St. Louis encephalitis in humans [24]. LCMV has worldwide geographic distribution by virtue of its natural reservoir host, the common house mouse subspecies *Mus musculus musculus* and *Mus musculus domesticus*. This reservoir host, often living in close association with humans, is persistently infected by intrauterine infection and fails to mount an immune response to the virus. The resulting chronic, lifelong infection results in the mice shedding large amounts of virus in urine and feces, as well as nasal secretions, saliva, milk, and semen [25]. Serological studies of wild mice suggest that the antibody prevalence ranges from 3% to 20% [26].

The incidence of human infection with LCMV is unknown, but considering the worldwide distribution of chronically infected mice, the disease is likely underrecognized and underreported. Humans are often infected through mucosal infection of aerosolized fomites contaminated with mouse excreta or by direct contact through bites. Congenital infections of the fetus can cause a severe form of disease that differs pathologically from its acquired version. In humans, serological studies in the Americas and Europe indicate that prevalence ranges from 1% to 9% [27]. In the United States, overall prevalence is around 5%; however, a 1992 study done in Baltimore, Maryland, found a 9% seroprevalence in mice, with a corresponding 13.4% in humans in inner city locations, the highest recorded in the United States [28].

Infected mice and Syrian hamsters in the pet trade and laboratory research have resulted in large outbreaks of human disease [29,30]. The largest LCMV outbreak occurred in 1973–1974 causing 181 human cases in 12 states. The source of the infections was traced back to infected pet hamsters from a single supplier [31,32]. Person-to-person transmission has occurred through solid-organ transplants and has resulted in a high mortality rate in the immunosuppressed recipients; however, this is not a normal route of infection [33,34]. One transplant-associated LCMV infection was traced to the organ donor infected by a pet hamster [35]. Approximately 3% of the hamsters in the pet supplier population were infected with LCMV and resulted in U.S. CDC issuing guidance to minimize risk of LCMV infection associated with rodents.

64.1.2.2 Lassa Virus

LASV, the cause of Lassa fever, occurs in West Africa and is hyperendemic in Sierra Leone, Guinea, Liberia, and Nigeria. It was first isolated in 1969 from a fatal case in a missionary nurse working in the town of Lassa in northeastern Nigeria [36–38]. Rodent-to-human infection occurs by contact with infected rodent excreta, tissue, or blood. Human-to-human transmission can occur through mucosal or cutaneous contact or nosocomial contamination with blood or other body fluids. Early studies of Lassa fever estimated hundreds of thousands of cases per year throughout its range resulting in about 5000 deaths [39]. LASV is of concern outside the hyperendemic region, being the most prominent exotic hemorrhagic fever imported to Europe, North America, Asia, and the Middle East [4]. The virus causes an acute human disease associated with a range of disease manifestations. In endemic areas, the high prevalence of LASV-specific antibodies in the general population suggests that most infections are mild or

asymptomatic [40]. An estimated 20% of infections cause moderate to severe disease that can progress to acute hemorrhagic fever with multi-organ failure [41]. Human infection of Lassa fever tends to peak in the dry season, January to March, but recent evidence suggests that it might persist through the transition from dry to wet season [42].

The primary LASV reservoir host is the multimammate rodent *Mastomys natalensis* that lives in close association with humans; however, an incomplete understanding of the genus taxonomy has led to some uncertainty about which species or subspecies may serve as reservoir hosts [43]. Infected rodent hosts excrete virus in urine and feces that can infect humans via inhalation or ingestion of virus-contaminated materials. Similar to LCMV, the rodent host is thought to be infected early in life and develop persistent infections that are a continuous source of contaminating virus in the environment. In studies in Guinea of natural populations of *M. natalensis*, where it is the only LASV reservoir, antibody data supported a model in which the rodents become horizontally infected, clear the virus, and develop antibodies [44].

64.1.2.3 Junin Virus

JUNV is the etiological agent of Argentine hemorrhagic fever. The virus was isolated in 1957 during an outbreak of hemorrhagic fever in the city of Junin, Buenos Aires Province, from which its name is derived [4,23]. Since its discovery, progressively expanding annual outbreaks of Argentine hemorrhagic fever occur during the agricultural harvest season with peak cases in the month of May [45]. The occupational risk of fieldwork results in adult men becoming disproportionately infected. Humans are usually infected through cuts or skin abrasions or aspiration of particles contaminated with urine, saliva, or blood from infected rodents [46].

The primary rodent reservoir of JUNV is the drylands vesper mouse, *Calomys musculinus* [47–49]. Serological evidence implicates other rodents in the Argentine hemorrhagic fever endemic region as possible reservoirs, but their role in the disease ecology is unclear [25]. Naturally and experimentally infected *C. musculinus* are known to have persistent viremias and shed virus in their saliva. The rodents can be infected horizontally and vertically; however, in nature, evidence suggests that the primary mode of infection is by horizontal transmission [47]. Male *C. musculinus* have a higher prevalence of JUNV infection probably due to greater movement and more aggressive behavior than females. Experimental JUNV virus infection, by vertical or horizontal transmission routes, may have an effect on animal fitness. Animals infected at birth had reduced weight gain that lasted until 60 days of age as compared to uninfected controls [50]. In contrast, when adult *C. musculinus* were infected, the mean body mass was no different than the uninfected controls [51]. Whether similar effects occur in the natural rodent populations is unknown.

64.1.2.4 Guanarito Virus

GTOV is the etiological agent of Venezuelan hemorrhagic fever and was first recognized during an outbreak of hemorrhagic disease in the municipality of Guanarito, Portuguesa State, Venezuela, in 1989 [52]. The disease was associated with human encroachment into newly forested regions and increased exposure to infected rodents [23,53]. Venezuelan hemorrhagic fever tends to be seasonal with human infections peaking in November to January when the rains end and the dry season begins [54]. The disease coincides with the increased agricultural activity of harvesting of crops and preparations for planting, when humans have greater contact with the rodent reservoir.

The rodent reservoir of GTOV is a grassland rodent, the short-tailed cane mouse, *Zygodontomys brevicauda* [55]. Originally, another rodent species, the Alston's cotton rat, *Sigmodon alstoni*, was also thought to be a reservoir of GTOV; however, the misidentification attributed to serologic cross-reactivity of arenaviruses was corrected with genetic characterization of viruses isolated from each. *S. alstoni* and *Z. brevicauda* coexist in the same geographic locations where GTOV and Pirital virus (PARV), not known to cause human disease, are sympatric arenaviruses. Genetic characterization of virus isolates from each of the rodent populations implicated *Z. brevicauda* as the reservoir for GTOV and *S. alstoni* as the reservoir for PARV [55,56].

Experimental infection of the cane mouse, *Z. brevicauda*, with GTOV has demonstrated that chronic, lifelong infections can be established and virus can be persistently shed in urine and oropharyngeal secretions [57]. In nature, evidence suggests that horizontal transmission in *Z. brevicauda* is the dominant mode of GTOV transmission and is acquired through allogrooming, mating, fighting, and other close physical contact between the rodents [56]. Vertical transmission may occur but is rare in *Z. brevicauda*. Chronic GTOV infection of experimentally infected rodent reservoirs did not cause illness or death; however, other aspects of host fitness were not evaluated [57].

64.1.2.5 Machupo Virus

MACV is the etiological agent of Bolivian hemorrhagic fever. The virus was first recognized in 1962 in samples from a 1959 outbreak of viral hemorrhagic disease in San Joaquin in northeastern Bolivia [58]. Natural human infections are acquired through direct contact with the rodent reservoir or by aerosols of fomites contaminated with infected rodent urine. The incidence of human disease increases from April to June, during the late rainy and early dry season. Epidemiologically, MACV causes sporadic cases and focal outbreaks of disease in Bolivia with years of dormancy intervening [59,60]. Cases of Bolivian hemorrhagic fever were not reported between 1976 and 1992 but reemerged in outbreaks in 1994 and 2007–2008 [61].

The rodent reservoir of MACV is the large vesper mouse, *Calomys callosus*, which is found in grasslands, savannas, and forest fringes throughout southeastern South America, but the disease is limited to northeastern Bolivia [62]. Genetic differences in the *C. callosus* populations in northeastern Bolivia compared to other populations in southeastern South America may explain the incomplete overlap of the virus and the geographic range of the reservoir.

Virus–reservoir dynamics are difficult to study in natural cycles, so the understanding of MACV maintenance in nature is incomplete; however, it is probably similar to other arenavirus reservoirs with most infected individuals becoming viremic, producing neutralizing antibodies, and then clearing the infection. A small group of individuals, usually infected early in life, become persistently infected and excrete virus for life. Experimentally infected *C. callosus*, infected as suckling mice, demonstrate immune tolerance and a persistent infection [63]. In contrast, mice more than 9 days of age can follow either course, clear the infection, or become persistently infected. The virus persistence affects the fitness of the animal causing runting, shorter life spans, and almost total reproductive failure in females as a result of fatal virus infections of the embryos.

64.1.3 Clinical Features and Pathogenesis

64.1.3.1 Lymphocytic Choriomeningitis Virus

Acquired LCMV often results in asymptomatic or mild disease. When the virus does cause disease, unlike other arenaviruses that cause hemorrhagic fever, LCMV infections often result in meningitis. Flu-like symptoms including fever, malaise, headache, and nausea develop and usually resolve within a few days. Occasionally in more severe cases, the symptoms retreat temporarily and are soon followed by a bout of aseptic meningitis. Symptoms progress to neck stiffness and CNS involvement with associated arthritis, meningeal inflammation, pancreatitis, and parotitis [64,65]. Mild cases usually resolve within 1–3 weeks with fatalities being rare (<1%); in severe cases, full recovery can take months [66].

LCMV can cause congenital infections, which is associated with severe fetal disease and low survival, particularly if infection occurs during the first trimester. Surviving infants have evidence of extensive neurotropic infection of the developing brain and result in brain dysfunctions that lead to a range of conditions, most commonly chorioretinitis resulting in vision impairment, hydrocephaly, macrocephaly or microcephaly, and varying degrees of mental retardation and motor skill deficiencies [64,66]. At 21 months of age, the mortality rate may reach 35% [67]. Even though LCMV is known to naturally cause meningitis, there have been isolated cases of it causing hemorrhagic disease, similar to Lassa fever. These rare cases were associated with organ donations, where transmission of LCMV to the organ recipients often resulted in fatalities [33,34,66]. Viral hemorrhagic fever symptoms and multi-organ failure were the prominent disease presentations, but evidence of CNS infection also occurred. This severe manifestation may be due to the immunosuppressive drugs and the resulting T-cell depletion, which plays a significant role in the body's defense to LCMV infection.

64.1.3.2 Viral Hemorrhagic Fevers

Arenaviruses are most notably associated with the hemorrhagic fevers they cause; however, the majority of arenaviruses are not known to cause human disease. One of the largest clinical studies of viral hemorrhagic fever–causing arenaviruses collected data from 441 Lassa fever hospitalized patients in the Lassa fever hyperendemic region in Sierra Leone [68]. The clinical course of the disease begins with a range of general symptoms, such as fever, cough, sore throat, and joint, back, and chest pain. Abdominal pain, vomiting, diarrhea, pharyngitis, and conjunctivitis may present midcourse. Late disease symptoms include respiratory difficulty, facial edema, and hearing loss. Neurological symptoms such as deafness, muscle spasms, and seizures have been reported but are rare. In a small subset of hospitalized patients, internal bleeding and mucosal hemorrhaging occurs, but it is a strong indicator of a negative patient outcome [68–70]. The combination of symptoms most diagnostic for Lassa fever was pharyngitis, retrosternal pain, and proteinuria. Fatal outcome was most strongly predicted by a combination of hemorrhage and sore throat. Although initial infection is predominantly in macrophages, it quickly becomes systemic, and virus can be isolated from internal organs, mucous, semen, urine, and blood [40,71]. Viremia is also strongly associated with a fatal outcome, with 91% of patients who succumb to the disease having measurable viremia at some point during infection that persists through the end (compared to 56% of survivors) [71]. Disease is resolved by recovery, or death, within 2 weeks of illness onset.

New World arenaviruses have symptoms and mortality rates similar to Old World arenaviruses. The greatest outbreaks are caused by JUNV (Argentine hemorrhagic fever), GTOV (Venezuelan hemorrhagic fever), and MACV (Bolivian hemorrhagic fever). While all present with the typical viral hemorrhagic fever symptoms as described earlier, each virus has signs and symptoms that are commonly associated with the particular disease. JUNV infections commonly begin with fever, malaise, or chills and may advance to more serious systemic symptoms within a few days, including neurological and gastrointestinal complications [45,65]. GTOV infection most frequently presents with fever, sore throat, abdominal, and joint pain [52,72]. A significant amount of GTOV patients (>18%) present with convulsions, and it is a strong indicator of a fatal outcome [54]. MACV infection case studies report that the most frequent symptoms are bleeding from the gums and gastrointestinal tract, petechiae, and tremors with an accompanying fever [61]. Pathologically, arenavirus viral hemorrhagic fevers produce marked thrombocytopenia and leukopenia. During the later stages of the disease, vascular shock and multi-organ failure is evident [4,73].

Other arenaviruses also cause viral hemorrhagic fever, but clinical data are extremely limited due to their infrequent appearances. These viruses, CHPV, FLEV, PICV, SABV, and LUJV, are limited to isolated laboratory infections or sporadic natural infections but have so far resembled typical viral hemorrhagic fever disease [74,75].

64.1.4 Diagnosis

A clinical diagnosis based on symptoms alone is not reliable. Arenavirus diseases, whether hemorrhagic or meningitis disease forms, have symptoms that resemble a variety of viral infections

in the early stages. Laboratory testing is necessary for a definitive diagnosis. The most common laboratory tools for clinical arenavirus diagnosis include isolation techniques and serology, with reverse transcription polymerase chain reaction (RT-PCR) used as a means for discriminating specific species and/or strains.

64.1.4.1 Virus Isolation

Virus isolation is considered the gold standard in the diagnostics of arenaviruses but is often not practical or safe without proper biocontainment controls. Virus isolation attempts to culture virus from patient blood or serum in susceptible cell lines such as Vero (African green monkey kidney) or BHK (baby hamster kidney) cell lines. The infected cultures are monitored for cytopathic effects (CPE); an exception to this method is GTOV, which shows minimal or no CPE [76].

64.1.4.2 Immunological Detection

ELISA is the standard used in many diagnostic laboratories. Detection of virus or virus components by antigen detection ELISA or seroconversion in paired acute and convalescent samples is the most common immunodiagnostics used today. Seroconversion is determined by a rise of IgM antibodies early (acute phase) in the infection and/or a fourfold rise in IgG antibodies in the later stages (convalescent phase) of the infection. A notable exception to the dogmatic rise and fall of IgM antibodies is a Sierra Leone study where convalescent patients were found to have persisting IgM antibody for months to years following LASV infection [77]. Although this would have significant implications on LASV statistics and diagnostic standards, more extensive studies need to be done to confirm this observation. Immunofluorescence assays such as the indirect fluorescent antibody have been used to detect LASV. This antibody-based assay treats slide-mounted, fixed, LASV-infected cell monolayers with patient serum and detects virus with fluorescein isothiocyanate–conjugated antispecies secondary antibodies. Even though the method is less sensitive and specific than current ELISA methods, these assays are still in use in laboratory and clinical settings due to their lower technological requirements and ease of use [78].

Complement fixation was once commonly used for detection of viruses or antibodies. The method was heavily relied upon for identification of LCMV infections, particularly in cerebrospinal fluid [64]. Detection of antibodies or viral antigen was accomplished by adding antigen (for antibody detection) or antibody (for antigen detection) to sheep red blood cells (RBCs) with complement and the patient serum. Absence of the target results in complement lysis of the RBCs, while its presence results in complement utilization and the RBCs stay intact. Modern detection methods have proven to be more efficient and sensitive, and the assay is rarely used anymore.

Today, there are new immunological assays being developed that will have advantages in clinical, laboratory, and field settings. Point-of-care diagnostics bring the diagnostic testing conveniently and immediately to the patient that will improve the patient outcome with quicker results for clinical management by the physician and care team. One example is the recently developed ReLASV™ for LASV, which was released by Corgenix (Broomfield, Colorado, United States) to the European market [79]. Tulane University, working at Kenema Government Hospital, Sierra Leone, developed the lateral flow immunoassay to rapidly test for LASV. This multiyear study resulted in a 15 min recombinant antigen-based test, which uses a small dipstick to detect LASV in the suspected blood sample. The test continues to be in routine use at the Kenema Government Hospital located in the Lassa fever hyperendemic region in West Africa, although the relative specificity and sensitivity compared to the traditional antigen detection ELISA is still being determined. Such assays are usually of low complexity and can be run by staff with minimal diagnostic training; however, they often suffer from drawbacks, most notably a lack of sensitivity. An understanding of the limitations of the particular assay is important for the correct interpretation of the results.

The ELISA is the workhorse of immunodiagnostics; however, it has changed little since it was first described [80]. Today, the plastic ELISA plate is being replaced with plastic or magnetic beads that act as the solid support. MAGPIX (Luminex Corporation, Austin, Texas, USA) is a particularly versatile system that uses individually addressed bead sets. The addressable microspheres are dyed with a specific ratio of red/infrared dye, which can be distinguished from each other by a charge-coupled device (CCD) camera system when illuminated with LED lights. These unique bead sets allows for the development of multiplex assays that can test for multiple targets in a single sample. Theoretically, the MAGPIX system is capable of detecting up to 50 targets in a single well. For antigen detection, antibodies to viral antigen can be covalently coupled to the microspheres and then mixed with an infected sample. A secondary antibody to the antigen is used for fluorescent detection of target, and beads are counted with the CCD camera system. For antibody detection, the assay is altered by adding an antibody capture step (sandwich or indirect ELISA) or by conjugating purified viral antigen directly to beads. Protocols are also available to conjugate oligonucleotides to the microspheres to detect complementary sequences. The MAGPIX system, while already popular in laboratory settings, is also attractive for field diagnostics because it is portable and does not use lasers requiring critical alignment. The CCD camera system can handle the rigors of travel to and work in austere environments. The system is being tested and evaluated at multiple sites in West Africa to detect and identify LASV, EBOV, and other circulating viruses that occur in the region.

64.1.4.3 Molecular Detection

Immunological cross-reactivity between arenavirus species is not uncommon and can confound diagnostic results. Today, complete genomic sequences are available for all established arenaviruses, making a specific diagnosis easily accomplished with nucleic acid testing. Molecular diagnostics relying on standard (gel-based) or real-time RT-PCR utilizing glycoprotein and/or NP-specific primer sequences are frequently used for clinical and research applications [18]. In real-time RT-PCR, the probe adds additional specificity to the assay to provide even greater confidence in the diagnostic result.

There are a variety of instruments that are used with the real-time RT-PCR assays. For clinical laboratories, there are high-throughput instruments like the Applied Biosystems® 7500 Real-Time PCR System (Applied Biosystems Incorporated, Carlsbad, California, USA) that use 96-well plates. The plate-based systems have replaced the more cumbersome glass capillary systems used in the early LightCycler® instruments (Roche Diagnostics, Indianapolis, Indiana, USA). The U.S. military uses a ruggedized capillary system, specially developed for mobile analytical laboratories and fields hospitals. The Ruggedized Advanced Pathogen Identification Device is a portable real-time PCR system designed to identify biological agents of military concern in challenging environments.

The advantages of PCR-based diagnostics are their extreme sensitivity and specificity; however, these characteristics can also be problematic in certain situations. Lassa fever is often diagnosed in West Africa using RT-PCR and qRT-PCR [81]. LASV strain divergence can hamper clinical molecular diagnostics. Strain sequence variation, when it coincides with the primers and/or probe hybridization regions, results in false negatives. The sequence variation between and within the arenaviruses illustrates the importance of an orthogonal system using both immunological and molecular diagnostics to provide the highest confidence in a diagnostic result.

64.2 METHODS

64.2.1 Sample Preparation

Sample preparation for culturing methods and immunological detection methods such as ELISA or MAGPIX is minimal, with serum, plasma, and/or whole blood used directly in the assays. For molecular detection, sample preparation techniques primarily focus on inactivation of viral material and purification of the target nucleic acid for downstream RT-PCR detection. Two different manual sample processing protocols are commonly used for extraction of genomic materials. TRIzol (Invitrogen, Waltham, MA, USA)-based methods utilize a phenol–chloroform phase separation and others, such as the QIAamp Viral RNeasy Kits (Qiagen Valencia, California, USA) utilize silica-membrane binding of nucleic acids in spin columns. These standard methods are used for RNA extractions according to manufacturer recommendations with a variety of matrices. They are relatively user-friendly and efficient at isolation of amplifiable RNA, and many companies have developed benchtop extractors that automate the same protocol.

A more recent advancement in nucleic acid extraction with improved efficiency over traditional methods utilizes binding of nucleic acids to magnetic beads for isolation and subsequent purification. Arenavirus RNA is efficiently isolated from diagnostic samples using kits such as the manual MagMAX AI/ND Viral RNA Isolation Kit (Ambion, Austin, Texas, USA). Viral particles are disrupted in the presence of TRIzol, to inactivate the virus and release the vRNA. Paramagnetic beads with a nucleic acid binding surface are then able to bind the target nucleic acids. The beads with the RNA bound are captured by magnets, and proteins and other contaminants are washed away. Pure, high-quality RNA is eluted from the beads, relatively free of contaminants and PCR inhibitors.

64.2.1.1 Procedure

1. Incubate aliquots up to 400 µL of TRIzol-treated arenavirus material with 800 µL of Viral Lysis/Binding Solution and mix by vortex for 30 s.
2. Add 20 µL of resuspended magnetic bead mixture to each sample. To ensure effective release of the RNA and binding to the beads, the samples are mixed by vortex during the 4 min incubation at room temperature.
3. Remove the magnetic beads with the bound RNA from solution by attraction to the magnetic source. The contaminants are removed with the discarded supernatant.
4. Wash the RNA bound beads once with Wash Solution 1, twice with Wash Solution 2, each time discarding the supernatant, and then dry.
5. Elute arenavirus RNA from the beads with 100 µL of water at room temperature, then store at −70°C.

64.2.2 Detection Procedures

64.2.2.1 ELISA Detection

ELISA can be used for virus antigen detection or serological detection of IgM and IgG antibodies with minimal changes. The IgM capture ELISA is outlined below. Although there are many variations, standard solutions are a coating buffer of phosphate buffered saline (PBS), wash buffer of PBS with 0.1% Tween (PBS-T), and dilution buffer of PBS-T in 5% skim milk to aid in blocking nonspecific binding. Samples should be tested against a negative antigen as a control. Different combinations of enzyme–substrate detection schemes may be used, although horseradish peroxidase (HRP) and 2,2′-azinobis[3-ethylbenzothiazoline-6-sulphonic acid] (ABTS) are the most common.

64.2.2.1.1 Procedure

1. Coat a 96-well plate with anti-IgM antibody at the recommended concentration diluted in coating buffer. Wrap the plate in plastic and let incubate overnight at 4°C.
2. Wash plate three times with wash buffer and add samples diluted in dilution buffer at desired concentration, usually 1:10 to 1:100. Incubate at 37°C for 1 h.
3. Wash plate three times with wash buffer and add the arenavirus antigen and negative control antigen in dilution buffer to the appropriate wells. Incubate at 37°C for 1 h.
4. Wash plate three times with wash buffer and add antiarenavirus antibody at the recommended concentration diluted in dilution buffer. Incubate at 37°C for 1 h. The arenavirus can be detected directly with

an antibody custom labeled with HRP or detected indirectly with an antiarenavirus antibody followed by an antispecies secondary detector antibody.
5. Wash plate three times with wash buffer and add ABTS substrate. Incubate at 37°C for 30 min.
6. Detect absorbance on a plate reader at 410 nm.

64.2.2.2 Real-Time RT-PCR Detection

Trombley et al. [82] developed virus-specific real-time RT-PCR assays targeting the GP, NP, Z, and/or L polymerase genes for detection of LASV, JUNV, MACV, GTOV, and SABV in diagnostic samples. Strains, primer–probe sets, and their sensitivities are listed in Table 64.2. Although these assays were optimized for the LightCycler (Roche Diagnostics), they can easily be altered with master mix and software adjustments to be used on any cycler platform.

64.2.2.2.1 Procedure

1. The cDNA synthesis and real-time PCR uses the SuperScript™ One-Step RT-PCR Kit (Invitrogen) as described by the manufacturer. The Master Mix (20 μL) contains 0.2 mM each of the dNTPs, the appropriate final concentration of each primer and TaqMan probe, 3 mM $MgSO_4$, and 1–10 ng/5 μL (or 1–1000 plaque-forming units per 5 μL) of extracted RNA. When using glass capillaries on the LightCycler 2.0 (Roche Diagnostics), bovine serum albumin is added to the reaction mix.
2. Add real-time RT-PCR Master Mix to the reaction tube or plate well followed by 5 μL of genomic RNA sample. Cap the tubes or cover the plates with sealing film.
3. Cycle the real-time RT-PCR tubes or plates as follows: 50°C for 15 min (1 cycle); 95°C for 5 min (1 cycle); 95°C for 1 s; 60°C for 20 s (45 cycles); 40°C for 30 s (1 cycle). A single fluorescence measurement is made at the end of each 60°C step.
4. Analyze the real-time RT-PCR curves with the software packages specific to the instrument utilized.

64.2.2.3 MAGPIX Bead-Based Detection

The MAGPIX (Luminex Corporation, Austin, Texas, USA) can be used for molecular as well as immunological detection. The customizable bead sets are conjugated to the capture antibody, antigen, or oligonucleotide depending on the target and format desired. For multiplexed assays, multiple different bead sets may be used in single wells once the interactions of the singleplex assays are optimized for the multiplex assay. While there are many variations that can be optimized for each protocol, a standard buffer used for both dilutions and washes is PBS with 0.05% Tween (PBS-T). Incubation times may range from 30 min to 1 h. Assays can be arranged with internal negative control bead sets or with separate negative control wells. Fluorescent detection can be observed using biotinylated detector antibodies and a subsequent fluorescent reporter or a directly labeled detector antibody. An example antigen detection protocol is outlined here. Plates and solutions should be protected from light throughout the procedure.

64.2.2.3.1 Procedure

1. Choose desired sets of capture antibody-coated beads. In an opaque 96-well plate, dilute bead sets to 2000–5000 beads/set/well. Combine bead and test sample at desired concentration, usually 1:100. Incubate at room temperature for 1 h.
2. Attach plate to magnet and wash three times with buffer. Add biotin-labeled, antiarenavirus antibody(s) to wells at the recommended concentration in PBS-T buffer. Incubate at room temperature for 1 h.
3. Attach plate to magnet and wash three times with buffer. Add Streptavidin-R-Phycoerythrin at 4 μg/mL. Incubate at room temperature for 30 min.
4. Attach plate to magnet and wash three times with PBS-T buffer. Insert plate into MAGPIX instrument and read with protocol directed to look for desired bead sets.

64.3 CONCLUSION AND FUTURE PERSPECTIVES

Arenaviruses are a diverse group of viruses commonly associated with rodents and humans; however, TCRV, associated with fruit-eating bats (*Artibeus* species), is a well-known exception. Other arenavirus reservoirs undoubtedly exist, and it is important to remain vigilant and receptive to other virus–host interactions. Recently, highly divergent arenaviruses were isolated from two species of boas suffering from inclusion body disease, an often fatal disease in snakes best characterized in boas and pythons [83–85]. Interestingly, these arenaviruses demonstrated sequence variation that may reflect geographical distances between the evolutionary origins of snake species, similar to what is hypothesized for rodent reservoirs. More in-depth study of the virus and snake association is needed to fully understand this unique group of arenaviruses.

The *Arenaviridae* family will continue to grow in the future as we gain a greater understanding of the viruses and their reservoir hosts. Improvements in high-throughput sequencing (or next-generation sequencing) technologies will provide better access to virus and reservoir host genome sequences, resulting in new species and host relationships that will help guide our understanding of arenavirus evolution. For example, the incomplete overlap of the geographic range of some rodent reservoirs and their associated arenaviruses may result from genetic differences in rodent subpopulations, which may become evident with better genetic characterization of regional populations. Similarly, it is hypothesized that shared structural motifs in the *Arenaviridae*, *Filoviridae*, and *Bunyaviridae* may be derived from common ancestry

Source: Adapted from Trombley, A.R. et al., *Am. J. Trop. Med. Hyg*., 82, 954, 2010.

[a] PCR, polymerase chain reaction; PFU, plaque-forming units; TM, TaqMan; MGB, TaqMan minor groove binder; NP, nucleoprotein; GP, glycoprotein; VP, virus protein; GPC, glycoprotein precursor.

[b] Limit of detection (LOD) for all assays were measured in PFU/PCR unless otherwise stated; all sensitivities were done in triplicate and were positive in three of three replicates.

[c] Synthetic RNA was used to determine LODs in genome copy number.

[d] LODs measured as dilution of stock RNA because PFU information was not available.

Machupo Mallele-TM assay run at 62°C.

or common functions. Genomic sequencing will be a critical tool in advancing our understanding of arenavirus and reservoir host relationships as well as identifying potential new arenavirus candidates. Nevertheless, it is important to remember that experimental work is still critical to demonstrate causality.

ACKNOWLEDGMENTS

The authors were funded in part by the Division of Global Emerging Infections Surveillance and Response System (GEIS) Operations at the Armed Forces Health Surveillance Center (RJS) and by the Department of Defense Cooperative Biological Engagement Program funding a National Research Council Research Associateship Award at the U.S. Army Medical Research Institute of Infectious Diseases (USAMRIID) (AEO).

65.1 INTRODUCTION

Enteric infections leading to acute gastroenteritis, together with respiratory tract infections, rank as the most common infectious disease syndromes of humans and animals affecting all age groups. It has been estimated that nearly 5 billion diarrheic episodes occur every year globally, and 15%–30% of severely affected patients succumb to the infection, which is generally higher at the extreme ages of life, particularly in low-income settings of developing countries. The clinical illness caused by enteric pathogens varies but usually involves diarrhea, vomiting, and fever of differing length and severity. Many microbial pathogens are the main causes of infectious gastroenteritis, and amid them, bacterial and parasitic infections have diminished occurrence as a result of progresses in public health practice. However, viral gastroenteritis has not dropped in an analogous manner from these interventions.

Enteric viral pathogens recognized since 1970 include viruses mainly belonging to four families: *Reoviridae* (rotavirus), *Caliciviridae* (calicivirus), *Astroviridae* (astrovirus), and *Adenoviridae* (adenovirus) and are known to cause billions of cases of enteric viral infections every year. During the last decade, the availability of next-generation sequencing as a new research tool to explore unknown viruses of human and veterinary importance has aided in the detection of putative novel pathogens and the documentation of the etiologic agents of numerous infections, cracking the long-standing anonymities of many genetically diverse and rapidly evolving viruses. This metagenomic approach has been employed in several studies probing fecal samples of livestock and companion animal species, providing evidence on the diversity of the animal fecal virome, helping the elucidation of the etiology of diarrheal disease in animals, and identifying potential zoonotic and emerging viruses in humans. In the past few decades, the molecular characterization of many of these gastroenteritis viruses has led to advances both in our understanding of the pathogens themselves and in the development of state-of-art diagnostics. Although the use of these highly accurate, reliable, and sensitive approaches to identify and characterize individual viral pathogens is in its infancy, it has opened new avenues to review disease burden and contemplate implementation of vaccination and improvements in public health measures and sanitary practices.

In contrast to some bacterial pathogens, there are no national notifiable diseases data on the prevalence of enteric viruses. The possible transmissibility of such viruses between animals and humans should be assessed as a number of known and emerging viruses have been associated with enteric infections in animals. Since the first detection of a small-sized bisegmented double-stranded RNA (dsRNA) virus named *Picobirnavirus* (PBV) in humans and black-footed pygmy rice rats in 1988 [1,2], it has been identified in various domestic and captive animals. The sequencing of partial segment 1 and full-length segment 2 of this virus by Rosen [3] unraveled some of the mysteries regarding its genome. Although accretion of genomic data of PBVs from different mammalian and

reptile species across the world resolved some of the ambiguity, quite a few questions and hypotheses regarding pathogenesis, persistence location, and evolution of PBVs remain unreciprocated. PBV, with main emphasis on its biology, epidemiology, viral persistence, and their zoonotic potential, has been reviewed recently [4,5].

65.1.1 Classification, Morphology, and Genome Organization

PBVs are small (35–41 nm in diameter), nonenveloped, double-stranded, bisegmented RNA viruses. The prefix "pico" denotes the small diameter of the viral particle, and "birna" suggests a genome composed of two segments of dsRNA [2]. Due to the bisegmented nature of the genome as revealed in polyacrylamide gel electrophoresis (PAGE), it was initially confused with birnaviruses. PBVs differ from members of *Birnaviridae* in respect of host, virion size, capsid, RNA polymerase, genome size, and organization (Table 65.1).

A complete new taxonomic order *Diplornavirales*, family *Picobirnaviridae*, genus *Picobirnavirus* was assigned to accommodate PBVs [6]. The two species under the genus *Picobirnavirus* are *Human picobirnavirus* (type species) and *Rabbit picobirnavirus* (designated species) [7]. The PBVs have a simple core capsid with a distinctive icosahedral arrangement, displaying 60 twofold symmetric dimers of a coat protein with a new 3D-fold as revealed from VLPs of a rabbit PBV generated in baculovirus [8]. This coat protein undergoes an autoproteolytic cleavage, releasing a posttranslational modified peptide that remains associated with nucleic acid within the capsid. The ability of PBV particles to disrupt biological membranes *in vitro* appears to reflect evolution of animal cell invasion properties of its simple 120 subunits capsid [8]. Also, PBVs are known to carry 4–10 copies of particular sequence motif (ExxRxNxxxE), which encode proteins of various sizes (106–224 residues and without proline and cysteine) [9].

A uniform nomenclature for PBV has been put forward, which reveals the genogroup (genogroup I [GI] or genogroup II [GII]), host, country of origin, strain, and year of isolation for a specific PBV identified in such order [10]. For example, GI/PBV/human/China/1-CHN-97/1997 specifies a PBV with GI specificity and strain name 1-CHN-97 detected in humans from China in 1997.

TABLE 65.1
Fundamental Differentiating Features between *Picobirnaviruses* and *Birnaviruses*

Properties	*Picobirnavirus*	*Birnavirus*
Hosts	Mammals	Fish, chicken, and turkey
Virion size	35–41 nm	65–70 nm
Capsid structure	Triangulation of 1, 3, or 4	T = 13 laevo symmetry
RNA polymerase	A–B–C motifs	C–A–B motifs
Genome size	Smaller segment (1.7 kb) and larger segment (2.5 kb)	Smaller segment (2.8 kb) and larger segment (3.3 kb)
Genome organization (segment 1)	Two ORFs	Single ORF

The segment 1 (2.2–2.7 kb) of PBV encodes the capsid protein, while gene segment 2 (1.2–1.9 kb) codes for the viral RNA-dependent RNA polymerase (RdRp) [11,12]. PBVs are classified into two genogroups, that is, GI (reference strain-1-CHN-97) and GII (reference strain-4-GA-91) based on the RdRp gene (segment 2) of human PBV [3,13]. Remarkably, more than 83% of PBV sequences available in the National Center for Biotechnology Information belong to GI and less than 3% to GII, while the rest remains undefined.

Recently, genogroup III (GIII) PBV has been identified in humans from the Netherlands (PBVIII/Homo sapiens/VS6600008/2008/NL/KJ206569) [14]. At present, limited full-length PBV genome sequences from humans, turkey, camels, and pigs are available in nucleotide sequences databases, that is, GI/PBV/human/THAI/Hy005102/2002 [15] and GI/PBV/California sea lion/Hong Kong/HKG-PF080915/2012 [16]. Complete nucleotide sequences of segment 1 of lapine PBV [17] and segment 2 of bovine PBV and monkey RdRp sequences are accessible. The variances in PBV genome from different species are presented in Table 65.2.

65.1.2 Epidemiology and Impact on Health

PBV prevalence reports across the world suggest that PBV has a wide host range. PBVs have been detected in a number of domestic as well as captive animal species [2,18–30]. Species-wise PBVs distribution across the world is presented in Figure 65.1.

Incidence studies carried out across the world in different species by different diagnostic assay indicated the presence of PBVs as 0.4%–27.1% by RNA-PAGE and 18.2%–65% by reverse transcription polymerase reaction (RT-PCR) in swine [22–24,31], 0.7%–3.7% by RNA-PAGE in bovines [27,32], 14.3% in equines by RT-PCR [29], 0.9%–1.8% by RNA-PAGE and 0.6% by RT-PCR in canines [18,33], 3.4%–15.3% by RNA-PAGE and 49.4% by RT-PCR in chickens [19,20], and 2.2%–25% by RNA-PAGE and 2.4%–47.9% by RT-PCR in other animals [18,34].

Reports associating PBV with gastroenteritis gave contradictory results, some with positive correlation [19,20,22], while others with negative correlation [31]. Remarkably, all such association studies in captive animals yielded negative correlation of PBV with diarrhea [18,34]. Concomitant infection having both genogroups (GI and GII) of PBVs in one host has also been detected in humans [35], pigs [36], and recently in bovines [26].

Persistence of PBV infection in asymptomatic carrier, greater rhea (Rhea americana), has elucidated where PBV infection was acquired during the early stages of life and maintained until the beginning of adulthood confirming that the PBV–host interaction is proved as a persistent and asymptomatic infection model [37]. The maintenance and evolution of PBV infection during adulthood was also ascertained in an adult orangutan (*Pongo pygmaeus*) recently, assuming the mechanisms by which persistent infections are maintained involve both modulation of

TABLE 65.2
Genomic Features of Different Species Picobirnaviruses

	Human PBV (Hy005102 Strain)	Otarine PBV (PF080915 Strain)	Lapine PBV (Strain 35227/89)	Bovine PBV (RUBV-P Strain)
Segment 1 (encodes for capsid protein)				
Length (bp)	2525	2347	2362	—
ORFs	ORF1 (224aa), ORF2 (552aa)	ORF1 (163 aa), ORF2 (576aa)	ORF1 (591aa), ORF2 (155aa), ORF3 (55aa)	—
Segment 2 (encodes for RNA-dependent RNA polymerase)				
Length (bp)	1745	1688	—	1758
ORFs	ORF1 (534aa)	ORF1 (532aa)	—	ORF1 (554aa)

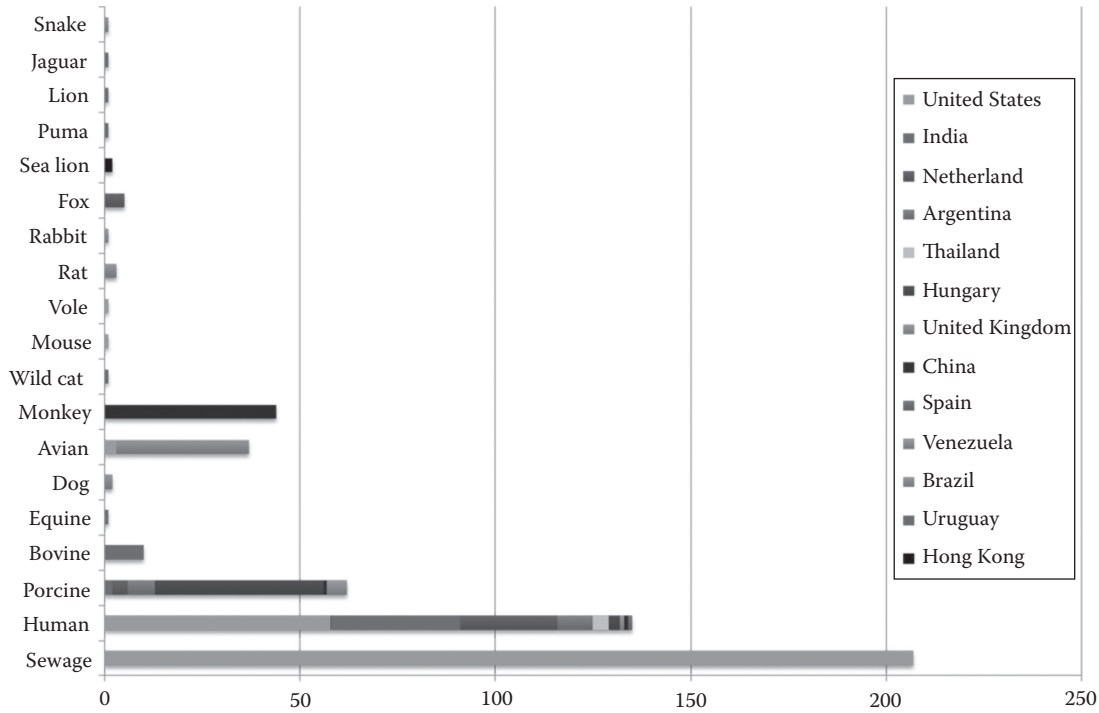

FIGURE 65.1 Global distributions of PBVs in different domestic and captive animal species. (Reprinted from Malik, Y.S. et al., *BioMed Res. Int.*, 2014, 780752, 2014. With permission.)

the virus and cellular gene expression and/or modification of the host immune response [38]. However, there is still a need to understand the molecular mechanisms governing persistent and asymptomatic coexistence with the host and the potential host suitability to maintain this relationship.

Studies on molecular epidemiology and evolutionary aspects of PBVs resulted in some intriguing observations. The sequence variation within any PBV genogroups may extend 50%, although some studies have reported complete or nearly complete sequence identities among PBV strains detected at distant locations and different host species. Prolonged infection and fecal shedding allowed insight into the intrahost evolution of PBVs; these recent studies have indicated significant divergence of genomic sequences over a relatively short period [37,38]. In addition to accumulation of single nucleotide mutations that leads to significant sequence diversity, recent findings have provided evidence for reassortment within GI porcine PBV genomes [39].

Based on the studies carried out by researchers across the world on association studies of PBVs with gastroenteritis, the authors predicted that PBV may not be the primary cause of diarrhea and may play synergistic effect in association with the primary enteric causative agents [40,41]. Further, captive animals might be acting either as the reservoir or persistent asymptomatic carriers.

65.1.3 Transmission, Clinical Features, and Treatment

PBVs have been associated with gastroenteritis either as sole entity or more commonly with other enteric causative agents. GI PBV is the most common genogroup detected in all the

species [5,42]. Transmission is suspected through contaminated water and environment [43] as PBVs have been detected typically in the feces of animals (e.g., contamination of surface waters with runoff from animal). However, PBV has been isolated from the respiratory tract of pigs [36], which may be a secondary location following viremia from the gut. At present, there is no evidence for PBV in airborne droplet. This may suggest the zoonotic potential of these viruses with possible emerging and/or reemerging risk to a number of animals in different geographical locations. Transmission from one species to another is defined in terms of genetic relatedness of one or more segments among the segmented genome viruses like rotavirus or PBVs infecting two different species from the same or different geographical areas. These studies indicated the genetic relatedness among different PBVs based on a short fragment of RdRp gene, for example, between swine and human [24,29], human and equine PBVs [29], and human and rodents PBVs [44].

Animals infected by PBV alone or with other enteric causative agents may have diarrhea (nonbloody and watery), nausea, and fever. Studies suggest that most of the infections caused by PBVs are asymptomatic in captive animals. Since there is no specific antiviral treatment and no vaccine to prevent the infection, prophylactic measures include maintenance of strict hygiene to prevent contamination of food, water, and environment, identification of mode of transmission, and prevention of spread of infection from animals to animals as well as animals to humans. Treatment mainly focuses on supportive care, especially preventing and treating dehydration.

65.1.4 Diagnosis

At present, three diagnostic methods are widely employed for detection of PBV: direct electron microscopy, PAGE, and RT-PCR. Of these, RT-PCR is widely used for detection and genotyping of PBVs.

Conventional techniques: The first report of PBV detection dates back to 1988, where it was detected in the stool samples surveyed for rotavirus, as two migrated segments in PAGE [1,2]. While direct visualization of PBV is possible under electron microscope [2,31], its use for epidemiological studies is impractical because of its requirement of highly skilled personnel and costly equipment. Given the current lack of immunological/serological assays and animal model as well as permissive cell lines for PBVs, molecular approaches play a vital role in the diagnosis and clinicopathological studies of PBV infections.

Molecular techniques: The beginning of the usage of molecular techniques for PBVs was with the first detection of bisegmented dsRNA virus in humans and black-footed pygmy rice rats by using PAGE [1,2]. Since then, PAGE has been used by different countries for detection of PBVs from different species as a reliable diagnostic assay. The most consistent indicator for diagnosis of PBV infection is the presence of PBV RNA in fecal samples. Therefore, the specimen of choice is fecal samples from diarrheal animals. The importance of RNA-PAGE lies in its specificity to resolve the PBV genome into two discrete bands and also can distinguish genome profiles (small or large genome profiles), which are missed in molecular assays. Electrophoretic patterns with banding of genomic segments in two patterns with larger genome profile and small genome profile, based on migrating distance and size of segment 1 and 2, after PAGE analysis with silver staining have been observed [5,26–28]. In the larger profile, the segments 1 and 2 correspond to 2.7 kb and 1.9 kb respectively, while size of these genome segments remain 2.2 kb and 1.2 kb for the short profile PBVs [5] (Figure 65.2). However, RNA-PAGE is a cumbersome, labor-intensive, and time-consuming technique.

With the successful cloning and sequencing of partial genome of two human PBV strains for the first time [3], RT-PCR assay has been widely employed as a tool for the routine diagnosis of PBV infection. Use of RT-PCR and DNA sequencing techniques for detection and characterization of PBV genetic background has markedly enhanced the understanding of the molecular epidemiology of PBV infection. For genogrouping of PBVs, oligonucleotide primers sequences targeting the RdRp gene are based on two prototype strains, GI/PBV/human/China/1-CHN-97/1997 and GII/PBV/human/USA/4-GA-91/1991, and have been validated across the world in different animals species [10,13,23,26–29,35]. However, to further improve the diagnosis and capture the highly diverse porcine PBVs, diagnostic primers sets (PBV2-19 [+] 5′-CGACGAGGTTGATAAGCGGA-3′ and

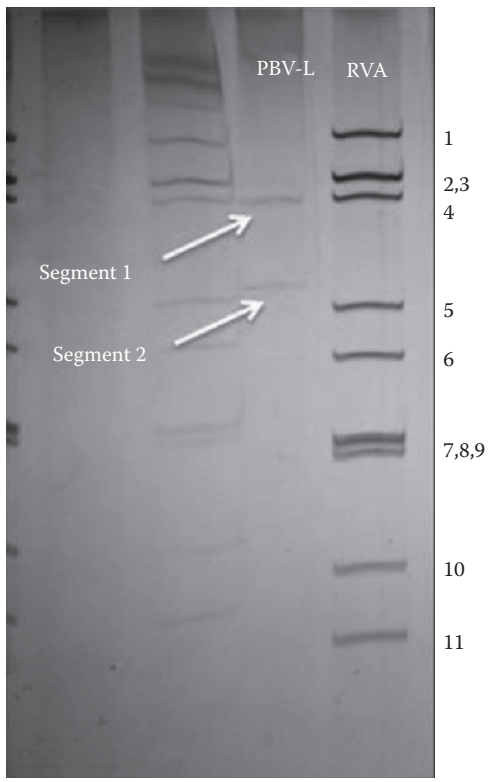

FIGURE 65.2 Electrophoretic separation of *Picobirnavirus* (PBV) segments in silver-stained polyacrylamide gel. PBV-L: large genome profile PBV; RVA: type A rotavirus. (Reprinted from Malik, Y.S. et al., *BioMed Res. Int.*, 2014, 780752, 2014. With permission.)

PBV2-281 [–] 5′-CACAGTTCGGGCCTCCTGA-3′) targeting conserved region of RdRp gene (824–1086 nt) were developed and also allowed detection of porcine-like PBVs in humans [45]. For specific identification of PBV GIII, real-time PCR has been described with primers VS791 (5′-CGATGGATCTTTATGTTCCCG-3′), VS792 (5′-GTAGTTGAAATGTTGATCCATTT-3′), and VS793 (5′-CAAACTTTCCAGCAACCGCTT-3′) [14].

The authors have also developed improved target set of diagnostic oligonucleotide sequences for segment 2–based RT-PCR for bovine PBVs with superior sensitivity and specificity (data not shown), and the same primer sets are also being found useful for detecting PBVs in pigs.

65.2 METHODS

65.2.1 Sample Collection and Preparation

65.2.1.1 Sample Collection

The clinical samples (feces) should be collected from the diarrheic animals, even though samples can also be collected from the nondiarrheic cases, as PBVs have also been isolated from nondiarrheic cases. The 10% fecal suspension is prepared in phosphate-buffered saline (PBS; pH 7.4) and centrifuged at 7500 rpm for 20 min after vortexing for 2 min to remove the particulate matter. The clear supernatant thus obtained is used for RNA extraction.

65.2.1.2 Virus Purification

Virus purification is done by taking clarified fecal suspension (10% w/v) prepared from samples that have been tested positive to PBV by PAGE. Centrifuge the sample at 7500 rpm for 20 min to pellet the unwanted matter. The virus is initially concentrated by passing the sample through a cushion of 40% sucrose in PBS by using ultracentrifugation at 1,00,000 × *g* for 3 h. Resuspend the pellet thus obtained in 500 µL PBS and finally concentrate the virus preparation by flotation in an isopycnic CsCl gradient. Collect the fractions and measure their refractive index. Pool the fractions with a refractive index between 1.3 and 1.4 with corresponding densities between 1406 and 1435 g/mL and pellet the virus particles by further centrifugation at 160,000 × *g* for 12 h at 4°C. Suspend the pellet thus obtained in 250 µL PBS and store at –70°C.

65.2.1.3 PBV Viral RNA Extraction

Different methods have been used for RNA extraction from PBVs before subjecting to RNA-PAGE and RT-PCR. If the sample size is large, guanidinium isothiocyanate–phenol–chloroform extraction (Tri reagent LS) method is preferred, considering its low cost and acceptable RNA purity. Briefly, 500 µL of Tri reagent is added to 500 µL of clear supernatant in a 1.5 mL microcentrifuge tube, vortexed thoroughly, and kept at room temperature for 15 min. Further, 100 µL of 1-bromo-2-chloropropane is added to the tube, brief vortexed, and kept at room temperature for 10 min. The tube is then centrifuged at 12,000 rpm for 15 min. The upper aqueous layer, thus obtained after centrifugation, is carefully collected in a fresh 1.5 mL microcentrifuge tube. To the aqueous layer, 500 µL of isopropanol is added and kept at –20°C for 1 h for precipitation of viral RNA. The PBV RNA is then pelleted by centrifugation at 12,000 rpm for 15 min followed by washing with prechilled 70% ethanol at 12,000 rpm for 10 min. Pellet is air dried. Finally, PBV RNA pellet is dissolved in 20 µL nuclease-free water (NFW) or 1× TE buffer. Concentration and purity of extracted PBV RNA is measured using Nanodrop spectrophotometer. The obtained PBV RNA can be stored at –80°C until further use as template for RT-PCR assay.

If the sample size is small, highly sensitive commercially available RNA extraction kits (QIAamp Viral RNA Mini Kit, Qiagen; Quick-RNA™ Mini Prep Kit, Prolab) are widely used for PBV RNA isolation as per the manufacturer's instructions.

65.2.2 Detection Procedures

The most commonly used PBV detection methods in various laboratories include RNA-PAGE and gel-based RT-PCR. Both of these assays should be performed, as PAGE gives indication about the genome profile (large/small), while RT-PCR about genogroups. Electron microscopy is also used for visualization of the complete virion particles.

65.2.2.1 Electron Microscopy

To visualize the PBV particles, purified viral suspensions as prepared earlier are directly observed under the electron microscope. The samples are negative stained with 2% phosphotungstic acid for approximately 1 min. The size of virus particles is measured and identified as PBV as per their morphology. PBV appear as spherical, with approximately 35 nm in diameter, nonenveloped, and with uniform structure and morphology, suggestive of icosahedral symmetry.

65.2.2.2 Polyacrylamide Gel Electrophoresis

Direct visualization of PBV genome (peculiar bisegmented excluding *Birnaviruses*) in PAGE after silver staining [46] has still been used in many parts of the world for reliable diagnosis. The PBV presents at least two genomic profiles in PAGE, that is, large genome profile (segment 1 [2.3–2.6 kb] and segment 2 [1.5–1.9 kb]) (Figure 65.2) and small genome profile (segment 1 [1.75 kb] and segment 2 [1.55 kb]) (Figure 65.3). Notably, a third genome segment has also been documented in chickens [47] and dogs [48]. These viruses with trisegmented dsRNA genome might be due to mixed infection of PBV strains or with other viruses; nevertheless, it needs further investigation to confirm and/or ascertain the identification.

65.2.2.3 Multiplex PCR

Owing to poor sensitivity of PAGE, molecular-based tests like multiplex PCR are the most preferred method for detection as well as genogrouping of PBVs [3]. For genogrouping of PBVs, oligonucleotide primers targeting the RdRp gene are based on two prototype strains (GI/PBV/human/China/1-CHN-97/1997 and GII/PBV/human/USA/4-GA-91/1991) and have been widely employed for genogrouping [13,23,26–28].

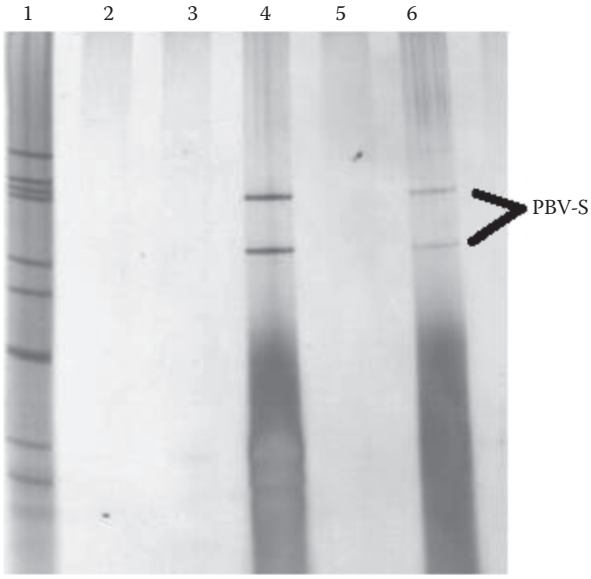

FIGURE 65.3 Electrophoretic separation of *Picobirnavirus* (PBV) segments in silver-stained polyacrylamide gel (small genome profile [PBV-S]). Lane 1 = RVA: type A rotavirus (SA11); lanes 4 and 6 = PBV-S.

65.2.2.3.1 Reverse Transcription

65.2.2.3.1.1 Procedure

1. The RT mix mentioned in Table 65.3 is prepared in a 0.5 mL microcentrifuge tube (volume indicated per sample). It is important to note that four components, that is, sample RNA, random hexamer, dimethyl sulfoxide, and NFW, are mixed first in the mentioned quantity followed by denaturation of dsRNA and snap chilling (Table 65.3).
2. Transfer the remaining reagents to microcentrifuge tube.
3. Spin the tubes briefly for uniform mixing of all the regents.
4. The reaction mixture is kept at 37°C for 1.5 h followed by inactivation of Moloney murine leukemia virus reverse transcriptase at 80°C for 2–3 min.
5. The cDNA thus obtained can be directly used for PCR or stored at –20°C until further use.

TABLE 65.3
Components of Reverse Transcription Mix

Components	Volume (µL)
RNA sample	7.0 (volume can vary depending on the concentration)
Random hexamer (100 ng/µL)	1.0
Dimethyl sulfoxide (DMSO)	1.0
Nuclease-free water (NFW)	4.0
After denaturing at 95°C for 5 min, followed by snap chilling on ice, the following reagents are added to microcentrifuge tube:	
RT buffer (5×)	4.0
Deoxynucleotide triphosphate mix (10 mM)	1.0
Moloney murine leukemia virus reverse transcriptase (M-MLV RT) (200 U/µL)	1.0
RNase inhibitor (Ribolock)	1.0
Total volume	20

65.2.2.3.2 PCR

The two sets of primer pairs mentioned in Table 65.4 are used to amplify the 201 bp fragment of the RdRp gene (segment 2), related to prototype PBV strain 1-CHN-97, representing GI and 369 bp product of the RdRp gene of reference strain 4-GA-91 of GII (Table 65.4).

The following multiplex PCR protocol has been modified in terms of thermal cycling conditions described in earlier methods [3,13]. The presence of a 201 bp product is indicative of PBV GI genogroup, while the presence of a 369 bp product is indicative of PBV GII genogroup.

65.2.2.3.2.1 Procedure

1. Allow all the PCR reagents to thaw on ice and spin briefly.
2. Prepare the multiplex PCR reaction mix in 0.2 mL PCR tube as follows (volume indicated per sample) (Table 65.5).
3. Spin the tubes at 5000 rpm in a microcentrifuge for 5 s at room temperature.
4. Place the sample tubes in a thermal cycler for 30 cycles of 94°C for 2 min 30 s, 48°C for 20 s, and 72°C for 30 s, and final extension at 72°C for 5 min.

TABLE 65.4
Picobirnavirus Genotyping Primers Based on RNA-Dependent RNA Polymerase Gene (Segment 2)

Genogroup Specificity	Primers	Oligonucleotide Sequences (5′–3′)	Nucleotide Positions	Amplicon Size (bp)	Reference Strains
Genogroup I	PicoB25[+]	TGG TGT GGA TGT TTC	(665–679)	201	1-CHN-97
	PicoB43[–]	A(GA)T G(CT)T GGT CGA ACT T	(850–865)		
Genogroup II	PicoB23[+]	CGG TAT GGA TGT TTC	(685–699)	369	4-GA-91
	PicoB24[–]	AAG CGA GCC CAT GTA	(1039–1053)

TABLE 65.5
Components of Multiplex Polymerase Chain Reaction Mix

Components	Volume (μL)
Dream Taq PCR master mix (2×)	12.5
PicoB25 forward primer (10 pmol/μL)	1.0
PicoB43 reverse primer (10 pmol/μL)	1.0
PicoB23 forward primer (10 pmol/μL)	1.0
PicoB24 reverse primer (10 pmol/μL)	1.0
cDNA	2.0
Nuclease-free water (NFW)	6.5
Total volume	25.0

5. Analyze the expected size of specific amplicons in 2% agarose gel electrophoresis and document the images using gel documentation system.

Note: Always include positive and negative controls while performing the multiplex PCR for PBV.

65.3 CONCLUSION AND FUTURE PERSPECTIVES

Among the most recently recognized viruses, PBVs are genetically diverse, small, nonenveloped viruses with a bisegmented dsRNA genome, classified under a new family, *Picobirnaviridae*, imposing possible risk for a number of host species including humans. The availability of genomic data from different PBVs of mammalian species has helped in resolving some of the abstruseness associated with this virus infection. However, there are still some unanswered questions including pathogenesis, persistent location, and evolution of PBVs. The genomic segment 2, encoding "RdRp gene" sequence-based genogrouping (GI, GII, and GIII), has aided in identifying viral genogroups circulating in animals across the different countries. Sequence and phylogenetic analysis studies suggest tremendous sequence diversity and varying evolutionary dynamics of PBVs in different host species. The recent detection of PBVs from respiratory tracts of swine and humans, the proposal for new genogroups [14,49], and the increasing popularity of viral metagenomics using different high-throughput sequencing platforms to detect viral diversity in clinical, pathological, and environmental samples are further expanding our knowledge on this highly diverse virus. Still, not much has been done on exploring replication strategies adopted by the virus and the role of innate and adaptive immunity. The close relatedness of animal PBVs with human along with detection of PBVs from the sewage designate the potential threat in terms of infection acquirement from the sewage and transmission of these viruses across the species. Although PBVs may have an inadequate or ambiguous clinical implication, they do pose a potential public health concern in humans, and the control of PBVs mainly relies on nonvaccinal approach.

66.1 INTRODUCTION

Marine shrimp farming started in Brazil only in the 1970s with Asian species *Marsupenaeus japonicus*. In the 1980s, the practice of shrimp farming emerged as an agribusiness following the introduction of exotic species *Litopenaeus vannamei*. Despite favorable conditions, it is only recently that Brazilian shrimp farming achieved a prominent place in the world [1,2]. Nevertheless, in 2004, the production of *L. vannamei* suffered a drastic drop due to various economic, environmental, and biological factors [3]. Among these, two viral epidemics caused great economic losses to Brazilian producers. The first epidemic, designated as infectious myonecrosis (IMN), occurred in the Northeast region of Brazil in 2002, and the second epidemic, named white spot infection, occurred in the South in 2004 [3–6].

Initially, IMN was recognized as a disease of unknown infectious agent (the so-called idiopathic myonecrosis). Extensive research was conducted into the identification and characterization of the etiological agent as a virus, which was named infectious myonecrosis virus (IMNV) [7]. Further description of IMNV particles was subsequently reported [8,9].

66.1.1 Classification

Analysis of the amino acid sequence of the RNA-dependent RNA polymerase (RdRp) of IMNV and comparison with other viral sequences allowed its classification into the *Totiviridae* family [8–12].

The *Totiviridae* family encompasses a diverse group of viruses that appear as isometric capsid particles of 40 nm in diameter and possess a nonsegmented, double-stranded RNA (dsRNA) genome. In most cases, the genome encodes only one capsid protein (major capsid protein, or MCP) and RdRp [9,11,13].

According to the International Committee on Taxonomy of Viruses report in 2008, the family *Totiviridae* is made up of three recognized genera: *Totivirus*, *Giardiavirus*, and *Leishmaniavirus*, which together include 18 viral species that infect fungi or protozoa. Viruses infecting yeast and filamentous fungi are placed in the *Totivirus* genus [9,11,13]. Considered as "putative" *Totivirus* by some authors [8,9,11,12], IMNV presents an analogy both in size and in genomic sequence to *Giardia lamblia* virus from the *Giardiavirus* genus. Tang et al. [9] proposed a new monotypic genus in the family *Totiviridae* to accommodate IMNV.

IMNV is the only member of the *Totiviridae* family that infects other hosts than fungi or protozoa and has been implicated in the disease process [8,9,13].

66.1.2 Morphology and Genome Organization

Virion of IMNV measures about 40 nm in diameter, is nonenveloped, contains a capsid with icosahedral symmetry

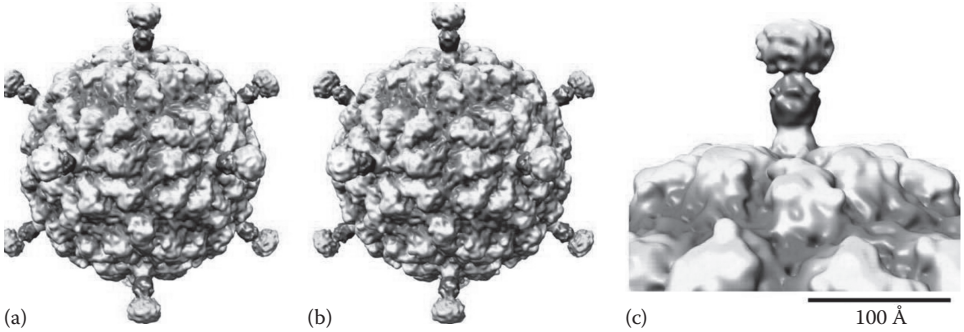

FIGURE 66.1 Fiber-like protrusions at 5f axes of infectious myonecrosis virus (IMNV) virion. (a) Radially color-coded surface view of IMNV virion, in stereo, with complex protrusions evident at the 5f axes. (b) Close-up view of one protrusion and the surrounding capsid. (c) Surface view of IMNV virion in black and white, with overlay of T_1 model and selected major capsid protein (MCP)-A subunits (blue, cyan) and MCP-B subunits (red, pink, orange). (Reprinted with permission from Tang, J., Ochoa, W.F., Sinkovits, R.S. et al., Infectious myonecrosis virus has a totivirus-like, 120-subunit capsid, but with fiber complexes at the fivefold axes, *Proc. Natl. Acad. Sci. USA*, 105, 17526, Copyright 2008 National Academy of Sciences, U.S.A.)

composed of 120 subunits, and shows a buoyant density of 1366 g/mL in cesium chloride (CsCl) [8,9]. Structurally, the 120 subunits consist of the same protein, the MCP. However, this protein shows two forms of arrangement within the capsid, and therefore, it was named MCP-A and MCP-B. Capsids possess 60 copies each of two chemically identical subunits, MCP-A and MCP-B, distinguished by their nonequivalent positions (Figure 66.1a and b). The A subunits form pentameric clusters around each of the 12 5f axes, and the B subunits form trimeric clusters around each of the 20 3f axes. Moreover, five B subunits lie in a staggered arrangement around each A pentamer so that together they form a compact decamer centered at each 5f axis [9].

Unusually for the *Totiviridae* family, IMNV shows fiber-like protrusions along the viral capsid (Figure 66.1a and b) [8,9]. These proteinous protrusions are likely to be important for virus entry through their binding to receptors on target cells or involvement in cellular internalization processes. This may help explain the unique ability of IMNV, among other members of the same family, in being transmitted in an extracellular way between host organisms [9].

IMNV genome harbors a nonsegmented, dsRNA of 7560 bp, localized in the interior to the capsid, and packaged as five or six concentric rings (Figure 66.2a and b). Similar to other members of the family, IMNV genome shows two open reading frames (ORFs). ORF 1 is located at nucleotide 136–4953 and encodes a protein of 179 kDa, which includes the N-terminal sequence of the capsid protein (MCP). The ORF 2 is located between the nucleotides 5241–7451 and encodes a protein of 85 kDa that corresponds to the RdRp [7–9,11,13–15].

66.1.3 Epidemiology

The first records of IMN in cultured *L. vannamei* were documented in Northeast Brazil (Piauí state) in 2002, after a period of heavy rainfall. Since 2003, IMN was reported in several marine shrimp farms, mainly in the states of Ceará, Rio Grande do Norte, Paraíba, and Pernambuco [16,17].

IMNV seems to be limited to the Brazilian Northeast, but shrimps with similar signs have also been found in Indonesia, with IMNV being posteriorly identified.

Species of penaeid shrimp *L. vannamei*, *L. stylirostris*, and *Penaeus monodon* are susceptible to IMNV and among these species, *L. vannamei* is most frequently affected [14].

IMNV is the major cause of mortality in shrimp farming and affects the quality of final product [14,18]. Juvenile and subadult shrimps are most severely affected by the disease, as they are grown in salt or low salinity [5,7].

Besides Brazil, IMNV has spread to other countries, with a confirmed case in Indonesia [15,19]. Senapin et al. [20] further confirmed that IMNV occurred in Indonesia but not in China, India, Malaysia, Thailand, and Vietnam. Thus, IMNV has not yet reached other Asian countries outside Indonesia.

Interestingly, the symptoms similar to those observed in myonecrosis caused by IMNV were observed in *Penaeus aztecuz* in the United States in 1970 and in Mexico in 1978 as well as in *Farfantepenaeus subtilis*, native species in the coastal zone of Piauí, in the 1980s [8,17]. Given these findings, Santana et al. [21] hypothesized that the IMNV may be a recurrence of a disease in a new host, *L. vannamei*. Some researchers believed that *F. subtilis*, infected in the Piauí coast, may be responsible for the contamination of farms of *L. vannamei* and caused the spread of the disease on farms in the Northeast.

66.1.4 Clinical Features and Pathogenesis

The manifestations of the disease are characterized by an extensive area of necrosis in the skeletal muscle, especially in the distal abdominal segment, and loss of transparency in the tail, which becomes opaque with milky areas [5,7,8]. The whitening may begin at the fifth or sixth abdominal segments or on the sides and distal areas of the tail close to pleopods [5]. Relative to the degree of severity, opacity extends progressively toward the telson and uropods. The disease is slowly progressive, with mortality reaching 70% in juvenile and subadult shrimps.

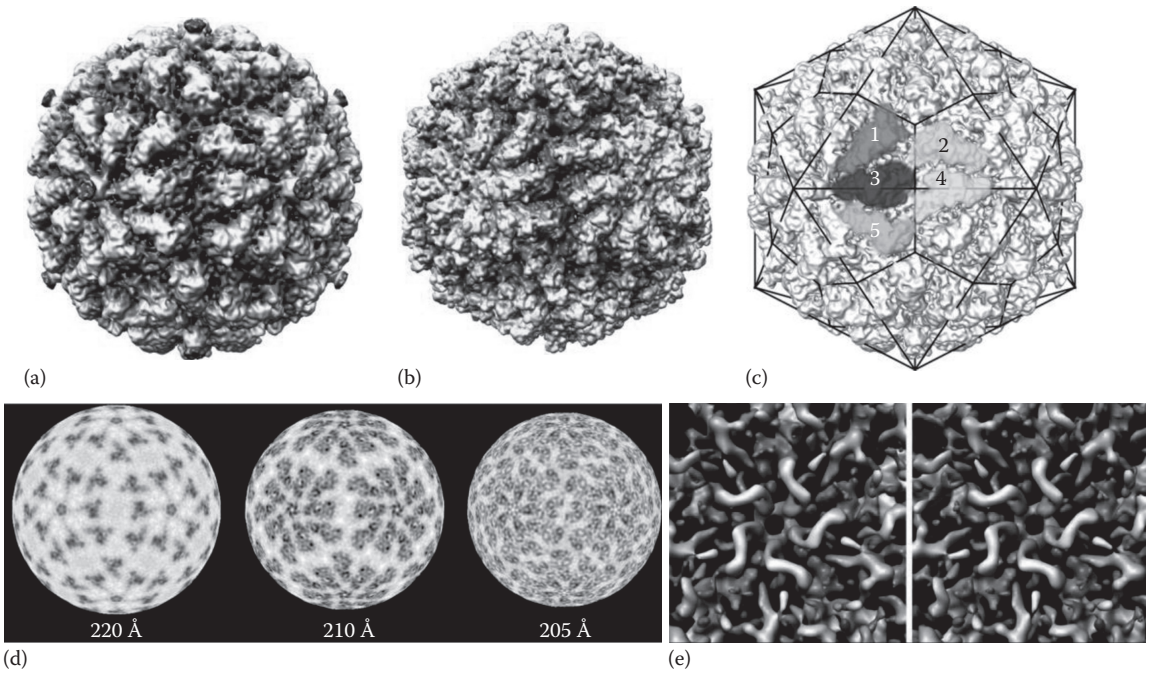

FIGURE 66.2 Infectious myonecrosis virus (IMNV) capsid at 8.0 Å resolution and comparison with x-ray model of ScV-L-A capsid computed to 8.0 Å resolution. (a) Radially surface view of IMNV virion, with outer parts of protrusions removed by zeroing densities above radius 225 Å. (b) Comparable surface view of ScV-L-A (14) to which the same radial color table was applied. (c) Surface view of IMNV virion in black and white, with overlay of T = 1 model and selected major capsid protein (MCP)-A subunits (3, 4) and MCP-B subunits (1, 2, e 5), was highlighted for reference in the text. (d) Spherical sections at different radii as indicated below each image, with density values coded in grayscale (darker, denser). (e) Space-filling slab view, in stereo, as seen from the inner surface of the IMNV capsid. Tube-like densities that form two concentric rings around the 5f axis (inner and outer rings from MCP-A and MCP-B subunits, respectively) are interpreted as α-helices. (Reprinted with permission from Tang, J., Ochoa, W.F., Sinkovits, R.S. et al., Infectious myonecrosis virus has a totivirus-like, 120-subunit capsid, but with fiber complexes at the fivefold axes, *Proc. Natl. Acad. Sci. USA*, 105, 17526, Copyright 2008 National Academy of Sciences, U.S.A.)

In the acute phase, it presents coagulative myonecrosis with some swelling between necrotic muscle fibers. Lesions may be present in a focal or multifocal way after the acute phase. In a chronic stage, lesions are accompanied by liquefaction of necrotic muscle fibers. At this stage, the muscles exhibit a reddish color, giving an appearance of cooked shrimp. Due to this, many producers have dubbed the dying individuals "zombie shrimp" or "living dead shrimp" because even with the appearance of being dead (red tail) and debilitated, animals still live for several days [5,17]. In some cases, symptoms may offer evidence of the severity of IMNV grown in population. However, it should not be used alone as a reference because mortality can be accentuated even in mild and moderate stages of the disease [4]. The animal may die at any stage of the disease, but most mortality occurs in the advanced stage of the disease.

The illness causes food restriction, decrease in volume of hepatopancreas (and subsequent reduction or absence of lipid storage), difficulty in hardening carapace, and also erratic swimming. Many animals present deformed intestine, or in the shape of "S" and a rigid bend in the abdominal muscle.

Larger animals die easily due to physical weakness [5,17,22]. Using *in situ* hybridization technique, Tang et al. [14] noted that IMNV infects the skeletal muscle tissue and also reaches the lymphoid organ and hindgut. On histological analysis, lesions in the muscle tissue and viral inclusion bodies in the cytoplasm of connective tissue cells and also in hemocytes of infected shrimps were observed. Hemocytic infiltration in the hepatopancreas and heart of shrimps also occur during infection [14]. It is also possible to observe the presence of ectopic spheroids in the lymphoid organ in proximity to the heart and antennal gland [8,17]. Tang et al. [14] showed that the presence of lymphoid organ spheroids is a typical histopathological finding of IMNV. The spheroids are a defense mechanism from lymphoid organ to play its role engulfing the invading agent by defense cells, aiming for its expulsion.

66.1.5 Transmission

IMNV transmission usually occurs through horizontal transfer. That is, transmission of an infectious agent from a sick or a bearer individual, either through direct or indirect contact or by means of a vector. In the case of IMNV, there are no specific data on vectors. Transmission occurs through contamination of water and/or cannibalism, for example, healthy shrimp feed on infected shrimp [8]. Vertical transmission is the transfer of an infectious agent from a sick individual to its

offspring, particularly from the mother to its offspring either through contamination of eggs or during lay. It is believed that vertical transmission may occur, but this is still not experimentally documented [8,23-25].

In most cases, contamination results from an improperly transboundary movement of broodstock by people or equipment cleaned in an inappropriate way [2]. It is likely that marine birds feeding on contaminated shrimp from farms may play a part in epizootic transmission of IMNV [14,15,23].

Additionally, acquisition of noncertified postlarvae and environmental imbalance represent other determinants of contamination [26].

66.1.6 Diagnosis

Conventional techniques: Histopathological examination of the tissue sections stained with hematoxylin–eosin has been widely employed to the diagnosis of IMN. Positive samples to IMNV show lesions characteristics of the acute phase such as coagulative necrosis of striated skeletal muscles fibers and hemocyte infiltration with edema formation among muscle fibers and fibrosis [7,17,22,27].

Molecular techniques: The diagnosis of IMNV infection based on clinical signs and histological examination is insufficient to rule out diseases caused by other pathogens such as *Penaeus vannamei* nodavirus [28] and *Vibrio* spp. [29].

Therefore, more specific methods such as molecular techniques need to be employed for IMN diagnosis. Reverse transcription polymerase chain reaction (RT-PCR), real-time RT-PCR, nested RT-PCR, and lamp RT-PCR are examples of molecular procedures that are increasingly applied for IMNV identification. In addition, immunoassays with highly specific monoclonal antibodies (MAbs) have also proven valuable for IMNV diagnosis.

66.2 METHODS

66.2.1 Sample Preparation

The first step in sample preparation involves the homogenization of gnathothoraces ("heads") from subadult *P. vannamei* showing signs of disease in a buffer Tris/HCl (pH 7.5) enriched with NaCl. Then, the suspension is cleared through low-speed centrifugation. The use of differential centrifugations further helps separate the viral particles from the cell debris [30]. Poulos et al. [8] used fumed silica and activated charcoal to clarify the suspension. Furthermore, the homogenate may be subjected to a sucrose gradient and an ultracentrifugation to obtain purified viruses.

66.2.2 Detection Procedures

66.2.2.1 RT-PCR

PCR utilizes oligonucleotide primers from regions of interest to amplify a specific DNA sequence from target organism. PCR mixtures containing target DNA, nucleotides, and thermostable DNA polymerase are typically subjected to cycles of temperatures that permit the separation of double strand (denaturation), primers pairing, and elongation of segment.

The entire genome from an organism can be sequenced after amplification of segments of DNA by PCR. Organisms that possess RNA as genome sometimes must be transcribed into DNA before PCR amplification. This is possible by utilizing a reverse transcriptase from retrovirus. The combination of RT and PCR amplification (RT-PCR) forms the basis of molecular diagnosis of RNA viruses such as IMNV.

Poulos et al. [8] determined the complete sequence of genomic RNA from Brazil IMNV, and Senapin et al. [15] cloned and sequenced the full 7.5 kb genome from Indonesia IMNV by using a commercial kit and primers to target regions (Table 66.1). These advances facilitated the development of RT-PCR for IMNV diagnosis. A commercial kit that amplifies a 227 bp fragment is also available, and nested RT-PCR and lamp RT-PCR have been subsequently designed on the basis of this fragment.

66.2.2.2 Real-Time RT-PCR

Real-time RT-PCR represents an improvement of RT-PCR. The introduction of a probe labeled with fluorescent dyes enables direct (real-time) detection of the amplified products.

Andrade et al. [22] described a real-time assay with primers and TaqMan probe derived from the IMNV genome (Genbank accession no. AY570982) [8]. This assay can detect a few IMNV copies (about 10 copies/μL RNA), which is more sensible than the nested RT-PCR (detecting 1000 copies/μL RNA).

Table 66.1 lists the primers utilized by several authors in various RT-PCR protocols. Andrade et al. [22] utilized a segment corresponding to the nucleotides 467–500 as probe (which is labeled with fluorescent dyes 5-carboxyfluorescein [FAM] on the 5′ end and N,N,N′,N′-tetramethyyl-6-carboxyrhodamine [TAMRA] on the 3′ end).

66.2.2.3 Nested PCR

Nested PCR is a modification of PCR with the goal to reduce the formation of incorrect/undesirable DNA sequences due to binding of the primer to the nonspecific sequences. The technique involves a second set of primers that amplify a secondary target localized within the segment produced by the first set of primers. Nested RT-PCR has been used for the detection of IMNV by several authors including Senapin et al. [20] and Poulos and Lightner [31].

66.2.2.4 Loop-Mediated Isothermal Amplification Assay

Loop-mediated isothermal amplification (LAMP) is a nucleic acid amplification technique that utilizes a set of four specially designed primers and a DNA polymerase with strand displacement activity to amplify DNA under isothermal conditions [32]. It has the advantages of being rapid, efficient, and specific, without relying on elaborate equipment.

The inclusion of additional primers (termed loop primers) further accelerates the LAMP reaction [32] and reduces the reaction time by half relative to the original protocol [31]. By incorporating a RT step into LAMP protocol together with the use of a ssDNA probe labeled with gold nanoparticle (AuNP), Arunrut et al. [33] demonstrated that IMNV could be detected with decreased testing time and increased sensitivity in comparison with RT-PCR methods.

66.2.2.5 Immunoassays

Immunological methods are widely used to detect and diagnose infectious diseases. Recently, an immunoassay using MAbs against segments of IMNV–MCP has been reported for highly specific detection of IMNV [34]. In another study, a recombinant fragment of the IMNV–MCP gene encoding amino acids 105–297 was heterologously expressed in *Escherichia coli* and the product was used to immunize Balb/c mice to generate Mabs [35]. Of the six MAbs obtained, four recognized IMNV in tissue homogenates from naturally infected shrimps by immunodot blot assay and three detected a 100 kDa protein that corresponds to MCP in western blot assay. Viral inclusion bodies were detected in muscle fibroses by western blot and immunohistochemistry. Two MAbs showed high specificity and sensitivity, as no cross-reaction was observed with healthy shrimp tissues in any assays, indicating their usefulness for IMNV detection.

Mello et al. [30] purified IMNV from infected shrimp and used the virions to immunize mouse. The resulting polyclonal antibodies were screened against crude extracts in western blot assay. Antibodies that did not react with the crude extract from uninfected shrimp appeared to be specific for IMNV and provided an efficient approach to detect IMNV.

66.3 CONCLUSION AND FUTURE PERSPECTIVES

Accurate and rapid diagnosis of IMNV is crucial for the control or eradication of IMN in shrimps. Complementing to classical methods of histopathology and microbiology, molecular and immunological diagnostic methods have played an increasingly important role in safeguarding the health and well-being of farmed shrimp [15,26].

Despite enormous efforts that have been made by researchers, no effective treatment and/or vaccine is currently available for the eradication or at least control of the spread of IMNV among carciniculture farms. Thus, prevention remains the only option against IMNV infection. Recently, a treatment based on interference RNA (iRNA) is being investigated as a way to prevent replication of the virus in shrimps. Bartholomay and Harris [36] showed that after receiving 5 mg of iRNA corresponding to portions of the IMNV genome, shrimps previously exposed to a lethal dose of IMNV did not succumb to the disease.

Other measures to prevent IMNV infection in shrimp consist of the use of specific pathogen-free stocks, selection of IMNV-resistant white shrimp [37], and satisfactory sanitation conditions.

67.1 INTRODUCTION

The worldwide spread of infectious bursal disease virus (IBDV) in poultry has been well documented over the past decades [1]. The virus usually affects young chickens, causing moderate to high mortality rate, loss of weight, poor flock performances, and immunodeficiency. In the best-case scenario, birds that recovered from infection may show good productivity later on. However, secondary viral or bacterial disease may hamper the recovery process and contribute to higher mortality rate than IBDV itself. Good management practice and vaccination is currently the most effective way to mitigate against infectious bursal disease (IBD). In the early 1970s, field strains usually caused immunosuppression in affected flocks. Many years of work by poultry specialists highlighted the value of vaccination, given the dramatic changes in pathogenic potential of the IBDV. An approach to vaccinate breeder flocks with inactivated vaccines (after priming with live attenuated viruses), to obtain high levels of maternally derived antibodies in progeny, has held promises for years. Due to the emergence of a new biotype of very virulent IBDV (vvIBDV), attempts have been made to protect broiler and layer flocks as soon as possible by introducing intermediate and intermediate plus vaccines. The concept of subcutaneous injection with immunocomplex vaccines [2] and in ovo vaccination applying automatic injectors is increasingly accepted for early protection purposes [3,4]. Thus, vaccination strategies have essentially evolved around the selection of an appropriate vaccine and the timing of vaccination [5,6]. Paying necessary attention to the epizootiology of IBDV is also important to prevent and combat the infection.

67.1.1 Classification, Morphology, and Genome Organization

Classified in the genus *Avibirnavirus*, family *Birnaviridae*, IBDV is a double-stranded RNA (dsRNA) virus with a bisegmented genome. Of the two distinct serotypes identified, serotype 1 is further divided into three major subtypes that cause disease in poultry, whereas serotype 2 strains are infectious for poultry, turkey, and other free-living birds but do not cause clinical illness and thus are not targeted for immunization.

In the early 1970s, the classical types of IBDV emerged all over the world. The mortality rate in young birds was up to 20% and immunosuppression was an important viral mechanism. In the early 1980s, the variant IBDV were isolated in North America. These viruses were discovered by introducing the sentinel unvaccinated birds in flocks that have received regular IBDV prophylaxis. The bursas of sentinel chickens were atrophic but an inflammatory reaction does not occur [7,8]. In the early 1990s, the very virulent biotype of the virus had emerged in Europe [9,10], and soon after, it was also diagnosed in Southeast Asia, Middle East, Africa, and America.

Analysis of the short linear sequences from the hypervariable domain of the VP2 and subsequent generation of the phylogenetic tree have facilitated improved virus classification. It is important to denote which amino acid exchanges contribute

to virulence and virus tropism. Sequence alignment is often performed for all virus proteins, but the hypervariable domain of the VP2 is the most frequently studied.

The next important breakthrough in research was the establishment of the reverse genetic system to obtain infectious cDNA, providing a chance to induce the specific amino acid exchanges, by site-directed mutagenesis technique [11]. When constructing the chimeric viruses, it was discovered that a single amino acid exchange Ala284→Thr at the VP2 was sufficient for partial attenuation and the virus retrieved grew on chicken embryo fibroblast [12]. A mutant virus obtained by the reverse genetic system from a vvIBDV strain UK661 with Ala284→Thr and Gln253→His transitions also became attenuated and induced mild transient lesions in the bursa [13]. It is interesting that such mutations could also occur naturally in the bursa environment [14]. Unexpectedly, after the passage in susceptible chickens, some of the genetically engineered IBDV has resulted in a clone that reverted to a pathogenic phenotype [15]. Since 002/73, F52/70, and UK661 strains derived from the bursa also have Gln253 and Ala284 on the VP2, but induced 0%, 10%, and 80% mortality in specific pathogen-free (SPF) chickens, these amino acids could not be solely contemplated as a marker of virulence. Therefore, the following amino acid composition was suggested for virus classification at molecular level:

Virus Biotype	Amino Acid Composition in the Hypervariable Domain of the VP2				
Very virulent	Ile 242	Gln 253	Ile 256	Ala 284	Ile 294
Classical	Val 242	Gln 253	Val 256	Ala 284	Leu 294
Attenuated	Val 242	His 253	Val 256	Thr 284	Leu 294

In total, four phylogenetic groups were obtained, but cluster II was further divided into IIa and IIb. It was also recorded that Australian virulent IBDV has evolved independently from very virulent viruses in Europe or the Far East countries and presented a different linage even though the same amino acid sequence Ala222 and Ser299 are shared between them (it was previously believed that Ala222 is a marker of virulence) [16]. A more recent phylogenetic work confines nine genetic clusters (from I to IX) in IBDV. Except for a few strains, 70% prove to have the same origin and it was concluded that vvIBDVs are probably clonally related because of the high sequence homology in both segments (A and B), which also suggests their coevolution [17]. Recently, the reverse genetics system and site-directed mutagenesis have been used to develop several recombinant viruses from the parent strain 94432, and it was discovered that amino acid valine at 321 modifies the most exposed part of the VP2 causing reduced pathogenicity. Similar attenuation effect was accomplished with threonine residue at 276 from the finger domain of the VP1 [18]. Thus, single amino acid exchanges at both viral proteins (i.e., VP2 and VP1) are sufficient to shift the virulent form of IBDV. It was also discovered recently that genetic rearrangements between vvIBDV and serotype 2 viruses may occur naturally, and it was postulated that because serotype 2 strains infected a wide variety of birds, they have a chance to counteract with viruses belonging to serotype 1 group [19].

Virus genome of IBDV is localized within a single-shelled capsid of icosahedral symmetry. With a diameter of 60 nm, the virus particle has a shape of a lettuce ($T = 13$) and is nonenveloped [20,21]. The virus possesses a bisegmented dsRNA genome [22,23]. The larger segment A (3.2 kb) encodes a polyprotein that is autocatalytically cleaved [24] to obtain VP2, VP3, and VP4 proteins. The small open reading frame (ORF) partially overlapping the large ORF encodes a VP5 [25]. This protein has an important role in the apoptosis processes and induces cell lyses [26,27]. The hypervariable region of the capsid protein VP2 encompasses amino acids from 206 to 350 having several important mutational "hot spots" that are affecting, in part, the pathogenic potential of the virus [28]. This region is also carrying important immunogenic determinants [29]. The VP3 is the ribonucleoprotein and scaffolding protein, while the VP4 is the virus protease [18]. The smaller segment B (2.9 kb) encodes the RNA-dependent RNA polymerase (RdRp) [30]. In birnavirus, transcription and replication processes are initiated by protein priming. This process is accomplished by RdRp. Recently, it was discovered that RNA polymerase motifs are arranged in a permuted order of sequence (this has not been found in other dsRNA viruses). The IBDV encodes polyprotein in gene segment A rather than produces single transcripts of the mRNA. The sequence ADN in polymerase motif C on the VP1 was found to be an unusual and new property of birnavirus polymerases that appears to function as a regulator of the growth rate of the virus. These features as well as the crystal structure of the viral capsid suggest the possibility that birnaviruses may have originated from their single-stranded RNA counterparts [31]. The nonstructural protein 17 kDa also has a significant role in IBDV pathogenesis and needs to be demanded when studying the virus replication mechanisms [32].

67.1.2 Clinical Features and Pathogenesis

Clinical symptoms appear in chickens infected with virulent IBDV after 24–48 h. The morbidity and mortality are most severe 3–5 days postinfection (dpi), although symptoms could last for another 10 days or longer. The final course of the disease depends excessively on secondary bacterial (e.g., *Escherichia coli*) and viral infections, which albeit influence the health status of the birds after IBDV has diminished from the flock.

The mean symptomatic index (MSI) has been introduced to monitor as close as possible the symptoms of the disease in chickens infected by IBDV [33]. The proposed model comprises the following: no signs of the disease (0); typical IBD signs such as ruffled feathers only in quiet birds; birds stimulated by a sudden change in the environment appear normal; motility is not reduced (score 1); dehydration and reduced motility, conspicuous even when the birds are stimulated (score 2); and prostration and death (score 3). This model enables statistical calculations in evaluating the severity of clinical symptoms of affected birds.

All IBDV strains replicate in dividing IgM-bearing B cells in the bursa of Fabricius. Mild strains (like mild vaccine strains) induce little depletion of B lymphocytes, while the pathogenic viruses cause severe inflammatory response, lymphocyte depletion, and bursal atrophy. The comparison of tissue lesions in birds infected with vvIBDV (strain Ehime/91) and J1 strain (which have been isolated in 1972 and did not induce clinical condition) has shown that vvIBD causes severe depletion of B lymphocytes in the bursa, spleen, cecal tonsils, and severe cortical atrophy in the thymus at 5 dpi. Such pathology is much less prominent in birds infected with the mild J1 virus. In the bone marrow, pathological changes are not detected in chickens infected with mild J1 strain while in those infected with vvIBDV, a reduced number of hematopoietic cells were found from 2 to 7 dpi. Pathological lesions in the bone marrow also include a decrease in myelocyte numbers in the extrasinusoidal space, and an increase in the number of macrophages and a slight decrease of erythrocytes in the sinusoidal space. Lesions in the bone marrow may indicate that chickens have been infected with vvIBDV [34]. Importantly, the recovery process in the bursa takes place after infection with vaccine viruses, while pathogenic viruses may damage the bursa permanently [35,36].

The influx of T lymphocytes in the bursa of the chickens infected with pathogenic IBDV was first discovered in 1997 [37,38]. Until 7 dpi, T cell accumulation in the bursa increases and thereafter declines. The role of the T cell in the bursa of the chickens infected with IBDV is extensively studied. It was discovered that T cells inflowing the bursas are activated and proliferated in vitro when stimulated with the purified IBDV antigen and Concanavalin A (Con A). Con A is a non-antigen-specific plant mitogen known to stimulate proliferative response of T cells [39]. Intrabursal T cells also release IL-2 and IFN-γ, promoting greater inflammatory response compared to T cell–immunodeficient chickens [40], and they actually participate in virus clearance as it was discovered in the model of cyclophosphamide-bursectomized chickens [41].

67.1.3 Diagnosis

Clinical symptoms (high morbidity and high mortality in young chickens, usually after 3 weeks of age) and typical postmortem findings closely indicate the IBDV infection. It is therefore important to dissect as many chickens as possible if an outbreak occurs. The most striking pathological changes are subcutaneous and intramuscular bleedings on tight and pectoral muscles, while the bursa is enlarged in the gelatinous edema. Urate accumulation and swollen kidneys (nephrosonephritis syndrome) also indicate the pathological processes caused by IBDV. Hemorrhages in the proventriculus–gizzard junctions are sometimes seen in severe cases. If hemorrhages in the proventriculus–gizzard junctions are recorded, it is important to exclude Newcastle disease virus infection, especially in endemic regions, even if IBDV infection is suspected with high certainty. For differential diagnosis, the following diseases sometimes need to be ruled out: coccidiosis, infection with nephrotoxic strains of the infectious bronchitis virus, and hemorrhagic syndrome [42]. If the flock is supervised after the onset of clinical symptoms, the bursa is atrophic but bleeding on the tight and pectoral muscles could be visible for some time. Atrophic bursas may be diagnosed also in Marek's disease and if the birds are infected with adenoviruses [42]. Since the bursa is the primary organ for virus infection in IBDV, it is best to collect bursal specimens during the acute phase of infection. In situations when it is not possible to send bursa samples to a diagnostic laboratory instantly, it is recommended to store the bursas at −20°C (in an appropriate disposable package) and send it to the laboratory at the earliest occasion.

67.1.3.1 Conventional Methods

IBDV is present in the bursa for up to 10 dpi. The virus could be confirmed by applying immunodiffusion assay (also called agar gel immunodiffusion [AGID] test) after obtaining the bursa homogenate [43]. High antibody titer to IBDV in young birds detected by enzyme-linked immunosorbent assay also indicates the recent infection. Approximately 7–10 days after the onset of first symptoms, it is also possible to detect precipitin antibodies conducting the AGID test.

The virus could be isolated in embryonated chicken eggs by applying chorioallantoic membrane inoculation technique. It is preferable to inoculate SPF eggs at 9–11 days of embryonation, but in the case that SPF eggs are not available, the commercial embryonated chicken eggs could be used as well. The chorioallantoic fluid is collected from embryos that have died 3–5 dpi (embryos that have died in the first 48 h are discarded) [43]. Pathological changes in the chicken embryos infected with IBDV could not be used solely for virus confirmation. If possible, a challenge experiment on susceptible chickens or those deprived of IBDV antibodies could be organized, even though it is not the popular method due to welfare reasons. Since the mortality rate in infected chickens accurately implicates the virulence of the strain (see MSI index in the clinical symptoms section), it is still used for research purposes. The challenge experiment has to be done in highly secured experimental rooms (the best is to use Horsfall isolators) under the observation of an experienced technician or veterinarian and after obtaining an agreement from the national regulation on animal welfare. The IBDV could also be confirmed by applying reverse transcription-polymerase chain reaction (RT-PCR), with the specific primers.

Vaccine strains usually grow in a cell culture, but pathogenic viruses require successive passage in the chicken's embryo before an actual adaptation on cell culture [44,45]. However, IBDV that has been adapted to the cell culture can revert to an attenuated phenotype and may restrain the pathogenic form.

Immunohistochemical staining of the bursa section is also commendable because lesions in the bursa caused by IBDV are quite typical and because it is possible to detect the virus in situ.

67.1.3.2 Molecular Techniques

The RT-PCR method is often used to confirm the presence of IBDV in the bursa, allantoic fluid collected from embryonated chicken eggs, or other specimens. This method is solidly replacing conventional techniques of virus detection and provides the possibility of simultaneous detection of vaccinal and pathogenic strains in the same specimen [14,46]. If the sequence of the hypervariable region of the VP2 is available, the alignment experiment is helpful in evaluating the type of the virus in question. Next, the phylogenetic analysis could be done by constructing the tree that places the virus to one of the IX clusters obtained to date [17].

67.2 METHODS

67.2.1 Sample Preparation

It is important to collect only the enlarged bursas in gelatinous edema for virus confirmation. When the bursas are dissected, intrafollicular hemorrhages are often visible or sometimes the whole bursa is hemorrhagic. For antigen preparation, it is recommended to select the enlarged bursas with less bleeding inside the organ. The bursas are homogenized with the tissue blender or manually. If manual homogenization is performed, this is achieved by freezing and thawing the homogenate at −20°C. An alternative approach for sample homogenization is to use sterile sand. When the homogenate is ready (the virus has been released from the cells), it is diluted in a sterile phosphate-buffered saline, pH 7.2–7.4 at a ratio of 1:10 w/v, centrifuged at 3000 × *g* for 10–15 min, and after which, the supernatant can be collected [43]. The obtained supernatant is enriched with the virus and needs to be handled with care (as for other infectious material, respecting the decontamination procedure before disposing the samples). It could also be used for the challenge experiment, for inoculation of embryonated chicken eggs, for the RT-PCR test, and also to detect the virus in AGID against the monovalent hyperimmune sera. The obtained homogenate could also be used as an antigen to test sera for the presence of IBDV antibodies. Except for the challenge test and for the purpose of inoculation of embryonated chicken eggs, the virus in the homogenate must be chemically inactivated.

Bursas and other lymphoid organs (the spleen, thymus, cecal tonsils, and bone marrow) may be collected for pathohistology examination and/or immunohistochemical staining. For that purpose, pieces of tissue are placed in 10% neutral buffered formalin. For immunostaining procedure, it is important to obtain a tissue section within 72 h. If the hematoxylin–eosin staining is only being performed, the tissue can be held in formalin for a longer period of time.

67.2.2 Detection Procedures

The bursal homogenate is placed in the central well of the agar while positive and negative sera are distributed apart. After 24–48 h of incubation at 37°C (providing moist chamber), the precipitin lines (sometimes three or four appear between wells) are detected under the light in a dark room [47].

Characteristic pathological changes of the embryo are as follows: edematous distention of the abdominal region; cutaneous congestion and petechial hemorrhages particularly along feather tracts; occasional hemorrhages on the toe joint and cerebral region; mottled-appearing necrosis and ecchymotic hemorrhages in the liver; pale and parboiled appearance of the heart; kidney congestion and mottled necrosis; and extreme lung congestion and pale spleen, occasionally with small necrotic foci. Variant strains usually do not induce mortality of embryos but splenomegaly and liver necrosis is visible during the infection [42].

67.2.2.1 RNA Extraction

RNA extraction should be performed using RNase-free gloves, labware, and reagents, which will help to prevent contamination of samples, with ubiquitous RNases and other agents. Double-stranded IBDV RNA can be extracted from infected tissues using commercial kits based on silica membrane or magnetic beads. As an alternative, the standard protocol for phenol/chloroform extraction or the Trizol protocol for RNA extraction can be used, after the digestion of the bursa suspension with lysis buffer and proteinase K. Extracted RNA should be stored at temperatures ≥−20°C or ≥−70°C.

67.2.2.2 Reverse Transcription

Extracted IBDV RNA must be denaturized before the RT reaction. This can be done by heating the RNA extract at 92°C for 3 min and then chilling it on ice, or heating the RNA extract at 95°C for 5 min and then incubating it at −80°C or in liquid nitrogen [43]. RT can be done with many commercially available reverse transcriptases by following the manufacturer's instructions and by using specific or random primers. In a routine diagnostic, one-step RT-PCR kits are often used, thus shortening the time of the reaction and avoiding the possibility of contamination.

67.2.2.3 PCR Amplification

Primers used for the detection and molecular characterization of IBDV are mainly designed for amplification of the middle third of the VP2 gene in segment A that contains a variable region (vVP2), or for amplification of the region on the 5′ extremity of the IBDV in segment B. Both regions are suitable for molecular epizootiological studies. Two of such protocols are described in the following [43].

Nucleotide sequence of the U3 and L3 IBDV-specific PCR primers specific for segment A, VP2 gene:

Upper U3: 5′-**TGT-AAA-ACG-ACG-GCC-AGT**-GCA-TGC-*GGT-ATG-TGA-GGC-TTG-GTG-AC*-3′

Lower L3: 5′-**CAG-GAA-ACA-GCT-ATG-ACC**-GAA-TTC-*GAT-CCT-GTT-GCC-ACT-CTT-TC*-3′

Nucleotide sequence of the +226 and −793 IBDV-specific PCR primers specific for segment B, VP1 gene [43]:

Upper +290: 5′-**TGT-AAA-ACG-ACG-GCC-AGT-**GAA-TTC**-***AGA-TTC-TGC-AGC-CAC-GGT-CTC-T*-3′

Lower −861: 5′-**CAG-GAA-ACA-GCT-ATG-ACC**-CTG-CAG**-***TTG-ATG-ACT-TGA-GGT-TGA-TTT-TG*-3′

The U3/L3 pair generates a 604 base pair (bp) product, 516 bp of which is specific for the amplified IBDV sequence and covers the region encoding the hypervariable region of the VP2 protein. The other pair, +290/−861, generates a 642 bp product, 549 bp of which are specific for the amplified IBDV sequence. Obtained PCR products can be sequenced in both directions and possess the restrictions sites (*Sph*I in primer U3, *Eco*Ri in primer L3 and +290, and *Pst*I in primer −861[underlined]) suitable for cloning experiment [43].

The procedure for both protocols are as follows:

1. Remove all PCR reagents, RNA extracts, and positive and negative controls from the freezer; vortex and spin them down before opening the tubes.
2. Prepare the one-step RT-PCR mix as follows (volumes indicated per specimen).

Component	Volume (μL)
2× reaction mix	25
Template RNA (0.01 pg–1 μg)	5
Lower primer (10 μM)	1
Upper primer (10 μM)	1
SuperScript® III RT/ Platinum® Taq Mix	2
Autoclaved distilled water	to 50

3. Add 45 μL of the prepared RT-PCR mix and 5 μL of extracted RNA to a 0.2 mL PCR tube.
4. Briefly spin the tubes in a microcentrifuge.
5. Program the thermal cycler as follows and put the tubes in the cycler: cDNA synthesis, 1 cycle at 50°C for 30 min; denaturation, 1 cycle at 94°C for 2 min; PCR amplification, 40 cycles at 95°C for 30 s (denature), 64°C for 45 s (anneal), and 68°C for 1 min; and final extension, 1 cycle at 68°C for 5 min.
6. Once the amplification is over, briefly spin the tubes and analyze the PCR products by agarose gel electrophoresis.
7. Electrophoresis of the PCR products and DNA molecular weight markers should be performed in a 1%–2% agarose gel, stained with ethidium bromide. (Caution: Ethidium bromide is toxic and carcinogenic.)
8. Before the sequencing of the amplified product, the unincorporated nucleotides, primers, and nonspecific products must be removed. This step can be done by excision of a specific band from agarose and purification using one of the commercially available spin column kits. The amount of purified DNA can be estimated by electrophoresis in a 1%–2% agar gel in parallel with DNA standards or measured by spectrophotometer or colorimeter.

If no internal amplification control is used, three PCRs should be performed for each cDNA sample (pure, 10-fold, and 100-fold diluted cDNA) to avoid false-negative results due to PCR inhibition in mixes containing high amounts of cDNA preparation. Each PCR should include negative and positive control reactions [43]. Using both segment A–targeted and segment B–targeted RT-PCR protocols increases the likelihood of serotype 1 IBDV detection. This also allows a thorough genetic characterization of the IBDV strains detected.

67.2.2.4 Real-Time PCR

More recently, real-time RT-PCR assays have quickly become one of the most promising methods for improving control and epizootiological surveillance programs [48]. This method is highly sensitive and enables detection of 10^2–10^3 copies of virus template. The advantage of real-time RT-PCR assay over the previously described assays is that it can be fully automated and it is suitable for processing large numbers of samples. The possibility of screening a large number of samples in a rapid, sensitive, and reproducible way makes this assay a suitable tool for routine testing in poultry diagnostic laboratories [49]. Several real-time RT-PCR assays have been developed for IBDV and some of them can simultaneously identify, characterize, and differentiate field strains from vaccinal strains using either fluorogenic probes or intercalating dyes [50–54].

67.3 CONCLUSION AND FUTURE PERSPECTIVES

IBD has a significant economic impact in many countries around the globe. In spite of very intensive research and improving knowledge on IBDV pathogenesis, we do not understand what the exact reason for the mortality in chickens is. We also do not know if the IBDV has reached the limit in its virulent and pathogenic potential. It is possible that some amino acid exchanges in virus proteins are strain specific, or they occur as a random event. For that reason, reverse genetic system is the best way to study their role in viral pathogenesis. The research on the crystallographic structure of virus proteins, the virus–cell synergy in apoptosis, and the replication process of the IBDV will provide a better understanding of virus–cell interactions caused by this family of viruses. The possibility for performing research on the IBDV of diverse virulence provides an opportunity to identify common features in the pathogenic processes they cause and thereafter to identify the differences between them. The goal is also to find the best immunizing strategy for chickens, keeping in mind that if there is no susceptible host, this contagious virus will not be able to spread.

68.1 INTRODUCTION

African horse sickness virus (AHSV) is the causal agent of African horse sickness (AHS), which is a highly infectious and deadly disease of horses, ponies, European donkeys, mules, camels, goats, and buffalo. The clinical presentations of AHS range from inappetence, severe pyrexia, widespread hemorrhages and edematous exudations, impaired respiratory and vascular functions, to death (with mortality as high as 95% in horses and 80% in mules). However, African donkeys and zebra are largely refractory to the devastating consequences of AHS and rarely show clinical signs. In addition, AHSV may infect carnivores such as dogs that ingest contaminated meat.

Although a disease resembling AHS was first recorded in 1327 in Yemen, with the natural zebra population acting as reservoir host, the disease was reported in imported horses in central and east Africa in 1569 and in southern Africa around 1710s. The first major outbreak of AHS in 1719 claimed the lives of about 1700 animals. Since then, >10 additional outbreaks of AHS were documented on the African continent. Along with the decline in the wild zebra population due to hunting throughout the last century and the introduction of AHS vaccines, the incidence of AHS in southern Africa has steadily declined. Currently, the endemic zones of AHS are restricted to sub-Saharan Africa, Yemen, and the Arabian Peninsula, but the disease has periodically emerged in other parts of the world, including India, Pakistan, Spain (1987–1990), and Portugal (1989) [1].

While not directly contagious, AHS is known to be transmitted by insect vectors, such as *Culicoides* midges, mosquitoes, black flies, sand flies, or ticks. Given the potential of AHSV to cause significant mortality and debilitating morbidity in naïve equid populations and its capacity for sudden and rapid expansion, AHS is listed as a notifiable disease by the Office International des Epizooties and is included on the list of select agents of the USDA. In order to support effective deployment of vaccination strategies (considering the fact that the current attenuated, inactivated, and subunit vaccines for AHSV are serotype specific), to demonstrate the absence of the virus in individual animals or animal products (for safe movements/export/import), and to declare a "virus free" status, especially after outbreaks in nonendemic countries or zones, it is important to have rapid, sensitive, and specific diagnostic tests available for identification and detection of AHSV type. By first presenting an overview on its classification, morphology, genome organization, epidemiology, clinical features, pathogenesis, diagnosis, treatment, and prevention, this chapter will provide streamlined molecular procedures for rapid detection and typing of AHSV.

68.1.1 Classification

AHSV is a double-stranded RNA (dsRNA) virus classified in the genus *Orbivirus*, subfamily *Sedoreovirinae*, family *Reoviridae*, which is divided into two subfamilies: *Sedoreovirinae* and *Spinareovirinae*. Whereas the subfamily *Sedoreovirinae* comprises six genera: *Cardoreovirus*, *Mimoreovirus*, *Orbivirus*, *Phytoreovirus*, *Rotavirus*, and *Seadornavirus*; the subfamily *Spinareovirinae* includes nine genera: *Aquareovirus*, *Coltivirus*, *Cypovirus*, *Dinovernavirus*, *Fijivirus*, *Idnoreovirus*, *Mycoreovirus*, *Orthoreovirus*, and *Oryzavirus*.

The genus *Orbivirus* is known to contain at least 17 species: AHSV, Bluetongue virus (BTV; the type species of the genus), Changuinola virus, Corriparta virus, epizootic hemorrhagic disease virus (EHDV), equine encephalosis virus (EEV), Eubenangee virus, Great Island virus, Orungo virus, Palyam virus (PALV), Peruvian horse sickness virus (PHSV), St Croix River virus, Umatilla virus, Wallal virus, Warrego virus, Wongorr virus, and Yunnan orbivirus [2]. Of these, AHSV, BTV, EHDV, EEV, PALV, and PHSV are highly pathogenic and economically important. With the exception of PHSV, which is likely spread by mosquitoes, most orbiviruses are transmitted by adult females of hematophagous *Culicoides* midges.

Currently, nine serotypes of AHSV (AHSV 1–9) are recognized, with AHSV serotype 9 being identified in 1960. Among AHSV serotypes, some cross-relatedness appears to exist between serotypes 1 and 2, 3 and 7, 5 and 8, and 6 and 9. Interestingly, while serotypes 1–8 are found only in restricted areas of sub-Saharan Africa, serotype 9 is associated with epidemics outside Africa. However, Spanish–Portuguese outbreaks between 1987 and 1990 were caused by AHSV-4 [3].

68.1.2 Morphology and Genome Organization

68.1.2.1 Morphology

As a nonenveloped particle of about 70 nm in diameter, AHSV virion is made up of an outer two-layered icosahedral capsid and a core that encloses the dsRNA genome [4,5].

The outer capsid is composed of two viral proteins (VP2 and VP5), with VP5 trimers forming globular domains and VP2 trimers in a three entwined leg formation (triskelions) on the virion surface. VP5 is positioned between the peripentonal VP2 molecules and around VP7 on the threefold axis of symmetry.

The core (inner capsid) consists of two major viral proteins (VP3 and VP7) and three minor viral proteins (VP1 [polymerase], VP4 [capping enzyme], and VP6 [helicase]). VP3 and VP7 are conserved among the nine AHSV serotypes and represent the group-specific epitopes. VP3 (a flat, triangular molecule organized in 60 asymmetric dimers) constitutes the innermost protein layer. Attached to the inner surface of the VP3 layer, VP1, VP4, and VP6 form a flowerlike transcriptase complex. VP7 (780 monomers arranged as 260 trimers) forms a second layer on top of VP3.

The AHSV genome (of 19.52 kb) is made up of 10 linear dsRNA segments of different sizes, with segments 1–3 (of 3965, 3203, and 2792 bp) being designated L1–L3 (large), segments 4–6 (of 1978, 1748, and 1566 bp) designated M4–M6 (medium), and segments 7–10 (of 1179, 1166, 1169, and 758 bp) designated S7–S10 (small). While the segments (L3, S7) coding for the core proteins (VP3, VP7) and the segments (M5, S8) coding for NS1 and NS2 proteins are highly conserved between different AHSV serotypes, the segment (S10) encoding NS3 and NS3a and the segments (L2 and M6) encoding the outer capsid proteins (VP2 and VP5) are more variable between AHSV serotypes [6–8].

68.1.2.2 Viral Proteins

The 10 segments of AHSV genome encode 7 structural proteins (VP1–VP7) and 4 nonstructural proteins (NS1, NS2, NS3, and NS3a), with NS3 and NS3a being synthesized from two in-phase overlapping reading frames of segment 10 (S10) [4,9,10].

VP1: Encoded by segment 1 (L1), VP1 is an RNA-dependent RNA polymerase, whose activity is highly dependent upon temperature, with an optimum between 27°C and 42°C and little or no activity below 12°C–15°C. This property permits AHSV undertaking viral RNA synthesis and replication within the insect vectors (ectothermic or ambient temperature) and mammalian hosts (about 37°C). As one of the core structural proteins, VP1 is very highly conserved and is unlikely to play a significant role in the specific adaptation of the virus to vectorial transmission [11].

VP2: Encoded by segment 2 (L2), VP2 (124 kDa) is susceptible to proteolytic cleavages (by equine serum proteases and the saliva of the insect host in vivo), which increase the infectivity of the virus in *Culicoides* insect. This may be attributable to a change in VP2-mediated receptor binding or increased efficiency of uncoating and exposure of VP7 during the early stages of infection and cell entry [12]. Similarly, cleavage of VP2 in the AHSV outer capsid by trypsin or chymotrypsin generates infectious subviral particles that demonstrate unchanged infectivity for mammalian cells but greatly enhanced infectivity for *Culicoides sonorensis* cells. Components (VP2 and VP5) of the outer capsid layer are released from the AHSV core below pH 6, an event that likely occurs in vivo within endosomes during the processes of infection and cell entry. This results in the activation of the transcriptase activity of the virus core, which is released into the host–cell cytoplasm. Therefore, besides its involvement in the initial cell attachment, the activated VP2 also contributes to virus entry in vivo. As a host specificity determinant, VP2 shows remarkable antigenic variability due to selective pressure from the host immune system. The specificity of interactions between components of the outer capsid, particularly protein VP2, and neutralizing antibodies forms the basis of serotype determination. Additionally, as a key immunogen and an important target for virus neutralization, VP2 is capable of inducing a protective immune response. VP2 contains 15 antigenic sites, with a major antigenic domain containing

12 of the 15 sites located in the region between residues 223 and 400 and a second domain contained the three remaining sites between residues 568 and 681. Based on in vitro experiments, 3 of the 15 sites are capable of inducing neutralizing antibodies, and two neutralizing epitopes have been defined, "a" and "b," between residues 321 and 339, and 377 and 400, respectively. A combination of peptides representing both sites induces a more effective neutralizing response [5,13,14].

VP3: Encoded by segment 3 (L3), VP3 is a flat, triangular molecule of about 103 kDa that forms the innermost protein layer (with 60 asymmetric dimers) of AHSV core (inner capsid). Similar to VP1, VP3 is a highly conserved structural protein, showing sequence variations that correlate with the virus species/serogroup and with the geographic origins of the virus isolate.

VP4: Encoded by segment 4 (M4), VP4 is a minor core protein of 642 amino acids (75 kDa) that functions as a capping enzyme.

VP5: Encoded by segment 6 (M6), VP5 (57 kDa) is a major structural protein forming the outer two-layered capsid with VP2. Containing coiled-coil motifs typical of membrane fusion protein, VP5 plays a part in membrane penetration during cell entry as well as introduction of AHSV-specific neutralizing antibodies. The most immunodominant region of VP5 is located in the N-terminal 330 residues, defining two antigenic regions (residues 151–200 and residues 83–120), which include 8 antigenic sites, with neutralizing epitopes situated at positions 85–92 (PDPLSPGE) and 179–185 (EEDLRTR) [15,16].

VP6: Encoded by segment 9 (S9), VP6 is a minor structural protein with putative helicase activity. In vitro experiments showed that VP6 binds double- and single-stranded RNA (ssRNA) and DNA in a NaCl concentration-sensitive reaction. The binding activity appears to vary with the pH of the binding buffer (ranging from pH 6.0 to 8.0).

VP7: Encoded by segment 7 (S7), VP7 is a 38 kDa molecule (with 780 monomers organized as 260 trimers) forming a second (surface) layer on top of VP3 in the AHSV core (inner capsid) [17,18]. Being highly conserved among different serotypes, VP7 may assist cell attachment and virus entry in insect systems, through involvement of a distinct cell surface receptor from that used by VP2 [19].

NS1: Encoded by segment 5 (M5), NS1 forms tubular structures within the cell cytoplasm, which are characteristically produced during virus replication in infected cells. These tubules have an average diameter of 23 ± 2 nm (which is less than half the width of the corresponding BTV tubules) and are more fragile at high salt concentrations or pH. NS1 protein is involved in cell lysis, which is the main mode of virus exit from infected mammalian cells and spreading to other cells.

NS2: Encoded by segment 8 (S8), NS2 is a major component of the granular viral inclusion bodies that form within the cytoplasm of infected cells. Sedimentation analysis and nonreducing sodium dodecyl sulphate-polyacrylamide gel electrophoresis (SDS-PAGE) revealed that NS2 is a 7S multimer with both inter- and intramolecular disulfide bonds, probably consisting of six or more NS2 molecules. The 7S NS2 multimer binds ssRNA nonspecifically.

NS3: Encoded by segment 10 (S10), NS3 is a proline-rich protein with strict sequence conservation and two hydrophobic domains (HD1 and HD2), which are linked to NS3 cytotoxicity. Variations in NS3 are found in HD1 and the adjacent variable region between HD1 and HD2. NS3 is associated with the membrane of infected cells and relatively exposed to the host immune system. In an attempt to avoid host immune recognition, the virus may constantly alter its NS3 through mutation, contributing its high variability. This variability corresponds to genetic differences in the insects that the virus infects. NS3 has the characteristics of lytic viral proteins that modify membrane permeability and contribute to viral pathogenesis. Modification of four amino acids (aa 165–168) from hydrophobic to charged amino residues in a predicted transmembrane region of NS3 alters its ability to interact (anchor) with cellular membrane components and largely abolishes its cytotoxic toxicity [20]. NS3 protein mediates virus budding, which is vital for virus exit from infected insect cells. This is reflected by the fact that NS3 is expressed at higher levels in insect cells than mammalian cells [21–23].

NS3a: Also encoded by segment 10 (S10), but via another in-phase overlapping reading frame (compared to NS3), NS3a is a truncated protein localized in areas of plasma membrane disruption and associated with events of viral release from cells [24].

68.1.3 Biology and Epidemiology

68.1.3.1 Biology

The establishment of AHSV infection and subsequent pathogenic changes in susceptible hosts involve a series of events: (1) proteolytic cleavage of VP2 in the serum or in midge saliva, (2) interaction with the host–cell receptor, (3) entry through an endocytic pathway, (4) activation of VP5 at low pH leading to exposure of the fusion peptide and subsequent insertion into the endosomal membrane, (5) release of the double-shelled core into the cytoplasm, (6) multiplication in the regional lymph nodes, (7) spreading to pulmonary microvascular endothelial cells, (8) breaking up the endothelial cell barrier (increased vascular permeability resulting in edema, effusion, and hemorrhage), (9) dissemination via the bloodstream (to the lungs, spleen, other lymphoid tissues, choroid plexus, and pharynx), and (10) replication in these organs producing a secondary viremia. The duration from initial infection to secondary viremia may vary between 2 and 21 days, but it usually takes <9 days.

Being acid sensitive, AHSV is inactivated at pH of <6.0 or ≥12.0, but remains relatively stable at pH 7.0–8.5. The virus is vulnerable to treatment with formalin, β-propiolactone, acetylethyleneimine derivatives, or radiation; however, it is resistant to lipid solvents and heat. In the presence of stabilizers such as

serum, sodium oxalate, carbolic acid, and glycerine, its infectivity is remarkably stable at 4°C. The virus shows minimal loss of titer after lyophilization or storage at −70°C in Parker Davis Medium, but it is labile between −20°C and −30°C [25].

68.1.3.2 Epidemiology

The natural reservoir host for AHSV is zebras (*Equus burchelli*), which display a detectable viremia for up to 40 days postinfection without visible clinical symptoms, while virus could be recovered from tissues and cells for up to 48 days. On the other hand, horses are highly susceptible to AHSV infection, with a short period of viremia (4–8 days) and high mortality rates (frequently exceeding 90%). Donkeys typically display a viremia for up to 4 weeks and a mortality rate of around 10% [26]. Other susceptible mammals include mules, asses, elephants, camels, and dogs (after eating infected horsemeat) [27].

The biological vector of AHSV is the *Culicoides* midges (Diptera: Ceratopogonidae), especially *Culicoides imicola*, which measures 1–3 mm, preferring warm, humid conditions, and which is also a transmitting vector for Akabane, bovine ephemeral fever, bluetongue, epizootic hemorrhagic disease, equine encephalosis, Schmallenberg, Oropouche, and the Palyams. *Culicoides variipennis* (*sonorensis*) (the American BTV vector), *Culicoides obsoletus* and *Culicoides pulicaris* (the northern European BTV vectors), and *Culicoides bolitinos* (present at higher altitudes in Africa than *C. imicola*) may also have the capacity to transmit AHSV. In addition, AHSV may be also transmitted by mosquitoes (e.g., *Aedes aegypti*, *Anopheles stephensi*, and *Culex pipiens*) and ticks (e.g., camel tick *Hyalomma dromadarii* and dog tick *Rhipicephalus sanguineus sanguineus*) [28–32].

In South Africa, AHS outbreaks chiefly occur in summer; no cases are reported in winter, from July to September. Apparently, AHSV survives the winter (overwintering) in the adult vector population, via transovarial transmission (vertical transmission of AHSV from adult females to their eggs), or retention in adult *Culicoides* that survive the winter drop in temperatures. Occurrence of AHS is often preceded by seasons of heavy rain that alternate with hot and dry climatic conditions. In particular, the cases of AHS in susceptible animals tend to appear as soon as *Culicoides* populations increase to a critical level.

AHSV serotype 9 (AHSV-9) is endemic in the northern parts of sub-Saharan Africa, while other serotypes are found in eastern and southern Africa (with AHSV-2 detected in Senegal and Nigeria in 2007, Ethiopia in 2008, and Ghana in 2010; AHSV-4 in Kenya in 2007; AHSV-7 in Senegal in 2007; and outbreak involving AHSV serotypes 2, 4, 6, 8, and 9 in Ethiopia in 2010). During 1959–1961, AHSV-9 emerged in the Middle East (Iran, Iraq, Syria, Lebanon, and Jordan), then Cyprus, Afghanistan, Pakistan, India, and Turkey. By 1965, AHSV-9 was identified in Libya, Tunisia, Algeria, Morocco, and Spain [33,34]. AHSV serotype 4 (AHSV-4) was reported in Spain (1988–1990), Portugal (1989), and Morocco (1989–1991) following the importation of a number of subclinically infected zebras from Namibia [35–40]. However, AHS has not been reported in the Americas, eastern Asia, or Australasia.

68.1.4 Clinical Features and Pathogenesis

68.1.4.1 Clinical Features

AHSV infections present four forms of clinical diseases of various severities in horses: acute (pulmonary), subacute (cardiac), mixed, or febrile (horse sickness fever) forms [41].

Pulmonary form: This acute form of AHS is characterized by a short incubation period (3–5 days), high fever (39°C–41°C, which usually corresponds with the onset of viremia), depression, respiratory distress, dyspnea, spasmodic coughing, dilated nostrils, and sweating. Standing with its legs apart and head extended, the affected animal experiences breathing difficulty (due to lung congestion), coughs frothy fluid from nostril and mouth, and displays signs of pulmonary edema. As the most serious form of AHS, its mortality rate exceeds 95%, with severely affected horses succumbing to the disease (anoxia) within 24 h of infection. The pulmonary form of AHS is also the form most usually seen in dogs. The virus is mainly localized in the cardiovascular and lymphatic system (which is also the case with the cardiac and mixed forms). At necropsy, the lungs are distended and heavy, with edema being visible in the intralobular space, and frothy fluid is present in the trachea, bronchi, and bronchioles. Also observed are edematous thoracic lymph nodes, congested gastric fundus and abdominal viscera, and petechiae in the pericardium.

Cardiac form: This subacute form of AHS has an incubation period longer than that of the pulmonary form, with clinical signs of disease appearing at days 7–12 after infection. The disease is usually characterized by high fever; progressive dyspnea; edema of the head, neck, chest, and supraorbital fossae; petechial hemorrhages in the eyes; ecchymotic hemorrhages on the tongue; and colic (abdominal pain) leading to notable swelling in the supraorbital fossae, eyelids, facial tissues, neck, thorax, brisket, and shoulders. The mortality rate is between 50% and 70% and surviving animals recover in 7 days. Postmortem examination reveals prominent petechiae and ecchymoses on the epicardium and endocardium; flaccid or slightly edematous lungs; yellow, gelatinous infiltrations of the subcutaneous and intramuscular tissues (especially along the jugular veins and ligamentum nuchae); and other lesions (e.g., hydropericardium, myocarditis, hemorrhagic gastritis, and petechiae on the ventral surface of the tongue and peritoneum).

Mixed form: The mixed form is often the most common form of the disease, with affected horses showing signs of both the pulmonary and cardiac forms of AHS. The mortality rate may exceed 70%, and death often occurs within 3–6 days.

Mild form: The mild (febrile) form (or horse sickness fever) of AHS is a subclinical disease that is seen in zebras and African donkeys as well as mules and partially immune horses. Infected animals may display mild to moderate fever, congested mucous membrane, and some edema of the supraorbital fossae despite having high virus titers in the blood. The survival rate is 100%. The virus is concentrated in the spleen and almost absent from the lungs and heart. Interestingly, the virus isolated from the spleen appears to

be less virulent than that from the lungs (as in the case of pulmonary and cardiac forms of the disease).

68.1.4.2 Pathogenesis

In a single infection cycle, AHSV has to pass through the skin of the equid host twice. Besides forming a mechanical barrier, the skin also represents an immunologically active organ that is capable of initiating an immune response against an invading pathogen. To mitigate the damaging aspects of host response in the skin, arthropod insects such as *Culicoides* secrete saliva with components that inhibit the phagocytic activity of host macrophages at the biting site, suppress the host's inflammatory reactions, prevent blood coagulation, and promote viral replication (the so-called saliva-activated transmission) [42].

With a predilection for the vascular endothelial cells throughout the body, AHSV increases vascular permeability, enhances effusions into body cavities and tissues, and causes widespread hemorrhages [43]. The appearance of fever in an infected host may disrupt the barriers to viral replication and dissemination, and invite additional insect feeding due to the elevated temperature. The induction of severe clinical signs in the host by AHSV will incapacitate the host to mount effective defense against vector attack [44].

68.1.5 Diagnosis

Presumptive diagnosis of AHS is often made on the basis of characteristic clinical signs, postmortem lesions, and presence of competent vectors. Differential diagnoses include equine infectious anemia, equine encephalosis, equine viral arthritis, Hendra virus, anthrax, babesiosis (*Babesia equi* and *B. caballi*), trypanosomiasis and purpura hemorrhagica.

For a definitive diagnosis of AHS, isolation and identification of the virus from clinical specimens have been traditionally performed. Clinical samples useful for AHSV isolation and detection include whole blood collected in anticoagulant (preferably EDTA) during the febrile stage of infection and the tissues of spleen, lung, lymph nodes, and salivary glands collected from newly dead animals. Blood may be preserved in OCG solution (50% glycerol, 0.5% potassium oxalate, and 0.5% phenol), and spleen samples may be preserved in 10% buffered glycerol. Usually, whole blood is washed and lysed and tissues ground in a mortar with sterile sand before inoculation in embryonated hen eggs, 2–4-day-old suckling mice, or in vitro cell culture (e.g., baby hamster kidney [BHK], African green monkey [Vero], monkey kidney, and *C. sonorensis* [KC] cells) for virus isolation [45].

Further confirmation of AHS is possible by using immunological techniques such as antigen capture ELISA, complement fixation, agar gel immunodiffusion, immunofluorescence, and virus neutralization for identification and serotyping [46–48]. Due to its reliance on virus isolation from clinical specimens in a suckling mouse brain and adaptation to tissue culture (BHK-21, Vero or KC [*C. sonorensis*] cells), AHSV serotyping using virus neutralization test often takes a minimum of 3–4 weeks. Given their time-consuming nature and their requirement for virus isolation and/or access to standard reagents (antibodies and antigens) that pose a potential biosecurity risk to lab personnel, immunological tests are increasingly superseded in recent years by molecular techniques such as PCR that facilitate direct detection of viral RNA in whole blood and other tissues with a rapid turnover time [49–58]. These techniques negate the need for virus isolation and reference antisera and thus reduce the use of lab animals. To date, reverse transcription polymerase chain reaction (RT-PCR) targeting conserved AHSV genome segments such as the genes encoding VP3, VP7, NS1, and NS2 have been reported for species and serotype-specific identification of AHSV.

68.1.6 Treatment and Prevention

As no specific treatment is currently available for animals suffering from AHS, rest and good husbandry represent the best approach for their recovery. In view of the fact that AHSV is only spread via the bites of infected vectors, control and prevention of the disease should center on (1) restricting the movement of infected animals, (2) slaughter of viremic animals, (3) husbandry modification (e.g., installing sand fly netting/mesh on windows and doors), (4) vector control (e.g., the use of insecticides such as synthetic pyrethroids, ivermectin, tetrachlorvinphos, and 5% temephos granulated with gypsum), and (5) vaccination of naïve animals against homologous AHSV serotype (including the use of polyvalent, monovalent, and monovalent inactivated vaccines) [59–75].

68.2 METHODS

68.2.1 Sample Preparation

For virus isolation, unclotted whole blood is collected in an appropriate anticoagulant at the early febrile stage. Spleen, lung, and lymph node samples are collected from freshly dead animals and placed in appropriate transport media. The samples are sent at 4°C to the laboratory and kept unfrozen.

For serology, serum samples (preferably paired) are taken 21 days apart and kept frozen at –20°C

AHSV dsRNA is extracted from cell-free tissue culture supernatant using QIAamp Viral RNA Mini Kit (Qiagen) or a Universal BioRobot (Qiagen). Alternatively, AHSV RNA may be prepared from infected cells using Trizol Reagent (Invitrogen).

68.2.2 Detection Procedures

AHSV genome segment 3 (Seg-1) and segment 3 (Seg-3) encode VP1 (viral polymerase) and VP3 (subcore shell protein), respectively, which are highly conserved virus species/orbivirus-serogroup-specific antigens. Primers derived from Seg-1 and Seg-3 provide a useful approach for AHSV species-specific identification [76].

On the other hand, AHSV genome segment 2 (Seg-2) encodes outer capsid protein VP2, which is the most variable of the AHSV proteins and also a primary target for AHSV

TABLE 68.1
Identity of Primers and Probes for African Horse Sickness Virus Species- and Type-Specific Detection

specific neutralizing antibodies. Primers designed from Seg-2 allow accurate determination of nine AHSV serotypes [55,76].

Bachanek-Bankowska et al. [76] utilized primers with AHSV virus species specificity (targeting AHSV Seg-1 or Seg-3) and type specificity (targeting Seg-2 of the nine AHSV serotypes) in real-time RT-PCR assays for rapid, sensitive, and reliable detection and typing of AHSV RNA in infected blood, tissue samples, homogenized *Culicoides*, or tissue culture supernatant (Table 68.1).

The real-time RT-PCR mixture is prepared using SuperScript III/Platinum Taq One-Step qRT-PCR Kit (Invitrogen) (Table 68.2). dsRNA samples are heat denaturated prior to addition to the reaction mix. Amplification for all of the assays is conducted in MX3005p (Stratagene) using the same conditions: 55°C for 30 min, 95°C for 10 min, followed by 45 cycles of 95°C for 30 s and 55°C for 1 min. Fluorescence is measured during the 55°C annealing/extension step. Cycle threshold values are measured at the point at which the sample fluorescence signal crosses a threshold value (the background level).

The real-time RT-PCR assays using AHSV Seg-1 and Seg-3 primers enable species-specific detection of all nine serotypes of AHSV down to 0.029 $TCID_{50}$ (or 60 copies of AHSV genome per reaction). The real-time RT-PCR assays using AHSV Seg-2 primers facilitate identification of AHSV serotypes 1–5, 7–9 down to 1 $TCID_{50}$/mL (0.019 $TCID_{50}$/assay), and AHSV-6 down to 10 $TCID_{50}$/mL (0.19 $TCID_{50}$/assay).

68.3 CONCLUSION

AHS is an economically important, noncontagious but infectious disease. Transmitted by *Culicoides* midges, the disease severely affects horses, ponies, and European donkeys as well as mules, but has little effect on African donkeys and zebra. Although AHSV is largely confined to sub-Saharan Africa, Yemen, and the Arabian Peninsula, it has the potential for sudden and rapid excursions and causes significant mortality in naïve horse populations in other parts of the world [34,77–79].

It is therefore critical that rapid, sensitive, and specific laboratory methods are available for prompt identification and typing of AHSV in case of unexpected AHS outbreaks. In particular, the use of real-time RT-PCR permits highly sensitive and specific detection, typing, and quantitation of AHSV RNA [76]. In addition, the development of effective vaccines against this deadly disease will help prevent the serious consequence of a sudden epidemic due to AHSV.

69.1 INTRODUCTION

69.1.1 Classification and Morphology

Bluetongue was first described as "malarial catarrhal fever of sheep" by Hutcheon[1] and Spreull.[2] The causative agent of bluetongue, that is, bluetongue virus (BTV), is the prototype of the genus *Orbivirus* within the family *Reoviridae*. In addition to BTV, the genus *Orbivirus* contains 21 other virus species and some of which, such as African horse sickness virus and epizootic hemorrhagic disease virus, are of veterinary importance.

The number of BTV serotypes had long held at 24 until the finding of Toggenburg Orbivirus, which was later designated the prototype of BTV serotype 25.[3] In 2010, BTV serotype 26 was identified in Kuwait.[4] This makes the total number of BTV serotypes to 26 to date.

The virion of BTV is nonenveloped and is made up of 10 segments of double-stranded RNA and approximately 1000 viral protein molecules that pack the RNA segments. The viral proteins form a double-shelled icosahedral capsid with a diameter of 69.2 nm[5] and a density of 1.337 g/cm.[3,6] The outer layer of the capsid consists of viral proteins VP2 and VP5; the inner layer comprises primarily VP3 and VP7 together with smaller amounts of VP1, VP4, and VP6 proteins.[7] The VP2 and VP5 proteins are in contact with VP7, linking the outer and inner layers.

69.1.2 Biology and Epidemiology

Animals susceptible to BTV are primarily ruminants, but BTV infections are not limited to these animals. Domestic cattle (*Bos taurus*), sheep (*Ovis aries*), and goat (*Capra aegagrus hircus*) are the susceptible species of economic concern. Wild ruminants susceptible to BTV include American white-tailed deer (*Odocoileus virginianus*),[8] mules (*Odocoileus hemionus*),[9] pronghorns (*Antilocapra americana*), desert bighorn sheep (*Ovis canadensis*), North American elk (*Cervus canadensis*),[10] roe deer (*Capreolus capreolus*), mouflons (*Ovis aries*), red deer (*Cervus elaphus*),[11] camels,[12] alpacas (*Vicugna pacos*), and llamas (*Lama glama*).[13] Besides ruminants, BTV is able to infect dogs naturally and via the administration of BTV-contaminated vaccines.[14-16] During the European bluetongue epidemic in 2007–2008, BTV-associated deaths in Eurasian lynx (*Lynx lynx*) were also reported.[17] A serological survey conducted in Africa showed that varying levels of seropositivity have been detected in lions (*Panthera leo*) and spotted hyenas (*Crocuta crocuta*).[18] Thus, BTV has the capacity to infect a variety of ruminants and carnivores.

As an arthropod-borne pathogen, BTV is naturally transmitted by blood-sucking, female *Culicoides* biting midges. Among the more than 1000 species of *Culicoides* worldwide, only a limited number of midge species are involved in the transmission of BTV, and the species responsible for

transmitting BTV in different geographical areas are varied. For example, *Culicoides imicola* is the primary BTV vector in Europe and Africa.[19,20] *Culicoides sonorensis* (formerly *Culicoides variipennis*) in North America,[21] and *Culicoides insignis* in South America.[22] Although transplacental transmission in sheep has been demonstrated experimentally,[23–25] the primary route of transmission of BTV is via the bite of *Culicoides* biting midges that carry the virus from viremic animals to susceptible animals.

The areas in which BTV infection is prevalent have previously been limited, but BTV-prevalent areas are expanding. The infection is traditionally prevalent in tropical, subtropical, and some temperate areas—roughly contained in a zone between the latitudes of 40°N and 35°S[26]—due to the limited availability of competent *Culicoides* vectors. More recently, however, the European epidemic that has been occurring since 1998, resulting from the introduction of multiple BTV strains from Turkey and northern Africa, has gone beyond these geographical boundaries. The epidemic has even moved northwestward to regions at latitudes higher than 50°N. This development suggests that the existing competent vectors may be extending their habitats northward, or that novel vectors may be involved in BTV transmission, or both, and that the invading BTV strains have developed overwintering mechanisms and adapted to local animal populations.

69.1.3 Clinical Features and Pathogenesis

The BTV infection is usually subclinical; however, it may cause clinical illness in some animals, primarily in some breeds of sheep. Moreover, both natural[27,28] and experimental[29,30] infections with certain BTV strains, such as BTV serotype 8, which caused an epidemic in Europe in the early 2000s, also lead to clinical disease in cattle.

Bluetongue in sheep primarily affects mucosal surfaces and the feet. The clinical signs of bluetongue in sheep include fever; excessive salivation; vomiting; respiratory distress; mucosal hyperemia; edematous and enlarged conical papillae; dilated gingival vessels; petechial hemorrhages of the gingival mucosa; crusting, erosion, and ulceration of the muzzle; necrosis of the oral mucosa; cyanotic tongue; subcutaneous edema of the face, head, ears, and neck; conjunctivitis; hemorrhagic excoriations of the epithelium of the external nares; enlarged lips; coronitis; acute hyperemia of the bulbs of the feet and between digits; stiff gait; and torticollis.[31–34] These symptoms lead to decreased feed consumption, general weakness, reluctance to move, and in some cases, death of the affected sheep.

Bluetongue causes clinical disease in cattle similar to that in sheep. In addition to the clinical signs observed in sheep, the disease may cause debilitation, ulceration of different surfaces of the oral cavity, copious nasal exudate, oral breathing, esophageal paresis, and a decrease in milk production.[35–38]

Bluetongue causes economic losses not only by affecting the health of adult animals but also by causing reproductive failure in pregnant animals and congenital abnormalities in newborns. Abortion and stillbirth have been reported in cows. The infection is also associated with excessive, purplish-red gingival tissue, agnathia, arthrogryposis, domed cranium, prognathism, dwarfism, blindness, and incoordination in newborn calves and weakness, inability to walk, difficulty in sucking, and muscular rigidity in newborn sheep.[29,39–41]

Bluetongue disease is principally a result of BTV-mediated vascular injuries. Although the clinical manifestations of the infection in ruminants can be highly variable between species and individuals, the pathogenesis of BTV infections follows essentially the same pattern in sheep and in cattle: BTV infections are initiated with regional BTV replication, followed by long-lasting viremia, which spreads the virus to other organs and results in damage to the vascular endothelium. When BTV is introduced from *Culicoides* saliva into animals, it initially proliferates in endothelial cells of skin capillaries and in leukocytes in the skin; the skin is considered an important organ for BTV replication in the early stage of infection.[42] Subsequently, BTV replicates in regional lymph nodes and is then disseminated throughout the blood by infecting a variety of blood cells. At this viremic stage, BTV can survive within blood cells, primarily platelets and erythrocytes, for as long as 54 days in sheep and goats[43] and 56 days in cattle.[44,45] In addition, the disseminating BTV particles are distributed unevenly in different viscera and lymph nodes. These differences in tissue predilection are proposed to result from variations in BTV strains and endothelial cell susceptibility.[42]

69.1.4 Diagnosis

Clinical diagnosis of bluetongue is neither easy nor reliable. Bluetongue is difficult to be differentiated clinically from some ruminant diseases such as foot-and-mouth disease, bovine viral diarrhea, and orf virus infection because of the similarities between the symptoms of bluetongue and other diseases. Moreover, BTV infections can be subclinical. Asymptomatic infections allow BTV to transmit silently between susceptible individuals in a population before it is known that BTV is present in the population. Thus, laboratory diagnosis plays an important role in the identification and surveillance of bluetongue.

Methods for the laboratory diagnosis of bluetongue, traditional or contemporary (Table 69.1), have been recommended by the World Organization for Animal Health, or the OIE, to monitor the antibodies against BTV, to estimate the prevalence of BTV infection, and/or to confirm BTV infection. As is true for many other infectious diseases, the laboratory diagnosis of bluetongue can be accomplished in three ways: by isolating the causative agent, by detecting the genome of the agent, and by detecting specific antibodies against the agent.

69.1.4.1 Conventional Techniques

BTV in specimens sampled from infected animals can be isolated by inoculation of the specimen into sheep, embryonated chicken eggs, and cell cultures. Although the isolation of BTV

provides definitive evidence of the presence of the virus in the specimen, the techniques required for virus isolation have not been changed substantially for decades. Attempting to isolate BTV by inoculating sheep is expensive and time consuming and is therefore not practical for routine diagnosis. Inoculation of embryonated chicken eggs is the most sensitive method for BTV isolation, particularly when the embryonated chicken eggs are inoculated intravenously.[47] Virus isolation is thus technically feasible, but such methods alone are unlikely to meet with the need for a rapid response in emerging outbreaks.

Techniques for detecting specific antibodies against BTV include agar gel immunodiffusion, complement fixation test, virus neutralization test (VNT), and enzyme-linked immunosorbent assay (ELISA). The agar gel immunodiffusion and complement fixation tests are neither efficient nor able to discriminate antibodies against BTV from those against other orbiviruses, particularly epizootic hemorrhagic fever virus; their unsatisfactory sensitivity and high labor intensity have limited their application. On the other hand, the VNT and ELISAs are more reliable and more rapid. The VNT is able to measure relative quantities of anti-BTV antibodies, that is, antibody titers, in serum samples. The assay is a reliable quantitative method for evaluating herd immunity against bluetongue, and it is also a qualitative method that can be used to clarify which BTV serotypes are currently circulating in a population. Nevertheless, the disadvantage of this assay, which limits its usefulness, is its dependence on serotype. The ability to measure antibodies against a given BTV serotype depends entirely on the availability of the corresponding serotype in the testing laboratory. Unfortunately, except for a few reference laboratories, nearly all of the veterinary diagnostic laboratories in the world possess only a very limited number of BTV serotypes. Thus, the diagnostic capacity of most laboratories is typically restricted to the serotypes present in nearby regions. When an unknown serotype is suspected, consultation with and technical support from reference laboratories are absolutely necessary. (The contact details of relevant reference laboratories are available on the World Organisation for Animal Health website: http://www.oie.int/our-scientific-expertise/reference-laboratories/list-of-laboratories/.)

Furthermore, when antibodies against more than one BTV serotype need to be measured, multiple tests must be performed for each serum sample. This conventional method remarkably amplifies the laboratory workload, even when robotic systems are used.

Despite being serotype-specific, the VNT is labor intensive. To enhance the effectiveness and specificity of anti-BTV antibody detection, several competitive ELISAs (cELISAs) have been developed since the 1980s. These cELISAs employ the serogroup-specific capsid protein VP7 as the immobilized antigen and an anti-VP7 monoclonal antibody as the competing antibody.[54–56] These changes improve the specificity of the assay and its ability to detect antibodies against BTV and to exclude cross-activity to other orbiviruses.

69.1.4.2 Molecular Techniques

In contrast, molecular methods, for example, reverse transcription polymerase chain reaction (RT-PCR), may compensate for the difficulties associated with classical viral isolation methods. Following the extraction of RNA or total nucleic acids from a clinical specimen, RT-PCR and real-time RT-PCR can detect a very small amount of BTV genomic RNA in the specimen within a few hours rather than a few days, remarkably shortening the interval between receiving a specimen and obtaining diagnostic results. Although molecular biology methods are often rapid and sensitive, it should be noted that greater diagnostic sensitivity is usually accompanied by a greater risk of false-positive results. To lessen this risk, RT-PCR results, particularly those obtained from interpreting gel electrophoresis data, should be confirmed by determining the nucleotide sequences of the RT-PCR products of interest. Moreover, when using molecular assays to detect BTV, it should be noted that BTV RNA is present in the blood much longer than infectious BTV is.[46]

Thus, detection of viral RNA by RT-PCR does not necessarily indicate that the sampled animal carries infectious and transmissible BTV.

RT-PCR and real-time RT-PCR allow rapid detection and identification of BTV RNA; many potential target genomic regions have been considered for specific amplification in these assays. The selection of regions of the BTV genome to amplify primarily depends on the purpose of the assays being designed. To detect the presence of BTV regardless of the serotype or genotype of the virus present in a sample, the region selected should be conserved among the BTV serotypes and distinct from the other orbiviruses. In this regard, regions in the VP1, VP7, and NS3 genes are preferred. In contrast, for serotype-specific detection, RT-PCR assays typically target the VP2 gene because the VP2 structural protein is the major determinant of serotype. Several RT-PCR and real-time PCR assays for BTV have been described previously.[48–53]

69.2 METHODS

69.2.1 Sample Preparation

69.2.1.1 Samples for Virus Isolation

Blood, spleen, liver, kidney, lung, and heart tissues collected at the peak of fever are the samples of choice for BTV isolation. The detailed procedures for preparing these samples have been described by Clavijo et al.[47]

Heparinized blood is centrifuged at 420 × *g* at 4°C for 10 min, and the supernatant is discarded. The sedimented blood cells are washed with sterile isosmotic buffer several times by repeatedly resuspending and centrifuging the cells and discarding the supernatant. The washed cells are then prepared as a 1/10 dilution in minimum essential medium supplemented with gentamicin (50 μg/mL), after which the blood cells are disrupted by sonication or simply repeated freezing and thawing. Alternatively, the washed cells can be disrupted first, brought to the original volume of the blood sample using the medium, and diluted. Prior to inoculation, dilution to 1:100 or lower concentrations may be necessary because less diluted samples can be lethal to chicken embryos.

To prepare tissue samples, the samples are weighed, phosphate-buffered saline is added, and the samples are emulsified using a tissue grinder to make a 10% (w/v) suspension. The suspension is sonicated and then clarified by centrifuging at 2000 × *g* at 4°C for 20 min. After centrifugation, the supernatant is collected as the undiluted inoculum. The undiluted inoculum then is diluted to 1:10 or 1:20 concentrations before it is being used to inoculate embryonated chicken eggs.

To use field-collected Culicoides biting midges as specimens for BTV isolation, the collected midges are pooled, with several dozen midges in each pool, and homogenized in 100 μL of cold Dulbecco's modified Eagle's medium (DMEM) using an electrical micro-grinder. The homogenized midges are centrifuged at 14,000 × *g* for 10 min, and the supernatant is transferred into a 1.5 mL microcentrifuge tube. One hundred microliters of DMEM supplemented with penicillin (100 IU/mL), streptomycin (100 μg/mL), gentamicin (5 μg/mL), nystatin (50 IU/mL), and fetal calf serum (20%) is then added.[57]

69.2.1.2 Samples for BTV-Specific RNA Detection

For detecting BTV RNA, anticoagulated blood is the specimen most commonly used. The viral RNA can be obtained by manual extraction with phenol/chloroform or extraction reagents (such as TRIzol; Invitrogen, Life Technologies, Carlsbad, CA), or silica-resin-based extraction kit (e.g., RNeasy Mini Kit; Qiagen, Valencia, CA); also, when a number of specimen are needed to be handled, extraction kits incorporating automatic systems can be used. The RNA that has been extracted either manually or automatically is generally pure enough to be used in reactions to detect BTV RNA. However, both the quality and quantity of the extracted RNA should be monitored, preferably through a laboratory accreditation system, because the quality and quantity of the RNA used in detection assays may alter the analytical sensitivity of the assays.

The RNA in collected Culicoides biting midges can be extracted and assayed for the presence of BTV viral RNA. The pooled midges are homogenized in 2 mL of phosphate-buffered saline containing two 4.5 mm copper beads using a TissueLyser (Qiagen). The homogenate is then clarified by centrifugation. After centrifugation, 200 μL of the clarified supernatant is mixed with 600 μL of TRIzol Reagent (Invitrogen) and finally eluted in 50 μL of DNase-free and RNase-free water.[58] Alternatively, a robotic system can be used when a large-scale survey is carried out. Approximately 50 collected biting midges of the same species can be pooled and homogenized in 400 μL of lysis buffer (NucleoSpin 96 Virus kit; Macherey-Nagel, Düren, Germany) containing a 5 mm steel bead using a TissueLyser instrument (Qiagen) for 2 min at 30 Hz. The homogenized midges are centrifuged at 12,000 × *g* for 1 min, and nucleic acids in 200 μL of the supernatant are extracted using a NucleoSpin 96 Virus kit on a Tecan Freedom EVO automatic platform (Tecan Group Ltd., Männedorf, Switzerland) or using other systems with similar functions.[59]

69.2.1.3 Serum Samples for Antibody Detection

Blood sampled for antibody detection is usually collected without anticoagulants such as EDTA and heparin. After the blood samples are allowed to clot, the serum is separated from the sampled blood by centrifugation.

69.2.2 Detection Procedures

69.2.2.1 Virus Isolation Using Embryonated Chicken Eggs

To select an appropriate blood vessel for intravenous injection, embryonated chicken eggs are observed under a strong light source. The triangular area of the egg shell immediately above a straight portion of a blood vessel is marked with pencil, and then the triangular piece of the shell is cut with a

small hand drill. The cut piece of the shell is removed, and care should be taken so that the shell membrane underneath remains intact. Before the embryo is inoculated with the clinical specimen, sterile mineral oil is dropped on the exposed shell membrane to render the membrane more transparent. Through the triangular window, a tuberculin syringe with a half-inch 27-gauge needle is used to inoculate 0.1 mL of the sample into the blood vessel. Blood displacement in the penetrated vessel can be observed when the inoculum is successfully introduced into the vessel. After the inoculation, the triangular window of the egg shell is sealed with surgical tape or hot melt adhesive, and the inoculated eggs are incubated at 33.5°C for 7 days.

The inoculated eggs are observed twice a day, and the embryos that die within 24 h are discarded. Those that die between 2 and 7 days are refrigerated, and the embryos' tissues (brain, liver, spleen, heart, and lungs) are used in virus identification assays.

69.2.2.2 Virus Isolation Using Cell Cultures

Baby hamster kidney (BHK-21) cell line is sensitive to BTV infection. Prior to the day of inoculation of clinical sample, BHK-21 cells are seeded in 24-well plates at a concentration such that the cells will have formed a 70%–90% confluent monolayer at the time of inoculation. One 24-well plate should be prepared for each specimen. Immediately before inoculation, the cell culture medium is removed, and 0.3 mL of fresh serum-free medium is added to each well. For each specimen, 0.2 mL of the 10% (w/v) tissue suspension is added to each of the six wells in a row. The same volumes of 10-fold dilutions (1:10 and 1:100) of the tissue suspension are also added to two additional rows of the same plate. Six wells of the cells, the last row, are used as negative controls; 0.2 mL of the serum-free medium alone is added to these wells. The inoculum is allowed to adsorb to the cells by incubating with orbital shaking at 4°C for 60 min in a humidified incubator with 5% CO_2. The inoculum is then removed, and 0.5 mL of the medium supplemented with antibiotics and 4% fetal bovine serum are added to each well. The inoculated cells are incubated at 37°C for 6 days in a humidified incubator with 5% CO_2 and observed daily for cytopathic effect. The cells demonstrating cytopathic effects are stored at 4°C until used for virus identification.

In addition to the BHK-21 cell line, several other cell lines are also susceptible to BTV infection, including the Vero cell line from African green monkey, calf pulmonary artery endothelial cell line, C6/36 cell line from the mosquito *Aedes albopictus*,[60] and HmLu-1 cell line from hamster lung.[61]

69.2.2.3 Detection of BTV RNA by RT-PCR

While several conventional RT-PCR assays targeting a variety of regions of the BTV genome have been described, the effectiveness of these assays varies. All of these assays consist of similar sets of reactions: first, cDNA is generated from RNA via the enzymatic activity of reverse transcriptase; next, samples are heated for a short time period to denature the cDNA template completely; the samples then undergo 30–40 repeats of a denaturing–annealing–extension thermal cycle; and lastly, the samples undergo a final extension period to ensure that all amplified DNA copies are synthesized completely. The major distinctions between the assays lie in the temperature and duration of the RT reaction and in the optimal temperature for primer annealing during thermocycling.

Here, two sets of RT-PCR assays used to detect BTV RNA are described. One is a duplex RT-PCR assay that amplifies full-length segment 7 of the BTV genome, and the other is a set of RT-PCR assays that are designed to identify BTV serotypes.

The following procedures of the duplex RT-PCR were developed by Anthony et al.[48] to target the VP7 gene. Two sets of primer pairs and a commercially available QIAGEN one-step RT-PCR kit (Qiagen) are used. The first primer set is composed of the forward primer BTV/S7/01 (5′-GTTAAAAATCTATAGAGATG-3′) and the reverse primer BTV/S7/02 (5′-GTAAGTGTAATCTAAGAGA-3′). The second set comprises the forward primer BTV/S7/03 (5′-GTTAAAAAATCGTTCAAGATG-3′) and the reverse primer BTV/S7/04 (5′-GTAAGTTTAAATCGCAAGACG-3′). The duplex RT-PCR is carried out in a final volume of 50 μL containing 28 μL of RNase-free water, 10 μL of 5 × QIAGEN one-step RT-PCR buffer, 2 μL of dNTP mix, 2 μL of enzyme mix, 0.5 μL of each of the four primers (0.6 μM), and 6 μL of an extracted RNA sample. The 50 μL reaction is performed as follows: one step of 45°C for 30 min; one step of 94°C for 15 min; 40 cycles of denaturation at 94°C for 1 min, annealing at 45°C for 1 min, and extension at 72°C for 2 min; and the RT-PCR is completed with an extension step at 72°C for 10 min. The products are analyzed on a 0.9% agarose gel, stained with ethidium bromide or other DNA stain such as SYBR Safe (Invitrogen), and then visualized under UV light. The predicted length of the product is 1156 base pairs.

The BTV structural protein VP2, encoded by genomic segment 2, is the outermost protein on the surface of the bluetongue virion. This protein is the main determinant of BTV serotypes.[62] To identify BTV serotypes based on the nucleotide sequences of genomic segment 2, Maan et al. developed a set of RT-PCR assays aiming to identify the 26 known BTV serotypes.[49]

Nucleotide sequences of the serotype-specific RT-PCR primer pairs are described by Maan et al. (Tables S1 and S2).[49] For RT-PCR amplification, two commercially available one-step RT-PCR kits are recommended: QIAGEN one-step RT-PCR Kit (Qiagen) and SuperScript III one-step RT-PCR system with Platinum Taq high fidelity (Invitrogen); both have been proven to be efficient in RT-PCR assays.[63] Before the RT-PCR assays are performed, the RNA samples can be denatured with methyl mercuric hydroxide at room temperature followed by the addition of 2-mercaptoethanol.[64] Alternatively, denaturation may be easier to achieve by incorporating a heat denaturation step right before the RT-PCR steps. The reaction would then be initiated by denaturing the RNA at 95°C for 30 min, after which the samples would be placed at 4°C for 10 min. After the initial denaturation step, RT is performed,

and the optimal temperature and duration of the RT step depend on the specific enzyme and kit used; the manufacturer's instructions should be followed. The reverse-transcribed cDNA is then used as a template for 40 cycles of denaturation at 94°C for 15 s, annealing at 55°C for 30 s, and extension at 68°C for 1 min. Finally, an extension step of 68°C for 5 min is performed to complete the RT-PCR assay. Five microliters of the RT-PCR products is analyzed by electrophoresis using a 1% agarose gel stained with ethidium bromide or another DNA stain such as SYBR Safe and then visualized under UV light. The electrophoresis-separated products are interpreted based on the patterns described by Maan et al.[49]

69.2.2.4 Detection of BTV RNA by Real-Time RT-PCR

The following procedures for a real-time RT-PCR assay targeting genomic segment 10 of BTV, which is applicable for most BTV serotypes, have been described previously by Hofmann et al.[65] The forward primer of the real-time RT-PCR is 5′-TGGAYAAAGCRATGTCAAA-3′, and the reverse primer is 5′-ACRTCATCACGAAACGCTTC-3′. The concentration of the working stock of both primers is 20 pmol/μL. The probe used in the reaction is 5′-FAM-ARGCTGCATTCGCATCGTACGC-3′ BHQ1 (FAM: 6-carboxyfluorescein), and the concentration of its working stock is 5 pmol/μL. Two microliters of the RNA sample (or controls) is mixed with 0.5 μL of each primer stock (20 pmol/μL), heated at 95°C for 5 min, and then chilled on ice for 3 min. After the heat-denaturation step, 22 μL of one-step real-time RT-PCR master mix, composed of reverse transcriptase, thermostable DNA polymerase, deoxynucleotides (dNTPs), appropriate salts, and the probe (final concentration of 0.2 pmol/μL), is added to the denatured RNA and primers, and the mixture is placed into a real-time thermocycler programmed as follows: 48°C for 30 min and 95°C for 2 min, followed by 50 cycles of 95°C for 15 s, 56°C for 30 s, and 72°C for 30 s. Samples with Ct-values lower than 50 are interpreted as positive.

69.2.2.5 Measurement of BTV-Specific Antibodies by VNT

Each of the serum sample, positive control serum, and negative control serum is twofold serially diluted with cell culture medium. Fifty microliters of the diluted sera are transferred to 96-well flat-bottomed microtiter plates, after which a virus suspension containing 100 $TCID_{50}$ of BTV of a specific serotype is added to each well. After incubation at 37°C for 1 h, BHK-21 or Vero cells are added to the wells, and the plates are incubated in a humid chamber with 5% CO_2 for 3–5 days. The virus neutralization titer of the tested serum is expressed as the $\log_2$ of the reciprocal of the serum dilution that protects cells from cytopathic effects.

69.2.2.6 Detection of BTV-Specific Antibodies by cELISA

A few cELISAs for the specific detection of antibodies against BTV have been developed and are commercially available. Most of these assays demonstrate satisfactory diagnostic sensitivity and specificity, although some inconsistencies in testing results may be present.[66,67] Although the volume of each serum sample that is needed, the antigen used to coat plates, the competitive labeled antibodies employed, and the incubation time between steps may be different among the kits, their general formats and test procedures are similar.

The following procedures are derived from one of the commercially available kits: Twenty microliters of serum (or controls) and 80 μL of dilution buffer are added to one of the wells in the 96-well plate coated with BTV VP7 protein. The mixture is then homogenized by gentle agitation and incubated at room temperature for 45 min. After the plate is incubated, 100 μL of a diluted, peroxidase-conjugated monoclonal anti-VP7 antibody is added to each well, and the plate is further incubated at room temperature for 45 min. After the second incubation, the plate is emptied and washed three times with washing buffer. After the plate is washed, 100 μL of substrate (3,3′,5,5′-tetramethylbenzidine, or TMB) and hydrogen peroxide solution is added. The plate is then incubated at room temperature for 10 min, avoiding exposure to the light. Finally, 100 μL of stop solution (usually 1 M sulfonic acid) is added. The optical densities of each well at a wavelength of 450 nm (OD_{450}) are read, and the S/N ratio (OD_{450} of the tested serum/OD_{450} of the negative control serum) is calculated. When the S/N ratio of a sample is equal to or lower than 70%, the sample is interpreted as a positive reactor.

Different enzyme substrate can be used in the cELISAs. In addition to the TMB, 2,2′-azino-bis(3-ethylbenzothiazoline-6-sulphonic acid) (ABTS) and *o*-phenylenediamine dihydrochloride (OPD) are the substrates of peroxidase as well. Notably, when ABTS or OPD are employed as substrate, optic densities of different corresponding wavelengths (410 nm/650 nm and 492 nm, respectively) are measured.

Regardless of the improvements in effectiveness and diagnostic specificity of these tests over those of the conventional VNT, it should be noted that cELISA and VNT assays are inherently different tests and that their results are not parallel. The targets of the two tests, neutralizing antibodies for the VNT and VP7-specific antibodies for the cELISA, share no antigenic determinant, and the results are interpreted and expressed in distinct ways. Therefore, the data obtained from these two assays are not interchangeable. Care should be taken when one intends to use and compare the results of cELISA and VNT assays.

69.3 CONCLUSION AND FUTURE PERSPECTIVES

Bluetongue has continued to threaten the livestock industry in many areas of the world, and the impacts of bluetongue seem to be increasing more than ever before, possibly in association with global climate changes. In particular, the bluetongue epidemic sweeping Europe since 1998 not only reveals the terrestrial expansion of BTV to the historically highest latitudes but also demonstrates the complexity of the disease situation and difficulties in BTV diagnosis and surveillance.

In most attempts to fight arthropod-borne viral diseases, such as dengue fever, yellow fever, and Japanese encephalitis, few of the diseases have been successfully eliminated from an endemic area. Instead, the diseases recur frequently, and a dynamic equilibrium between sporadic outbreaks and severe epidemics is established. People maintain this equilibrium with improvements in hygiene, pest control, and intensive vaccination. Meanwhile, vigorous elimination of arthropod vectors may decrease the incidence of the disease to a certain extent, but such reductions in the vector population may also unbalance the ecosystem simultaneously. In contrast, vaccination may be a better alternative to combat the disease effectively without upsetting the ecological balance.

With regard to the control of bluetongue by vaccination, a few European countries have adopted it as one of their strategies for controlling bluetongue epidemics. When facing multiple BTV serotypes and strains cocirculating in the continent, offering a vaccine with the serotype corresponding to the serotype of BTV that currently exists in the field determines whether the vaccine will be able to deliver protective immunity to vaccinated animals. From this aspect, the abilities to determine the serotype of a BTV isolate and the serotype of BTV against which detected serum antibodies were elicited play a critical role in deciding the direction in which control and preventive measures should be implemented. Currently, although conventional and molecular methods for serotyping are available, adaptations of new techniques continue to be in demand. RT loop-mediated isothermal amplification[68] and next generation sequencing[69] have been tested in this capacity. To detect anti-BTV antibodies, multiplexed immunoassays employing flow cytometry[70] may be a rational approach for simultaneously analyzing antibodies elicited by a variety of serotypes of BTVs in a sample.

There is no doubt that the impact of bluetongue is global in scope. The variety of BTV serotypes and variation in BTV strains will continue to challenge the diagnostic capacities of the available assays, both traditional and molecular. It is essential to continue to develop novel technologies and to evaluate the existing methods.

70.1 INTRODUCTION

Epizootic hemorrhagic disease (EHD) is an insect-transmitted disease of wild and domestic ruminants, resulting from infection with either epizootic hemorrhagic disease virus (EHDV) or bluetongue virus (BTV).[1] First described in white-tailed deer (WTD) in New Jersey in 1955, EHD was associated with severe clinical signs and death in naive population of wild and domestic ruminants including endangered species.[1–4] For this reason, EHD is considered an economically important disease, and a ban has been imposed on trading livestock, ova, and semen from affected countries. This chapter presents an overview on the classification, morphology, genome organization, biology, epidemiology, and diagnosis of EHDV.

70.1.1 Classification, Morphology, and Genome Organization

70.1.1.1 Classification

EHDV is classified in the genus *Orbivirus*, subfamily *Sedoreovirinae*, family *Reoviridae*.[1]

The *Reoviridae* family covers viruses with naked, icosahedral capsids and 10–12 segments of linear double-stranded RNA (dsRNA). It is separated into two subfamilies: *Sedoreovirinae* and *Spinareovirinae.*

The subfamily *Sedoreovirinae* (*sedo* = smooth) contains viruses that are characterized by the absence of a turreted protein on the inner capsid to produce a smooth surface. Currently, six genera are recognized in this subfamily: *Cardoreovirus*, *Mimoreovirus*, *Orbivirus*, *Phytoreovirus*, *Rotavirus*, and *Seadornavirus.* Apart from EHDV, other notable livestock-infecting viruses in the genus *Orbivirus* include BTV and African horse sickness virus, among others.

The subfamily *Spinareovirinae* consists of viruses that are distinguished by the presence of a turreted protein on the inner capsid. At present, nine genera are recognized in this subfamily: *Aquareovirus*, *Coltivirus*, *Cypovirus*, *Dinovernavirus*, *Fijivirus*, *Idnoreovirus*, *Mycoreovirus*, *Orthoreovirus*, and *Oryzavirus.*

Being transmitted by biting midges in the genus *Culicoides*,[1] EHDV is widespread in WTD and occasionally causes serious epidemics in wild populations and domestic animals.[1–4] Clinically, WTD are often severely affected.[1–4] Mule deer and pronghorn antelope are affected to a lesser extent and show mild disease symptoms.[1,5–7] Black-tailed deer, mule deer, red deer, wapiti, fallow deer, roe deer, and *Gazella subgutturosa subgutturosa* were seropositive for EHDV.[1,6,8,9] Yaks are susceptible to EHDV infection and exhibit histological lesions of hemorrhagic disease as observed in other ruminants.[10] Sheep can be infected experimentally but rarely develop clinical signs and have a negligible role in the epidemiology of EHDV.[11,12] Goats and pigs are not susceptible to EHDV infection.[9,13]

70.1.1.2 Morphology and Genome Organization

EHDV is structurally, antigenically, and genetically related to BTV, the type species of the genus that causes disease in

ovine, bovine, and other species.[1,14–16] EHDV contains 10 segmented linear dsRNA genome.[1] The genome encodes a total of seven structural proteins (VP1 to VP7) and four nonstructural proteins (NS1, NS2, NS3, and NS3a).[1,17–19] VP2 and VP5 are the most variable viral proteins and are responsible for viral attachment and entry to the host cell.[1,17,20] Specificity of VP2 interaction with neutralizing antibodies determines the virus serotype.[1,17,20] VP2 and VP5 trimers are located on the outer core layer formed by VP7.[1,17,20] VP3, an RNA-binding protein, forms the inner subcore layer and interacts with both the viral RNA genome and the minor proteins VP1, VP4, and VP6.[1,17,19] Self-assembly of VP3 controls the size and organization of the capsid structure.[19] VP1, a highly conserved protein, functions as a viral RNA-dependent RNA polymerase (RdRp).[1,17,19] VP4 is a capping enzyme, and VP6 is believed to be the viral helicase.[1,17,19]

The outer coat proteins VP2 and VP5 are the most variable proteins in EHDV and they determine the serotype. Although VP2 sequences were quite variable (47%–53% identity) between the serotypes, they have 97%–99% identity within the serotypes.[21] Similarly, VP5 sequences that are quite variable (64%–69% identity) between the serotypes have 97%–99% identity within the serotypes.[21] However, VP7 sequences had 97%–99% nucleotide identity within ST1 and ST2 isolates, and only 78%–80% identity between serotype 1 and 2 viruses.[21]

Whole genome sequence analysis of serotype 1 and 2 viruses demonstrated preferential reassortment of VP2, VP5, and VP7 within the homologous serotype.[21] The results suggest incompatibility between the surface proteins VP2 and VP5 and the outer core protein VP7 from the heterologous serotype.[21] However, VP2 and VP5 from ST6 are compatible with VP7 from serotype 2.[21] Also, high genetic identity (>94%) was observed between ST1 and ST2 reference viruses for segments encoding VP1, VP3, VP4, VP6, NS1, NS2, and NS3, preventing conclusive identification of reassortment events between these segments for serotype 1 and 2 viruses.[21]

Based on the serological reactivity, eight serotypes of EHDV are proposed.[22] EHDV serotypes 3 and 4 are reported in Africa.[4,23–25] EHDV serotypes 5, 6, 7, and 8 are reported in Australia.[4,26] EHDV-6 has been identified in Bahrain, the Sultanate of Oman, The Sudan, Morocco, and Algeria.[27] Historically, in the United States, only two serotypes, EHDV-1 (New Jersey strain) and EHDV-2 (Alberta strain), were identified.[4] However, in 2006, a novel reassortant serotype 6 EHDV (ST6) containing two variable surface antigens (VP2 and VP5) from an exotic EHDV-6 with the remaining segments derived from endemic EHDV-2 was isolated from moribund and dead WTD in Indiana and Illinois.[4] Subsequently, reassortant serotype 6 EHDV was identified in several other states demonstrating that the virus is geographically widespread.[4] This strain is currently endemic in the United States.[4] Reassortment between native and exotic EHDV illustrates the plasticity of EHDV and their ability to become established in new environmental niches.[4]

70.1.2 Epidemiology, Transmission, and Pathogenesis

Epidemiology: EHDV has been isolated from bovines throughout the world, including North America, Australia, Japan, Turkey, and Israel.[1,8,16,20,28–32] An EHDV serogroup virus, Ibaraki virus, which is now recognized as a strain of EHDV-2, caused serious epidemics in Japan.[29,33] EHDV-7 was associated with outbreaks in bovines from Israel.[16] EHDV-6 was associated with outbreaks in bovines from Morocco and Turkey.[16,20,28,34] In the United States, EHDV infection in bovines is typically subclinical and has only been rarely reported.[35] However, recent reports indicate that EHDV serotype 2 can cause clinical disease in bovines from the United States.[36]

Transmission: EHDV is transmitted by species of *Culicoides* biting midges. In North America, *C. mohave*, *C. lahillei*, *C. sonorensis*, *C. debilipalpis*, and *C. venustus* species are suspected as vectors for EHDV.[37–40] However, *C. sonorensis* is the only species that complies with the criteria provided by the WHO for vector implication.[1] In North America, majority of EHDV cases occur in late summer and autumn when the *C. sonorensis* season is at its peak.[1]

Pathogenesis: EHDV replicates in endothelial cells of lymphatic vessels and lymph nodes present at the site of infection.[1] It then disseminates through the bloodstream to other sites of replication such as the lymph nodes and spleen.[1] In the blood, the virus is associated with lymphocytes and red blood cells, where it is found in high titers for a long period of time.[9,41] Eventually, virus replicates in vascular endothelium causing vascular damage and thrombosis, with disseminated intravascular coagulopathy in some cases.[42–44] The extent of endothelial damage might in turn cause differences in clinical diseases observed with the infected ruminant species.[43,44]

Experimental infection of EHDV-2 in deer identified that the virus could be detected 2 days postinfection (pi).[45–47] All the infected animals were viremic at 4 days pi. In a few deer, EHDV was isolated for more than 50 days pi.[45–47] However, in most of the cases, virus could not be detected after 3 weeks from infection.[45–47] In EHDV-2-infected deer, interferon gamma was identified from day 4 to day 10 pi.[45] In EHDV-1-infected deer, neutralizing antibodies were identified from day 10 to day 14 pi.[9] Although virus and antibodies were identified at the same time, neutralizing antibodies were unable to completely remove the virus from circulation.[9] In serum collected from young deer, maternal antibodies against EHDV were detected up to 17–18 weeks of age.[47] Although passive immunity could not prevent infection or viremia in fawns, it can protect them against several clinical diseases.[47]

In cattle experimentally infected with EHDV-1, EHDV-2, or EHDV-6, virus can be detected anywhere from 9 to 50 days pi.[9,34,48,49] Antibodies against EHDV were first detected 7 days post infection (dpi) and persisted up to 35 dpi.[9,34,48,49] Although cattle remained clinically unaffected after experimental inoculation, they display high levels of viral RNA and virus in their blood, confirming that subclinical infection of cattle likely plays an important role in EHDV transmission.[9,34,48,49]

70.1.3 Clinical Features

Clinical signs of EHDV are observed in WTD, cattle, and other wild and domestic ungulates. WTD are most severely affected by EHDV. In cattle, the mortality is usually low. Three clinical forms of EHD were observed in WTD, peracute, acute, and chronic.[1] In the peracute stage, animals display high fever, anorexia, weakness, respiratory distress, and severe and rapid edema of the head and neck.[1] Swelling of tongue and conjunctivae is also common.[1] Hemorrhagic diathesis with bloody diarrhea and/or hematuria and dehydration are commonly found in dead animals.[1] Deer with the peracute form usually die rapidly, within 8–36 h, sometimes without clinical signs.[1] Deer with the acute form of the disease exhibit hemorrhages in many tissues including the skin, heart, and gastrointestinal tract.[1] Hyperemia of the conjunctivae and the mucus membranes of the oral cavity with excessive salivation and nasal discharge that is blood-tinged is common in animals with the acute form of the disease.[1] These animals can also develop ulcers or erosions of the tongue, dental pad, palate, rumen, and abomasums.[1] Mortality rate is high in both the peracute and acute forms. In the chronic form, deer are ill for several weeks but slowly recover.[1] Even after recovery, due to the growth interruptions that occur during the disease, some animals develop breaks or rings in the hooves and become lame.[1] In some cases, due to sloughing of the hoof wall or toe, animals crawl on their knees or chest.[1] In the chronic form, deer might also develop ulcers, scars, or erosions in the rumen.[1] Even when there is no shortage of food, animals might look thin and weak.[1] Notable histopathological lesions include widespread vasculitis with thrombosis, endothelial swelling, hemorrhages, degenerative changes, and necrosis in multiple organs, more specifically in the tongue, salivary glands, walls of forestomachs, aorta, and papillary muscle of the left ventricle of the myocardium.[1] In addition, animals may be hyperthermic and become hypothermic prior to death.[1,50] Testicular lesions and antler abnormalities observed in mule deer are considered a sequel of EHDV infection.[51]

In yaks, clinical signs comparable to the disease in WTD such as intermittent tremors, dysphagia, oral ulcerative lesions, hemorrhagic enteritis, tachypnea, and thrombocytopenia were observed.[52] Recently, head tremors and excessive lip smacking were observed in yaks from Colorado.[52] The dysphagia observed in yaks is comparable to the excess salivation found in WTD and is most likely secondary to decreased swallowing due to pain from oral mucosal erosions and ulcerations.[52]

In bighorn sheep, widespread edema, yellowish fluid accumulation in the thorax and pericardial sac, greenish discharge from the nose, and blood around the anus were also observed.[1] Multifocal hemorrhages in the epicardium and in the papillary muscle of the left ventricle are also reported.[1] Hemorrhages were also reported on the conjunctival membranes of the eye and on the serosal surfaces of the rumen and intestine.[1] Petechial hemorrhages were identified in the central nervous system, myocardium, epicardium, tunica muscularis, and submucosa of the rumen bur.[1] It is hard to determine morbidity and mortality rates due to EHDV infection in wildlife population.[1] However, the estimated number of affected animals and population in at-risk areas suggests an infection rate of 29% and mortality rate of 20% in WTD.[1,2,53]

The first major outbreak of EHDV in cattle was reported in 1959.[29] During the first epidemic, the disease was characterized by fever, anorexia, and difficulty in swallowing.[29] The second major epidemic occurred in 1997 in Japan, which was characterized by abortions, stillbirths, fetal malformations, and infertility problems.[54] Generally, EHDV infection in cattle characterized by hemorrhages, erosions, and ulcerations were seen in the mouth, on the lips, and around the coronets.[28,33] Cattle can also show stomatitis, swelling of eyelids, respiratory distress, nasal and ocular discharge, redness and scaling of muzzle and lips, lameness, and udder erythema.[28,33] In most cases, animals became stiff and lame, and their skin were thickened and edematous.[28,33] The most noticeable clinical sign of the disease was a sharp reduction in milk production. Animals may also look dehydrated and emaciated, and in some cases, death may occur due to aspiration pneumonia.[28,33]

Until recently, in North America, EHDV infections of bovines are typically considered subclinical. However, recently, EHDV-2 was isolated and characterized from a cow that aborted and showed clinical signs of EHDV disease.[36] Also, the calf born from an EHDV PCR-positive cow in the same herd displayed clinical signs of EHDV at birth.[36] Although the evidence in this case is circumstantial, it is suggestive of vertical EHDV transmission.[36] The clinical signs that the cow exhibited were similar to the EHDV virus that caused an epidemic in western Japan in 1997 suggesting that EHDV infection in bovines has the potential to cause severe epidemic disease in the United States.[36] The bovine EHDV was nearly identical to the WTD EHDV concurrently circulating in a similar geographical area.[36] These results justify further EHDV surveillance and diagnostic investigation given the widespread distribution of these viruses and their ability to cause severe clinical disease, both in wildlife and domestic animals.

70.1.4 Diagnosis

Given that EHD may be caused by either EHDV or BTV,[1] it is important that the causal agent is accurately identified. Methods for identification and detection of EHDV range from virus isolation, serological assays, and molecular techniques.[55–60]

EHDV can be grown on Vero or baby hamster kidney (BHK) cells as well as embryonated chicken eggs. ATM, *Culicoides sonorensis* cell lines (Kc), and cow pulmonary artery endothelial cells are also useful for virus isolation.[3,55] Cytopathic effect (CPE) is observed in mammalian cells anywhere between 2 and 7 days after virus inoculation. Generally, virus isolation takes 2–4 weeks.

Serum neutralization (SN) tests provide a means to identify and quantitate antibodies against EHDV serotypes. SNs require viruses from all the serotypes to be included in the assay making it time consuming and labor intensive. Agar gel immunodiffusion test was used for animal trade to detect

antibodies against EHDV.[58–60] It is a very simple and economical test. Since cross-reactions occur among different *Orbivirus* serogroups, this test is not predominantly used to detect EHDV. Complement fixation test detects and quantitates EHDV antibodies[1] and appears to be sensitive and specific for EHDV diagnosis. It detects antibodies for 4–12 months after infection but is less reliable after this period. The test was once relied upon for diagnosis and certification of animals for export.

By contrast, molecular techniques such as reverse transcription polymerase chain reaction (RT-PCR) are less time consuming and much faster than virus isolation and serological assays. It is no surprise that these techniques have been increasingly applied in laboratories worldwide for identification and typing of EHDV. Indeed, several serotype-specific RT-PCR assays have been designed to amplify EHDV VP2.

70.2 METHODS

70.2.1 Sample Collection and Preparation

Sample collection: EHDV has been isolated from tissue samples such as spleen, lung, and lymph nodes of infected animals. Some labs were successful in recovering virus from unclotted blood. If samples have to be collected from dead deer, necropsy has to be conducted as soon as possible after death. Temperature is also a primary factor; necropsy should be done within 6 h at the most and less if the deer is in the direct sun. At least a fist-sized spleen sample should be collected with plenty of ice in an insulated diagnostic shipper box for next-day delivery to the laboratory. Whenever possible, freezing is recommended.

Viral RNA isolation: Several methods have been used for the extraction of EHDV RNA from clinical specimens prior to RT-PCR.

70.2.1.1 RNA Isolation Using QIAamp Viral RNA Isolation Kit (Qiagen, Valencia, CA)

70.2.1.1.1 Procedure

1. Centrifuge samples at 1500 × *g* for 10 min to remove cell line and debris. Remove supernatant to a 1.5 mL centrifuge tube.
2. Add 140 µL of the supernatant to AVL buffer. Pulse vortex for 15 s to mix.
3. Incubate at room temperature for 10 min.
4. Add 560 µL of ethanol (96%–100%) and mix by pulse vortexing for 15 s.
5. Apply 630 µL of the sample to the spin column and centrifuge at 6000 × *g* for 1 min.
6. Discard filtrate.
7. Repeat steps 5 and 6 with the remaining sample.
8. Add 500 µL of AW1 buffer to the spin column. Centrifuge at 6000 × *g* for 1 min. Discard filtrate.
9. Add 500 µL of AW2 buffer and centrifuge at full speed for 3 min. Place spin column in new collection tube and repeat full speed centrifugation step for 1 min.
10. Place spin column in sterile Eppendorf tube.
11. Add 60 µL of AVE buffer directly to the center of the filter in the spin column.
12. Incubate at room temperature for 1 min.
13. Centrifuge at 6000 × *g* for 1 min.
14. Transfer filtrate containing the RNA to a labeled, sterile microcentrifuge tube.

70.2.1.2 RNA Isolation Using Ambion MagMAX-96 Viral RNA Isolation Kit (Life Technologies, Grand Island, NY)

70.2.1.2.1 Procedure

1. Pipet 130 µL of prepared lysis/binding solution (carrier RNA and isopropanol added) into each well of the processing plate.
2. Transfer 50 µL of sample into the lysis/binding solution in the processing plate and pipet up and down to mix.
3. Shake the plate for 5 min on an orbital shaker.
4. Add 20 µL of bead mix (10 µL of beads and 10 µL of lysis/binding enhancer) to each sample and pipet up and down to mix.
5. Shake the plate for 5 min.
6. Move processing plate to magnetic stand to capture the RNA binding beads. Leave plate on the magnetic stand for at least 5 min.
7. Carefully aspirate and discard the supernatant without disturbing the beads and then remove the plate from the magnetic stand.
8. Add 150 µL of wash solution 1 (isopropanol added) to each sample and shake the plate for 1 min.
9. Capture the RNA binding beads on a magnetic stand for at least 1 min or until the mixture becomes clear, indicating that the capture is complete.
10. Carefully aspirate and discard the supernatant without disturbing the beads and remove the plate from the magnetic stand and repeat steps 9–11 to wash a second time with 150 µL of wash solution 1.
11. Add 150 µL of wash solution 2 (ethanol added) to each sample and shake for 1 min.
12. Capture the RNA binding beads on a magnetic stand for at least 1 min or until the mixture becomes clear, indicating that the capture is complete.
13. Carefully aspirate and discard the supernatant without disturbing the beads and then remove the plate from the magnetic stand and repeat steps 12–13 to wash with a second 150 µL of wash solution 2.
14. Move the processing plate to the shaker (after removing plate lid) and shake for at least 5 min to allow any remaining alcohol from the wash solution 2 to evaporate.
15. Inspect the wells and if there is any residual solution, shake the plate for 1–2 min to let it evaporate.

16. Add 30 µL elution buffer to each sample and pipet up and down to mix. Shake the plate for 5 min.
17. Capture the binding beads as in the previous steps. The supernatant will contain the purified RNA for PCR. The supernatant should be saved in a sterile, nuclease-free microcentrifuge tube.

70.2.2 Detection Procedures

70.2.2.1 Multiplex PCR Detection of Eight EHDV Serotypes

70.2.2.1.1 Procedure

1. Denature dsRNA by placing purified RNA at 95°C for 5 min, then immediately place sample on ice and set up PCR mix.
2. Prepare the RT mix as follows:

Component	Volume/Final Concentration	References
2× Reaction Mix with ROX	12.5 µL	
Primer Mix	0.4 µM of each primer	[56]
Probe Mix	0.08 µM of each probe	[56]
SuperScript III Reverse Transcriptase (Life Technologies)	0.5 units	
Molecular Grade Water	Make it up to 22 µL	

3. Aliquot 22 µL/0.2 mL PCR tube on ice.
4. Add 3 µL of extracted RNA.
5. Place the sample tubes in the thermocycler for 55°C for 25 min, 95°C for 2 min, and 95°C for 15 s followed by 40 cycles of 95°C for 10 s and 55°C for 1 min.[56]
6. A sample with Ct value <37 is considered positive.

70.2.2.2 Whole Genome Sequencing

70.2.2.2.1 RNA Isolation

1. BHK cells that showed 100% CPE following EHDV virus infection should be used for RNA extraction.
2. Filter 40 mL of cell culture supernatant using the 0.2 µm bottle top filters (Thermo Fisher Scientific, Lenexa, KS).
3. Centrifuge filtrate at 50,000 × *g* for 2 h.
4. Discard the supernatant and resuspend the pellet in 1000 µL of water.
5. Concentrate the sample to a final 100 µL volume using Amicon Ultra Centrifugal Filters (0.5 mL; 50 kDa) (Millipore, Tullagreen, Ireland).
6. Remove cellular DNA and RNA removed by incubation with DNase I (25 units) (New England Biolabs [NEB], Ipswich, MA) and RNase A (25 units) (Qiagen) at 37°C for 1 h.
7. Extract RNA using QIAamp viral RNA isolation kit (Qiagen) by standard methods and elute in 35 µL of the supplied elution buffer.

70.2.2.2.2 Genome Amplification

1. Ligate dsRNA to PC3-T7 loop (5′-p–GGATCC CGGGAAT TCGGTAATAC GAC TCACTATA TTTTTATAGTGAGTCGTATTA–OH-3′)[57] as given in the following:
2.

Reagents	Final Concentration
ATP (NEB)	1 mM
RNasin (Promega, Madison, WI)	40 U
PC3-T7 loop (200 ng/µL)	200 ng
DMSO (Sigma-Aldrich)	10%
T4 RNA Ligase buffer (NEB)	1×
T4 RNA Ligase 1 (NEB)	30 U

3. Incubate the reaction mix at 16°C overnight.
4. Purify ligated dsRNA using RNA Clean & Concentrator (Zymo Research, Irvine, CA) according to manufacturer's instructions. Elute in 10 µL of sterile H_2O.
5. Add DMSO (15% [v/v] final concentration) to the purified ligated dsRNA and incubate in a thermal cycler at 95°C for 5 min and 4°C for 5 min.
6. Reverse transcribe RNA to cDNA using GoScript Reverse Transcription System (Promega) as follows:

Reagents	Final Concentration/Volume
GoScript 5× Reaction Buffer	1×
$MgCl_2$	2 mM
PCR Nucleotide Mix	0.5 mM each dNTP
RNasin	20 units
GoScript Reverse Transcriptase	1 U
H_2O	Make it up to 20 µL

7. Incubate the reaction in a thermal cycler at 25°C for 15 min, 42°C for 60 min, and 5°C for 15 min.
8. Remove RNA using RNase H (2.5 units, NEB) by incubating in a thermal cycler at 37°C for 20 min. Anneal cDNA at 65°C for 4 h.
9. Amplify cDNA using primer PC2 (5′-p–CCGAATTCCCGGGATCC-3′) using the PCR mixture given in the following:

Reagents	Final Concentration
10× Ex Taq Buffer (Clontech, Mountain View, CA)	1×
dNTP Mix (NEB)	0.2 mM each dNTP
PC2	80 µM
Takara Ex Taq (Clontech)	2.5 U
H_2O	Make it up to 50 µL

10. Place the samples in a thermocycler and incubate at 72°C for 1 min, 94°C for 2 min followed by 40 cycles of 94°C for 30 s, 67°C for 30 s, and 72°C for 4 min and 1 cycle of 72°C for 5 min.
11. Analyze the PCR products after separation on 1.5% agarose gels (TBE) containing ethidium bromide.
12. Amplified products can be purified and sequenced using Ion Personal Genome Machine™ (PGM™) sequencing platform (Life Technologies) according to manufacturer's instruction.

70.3 CONCLUSION

EHDV was once considered a disease of minor importance and not much attention was given to the virus. However, emergence of exotic serotypes such as EHDV-6 in North America and North African countries, introduction of EHDV-7 in Israel, wide distribution of clinical forms of EHDV in cattle from the United States, and economic losses caused by several outbreaks have put this virus on the spotlight. As a consequence, several diagnostic tests have been developed to distinguish EHDV from other orbiviruses. Nonetheless, there is a considerable lack of information about the susceptibility to different EHDV serotypes, vector capacities, and epidemiology. More work needs to be done to fill these gaps and to guide the future control and prevention campaigns against this highly infectious, economically damaging virus.

71.1 INTRODUCTION

Equine encephalosis (EE) is an arthropod-borne, febrile, noncontagious disease of equines, initially referred to as equine ephemeral fever by Theiler in 1910 [1]. The causal agent—equine encephalosis virus (EEV)—was first identified in 1967 in South Africa from a thoroughbred mare displaying marked neurological signs, including listlessness, tightening of the muscles of the face, high temperature, and elevated pulse rate about 24 h before death. Transmitted by *Culicoides* biting midges, the virus was also isolated from the blood samples of other horses located nearby, which showed no overt clinical signs apart from a febrile reaction [2]. Although EEV is capable of causing <5% mortality in affected animals, it is noninfective to humans and thus poses no public health risk. The real significance of EEV infections lies in the fact that the mild forms of EE are clinically similar to those of African horse sickness (AHS), which is caused by African horse sickness virus (AHSV) (see Chapter 68). AHSV utilizes identical vectors for transmission and represents one of the most devastating equine pathogens. It is, therefore, important to differentiate EE from AHS, so that tailor-made strategies are implemented for effective control and prevention. In this chapter, we focus on EEV in relation to its classification, morphology, genome organization, epidemiology, clinical features, and diagnosis.

71.1.1 Classification

EEV is a double-stranded RNA (dsRNA) virus classified in the *Orbivirus* genus, *Sedoreovirinae* subfamily, *Reoviridae* family, which contains another subfamily named *Spinareovirinae*. While the subfamily *Sedoreovirinae* is subdivided into six genera (*Cardoreovirus*, *Mimoreovirus*, *Orbivirus*, *Phytoreovirus*, *Rotavirus*, and *Seadornavirus*), the subfamily *Spinareovirinae* is separated into nine genera (*Aquareovirus*, *Coltivirus*, *Cypovirus*, *Dinovernavirus*, *Fijivirus*, *Idnoreovirus*, *Mycoreovirus*, *Orthoreovirus*, and *Oryzavirus*). Currently, the genus *Orbivirus* consists of 22 recognized species and 13 unassigned viruses, involving midges (AHSV, bluetongue virus [BTV], Chuzan virus, epizootic hemorrhagic disease virus [EHDV], EEV, Eubenangee virus, Palyam virus, Wallal virus, and Warrego virus), mosquitoes (Corriparta virus, Peruvian horse sickness virus, Wongorr virus, Umatilla virus, and Yunnan virus), and ticks (Broadhaven virus, Great Island virus, Kemerovo virus, Lipovnik virus, and Tribec viruses) in their transmission. Among the known orbiviruses, BTV (the type species of the genus), AHSV, and EHDV are economically the most important. The significance of EEV lies in its similarity to AHSV in terms of morphology, cytopathology, disease symptoms, host range, and vector usage. In fact, EEV, AHSV, BTV, and EHDV are all transmitted by *Culicoides* biting midges.

Phylogenetically, EEV isolates appear to form a lineage independent from other orbiviruses, which is further distinguished into two clusters (according to the analysis of the NS3 protein) in line with the northern and southern regions of South Africa and in association with the distribution of two transmitting *Culicoides* spp. (*C. imicola* and *C. bolitinos*) [3–5]. Based on serological reactions, seven EEV serotypes (EEV 1–7) have been identified to date: EEV-1 (Bryanston), EEV-2 (Cascara), EEV-3 (Gamil), EEV-4 (Kaalplaas), EEV-5 (Kyalami), EEV-6 (Potchefstroom), and EEV-7 (E21/20), with Kyalami, Bryanston, and Cascara being the best known [6,7]. Although EEV 1–7 have been largely found in Africa, including southern Africa (Kenya, Botswana, and South Africa),

eastern Africa (Gambia, Ethiopia, and Ghana), and western Africa, a recent report provided evidence on the emergence of EEV in regions of Israel [8–11]. Given the notable absence of EE in Morocco, it is possible that the Sahara desert may act as a natural barrier to its spread.

71.1.2 Morphology and Genome Organization

Similar to other members of the genus *Orbivirus* (from Latin orbi, meaning "ring" or "circle," referring to the structure at the surface of core particles), EEV possesses a nonenveloped, spherical, icosahedral virion of 73 nm in diameter, with a triple capsid structure [12]. The outer capsid is made up of structural proteins VP2 and VP5 trimers; the intermediate capsid is formed by 780 copies of structural protein VP7 in a T = 13 icosahedral symmetry; the inner capsid is formed by 120 copies of structural protein VP3 in a T = 2 icosahedral symmetry.

Underneath the icosahedral shell, the EEV genome (of 19 kb in total) is located, consisting of 10 dsRNA segments that are packaged along with minor enzymatic proteins VP1, VP4, and VP6. These 10 genomic segments are of 800–3900 bp in length and encode at least 7 structural (VP1–VP7 of 36–120 kDa in molecular weight) and 4 nonstructural (NS1–NS3) proteins [13]. Specifically, segment 1 codes for VP1 Pol (the viral polymerase), segment 2 for VP2 (the outer capsid protein containing serotype-specific antigenic epitopes), segment 3 for VP3 (the inner capsid protein containing serogroup-specific antigens), segment 4 for VP4, segment 5 for NS1, segment 6 for VP5, segment 7 for VP7 (the intermediate capsid protein containing serogroup-specific antigens), segment 8 for NS2, segment 9 for VP6 (the viral helicase), and segment 10 for NS3 and NS3A (via alternative initiation) [14].

Like AHSV and BTV, EEV genes have conserved termini (5′ GUU and UAC 3′). The structural proteins VP2 and VP5 in the outer capsid layer mediate cell attachment and penetration during the initiation of the infection. The VP2 protein is more variable than the core proteins and the most variable among the nonstructural proteins, and the specificity of their reactions with neutralizing antibodies determines the virus serotype. The structural proteins VP3 and VP7 are coexpressed and subsequently assembled into core-like particles with typical orbivirus capsomeres [15]. Phosphorylated by cellular kinases, the NS2 protein is an important matrix component of the granular viral inclusion bodies that form within the cytoplasm of infected cells. The membrane glycoproteins NS3 and NS3a are involved in the release of progeny virus particles from infected cells and also in determination of both vector competence and virulence [5].

71.1.3 Replication and Epidemiology

Replication of orbiviruses in host cells involves a number of steps: (1) virus attachment to host receptors and entry into host cells via clathrin-mediated endocytosis; (2) partial uncoating of virus particle and removal of the outer capsid (preventing cellular activation of antiviral state) in endolysosomes, and then penetration into the cytoplasm; (3) synthesis of capped mRNA from each dsRNA segment by viral polymerase VP1 (reducing potential exposure of dsRNA to the cytoplasm); (4) translocation of the capped mRNA to the cytoplasm; (5) translation of viral proteins and accumulation of genomic RNAs in cytoplasmic viral factories; (6) encapsidation of translated viral proteins and genomic RNAs in the subviral particle, transcription of RNA (+) into RNA (–), and base pairing of RNA (+) and RNA (–) into dsRNA genomes; (7) assembly of capsid on the subviral particle; and (8) release of mature virions after breakdown of host plasma membrane in the event of cell death.

EEV is infective to all species of equids (horse, donkey, and zebra), with zebra and elephants acting as maintenance host [16–18]. Being an arthropod-borne virus, its transmission is facilitated by *Culicoides* biting midges, particularly *C. imicola* (sensu stricto) and *C. bolitinos* during a blood meal. *C. imicola* and *C. bolitinos* are widespread in sub-Saharan Africa, and also present in regions of Northern America, Southern Europe, and South Asia. Regarded as the main vector of EEV, *C. imicola* is closely associated with livestock in the summer rainfall region of southern Africa [3,19]. Other *Culicoides* species such as *C.* (*Meijerehelea*) *leucostictus*, *C. magnus*, and *C.* (*Hoffmania*) *zuluensis* appear to be susceptible to EEV1 and/or EEV2 infections under experimental conditions. Given the presence of *C. imicola* and *C. bolitinos* as well as other *Culicoides* species in various geographic locations, EEV has the potential to spread to regions of the world besides sub-Saharan Africa and Israel.

EE is endemic in southern, eastern, and western Africa (including Kenya, Botswana, South Africa, Gambia, Ethiopia, and Ghana) [3,7,10]. In South Africa, >75% of horses and 85% of donkeys have been shown to be seropositive for EEV, with serotypes 1 and 6 being the most frequently and extensively identified, while serotypes 2, 3, 5, and 7 being identified as sporadic and localized infections affecting individual horses [20,21]. The prevalence of neutralizing antibodies in thoroughbred horses against one or more serotypes of the EEV was 56.9% [7]. Antibodies to EEV have been also demonstrated in zebra and African elephant [17,22]. The relatively high prevalence of EEV in southern parts of Africa may be attributed to immunization of horses against AHSV or related viruses but not EEV, for which no vaccine is available. In addition, serological evidence suggests that EEV was circulating in Israel as early as 2001, with incidence ranging from 20% to 100% during 2001–2008 [8,9].

Outbreaks of EE in horses often take place in late summer and autumn as these seasons are favorable for the replication of transmitting vectors. Anti-EEV antibodies may be occasionally detected in elephants [17]. Wild animals such as zebra and, to a lesser extent, elephants appear to help in sustenance of the virus in the equine population in the African continent. Therefore, eventual eradication of EE from Africa is reliant on prompt identification and effective control of EEV in zebra and elephants [16].

71.1.4 Clinical Features and Pathogenesis

In the majority of cases, EEV infection in equids is a mild febrile disease without overt clinical signs. However, in some severe cases, EE may produce clinical syndromes that are similar to AHS. These include fever (up to 41°C, typically lasting for 2–5 days), lassitude, unrest, anorexia, cough, edema (of the neck, legs, lips, and eyelids; leading to stiff facial expression, stiffness of the mouth and commissures; in fact, the swelling of the lips and eyelids represents a characteristic of the disease), blood-tinged nasal discharge, petechial hemorrhages of the conjunctivae, abnormally colored mucous membranes (ranging from yellow to a brick red color), accelerated pulse and breathing rates, muscle pain, hindquarter ataxia, convulsions, hyperexcitability, depression, enteritis, encephalitis, and occasional death (<5%) [2,8,23]. In addition, EEV infection may be associated with equine fetus abortion during the first 5–6 months of gestation. Incubation period is short but variable between 3 and 6 days, and clinical signs may appear just 24 h before the death of the animal. Most horses recover from the disease without complications.

Postmortem examinations of the affected horses reveal general venous congestion, fatty liver degeneration, brain edema, localized catarrhal enteritis (particularly in the distal half of the small intestine), degeneration of cardiac myofibers and myocardial fibrosis [20].

The predilection site of EEV attacks is the lining of the blood vessels, and the fluid leaks from damaged blood vessels into the interstitial spaces are responsible for edema and other associated clinical signs. Despite the inclusion of encephalosis in its disease name, it is not primarily a neurological disease.

71.1.5 Diagnosis

As EE presents many nonspecific clinical signs that are indistinguishable from those of AHS and equine viral arteritis, laboratory tests are required for accurate diagnosis.

Traditionally, EEV identification involves virus isolation using baby hamster kidney cells, suckling mice brains, or embryonated hen's eggs, and subsequent serotyping using plaque inhibition neutralization assay. In addition, for group-specific antibody detection, complement fixation, agar gel immunodiffusion, indirect immunofluorescent antibody, and enzyme-linked immunosorbent assay (ELISA) are available [22]. For group-specific detection of EEV antigen, indirect sandwich ELISA may be utilized [24,25].

However, the previous methods suffer from the drawbacks of being time consuming and difficult to interpret, having insufficient sensitivity, and providing only a retrospective diagnosis. Therefore, alternative methods targeting nucleic acids have been developed for improved diagnosis of EEV infection [7]. For example, gene probes derived from the EEV genome segment encoding nonstructural protein NS1 enabled rapid detection for minute quantity of virus-specified RNA in infected cells [26]. EEV was diagnosed using a novel DNA array with subsequent reverse transcription polymerase chain reaction (RT-PCR) and sequence analysis [8]. A novel real-time PCR assay targeting the gene VP7 was reported for specific and sensitive diagnosis of EEV infection [27].

71.1.6 Treatment and Prevention

Currently, no specific treatment is available for EE. Supportive treatment includes administration of anti-inflammatories, vitamins, and appetite stimulants. Horses that are unresponsive to supportive treatment may have to be hospitalized. As 90% of infected horses recover without complications, antibiotics are only provided to prevent secondary infections.

Due to the absence of an effective vaccine, vector control remains the most important way of minimizing exposure of horses to EEV. This may include the following: (1) keeping horses in stable at night (putting in 2 h before sunset and letting out once the dew has dried on the ground; as the period of dawn and dusk is the time when vector is more active); (2) avoiding paddocks with long grass or standing water; (3) turning stable lights off at night; (4) keeping window screen intact and being vigilant with fly repellants and day sheets; (5) using fans in stables (as the midges are weak fliers); and (6) restricting horse movement between stables and farms.

EEV is not a zoonotic pathogen and thus poses no public health risk to human populations.

71.2 METHODS

71.2.1 Sample Preparation

For virus isolation, 1 mL of blood is inoculated onto 1-day-old monolayers of Vero cells (ATCC) at 90% confluency in a 25 cm^2 flask. The flask is incubated for 1 h at 37°C in 5% CO_2 to allow the virus to adsorb, and then the inoculums are washed off and overlaid with 10 mL of minimum essential medium (MEM) supplemented with 5% fetal bovine serum (Life Technologies). The cultures are examined daily for up to 5 days incubation, before being harvested by freeze/thawing and passaging onto fresh cell cultures [27].

Viral dsRNA is extracted from EEV cell culture isolates. The contents of a flask are agitated and 500 μL is transferred to a 1.5 mL Eppendorf tube. Samples are centrifuged at 11,000× *g* for 5 min. The supernatant is discarded and the cell pellet is mixed with 50 μL of phosphate-buffered saline. Total nucleic acid extraction from the cell pellet is performed using a MagMax™-96 Total RNA Isolation Kit (Life Technologies) together with a MagMax™ Express Particle Processor (Life Technologies). The extracted RNA is eluted in a 50 μL elution buffer and stored at –20°C until use. Similarly, EEV nucleic acids may be extracted from a 50 μL of heparinized blood using a MagMax-96 Total RNA Isolation Kit (Life Technologies) [27].

71.2.2 Detection Procedures

Rathogwa et al. [27] described a real-time RT-PCR assay using primers from the 5′ end of the S7 (VP7) gene and a TaqMan® minor groove binder (MGB™) hydrolysis probe for the sensitive and specific detection of EEV in samples from horses infected with EEV (Table 71.1).

TABLE 71.1
Primers and Probe from S7 (VP7) Gene for Real-Time RT-PCR Detection of EEV

Identity	Type	Sequence (5′–3′)	Position
EEV_VP7_F0028_0048	Forward primer	GAT AGC GGC TAG AGC CCT TTC	28–48
EEV_VP7_P0054_0072	MGB probe	TAA GAG CAT GTG TTA CTG C	54–72
EEV_VP7_R0085_0106	Reverse primer	AAC TTG AGG AGC CAT R*GT AGC T	85–106

71.2.2.1 Procedure

1. Add 5 µL RNA to a 1 µL 25× primer/probe mixture (400 nM/120 nM final concentrations, with the probe containing NED™ label) (Life Technologies) and a 4 µL nuclease-free water. The probe was labeled with NED (Life Technologies).
2. Denature the mixture by heating at 95°C for 1 min on a heat block, and then cool quickly on ice.
3. Add 12.5 µL 2× RT-PCR buffer, 1.5 µL nuclease-free water, and 1 µL enzyme (VetMAX™-Plus One-Step RT-PCR Kit, Life Technologies) reagents.
4. Conduct the assay on a StepOnePlus™ Real-Time PCR System (Life Technologies) according to the manufacturer's recommendations.
5. Classify samples as positive if the normalized fluorescence for the EEV assay exceeds the 0.1 threshold.

Note: The EEV real-time RT-PCR assay recognizes all 7 serotypes of EEV and is nonreactive with 24 serotypes of BTV and 9 serotypes of AHSV tested. The assay has a sensitivity of $10^{2.9}$ $TCID_{50}$/mL blood (95% confidence interval: $10^{2.7}$–$10^{3.3}$), corresponding to a C_T of 38.42.

71.3 CONCLUSION

As a dsRNA virus in the genus *Orbivirus*, family *Reoviridae,* equine encephalosis virus (EEV) is shown to contain seven antigenically distinct serotypes (EEV1–EEV7). Similar to African horse sickness virus (AHSV) and bluetongue virus (BTV), EEV is transmitted by *Culicoides* midges (particularly *C. imicola* and *C. bolitinos*). EEV is infective to all equine species, with zebra and elephants acting as maintenance hosts. Endemic in southern, eastern, and western Africa, EE has also been detected in Israel.

Clinically, EE often presents as a mild febrile disease, with abortion and death occurring in more severe cases. Other less frequent clinical symptoms include swelling of the eyelids, the supraorbital fossa, and the entire face; ataxia and stiffness; convulsions; respiratory distress and blood-tinged nasal discharge; petechiae in the conjunctiva; and acute heart failure. As these signs are indistinguishable to those caused by AHSV, which is a high impact disease of horses with lethal consequence and requires different control measures, it is essential to discriminate EE from AHS.

Laboratory confirmation of EEV infection has traditionally relied on various serological assays such as complement fixation test, serum neutralization test, and ELISA. Due to their obvious shortcomings, these phenotypic procedures have been increasingly superseded by new generation molecular techniques, which are much faster, more sensitive, and more specific for identification and typing of EEV. It can be envisaged that molecular methods such as real-time RT-PCR will play a vital role in the tracking and epidemiological investigation of future outbreaks of EE, contributing to effective control and prevention against this disease.

72.1 INTRODUCTION

First identified in 1973 by electron microscopy in epithelial cells of duodenal mucosal samples from children, rotaviruses (RVs) were soon recognized as a major cause of gastroenteritis in the young of many animal species, including humans.[1–3] In humans, RV-associated disease typically occurs in children less than 5 years of age, but RV can infect all ages, including adults[4,5]; in 2008, an estimated 453,000 deaths worldwide were attributed to RV infection, with most deaths occurring in resource-poor countries.[6]

72.1.1 Virus Structure and Classification

RVs are medium-sized, icosahedral, triple-layered particles (TLPs, ~100 nm in diameter), with a segmented, double-stranded RNA (dsRNA) genome (Figure 72.1). The 11 segments encode six virion proteins (VP1–4, 6–7) and six nonstructural proteins (NSP1–6) (Table 72.1). The genome is enclosed in a triple-layered particle/capsid (consisting of VP2, VP6, and VP7, representing the inner, intermediate, and outer layers, respectively [Figure 72.1]), with the VP4 spikes on the surface giving the virion its distinct "wheel" shape when viewed using the electron microscope ("rota" is Latin for wheel). Proteins VP1 and VP3 form an inner complex, responsible for genome replication and capping of viral mRNAs, respectively. The NSPs are responsible for sequestering host cell components necessary for viral replication (NSP3), evasion of the innate immune response (NSP1), viroplasm formation (NSP2 and NSP5), and formation of the mature virion (NSP4).[7–12]

Taxonomically, RVs are classified in the genus *Rotavirus*, subfamily *Sedoreovirinae*, family *Reoviridae*, which includes an additional subfamily *Spinareovirinae*. While six genera (i.e., *Cardoreovirus*, *Mimoreovirus*, *Orbivirus*, *Phytoreovirus*, *Rotavirus*, and *Seadornavirus*) are recognized in the subfamily *Sedoreovirinae*, nine genera (i.e., *Aquareovirus*, *Coltivirus*, *Cypovirus*, *Dinovernavirus*, *Fijivirus*, *Idnoreovirus*, *Mycoreovirus*, *Orthoreovirus*, and *Oryzavirus*) are known in the subfamily *Spinareovirinae*.

The genus *Rotavirus* is further separated into eight antigenically distinct groups (A–H), using immunological and phylogenetic analysis of the VP6 gene.[3,13,14] RV groups A, B, C, and H have been identified in mammals, including humans, while RV D–G to date have only been identified in nonhuman mammal and avian species. The focus of this chapter is on group A rotaviruses (RVAs). Within the RVA group, the viruses are

Number identified to date	27	37	16	9	9	8	16	9	12	14	**11**

classified antigenically and genetically, based on the main antigenic determinants, the outer capsid proteins VP7 and VP4, which specify the G and P serotypes/genotypes, respectively. RVAs are a genetically diverse group of viruses with variations in circulating genotypes being observed temporally and geographically.[15] Additionally, similar to influenza virus, RV has a segmented genome (Figure 72.1) and so is capable of genetic reassortment, leading to genetic shift, which can facilitate the emergence of new strains.

A whole genome classification system has been adopted recently for classification of all 11 segments of the RV genome, applying nucleotide homology cutoff values to distinguish genotypes.[16]

72.1.2 Virus Replication

RV infects mature enterocytes on the villi of the small intestine, with the outer surface proteins (VP4 and VP7) facilitating virion attachment and entry into host cells. Enzymatic cleavage of the VP4 spikes into VP5* and VP8* is a prerequisite for infection. Different strains of RV utilize different receptor molecules that include sialylated and nonsialylated glycans via interactions with VP8*, and such interactions can impact on cell tropism and host susceptibility to infection and disease.[17] Different entry mechanisms have also been proposed, such as fusion or Ca^{2+}-dependent endocytosis, with the latter being generally accepted as the more likely model.[18] Once internalized, the outer surface proteins are digested within endosomes, and the release of the double-layered particle (DLP) into the cell cytoplasm[19] is mediated by conformational changes of the VP8* subunit of the viral spike (VP4). The DLP is the transcriptionally active form of the virus; each of the 11 gene segments is packaged with a VP1 (RNA-dependent RNA polymerase) and VP3 (RNA-capping enzyme) complex, which transcribes negative-sense RNA from the double-stranded template, releasing capped mRNAs into the cell cytoplasm.[20,21] Each mRNA acts as a template for translation but also functions as a template for the production of genomic dsRNA. The translation of NSPs 2 and 5 activates viroplasm formation (non-membrane bound perinuclear inclusion bodies surrounded by progeny virions), which is essential for replication and assembly of virus progeny.[22,23] The progeny virions are assembled into the DLP within the viroplasm; here, interactions between dsRNA segments and proteins (VP1, VP3, NSP2, and NSP5) facilitate DLP formation.

Two models have been proposed for assembly and packaging: a concerted model and a core-filling model.[24,25] Newly assembled DLPs then bud into the host endoplasmic reticulum (ER) (facilitated by NSP4, which acts as an intracellular receptor for VP6) and acquire a transient membrane studded with NSP4, VP4, and VP7 proteins.[3,7,8] NSP4 is a multifunctional protein as, in addition to mediating DLP translocation into the ER, it is also associated with the formation of tubelike projections from the cell cytoplasm, which can mediate infection of adjacent cells.[26,27] Within the ER, TLPs are assembled through membrane displacement,[3,28,29] which are then released into the intestinal lumen.

72.1.3 Pathogenesis and Clinical Features

Diarrhea is believed to be the result of several factors. First, there is malabsorption of fluids and electrolytes from the intestine due to damaged enterocytes as a result of viral replication. Second, loss of mature enterocytes through viral infection causes the loss of digestive enzymes, especially disaccharidases. This causes lack of digestion of carbohydrates in the lumen and so increases the osmotic pressure of the lumen contents, attracting water into the lumen. Third is the action of NSP4, the only known viral enterotoxin, which stimulates Ca^{2+} secretion, thus altering the osmotic pressure of the cell and causing lysis.[30,31] In animal models, there is onset of diarrhea prior to the detection of histopathological changes, possibly due to the action of the NSP4.[32,33] Clinical signs are further exacerbated by stimulation of the host's enteric nervous system by NSP4.[34] Infection of the enterochromaffin cells within the digestive tract leads to the stimulation of secretion of serotonin and of brain stem structures that control vomiting.[35,36] RVA may spread extraintestinally[37,38]; however, the role of this spread in pathology is unclear.[39,40]

The first infection with RV in infants is characterized by watery dehydrating diarrhea and vomiting, often accompanied by abdominal cramps and low-grade fever, lasting 6–10 days. Subsequent reinfections are associated with mild or subclinical presentations[41,42]; however, such reinfections are important in boosting immunity and maintaining long-term protection from RV disease.

72.1.4 Immune Response

Although many of the immune responses, both innate and acquired, induced after RV infection or vaccination in relevant species are known, the specific mechanisms mediating protection are less clear.[43–45] This lack of clarity is compounded by the possibility that important mechanisms vary between species.

RV infection stimulates both innate and acquired immune responses. At present, the extent to which the disease is modified or RV is cleared by the action of innate immune responses is not fully clear. Interferon (IFN) production is a common feature after RV infection in mice, pigs, and humans. Mice deficient in IFN signaling (*Stat1*$^{-/-}$) demonstrate increased levels of virus replication[46]; however, direct evidence for a protective role for type I and II IFN in adult mice has been more difficult to show,[47–49] although there is evidence for protective effects in young animals.[50,51] It is now thought that type III IFN (IFN-λ) may be the important protective IFN *in vivo*.[48] Evidence for the importance of the antiviral pathways induced by IFN also comes from how RV actively attempts to evade these responses. RV NSP1 interferes with IFN and NF-κB signaling,[52,53] although the ability of NSP1 to function in this manner can vary with viral strain and host species.[54] VP3 also functions in evasion of the IFN-induced antiviral pathways by interfering with RNase L activation by degrading 2′–5′ adenylate oligomers.[55] In contrast, NSP4 has been associated with the stimulation of proinflammatory cytokines,[56,57] although in the context of infection this signaling may also be inhibited.[58]

Acquired immune responses include both B-cell and T-cell activation. Studies in mice suggest that cellular immunity is important for clearing RV after primary infection, while RV-primed memory B cells are responsible for long-term protection.[59]

The involvement of $CD8^+$ lymphocytes in limiting primary infection by RV has been shown in mice[60] and calves.[61] In humans, the role of $CD8^+$ T cells is less clear, although RV-specific T cells including IFN-γ-secreting $CD4^+$ and $CD8^+$ cells may be detected in the blood of most adults after infection,[62–64] and RV-specific $CD4^+$ T lymphocytes show gut-homing potential.[65]

Humoral responses are primarily directed against VP2 and VP6 in humans,[66] but VP7 and VP4 contain the major neutralizing epitopes of the virus, and many of these antibodies are protective *in vivo*, as demonstrated by passive transfer in mice and gnotobiotic piglets.[67–69] However, protection from RV infection does not correlate with the concentration or breadth of VP4-specific and VP7-specific neutralizing antibodies in serum. VP6 may contain a protective epitope as VP6-specific antibodies can neutralize RV infection intracellularly *in vitro* by blocking DLP transcription.[70–73] *In vivo*, it is thought that mucosal anti-VP6 IgA may inhibit virus replication intracellularly in enterocytes that are transcytosing the antibody.[72,73] However, IgA-deficient mice and humans can still clear RV infection, possibly via compensatory IgM and IgG responses.[74,75]

Similarly in piglets, although non-neutralizing antibodies against VP4 and VP7 are induced after infection, the levels of serum and intestinal nonneutralizing IgA correlate better with protection from reinfection, and these antibodies show immunodominant recognition of VP6.[76–80]

It has been suggested that local mucosal production of antibody (IgA) is important in protection, which correlates with the majority of circulating RV-specific B cells expressing the gut-homing integrin, $\alpha_4\beta_7$, and being IgM or IgA positive.[81,82] In humans, the presence of high serum and fecal total antibody and, more specifically, IgA titers has been associated with protection from reinfection and RV disease,[83–87] and a recent systematic review suggests that a critical level of serum IgA still correlates with protection.[88] However, data from

natural infection and vaccination studies in developing countries suggest that IgA seroconversion is not a good correlate of protection in settings with high level of infection.[44,89]

In cattle, RV infection induces virus-specific antibody in feces, nasal secretions (IgM and IgA, probably produced locally), and serum (IgM then IgA, then IgG1 predominates later in the response).[90,91] Anti-RV IgG1 in colostrum fed to calves is associated with reduced incidence of infection and diarrhea when these neonates are infected,[92–94] and it is this information that has led to current vaccine strategies. Similar to other species, VP7 and VP4 neutralizing antibodies do not absolutely correlate with protection, and VP6 vaccines are protective.[95]

72.1.5 Epidemiology

The predominant mode of transmission of RV is fecal–oral. In humans, RVs are ubiquitous, with 95% of children 3–5 years of age being infected worldwide.[96] Prior to the introduction of RV vaccines, RVAs could be detected in up to 50%–60% of all childhood hospitalizations due to acute gastroenteritis each year and were estimated to cause 138 million cases of gastroenteritis annually[97] and 527,000 deaths in children <5 years of age living in developing countries.[6] In other animals, RV disease also occurs in the young of the species and in farm animals, leading to significant economic losses.

72.1.5.1 Humans

Although RVA infection usually occurs in children <5 years old, it can occur in all age groups, with the elderly and immunocompromised being particularly vulnerable.[4,5,98–100] Although, in total, 12 G and 15 P genotypes have been reported to date, the most prevalent human RVAs include G1, G2, G3, G4, and G9, in combination with P types P[8], P[4], or P[6]; strains with these types account for over 80% of the RV-associated gastroenteritis cases worldwide.[15,99,101] The most common genotype combinations are G1P[8], G2P[4], G3P[8], G4P[8], and G9P[8], accounting for 74.7% of all strains detected globally,[15] although in developing countries animallike RV genotypes can also be detected regularly.[101–105] The virulence of different genotypes has been investigated, with some studies indicating that G9 may have been associated with more severe disease in some instances, but these findings have not been observed consistently.[106–109]

72.1.5.2 Bovines

Diarrhea in young calves remains an important problem in cattle herds worldwide, with bovine RV being one of the most common pathogens associated as a causative agent.[110] In the United States, RV was found to be responsible for 46% of scours in dairy herds.[111] As a consequence of RVA infection in cattle, substantial economic losses occur due to increased morbidity and mortality rates, treatment costs, and reduced growth rates of these animals. Most at risk are very young calves between 4 days and 3 weeks old.

Seven G types have been detected in cattle (G1, G3, G6–G8, G10, and G15), with G6, G8, and G10 being the common types reported.[112] Six P types have been detected in bovines (P[1], P[5], P[11], P[14], P[17], and P[21]), with P[1], P[5], and P[11] being the common types reported.[113–115]

72.1.5.3 Porcines

Porcine RVs are one of the most frequently detected viral agents associated with diarrhea, affecting piglets between 1 and 8 weeks of age.[116] RVA infection of pigs has been recognized in both enzootic and epizootic forms of diarrhea, resulting in economic losses in commercial piggeries.[116]

Antigenic and molecular characterization of porcine RVAs has revealed a broad heterogeneity in the VP7 and VP4 genes. The most common G types identified in pigs are G3, G4, G5, and G11, associated with common P types, P[6] and P[7].[117,118] Porcine RVA strains with additional P types, P[13], P[19], P[23], P[26], and P[27], have also been described but more sporadically. Furthermore, porcine strains displaying human-like G types (G1, G2, G9, and G12) and P types (M37-like P[6], P[8]) and bovine-like G types (G6, G8, and G10) and P types (P[1], P[5], and P[11]) have also been described.[117–126]

72.1.5.4 Equines

Control of equine RV is a major concern each foaling season in horse-breeding farms/centers throughout the world.[127–129] It causes diarrheal disease in foals, leading to grave economic loss due to morbidity and mortality attributed to a high prevalence of infection estimated at between 50% and 90% in outbreaks.[129–132] Symptoms of equine RVA infections include diarrhea, dehydration, anorexia, abdominal pain, and depression. The disease is usually self-limiting, but dehydration alone can be fatal in young foals.[133–135] Two genotypes, G3P[12] and G14P[12], are commonly detected, with other genotypes being detected sporadically in individual cases. Infection with genotype G3P[12] is the most common, contributing 48%–72% of RVA cases.[129] Although G3 RVA can be detected in many other animal species, equine G3 RVA appears to be evolutionarily distinct and so is not subclassified into commonly used lineages. Instead, antigenic subtypes have been defined based on cross-neutralization assays, G3A and G3B.[136] Alternatively, G14 RVA is unique to equine RVA and contributes between 10% and 38% of cases.[129] Additionally, other RVA genotypes have been detected in horses, usually in sporadic individual cases: RVA/Horse-tc/GBR/L338/1991/G13P[18],[137,138] RVA/horse-wt/ARG/E3198/2008/G3P[3],[139] porcine-like RVA strain RVA/Horse-wt/GBR/H-1/1975/G5P[7],[140,141] or bovine-like RVA strains with the G10P[1] or G8P[1] genotypes.[142,143]

72.1.5.5 Other Animal Species

RVA infection appears to be ubiquitous in nature; infection has been characterized in companion, livestock, and wild (exotic) animals including ungulates, nonhuman primates, bats, and birds. Clinical signs are generally similar to those described previously: diarrhea, depression, dehydration, anorexia, and in

some instances stunted growth. RVA infection in certain animal species appears to be associated with particular genotypes, suggesting a host-species barrier to infection.[103]

72.1.5.6 Zoonotic Potential of Rotavirus A

The accumulation of point mutations (genetic drift) and reassortment (genetic shift) is responsible for the huge genetic heterogeneity of RVs. These mechanisms, in combination with the potential for interspecies (zoonotic and anthroponotic) transmission, can also lead to the emergence of "novel" strains in a given species with a potential for epidemic or epizootic spread.[16,103] The zoonotic potential of RVA has been documented on several occasions.[103] Uncommon human RVA G genotypes include G5, G6, G8, G10, and G11, in combination with P types including P[3], P[9], P[10], P[11], and P[14], and are generally considered to be animal-to-human reassortment variants. However, certain animallike genotypes have become established in human circulation, particularly in developing countries. RVA G9 and G12 were formerly considered porcine RVA strains but emerged in human circulation in the 1990s and 2000s, respectively.[15,144] Today, G9 has become the fifth most common genotype detected in humans worldwide, while G12 strains appear to have spread globally.[15] Another animal like genotype, G8, has appeared and become established in certain geographical regions, for example, Africa. G8 RVAs are detected with high frequency in African countries,[15,101] with increasing reports from other countries, for example, Iraq, America, Brazil, and Australia.[15,105,145–147] Other animallike RVA genotypes (i.e., G5 and G10) have been associated with infections in children in Brazil, Thailand, and India.[101,104,105] Conversely, human-to-animal and animal-to-animal reassortments have also been reported.[126,148–150] Although reassortment is a driving force in RV evolution, some genotypes appear to remain stable across species,[103] with others appearing to be restricted to particular hosts, for example, equine RV G14 and porcine P[13].

Studying animal RVs is fundamental to obtaining a better understanding of RV ecology and the mechanisms by which RVs evolve. Along with cattle, pigs are regarded as important reservoirs for the diversification of human RV.[103] Novel human RVA strains are likely to have originated through direct zoonotic transmission from pigs, and porcine–human reassortant strains have spread successfully throughout the human population in Latin America, Southeast Asia, and Europe, demonstrating the impact of animal RVA on human health.[118,124,151–156] However, there are also important animal welfare and economic impact reasons for the study of animal RVs in order to improve the prophylactic tools for use in livestock.

72.1.6 Prevention and Treatment

72.1.6.1 Human Vaccines

Since its discovery, many attempts have been made to produce effective RV vaccines, with an emphasis on those directed to the prevention of human disease. In 1998, the first human vaccine, RotaShield, was licensed. This multivalent vaccine contained the VP7 genes of common human genotypes, G1, G2, and G4, and rhesus RVA G3.[157] However, despite the proven efficacy of RotaShield, it was withdrawn from the market a year later, due to a temporal association with intussusception.[157,158] Today, two oral live-attenuated vaccines are being used in RV immunization programs globally: RotaTeq™, which is a pentavalent human–bovine reassortment containing human RVA-derived G1–G4 and P[8] types within the backbone of the WC3 bovine strain, and Rotarix™, a monovalent human G1P[8] live-attenuated vaccine. Both vaccines are efficacious and endorsed by the WHO, which recommends the implementation of these vaccines in national immunization programs.[159] In 2010, porcine circovirus DNA was detected in Rotarix by researchers at the Blood Systems Research Institute and the University of California, San Francisco, using microarray and high-throughput sequencing. The vaccine was subsequently found to contain infectious virus and was withdrawn temporarily from sale in the United States but not in the European Union. Follow-up research also found the presence of porcine circovirus DNA in RotaTeq.[160]

The introduction of universal mass vaccination (UMV) has resulted in a significant decrease in childhood RV infection morbidity and mortality.[161–166] Despite this, speculation on whether UMV may exert selective pressure on the RVA genotypes in circulation and result in a shift in genotype distribution or lead to changes in age distribution of the disease in the longer term due to differential levels of cross protection still remains. The backbone of Rotarix is a human G1 (Wa-like) virus, while that of Rotateq is a bovine–human reassortant (similar to DS-1).[167] A recent review of genotypes in circulation globally during the prevaccination era shows that fluctuations in genotype distribution from 1996 to 2007 are common.[15] Countries where UMV has been implemented have been monitoring circulating genotypes post-UMV to determine whether vaccination is exerting selective pressure on genotype distribution. Belgium and Brazil have reported a marked increase in G2 RVA from 2006 to 2007[166,168,169]; however, this increase was also noted in other countries where there is no UMV[165]; thus, it is far more likely that this shift was a result of normal fluctuations in RV diversity.[165,166,170] Additionally, a similar study in Finland has not reported any selective pressure effects from UMV.[171]

72.1.6.2 Animal Vaccines

The physiology of the placenta in ruminants and pigs blocks the transfer of antibody and immune cells from the dam to the fetus. These species therefore rely on the uptake of antibody (and immune cells) from colostrum and milk before gut closure to mediate passive transfer of maternal immunity. IgG1 is the predominant antibody in colostrum and milk due to expression of the neonatal Fc receptor (FcRn) by mammary gland epithelial cells that transports IgG1 into the

ductal lumen. Neonates in these species also express FcRn on the duodenal and jejunal epithelium that aids the uptake of this IgG1 into the circulation of the neonate. Therefore, neonates that have received sufficient colostrum will have high levels of circulating and gut lumen maternal antibody.[172] Early work demonstrating that feeding RV-immune colostrum to calves limited RV infection and reduced disease severity[92] has been used as the basis for farm animal vaccination strategies. Unlike human vaccination strategies, most veterinary vaccines licensed for use vaccinate dams in late gestation in order to increase antibody titers against the virus in colostrum and milk.

Vaccines in pigs: Currently, there is no vaccine licensed in Europe for the prevention of RVA-associated enteritis in piglets. A porcine RV vaccine is available in the United States and is administered to sows before and after farrowing or to young piglets for protection against RVA enteritis. However, given the broad genetic/antigenic heterogeneity of the RVA strains detected in previous studies, it remains unclear whether this diversity may pose a challenge for future prophylactic programs for the prevention of enteritis in suckling and weaning piglets.

Vaccines in cattle: Currently, a bovine RV vaccine, derived from the G6P[5] UK strain is available for late gestation dams. In a recent study in France,[173] the use of this vaccine did not seem to promote the emergence of RV strains with genotypes or variants different from those of the vaccine, suggesting a significant degree of cross protection given the diversity of circulating bovine RVAs. In addition, RVA vaccination was not associated with increases in other viruses such as caliciviruses, which also cause calf diarrhea, which suggests that RVA vaccination of dams should result in a net decrease of diarrheal illness in calves.

Vaccines in horses: Following rigorous management to try to prevent RV infection, vaccination is the only effective means to prevent RVA outbreaks. In horses, vaccine is also administered to mares in late pregnancy to boost levels of immunity that will be transferred to foals in colostrum. Antigenic/genetic characterization of equine RVAs identified in Japan, Australia, the United Kingdom, and Germany has revealed that most strains are either G3P[12] or G14P[12].[79,130,137,174] Currently, three inactivated vaccines are available for equine RVA immunization; two are monovalent and the third is trivalent. In Ireland, the United Kingdom, and the United States, an inactivated monovalent vaccine is used based on the strain RVA/Horse-wt/UK/H-2/1976/G3AP[12],[175] while in Japan, another inactivated monovalent vaccine based on the strain RVA/Horse-tc/JPN/HO-5/1982/G3BP[12] is in use.[176] In Argentina, a trivalent vaccine incorporating three animal strains is in use: equine H-2, bovine RVA/Cow-tc/JPN/NCDV/200X/G6P[1], and simian RVA/Simian-tc/ZAF/SA11/1958/G3P[2] strains.[177] However, recently, the effectiveness of vaccines administered to horses has been questioned and suggested to be only partially protective, as in most recent studies of RVA outbreaks in horses, the animals had been vaccinated.[127] This may be caused by a shift in the prevalent strain type to G14, which is not included in any of the vaccines.[131,178,179] Experimental studies on vaccinated animals have also observed the failure of circulating antibodies to neutralize infection in challenged animals.[133,180] An oral passive immunotherapy using equine hyperimmune serum from animals vaccinated with the RVA/Horse-wt/UK/H-2/1976/G3AP[12] vaccine has also been developed for use in clinically affected foals (Veterinary Immunogenics Ltd., U.K.), although no peer-reviewed trials are available for this product.

72.1.7 Diagnosis

RVA infection is diagnosed by collecting stool samples from the suspected cases and investigating the presence RVA particles, antigens, or RNA. A variety of methods can be used, ranging from electron microscopy to molecular methods. Electron microscopy, which led to the discovery of RVs, is currently rarely used for diagnostic purposes. This is a labor-intensive process that requires highly skilled personnel, and it has been superseded by other less expensive and higher-throughput techniques such as antigen detection or molecular methods, with the latter also allowing strain characterization (Table 72.2).

Routine laboratory RVA diagnosis generally relies on the detection of RV antigen in stool samples using a variety of immunological methods such as enzyme-linked immunosorbent assays (ELISAs), latex passive agglutination tests, and immunochromatographic methods. All of these methods are currently available commercially and can be performed in most laboratories as they do not require specific equipment or highly skilled staff (Table 72.2). In many settings, the use of ELISA has diminished in favor of the rapid analyses offered by latex agglutination and immunochromatographic tests. A particular advantage of these tests is that they can be used to test single or small numbers of samples, without reagent waste, and test controls are contained within each test. These methods also offer the advantage that they can be performed by nonlaboratory staff at the bed or pen side, not only reducing diagnosis times very significantly but also reducing sample transport and laboratory costs.

The first ever molecular method for the detection of RVs, and the simplest, is the visualization of the 11 RV genome segments by polyacrylamide gel electrophoresis (PAGE). In addition, this technique can be used to electropherotype isolates, based on banding patterns of the gene segments, which serves to distinguish RV belonging to different groups as well as some genome constellations within RVA. Further characterization can also be achieved through genome–genome hybridization,[181] a method that was central for the detection of mixed infections and interspecies transmission and reassortment, prior to the development and spread of the use of genome amplification methods.

TABLE 72.2
Methods for Rotavirus A Detection, Use for Rotavirus A Diagnosis, Suitability for Rotavirus A Typing, Sensitivity, Specificity, Throughput, and Cost Information

Method	Useful for Diagnosing RVA Gastroenteritis	Suitable for RVA Typing (Reference Work)	Sensitivity	Specificity	Throughput	Cost	Comments
Electron microscopy	Yes	No	++	+++	Low	High	Cannot distinguish RVA from other RV groups unless used in conjunction with antibody capture Few laboratories have equipment and/or skill
ELISA	Yes	No	++	+++	High	Low	Detection of RVA antigen proven to correlate with clinical disease in humans Many commercially available
Immunochromatography	Yes	No	++	++	Medium/high	Low	Cost effective specially for on-demand diagnostic
Passive agglutination	Yes	No	+/++	++	Medium/high	Low	Cost effective specially for on-demand diagnostic
PAGE	Yes	Limited	+	+++	Low	Moderate	Allows group and broad genome constellation discrimination
Conventional RT-PCR	Yes, but some limitations	Yes	+++	+++	Medium/high	Moderate/ high	May detect asymptomatic shedding due to high sensitivity
Real time RT-PCR	Yes	Limited	+++	+++	High	High	Allows for the calculation of viral load cutoff that is associated with disease Not widely used for typing as use of multiple probes/dyes is a limiting factor and also increases cost
Sanger sequencing	No	Yes	++	+++	Medium/low	High	Requires amplicon generation and relatively high Different sensitivities for each gene Inherent biases make it difficult to distinguish mixed infections and strain mixtures from reassortant strains
Next-generation sequencing	Only in a metagenomic context	Yes	++/+++	+++	High	High/medium	Highest throughput, allows for high level of multiplexing, reducing cost per base Sensitivity may be compromised unless there is high viral load which is typical in the acute phase Introduces less bias and greater potential for detection of mixed infections but bioinformatic analysis challenging in particular for discrimination of mixtures and reassortment

72.2 METHODS

72.2.1 RNA Extraction

All molecular methods for detection or characterization of RVs require a nucleic acid purification step.

Total nucleic acid can be extracted from the stool samples using a standard phenol–chloroform method for use in molecular diagnostic methods.[182] This method is relatively inexpensive and does not require specialized equipment, yielding good quality RNA for separation by PAGE. If the RNA is to be used in subsequent reverse transcription polymerase chain reaction (RT-PCR) for detection or typing purposes, a further purification step or an alternative nucleic acid method is often recommended in order to minimize the risk of PCR inhibition due to the presence of residual solvents in the purified sample.

Currently, there are many suitable nucleic acid extraction kits commercially available, all based on similar principles; the nucleic acid extraction typically involves the use of detergents and proteases in conjunction with chaotropic agents to inactivate enzymatic activity and prevent nucleic acid degradation of the exposed nucleic acid, and then fractionated silica is used to bind the exposed nucleic acid and allow the removal of all other contaminants in the samples. The silica may be used in solution, coupled to magnetic particles or immobilized onto filters, and the purification requires the use of vacuum or centrifugal force for washing steps and final nucleic acid elution into molecular-grade nuclease-free water or appropriate buffer (e.g., TE buffer).

72.2.2 Detection Procedures

After the RNA has been purified from the clinical sample, it must be converted into complementary DNA (cDNA) in order to perform subsequent gene-specific amplification. This may be achieved in a separate RT reaction using either RV gene-specific primers or random primers that will yield cDNA from all RNA present in the extract, which is then followed by a specific PCR. Alternatively, one-step RT-PCRs with specific primers can also be performed in a single reaction mix that contains both a reverse transcriptase and a DNA polymerase. A number of highly sensitive and specific RT-PCR involving the amplification of different RVA genes have been developed and are in use in different laboratories.[183–186] In particular, one-step qRT-PCR (real time RT-PCR) methods are increasingly being used in medical diagnostic laboratories. These methods are amenable to automation and multiplexing with methods for the detection of other enteric pathogens, increasing throughput and reducing costs and turnaround times. However, their high sensitivity of detection can be problematic as this can lead to the detection of low loads of RVA that may not be associated with the disease.

Since the mid-1990s, investigations of RVA diversity have relied upon G and P genotyping. Oligonucleotide primers directed to conserved regions of the VP7[182] or the VP4[187] genes are effective for consensus amplification of all animal RVA. However, genotyping is performed using nested type-specific primers in multiplex reactions. This means that when deciding on the composition of the multiplex reactions, prior knowledge of the expected types for the species being investigated is necessary. Furthermore, significant differences may occur between sequences of the same viral genotype prevalent in different species, requiring alternative oligonucleotide primers for detection of a given genotype in different species. For example, G3 strains are ubiquitous and prevalent in many species, including humans, monkey, cats, dogs; however, although they are all classified as G3 on the basis of the overall sequence homology of the entire VP7 encoding gene, primers designed for the detection of G3 strains in some species are unable to reliably detect G3 strains in other species.

Since the adoption of RT-PCR for genotyping RVs, many primers have been developed and used worldwide, depending on the particular species or settings involved. For the typing of human RVA, several protocols and a variety of primers are available for use.[188]

For genotyping of RVA in the veterinary field, amplification and typing of the VP7 gene is carried out using nested multiplex PCR in swine,[189] cattle,[190] and horses.[131] For equine RVA, the G type can be determined using primers described by Gouvea et al.,[182] and primers are also available for G3 and G14 genotyping.[174,179] Equine RVA P types can be investigated using primers described by Gentsch et al.[187] and typing primers described by Fukai et al.[191]

Although G and P typing have been used in informing vaccine design and surveillance, there has been a recent drive toward whole genome sequencing to further understand RVA diversity and evolutionary dynamics. To take this approach, primers, which amplify all 11 gene segments, have been described and can be applied to RVA from most animal species.[16] Additionally, an online genotype classification tool can also be used to rapidly analyze sequence data: RotaC, http://rotac.regatools.be/.[192]

A protocol for characterization and strain nomenclature has been detailed by the Rotavirus Classification Working Group, which provides a common baseline to molecular epidemiology studies of RV worldwide.[16,193,194] Phylogenies are studied, based on nucleotide sequences using neighbor-joining analysis, as the nucleotide sequences are deemed more informative than amino acid sequences for phylogenetic and other molecular analyses, including the detection of new genotypes.[16,194] Neighbor-joining phylogenies are based on distance-based models of molecular evolution; however, with advances in maximum likelihood and Bayesian methods (character-based models), distance methods have decreased in popularity for inferring relatedness and evolution.[195] Distance-based models are, however, sufficient to elucidate relationships and clustering among closely related sequences with a low level of divergence. For RVA, these models are capable of distinguishing different genotypes, with the advantages of relative accuracy and computational/time efficiency.

72.3 CONCLUSION AND FUTURE PERSPECTIVES

RV diversity across the animal kingdom is vast. In particular, the segmented nature of the RV genome can lead to gene reassortment during coinfection with more than one RV. This impacts on the diversity associated with the outer capsid proteins VP7 and VP4, targets for neutralizing antibody responses. Numerous reports have described interspecies transmission events leading to sporadic cases of human disease with RVs from different animal species origin,[129,196–199] and the emergence of epidemiologically important strains in the human population such as G9P[8] globally, G10P[11] in India, G8P[4] in Africa, Europe, and the United States is postulated to have resulted from reassortment among human and other animal RVs.[147,200–207] Whole genome sequencing of human RVA strains has revealed that among human RVA strains, with the exception of VP7 and VP4, the remaining gene constellation is relatively well conserved, and most strains can be classified as belonging to a Wa-like G1 or a DS-1 G2 gene constellation. In human infections from suspected direct zoonotic transmission, gene constellations different from those typically associated with human RVAs are seen. However, epidemiologically significant emergent strains, suspected to have originated through zoonosis, are typically associated mostly with a human RVA characteristic gene constellation, likely to have originated through reassortment and to be associated with species adaptation. Despite the increasing number of whole genome data available from human strains, similar data from other animal species are scarce. Structured surveillance in animals that includes whole genome characterization of RV strains from different animal hosts may provide important leads to better understand drivers and constraints to interspecies transmission and reassortment.

73.1 INTRODUCTION

Beak and feather disease virus (BFDV) is the causative agent of a disease associated with feather dystrophy and beak deformity in psittacine birds named psittacine beak and feather disease (PBFD).[1] The virus belongs to the genus *Circovirus* in the *Circoviridae* family that includes the smallest known viruses. All members of this genus share similar morphology and genome organization. Circoviruses are nonenveloped viruses with icosahedral nucleocapsids that contain a single-stranded circular DNA genome of about 2000 nucleotides.

There is evidence that BFDV occurs naturally in wild Australian birds for more than one century.[2,3] The first outbreak of PBFD was reported in 1907 by Ashby from wild red-rumped parrots (*Psephotus haematonotus*) in Adelaide hills in 1988.[4] However, BFDV was only officially confirmed in 1975 in Australian cockatoos, including sulfur-crested cockatoos, lovebirds, budgerigars, and galahs.[5] The international trade of exotic parrots, both through legal trade and illegal trafficking, has facilitated the spread of BFDV that is now found in many countries, including Thailand,[6] New Zealand,[7] Germany,[8] South Africa,[9] the United States,[10] Italy,[11] Taiwan,[12] Japan,[13] and Portugal.[14] The prevalence of BFDV is highly variable, with reported viral DNA positive rates ranging from 3.5% to 4.0% in the United States[10] to 41.2% in Taiwan.[12] PBFD is nowadays considered a global disease[15] and is the most important viral infection in psittacine birds in many countries.[16]

All psittacine species are considered susceptible to BFDV since the virus has been reported to affect more than 60 wild and captive species of cockatoos and parrots.[17] The disease is recognized as a key threat to endangered psittacine birds in Australia[18] and other countries.

73.1.1 Classification

BFDV is classified in the family *Circoviridae* that covers the smallest known autonomously replicating animal viruses. The family's name, "circo," is derived from the Greek root "gyro," which means ring or circular and refers to the characteristic circular shape of the viral genome. In the classification of Baltimore,[19] members of this family are included in Class II of viruses with a single-stranded DNA (ssDNA) genome. The family *Circoviridae* contains two accepted genera, *Gyrovirus* and *Circovirus*, and one proposed genus, *Cyclovirus.*

Currently, there is only one recognized member of the *Gyrovirus* genus, chicken anemia virus (CAV), a ubiquitous pathogen of chickens with a worldwide distribution. This virus was discovered in Japan in 1979 and is responsible for anemia and immunosuppression in newly hatched chickens.[20] CAV is distinguishable from members of the *Circovirus* genus both by its size and its genome organization. The recent discovery of viruses with CAV-like genomes in chicken sera (AGV2),[21] human skin swabs (HGyV),[22] and human feces (GyV3 and GyV4)[23,24] indicates that there may be significantly more diversity within this genus. However, these viruses were not yet accepted by the International Committee on Taxonomy of Viruses (ICTV) as members of the genus *Gyrovirus*.

The first member of the *Circovirus* genus reported was porcine circovirus type 1 (PCV1), a nonpathogenic virus detected in 1974 as a contaminant of the porcine kidney cell line PK15.[25,26] BFDV was detected 1 year later in Australian cockatoos. Another type of porcine circovirus, PCV2, was initially identified in a Canadian swine herd in 1991 and has been implicated as the etiological agent of a disease named postweaning multisystemic wasting syndrome.[27] Heretofore, circoviruses have been detected in a large variety of host species. Besides PCV1, PCV2, and BFDV, the best characterized of the circoviruses, there are eight more species within this genus currently accepted by ICTV 2013, all of them are isolated from birds, revealing strong host specificity. These include pigeon circovirus,[28] canary circovirus,[29] goose circovirus,[28] duck circovirus,[30] starling circovirus,[31] finch circovirus,[32] gull circovirus,[32] and mute swan circovirus.[33] Circoviruses were also detected in other hosts, including ostriches,[34] ravens,[35] bats,[36] fishes,[37] dogs,[38] and minks,[39] but to date they were not yet recognized. There are two criteria adopted to differentiate species in the genus *Circovirus*, which are a complete nucleotide sequence identity of less than 75% and capsid protein amino acid sequence identity of less than 70%.[21]

Metagenomics approaches led to the identification of a novel proposed genus, *Cyclovirus*. The identification of viruses similar to circoviruses, but with sequences unknown or sharing low homology with known viral proteins revealed the existence of undescribed species that could eventually be assigned to the *Circoviridae* family. The first cyclovirus was identified from a metagenomic analysis of fecal samples from children, with the finding of a nucleic acid fragment that encodes a protein showing close similarity to the Rep protein of circoviruses.[40] The new genus was proposed by Li et al.,[41] after the identification of circovirus-like, circular DNA viral genomes in human and chimpanzee stool samples. The name *Cyclovirus* was proposed, from the Greek "cyclo" meaning circular. Cycloviruses were also found to be prevalent in the muscle tissue of farm animals, such as chickens, cows, sheep, goats, and camels, which suggests the potential for frequent cross-species exposure and zoonotic transmissions.[41] The identification of cycloviruses in abdomens of dragonflies, together with the evidences found of recombination among different viral isolates, suggests that dragonflies may be natural hosts of cycloviruses.[42] The existence of this proposed genus is pending by the ICTV.

Two different lineages may be considered within BFDV, one including the budgerigar isolates (BG lineage) and the other is composed of viruses from cockatoos and other psittacine species (CT lineage). A high divergence is observed within the CT lineage, and therefore, different classifications have been proposed. Heath et al.[9] suggested the existence of eight genotypes, I–VIII, and a new genotype IX was proposed by Henriques et al.[14] The inclusion of more recent strains in the analysis enabled Varsani et al.[43] to consider 14 genotypes, A to N, within the CT lineage of BFDV. A Bayesian tree showing the 14 genotypes proposed by Varsani et al.[43] and their correspondence to the classification of Henriques et al.[14] is represented in Figure 73.1.

73.1.2 Morphology and Genome Organization

BFDV is a spherical nonenveloped virus of icosahedral morphology. It is among the smallest known viruses, having a diameter of 14–16 nm.[44] BFDV virions consist of 60 identical subunits of capsid protein arranged in 12 pentamer clustered units forming a pentagonal capsomere. Under electron microscope, capsomeres of BFDV exhibit a smooth appearance.[45] The density of this virus cesium chloride is 1.378 g/mL.[46]

The genome of BFDV is monomeric, nonsegmented, and single stranded. It consists of a covalently closed circular DNA molecule of approximately 2 kb, with an ambisense organization, composed by an intergenic region flanked by two head-to-head arranged open reading frames (ORFs).[7] The intergenic region located between the 5′ ends of the two major ORFs includes a potential stem-loop structure formed by a pair of inverted repeats (Figure 73.2). At its apex is present a nonanucleotide motif that constitutes an essential cis-acting element required for DNA replication.[47] This nonanucleotide sequence NANTATTAC is highly conserved among circoviruses, geminiviruses, and nanoviruses, but only part of the conserved sequence (TATTAC) is essential for the cleavage of the viral strand.[48] Indeed, although circoviruses infecting different species have different nonanucleotide motifs, the last six nucleotides of the sequence are conserved among them.[35] The consensus sequence of BFDV is TAGTATTAC.[49] The most common nucleotide numbering used was adopted from Todd et al.,[28] with position 1 corresponding to the "A" residue that occurs at the nucleotide position 8 in the nonanucleotide sequence.

Two direct tandem repeats of eight nucleotides are present in the genome of BFDV. The octamer repeat is located directly downstream the stem-loop structure and probably play a role in virus replication, perhaps by acting as putative binding sites for the Rep protein.[29,31] Although not conserved in all BFDV isolates, the octamer sequence is GGGCACCG in most viruses[50] (Figure 73.2). Also, direct and inverted hexamer repeats may be observed in the genome of BFDV, but between isolates, they are not conserved in number nor in sequence.[14] Indeed, a study performed with PCV1 demonstrated that from the four existing hexamers only two are essential for an efficient replication of the virus.[51]

Two major ORFs are present in the genome of BFDV (Figure 73.2). ORF1 (rep gene) occurs in the viral strand and encodes the replication-associated protein Rep of about 33.5 kDa,[14] essential to initialize viral replication. The Rep protein contains three amino acid motifs, I, II, and III, conserved among circular ssDNA genomes employing the rolling circle replication (RCR) method of DNA replication, indicating that BFDV also replicate via this method.[52] Motifs I, II, and III are located in the N-terminus of the protein and are, respectively, FTLNN, GxxHLQGY, and YxxK.[53] Also, a P-loop for dNTP binding (GPPGCGKS) and three additional conserved motifs (WWDGY, DDFYGWLP, and DRYP) of no known function are present in the amino acid sequence of Rep protein.[14] It has been suggested that this protein is a recombinant between plant and mammalian viruses, with the N-terminal portion showing close similarity to the N-terminal region of the Rep protein

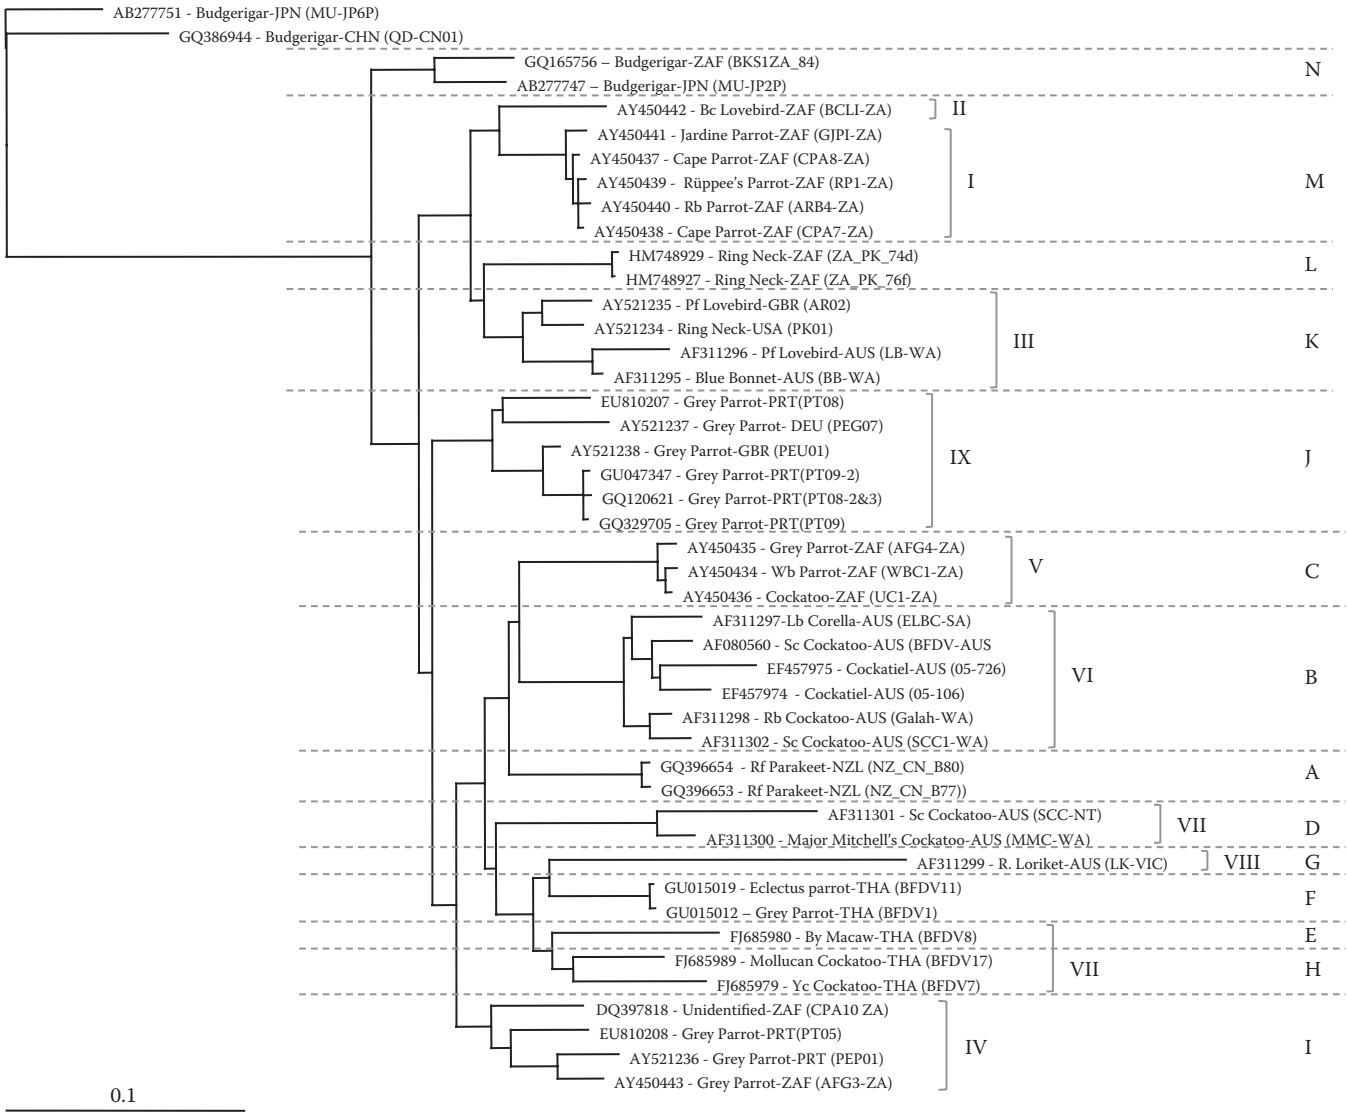

FIGURE 73.1 Bayesian analysis of the beak and feather disease virus genome, showing the correspondence between the 9 genotypes described by Henriques et al. (I–IX) and the 14 strains considered by Varsani et al. (A to N).

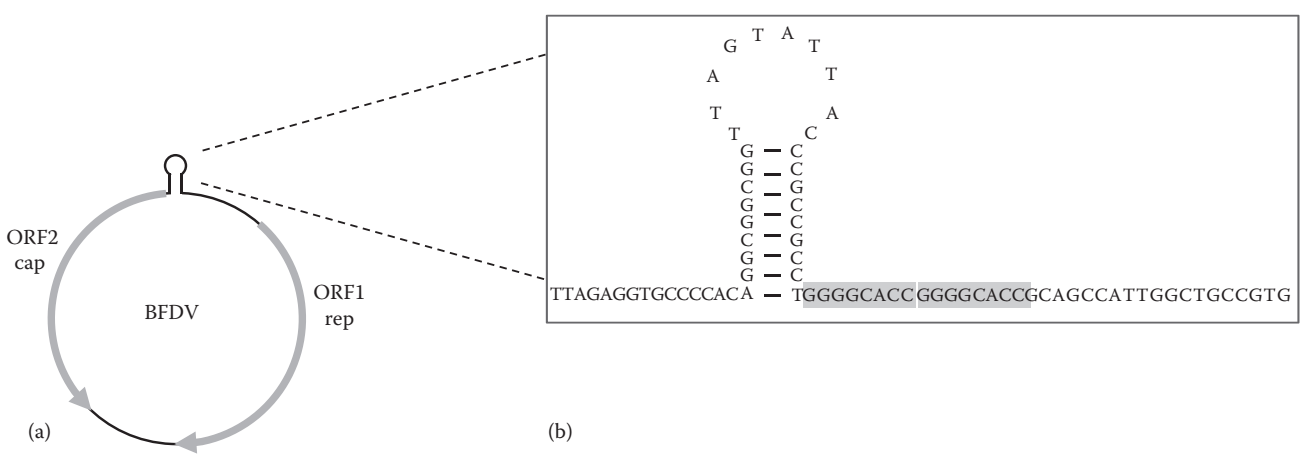

FIGURE 73.2 Schematic representation of the beak and feather disease virus genome. (a) Diagram of the putative replicative form, showing the two principal open reading frames and the stem-loop structure; (b) Nucleotide sequence of the intergenic region. The stem-loop, the nonanucleotide, and the octamer repeats (shaded) are represented.

from nanoviruses and geminiviruses, and the C-terminal portion being related to an RNA-binding protein encoded by calicivirus. This recombination may have occurred through a transition of RNA to DNA made by an endogenous mammalian retrovirus.[54]

ORF2 (cap gene) occurs in the complementary strand of the double-stranded replicative form (RF) and encodes the major structural capsid protein Cap of about 29.3 kDa.[14] Although the start codon for most BFDV isolates is the conventional ATG, a variety of alternative start codons in different positions for this ORF have been described, such as CTG,[50,55] TCT,[55] ATA or AGG,[56] and ATT.[14] The Cap protein contains a putative bipartite nuclear localization signal (NLS) consisting of 41 amino acid residues at N-terminus[57] that directs viral DNA through the nuclear membrane to the nucleus for DNA synthesis.[58] Also present in the Cap protein is a highly basic N-terminal region arginine rich, probably necessary for packaging of the viral genome into the viral capsid.[45]

Five other potential ORFs, ORF3–ORF7, that potentially encode proteins were detected in the putative RF of BFDV,[50] two of which are situated on the virus-sense strand (ORF4 and ORF5) and the other three on the complementary-sense strand (ORF3, ORF6, and ORF7).[14] The protein encoded by ORF3 seems to play a role in virus-induced apoptosis and in viral pathogenesis,[59] although it was shown that the protein was not essential for viral replication.[60] Indeed, there are two isolates from grey parrot from Portugal that lack this ORF.[60] The function of the other four ORFs is unknown and they are not all present in all isolates,[14] raising doubts regarding their requirement and significance.

Two potential TATA boxes are present in the virion strand in most isolates; the first (TATA) is positioned at nt 86–89, upstream Rep protein, while the second (TATAAAA) is located around nt 680. However, the utility of these sequences is unclear since BFDV strains were detected with only one or three TATA boxes.[14]

Three polyadenylation signals, two direct (AATAAA) and one inverted (TTTATT), were also detected in the majority of viruses, but as occurs with TATA boxes, the sequence, number, and location of these signals are not universal in all BFDV isolates.[14]

73.1.3 Replication

Replication of BFDV is dependent on the replication machinery of the host cell since this virus does not have an autonomous DNA polymerase for the *de novo* DNA synthesis.[58] The Rep protein is essential to initialize viral replication, but continuation of the process requires cellular enzymes expressed during S phase of the cell cycle and initiates only after mitosis of the host cell.[61] BFDV is thought to replicate in rapidly dividing tissues, with evidence suggesting that the liver is an important site of replication.[62]

DNA replication occurs in the nucleus of infected cells, and therefore, before establishing a productive infection the viral DNA needs to cross the nuclear membrane through protein-mediated nuclear transport.[63] Proteins are directed in the nucleus via NLSs such as those existing at the N-terminus of the Cap protein, so is this protein that transports the viral genome across the nuclear membrane before replication can occur.[58]

Once inside the nucleus of the host cell, the circular ssDNA genome replicates using RCR.[64] The initiation of the RCR of the virus has been ascribed to the nonanucleotide motif located at the apex of the stem-loop structure, in the nontranslated intergenic region.[29] The two octanucleotides located downstream of the stem loop are thought to be the binding sites for BFDV replication-associated protein.[64] The ssDNA genome serves as the template for the formation of a complementary strand of DNA, originating a double-stranded DNA (dsDNA) intermediate, known as the replicative form (RF). When one unit of the genome has been replicated, the loop is covalently closed, with the release of a positive circular single-stranded parental DNA molecule and a circular dsDNA molecule composed of the negative parental strand and the newly synthesized positive strand. The ssDNA molecule will then be encapsidated,[65] while the dsDNA RF forms the template for production of mRNA, with ORFs potentially on both the original virion strand and also on the complementary strand of the replicative intermediate.[52]

73.1.4 Clinical Features and Pathogenesis

BFDV is the causative agent of a disease typically characterized by symmetric feather dystrophy (Figure 73.3) and beak deformities, therefore named psittacine beak and feather disease (PBFD). As BFDV is dependent on the hosts' machinery for replication, it is predominantly found in rapidly dividing cells such as those of the epithelium and consequently, the skin, feathers, beak, esophagus, and crop, as well as organs of the immune system such as thymus, cloaca, bursa of Fabricius, and bone marrow are affected.[66]

PBFD is a potentially fatal disease that can be present as a peracute, acute, or chronic disease. Peracute and acute forms affect predominantly younger birds, from hatching to 3 years old, in which sudden death occurs with no evidence (peracute) or mild evidence (acute) of feather dystrophy.[67] Chronic disease was not described until now in nestling and fledgling parrots,[15] due to host conditions rather than antigenic or genotypic traits of BFDV.[7] Older birds may overcome the infection to become carriers of the virus, and maternal antibodies have been shown to provide immunity to offspring.[68]

The chronic form of the disease, also known as the "classical form," is the most frequent and affects birds up to 3 years of age. The disease begins with depression, lethargy, and diarrhea followed by a chronic, progressive, bilateral, and symmetrical feather dystrophy occasionally accompanied by beak and occasionally claw deformities. The abnormal appearance of feathers is the result of a dystrophic process that consists of necrosis and hyperplasia of epidermal cells.[69] The developing feathers will have a host of deformities including shortening, retention of a thick outer sheath, constrictions or necrosis of the shaft, stress lines in the vane, curled or clubbed feathers, and hemorrhage into the feather shaft.[44,69,70] Beak deformities are not always present and seem to occur in specific species or

(a) (b)

FIGURE 73.3 Clinical signs of the beak and feather disease virus. (a) Cockatoo exhibiting feather loss. (b) Grey parrot showing down feathers as a result of cover feathers loss. (Photo courtesy of Dr. Filipe Martinho from Nyctea, Lda, Lisbon, Portugal.)

are dependent on other factors.[46] Indeed, although symptoms are most often associated with the feathers rather than with the beak, species such as sulfur-crested cockatoos (*Cacatua galerita*), galahs (*Eolophus roseicapillus*), little corellas (*Cacatua sanguinea*), and Moluccan cockatoos (*Cacatua moluccensis*) are more susceptible to beak changes.[46] Possible beak deformities include elongation, transverse or longitudinal cracking, and palatine necrosis.[44,69,70] The feather and beak abnormalities associated with BFDV are the result of necrosis resultant by the targeting of feather, follicular, and beak epithelial cells by BFDV, observed in histopathological examinations. In addition to beak and feathers abnormalities, BFDV-infected birds typically display lymphoid depletion associated to an immunosuppression that favors the appearance of opportunistic secondary infections, which are the cause of death in most infected birds.[62] Psittacine species may be susceptible to gram-positive and gram-negative septicemia, localized bacterial infections, and fungal or parasitic infections: chlamydiosis, severe pulmonary aspergillosis, severe enteric cryptosporidiosis,[66] herpes virus, and polyomavirus adenovirus.[67]

Transmission of BFDV is not fully elucidated, but apparently can occur both horizontally and vertically.[71] Horizontal transmission may occur through inhalation or ingestion of virus particles shed in feather dust, crop secretions, or feces, as indicated by the presence of viral antigen in many organs associated with the alimentary tract.[72] Nuclear inclusions were observed within testicular germinal epithelium, showing that BFDV may be gonadotrophic.[66] Horizontal transmission may also occur when adults feed their young. Vertical transmission, from infected hens to embryonated eggs, has been reported.[8] Also, infection of the ovary or oviduct[66] and the BFDV detection in nestlings of BFDV-positive parents[71] suggest a route for the vertical transmission of the virus. It has been reported that asymptomatic parents may produce offspring showing clinical signs of BFDV, suggesting that a carrier state exists with vertical or horizontal transmission and/or an existence of a genetic predisposition to the disease.[73] Within a captive environment, horizontal spread through environmental contamination is probably the most prevalent route of transmission. It is speculated that humans are also vehicles of disease transmission as the disease can be spread by handling a healthy bird after coming into contact with infected birds.

Currently, there is no cure or effective treatment for the disease caused by BFDV. Moreover, the production of a protective vaccine is hampered by the lack of success in culturing BFDV *in vitro*.[15]

73.1.5 Diagnosis

PBFD is difficult to diagnose based on clinical signs alone as feather abnormalities may be due to other causes such as infection by avian polyomavirus.[46] Histopathological examinations have revealed the presence of basophilic intranuclear and intracytoplasmic inclusion bodies in feather and feather follicle epithelial cells or in macrophages present in the feather epithelium, follicular epithelium, or pulp cavity, with evidence of the presence of BFDV in such inclusion bodies.[66] Basophilic to amphophilic inclusion bodies were found in histological sections of feathers and follicular epithelium using hematoxylin and eosin stains.[66] However, similar basophilic

inclusions have been observed with other viruses like avian polyomavirus and adenovirus, hindering diagnosis based solely upon histopathology. For that reason, specific assays for BFDV infection detection have been developed: hemagglutination and hemagglutination inhibition,[74] *in situ* hybridization,[75] electron microscopy,[46] ELISA,[76] polymerase chain reaction (PCR),[77] real-time PCR,[78,79] and RCA.[80]

73.1.5.1 Conventional Techniques

The discovery that BFDV has the ability to agglutinate erythrocytes allowed the development of hemagglutination (HA) test for the detection of BFDV that can be also used to evaluate the amount of virus present in a sample.[81] Virus can be detected in affected feathers.[74] Hemagglutination inhibition (HI) assays can correspondingly be used to detect antibodies against BFDV that can be useful in diagnosing clinically normal birds that have mounted an immune response following exposure to the virus. Antibodies can be detected in blood, serum, plasma, or yolk.[74,82] The HA assay has been shown to be ineffective in identifying carriers of the disease as it does not detect latent or incubating BFDV infection. The use of HA and HI tests as serological tools is limited because persistently infected birds are required and inadequate amounts of virus are usually obtained from feather follicle tracts.[83] The suitability of these techniques is also limited by the possibility of genetic and antigenic diversity of BFDV.[84]

Several ELISA reactions had been developed for the detection of BFDV-specific antibodies. The advantages of these tests include their use as noninvasive diagnostic tests and the ability to screen multiple samples simultaneously. However, as occurs with HA and HI, a drawback of ELISA tests is the inability to produce large amounts of standardized serological diagnostic test antigen, which is safe to use. Also cross-reactivity may occur. For that reason, a competitive ELISA was developed, using a baculovirus-expressed recombinant BFDV capsid protein and a newly developed monoclonal antibody raised against this protein. This competitive ELISA has proven to be a sensitive and specific diagnostic test that should have wide application for the serodiagnosis of BFDV.[76]

As BFDV cannot be cultivated in cell cultures or in embryonated eggs, due to either its high *in vivo* tissue specificity or its specific growth requirements,[62] diagnosis must be confirmed by detection of either viral antigen or viral nucleic acid. The detection of viral nucleic acid may be performed by molecular techniques.

73.1.5.2 Molecular Techniques

Once the BFDV genome was fully sequenced,[50,64] universal primers designed to bind to and amplify a portion of the rep gene were developed[77] and later refined[7] to enable diagnosis of BFDV through the PCR. The oligonucleotide primers hybridize within the ORF1 (Rep) of the BFDV genome and allow for the detection of clinically infected as well as latently infected birds. Compared with HA and HI, PCR has proven to be more specific and have greater sensitivity.[85] The quantitative real-time PCR is even more specific and sensitive, allowing the detection of asymptomatic infections with simultaneous quantification of the amount of virus present in a sample. The indication of the viral titer may be useful to determine the clinical relevance of the infection. Katoh, Shearer, and colleagues developed real-time PCR based on the SYBR Green[78] or SYTO9[79] assay systems. Eastwood and collaborators[86] developed a real-time PCR based on a TaqMan probe. Real-time PCR assays exhibit low inter- and intra-assay variability and may eventually replace conventional PCR methods as the gold standard for the diagnosis of BFDV infection.[78]

More recently, the bacteriophage phi29 DNA polymerase has been used for the efficient isothermal amplification of circular DNA viral genomes without the need of specific primers by a rolling circle amplification (RCA) mechanism.[80] Major advantages of this technique is that the amplification is performed at isothermal conditions, the single-step amplification of the whole genome is possible and is independent of DNA sequence, making it possible to detect viruses with very low sequence similarities to known viruses.[31] RCA has been successfully applied to BFDV positive samples.[43]

The loop-mediated isothermal amplification has been used with success for the detection of goose,[87] pigeon,[88] and duck[89] circoviruses and, therefore, may be also applied for the diagnosis of BFDV. This molecular method developed by Notomi et al.[90] to amplify DNA or RNA under isothermal conditions is highly specific and sensitive and, advantageously, it can be completed within less than 45 min under isothermal conditions, without the need of a thermal cycler and/or specialized laboratory.

73.2 METHODS

73.2.1 Sample Preparation

The most widely used methods for the diagnosis of BFDV are PCR and real-time PCR since they are cheap, easy to implement, and highly sensitive and specific methods. Before these techniques can be carried out, DNA extraction is required, what may be performed from several matrices.

The presence of BFDV can be detected in live animals in blood, cloacal swabs, or feather samples.[91] After death, several organs may be collected at necropsies and pooled for DNA extraction. Sample preparation depends on the matrix used. When blood samples are used, the sample must be diluted to 5% in phosphate buffered saline (PBS) prior to DNA extraction, since avian erythrocytes are nucleated. Dry cloacal swabs are resuspended in PBS containing 200 units/mL of penicillin, 200 mg/mL of streptomycin, and 100 mg of gentamicin/mL. For DNA extraction from feathers, a 0.5–1 cm section is cut from the terminal portion of the feather quill and placed in a 1.5 mL Eppendorf tube containing 300 μL Buffer ATL (QIAGEN, Valencia, CA) and 20 μL dithiothreitol (DTT) 1 M. Incubation at 56°C must be performed until the sample is completely lysed. When organs collected from a dead animal at necropsy are used, the pool of organs is homogenized and suspended 10% in PBS containing antibodies as described earlier.

Several approaches may be used for DNA extraction, from the classical method of extraction with phenol and

chloroform/isomayl alcohol followed by ethanol precipitation to highly sensitive and reproducible DNA extraction kits introduced by various commercial companies and widely applied. For processing of a large number of samples, the nucleic acid extraction workstation BioSprint 96 (QIAGEN, Valencia, CA) may be employed, with the advantage of providing high-quality DNA in a quick way reducing the risk of contamination. This kit uses MagAttract magnetic-particle technology that combines the speed and efficiency of silica-based DNA purification with the convenient handling of magnetic particles. The protocol must be performed according to the manufacturer's instructions. Briefly, 200 µL sample are mixed by pulse vortexing with 200 µL Buffer AL. The mixture is transferred to an s-block followed by the addition of 20 µL QIAGEN Protease. After 10 min incubation at 70°C, 200 µL isopropanol and 30 µL MagAttract Suspension G are added. The BioSprint 96 is loaded with s-block, the other s-blocks already prepared (two with 500 µL Buffer AW1 per well, two with 500 µL Buffer AW2 per well, and one with 500 µL RNase-free water with 0.02% Tween 20 per well) and a 96-well microplate containing 100 µL Buffer AE for elution of the DNA. Start button is pressed to start the protocol run. After the samples are processed, s-blocks are removed and discarded and the elution plate is stored at 4°C. The DNA extracted is ready for use as template for PCR amplification.

73.2.2 Detection Procedures

73.2.2.1 Polymerase Chain Reaction

The presence of BFDV can be detected by PCR amplification using degenerate primers 174 and 175 described by Mankertz and collaborators.[56] These primers are directed to regions of the *rep* gene that are conserved in vertebrate circoviruses. Primer 174 (5′-GTGTTTCACBCTYAAYAAYCCTWCMGA-3′) recognizes protein motif FTLNN involved in RCR, while primer 175 (5′-ATCTTCCCCRTSRTAWCCATCCCACCA-3′) is directed against the conserved amino acid motif WWDGY. The reaction is performed with 500 ng of the total DNA and 25 pmol of each primer, using High Fidelity PCR Master (Roche Diagnostics, Indianapolis, IN), according to the manufacturer's protocol.

73.2.2.1.1 Procedure

1. Remove all of PCR reagents from the freezer and allow them to thaw. Vortex and spin down all microcentrifuge tubes of PCR components before use.
2. Prepare the reaction mix as follows (volumes indicated are per sample):

Component	Volume (µL)
High-fidelity PCR master mix (2×)	12.5
Primer 174 (50 pmol/µL)	0.5
Primer 175 (50 pmol/µL)	0.5
H_2O	9.5
Total	23.0

Note: Positive and negative controls are always included along with the test samples in order to monitor the reaction and any possible contamination that might occur during the PCR procedure, respectively.

3. Distribute 23.0 µL of PCR mix into each 0.2 mL PCR tube.
4. Add 2 µL of DNA sample.
5. Spin the sample tubes in a microcentrifuge at 14,000 × *g* for 30 s at room temperature.
6. Place the sample tubes in the thermal cycler for an initial denaturation at 95°C for 10 min, followed by 45 cycles of denaturation at 95°C for 30 s, annealing at 52°C for 30 s, and extension at 72°C for 1 min. A final extension is performed at 72°C for 10 min.
7. Analyze the PCR products by agarose gel electrophoresis through 1% agarose gel in TBE buffer at 100 V for 30 min. Use GelRed (Biotium Inc., Hayward, CA) for staining.
8. Observe under ultraviolet light source.
9. Excise the expected fragments of about 561 bp for DNA sequencing.

For the amplification of the full-length genome of BFDV, four additional PCR may be performed as stated earlier using primers indicated in the following table. The name and the sequence of each primer are shown, as well as their location in the BFDV genome. Also, the annealing temperature at which each reaction must be performed and the length of the amplified fragment are indicated.

Name	Sequence (5′–3′)	Local (nt)	Temp. Annealing (°C)	Fragment Length (Base Pairs)
Pap (F)	CACGTGACTTC AAGACTGAG	588–607	50	509
1096 R	CCTGACGGCCC TGCGAGC	1096–1079		
921 F	TCACTCGTGTT TGGTGGTAC	921–940	55	631
1551 R	CACAAGACCCA GTGGCACC	1551–1533		
1441 F	CGCTGTGGTCAG GTCGTCTATTG	1441–1461	58	530
1970 R	CACCTCTAACTG CGCATGCG	1970–1951

Pap (R)	TCACGTGGACT GGAACCAAC	594–575		

73.2.2.2 DNA Sequencing

The nucleotide sequence of the full-length genome of BFDV may be obtained by direct sequencing of the five amplicons obtained in PCR. Prior to sequencing, the amplified fragments

must be purified from the agarose gel, for example, using NZYGelpure Kit (NZYTech, Lda., Lisbon, Portugal). DNA sequencing may be performed using a BigDye Terminator Cycle Sequencing Kit (Applied Biosystems, Foster City, CA) according to the manufacturer's instructions and the nucleotide sequences are determined on an automated 3130 Genetic Analyzer System (Applied Biosystems, Foster City, CA).

73.2.2.2.1 Procedure

1. Mix the following reagents in a labeled tube for each sequencing reaction.

Component	Volume (μL)
Terminator ready reaction mix (v1.1)	4.0
Sequencing buffer	2.0
Sequencing primer (5 pmol/μL)	1.0
Purified PCR product	1.0
H_2O	12.0
Total	20.0

2. Spin the sample tubes in a microcentrifuge at 14,000 × *g* for 30 s at room temperature.
3. Place the sample tubes in a thermocycler for 25 cycles of 96°C for 10 s, 5 s at annealing temperature of the primer, and 60°C for 1 min.
4. Precipitate the DNA sequencing product with 50 μL ethanol 95%, 2 μL EDTA 2 mM, and 2 μL sodium acetate 3 M pH 5.2.
5. Centrifuge for 20 min at 14,000 × *g* at 4°C.
6. Wash with 200 μL ethanol 70%.
7. Centrifuge for 7 min at 14,000 × *g* at 4°C.
8. Resuspend the dry pellet in 15 μL formamide.
9. Finally, obtain the nucleotide sequence of the DNA products on an automated 3130 Genetic Analyzer System (Applied Biosystems, Foster City, CA).

73.2.2.3 Bayesian Analysis

In order to evaluate the genotype of the strain in study, it is necessary to perform a phylogenetic analysis with representatives of each genotype retrieved from a database such as GenBank. Multiple alignments of the nucleotide sequences are generated by Clustal W,[92] and the results are converted to the NEXUS format using Mesquite software.[93] The phylogenetic tree is obtained with a Bayesian inference of phylogeny throughout the MrBayes version 3.1.2 software that uses a simulation technique called Markov chain Monte Carlo to approximate the posterior probabilities of trees.[94,95] MrBayes analysis is performed using the general time reversible (GTR) model (nst=6) with gamma-shaped rate variation with a proportion of invariable sites (rates=invgamma). The analysis is run for 10^6 generations (ngen=106) with four chains of temperature (nchains=4), and each chain is sampled every 10th generations (samplefreq=10).

The position of the strain in study in the Bayesian tree obtained will indicate the genotype of the isolate. Genotypic differentiation of BFDV isolates is crucial to establish effective control strategies for the conservation of endangered species and epidemiological investigations of disease outbreaks.

73.3 CONCLUSION

BFDV is an important pathogen responsible for PBFD, characterized mainly by feather dystrophy and beak deformities. The immunosuppression often associated with the presence of the virus favors the appearance of opportunistic secondary infections, which are the cause of death in the majority of infected birds. Nowadays, PBFV is considered a global disease, with prevalence highly variable country by country.

Molecular detection of BFDV genome is of major importance for the diagnosis of the disease, and the application of sensitive molecular techniques all over the world contributes to a great recognition of the overall prevalence and economic impact of this virus. The prompt diagnosis of PBFD is crucial to prevent rapid spread of the virus among birds and also to control international trade of psittacides. This virus remains infectious for long periods in the environment and is highly resistant to disinfection, requiring strict quarantine procedures to prevent contamination and spreading within the facility. Molecular characterization and genotyping of the virus is critical to establish effective control strategies for the conservation of endangered species.

There is currently no cure or treatment for BFDV, with therapeutic intervention being limited to treating secondary infections. The management of the disease lies thus mostly in prevention, and infected birds must be culled to stop viral spread to healthy members of the flock. Candidate vaccines against BFDV infection are being tested, but so far no suitable vaccine is available. Further development and implementation of improved prevention and treatment measures are warranted and indeed essential for the eventual eradication of BFDV infection.

74.1 INTRODUCTION

Porcine circovirus–associated diseases (PCVAD) result from infection with porcine circovirus type 2 (PCV2).[1] PCV2 has been demonstrated to infect the lymphoid, respiratory, nervous, digestive, urinary, reproductive, integumentary, cardiovascular, and skeletal systems.[2] Regardless of the organs affected, all PCV2-induced diseases, including postweaning multisystemic wasting syndrome (PMWS),[3] porcine dermatitis and nephropathy syndrome (PDNS),[4] porcine respiratory disease complex,[5] and reproductive failure,[2] are classified as PCVAD. Commonly occurring in pig industry, PCVAD cause significant economic losses worldwide.[1,6–12]

74.1.1 Classification

PCV2, belonging to the genus *Circovirus* of the family *Circoviridae*, is a small, nonenveloped, single-stranded, circular DNA virus with a diameter of 16–18 nm.[13] Of the three genera (*Circovirus*, *Cyclovirus*, and *Gyrovirus*) within the family *Circoviridae*, the genus *Circovirus* encompasses porcine circovirus (PCV), beak and feather disease virus, canary circovirus, duck circovirus, finch circovirus, goose circovirus, gull circovirus, starling circovirus, and swan circovirus; the genus *Cyclovirus* includes dragonfly cyclovirus and Florida woods cockroach–associated cyclovirus; and the genus *Gyrovirus* comprises chicken anemia virus, avian gyrovirus 2, and human gyrovirus 3 and 4.[14–17]

PCV is composed of two subtypes: PCV type 1 (PCV1) and PCV type 2 (PCV2). First identified in 1974,[18] PCV1 frequently causes contamination in the PK15 cell line (ATCC-CCL31) and is generally considered nonpathogenic in swine. PCV2 was first isolated from PMWS-affected pigs in the 1990s and is pathogenic in swine.[19] PCV2 exhibits 68% and 66% identity to PCV1 in the full genomic and ORF2 sequences, respectively.[20] The various PCV2 strains have 95%–100% sequence identity.[21] According to the sequence diversity, PCV2 is further subdivided into PCV2a (with five subclusters, 2A-2E), PCV2b (with three subclusters, 1A-1C), and PCV2c genotypes,[22,23] which have been retrospectively studied and found as early as 1985, 1988, and 1980, respectively.[23,24] In the past, the genotype PCV2a was the predominant virus causing PCVAD in pigs. The shift from the genotype PCV2a to PCV2b occurred between 2003 and 2006. Since 2006, the genotype PCV2b has been the predominant PCV2 subtype worldwide.[24–28] The genotype PCV2c has only been found retrospectively in Denmark.[23]

The genome of PCV2 is made up of 1767–1768 nucleotides forming a stem-loop structure and 3-hexameter repeats. Of 11 open reading frames (ORF) contained in the genome, the ORF1, ORF2, and ORF3 encode the replication-related proteins, capsid protein, and apoptosis-related protein, respectively.[13] More specifically, the ORF1 encodes two replication-related proteins, Rep and Rep′. The Rep protein is translated from the full-length transcripts consisting of 341 amino acids with a dNTP-binding domain (P-loop) and three motifs of rolling-circle replication (RCR): RCR-I (FTLN), RCR-II (HxQ),

and RCR-III.[13] However, the C-terminus of the Rep′ protein has entire deletion of the 128 amino acids in the P-loop and consists of only RCR-I, RCR-II, and RCR-III. In the transcription of ORF1, the mRNAs of both Rep and Rep′ proteins carry three nuclear location signals (NLS) in their N-terminus. NLS1 and NLS2 mediate the nuclear accumulation, and NLS3 enhances nuclear transport of both Rep and Rep′ proteins.[13] The ORF2 encodes the capsid protein. The sequence similarity of ORF2 among various PCV2 strains is 91%–100%.[21] The mRNA of the capsid protein carries an NLS that can carry the capsid protein into the nucleus. The capsid protein, consisting of 233 amino acids, is rich of arginine in the N-terminus, which binds to the viral DNA.[13] The ORF3 encodes an apoptosis-related protein and can induce apoptosis via caspase 8 and 3.[29]

74.1.2 Physiochemistry of PCV

PCV has a buoyant density of 1.37 g/mL in CsCl and a sedimentation coefficient of 57S. It does not hemagglutinate erythrocytes and is capable of resisting the acid inactivation of acidity at pH 3, chloroform, and 70°C for 15 min. However, the titer of PCV2 is reduced following exposure to chlorhexidine, formaldehyde, iodine, or alcohol at room temperature for 10 min.[30]

74.1.3 Transmission and Epidemiology

Horizontal and vertical transmissions of PCV2 have been demonstrated experimentally.[31] In horizontal transmission, favorable factors for transmission are the ocular, nasal, tonsillar, and bronchial secretions, saliva, feces, urine, milk, and semen.[31–33] PCV2 infection in pigs is usually via direct or indirect contact with these secretions or uncooked tissues of PCV2-infected pigs by the oral–nasal route.[34] Horizontal transmission of PCV2 has also been demonstrated by intermingling of PCV2-infected pigs and naïve pigs.[31] In vertical transmission, PCV2 can pass via the placenta to the fetus in pregnant sows, causing late-term abortions and stillborn piglets.[31,35] PCV2 has also been demonstrated to infect the embryo and fetus with PCV2-infected semen via artificial insemination.[36]

Although PCV2 was initially identified in PMWS-affected pigs from SPF herds in Canada in 1991,[19] several retrospective studies have shown that PCV2 infection can be traced in PCVAD-suspected cases as early as the 1960s.[24,37] The earliest evidence of PCV2 infection in PDNS-associated lesions, including systemic vasculitis, dermal and epidermal necrosis, and necrotizing glomerulonephritis, was in 1985,[37] and PMWS-related lesions, including lymphoid depletion and granulomatous inflammation, were revealed in the 1960s. A retrospective serological survey of PCV2 antibodies also showed that PCV2 is not a new virus; in fact, it may have existed for more than 50 years.[24,37]

74.1.4 Clinical Features and Pathogenesis of PCVAD

74.1.4.1 Subclinical Infection of PCV2

PCV2 infection in pigs can be either subclinical or clinical. Most PCV2-infected pigs are healthy and subclinical. They show no clinical signs and exhibit normal to mild lymphoid depletion, with small amounts of PCV2 antigens present in lymphoid tissues. PCV2-associated lesions and antigens are also restricted in one or two lymphoid tissues.[1,38] Although subclinical PCV2-infected pigs have no significant clinical symptoms, the reduction in the efficacy of porcine reproductive and respiratory syndrome virus (PRRSV) and classic swine fever virus (CSFV) vaccination has been demonstrated in *in vivo* models.[39,40] In addition, subclinical PCV2-infected pigs could develop clinical disease when a cofactor is present.[38,41]

74.1.4.2 Characteristics and Pathogenesis of PMWS

A diagnosis of PMWS in PCV2-infected pigs must meet the following criteria: (1) wasting syndrome with frequent dyspnea and enlargement of inguinal lymph nodes; (2) histopathologically, lymphoid tissues showing moderate to severe lymphoid depletion and formation of basophilic or amphophilic grape-like intracytoplasmic inclusion bodies; and (3) lymphoid tissues containing a moderate to high level of PCV2 load.[1,2,42] None of the three criteria can be excluded in PMWS identification.

PMWS primarily affects pigs at ages between 25 and 120 days, with the highest prevalence between 60 and 80 days. The morbidity and mortality in affected herds range from 4% to 30% and 4% to 20%, respectively.[38,43] The clinical characteristics of PMWS include weight loss, pallor of skin, respiratory distress, diarrhea, and occasionally, jaundice.[38,43] Grossly, the most predominant feature is the enlargement of lymph nodes, mainly in the inguinal, submandibular, mesenteric, and mediastinal lymph nodes. The lungs show extensive to diffuse mottling with consolidation in the anterio-ventral aspect. The thymus is usually atrophied. The liver shows orange-yellow discoloration. In the kidney, multiple variably sized pale foci may be observed.[38,44]

Histopathologically, the characteristic lesions in PMWS-affected pigs are granulomatous inflammation and the presence of basophilic intracytoplasmic inclusion bodies in histiocytic lineage cells. Multifocal to locally extensive coagulative necrosis and variable lymphoid depletion together with histiocytic infiltration and formation of multinucleated giant cells are present in almost all lymphoid tissues, including lymph nodes, tonsils, Peyer's patches, and spleen. In the thymus, the cortex is atrophied. Lesions in the lungs are characterized by the infiltration of lymphocytes, macrophages, and multinucleated giant cells in the alveolar walls. The liver is infiltrated by lymphohistiocytic inflammatory cells in the portal triads, with swelling, vacuolation, and coagulative necrosis of hepatocytes. There is also lymphohistiocytic cell infiltration in the renal interstitium in PMWS-affected pigs.[1,38]

The role of PCV2 in the pathogenesis of PMWS has been demonstrated experimentally.[45,46] PCV2 is transmitted via direct contact between infected and naïve pigs through either the oral or the respiratory route. After exposure to PCV2, the virus first enters the tonsil and lymph nodes of the head. Although PCV2 antigens can be detected within monocytes, macrophages, and follicular dendritic cells, PCV2 usually does not replicate within these cells.[3,38,47] The presence of

PCV2 on the surfaces of dendritic cells does not modulate the MHC class I and II expression.[47] Dendritic cells and monocytes/macrophages can harbor PCV2 without getting killed.[47] These cells function as a vehicle that allows the virus to spread throughout the body and infect lymphoid organs. In secondary lymphoid tissues, PCV2 also infects B and T cells, where viral replication takes place.[38,48] It has been shown that stimulation and/or activation of the immune system in PCV2-infected pigs by other viruses,[49,50] bacteria,[65] or noninfectious agents[51,52] could upregulate PCV2 replication and increase the PCV2 load in the tissue. As PCV2 replication depends on the cell polymerases present in the nuclei of cells during the S phase of the cell cycle, immune stimulation with a mitogen such as concanavalin A may activate lymphocyte proliferation and lead to the upregulation of PCV2 replication.[52,53]

The characteristic pathological changes in lymphoid tissues of PMWS-affected pigs are lymphoid depletion and granulomatous lymphadenitis. Although PCV2 can induce apoptosis of CD79α$^+$ B-lymphocytes and PK-15 cells by ORF3 protein-induced activation of caspase 3 and 8 *in vitro*,[29,54] the apoptotic index of lymphoid tissues in PMWS-affected pigs is either normal or lower than that of normal pigs.[55] In contrast, the proliferation index and apoptosis/proliferation rate in lymphoid tissues of PMWS-affected pigs are lower than those in normal pigs. Therefore, PCV2-induced lymphoid depletion may not be fully due to apoptosis, but rather largely due to reduced lymphocyte proliferation.[56] The downregulation in lymphocyte proliferation caused by PCV2 infection is resulted from the decreased expression of lymphocyte growth factor, IL-2 and IL-4.[57,58] In addition, PCV2 infection may induce the proliferation of blood monocytes and monocyte-derived macrophages; the formation of multinucleated giant cells and expression of monocytic chemokines and proinflammatory cytokines such as monocyte chemoattractant protein-1, macrophage inflammatory protein-1, IL-1β, and IL-8; and the directional movement of blood monocytes and neutrophils. Experimental results confirmed that PCV2 plays a role in the induction of the granulomatous inflammation occurring in PMWS-affected pigs.[59]

74.1.4.3 Cofactors of PMWS

PCV2 is recognized as the essential infectious agent in the development of PMWS, but experimental inoculation of PCV2 alone cannot reproduce all the clinical signs and pathological changes of PMWS in pigs.[1,2,38,49,50] The seroprevalence of PCV2 infection in commercial pig herds is nearly 100%, but only 5%–30% of PCV2-infected pigs show the representative signs of PMWS. Among these PMWS cases, more than 98% of the affected pigs have coinfection with other pathogens. Singular PCV2 infection occurs only in 1.9% of PMWS-affected cases.[48] These observations suggest that the development of PMWS requires the combination of PCV2 and other cofactors, including coinfection,[49,60] immunomodulation, different PCV2 genotypes,[31] and the ages and breeds of pigs.[61–63]

Porcine parvovirus,[49] PRRSV,[64] and *Mycoplasma hyopneumoniae*[65] have been demonstrated to enhance PCV2 replication, increase the severity of PCV2-associated lesions, and heighten the risk of PMWS development under experimental and field conditions. Nonspecific immune stimulation by various vaccines of *M. hyopneumoniae*, *Actinobacillus pleuropneumoniae*, PRRSV, and CSFV may also promote PCV2 replication and increase the severity of PMWS.[66–68] The oil-in-water adjuvant and keyhole limpet hemocyanin in incomplete Freund's adjuvant have been shown to cause a longer duration of viremia, increased serum and tissue viral loads, and more severe lymphoid depletion as compared to pigs vaccinated with aqueous and aluminum hydroxide products.[69] In addition, cyclosporine- and dexamethasone-induced immunosuppression can enhance the development of PMWS in PCV2-infected pigs.[69,70]

74.1.5 Diagnosis

PCV2 can be diagnosed by several methods: indirect fluorescent antibody (IFA) assay in monolayer,[71] immunoperoxidase monolayer assay,[72] enzyme-linked immunosorbent assay (ELISA),[73] and serum virus neutralization assay[74] for anti-PCV2 antibody detection; PCR,[75,76] multiplex PCR,[77–80] quantitative real-time PCR,[32,81–86] *in situ* PCR,[87] and *in situ* hybridization (ISH)[3,88–90] for PCV2 nucleic acid detection; and virus isolation,[52,91] immunohistochemical (IHC) staining,[92–94] antigen detection capture ELISA,[95,96] and IFA[97] for PCV2 virus or viral antigen detection. Given that most pigs in the field, regardless of their health status, are infected with PCV2,[86] use of conventional PCR, detection of anti-PCV2 antibodies, or direct or indirect demonstration of PCV2 infection in pigs is not considered a replacement for clinical assessment of pigs and microscopic evaluation of tissues for confirmative diagnosis of PCVAD. For PCVAD diagnosis, it is important to demonstrate characteristic lesions in conjunction with the presence of PCV2 antigens or nucleic acids in the affected organs. A confirmative diagnosis of PCVAD cannot be made without evaluating microscopic lesions and demonstrating that PCV2 is associated with the characteristic lesions (lymphoid depletion, histiocytosis, syncytial cells, and/or basophilic cytoplasmic inclusion bodies in lymph nodes, Peyer's patches, or lamina propria of the intestinal villi). Currently, IHC staining and ISH for localizing intralesional PCV2 are considered gold standard methods for the diagnosis of PCVAD.[44,87,98] In addition, quantitative PCR for detecting the amount of PCV2 nucleic acids in serum and tissue has been demonstrated to be predictive for the clinical outcome,[81,86] such as in PCV2-associated reproductive failures.[99]

74.1.5.1 Viral Isolation

Viral isolation is the traditional method for the diagnosis of PCV2 infection. It is performed using the PK-15 cell line treated with D-glucosamine.[52,100] D-glucosamine has been shown to initiate PCV replication by enabling the PCV genome to enter the cell nucleus, which normally can be achieved only by inclusion in the daughter nuclei at the end of mitosis.[100] As PCV2 is a slow-growing virus and its replication in cell culture has no distinct cytopathic effect,[42] it may require a couple of weeks for PCV2 to grow, after which IFA

or PCR can be used to confirm the viral isolation. Therefore, even though it has been demonstrated that the quantitative virus isolation using a serial tenfold dilution of clinical specimens could differentiate clinical and subclinical PCV2 infections,[95] virus isolation is laborious.

74.1.5.2 Molecular Techniques

Quantitative PCR can accurately differentiate PCV2 infection from PCVAD by copy numbers of PCV2 DNA present in the serum or tissue. A PCR result of less than 10^6 PCV2 DNA copies is generally not considered a PCVAD case. A threshold of 10^7 or greater PCV2 genomic copies per milliliter of serum has been found to correlate well with severe PCV2-associated lesions and clinical disease, as well as poor prognosis.[84,86]

ISH using a labeled DNA probe corresponding to a specific portion of the PCV2 genome and the IHC staining using a monoclonal or polyclonal antibody targeting PCV2 antigens are able to correlate the distribution of PCV2 with the lesion area using formalin-fixed, paraffin-embedded tissue sections. These two methods are important for the diagnosis of PCVAD. Furthermore, ISH has been found to be more specific than IHC staining, especially when the IHC staining is performed using polyclonal antibodies.[101] Considering the ease of preparing DNA probes and the convenience of using nonradioactive digoxigenin-labeled probes, an ISH using a 5′ end digoxigenin (DIG)-labeled 40 bp oligonucleotide probe specific for PCV2 ORF2 is described herein.

74.2 METHODS

74.2.1 In Situ Hybridization

74.2.1.1 Procedure

The method of ISH for PCV2 nucleic acid detection is modified from previous studies.[51,88,102]

1. Tissue samples are fixed in 10% formalin and paraffin embedded. Sections of the paraffin-embedded tissues are dewaxed in xylene and rehydrated in graded ethanol (100%, 90%, 70%, 50%, and 30%).
2. After being washed twice with phosphate buffered saline (PBS), tissues are digested with 4 μg/mL proteinase K in sterile water for 5 min at room temperature.
3. After being washed twice with PBS, slides are covered and prehybridized with the hybridization buffer (50% formamide, 0.9 M NaCl, 0.02 M Tris HCl, and 0.01% SDS) at 47°C for 1 h.
4. During prehybridization, the 5′ end digoxigenin (DIG)-labeled 40 bp oligonucleotide probe (5′-CAGTAAATACGACCAGGACTACAA TATCCGTGTAACCATG-3′) complementary to nucleotides 1085–1124 of ORF2 from PCV2[88] is diluted with hybridization buffer to a concentration of 5 ng/μL. The probe is denatured at 95°C for 3 min and then quenched on ice.
5. The prehybridization buffer is removed.
6. The probe is added in hybridization buffer for hybridization at 47°C overnight.
7. The probe is removed and the slides are washed with graded (4×, 2×, 0.5×, 0.1×, and 0.01×) saline-sodium citrate (SSC) buffer (1× SSC contains 50 mM NaCl and 15 mM sodium citrate, pH 7.0) at 47°C for 15 min each.
8. After being washed with tris-base solution (TBS) buffer (0.1 M Tris HCl, 0.4 M NaCl, pH 7.5), sections are then treated with the blocking solution (Roche, Nonnenwald, Penzberg, Germany) for 30 min.
9. For detection of hybridized signals, the probe is labeled with 1:200 anti-digoxigenin antibody conjugated with alkaline phosphatase (anti-DIG APase) (Roche, Nonnenwald, Penzberg, Germany) in TBS.
10. After three washes in buffer II (0.1 M Tris HCl, 0.1 M NaCl, 0.05 M $MgCl_2$) for 5 min each, color detection is developed by NBT/5-bromo-4-chloro-3-indolyl phosphate (Roche, Nonnenwald, Penzberg, Germany) and counterstained with 1% methyl green.
11. Positive cells contain bluish-purple intranuclear and/or intracytoplasmic precipitates.

The combination of PCVAD-associated lesions coupled with the presence of abundant viral nucleic acid within the developing granulomas and germinal centers is important in making a diagnosis of PCVAD.

74.2.2 Real-Time PCR

The method of real-time PCR for PCV2 nucleic acid detection is modified from that reported by Huang et al.[40] Tissue DNA extraction follows the protocol of the QIAamp® DNA Mini kit. The real-time PCR is carried out by the LightCycler® 480 system (Roche, Mannheim, Germany).

74.2.2.1 Procedure

1. The tissues are ground to 10% tissue emulsion with minimal essential medium and centrifuged at 3000 × *g* for 10 min.
2. After tissue preparation, 200 μL of the supernatant is mixed with 20 μL of protease K and 200 μL Buffer AL by pulse vortexing for 15 s.
3. The mixture is incubated at 56°C for 10 min and then mixed with 200 μL of ethanol (96%–100%) by pulse vortexing for 15 s.
4. The mixture from step 3 is transferred to the QIAamp Spin column and centrifuged at 6000 × *g* for 1 min to allow DNA to bind to the membrane of the spin column.
5. Following DNA binding, the QIAamp Spin column is subsequently washed with 500 μL of Buffer AW1 at 6,000 × *g* for 1 min and 500 μL of AW2 at 20,000 × *g* for 3 min.
6. The DNA in the QIAamp Spin column is then eluted by addition of 200 μL of Buffer AE, incubated at

2× Kapa Probe Fast qPCR Master mix	10
Double distilled water	2.4

room temperature for 1 min, and centrifuged at 6000 × *g* for 1 min.

7. Real-time PCR is carried out by the LightCycler® 480 system (Roche, Mannheim, Germany). The primers and probe are shown in Table 74.1.
8. The reaction mixture of the real-time PCR is prepared as shown in Table 74.2.
9. The reaction conditions consist of initial incubation at 95°C for 10 min, followed by 45 cycles of denaturation at 95°C for 20 s, annealing at 60°C for 30 s, and extension at 72°C for 20 s. A sample is considered PCV2 negative when the threshold cycle is above 40.
10. The quantification of PCV2 load in the tissue is calculated according to the standard curve of PCV2.

Establishment of the standard curve of PCV2

1. The PCR products of PCV2 are cloned using the pGEM-T Easy vector system (Promega, Madison, Wisconsin).
2. The PCV2 plasmid is propagated in *Escherichia coli*, JM109, and purified by the QIAamp plasmid Maxi Kit (Qiagen, Valencia, California).
3. The concentration of PCV2 plasmid is quantified by the measurement of OD_{260} with a spectrophotometer DU®640 (Beckman, Palo Alto, California). The copy number of viral DNA of the extracted plasmid is calculated using the formula

$$[X\ (g/\mu L\ DNA) \times 6 \times 10^{23}]/[\text{Plasmid length (bp)} \times 660] = Y\ \text{viral copy}/\mu L.$$

4. The PCV2 plasmid is optimized to 1×10^{10} copy number/mL. Following optimization of the concentration, the standard plasmid is subjected to a 10-fold serial dilution and then detected with real-time PCR for PCV2.
5. The standard curve is drawn using the known concentration of PCV2 plasmid and the corresponding Ct value.

74.3 CONCLUSION

Although PCV2 is the essential causative agent of PCVAD, PCV2 alone rarely leads to the development of clinical disease. The level of PCV2 load and the severity of its associated lesions can be enhanced by concurrent infection with other viruses or bacteria.[11,60,103–107] While the exact mechanisms of how concurrent pathogens or cofactors upregulate PCV2 replication are not completely known, it is important to further identify possible concurrent pathogens and cofactors in PCVAD cases. Such knowledge would be helpful for the development of the most appropriate and effective control strategies against PCVAD.[108]

75.1 INTRODUCTION

Parvoviruses can infect many animals, usually producing acute, systemic disease. Mink are hosting two distinct parvoviruses, mink enteritis virus (MEV) and Aleutian mink disease virus (AMDV). MEV represents the typical parvovirus and is closely related to parvoviruses in cats and dogs; its infection results in highly contagious systemic and enteric disease. Effective vaccines toward MEV are used worldwide to prevent disease. AMDV can cause chronic progressive disease with persistent viremia and extreme antibody production. The disease is related to immune complexes and no vaccines exist. This chapter focuses on the persistent ADMV infection.

Compared to most other domestic animals, commercial mink breeding is rather new. Globally about 50 million mink skin are produced every year. In Denmark, mink farming was initiated around 1930. The rearing of mink for production of fur and the sale of skin generate a turnover of US $2.48 billion per year in Denmark alone [1]. Besides Scandinavia, mink farming also takes place in the Netherlands, Poland, Russia, China, and North America.

Aleutian disease in mink due to infection with the parvovirus AMDV is a significant problem for mink farming worldwide, leading to nonoptimal health status and decreased production. Affecting the purebred Aleutian mink, the disease was originally described by Hartsough and Gorham [2]. The fur of Aleutian mink was bluish-gray, resembling the fur of the Aleutian fox, which also contributed to the name of the disease. The Aleutian mink has a defect in its immune system, the Chediak–Higashi syndrome. Due to this immunodeficiency, the pathology is more severe in the Aleutian genotype of mink, but all mink breeds are susceptible to infection. The disease is chronic and no treatment or prophylactics is currently available. Therefore, the only control method is to detect and eliminate the infected animals.

The mink excrete AMDV DNA 2–8 weeks after experimental infection in feces [3], which results in a very heavy contamination of the premises. For proper eradication, the herd need to be culled and the farm intensively cleaned and disinfected in order to remove the remaining parvovirus. Studies on the closely related parvovirus MEV have shown that virus is infectious in feces after storage under outdoor conditions for up to 10 months [4]. Even after culling and disinfection, ADMV is likely to reoccur in the farm [5,6]. In Norway and Denmark, intensively culling has resulted in AMDV-free areas with improved health of the mink, increased breeding results, and enriched fur quality.

However, when mink kits were born from dams without AMDV antibodies, they were naïve and resultantly suffered from a new type of Aleutian disease characterized by acute pneumonia with high mortality of newborn mink kits [7]. Acute pneumonia caused by AMDV was first detected in mink farms in 1982 [7] and later on reproduced experimentally [8]. The combination of an environmentally extremely stable parvovirus, acute viral pneumonia with high virus excretion and the traditional farming systems with many mink farms in confined areas compromised the eradication program.

75.1.1 Classification, Morphology, and Genome Organization

AMDV is a negative single-stranded DNA virus belonging to the family *Parvoviridae* [9]. The family *Parvoviridae* is divided into two subfamilies: *Densovirinae* and *Parvovirinae.* While the subfamily *Densovirinae* contains

five invertebrate-infecting genera: *Ambidensovirus*, *Brevidensovirus*, *Hepandensovirus*, *Iteradensovirus*, and *Penstyldensovirus*, the subfamily *Parvovirinae* comprises eight vertebrate-infecting genera: *Amdoparvovirus*, *Aveparvovirus*, *Bocaparvovirus*, *Copiparvovirus*, *Dependoparvovirus*, *Erythroparvovirus*, *Protoparvovirus*, and *Tetraparvovirus*.

Being the type species of the genus *Amdoparvovirus*, AMDV is a small icosahedral nonenveloped virus with a capsid surface and a genome of about 4748 nt [9]. The virion consists of three nonstructural proteins (NS1, NS2, and NS3) and two structural proteins (VP1 and VP2) [10,11]. All these proteins (NS1, NS2, NS3, VP1, and VP2) are necessary for viral replication [11–16]. The VP genes encode for the majority of the viral capsid [10,12] and together with the NS1 gene, the two VP genes are essential for capsid assembly [12]. The VP2 protein harbors at least one epitope important for pathogenesis of AMDV including antibody binding, virus neutralization, and antibody-dependent enhancement of infection [17]. Genetic variations between different AMDV strains have been described to occur at both the NS1 [18,19] and VP2 genes [10,20].

Parvovirus replication is dependent on actively replicating cells [21]; even with optimal cell lines, wild-type ADMV cannot be grown in cell cultures. Only a few AMDV strains have adapted to cell culture, such as the AMDV-G that is used for the production of antigens for countercurrent immunoelectrophoresis (CIEP) [10].

75.1.2 Transmission, Clinical Features, and Pathogenesis

AMDV can be transmitted by many routes: (1) feces, saliva, and oronasal secretions [3,22]; (2) urine [22,23]; (3) mechanical transmission via fomites [20]; (4) vertical via transplacental transmission [24]; (5) free-ranging mink and other furbearing animals [25–28]; (6) insect vectors [29]; (7) airborne transmission has been found experimentally [30], hypothesized in mink farms [31] but not proven [6].

The outcome of AMDV infection in mink depends on the age and genotype of the mink as well as the virus strain [32–34]. Mink carrying the Aleutian gene (e.g., sapphire and pastel mink) are most susceptible for developing severe and rapidly progressive Aleutian disease [32]. Neonatal kits suffer an AMDV-induced acute pneumonia [35–37]. The interstitial pneumonia is caused by the destruction of the surfactant producing alveolar type II cells [36]. AMDV infection of adult mink can cause either a multisystemic disease [32] or a chronic asymptomatic disease [3,38,39]. Older literature reported potential but not well-documented clearing of the virus infection [40]. The various clinical symptoms experienced by adult mink are related to chronic immune complex-mediated disease with hypergammaglobulinemia, glomerulonephritis [41,42], arteritis, [43] reduced reproductive performance including reduced litter size and abortions [24,35,44], nonsuppurative meningoencephalitis [45,46], and abnormal fur color [47]. These very diverse clinical features are mainly caused by the destruction of the actively dividing cells, which are necessary for the ADMV multiplication. The fetus, the kidneys, and the hair follicles are all vulnerable due to high cell multiplication rate. In commercial fur production, the single depigmented hairs in brown or black fur severely reduce the fur value.

Antibodies against AMDV develop between 2 and 7 weeks after experimental infection as detected with CIEP [31,32,34,48] and even as short as 1 week after infection using rocket line immunoelectrophoresis [49]. The antibodies persist throughout the course of infection and are therefore used as the primary diagnostic method [3,48]. AMDV DNA has been detected by PCR in serum samples as early as 5 days after sapphire and pastel mink were infected with AMDV-Utah and AMDV-Pullman and 10 days after infection with AMDV-TR [34,48]. AMDV DNA was found in full blood from brown/wild-type mink 1–2 weeks after infection with a Danish field strain of AMDV [3]. In another study, AMDV DNA was found in leucocytes 2 weeks after infection of black mink with an American field AMDV strain [31]. The course of viremia varies in the individual mink; it can be transient with potential relapses or it can persist (Figure 75.1).

The immune complex-mediated disease results from conglomerates of antibodies and virus in the mink. Thus, antibodies in adult mink will have a severe negative effect on the progression of disease, meaning that traditional vaccination by killed vaccines causing antibodies will only aggravate the disease [50]. In spite of much effort, no vaccines have yet resulted in solid protection; only partial protection following DNA vaccination has been observed [51].

American mink (*Neovison vison*) is the primary host for AMDV, while European mink (*Mustela lutreola*) is also susceptible to AMDV [27]. AMDV infection has been described in a number of other carnivores such as raccoons (*Procyon lator*) [25,34], striped skunk (*Mephitis mephitis*) [34,52–54], ferrets (*Mustela putorius furo*) [23,55–57], Eurasian otter (*Lutra lutra*) [27], bobcat (*Lynx rufus*), short-tailed weasels (*Mustela erminea*), and North American river otter (*Lontra Canadensis)* [25].

Experimentally, a number of carnivores including Finn raccoons (*Nyctereutes procyonoides*), ferrets, dogs, mice, and cats have been inoculated with highly virulent ADV-Utah without developing clinical symptoms, but their organs could infect naïve mink [58]. Additionally, Finn raccoon, mink, and dog produced antibodies toward the nonstructural proteins after infection indicating virus replication in these species [58]. Kenyon et al. experimentally infected 14 members of the family *Mustelidae* besides mink, ferret, and striped skunk AMDV inoculation resulted in antibody production in short-tailed weasel, fisher (*Martes pennanti*), and American marten (*Martes americana*) [53].

Serological evidence of AMDV has been found in free-ranging American mink (N*eovison vison*) in Canada, the United States [25,28,59,60], and Europe [26,27,61,62] as well as in a number of other mustelids and small carnivores including free-ranging, European mink (*Mustela lutreola*) [62], polecats (*Mustela putorius*), stone martens (*Martes foina*), pine martens (*Martes martes*), and common genets (*Genetta genetta*) [61].

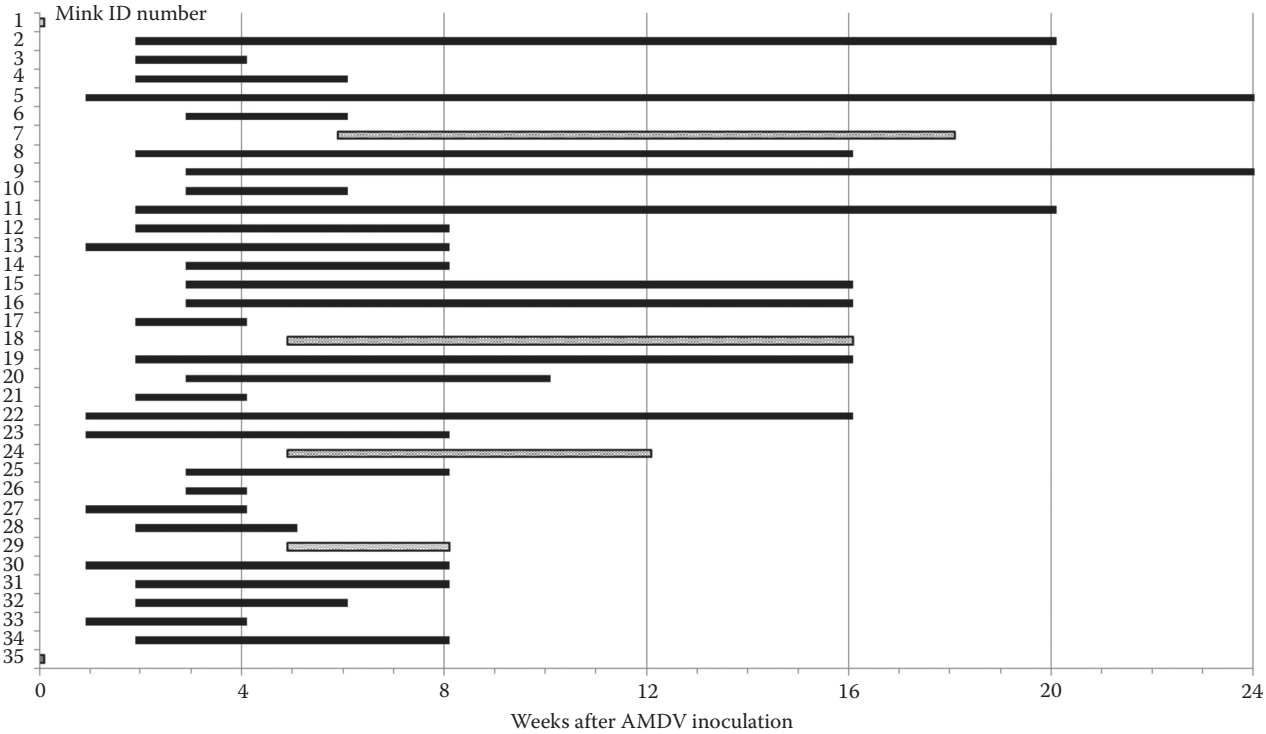

FIGURE 75.1 Viremia in 35 mink following Aleutian mink disease infection. The wild-type mink (black bars) were inoculated with AMDV at week 0, and the sapphire mink (gray bars) were kept as noninoculated sentinels. The bars represent the duration of viremia starting within the first week after challenge inoculation with AMDV. Viremia was detected as AMDV DNA by PCR on full blood. Mink number 1 and number 36 did not develop viremia, and mink number 27 was not included in the experiment. The asterisk indicates that the mink were diseased and euthanized before the others in the group (mink 1–12 were euthanized 24 weeks after AMDV inoculation, mink 13–24 after 16 weeks, and mink 25–36 after 8 weeks). (From Jensen, T.H. et al., *Vet. Microbiol.*, 168, 420, 2014.)

Reports of a possible relationship between AMDV and human infection are rare [63].

75.1.3 Diagnosis

75.1.3.1 Conventional Techniques

Mink infected with ADMV produce massive amounts of antibodies toward ADMV. Serum from healthy mink has approximately 7 mg gammaglobulin/mL serum, whereas the average levels in ADMV-infected mink are 35–56 mg/mL [64]. In spite of the high levels, these antibodies are not able to neutralize the virus neither *in vitro* in cell cultures nor in the persistently infected mink host. The detection of hypergammaglobulinemia [65,66], based on antibody detection, has been the key of the eradication program in Scandinavia. As the nail in carnivores contain blood vessels, it was quite easy for the farmer to obtain a blood sample from mink without needles or special sanitary risks. Blood was collected in capillary tubes for centrifugation on the farm. Initially, the farmers quantified the level of gammaglobulins aspecifically using the iodine test (Mallens test) [67]. As the mink farmers organized, they also build central laboratories for research and improved diagnostic. As part of the international collaboration, an agar gel–based CIEP was developed and has been used worldwide for the diagnosis of ADMV [44,59]. This gel-based test has proven to be a sensitive and cheap method to analyze mink sera for the presence of specific antibodies toward ADMV [68]. Annually 3.5–4 million sera are tested using this method [69]; a disadvantage is the dependence on manual reading of all samples after gel electrophoresis, and specially trained technicians are necessary. The CIEP are being replaced in Denmark by an automated ELISA based on whole AMDV-G [69]. In Finland, an ELISA based on VP2 recombinant antigen has been used for years [70,71].

75.1.3.2 Molecular Techniques

The pathogenesis of older AMDV strains such as AMDV-Utah, AMDV-Pullman, AMDV-Demark have been extensively studied using immunohistochemistry, southern blots, and *in situ* hybridization together with countercurrent and rocket line immunoelectrophoresis (reviewed by [18,31,35]). Genetic variations between different AMDV strains have been described to occur at both the NS1 [12,13] and VP2 genes [2,14]. More recently, various PCR primers have been used to detect AMDV in spleen and mesenteric lymph nodes, some amplifying capsid gene (VP2) for diagnostic and for molecular biological characterization [19,32] as well as targeting AMDV in the brain [36]. Other primers amplifying the nonstructural protein (NS1) primarily for molecular biological characterization have been used in Finland [37] and Sweden [38] but also for diagnostic purposes in Denmark [39].

75.2 METHODS

75.2.1 Sample Preparation

In vivo samples include swabs from oronasal region, blood, and feces, which can be sampled from trapped or anesthetized animals. Swabs are easily processed by direct DNA isolation of the swab media such as phosphate-buffered saline (PBS) using QIAamp® Blood Mini Kit [3]. Blood can be processed either as full blood (e.g., EDTA stabilized [3]), as serum [34,72], as plasma [25], or as blood leukocytes [31], using various protocols such as QIAamp Blood Mini Kit [3], Dynabeads Silane Viral NA Kit [25] or polysucrose–sodium diatrizoate gradients, and phenol–chloroform extraction [31]. Total DNA from feces can be isolated with QIAamp DNA Stool Mini Kit [3].

Environmental samples, such as swabs from various surfaces at the farm and surroundings including soil samples, may be tested by real-time PCR as a way to uncover disease transmission paths [73]. This real-time PCR utilized primers from the NS1 gene and FAM-labeled plus VIC-labeled TaqMan® probes [73].

Postmortem a number of tissues have been investigated for AMDV [3], and the spleen and mesenteric lymph nodes appear to be the most consistent organs for AMDV diagnosis. The assay sensitivity and specificity increase notably if both organs are simultaneously tested [74,75]. Tissues, for example, spleen and mesenteric lymph nodes, can be processed for PCR analysis by homogenizing tissue (0.1 g) either manually or by Qiagen Tissue Lyser (Qiagen, Hilden, Germany). Subsequently, the tissue must be suspended in PBS containing 10% Qiagen protease (Qiagen) and incubated at 56°C for 1 h. Total DNA can be extracted from the tissue by QIAamp Blood Mini Kit according to the manufacturer's instructions (Qiagen, Hilden, Germany).

75.2.2 Detection Procedures

The frequent genetic variation of AMDV highlights the importance of using primers targeting a conserved part of either the NS1 or the VP2 genes to enhance the sensitivity of the PCR. PCR amplifying a part of the VP2 gene was used to diagnose AMDV infection in raccoons, mink [27,34,76], ferrets [20,23,34,55–57], and a captive skunk [52]. PCR targeting the NS1 gene has been employed to characterize a high genetic diversity of AMDV strains from mink farms from Sweden [77], Finland [75], and Denmark [5]. An obvious advantage of the PCR as diagnostic tool is the ability to allow subsequent sequencing analysis of the AMDV gene products, which helps reveal the possible introduction and spread of certain AMDV strains. The definition of AMDV strain is not clear. However, there are strong indications for multiple different strains in certain geographical areas [5,75,77,78]. The old AMDV strains seem to vary significantly from the recent strains. There is evidence for wild mustelids to carry similar strains as the farmed mink but also different strains [18,20,27,57].

Primers amplifying a fragment of 374 bp of the NS1 gene have been used for diagnostic purposes and pathogenesis studies in Denmark for years [3,5,63,74]. These primers were blasted against all AMDV sequences available at GenBank and found able to detect them. The PCR procedure employing NS1 primers has also been applied together with the VP2 primers of Saifuddin et al. [57]. This PCR procedure is described in detail as follows:

Primer	Sequence (5′–3′)	Expected Product (bp)	Specificity	Reference
ADV-F-7-H-PN1	CATATTCACTG TTGCTAGGTTA	374	NS1	[3]
ADV-R-7- HPN2	CGTTCTTTGTTA GTTAGGTTGTC	374	NS1	[3]
P1	AGAGCAACCAA ACCAACCC	401	VP2	[57]
P2	TCACCCCAAAA GTGACC	401	VP2	[57]

75.2.2.1 PCR Detection

1. Prepare the PCR amplification reaction mixture in a cool rack as follows:
   a. 0.8 μL dNTPs (25 mM, Stratagene, Edinburgh, Scotland)
   b. 5 μL of each primer AMDV-F-7-H-PN1 and AMDV-R-7-HPN2 (each 2 pmol/μL)
   c. 79.2 μL DNAse-free water
2. Add 10 μL DyNAzyme™II DNA polymerase (Finnzymes, Espoo, Finland) just before use of the amplification mixture.
3. Add the 5 μL sample DNA (extracted as written earlier).
4. Place the samples in a thermocycler programmed to initial preheating (also the lid) at 94°C for 5 min, followed by 45 cycles of denaturation at 94°C for 30 s, annealing at 55°C for 30 s, elongation at 72°C for 30 s, and a final elongation at 72°C for 7 min.
5. Separate the PCR products by 1.5% agarose gel electrophoresis (in TAE buffer) at 75 V for 45 min. Stain the gel with ethidium bromide and visualize under ultraviolet light.

Note: To monitor any possible contamination that could occur during the PCR procedure, negative and positive controls are included along with the DNA extraction. The negative tissue sample is from a Danish AMDV-free farm. The positive control is from a non-Danish AMDV-infected mink to verify potential contamination by sequencing.

75.2.2.2 Sequencing

DNA is purified for sequencing using the QIAquick PCR Purification Kit (Qiagen). Sequencing is performed with the PCR primers either by DNA Technology, Aarhus, Denmark or LGC Genomics, Berlin, Germany. The sequences are

assembled and proofread by the use of CLC DNA Workbench (http://www.clcbio.com/). Sequence similarity is detected by BLAST search (http://blast.ncbi.nlm.nih.gov/) and alignment with existing Danish AMDV sequences [5] by ClustalW (24) included in CLC DNA Workbench.

75.3 CONCLUSION AND FUTURE PERSPECTIVES

The optimal diagnostics for AMDV is by PCR because the virus cannot be cultured. Since AMDV is environmentally stable, the samples do not require specific care, and a variety of DNA isolation methods may be used. Organs, especially spleen and mesenteric lymph node, are ideal starting materials for sensitive and specific detection of AMDV at any time during infection, which is often chronic asymptomatic [3,75]. The advantage of PCR diagnostic is that the resulting product can be sequenced and then characterized and compared to other AMDV sequences. This can be valuable for investigation of disease transmission. However, for screening purposes, AMDV serology is found to be superior to PCR detection of AMDV on blood or secretions because AMDV tends to cause a transient unpredictable viremia and virus excretion [3]. ELISA analysis of serum antibodies is amenable to high-throughput automation. Environmental samples have been investigated for screening purposes but their use is limited due to the fact that they often contain very small amount of virus DNA. To eliminate the gel electrophoresis and speed up the diagnosis, adaptation of conventional PCR to a real-time platform is critical, thereby also allowing for a quantification of the virus in target organs. Finally, optimization of a DNA isolation procedure for environmental samples will greatly benefit future screening programs.

76.1 INTRODUCTION

Canine parvovirus (CPV), a highly contagious virus causing acute gastroenteritis in domestic dogs, is prevalent all over the world, mainly because this virus can survive in adverse environmental conditions for a long time [1]. Natural CPV-2 infection has been reported in domestic dogs, bush dogs, cats, coyotes, bears, and wolves. The disease is clinically characterized by severe vomiting, pyrexia, anorexia, and diarrhea leading to fatal dehydration as well as myocarditis particularly in young pups. CPV-2 is a nonenveloped, single-stranded DNA virus belonging to the *Parvoviridae* family and genus *Parvovirus*, along with feline panleukopenia virus (FPLV) and other parvoviruses of carnivores [2]. A wide range of species are affected by viruses of the *Parvoviridae* family; however, CPV-2 does not cross species lines [2]. After its emergence in the 1970s, CPV-2 underwent a rapid evolution, and within a few years, new antigenic types emerged at regular intervals, termed CPV-2a in 1978, CPV-2b in 1984, and CPV-2c in 1997 and completely replaced the original CPV-2. Presently, the original CPV-2 type no longer circulates in the dog population, whereas CPV-2a and CPV-2b types are distributed worldwide; now, CPV-2a and CPV-2b types have further undergone several mutations that produced variants of CPV-2a (New CPV-2a) and CPV-2b (New CPV-2b). Mutations affecting the VP2 gene of CPV have been responsible for the evolution of different antigenic variants. Sequence analysis of the VP2 gene of the virus and subsequent characterization is important for molecular epidemiology of CPV [3].

76.1.1 Classification and Morphology

Of the two types of CPV identified to date (i.e., canine minute virus [CPV-1] and CPV-2, CPV-2 causes the most serious disease and affects domesticated dogs and wild canids. CPV-2 was first isolated in 1978 [4,5]; however, further studies on the rate of CPV molecular evolution indicate that the virus likely emerged 10 years earlier [5,6]. The exact origin of CPV-2 is not known, although it is thought to have originated as a host range variant from FPLV or other parvoviruses. Since the original type CVP-2 was discovered, several antigenic variants—CPV-2a, CPV-2b, and CPV-2c—have replaced it entirely and have become distributed throughout the canine population worldwide [2]. Another CPV variant has an amino acid substitution of Asp-426 to Glu, which occurs in a residue of the capsid protein that is considered important for the antigenic properties of CPV-2. This variant (CPV-2/Glu-426 mutant) was named CPV- 2c that was first observed in Italy and was broadly distributed worldwide with CPV-2a and CPV-2b types [2]. CPV infections are also caused by New CPV-2a/CPV-2b variants, which have additional amino acid difference in both CPV-2a and CPV-2b at position 297 (Ser to Ala) (Table 76.1). This mutation first appeared in 1993 in German CPV isolates and was designated as New CPV-2a/CPV-2b [3].

The CPV-2 belongs to the family *Parvoviridae*. The genome consists of a single molecule of linear single-stranded DNA, which is 5.2 kb in size. It is a nonenveloped, icosahedral symmetry. The organization of CPV capsid is similar to that of other autonomous parvoviruses, in that it contains two

TABLE 76.1
Amino Acid Variation in the VP2 Protein of Different CPV-2 Types

CPV-2	TCT/Ser	GCT/Ala	GAT/Asp	AAT/Asn	AAT/Asn
CPV-2a	TCT/Ser	GGT/Gly	TAT/Tyr	GAT/Asp	AAT/Asn
CPV-2b	TCT/Ser	GGT/Gly	TAT/Tyr	GAT/Asp	GAT/Asp
New CPV-2a	GCT/Ala	GGT/Gly	TAT/Tyr	GAT/Asp	AAT/Asn
New CPV-2b	GCT/Ala	GGT/Gly	TAT/Tyr	GAT/Asp	GAT/Asp
CPV-2c	GCT/Ala	GGT/Gly	TAT/Tyr	GAT/Asp	GAA/Glu

largely overlapping proteins, VP1 (82 kDa) and VP2 (62 kDa) [7,8]. There is a third protein, VP3 (63 kDa), which is produced by proteolytic processing of VP2. The 22 nm parvovirus capsid comprises of about 10 copies of VP1 and 60–70 copies of VP2. Epitope mapping experiment showed that all of the epitope neutralizing antibodies are within the VP2 region. Amino acid substitutions in the VP2 sequence are known to affect the antigenic properties [9,10].

76.1.2 Biology and Epidemiology

All CPV isolates are thought to descend from a related feline parvovirus (FPV) strain. The differences in DNA sequence between CPV and FPV isolates can be as little as 0.5% [11]. Two substitution mutations of two key amino acids—changed 93 from Lys to Asn and 323 from Asp to Asn—on the VP2 residues allowed for CPV to extend its host range to canines [5,11]. Thus, CPV acquired the ability to infect canines as a result of the changes made to the capsid protein surface. CPV is able to infect canine cells by binding to the canine transferrin receptor (TfR). CPV-2 capsids enter cells via "clathrin-mediated endocytosis," colocalize with transferrin (Tf) in perinuclear endosomes, and then slowly leave the endosome and enter the cytoplasm prior to the DNA gaining access to the nucleus for replication [11]. Parvoviruses are small (18–26 nm in diameter), which are made up of single-stranded DNA consisting of 5000–5200 nucleotides. As these viruses contain small DNA molecules with limited genetic information, they must replicate in the cell nuclei and require rapidly dividing cells in the synthesis phase of the cell cycle for optimal replication. This makes tissues with high replication rates—like those of fetuses and neonates, in addition to the hematopoietic and epithelial tissues in adults—targets of parvovirus infection [2].

Prevalence study of CPV revealed that the oldest CPV-2c strain was identified in 1996 in Germany [12], and the results from European epidemiological surveys show that CPV-2c is now predominant in Italy, Germany, and Spain and is also widely codistributed with CPV-2a or CPV-2b in Portugal, France, and Belgium [12]. Outside of Europe, CPV-2a and CPV-2b isolates are common in the United States [13], whereas CPV-2c is more widespread in Uruguay and Brazil [14]. Surprisingly, variants of CPV-2a and CPV-2b are predominant in Asian countries [3,15]. The adaptation of CPV to dogs led to the natural global replacement of CPV-2 by the CPV-2a variant and later by the CPV-2b strain, through the addition of a point mutation [11]. As CPV is a relatively new virus that continues to evolve and produce new antigenic types, the more predominant mutants are selected for by their ability to bind to the TfR and by extending host range, in newer antigenic types, to include both dogs and cats [5]. Puppies between the age of 4 and 12 weeks are the most susceptible to CPV-2 infection, as this is when the maternally derived antibodies (MDA) typically wanes [2], while unvaccinated young (6 weeks to 6 months old) dogs also remain vulnerable. Some breeds, such as Rottweilers, Doberman pinschers, American pit bull terriers, English springer spaniels, and German shepherd dogs are also thought to be at higher risk to CPV-2 infection [7]. The morbidity may reach up to 100% and mortality may be as high as 10%. CPV-2 is highly contagious and can be spread through direct contact, fecal–oral route, or vectors such as fomites. Most frequently, the virus is spread by indirect contact with infected feces, as they are highly infectious, containing billions of CPV-2 virions per gram [2]. CPV-2 is shed in the feces of infected dogs within 4–5 days prior to the onset of clinical symptoms, throughout the period of illness, and up to 3 weeks after clinical recovery [1]. The clinical manifestation of CPV infection depends on the age and immune status of the animal, the virulence of the virus, the dose of infectious virus, and the preexisting or concurrent parasitic, bacterial, or virus infections [16].

There are three key factors in preventing the spread of CPV-2: (1) sanitation, (2) isolation, and (3) vaccination. Under ideal conditions, CPV-2 can live in an environment for up to a year, and it has been found to be resistant to most common detergents and disinfectants and extreme temperatures. However, the virus can be killed by dilute bleach on hard surfaces. As CPV-2 is highly contagious, infected dogs should be hospitalized in an isolation ward to prevent the spread of the virus. Isolation will also help protect the infected dog against contracting a secondary infection by minimizing their exposure to other sick canines [1]. However, vaccination is the most successful means of preventing the spread of CPV-2 infection in domestic dogs. There are both inactivated and attenuated vaccines available for use against CPV-2. Live vaccines are most commonly used in domestic dogs because the inactivated vaccines only provide short-term immunity. These vaccines are made using either the original type CPV-2 or the CPV-2b variant; however, there are concerns about the effectiveness of CPV-2-based vaccines against variant CPV-2 strains [2].

76.1.3 Clinical Features and Pathogenesis

Virus can spread through direct contact, the fecal–oral route, or vectors such as fomites [1]. Virus enters the host by indirect contact with infected feces, as they are highly

infectious, containing billions of CPV-2 virions per gram [2]. Clinical features of infected dogs range from asymptomatic infection to fulminant disease and sudden death. Clinical disease is usually seen in young and immunocompromised dogs, as well as predisposed breeds. Clinical signs often start with anorexia, lethargy, and fever. The condition progresses within 1–2 days to include vomiting and diarrhea, which may be yellow, mucoid, or hemorrhagic. More severe GI signs can be expected in puppies with intestinal parasites or other concurrent intestinal disease. Uncommonly, clinical signs of myocarditis may be observed in puppies, typically those younger than 8 weeks of age with failure of passive transfer of maternal immunity. These puppies may die acutely or after exhibiting signs of enteric disease. Those that survive acute myocardial infection may succumb later to congestive heart failure. CPV-2 is shed in the feces of infected dogs within 4–5 days prior to the onset of clinical symptoms, throughout the period of illness, and up to 3 weeks after clinical recovery [1].

After initial infection, the virus replicates in the lymphoid tissues of the oropharynx, mesenteric lymph nodes, and thymus [2] and then spreads through the blood stream [1]. CPV will infect and attack the rapidly dividing tissues or cells of the intestinal crypt, lymphopoietic tissue, and bone marrow [1,7]. The viral attack on the intestinal crypt epithelium results in massive lysis and necrosis of enterocytes, which impairs the absorptive capacity and cell turnover at the villi tips, and results in hemorrhagic diarrhea characteristic of the clinical disease that results from a combination of increased intestinal permeability and malassimilation from an abnormal mucosal function. In addition, the virus infects white blood cells and bone marrow and lymphopoietic tissues, inducing lymphopenia and neutropenia, often resulting in secondary infections. In 2–3-week-old puppies, often lacking MDA, CPV-2 can replicate in cardiac cells, without signs of enteritis, and result in fatal myocarditis [2,7].

The appearance of clinical symptoms of CPV-2 infection generally surfaces within 3–7 days of initial infection. However, subclinical infection is also common and some dogs can be asymptomatic carriers of the virus [1]. Initially, nonspecific symptoms, such as fatigue, fever, dehydration, and inappetence, will manifest. These symptoms will often develop into vomiting and hemorrhagic diarrhea (which has a distinct odor) within 24–48 h [1,7]. Intestinal loops can also become dilated and fluid filled, causing abdominal pain. Animals with severe infections commonly exhibit signs of septic shock, characterized by a decrease in time, tachycardia, and hypothermia. Necropsies reveal CPV-2 infection that can cause thickening of the cell wall, hemorrhagic and watery intestinal contents, and edema of abdominal and thoracic lymph nodes. In cases of CPV-2-induced myocarditis, pale streaks can be observed in the heart muscle tissue [7].

76.1.4 Diagnosis

A rapid diagnosis of CPV infection is especially important in order to isolate infected dogs and prevent secondary infections of susceptible contact animals. Clinical diagnosis of CPV infection is difficult because the main clinical signs of the disease, which include vomiting and diarrhea, are common to many other enteric diseases like several other viral pathogens such as coronaviruses, adenoviruses, morbilliviruses, rotaviruses, reoviruses, and noroviruses. Several methods have been used to detect CPV, its proteins or nucleic acids, and include electron microscopy (EM), virus isolation (VI), latex agglutination, hemagglutination (HA), in situ hybridization, ELISA, polymerase chain reaction (PCR)-based assays, and loop-mediated isothermal amplification (LAMP) assay. Molecular diagnostic techniques like PCR-based methods are emerging as the most reliable techniques and have a high degree of sensitivity and specificity in detecting CPV from fecal samples [17]. PCR-based molecular typing of CPV also helps to gain new insights into the pathogenesis of CPV-2 infection and is extremely useful to comprehend whether the antigenic differences between CPV type 2a, 2b, or 2c and the original type 2 may account for partial or total failure of the conventional vaccines based on CPV-2 in protecting pups against the antigenic variants [2]. PCR-based assays can only be done in a diagnostic or commercial laboratory with access to specialized equipment not common to veterinary clinics. A new technique called loop-mediated isothermal amplification (LAMP) involves autocycling strand displacement DNA synthesis carried out by the use of a DNA polymerase with high strand displacement activity and a set of specific primers that recognize a total of six distinct sequences in the target DNA. This technique amplifies the target DNA sequence with a high selectivity; the assay can be completed within 1 h, has a high sensitivity, and produces an end product that is visible to the naked eye.

76.1.4.1 Conventional Techniques

EM is a vital diagnostic tool utilized to view the morphological characteristics of extremely small organisms, like parvoviruses, when a standard microscopy will not suffice. Even with all the newest forms of diagnostic methods, EM is still extensively used as a reference technique, especially in cases of specimens expected to contain high concentrations of the virus in diarrheic stool samples [18]. The HA test is simple and rapid for detecting CPV in feces. The HA activity of CPV is utilized diagnostically in estimating amounts of viral hemagglutinin in fecal samples [19] and is the most widely used test for detecting CPV in feces. CPV hemagglutinates with porcine, rhesus monkey, and human "O" RBCs. The HA is considered positive and specific when a HA titer of 32 and above is obtained, and the HA is inhibited by a specific antiserum [19]. But the HA and hemagglutination inhibition tests require continuous supply of quality porcine or human "O" erythrocytes. Moreover, nonspecific HA by fecal material and no HA activity by some strains of CPV [20] may complicate the scenario.

Virus isolation and identification in cell cultures like primary cell cultures of feline kidney and canine kidney cell lines is considered as a very reliable technique for the detection of CPV, but it is too labor intensive and time consuming.

The virus, having low cytopathogenicity, requires 3–5 blind passages for producing minimal cytopathic effect, or one may have to depend on indirect methods of diagnosis like HA and hemagglutination inhibition tests, fluorescent antibody technique, and PCR [21]. Latex agglutination test (LAT) is a rapid test for screening CPV infections, but it fails to detect low concentration of the virus. LAT also gives false-positive results, when hemorrhagic feces are employed for testing [22]. Immunochromatographic test is the most common rapid field diagnostic test used in clinical practice because the test procedure is simple and rapid and can be performed by veterinarians as well as by owners. However, large amounts of viral antigen are required to produce a clearly visible band [23]. ELISA is also used for screening CPV infections and has a high specificity, but it cannot detect samples with low virus concentrations. ELISA needs a minimum of 10^6 PFU/g of feces unlike PCR that can detect very small quantities of virus up to 10^3 PFU/g of feces [24].

76.1.4.2 Molecular Techniques

Diagnosis of CPV infection by traditional methods has been shown to be poorly sensitive, especially in the late stages of infections. New diagnostic approaches based on molecular methods have been developed for sensitive detection of CPV in clinical samples and rapid characterization of the viral type. Parvovirus PCR testing has been shown to be a very effective and sensitive way to detect CPV. The PCR test will also find the presence of fecal parvo DNA even when an antigen test (ELISA) showed a negative result. Real-time PCR is the newest technology using a minor groove binder probe assay to specifically identify CPV-2 vaccine strains and field strain types (2a, 2b, and 2c). It is based on the TaqMan technology, which allows the detection of single nucleotide polymorphisms, and this real-time PCR has been proven to be even more specific, sensitive, and reproducible than other conventional methods such as HA assays, immunochromatographic tests, VI, and even gel-based PCR [15]. Amplification of the VP2 gene fragment of CPV (capsid protein) using primers like H_{for}/H_{rev} and subsequent sequencing of the PCR products covering the informative amino acids would definitely help in detecting genetic variation that exists between CPV-2 and its variants [25].

LAMP is a novel, sensitive, and rapid technique for the detection of genomic DNA. The end product of the technique is a white precipitate of magnesium pyrophosphate that is visible without the use of gel electrophoresis [26]. The LAMP method was applied to the detection of CPV genomic DNA. A set of four primers, two outer and two inner, were designed from the CPV genomic DNA targeting the VP2 gene. The optimal reaction time and temperature for LAMP were determined to be 60 min and 63°C, respectively. This technique amplifies the target DNA sequence with a high selectivity; the assay can be completed within 1 h, has a high sensitivity, and produces an end product that is visible to the naked eye. The detection limit of the LAMP was 0.0001 $TCID_{50}$ mL^{-1}, whereas the detection limit of the PCR was 1000 $TCID_{50}$ mL^{-1} [26].

76.2 METHODS

76.2.1 Sample Preparation

The main source of infection is feces from infected dogs. More than 10^9 virus particles per gram of feces were shed during the acute phase in the enteric form. The feces are the suitable clinical material for the detection of virus in the enteric form of the disease. Fecal/rectal swabs samples are collected from CPV-suspected animals as soon as possible after the onset of acute gastroenteritis. The amount of virus shedding begins to decline 6 days postinfection, and after the 12th day, the virus is rarely recovered in feces, which may give false-negative diagnosis. The fecal samples/rectal swabs obtained from the suspected/healthy animals are emulsified in 1 mL of 0.1 M PBS of pH 7.4, stored at 4°C, and transported as early as possible to the laboratory under refrigeration. The emulsions will be centrifuged at 6000 rpm for 15 min at 4°C and the supernatants will be collected and stored at −40°C until further use.

Hundred microliters of the supernatants will be used for template DNA preparation by boiling at 96°C for 10 min and chilling immediately in crushed ice. Then, they will be centrifuged at 10,000 rpm for 10 min and the supernatants will be diluted 1:10 in distilled water to reduce residual inhibitors of the DNA polymerase activity [27,28].

76.2.2 Detection Procedures

PCR-based methods had been the most reliable techniques, having high degree of sensitivity and specificity in detecting CPV from fecal samples [28]. Amplification of the VP2 gene fragment (capsid protein) using primers H_{for}/H_{rev} and subsequent sequencing of the PCR products covering the informative amino acids would definitely help in detecting genetic variation that exists between CPV-2 and its variants [29].

Buonavoglia et al. [29] designed a primer pair 555 (F)/555 (R), which also amplified the gene encoding for the VP2 protein located at nucleotide position 4003–4022 and 4561–4585 of the CPV genome yields 583 bp product. Sequencing of the PCR product amplified by this primer pair provides information about amino acid changes in residues 426 and 555 to distinguish the new variants CPV-2a, CPV-2b, and CPV-2c from the original CPV-2.

76.2.2.1 PCR-Based Detection of CPV Using Primer Pair H_{for}/H_{rev} and Subsequent Sequencing

The processed samples were screened by primer pair H_{for} (5′-CAGGTGATGAATTTGCTACA-3′) and H_{rev} (5′-CATTTGGATAAACTGGTGGT-3′) that amplifies 630 bp fragment of the gene encoding the capsid protein. PCR amplification was carried out as per Buonavoglia et al. [29], and the products were analyzed by electrophoresis using a 1.5% agarose gel in Tris-acetate-EDTA buffer (1×). The amplified PCR products were gel extracted and custom sequenced with primer pair H_{for}/H_{rev} using the automated sequencer, Applied Biosystems 3100. The specificity of the sequences obtained and

the nucleotide and amino acid variations with respect to the VP2 gene sequence of CPV were determined using the Basic Local Alignment Search Tool (http://www.ebi.ac.uk/) [15]. The nucleotide sequences of the VP2 gene were aligned with the sequences of prototype CPV strains (M38246-FPV; M38245-CPV-2; M24003-CPV-2a; M74849-CPV-2b; AY742953-New CPV-2a; AY742955-New CPV-2b; FJ222821-CPV-2c) using the Clustal W (www.ebi.ac.uk/clustalw) and analyzed for the nucleotide variation of the VP2 gene at positions 3675, 3685, 3699, 3909, and 4064 with the corresponding amino acid residues at 297, 300, 305, 375, and 426, respectively [15]. For the phylogenetic studies, sequences were aligned using the Clustal W 1.8 program, and .aln and .nxs files were generated. The .aln file was converted into .meg file using the Mega 4.1, and the neighbor-joining tree was constructed (bootstrap replicates = 1000; seed = 64,248) using the Kimura 2 method for pairwise deletion at uniform rates [15].

76.2.2.2 Detection of Canine Parvovirus in Fecal Samples Using Loop-Mediated Isothermal Amplification Assay

A new technique called loop-mediated isothermal amplification (LAMP) involves autocycling strand displacement DNA synthesis carried out by the use of a DNA polymerase with a high strand displacement activity, and a set of four primers, two outer and two inner, were designed from CPV genomic DNA targeting the VP2 gene that recognize a total of six distinct sequences in the target DNA (Table 76.2). This technique amplifies the target DNA sequence with a high selectivity; the assay can be completed within 1 h, has a high sensitivity, and produces an end product that is visible to the naked eye [30]. LAMP is a novel, sensitive, and rapid technique for the detection of genomic DNA.

The LAMP technique was performed with a set of four primers (B3, F3, BIP, and FIP) recognizing a total of six distinct sequences (B1–B3 and F1–F3) on the VP2 gene of CPV DNA, which were designed using the Primer Explorer V3 software. The LAMP technique was performed with a 25 μL reaction mixture containing 1 mL (40 pmol) of each of the primers CPV-BIP and CPVFIP, 1 mL (5 pmol) of the primers CPV-F3 and CPV-B3, 12.5 μL of a 2× reaction mixture (40 mM TrisHCl, 20 mM KCl, 16 mM $MgSO_4$, 20 mM $[NH_4]_2$ So_4, 0.2% Tween 20, 1.6 M betaine, 1.0 μL [8U] of *Bst* DNA polymerase, and 2.8 mM each dNTP), 1 μL of target DNA, and 7.5 μL of distilled water. To determine the optimal temperature for the LAMP assay, the primer and sample mixtures were incubated at 65ºC for 15, 30, 45, and 60 min, respectively, and, at the end of each incubation period, the reaction was terminated by heating at 80ºC for 10 min. The reaction temperature was optimized (60ºC, 63ºC, and 65ºC), and the LAMP was carried out for a predetermined period (60 min). The end product of the technique is a white precipitate of magnesium pyrophosphate and by adding propidium iodide (1 mg/mL), a DNA-binding dye and exposure to UV light. A change in color from reddish orange to pink under ambient light and fluorescence under UV light by propidium iodide indicated a positive reaction. The LAMP end product (5 μL) was analyzed by gel electrophoresis with a 1.5% agarose gel. Positive cases yield bands in a ladderlike pattern [31,32].

The LAMP technique offers several advantages over the PCR analysis for the detection of CPV DNA in dog feces; the assay requires only 2 h to complete and is a sensitive method that can amplify a few copies of DNA to about 10^9 molecules in ≤1 h under isothermal condition. The specificity of the LAMP assay can be further confirmed by sequencing the gel-extracted products. The detection limit of the LAMP was 0.0001 $TCID_{50}$/mL, whereas the detection limit of the PCR was 1000 $TCID_{50}$/mL [31,32].

TABLE 76.2
Sequence of Each Primer Used in the Loop-Mediated Isothermal Amplification Assay

No.	Primer Identity	Primer Sequence
1	CPV B1P	5′-CATCTCATACTGGAACTAGTGGCA-TGAACATCATCTGGATCTGTAC-3′ (B1c-B2)
2	CPV F1P	5′-TCTCCATGGAGTTGGTATGGT-TATGAGATCTGAGACATTGGGT-3′ (F1c-F2)
3	CPV B3	5′-AGTAAGTGTACTGGCACAG-3′
4	CPV F3	5′-GCCATTTACTCCAGCAGC-3′

76.3 CONCLUSION

CPV infection, a highly contagious disease of canines, is prevalent in many parts of the world. The disease is characterized by two prominent clinical forms, enteritis with vomiting and diarrhea in dogs of all ages and myocarditis and subsequent heart failure in pups of less than 3 months of age with high morbidity (100%) and frequent mortality up to 10% in adult dogs and 91% in pups. The virus affects dogs' gastrointestinal tracts and is spread by direct dog-to-dog contact and contact with contaminated stools, environments, or people. The virus can also contaminate kennel surfaces, food and water bowls, collars, and leashes, and the hands and clothing of people who handle infected dogs make the disease highly contagious. The disease condition has been complicated further due to the emergence of a number of variants—CPV-2a, CPV-2b, CPV-2c, New CPV-2a, New CPV-2b, and Asp 300 (2a/2b) over the years—and the involvement of domestic and wild canines.

The molecular era of CPV studies begins with successful isolation of CPV from the fecal samples. The availability of molecular techniques to amplify, sequence, and express the genome of CPV stains provides the tools necessary for characterization of CPV stains both genetically and antigenetically, leading to the development of several new diagnostic assays. The application of these sensitive methods for the detection and characterization of CPV infection in different parts of the world contributes a greater recognition of the overall health and economic impact of this virus. Vaccination is the most cost-effective and ideal method to control CPV infections in canines. Both live-attenuated and inactivated vaccines are

available to control the disease in animals. Vaccines used during the late 1970s and early 1980s were of FPLV origin, which was followed by the use of inactivated and live-attenuated vaccines of CPV-2 and CPV-2b of canine origin. High-titer, low-passage CPV vaccines containing a canine origin attenuated virus are currently the vaccines of choice for use in pups of any breed. Live vaccines are most commonly used in domestic dogs because the inactivated vaccines only provide short-term immunity. Continuous evolution of CPV through accumulation of point mutations in the viral genome presents two different, but equally important, implications: (1) the emergence of new antigenic variants displaying different biological and antigenic properties may require an extensive revision of the vaccination programs and an update of the viral strains contained in the commercially available products and (2) the sophisticated molecular methods able to detect and characterize the CPV strains, which are based on perfect matching between viral DNA and assay oligonucleotides, may be affected by the onset of point mutations and should be, therefore, updated as well. Thus, a continuous epidemiological surveillance is needed to detect new CPV variants potentially escaping the host immune system and detection methods.

77.1 INTRODUCTION

77.1.1 Classification, Morphology, and Genome Organization

Goose parvovirus (GPV) is a well-known causative agent of gosling plague (GP), which is an acute, contagious, and fatal disease often referred to as Derzsy's disease [1]. Being a member of the genus *Dependoparvovirus* within the family *Parvoviridae* [2–5], GPV was first described as a clinical entity by Fang in 1962 [6]. GPV has attracted much attention owing to its ability to induce high rates of morbidity and mortality in geese, contributing to enormous economic losses in commercial goose production worldwide [1,7,8,9].

The GPV genome is a single-stranded DNA of 5106 nucleotides long and contains two open reading frames (ORFs) that encode regulatory and structural proteins. The left ORF encodes regulatory proteins, while the right ORF encodes three capsid proteins: VP1, VP2, and VP3, which are derived from the same gene by differential splicing. Additionally, VP2 is contained within the carboxyl terminal portion of VP1, and VP3 is contained within that of VP2 [10,11]. The capsids of GPV are nonenveloped, 20–22 nm in diameter, and assembled from 32 capsomers [12–15]. The classical detection of GPV by virus isolation in gosling, cell cultures, and serological assays like enzyme-linked immunosorbent assay (ELISA) is dependent on the availability of specific pathogens free (SPF) gosling embryos and standard positive control sera [16].

77.1.2 Replication

Similar to other parvoviruses, GPV binds to a sialic acid–bearing cell surface receptor before entry into the host cell through clathrin-mediated endocytosis. Making use of the phospholipase A2 activity conferred by the amino-terminal peptide of the capsid VP1 protein, GPV penetrates into the cytoplasm and then permeabilizes the host endosomal membrane to facilitate its microtubular transportation toward the nucleus. Inside the nucleus, GPV begins uncoating, and its ssDNA is converted by cellular proteins into dsDNA, which functions as template for synthesis of mRNAs encoding the nonstructural (NS) proteins, NS1 and NS2, when host cell reaches to S phase. Moving out of the nucleus into the cytoplasm, the viral mRNAs are translated into viral proteins by the host ribosomes. After covalent binding to the 5′ genomic end, the NS1 endonuclease transactivates an internal transcriptional promoter that directs synthesis of the structural VP polypeptides. This initiates viral DNA replication via

a unidirectional strand displacement mechanism, with the hairpin structure at the 3′ end acting as a self-primer to synthesize a plus-sense DNA, leading to the formation of double-stranded DNA. The growing strand can replicate back on itself to produce a tetrameric form that is then cleaved to generate two plus-sense and two minus-sense strands of DNA. Individual ssDNA genomes excised from replication concatemers can be further converted to dsDNA and serve as a template for transcription/replication, or encapsidated and packaged in a 3′–5′ direction to form new virions that are released by cell lysis.

77.1.3 Clinical Features

GP was noted among goslings showing anorexia, wheezing, and locomotor dysfunction [1,17]. The specific lesions observed in the affected geese include myopathy of skeletal muscle, hepatitis, myocarditis, sciatic neuritis, and polioencephalomyelitis [3]. The disease affects mainly young goslings between 2 and 4 weeks old. However, infections in older birds also occur and are often asymptomatic except ascites or loss in featheriness. Under natural conditions, the adult geese can be infected without showing clinical symptoms, but can be spread by excreta and eggs of the disease. The disease has been reported in major goose-producing countries in the world.

77.1.4 Diagnosis

For diagnosis of GPV infection, many methods are available, including direct electron microscopy, virus isolation and identification, agar diffusion test, immunoelectron microscopy, latex agglutination test, polymerase chain reaction (PCR), real-time PCR, hemagglutination inhibition (HI), ELISA, and nucleic acid sequence analysis. Agar diffusion test and HA/HI are complex and time consuming, while ELISA, which is used to detect GPV antigen, is prone to false-positive and false-negative results [18]. The advent of molecular diagnostic techniques such as PCR has vastly improved the sensitivity, specificity, and speed of laboratory diagnosis of GPV.

77.2 METHODS

77.2.1 Sample Collection and Preparation

Sample should be collected from affected geese as soon as possible. Collect the liver, spleen, kidney, thymus, and brain and grind them into the suspension. Then clarify the suspension by centrifugation at 3000 rpm for 30 min. Extract DNA by using virus genomic DNA kit [19].

77.2.2 Detection Procedures

77.2.2.1 Virus Isolation

Inoculate susceptible goose embryos (12–14 days of age) via embryo allantoic cavity with 0.2 mL of virus suspension prepared earlier. Observe daily for a total of 8 days. Embryo's death may start on day 3, and most of the deaths usually occur in 5–7 days. Dead embryos often display thickening in chorioallantoic membrane, congestion in body skin, bleeding (in wing tips, toes, chest pores, neck, and beak), congestion in liver, hemorrhage in the heart and brain, and subcutaneous edema in head skin and ribs. At day 7, the embryo stops developing and appears very small. The virus may be detected in urine.

77.2.2.2 Passive Immunity Test

The LD50 of the virus is first determined in susceptible goslings. Take 10 susceptible goslings, inject subcutaneously 5 goslings with 0.5 mL GPV hyperimmune serum, and the other 5 with 0.5 mL of saline as a control group. After 6–12 h, both groups of goslings are injected subcutaneously or intramuscularly with 100 LD50 dose of virus and observed for 10 days. If serum group has no gosling death, while the control group dies, GPV is present [20].

77.2.2.3 Neutralization Test

The virus to be tested is divided into two equal portions: one is added four times the amount of GPV hyperimmune serum (serum or rehabilitation) as the serum group and the other is added four times the amount of saline as a control group. After mixing, both preparations are kept at 37°C for 60 min.

Virus preparation (0.2 mL) is then inoculated into the chorioallantoic membrane cavity of five susceptible goose embryos (of 12–14 in age), and the embryos are incubated at 37°C–38°C to hatch. Observation is made once daily until the seventh day. If serum group is healthy and alive, while the control group dies, displaying most or all of the typical embryo lesions, GPV is present. Gosling may also be used in place of the susceptible embryos for neutralization test, and the results are determined similarly [21].

In addition, virus neutralization test may be utilized to assess antibody levels in goose serum as well as antigen in dead geese [22]. A neutralizing index of <1.5 indicates the absence of specific parvovirus neutralizing antibodies.

77.2.2.4 Cattle Sperm Agglutination Inhibition Test

GPV can agglutinate cattle sperm, and this feature can be used for virus identification. The virus to be tested is diluted in saline (ratio 1:5) and added to two small test tubes, each containing 0.25 mL. The first tube is added 0.25 mL of GPV-positive serum, while the second tube is added 0.25 mL of physiological saline as control tube. After mixing, the tubes are incubated at 37°C for 50 min, then 0.25 mL cattle semen (one tablet semen added 1 mL 2.9% trisodium citrate solution at 42°C) is added to each tube, mixed, and set at room temperature for 6 h before observation. As the first one agglutinates and the second one does not agglutinate, the virus can be judged as GPV.

77.2.2.5 Agar Gel Precipitin Test

Eight of embryonating Khaki Campbell duck eggs (9 days of age) are each inoculated via the allantoic cavity with 0.2 mL of a 10^{-2} dilution of the 22nd passage of duck embryo adapted parvovirus [22]. After 6–8 days, the dead embryos and amnio-allantoic fluids (AAF) are harvested, the embryos' head and limbs removed, and a 20% (W/V) suspension prepared in the AAF. After homogenization, the suspension is mixed with an equal volume of trichlorotrifluoroethane (Arcton 113, ICI Ltd, London) for 30 min followed by centrifugation at 3000 × *g* for 15 min. The supernatant is removed and further centrifuged at 46,000 × *g* for 2 h at 4°C. The resulting pellet is resuspended in deionized water to 5% of the original volume and treated with 0.1% *N*-lauroylsarcosine (Sigma Chemical Co., Poole, Dorset). Agar plates are prepared using 1% Ionager No. 2 (Oxoid, London) in 8% sodium chloride solution, buffered to pH 7.8. The gel pattern consists of a central well 5 mm in diameter containing antigen surrounded by six outer wells of the same diameter containing test sera. All the wells are spaced 3 mm apart.

Diffusion of antigen and antibody takes place at room temperature, and the plates are examined for precipitin lines after approximately 24 h. Sera recorded as positive are diluted by twofold series in phosphate buffered saline and further tested to ascertain the agar gel precipitation (AGP) titer. The titers are expressed as the log 2 of the reciprocal of the highest dilution of serum producing a precipitin line.

The concentrated parvovirus antigen used for the AGP tests has an EID 50 titer of between 10^8 and 10^9/mL, calculated by the method of Reed and Muench [23]. Antigen is also prepared from normal duck embryos and used in the AGP test as a control to check for nonspecific precipitin lines.

77.2.2.6 Enzyme-Linked Immunosorbent Assay

ELISA is a common diagnostic test for detection of various infectious pathogens, and different versions are available including direct ELISA, antigen capture ELISA, sandwich ELISA, and dipstick ELISA. In 1996, Kardi and Szegletes used ELISA procedure to detect Derzsy's disease virus of geese and antibodies produced against it. Recently, Wang et al. developed a competitive ELISA using a monoclonal antibody for the detection of GPV virus-like particles and vaccine immunization in goose sera. The procedural details for ELISA and competitive ELISA are available in published reports [24–26].

77.2.2.7 Western Blotting

In 2005, Wang et al. used sera collected from experimentally infected ducks in Western blotting and showed that antibodies against the NS protein appeared first after infection, followed by antibodies against the capsid protein. While a number of methods are available for the detection of antibodies against waterfowl parvoviruses, none is able to differentiate responses against the capsid and NS proteins. Procedures for the Western blotting assay are available in detail elsewhere [21].

77.2.2.8 PCR

The following PCR procedure for GPV detection is based on published literature [18,21,22]:

1. Primers (see Table 77.1).
2. PCR mixture is submitted to 30 cycles of amplification involving denaturation at 95°C for 1 min, annealing at 48°C for 1 min, and polymerization at 72°C for 1 min. PCR products are electrophoresed on 1.2% agarose gels; gels are stained with ethidium bromide and then visualized with ultraviolet (UV) light.

77.2.2.9 Multiplex PCR

Chen et al. [27] developed a multiplex PCR for rapid diagnosis of goose viral infections. The goose viral infections include GPV (GenBank accession number JF333590), goose paramyxovirus (GenBank accession number GQ245793), goose herpesvirus (GenBank accession number EF053033), and goose adenovirus (GenBank accession number EU979376).

1. Primers (see Table 77.2).
2. Prepare PCR premix containing the following components: 1.25 U of Taq DNA polymerase (TaKaRa, Dalian, China), 2.5 μL of 10× reaction buffer (200 mM Tris–HCl, pH 8.55, 160 mM $[NH_4]_2SO_4$, and 20 mM $MgCl_2$), 10 mM of each dNTPs (TaKaRa, Dalian, China), and 50 pmol of each primer (Table 77.1). Mix these components with 4 μL of template cDNA/DNA in a total volume of 25 μL.
3. Perform PCR amplification using the following cycling programs: an initial denaturation step at 95°C for 5 min; 35 cycles of denaturation at 94°C for 30 s, primer annealing at 58°C for 30 s, and elongation at 72°C for 30 s; and final elongation step at 72°C for 7 min.
4. Separate the PCR products by electrophoresis on 2.5% agarose gels, stain with ethidium bromide and visualize under UV light.

77.2.2.10 Fluorescent Quantitative Real-Time PCR

In 2009, Yang et al. developed a fluorescent quantitative real-time PCR for the detection of GPV in vivo [28].

1. Primers (see Table 77.3).
2. The reaction, data acquisition, and analysis are carried out using iCycler IQ Optical System Software. The **fluorescent quantitative** (FQ)-PCR is performed in a 25 μL reaction mixture containing 1× PCR buffer,

0.3 mmol/L dNTPs, 1.25 U Taq, and 1 μL DNA template according to the manufacturer's instructions. Autoclaved nanopure water is added to make the final volume to 25 μL. Each run comprises an initial activation step of 30 s at 95°C, followed by 40 cycles of denaturation at 94°C for 10 s and annealing at 60°C for 30 s; the fluorescence is measured at the end of the annealing/extension step. The tests are performed using 0.2 mL PCR tubes (ABgene, United Kingdom). FQ-PCR is optimized in triplicate based on the primer, probe, and $MgCl_2$ concentration selection criteria, which is performed according to 4 × 4 × 4 matrix of primer concentrations (0.10, 0.12, 0.16, and 0.20 μmol/L), probe concentrations (0.10, 0.12, 0.16, and 0.20 μmol/L), and $MgCl_2$ concentrations (1.0, 5.0, 10.0, and 15.0 mmol/L). Conditions are selected to ensure that both the fluorescence acquisition curves are robust and Ct values are the lowest possible to the known template DNA concentrations.

77.3 CONCLUSION

Goose parvovirus (GPV) infection, also known as gosling plague (GP), is an important disease of geese and Muscovy ducklings under the age of 4–20 days [29]. The genomes of GPV and MDPV contain two major ORFs: the first encoding the NS protein involved in viral replication and regulatory functions and the second the three capsid proteins VP1, VP2, and VP3. The proteins VP1, VP2, and VP3 are derived from the same gene, and the entire amino acid sequences of VP2 and VP3 are contained within the carboxyl terminal portion of VP1 [29]. VP3 appears to be the most abundant of the three capsid proteins in purified virions [30,31]. Sequence comparisons have shown that VP1 of GPV and MDPV have 87.4% amino acid sequence identity and the NS proteins have 90.6% identity [32,33]. Laboratory diagnosis of GP is possible through the use of virus isolation, and various immunological/molecular procedures. The development and application of hyperimmune serum and attenuated vaccine have proven effective for the control of GP in China.

78.1 INTRODUCTION

Penaeus monodon hepandensovirus (PmoHDV) is a parvovirus that causes high mortality and stunted growth in juvenile shrimp in Asia Pacific regions, Africa, Australia, and North and South America. Along with white spot syndrome virus (WSSV, see Chapter 98), yellow head virus (YHV; see Chapter 33), infectious myonecrosis virus (IMNV, see Chapter 66), Taura syndrome virus (TSV, see Chapter 3), *Penaeus stylirostris* penstyldensovirus (PstDV or infectious hypodermal and hematopoietic necrosis virus [IHHNV]; see Chapter 79), and *Penaeus monodon* nucleopolyhedrovirus (PemoNPV or monodon baculovirus [MBV]), PmoHDV is responsible for approximately 60% of disease losses in shrimp aquaculture. Furthermore, abdominal segment deformity disease due possibly to an undescribed retrovirus-like agent and monodon slow growth syndrome due to Laem-Singh virus create additional problems to *Penaeus vannamei* and *Penaeus monodon* shrimp farming in Asia. Despite their distinct taxonomical and ecological backgrounds, the aforementioned viruses have one thing in common, that is, they all demonstrate a capacity to decimate the cultured and wild shrimp populations throughout the world.

78.1.1 Classification

PmoHDV (formerly hepatopancreatic parvovirus [HPV]) is a single-stranded DNA virus classified in the genus *Hepandensovirus*, subfamily *Densovirinae*, family *Parvoviridae*.

Of the two subfamilies (*Parvovirinae* and *Densovirinae*) within the family *Parvoviridae*, the subfamily *Parvovirinae* consists of viruses that infect vertebrate hosts and is organized into eight genera (*Amdoparvovirus*, *Aveparvovirus*, *Bocaparvovirus*, *Copiparvovirus*, *Dependoparvovirus*, *Erythroparvovirus*, *Protoparvovirus*, and *Tetraparvovirus*), whereas the subfamily *Densovirinae* covers viruses that infect invertebrate (insect) hosts and is divided into five genera (*Ambidensovirus*, *Brevidensovirus*, *Hepandensovirus*, *Iteradensovirus*, and *Penstyldensovirus*) [1].

According to the latest release from the International Committee on Taxonomy of Viruses, the genus *Hepandensovirus* is composed of a single species Decapod hepandensovirus 1, which includes seven isolates: PmoHDV1, PmoHDV2, PmoHDV3, PmoHDV4, *Penaeus merguiensis* hepandensovirus (PmeDV), *Penaeus chinensis* hepandensovirus, and *Fenneropenaeus chinensis* hepandensovirus [1,2]. These viruses are monophyletic and all have relatively large (~6.3 kb), monosense, heterotelomeric genomes that lack discernable PLA2 motifs. Members of the species Decapod hepandensovirus 1 are associated with hepatopancreatic disease in black tiger shrimp (*P. monodon*) and Chinese white shrimp (*Penaeus chinensis*), resulting in stunted growth (with growth stopping at approximately 6 cm in length) but rarely death. For convenience, we will refer to the viruses of the species Decapod hepandensovirus 1 as PmoHDV in this chapter.

Closely relating to the genus *Hepandensovirus* in the subfamily *Densovirinae*, the genus *Penstyldensovirus* comprises a single species Decapod penstyldensovirus 1, which has four isolates: PstDV1, PstDV2, *Penaeus monodon* penstyldensovirus 1 (PmoPDV1), and PmoPDV2 [1,2]. These viruses are monophyletic and all have small (~4 kb), monosense, homotelomeric genomes that lack discernable PLA2 motifs.

Members of the species Decapod penstyldensovirus 1 are responsible for high mortality in juveniles and subadults of American blue shrimp (*Penaeus stylirostris*) and cuticular deformities and growth retardation (collectively called runt-deformity syndrome, or RDS) in pacific whiteleg shrimp (*P. vannamei*, which is currently known as *Litopenaeus vannamei*). For convenience, we will refer to the viruses of the species Decapod penstyldensovirus 1 as PstDV in this chapter (see Chapter 79, Section 79.1.1).

78.1.2 Morphology and Genome Organization

PmoHDV is a nonenveloped, icosahedral virus of 22–24 nm in diameter, with a linear, negative-sense, single-stranded DNA genome of approximately 6000 nucleotides (ranging from 6336, 6321, 6310, 6299, 5936, 5742, to 5740 nt) in PmoHDV isolates from Korea, Thailand, India, Australia, and Madagascar [3–7].

As exemplified by the isolate from infected *P. monodon* in Thailand, the PmoHDV genome of 6321 nucleotides includes 5′- and 3′-noncoding termini (containing hairpin-like structure of 222 and 215 nt in length, respectively) flanking three open reading frames (ORF1 [NS2 gene], ORF2 [NS1 gene], and ORF3 [VP gene]) [3].

The ORF1 (nt 216–1500) encodes putative nonstructural protein-2 (NS-2) of 428 amino acids with a molecular mass of 50 kDa. The NS-2 protein may have a role in the production of other viral replicative forms as well as the enhancement of NS1-associated parvovirus-induced cell killing in some cell lines [3].

The ORF2 (nt 1487–3224) encodes a major nonstructural protein (NS-1) of 579 amino acids with a molecular mass of 68 kDa. The NS-1 protein contains two regions of highly conserved motifs commonly found in all parvoviruses, including replication initiator motifs located between aa 87 and 134 and NTP-binding and helicase domains located between aa 390 and 490. Analysis of the 119 amino acids conserved region of NTP-binding and helicase domain suggests that PmoHDV is closely related to PstDV (or IHHNV) and two mosquito brevidensoviruses *Aedes aegypti* densovirus and *Aedes albopictus* densovirus. The NS-1 protein may be involved in viral capsid assembly and in the generation of viral single-stranded DNA [3].

The ORF3 (nt 3642–6096) encodes a capsid protein (VP) of 818 amino acids with a molecular mass of 92 kDa. This protein may be cleaved at two arginine residues located upstream (aa 271) and downstream (aa 298) of the glycine-rich region to produce a 57 or 54 kDa structural protein, respectively, which display a doublet band on SDS-PAGE. The 57 kDa protein presumably acts as capsid protein and the 54 kDa protein has unknown function. Phylogenetic analysis of the amino acid sequence of the ORF3 allows division of PmoHDV isolates into three genotypes (I, II, III): genotype I (from *P. chinensis* of Korea, and *P. monodon* of Madagascar, Mozambique, and Tanzania), genotype II (from *P. monodon* of Thailand, Indonesia, and India), and genotype III (from *P. merguiensis* of Australia, and New Caledonia), which largely reflect the geographic distribution of the hosts. Like other parvoviruses, PmoHDV a highly conserved glycine-rich sequence was found in structural protein of HPV, whereas phospholipase A2 (PLA2) signature sequence was found to be absent in this shrimp densovirus [3].

78.1.3 Biology and Epidemiology

PmoHDV targets hepatopancreatic epithelial cells of shrimps such as black tiger shrimp (*P. monodon*) and Chinese white shrimp (*P. chinensis*). After uptake by the host, PmoHDV attaches to the microvilli and gains entry into the host cell by pinocytosis. Inside the nucleoplasm, PmoHDV replicates and mature viruses accumulate in the main inclusion bodies. After disrupting the nuclear membrane, the mature virus particles are released into the cytoplasm. Subsequently, the viruses move into the hepatopancreatic tubule lumens and spread to new host cells [8,9].

The natural hosts of PmoHDV include an ever-increasing number of cultured and captured shrimp species, such as *P. monodon*, *P. merguiensis*, *P. semisulcatus*, *P. esculentus*, *P. penicillatus*, *P. japonicus*, *P. schmitti*, *P.* (*Fenneropenaeus*) *chinensis*, *P.* (*Fenneropenaeus*) *indicus*, *P.* (*Litopenaeus*) *vannamei*, and *P.* (*Litopenaeus*) *stylirostris*. Other shrimp species (e.g., *Parapenaeopsis stylifera*, *Metapenaeus monoceros*, *M. affinis*, *M. elegans*, *M. dobsoni*, *M. ensis*, *Solenocera choprai*, and *Macrobrachium rosenbergii*), crayfish (*Cherax quadricarinatus*), and mud crab (*Scylla serata*) may be also affected [9,10].

First described in *P.* (*Fenneropenaeus) chinensis* in Korea, PmoHDV has been shown to occur in wild, cultured, and hatchery reared shrimps throughout the Indo-Pacific region, including Thailand (*P. monodon*), Singapore (*P. merguiensis*), Kuwait (*Penaeus semisulcatus*), the Philippines (*P. monodon*), China, Taiwan, India (*P. semisulcatus*, *P. monodon*, and *P. indicus*), New Caledonia, Indonesia, Malaysia, and Australia (*P. esculentus*, *P. merguiensis*, *P. monodon*, and *P. japonicus*) [11–15]. In addition, PmoHDV has also been identified in Madagascar, Mozambique, Kenya (*P. penicillatus*), and Tanzania in Africa. After introduction to Hawaii through importation of *P.* (*Fenneropenaeus*) *chinensis* from Korea and to Israel with the importation of *P. penicillatus* from Kenya, PmoHDV has since spread to wild shrimp in North and South America. The movements of infected *P.* (*Litopenaeus*) *vannamei* further facilitated its incursions into the Pacific coast of Western Mexico and along the coast of coastal El Salvador [16].

PmoHDV is capable of both horizontal and vertical transmissions. The horizontal transmission of PmoHDV is made possible by cannibalism that occurs in shrimp farms, and the vertical transmission from parental broodstock to F1 progeny is not uncommon [17].

78.1.4 Clinical Features and Pathogenesis

Clinical signs in shrimp due to PmoHDV infection are largely non-specific, and may include anorexia, decreased preening

activity, increased surface and gill fouling by epicommensal organisms, sporadic opacity of tail musculature, and atrophy of the hepatopancreas, with mortality rates of 50%–100% in juvenile stages (which is exacerbated by stress and overcrowding conditions) after 4–8 weeks of infection and stunted growth rates in surviving juveniles [18].

More often, PmoHDV infection appears as coinfections with other hepatopancreatic pathogens such as YHV and PemoNPV (formerly MBV) [19,20].

Histopathologically, PmoHDV infection is characterized by the presence of single, large basophilic intranuclear inclusion bodies in hypertrophied nuclei of hepatopancreas tubules and adjacent midgut cells. The fully formed inclusion bodies cause nuclear hypertrophy and compression and displacement of the host cell nucleolus [21]. Transmission electron micrograph of a thin section of hepatopancreatic tissue of *P. monodon* infected with PmoHDV reveals ovoid to spherical inclusion bodies of 5–11 μm in a diameter. These inclusion bodies are composed of electron-dense granular material and virions, which lead to the lateral displacement of the nucleoli and margination of the chromatin [22,23].

78.1.5 Diagnosis

Given the absence of distinctive gross signs, diagnosis of PmoHDV infection in shrimp requires the use of laboratory methods such as histopathology, serology, and molecular techniques [24].

For histopathological examination, smears of hepatopancreatic tissue are prepared on a microscope slide and fixed with a drop of 10% formalin solution containing 2.8% NaCl. After drying and normal H&E staining, intranuclear inclusion bodies are visualized under microscope [22,25].

In vitro culture of PmoHDV may be performed. An insect model, *Acheta domesticus*, allows growth of PmeDV [26].

Serological detection of PmoHDV is feasible with the use of monoclonal antibodies (Mabs) against the 54 kDa protein [27,28].

Molecular techniques detect PmoHDV DNA and permit rapid and nondestructive diagnosis of PmoHDV infection in shrimp larvae, parental broodstock, and carrier host. Early generation molecular techniques are based on using short nucleic acid fragments of PmoHDV as probes through in situ hybridization or dot blot hybridization procedures [25]. With the development of nucleic acid amplification technologies such as polymerase chain reaction (PCR) and loop-mediated isothermal amplification (LAMP), accurate diagnosis of PmoHDV infection is possible. In particular, PCR and its derivatives such as nested PCR, PCR-enzyme-linked immunosorbent assay, and real-time PCR have been widely applied in clinical laboratories for routine diagnosis of PmoHDV infection [5,29–43]. Table 78.1 presents some of the PCR primers reported for PmoHDV identification. In view of their superior sensitivity, specificity, and speed, PCR-based methods are recommended by the World Animal Health Organization (the Office International des Epizooties [OIE]) for the detection of shrimp viruses. LAMP by itself or in combination with lateral flow chromatographic strips offers another useful approach for PmoHDV identification [44–46].

78.1.6 Treatment and Prevention

Being endemic in Asia and many other parts of the world, PmoHNV infection causes high mortality and stunted growth in cultured shrimp. In the absence of specific treatment, control and prevention of PmoHNV infection in shrimp farms are mainly achieved by prompt identification and diagnosis, isolation of affected shrimp, disinfection, quarantine and hygiene measures, use of specific pathogen-free stocks, and vaccination [47,48].

78.2 METHODS

78.2.1 Sample Preparation

Virus purification: Hepatopancreata are removed from the gnathothoracies of shrimp and homogenized in TN buffer (0.02 M Tris-HCl, 0.4 M NaCl, pH 7.4). The homogenate is centrifuged at 7,000 and 13,000 × *g,* respectively, for 15 min each at 4°C using Suprafuge 22 12.50 rotor. Liquid supernatant is vacuum filtered through Whatman GF/B, Whatman GF/F filter, and Millipore Nitrocellulose 0.45 μm membrane filter, respectively. The filtered supernatant is subsequently centrifuged at 4°C for 1 h at 142,459 × *g* using Beckman Coulter Optima L-90K Ultracentrifuge (Beckman Coulter) Type 70 Ti rotor. The pellet is resuspended in 500 μL of TN buffer, layered onto the top of a 20%–40% sucrose gradient, and recentrifuged at 113,652 × *g* in a SW 40 Ti rotor for 3 h at 4°C. The pellet is resuspended in 200 μL of TN buffer and stored at −80°C until required [4].

DNA extraction: Pereiopod (about 20 mg) is removed from shrimp and homogenized in 500 μL of buffer containing 0.1 M NaCl, 20 mM Tris-HCl, EDTA, and 0.5% SDS. DNA is extracted from the homogenate using the same volume of phenol/chloroform/isoamylalcohol (25:24:1) mixture. DNA is precipitated with 0.1 volume of 3 M NaOAc (pH 5.3) and 2 volumes of absolute ethanol. The pellet is washed with 70% ethanol, and the air-dried pellet is resuspended in 100 μL of TE buffer. The DNA concentration is determined by measuring the ratio of the optical density at 260 nm to that at 280 nm (OD260/OD280) with an spectrophotometer [42].

Alternatively, nucleic acids from shrimp samples are extracted using CTAB extraction method. Briefly, one swimmeret or uropod of shrimp is homogenized in 500 μL of CTAB buffer (2% [w/v] CTAB, 1.4 M NaCl, 20 mM EDTA, 100 mM Tris-HCl, pH 7.5, 0.25% [v/v] β-mercaptoethanol) and incubated at 25°C for 3 h. The supernatant is collected by centrifugation at 12,000 × *g* for 5 min. Then, 1× phenol/chloroform/isoamyl alcohol (25:24:1, v/v) is added to the supernatant, incubated at 25°C for 5 min, and centrifuged at 12,000 × *g* for 5 min. The aqueous phase is transferred into a new tube and mixed with 1× chloroform/isoamyl alcohol (24:1, v/v). After centrifugation, the upper phase is collected, and nucleic acids are precipitated using 0.9 volumes of cold isopropanol. The pellet is washed with 70% ethanol, air-dried, and resuspended in nuclease free water [41]. Nucleic acids from larvae, gill, hemolymph, and hepatopancreas samples are extracted as described previously [37].

In addition, total DNA may be extracted from 200 μL of the viral suspension using High Pure PCR Template Preparation Kit (Roche Diagnostics) [4] or DNeasy Kit (Qiagen) [40].

78.2.2 Detection Procedures

78.2.2.1 Conventional PCR

Khawsak et al. [37] developed a PCR assay with primers HPV-F (5′-CATACATACAAGGCTTTCAGACA-3′) and HPV-R (5′-GGCTCATCGTCTTTCTTCTCC-3′) for specific detection of PmoHNV.

PCR mixture (10 μL) is made up of 1 μL of 10× PCR buffer, 0.5 μL of 50 mM $MgCl_2$, 1 μL of 10 mM dNTPs, 0.5 μL each of 1 μM of primers HPV-F and HPV-R, 1 U of *Taq* DNA polymerase (Invitrogen), and 1 μL of DNA.

PCR amplification is performed with the following conditions: denaturation at 94°C for 5 min, 30 cycles of denaturation at 94°C for 1 min, annealing at 55°C for 1 min, extension at 72°C for 1 min, and final extension at 72°C for 5 min.

PCR products are mixed with loading dye, separated on agarose gel electrophoresis (1.5% gel), stained with ethidium bromide, and visualized under UV transilluminator.

The use of 100 bp DNA ladder (Fermentas) allows easy observation of a specific 659 bp band, which is indicative of PmoHNV [41].

78.2.2.2 Real-Time PCR

Jeeva et al. [42] developed a real-time PCR kit for identification of PmoHDV with primers RT-2F (5′-ACG ATC AGA GCA ATC CGA AG-3′) and RT-2R (5′-TGG CTC TCT CCA GGT ATT CG-3′) and FAM-conjugated TaqMan probe (5′-CGGAGGGAGCTAACGAAATTAACGA-3′).

PCR mixture (20 μL) is made up of the necessary components for real-time PCR (Bioneer Corporation), 15 pmol of RT-2F and RT-2R primers, 15 pmol of the probe, and 80 ng of total DNA.

Real-time PCR thermal cycling is conducted using Exicycler (Bioneer Corporation) with a program consisting of predenaturation at 95°C for 7 min followed by 40 cycles of denaturation at 95°C for 30 s and primer annealing and DNA synthesis at 55°C for 40 s.

Note: The PCR product (129 bp) may be verified by 2% agarose gel electrophoresis.

78.3 CONCLUSION

PmoHDV is a major cause of slow/stunted growth and mortality in juvenile penaeid shrimp. Considering its high prevalence, widespread distribution, and ferocious pathogenicity, it is vital for us to have the capability to accurately and rapidly identify the culprit agent and develop the preparedness to respond to any future outbreaks of PmoHDV infection. Undoubtedly, the recent advances in molecular detection technologies have adequately prepared us for the diagnostic challenge in dealing with PmoHDV; much has to be done in the areas of antiviral and vaccine research and development against PmoHDV infection in shrimp aquaculture.

79.1 INTRODUCTION

With their delicious taste and high nutritional value, shrimps have long been an important food source for human society. In Asia, Indo-Pacific, and the United States, shrimp farming represents an enormously profitable activity [1,2]. Worldwide, the shrimp farming industry has confronted several emergencies due to viral diseases implicated in mass mortalities in cultured shrimps, such as white spot syndrome virus (WSSV), yellow head virus (YHV), Taura syndrome virus (TSV), and infectious hypodermal and hematopoietic necrosis virus (IHHNV), the latter of which was lately classified into the family *Parvoviridae*, as *Penaeus stylirostris* penstyldensovirus (PstDV) [3], which will be referred to as IHHNV or PstDV in this chapter. The social and economic impacts of the pandemics caused by these viral pathogens have been dramatic in countries in which shrimp farming constitutes a significant industry [1].

IHHNV (PstDV) was first reported as a cause of acute epizootics and mass mortalities in juvenile and subadult *Litopenaeus stylirostris* in Hawaii in the early 1980s [4]. It causes a disease condition called runt-deformity syndrome (RDS), characterized by reduced growth, deformities of the cuticle and rostrum in stocks of *L. vannamei* and *L. monodon* [5]. To date, infectious IHHNV (PstDV) is distributed broadly throughout shrimp cultures in several distinct geographical regions, including the United States, Oceania, and Asia [6], and noninfectious IHHNV-related sequences have also been detected in the genome of *L. monodon* from Africa and Australia [7]. According to the World Organization for Animal Health (OIE) report [8], two distinct genotypes of infectious IHHNV have recently been identified as type 1 (from the United States and East Asia) and type 2 (from Southeast Asia). Furthermore, recent studies have documented the presence of IHHNV in wild crustaceans in an asymptomatic manner [9,10].

79.1.1 Classification

The International Committee on Taxonomy of Viruses has assigned IHHNV to the genus *Penstyldensovirus*, subfamily *Densovirinae,* family *Parvoviridae*, which includes a second subfamily *Parvovirinae* [3].

Currently, the genus *Penstyldensovirus* consists of a single species, *decapod penstyldensovirus 1*, which includes four isolates: PstDV1, PstDV2, *Penaeus monodon penstyldensovirus* (PmoPDV) 1, and PmoPDV2. Being monophyletic, these viruses all have small (~4 kb), monosense, homotelomeric genomes that lack discernible PLA2 motifs.

Members of the species *decapod penstyldensovirus 1* are responsible for the high mortality in juvenile and subadult American blue shrimp (*Penaeus stylirostris*) and cuticular deformities and growth retardation (collectively called runt-deformity syndrome, or RDS) in pacific whiteleg shrimp (*Penaeus vannamei*, which is now known as *Litopenaeus vannamei*). For convenience, we will refer to the viruses of the species *decapod penstyldensovirus 1* as IHHNV or PstDV in this chapter.

Further phylogenetic alignment data suggest that IHHNV is most closely related to the genus *Brevidensovirus*, which includes two mosquito densoviruses (DNVs) isolated from *Aedes aegypti* and *Aedes albopictus* (AaeDNV and AalDNV) [11]. Virus assigned to the subfamily *Densovirinae* infects

arthropods and multiplies efficiently in most of the tissues of larvae, nymphs, and adult host species without the involvement of helper viruses [3].

79.1.2 Morphology and Biology/Epidemiology

IHHNV is the smallest known member of penaeid shrimp viruses. The IHHNV virion is a nonenveloped, icosahedral-shaped particle with a diameter of 22 nm and a density of 1.40 g/mL in CsCl. Its genome is a linear single-stranded DNA molecule of 4.1 kb in length that encodes three open reading frames (ORFs). ORF1 comprises approximately 50% of the genome encoding a polypeptide of 666 amino acids, which is predicted to produce a nonstructural protein 1 (NS1) based upon its degree of homology with 2 mosquito brevidensoviruses. ORF2, which starts 56 nucleotides upstream and overlaps ORF1, theoretically encodes a 343 amino acid putative nonstructural protein 2 (NS2). The 5′ end of ORF3 also overlaps ORF1, and the ORF3 encodes a 329 amino acid polypeptide. At least four structural proteins (74, 47, 39, and 37.5 kDa) are found in the purified virions [12–14]. IHHNV was first described in the early 1980s in Hawaii, mainly in shrimp specimens of *L. stylirostris*. It has been reported from every country or region where either *L. vannamei* or *L. stylirostris* are farmed and documented in both captive *Penaeus monodon* and *Marsupenaeus japonicas* brood stocks collected from the wild and their cultured progeny, which suggests that Asia is within the natural geographic range of the virus. It has been detected in different regions of Australia, Brazil, and Asia and is widely distributed in wild and cultured species in SE Asia, where it apparently does not produce losses [9,15,16]. This virus is also commonly present in North, South, and Central America, the Caribbean, the Indo-Pacific, the Gulf of California, and Mexico, in both shrimp farms and wild populations of *L. Vannamei*, *L. stylirostris*, and *Farfantepenaeus* [17,18].

Molecular studies show considerable variation among Asian isolates of the virus [12,19]. IHHNV-related sequences have also been detected in the genome of *L. monodon* from Africa and Australia exhibiting 86% and 92% identities to the viral genome [20]. The virus-related sequences are classified into two groups: type A, which was reported from Madagascar and Australia, and type B, reported from Tanzania in Africa [19]. Both types of virus-related sequences showed similarity with the IHHNV genome by having the three ORFs in them [21]. This shows a close relationship between the IHHNV and virus-related sequences found in *P. monodon* from Tanzania, Madagascar, and Australia [7]. According to the OIE report [8], two distinct genotypes of infectious IHHNV have recently been identified as type 1 (from the United States and East Asia) and type 2 (from Southeast Asia), although these designations remain somewhat controversial [22]. Different studies have revealed phylogenetic relationships among different geographic IHHNV isolates, which suggest that the Philippines was the most likely source of the original infection in the shrimp farming areas of Latin America [23]. As for the U.S./Philippine genotype of IHHNV, three other genetic variants of the virus have been documented: IHHNV-I; IHHNV-II, the variant from Southeast Asia; and IHHNV-III, the IHHNV variant from East Africa, Madagascar, Mauritius, and Australia. Both IHHNV-I and IHHNV-II are infectious to the representative penaeids, *L. vannamei* and *P. monodon*, while the genetic variant IHHNV-III has been demonstrated to be not infectious to these but can result in RDS [12,20]. All isolates of IHHNV from the United States are nearly identical to IHHNV from the Philippines. This finding, along with other aspects of its history and epidemiology of IHHNV in the United States, suggests that IHHNV was introduced from the Philippines, perhaps with live *P. monodon* that were imported in the early 1970s as a candidate aquaculture species during the very early development of shrimp farming in the United States [1].

79.1.3 Clinical Features and Pathogenesis

The IHHNV is highly contagious to several penaeid species. The initial recognizable signs in *P. stylirostris* are lethargic surface swimming followed by motionless, inverted sinking to the bottom, muscle opacity, lack of mobility, and death; in addition to the high mortalities associated with this virus, IHHNV causes abnormal physical defects, often resulting in permanent slow growth, small size, and deformities of the rostrum, antenna, thoracic, and abdominal areas [18,24]. In contrast, the impact of this virus in other penaeid species is not severe. In *P. vannamei*, it has been associated with RDS, causing significant reduction on the growth rate, and cuticular deformities as bent rostrum, blistered cuticle, bent telson, abdominal anomalies, and curly antennae [18]. In *P. monodon*, no important diminution on growth rate, deformities, or affect fecundity of lightly infected brood stock has been observed [25].

It has been reported that the disease is more severe in groups of small-sized animals (5.0 mg to 3.7 g) than in larger-sized groups (14.5–36.9 g). This virus was recognized as the etiological agent of high mortalities (over 50%) in juvenile and subadult blue shrimp *P. stylirostris* farmed in Hawaii in 1981. Within 14 days of appearance of gross signs of the disease and by the time the disease had run its course, the mortalities increased to 80%–90%; *P. stylirostris* specimens surviving IHHNV may become carriers and transmitter of the virus for life, despite the absence of evident gross signs of disease, and thus, vertically infected larvae and early postlarvae undergo mass mortalities when reaching the juvenile state [26]. Using traditional techniques (tissue histopathology and electron microscopy) of acute and subacute organisms of species *P. stylirostris*, *P. monodon*, and *P. vannamei* have been reported with large Cowdry type A intranuclear inclusions in gills, nerve cord, stomach mucosa, antennal gland, cuticular hypodermis, and hematopoietic and connective tissues. *P. stylirostris* presented a higher degree of tissue damage in the gills and nerve cord ganglia compared with *P. vannamei*. The damage provoked by such histopathology may be the cause for the characteristic clinical signs observed in IHHNV-infected shrimps [27]. Furthermore, in a survey study performed in two stations in the northern part of the Gulf of California, a high prevalence of this virus was found in wild adult females (86% and 89%) and males (56% and 57%) of *P. stylirostris*. On the other hand, it has been shown that

TABLE 79.1
Recommended Primer Sets for End-Point PCR Detection of IHHNV

Primer	Product	Sequence (5′–3′)	GenBank	References
389F	389 bp	CGG-AAC-ACA-ACC-CGA-CTT-TA	AF218266	[26]

MG831R		GTC-CAT-CCA-CTG-ATC-GGA-CT		

the prevalence of IHHNV in wild shrimp *P. setiferus* (white shrimp) and *P. aztecus* (brown shrimp) from the estuary of La Pesca in La Laguna Madre, Tamaulipas, Mexico, is low (only 4.4%) [28]. However, high prevalence of IHHNV has been also reported in other regions of the world, such as China. Some members of populations of *P. stylirostris* and *P. vannamei* that survive IHHNV infections and/or epizootics may carry the virus for life and pass the virus onto their progeny and other populations by horizontal and vertical transmission [24].

79.1.4 Diagnosis

Due to the importance of penaeid shrimp culture, the availability of easy and rapid methods that allow early diagnosis is essential for the routine monitoring of viral diseases. In early studies, IHHNV detection was achieved mainly by histological examination [29]. Lately, different molecular techniques have been used, such as dot blot and *in situ* hybridization (ISH) assays, end-point polymerase chain reaction (PCR), nested PCR, real-time quantitative PCR (qPCR), duplex qPCR, and loop-mediated isothermal amplification (LAMP) [10,20,29].

79.1.4.1 Conventional Techniques

Traditionally, the diagnosis of IHHNV infection is by examining histological sections where the nuclear Crowdy type A inclusion body, which is the principal histological diagnostic characteristic of this disease, is observed and strongly labeled [29]. The detection and identification of IHHNV with an immunoassay is a simple and low-cost alternative that can be specific and sensitive. An indirect enzyme-linked immunosorbent assay (ELISA) was developed for the detection of IHHNV using 6 IgM murine monoclonal antibodies (MAbs) generated against purified IHHNV [30]. Unfortunately, the detection was not reliable as some of the shrimp samples were negative by ELISA and produced positive results for PstDV by histopathology or DNA hybridization and vice versa. In 2009, Sithigorngul generated MAbs specific to a recombinant capsid fusion protein of PstDV to detect PstDV-infected shrimps by immunodot, Western blot, and immunohistochemical assays [31].

79.1.4.2 Molecular Techniques

79.1.4.2.1 End-Point PCR and Nested PCR

PCR is a highly sensitive and robust technique for the detection of IHHNV infection in shrimps. Besides its specificity, and the sensitivity of this detection system allows diagnosis during early infection. The PCR assay's success is a function of several factors such as primer composition, structure, and homology of the target molecule. PCR methods have been used to develop, maintain, and document the SPF (specific-pathogen-free) status of *L. vannamei* lines developed in the United States for use by the domestic and international shrimp farming industries [32]. A number of commercial PCR kits are available for IHHNV detection. There are multiple geographical variants of IHHNV, some of which are not distinguishable by all of the available methods for IHHNV detection. Different recommended primer sets for end-point PCR detection of IHHNV are enlisted in Table 79.1.

The two primer sets 392F/R and 389F/R are the most suitable for detecting all known genetic variants of IHHNV [19,34], including types 3A and 3B, which are inserted into the genome of certain geographic stocks of *P. monodon* from Western Indo-Pacific, East Africa, Australia, and India [7,20,35]. Primer set 309F/R amplifies only a segment from IHHNV types 1 and 2 (the infectious forms of IHHNV) but not types 3A and 3B, which are noninfectious and part of the *P. monodon* genome [7,20]. Primer set MG831F/R reacts only with types 3A and 3B. The primer set 77012F/77353R binds to a region between the nonstructural and structural (coat protein) protein-coding regions and amplifies a 356 bp product [33]. Different nested PCR–based commercial kits were also developed for improved sensitivity of detection [24]. A nested PCR has also been used to increase sensitivity for IHHNV detection in wild crustaceans and shrimp samples collected in India [21] and Mexico [10].

79.1.4.2.2 Single and Duplex Quantitative PCR

qPCR, which is used to amplify and simultaneously quantify a targeted DNA molecule, enables detection and quantification of the viral pathogen in the tissues of infected shrimps. By using this technique, the viral titer in infected shrimps can

be accurately determined, which in turn helps in risk assessment as well as disease monitoring during culture. qPCR assays have been successfully applied for the detection and quantification of IHHNV infection in shrimps. In 2001, Tang and Lightner developed a method using a TaqMan probe in a 50-nuclease assay to detect the virus in penaeid shrimps [36]. A pair of PCR primers that amplified an 81 bp DNA fragment and a fluorogenic probe (TaqMan probe) was selected from a conserved region of ORF1 of the IHHNV genomic sequence (GenBank AF218266). Dhar et al. [37] developed a duplex qPCR for detection and quantification of both IHHNV and WSSV using SYBR Green chemistry. In 2008, a multiplex qPCR for the detection of three viral pathogens WSSV, IHHNV, and TSV of penaeid shrimps was developed, and sensitivity in comparison to routine PCR was 10, 1000, and 10 times higher, respectively, for the three viruses [38]. In a more recent report, Leal et al. [39] developed and standardized a duplex qPCR assay for the simultaneous detection of the WSSV and the IHHNV, showing that this method is more effective than assaying for each virus separately.

79.1.4.2.3 Loop-Mediated Isothermal Amplification

LAMP is a novel DNA amplification method originally developed by Notomi et al. [40]. The LAMP reaction involves an autocycling strand displacement DNA synthesis that is performed by a DNA polymerase with high strand displacement activity and a set of two specially designed inner and outer primers. The amplification products are stem-loop DNAs with several inverted repeats of the target and exhibit cauliflower-like structure with multiple loops. The LAMP reaction can be conducted under isothermal conditions ranging from 60ºC to 65ºC. Using the LAMP method, a highly specific and sensitive diagnostic system for IHHNV detection was designed [41]. Recently, Arunrut et al. described a rapid and sensitive detection system of IHHNV by LAMP combined with a lateral flow dipstick and it was faster than the usual LAMP reactions as described [41,42]. The results obtained using this method were comparable to nested PCR.

79.1.4.2.4 Dot Blot and In Situ Hybridization

DNA probes are useful for the diagnosis of various viral diseases providing greater diagnostic sensitivity than conventional histopathology procedures. They find application in the nonlethal testing of valuable brood stock. Dot blot and ISH methods for the detection of IHHNV have been developed, and commercial kits are available [8]. The first generation of gene probes was developed in 1993 [29]. The specificity of BS4.5 probe labeled with nonradioactive digoxigenin (DIG)-11-dUTP was investigated by dot blot, ISH, and Southern blotting. Detection of IHHNV DNA was highly specific since cross-reaction with insect parvovirus DNA and HPV-infected tissues was not detected [29,43]. A nonlethal serodiagnostic field kit was used for screening of candidate SPF *P. vannamei* brood stock by using specific gene probe [44]. Lately, a DIG-labeled probe I703 was developed for the detection of IHHNV infection in *P. vannamei* by dot blot and ISH [45].

79.2 METHODS

79.2.1 Sample Preparation

Several methods have been used for the DNA extraction from specimens prior to analysis. Tang and Lightner obtained total DNA extracts from either gills or pleopods of shrimps with the High Pure DNA Template Preparation Kit (Roche Bioscience) whereas Kim et al. used gills or shrimp pleopods pooled and homogenized in phosphate-buffered saline (PBS; pH 7.4), and the viral DNA was extracted using DNeasy Blood & Tissue Kit (Qiagen, Valencia, CA) [7,22]. Galván-Álvarez et al. obtained total DNA extracts from pleopods' muscle using glassmilk (GeneClean Spin Kit, MP Biomedicals) according to the manufacturer's instructions. Silva et al. described the sample preparation and DNA extraction of muscular tissue extracted from the third abdominal segment [46,47]. Tissue samples were cut and immediately transferred to a buffer containing proteinase K, according to the specifications of NucleoSpin® Tissue kit. Recently, Macías-Rodríguez et al. published another methodology for wild organisms and shrimps using 50 mg of lamellar, intestinal, or muscle tissue in 400 µL of lysis buffer from DNAzol kit (Invitrogen, Carlsbad, CA) that is centrifuged at 13,000 × g for 10 min, and then, 200 µL of supernatant was transferred to another Eppendorf tube with 150 µL of 100% ethanol, mixed by inversion and incubated for 3 min at room temperature before being centrifuged at 12,000 × *g* for 5 min. Subsequently, the sample with 150 µL of 75% ethanol is washed and centrifuged at 13,000 × *g* for 3 min, and DNA pellet is dried at room temperature and finally resuspended in 30 µL of ultrapure water before being stored at −20°C [10].

79.2.2 Detection Procedures

A number of molecular methods for IHHNV detection are available: end-point PCR [26], nested PCR [10], and qPCR [37].

79.2.2.1 End-Point PCR and Nested PCR

79.2.2.1.1 Procedure

1. Prepare the PCR mix as follows (volumes indicated per reaction).

Component	End-Point PCR (µL)	Nested PCR (µL)
Buffer 10×	2.5	2.5
$MgCl_2$ (50 mM)	1.0	1.0
dNTP (10 mM)	0.3	0.5
Primer 392F (10 pmol/µL)	0.5	—
Primer 392R (10 pmol/µL)	0.5	—
Primer NNJ208F (10 pmol/µL)	—	0.5
Primer NNJ208R (10 pmol/µL)	—	0.5
Taq polimerasa (5 U/µL)	0.5	0.2
ddH_2O	Up to 24	Up to 24

2. Add 24.0 µL of the PCR mix and 1 µL of cDNA into a 0.2 mL PCR tube.
3. Turn on a thermocycler and preheat the block to 94ºC.
4. Spin the sample tubes in a microcentrifuge at 14,000 × *g* for 30 s at room temperature.
5. Place the sample tubes in the thermal cycler at 95°C for 4 min; 35 cycles of 55°C for 30 s and 72°C for 90 s; and 1 cycle of 72°C for 5 min.
6. Following amplification, pulse spin the reaction tubes to pull down the condensation droplets at the inner wall of the tubes. The samples are now ready for electrophoresis or to be stored frozen at –20°C.
7. Analyze the PCR products by agarose gel electrophoresis through 2.0% agarose gel in 1× TAE buffer at 90 V for 40 min.
8. Stain the gel with ethidium bromide and then visualize under ultraviolet light source.

Note: Negative control is concurrently included along with the test samples in order to monitor any possible contamination during the PCR procedure. The presence of a 392 bp product is indicative of IHHNV by single PCR [26] and a 208 bp fragment is indicative of IHHNV by nested PCR [10].

79.2.2.2 Real-Time qPCR

79.2.2.2.1 Procedure

1. Prepare the real-time qPCR mix as follows.

Component	Volume (µL)	Component	Concentration
SYBR Green Master Mix 2× (PE Applied Biosystems)	7.1	TaqMan Universal PCR Master Mix (Applied Biosystems)	1×
Primer 313F (0.24 µM)	1.0	Primers IHHNV1608F	0.3 µM
Primer 363R (0.24 µM)	1.0	Primers IHHNV1688R	0.3 µM
DNA (1 ng)	1	DNA	5–50 ng
—	—	TaqMan probe	0.15 µM
ddH_2O	Up to 25	ddH_2O	Up to 25 µL

2. The reactions were carried out in a 96-well plate in a 25 µL reaction volume.
3. The thermal profile for all SYBR Green PCRs was 50°C for 2 min and 95°C for 10 min, followed by 40 cycles of 95°C for 10 s and 60ºC for 1 min. Melting curves were obtained after a final step of 60 cycles under a ramp rate of 0.5ºC every 10 s from 60ºC to 90ºC. Cycling profile for TaqMan is activation of AmpliTaq Gold for 10 min at 95°C, followed by 40 cycles of denaturation at 95°C for 15 s and annealing/extension at 60°C for 1 min.
4. In each 96-well plate, serial dilutions of plasmids harboring the target sequences were used as standards for the respective virus. Standard curves were run in parallel, with the unknown samples for the corresponding virus and their β-actin amplification for each sample used as reference gene.

The PCR primers and TaqMan probe are selected from a region of the IHHNV genomic sequence (GenBank AF218266) that encodes for nonstructural protein. The primers and TaqMan probe are designed by the Primer Express software (Applied Biosystems). The upstream (IHHNV1608F) and downstream (IHHNV1688R) primer sequences are 5′-TACTCCGGACACCCAACCA-3′ and 5′-GGCTCTGGCAGCAAAGGTAA-3′, respectively. The TaqMan probe (5′-ACCAGACATAGA-GCTACAATCCT CGCCTATTTG-3′), which corresponds to the region from nucleotide 1632–1644, is synthesized and labeled with fluorescent dyes 5-carboxyfluoroscein (FAM) on the 5′ end and *N*,*N*,*N*′,*N*′-tetramethyl-6-carboxyrhodamine (TAMRA) on the 3′ end (Applied Biosystems).

Note: SYBR Green PCR amplifications were performed in a GeneAmp 9600 thermocycler coupled with a GeneAmp 5700 Sequence Detection System [37]. Each sample was replicated two to three times. All reactions were repeated at least three times independently to ensure the reproducibility of the results. The absolute levels of IHHNV in the experimental samples were determined by extrapolating the C_q values from the standard curves of the viruses. TaqMan PCR amplifications were performed in a GeneAmp 5700 Sequence Detection System (Applied Biosystems) or ABI PRISM 7000, 7300, or 7500 [36].

79.3 CONCLUSIONS AND FUTURE PERSPECTIVES

IHHNV (PstDV) is one of the major viral pathogens of penaeid shrimps worldwide causing acute epizootics and mass mortalities in juvenile and subadult *L. stylirostris*. It also causes a disease condition called RDS, deformities of the cuticle and rostrum, bubbleheads along with wide size variations, and reduced growth. Currently, infectious IHHNV (PstDV) occurs throughout shrimp cultures in several distinct geographical regions, including the United States, Oceania, and Asia, and noninfectious IHHNV-related sequences have also been detected in the genome of *L. monodon* from Africa and Australia. Recent studies have shown that IHHNV is prevalent in wild crustacean population and in shrimp brood stock. The available evidence implies that IHHNV has a potential of persisting in wild organisms in the vicinity of shrimp farms. When wild organisms gain entry into the ponds, they may cause disease outbreaks. Further studies are required to determine the role of IHHNV in viral diseases of shrimps in terms of synergistic or antagonistic interaction with other viruses or pathogens. Existing data remain controversial with regard to the ability of IHHNV to modify the susceptibility of

a second infection either by virus or bacteria. Therefore, research should be focused on the elucidation of IHHNV host range, IHHNV–pathogens interactions, and epidemiology to better understand the origin of the present and emerging shrimp diseases.

80.1 INTRODUCTION

Porcine parvovirus (PPV) is considered to be one of the major causes of reproductive failure in swine [1,2]. First described from aborted fetal swine in 1967 by Cartwright and Huck [3], PPV is linked to the reoccurrence of estrus, abortion, and the delivery of mummified or stillborn fetuses [4], the so-called SMEDI (stillbirth, mummification, embryonic death, and infertility) syndrome. The virus is endemic in most areas of the world and can be found in all pig herd categories.

80.1.1 Classification

PPV is a single-stranded DNA virus classified in the family *Parvoviridae*. Of the two subfamilies (*Parvovirinae* and *Densovirinae*) within the family *Parvoviridae*, the subfamily *Parvovirinae* covers viruses that infect vertebrate hosts and are separated into eight genera (*Amdoparvovirus*, *Aveparvovirus*, *Bocaparvovirus*, *Copiparvovirus*, *Dependoparvovirus*, *Erythroparvovirus*, *Protoparvovirus*, and *Tetraparvovirus*), whereas the subfamily *Densovirinae* contains viruses that infect insect hosts and are divided into five genera (*Ambidensovirus*, *Brevidensovirus*, *Hepandensovirus*, *Iteradensovirus*, and *Penstyldensovirus*) [1,6].

To date, at least seven genetically divergent parvoviruses that infect pigs have been identified. These include PPV type 1 (PPV1), PPV2, PPV3 (also known as porcine PARV4, hokovirus, or partetravirus), PPV4, PPV5, and PPV6, as well as porcine bocavirus (of the genus *Bocaparvovirus*) [1,6–10].

Recent genetic evidence suggests that PPV2 and PPV3 demonstrate a close relationship to human parvovirus 4 (PARV4) of the genus *Tetraparvovirus*, whereas PPV5 and PPV6 are similar to PPV4 (of the ungulate copiparvovirus 2 group in the genus *Copiparvovirus*) [7–10]. On the other hand, the nonpathogenic PPV strain NADL-2 (PPV-NADL2) (which is currently used as an attenuated vaccine) and the dermatitis-associated PPV strain Kresse belong to the ungulate protoparvovirus 1 group in the genus *Protoparvovirus*. Interestingly, a natural attenuated PPV-N strain, isolated in 1989 from the viscera of a stillborn fetus farrowed by a gilt in Guangxi, southern China, resembles attenuated PPV-NADL-2 strain [11].

Antigenically, PPV appears to be related to canine parvovirus and feline panleukopenia virus. However, it is genetically distinct from parvoviruses of all other species.

80.1.2 Morphology and Genome Organization

PPV is a nonenveloped virus of about 20 nm in diameter, with a round or hexagonal appearance. The capsid of PPV is a spherical shell consisting of 60 identical copies of viral proteins arranged in an icosahedral symmetry [12].

The PPV genome consists of a single-stranded DNA molecule of about 5.2 kb with terminal palindromic sequences [1]. Two large open reading frames (ORFs) are present in the genome, one (located at the 3′ end) coding for the structural (capsid) protein (or VP) and the other (located at the 5′ end) coding for the nonstructural protein (or NSP). It is notable that 60 copies of VP are required to assemble the icosahedral

viral capsid. In each of these copies (capsid subunit), a spike on the threefold axis, a depression or canyon around the fivefold axis, and a dimple on the twofold axis can be observed [13,14].

However, in some parvoviruses such as PPV4 and members of the genus *Bocaparvovirus*, an additional ORF3 (encoding accessory protein) has been found in the middle of the viral genome [15,16].

80.1.3 Epidemiology

PPV infection is common in gilts, usually endemic; and occurrence of the disease seems closely related to season, from April to October each year, after farrowing and mating the disease multiples [17]. Once the disease occurs, it can continue for several years. The virus mainly infects newborn piglets, embryo, and embryo pig. When a sow becomes infected in early pregnancy, the mortality of its embryo and embryo pig can be as high as 80%–100%. In addition, PPV infection may induce viremia in the first 6 days, and from days 3 to 7 the infected swine starts to detox to the outside through feces and continue to pollute the environment by detoxing irregularly afterward.

Hemagglutination inhibition antibody can be detected as early as one week after infection. Antibody titers can be up to 1:15,000 within 20 days and can last for several years.

Sources of PPV infection include infected sows and boar, which may sometimes be apparently healthy, asymptomatic carriers. Stillbirths, live births, low earners, and uterine secretions of infected sows contain high titers of the virus, and the environment of pens both inside and outside can be polluted. Sperm cells, spermatic cord, epididymis, and vice gonads of infected boar can contain the virus, so that susceptible sows may acquire infection during mating. If pregnant sows have been infected with the virus for >55 days, the farrow may develop immune tolerance leading to the state of persistent infection. Under this circumstance, the piglets may not have detectable specific antibodies, and will poison and detoxify in their lifetime. The virus is mainly distributed in the lymphoid tissue (such as gut lymphoid tissue, renal interstitial cells, turbinate periosteum) of the infected swine [1].

The disease can be transmitted vertically through the placenta and mating, as well as the respiratory and gastrointestinal routes. Mechanically, rodents can also play a role in the spread of the disease.

80.1.4 Clinical Features and Pathogenesis

Clinical features: Pigs infected with PPV are generally in subclinical form, with reproductive failures in sows being the key clinical sign. In infected sows, the pathological sequela caused by PPV is related mainly to the gestational period in which infection occurs. In the beginning of gestation, the conceptus is protected by the zona pellucida and is therefore resistant to infection. During the embryo stage, infection with PPV results in embryonic death and resorption. From the 35th day onward, ossification starts, and the infection results in death and subsequent mummification. Finally, around the 70th day of gestation, the fetus is already immune competent and may resist viral infection. An infection in this stage is then usually controlled, and the piglet is born with anti-PPV antibodies [18].

Pathogenesis: The primary replication of the PPV is suggested to occur in lymphoid tissues. From there, the virus is distributed systemically via viremia. In the epitheliochorial placenta, six tissue layers completely separate the sow and the fetal blood circulation. Since these cells are closely connected, not allowing the passage of even small molecules such as antibodies, it is still not understood how PPV crosses the placental barrier and reaches the fetus [4]. Probably, as the virus was already detected in lymphoid tissue from pigs and in fetal lymphocytes and is able to remain infectious after phagocytosis by macrophages [1], PPV could use them to infect the fetus. Inside the fetus, PPV replicates due to the high mitotic activities present in the fetal tissues [5].

PPV enters cells through a series of interactions that culminate in the release of viral genetic material into a cell compartment in which replication can occur [1]. The mechanisms of PPV entry are not fully understood but may include clathrin-mediated endocytosis or macropinocytosis followed by transportation through the endosomal pathway. Endosomal trafficking and acidification are essential for PPV to enter in the nucleus [1]. Endosome acidification results in reversible modifications of the virus capsid that allow the virus to escape from the endosome [1]. This motif activity is essential for breaking the vesicular membranes, resulting in the formation of pores. After arriving in the nucleus, PPV replicates using the host cell's own machinery, including cellular DNA polymerase for DNA replication. As virus replication takes place in the replication phase (S) of the cell, cells with a higher replication index are necessary for optimal outcome [1].

80.1.5 Diagnosis

80.1.5.1 Conventional Techniques

Virus isolation represents the primary method for PPV detection. A bacterial suspension mixed with the brain, kidney, testis, lung, liver, and mesenteric lymph nodes of aborted fetuses, stillbirths, mummified and low earners of gilts or placenta, and vaginal secretions of sows is inoculated on cells and cultured. If the specimen contains the virus, the inclusion bodies can be observed in the nucleus after 16–36 h, and the characteristic cytopathic effect can be seen after 5–10 days. Initially, cells appear diffused and granular, and then they turn round, clustered, and condensed. Next, cells disintegrate and their shape is not whole. Finally, the cells detach from the bottle wall.

As the virus isolation is time-consuming and laborious, it is not conducive for routine application. Instead, a range of serological assays are commonly used. These include hemagglutinin assay (HA), hemagglutination inhibition (HI) test, ELISA, serum neutralization test, and indirect immunofluorescence. Of these, HA and HI are the most

common methods. Sera for HI test need to be pretreated by heat inactivation followed by adsorption with kaolin [1]. HA and HI are simple, convenient, and fast, but their low sensitivity and low specificity limit their use for secondary diagnosis only [19–23].

80.1.5.2 Molecular Techniques

In comparison with conventional diagnostic techniques, molecular methods such as nucleic acid probes technology [24] and PCR [25] demonstrate relatively high sensitivity and specificity for the detection of PPV.

Not surprisingly, multiplex PCR, real-time PCR, and nano-PCR are increasingly employed as a tool for the diagnosis of PPV infection. Multiplex PCR utilizes a plurality of pairs of primers in the same PCR system so that multiple target genes are amplified at the same time. It enables a sample to be tested simultaneously for multiple pathogens or multiple gene types so various diseases can be diagnosed in a single run, thus shortening the detection time and reducing reagent consumption. Real-time PCR combines the conventional PCR technique and fluorescence detection. By eliminating manual handling after amplification, real-time PCR is not only rapid but also reduces potential cross-contamination [26]. Nano-PCR represents a further advance in PCR technology and enables amplification of DNA with complex structures [27]. Nucleic acid probe technology also has high specificity and sensitivity, but its high cost is inappropriate for use in routine diagnostic laboratories.

80.2 METHODS

80.2.1 Sample Collection and Preparation

Suitable samples for PPV detection include aborted fetuses, stillbirths, mummified and weak earner's brain, kidney, testis, lung, liver, and mesenteric lymph nodes or placenta, and vaginal secretions of sows.

Add 0.5% solution of hydrolyzed milk protein containing penicillin (1000 units/mL), streptomycin (1000 units/mL), and kanamycin (1000 units/mL) to the specimen, with the proportion of specimen and solution being 1:5–10. Grind the specimen, centrifuge it 10 min at 3000 rpm, and store the supernatant at –20°C.

80.2.2 Detection Procedures

80.2.2.1 Nano-PCR Detection of PPV

1. *Primers*: Two pairs of primers are designed using Primer Premier 5.0 software from PPV gene sequence of PPV retrieved from GenBank (http://www.ncbi.nlm.nih.gov/nuccore/194277764) [28] (Table 80.1).
2. *Construction of a plasmid containing the NS*1 *gene*: The complete sequence of the NS1 gene was inserted into the vector pGBKT7 as the standard plasmid, amplified in *E. coli* DH5a, and the recombinant plasmids were purified *using* the related kit. Finally, the constructs were confirmed by digestion with restriction enzymes *EcoR*I and *Sal*I and sequencing. The verified products we*re k*ept at −20°C until used [28].
3. *Optimization of PPV nano-PCR assay conditions*: PCR conditions such as temperature and primer volume need to be optimized.

80.2.2.1.1 Procedure

1. Remove all aliquots of PCR reagents (2× nanobuffer, Taq DNA polymerase, ddH_2O) from the freezer. Vortex and spin down all reagents before opening the tubes.
2. Prepare multiplex PCR mix as follows (volumes indicated per specimen).

Component	Volume (μL)
2× nanobuffer	6.0
F/R primers (10 μmol/L)	1.0
Taq DNA polymerase (5 U/μL)	0.2
ddH_2O	3.3
Total	11.5

3. Add 11.5 μL of PCR mix and 0.5 μL of plasmid into a 0.2 mL PCR tube.
4. Turn on thermocycler and preheat the block to 94°C.
5. Spin the sample tubes in microcentrifuges at 14,000 × *g* for 30 s at room temperature.

TABLE 80.1
Primers Used to Amplify the NS1 Gene (1989 bp) and the Primers Used to Amplify a Porcine Parvovirus (PPV)-Specific 142-bp Portion of the NS1 Gene

Fragment	Length (bp)	Primer Sequence (5′–3′)	Enzyme Sites
NS1	1989	F: 5′-CCGGAATTCATGGCAGCGGGAAACAC-3′	*Eco*RI
		R: 5′-ACGCGTCGACGTTATTCAAGGTTTGTTG-3′	*Sal*I
NS1 (nt 1694–1835)	142	F: 5′-AGCCAAAAATGCAAACCCCAATA-3′	
		R: 5′-CTTTAGCCTTGGAGCCGTGGAG-3′	

Source: Cui, Y. et al., *Lett. Appl. Microbiol*., 58, 163, 2013.
F, forward primer; R, reverse primer.

6. Place the sample tubes in thermocycler for 30 cycles at 94°C for 30 s, 55°C for 30 s, 72°C for 30 s, and a final elongation of 72°C for 10 min.
7. After amplification, pulse-spin the reaction tubes to pull down the condensation droplets at the inner wall of the tubes. The samples are now ready for the electrophoresis or stored frozen at –20°C.
8. Analyze the PCR products by agarose gel electrophoresis through 1% agarose gel in Tris-acetate-EDTA (TAE) buffer at 120 V for 30 min.
9. Stain the gel with ethidium bromide and then visualize under ultraviolet light source.

80.2.2.2 Nucleic Acid Probe Detection of PPV

DNA probe: Specific gene of PPV is cloned into pUC-plasmid and then digested by endonucleases and labeled with biotin or isotope before use [22].

80.2.2.2.1 Procedure

1. *Spotting*: Take an appropriate size nylon membrane, mark the grid, add DNA samples at the center of membrane, and air dry.
2. *Denaturation*: Put the nylon membrane on the double filter paper saturated with denaturing solution for 10 min.
3. *Neutralization*: Move the nylon membrane onto the double filter paper saturated with neutralized solution and leave it for 5 min; dry the membrane at 37°C for 30 min and then bake it in an oven at 120°C for 30 min to fix the DNA.
4. *Prehybridization*: Transfer the nylon membrane in hybridization tube, add prehybridization solution, and leave it in the hybridization furnace 68°C for 2 h.
5. *Hybridization*: Denature the probes for 10 min in boiling water, immediately quench for 5 min in ice water, remove the hybridization tube, decant prehybridization solution, and then add the denatured DNA probe, and hybridize at 68°C overnight.
6. *Washing the membrane*: Follow instructions of the kit insert.
7. *Chromogenic reaction*: Place the membrane in chromogenic solution; once spotting spots change color, add TE buffer to terminate chromogenic reaction.

80.3 CONCLUSION AND FUTURE PERSPECTIVES

PPV is a small, ssDNA virus that is responsible for causing reproductive failure in swine worldwide. The significant expansion in human populations in recent decades has created a huge demand for large-scale pig farming, which in turn has contributed to a marked rise in the incidence of PPV infections.

For the diagnosis of PPV infection, serological assays (especially hemagglutination and hemagglutination inhibition test) have been widely applied. Nonetheless, virus isolation remains valuable for precise and complete determination of PPV. Due to their high sensitivity, specificity, reliability, and rapid turnover, molecular techniques (e.g., PCR and nucleic acid probes) have been used with increasing frequency in clinical diagnostic laboratories. Further development in automation will help streamline the diagnostic operation for PPV infection.

Currently, no specific treatment is available for PPV infection. The widespread and resistant characteristics of this virus make its control difficult. Regular vaccination of the breeding stock is still the most effective preventive measure for PPV infection [1,5]. Although the first vaccines were developed in the late 1970s [29,30], the constant evolution and mutation of PPV and identification of novel PPVs (e.g., PPV2, PPV3, PPV4, PPV5, and PPV6) [7–10,31–37] have reduced the effectiveness of existing vaccines. Continuing efforts to develop new vaccines, including genetic engineered vaccines, that take account of virus mutations and emergence of novel strains are vital to strengthen control and prevention campaigns against PPV infection.

81.1 INTRODUCTION

Increased production of waterfowl and ornamental birds in recent years has heightened the epidemiological risk of poultry diseases, especially those of viral origins. Viral diseases cause significant losses in birds and reduce the profitability of the poultry industry.

Polyomaviruses represent an important group of pathogens that affect birds and mammals. For example, hemorrhagic nephritis and enteritis of geese (HNEG) viruses are responsible for causing severe disease in waterfowl, and budgerigar fledgling disease virus (BFDV) is associated with health problem in ornamental birds [1,5,28]. Currently, avian polyomaviruses (APyVs) are widely distributed throughout the world. While chronic cases dominate in Europe, acute cases of high mortality are diagnosed in the United States and Canada [5,6,21].

Focusing on polyomaviruses infecting birds, this chapter provides an overview on their characteristics, clinical symptoms, pathological changes, and most aspects of its diagnosis [1,5,6,11,16,21,24,32,33].

81.1.1 Classification

Polyomaviruses are classified in the *Polyomaviridae* family, which consists of three genera: *Avipolyomavirus*, *Orthopolyomavirus*, and *Wukipolyomavirus*, according to the recent recommendation by the International Committee on Taxonomy of Viruses [16]. In addition, there are a number of viruses with similarities to members of the family *Polyomaviridae* that have not been assigned to a polyomavirus species.

The genus *Avipolyomavirus* is divided into five species: avian polyomavirus (formerly known as budgerigar fledgling disease virus), canary polyomavirus, crow polyomavirus, finch polyomavirus, and goose hemorrhagic polyomavirus (GHPV) [15,16]. HNEG syndrome is caused by GHPV. The phylogenetic analysis revealed small differences in the nucleotide sequences of the VP1 protein of GHPV isolates [6].

The genus *Orthopolyomavirus* is known to have at least 16 species, including B-lymphotropic polyomavirus (formerly known as African green monkey polyomavirus), baboon polyomavirus 1 (formerly known as simian agent 12),

BK polyomavirus, bovine polyomavirus (BPyV), John Cuningham (JC) polyomavirus, simian virus 40 (SV40, type species; formerly known as simian vacuolating virus 40), etc.

The genus *Wukipolyomavirus* is composed of four species: human polyomavirus 6, human polyomavirus 7, KI polyomavirus (formerly known as the Karolinska Institutet polyomavirus), and WU polyomavirus (formerly known as the Washington University polyomavirus).

81.1.2 Morphology, Genome Organization, and Biology

81.1.2.1 Goose Hemorrhagic Nephritis and Enteritis Virus

HNEG syndrome was first described in 1969 in Hungary. The disease was initially called the "disease of young geese" or "late Derzsy's disease form [3]." A few years later, it was described in Germany and France. This epizootic has become a serious problem since the late 1980s. So far, it was mostly observed in geese, because mallard and Muscovy ducklings are resistant to the infection. The etiological agent of the disease was described 30 years later by a French researcher, Guerin [11,12].

The etiological agent of the disease is a DNA virus with a virion diameter of 40–50 nm. Its buoyant density is of 1.20 g/cm^3 in sucrose gradient, while in the cesium chloride, it is of 1.35 g/cm^3 [6,11].

GPHV genome consists of a circular double-stranded DNA of approximately 5200 bp (5256 bp). There are five open reading frames (ORFs), which encode the following proteins: large T antigen, small T antigen, and proteins VP1, VP2, and VP3. In addition, one reading frame (ORF-x) is located in the 5′ region of the mRNA and encodes a 169 amino acid sequence, which has a low degree of homology (11.2%) of the VP4 protein of other APyVs. Encoded viral proteins are shown in Table 81.1 [17].

GHPV is very resistant to heating and retains full virulence even after 2 h of heating at 55°C. It is also resistant to freezing and thawing, as well as to fat solvents [17].

TABLE 81.1
Proteins Encoded by the Genome Goose Hemorrhagic Polyomavirus

Name	Genome Localization	Number of Amino Acid	Molecular Weight (kDa)
Large T antigen	5256–4960 4767–3157	636	71,966
Small T antigen	5256–4776	160	18,487
VP1	1965–3023	353	38,542
VP2	1085–2062	326	35,109
VP3	1412–2062	217	24,658
ORF-x	349–426 500–928	169	16,756

81.1.2.2 Budgerigar Fledgling Disease Virus

Budgerigar fledgling disease (BFD) occurs in young, feathering parrots. The first cases of the acute form of the disease were described in North America and Europe in the 1980s. Then, it was given the name "French moult." The disease occurred in the south of France in large aviaries, mainly in budgerigar *Melopsittacus undulatus* genus [4,13].

BFDV has been identified as the first avian virus of the family *Papovaviridae*. Its virions are icosahedral and nonenveloped, and their diameter is 42–49 nm or 50–55 nm [4,7].

By understanding the complete DNA sequence of the virus, its similarity to monkey virus (SV 40) and mouse virus (SE [S.E. polyomavirus]) was demonstrated.

It was found that BFD is caused by BFDV-1, although other strains were isolated from chickens and parrots [19].

Early BFDV regions encode large and small T antigens, and the late region encodes three structural capsid proteins: VP1, VP2 and VP3. Large T antigens play a role in the lytic and neoplastic transformation. The presence of protein agno-2a was also confirmed. The protein appeared to be involved the later phase of the infection in the process of cell lysis. Additionally, BFDV does not agglutinate chicken, turkey, budgerigar, and guinea pig red blood cells [7,19,30].

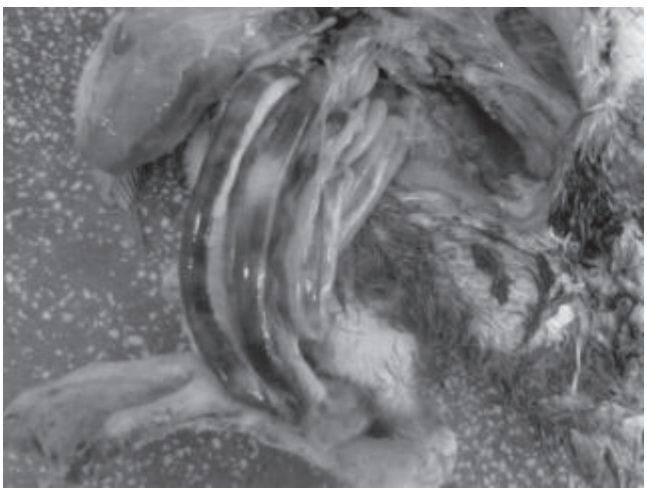
81.1.3 Clinical Features and Pathogenesis

81.1.3.1 Hemorrhagic Nephritis and Enteritis of Geese Virus

Goslings are susceptible to GHPV infection, although experimental infection was also reported in ducklings. Infected birds excrete virus in the feces to the environment. There was no transmission of the infection by vectors.

So far, the vertical transmission of the virus was not described, but the DNA GHPV already was observed in 4-day-old ducklings, which may indirectly indicate the existence of a vertical route of infection [8].

The incubation period of the disease depends on the age of the birds. After the infection of 1-day-old goslings, the disease symptoms are visible after 68 days, while in the case of 3-week-old goslings after 15 days. In older birds, the infection is usually subclinical.



HNEG syndrome is generally described in growing geese between 4 and 10 weeks of age. The mortality rate of the birds in the flock can range from 10% to 80%, and clinical symptoms are visible only a few hours before death. Birds sit alone or focus on the source of warmth, and listlessness and opisthotonus are visible. In the chronic form, several deaths of birds per day up to the age of 12 weeks were observed. In the feces, partly digested blood can be seen [2,18].

During the necropsy, subcutaneous edema, ascites (liquid with the consistency of gelatin), enlargement and inflammation of the kidneys, and bleeding in the intestinal mucosa are observed (Figure 81.1). Urate deposits in the internal organs and joints are often found.

The only form of prevention of the disease is bioasecuration consisting in properly done disinfection of premises, equipment,

(a)

(b)

FIGURE 81.1 Necropsy changes in the intestine of geese with bleeding occurring in the intestinal mucosa (a, external; b, internal).

and catwalks. It is recommended to use disinfectants based on chlorine compounds. In addition, a sound selection of birds during rearing, a good quality feed, and avoiding stress in birds should prevent the occurrence of the disease in geese. HNEG is supposed to have no public health implication [29].

81.1.3.2 Budgerigar Fledgling Disease Virus

All species of parrots show susceptibility to the infection. Young budgies, macaws, great lory, and lovebirds are the most susceptible to the infection.

The route of infection with BFDV is not fully understood. It is believed that the infection may occur in vertical and horizontal route [13].

Asymptomatic carriers may be in the aviary. In the case of a horizontal route, the infection of adult birds should take place during feeding. Moreover, the infection can occur by aerogenic route and by contaminated water.

Budgies aging 1–23 days become frequently affected. However, the occurrence of characteristic clinical symptoms depends on the age and condition of the birds. Usually, the birds thrive for 10–15 days, despite the existence of BFDV infection in aviary. Then, it comes to a halt in the volumetric content of food and to sudden deaths of birds. On the other hand, abdominal edema, skin discoloration, bruising under the skin, torticollis, and ataxia can be observed in other birds [13].

There is a decline in hatchability by 90%. At the same time, hatched chick mortality rate increases from 10% to 60% [30].

In birds, which survived the infection, plumage disorders, most commonly in the form of dystrophy of feathers including tail feathers, occur [19].

During the necropsy, significant abdominal edema, skin redness, or bruising is observed. In infected birds about 50% less body weight compared to healthy birds is noticed. Additionally, there are hydropericardium, numerous pallor myocardial necrotic foci, hepatomegaly, ascites, and splenomegaly observed. The liver may be enlarged, congested, or with numerous necrotic foci [37].

The best way to prevent the infection is the detection and elimination of sick birds and carriers.

Specific immunoprophylaxis is performed with the use of inactivated vaccine. The vaccination of all birds in the aviary or home breeding is recommended. A suitable bioasecuration is also important [29].

81.1.3.3 Polyomaviruses in Other Birds and Mammals

81.1.3.3.1 Polyomaviruses in Other Passeriformes

Polyomaviruses in *Passeriformes* are also morphologically and antigenically similar to each other. However, clinical signs and postmortem lesions vary widely between budgerigar and large birds in the parrot family.

The characteristic feature observed often in large young birds is a peracute form of the disease without any clinical symptoms [13].

The acute form is characterized by mortality among birds occurring within 12–48 h after the infection and clinical symptoms in the form of depression, anorexia, body weight loss, diarrhea, bleeding under the skin, difficulty breathing, and polyuria.

During the postmortem examination, the clear fluid in the abdominal cavity, fibrin deposits in visceral organs, and small pale spleen are observed [13].

81.1.3.3.2 Polyomaviruses in Finches

In young and older birds with acute mortality, disturbances in the shape of the beak (most common in young birds) were demonstrated. In addition, increased mortality, hepatitis, nephritis, and dermatitis on the head were observed [15].

81.1.3.3.3 Bovine Polyomavirus

BPyV was first described by Rang et al. as a contaminant of macaque kidney cell cultures. The source of infection was contaminated calf serum, which was used for the preparation of cell culture. Its occurrence was also described in the sewage and sediment from the slaughterhouse and waters of the rivers polluted by sewage farms. The virus was present in urban

sewage. BPyV was detected in about 30% of the bovine urine samples. It has also been shown that 70% of the bovine serum may contain polyomavirus. The virus does not induce any disease in cattle so far; however, it plays an important role in biotechnological techniques in which calf serum is used [14,22,34,35].

BPyV is a circular double-stranded DNA, 4697 bp in size, corresponding with 89.6% of the size of SV40). Its similarity to other polyomaviruses is about 58.6% [14,38].

81.1.3.3.4 Polyomavirus in Ducks

Polyomavirus infection in Muscovy ducks (*Cairina moschata*) and mule ducks (hybrid from a Muscovy duck and Pekin duck) was recently described.

Weight loss, dysfunction in plumage, and increase in the number of secondary bacterial infections and mortality were recorded in the birds [26].

81.1.3.3.5 Polyomavirus in Baboons

Polyomavirus was isolated from the baboon's kidneys and the presence of polyomavirus antibodies in the baboon's sera was observed [10,27].

81.1.4 Diagnosis

81.1.4.1 Conventional Techniques

81.1.4.1.1 Hemorrhagic Nephritis and Enteritis of Geese Virus

In differential diagnosis, Derzsy's disease and mineral–vitamin deficiency should be considered primarily, and then bacterial infections (pasteurellosis) and gout.

Laboratory diagnosis is based on virological examination with regard to virus isolation, molecular biology techniques, and histopathology. Isolation of the virus is performed in cell cultures (kidney cell culture), but especially in the embryos of geese. Serological examination is useless [12].

81.1.4.1.2 Budgerigar Fledgling Disease Virus

Circovirus infection should be considered in the differential diagnosis. In older birds, the circovirus and polyomavirus infection may exist at the same time.

Currently, conventional methods such as serological methods are not widely applied, but they are used in research [13,36].

In budgerigars, specific antibodies can be detected already around 10 days after infection, while in other bird species on 14–18 days of age. The maximum antibody level is found in birds 4–6 weeks of age [31].

Histopathological examination, which allows detecting inclusion bodies in the internal organs, and gel immunodiffusion are among other possible serological methods [37].

Virological methods, which involve the multiplication of the virus in cell cultures prepared from tissues of sick birds, are also used, but these methods are time consuming. The presence of virus particles in tissues (inclusion bodies) is demonstrated by electron microscopy [13].

81.1.4.2 Molecular Techniques

HNEG virus: PCR and real-time PCR are used to detect DNA of the virus. Total DNA is isolated from the spleen, liver, kidneys, cloacal swabs, and blood. However, it should be remembered that in the case of blood, the virus is present only for about a month after infection. Primers for the amplification reaction are based on the sequence of the VP1 gene [20,21,23,25].

BFDV: Currently, PCR method was applicable for the detection of viral DNA in the blood and cloacal swabs. For molecular examination, the mucosa swabs and feather samples may also be used [9,23,25].

81.2 METHODS

81.2.1 Sample Preparation

81.2.1.1 Hemorrhagic Nephritis and Enteritis of Geese Virus

81.2.1.1.1 Preparation of Internal Organ Sample

1. Obtain 5–10 sick live birds from the flock or internal organs (liver, kidneys, intestine) from sick birds.
2. After necropsy, homogenize sections of the internal organs immediately.
3. Suspend 1 mL of the homogenate of internal organs in a liquid PBS containing 500–1000 IU/mL of penicillin and 50–10 mg/mL of streptomycin, or 1 mL/100 mL of a mixture of antibiotics (Antibiotic-Antimycotic, Gibco).
4. Centrifuge at 1600 × *g* for 20 min at 4°C.
5. Collect supernatants and filter through a Millipore filter with a pore diameter of 45 μm.
6. After confirmation of sterility, inoculate the filtrate into blood agar plates, and/or goose embryo cell cultures.
7. Store remaining filtrate at –20°C.

81.2.1.1.2 Isolation of Total Cellular DNA

Commercial kits are recommended for the isolation of total cellular DNA from 1 mL of organ homogenate.

81.2.1.1.3 Preparation of Goose Embryo Fibroblast Cells (GEF)

1. Disinfect the shells of eggs (at the age of 13–15 days from flocks no evidence of infectious diseases) with 70% alcohol.
2. Remove the embryos to sterile Petri dish and then remove the eyes, wings, legs, and internal organs.
3. Powder the embryos with scissors and rinse four times with PBS at temperature 37°C to remove red blood cells.

4. Trypsinize (0.25% trypsin) the material on a magnetic stirrer two times for 15 min and after each trypsinization filter the material through a layer of gauze. Use about 20 mL of trypsin per embryo.
5. Centrifuge for 5 min at 800 × *g*.
6. Decant supernatant and add 9 mL of Eagle fluid and 1 mL of calf serum to cell pellet.
7. Centrifuge 2–3 min at 1200 × *g* and remove the supernatant.
8. Suspend the cell pellet at a dilution of 1:400 in growth liquid containing: Eagle's fluid, with 1% of antibiotics (Gibco) and 10% of calf serum. Keep cell density at approx. 1 × 106 in 1 mL of suspension.

81.2.1.2 Budgerigar Fledgling Disease Virus

1. Blood, cloacal and mucosal swabs, feather follicles, and visceral organs (liver, heart, spleen, kidney, lung) can be used.
2. For the isolation of total cellular DNA from feathers follicles, swabs, and visceral organs, commercial kits are recommended to be used.

81.2.2 Detection Procedures

81.2.2.1 Isolation of Hemorrhagic Nephritis and Enteritis of Geese Virus

1. Inoculation of goose embryos
   a. For the isolation, 10–15-day-old goose embryos are used. The embryos are inoculated with homogenates of internal organs into the allantoic cavity (CAV).
   b. Indicate the air chamber and a point located approximately 1–1.5 cm below the air chamber line on the side of the embryo between the large blood vessels. Marked places on the shell should be disinfected with iodine.
   c. Using a metal drill, make a hole at the site of inoculation and the air chamber.
   d. Insert 0.2 mL of test material into the allantoic cavity.
   e. Introduce 0.2 mL of liquid PBS to control embryos.
   f. Use 3–5 embryos for each material.
   g. The embryos are incubated at 37°C at a relative humidity of about 70%.
   h. The embryos must be examined every day for 8 days.
   i. The dead embryos must be rejected within 24 h p.i., and the fluid of embryonic membranes is taken after 8 days from all dead and cooled (24 h in a refrigerator) embryos and from the liver.
   j. During the collection of the material, necropsy lesions should be evaluated.
   k. In addition to changes characteristic of HNEG in the form of congestion in embryonic membranes, embryos, and liver, necrotic foci may also be present.
2. Inoculation of the GEF cell culture
   a. The cell cultures are infected with a viral material (homogenate of visceral organs) after the 24 h of incubation period.
   b. The infected cultures are incubated in an incubator at 37°C with 5% CO_2 and 85% humidity. The cell culture should be observed every day under the microscope. The infected cultures create a cytopathic effect (CPE) after 5–7 days of incubation. The cells shrink and become fine and highly refractile. Gradually, the single cell layer becomes disrupted. Syncytia are also visible.
   c. If CPE is not observed in the first passage, two to three other passages are performed.

81.2.2.2 Gel-Based PCR

1. Reagents

Primers (oligonucleotides)

PCR Kit:

   a. PCR buffet
   b. A mixture of deoxynucleotides (dNTPs)
   c. $MgCl_2$
   d. Thermostable DNA polymerase
   e. 1 M betaine solution (*N*, *N*, *N*—trimethylglycine)
   f. Double-distilled water

Reagents for electrophoresis:

   a. 10× TBE (Tris/Borate/EDTA) buffer concentrate: the buffer is used for electrophoresis. To 100 mL of the buffer, add 900 mL of bidistilled water.
   b. 1% or 2% agarose gel: dissolve 1 g (1% agarose gel) or 2 g (2% agarose gel) agarose in 100 mL 1× TBE buffer concentrate. The suspension should be warmed up to complete the dissolution of the agarose.
   c. DNA molecular weight marker (commercial).
   d. Loading buffer for DNA samples (commercial).
   e. Ethidium bromide solution.
2. PCR setup
   a. The isolated DNA is verified by electrophoresis on a 1% agarose gel. Electrophoresis is performed at 120 V for about 1 h. After electrophoresis, the gel is stained with ethidium bromide solution for about 20 min. Visualization and recording of the results of electrophoresis are performed using a gel documentation kit.
   b. The primers should be diluted with redistilled water, in accordance with the manufacturer's instructions, to a concentration of 10 μM. The volume of the reaction mixture used in the PCR

method is 25 μL (for each sample) with the following ingredients:

i. PCR buffer—2.5 μL
   – dNTPs—1 μL
   – $MgCl_2$—1 μL
   – Primer GPOL1—1 μL
   – Primer GPOL2—1 μL

Primers	Amplified Gen	Primer Sequence
GPOL1	VP1	GAG GTT GTT GGA GTC ACC ACA ATG
GPOL2	VP1	ACA ACC GTG CAA TCC CAA GGG TTC

   – Betaine—4 μL
   – DNA polymerase—0.5 μL
   – Double-distilled water—11 μL
   – 3 μL of the isolated DNA added to the prepared mixture
   – The PCR conditions are outlined as follows:

Reaction	Temperature (°C)	Time (min)	Number of Cycles
Initial denaturation	95	5	1
Denaturation	94	1	35
Annealing	60.2	1	
Elongation	72	1	
Final elongation	72	10	1

3. Electrophoresis of PCR products and result analysis

Electrophoresis is performed in a 2% agarose gel (2 g + 100 mL of electrophoresis buffer 1× TBE). Electrophoresis occurs at a constant voltage of 120 V for approximately 50 min. After the electrophoresis, the gel is stained in ethidium bromide solution for about 20 min and viewed using a gel documentation kit.

A positive PCR result indicates the presence of PCR product of 570 bp.

81.2.2.3 Real-Time PCR

1. The primers for this reaction are based on the sequence of the VP1 protein GHPV (Leon):

Primers	Sequence (3′–5′)	Position on VP1 Gene
VP1F	GAG GTT GTT GGA GTG ACC ACA ATG	396–419
VP1R	ACA ACC CTG CAA TTC CAA GGG TTC	516–539
VP1-SBF	GAT GGT GCT TAT CCG GTG GA	645–664
VP1-SBR	TTC ATT CCG GGA TGG GTC	678–695

2. Real-time SYBR Green
3. 95°C—5 min, 35 cycles (initial denaturation); 94°C—30 s (denaturation); 52°C—30 s (annealing); 72°C—40 s (elongation); 72°C—10 min (final elongation)

81.2.2.4 PCR for Budgerigar Fledgling Disease Virus

1. Primers (oligonucleotides)

Primers	Sequence (3′–5′)	Position on VP1 Gene
BFDV1	CTT ATG TGG GAG GCT GCA GTG TT	2183–2206
BFDV2	TAC TGA AAT AGC GTG GTA GGC CTC	2709–2732

2. PCR conditions

Reaction	Temperature (°C)	Time	Number of Cycles
Initial denaturation	95	5 min	1
Denaturation	94	30 s	40
Annealing	56	30 s	
Elongation	72	4 min	
Final elongation	72	10 min	1

Electrophoresis of PCR products is performed in the same way as before. A positive PCR result indicates the presence of PCR product of 550 bp.

81.2.2.5 Histopathological Examination

For both HNEG virus and BFDV, the following apply:

1. Section of internal organs should be fixed in 10% buffered formalin, and then paraffin sections stained with hematoxylin and eosin are prepared.
2. During the microscopic examination, the following characteristic lesions for GHPV are observed: necrotic–hemorrhagic foci on the duodenum and jejunum, degenerative epithelial tubular lesions on the kidneys, and marked pyknosis on the medullar area of bursa Fabricius lobules.
3. During the microscopic examination of the liver, lesions characteristic of BFDV are observed: multifocal to confluent hepatic necrosis, mild accumulation of heterophils, and amphophilic intracellular inclusions in hepatocytes.

81.3 CONCLUSION

Recent findings suggest a significant spread of APyVs in duck populations worldwide [5,8]. Due to the limitations of current diagnostic methods, polyomavirus infections may have been under-detected. Besides occasional isolations from clinically healthy birds, polyomaviruses are often isolated from geese displaying the clinical form of Derzsy's disease. Future study on improving intravital and serological diagnosis is clearly relevant, which will contribute to the elimination of infected birds from flocks.

82.1 INTRODUCTION

Papillomatosis is generally described as a group of diseases/disorders in which the most notable clinical symptoms are hyperkeratotic lesions that lead to tissue damage. It has been found in virtually all vertebrate species, including reptiles, birds, and mammals [1]. The correlated lesions are usually characterized as warts or papillomas, and their development may result in different grades of cutaneous and/or mucosal tumors, including cancers. Among mammals, human and bovine papillomatosis have been best studied. It has been shown that bovine papillomavirus (BPV) has the ability to infect other hosts, particularly equines, causing a disease known as sarcoids. Furthermore, malignant tumors are also associated with BPV infection in cattle.

Lesions related to bovine papillomatosis have commonly been found in the form of cutaneous, genital mucosa and orofaringeous papillomas in 2-year-old animals [2]. Bovine papillomas are benign lesions, which generally regress but occasionally persist and undergo a malignant transformation into squamous cell carcinoma, as in the cases of urinary bladder and upper alimentary canal cancers [3]. However, some animals are unable to resolve their lesions and succumb to widespread cutaneous or mucosal involvement. These forms of papillomatosis are troublesome and of economic significance [4], because in addition to causing a depreciation in the value of pelt, teat papillomas reduce the lactation period, and the affected sites may become vulnerable to injuries and infections. Moreover, cattle infected with BPV are susceptible to extensive hyperproliferative lesions in the upper gastrointestinal tract and, as a result, experience difficulty in feeding and breathing and thus become debilitated [5]. Perhaps, one of the most severe consequences of bovine papillomatosis is enzootic hematuria, in which bladder lesions show malignant progression in cattle that feed on bracken fern (*Pteridium aquilinum*) [6]. Thus, bovine papillomatosis has a serious economic effect on livestock farming.

The widely recognized causative agent associated with bovine papillomatosis is the BPV group [4]. BPVs are members of the *Papillomavirus* (*PV*) genus, a group of epitheliotropic viruses that often cause asymptomatic infections [7]. This group of papillomaviruses was originally described as species specific, but, in recent years, some types have been implicated in cross-species transmission events.

An equine skin tumor, described as equine sarcoid [8], has often been diagnosed in equids [9]. Although its lesions are hyperproliferative, in the same way as those from bovine papillomatosis, sarcoids very rarely regress; in fact, it is more common for them to persist and to be locally aggressive. Six clinical types of sarcoids have been classified so far: occult, verrucous, nodular, fibroblastic, mixed, and malignant [10]. Sarcoid-bearing species include horses, zebras, donkeys, tapirs, and mules [11–15], and its lesions have often been found in the skin of the lower abdomen, head, neck, and limbs [16,17]. In general, these tumors do not metastasize, and although they may have different levels of invasiveness, some sarcoids may cause ulceration as well. When they occur near the eyes or on the eyelids, they may impede vision. Equine sarcoids seem to be a disease confined to young horses, since they rarely affect horses older than 7 years [18].

Despite their differential progression as a disease, bovine papillomatosis and equine sarcoids share a common factor;

both have the same oncogenic virus as an etiological agent: the well-known BPV [4]. While all BPVs are strictly species specific, BPV-1 and BPV-2 have been reported in cross-species infection, which allows infections to occur in a wide range of hosts between bovids and equids. Important financial considerations are involved in both cattle and horse breeding, which means that diagnostic tools are essential to define BPV-related epidemiological factors and therapeutic approaches. In view of this, a good deal of research is being carried out in the hope of making advances in early BPV detection so that new guidelines can be drawn up about how to deal with animal papillomatosis. In this chapter, we describe important aspects of BPV infection, including the most recent and accurate molecular techniques for the diagnosis of these diseases.

82.1.1 Classification

The *Papillomaviridae* family comprises 18 genera (*Alphapapillomavirus* to *Sigmapapillomavirus*), in which each genotype is distributed in accordance with its genomic DNA sequence similarity [19]. The standard method employed to characterize a new BPV type is by sequence determination of the highly conserved L1 region and by phylogenetic analysis [20]. Thirteen BPV types are known, and these have been classified into three genera: *Deltapapillomavirus* (BPV-1 and BPV-2), *Epsilonpapillomavirus* (BPV-5 and BPV-8), and *Xipapillomavirus* (BPV-3, BPV-4, BPV-6, BPV-9, BPV-10, BPV-11, and BPV-12). In the past few years, BPV-7 has been reported and still remains unclassified [21–23]. It has been suggested that BPV-7 may represent a member of a new *PV* genus. BPV-13 is one of the most recent types reported so far [24]. BPV types also cause some characteristic histopathological lesions, which allow a classification to be made. Xipapillomaviruses are strictly epitheliotropic, Deltapapillomaviruses induce fibropapillomas, and Epsilonpapillomaviruses appear to cause both fibropapillomas and true papillomas [22]. Members of the *Deltapapillomavirus* genus have been implicated in the development of equine sarcoids [23]. Until now, only three types of BPV (BPV-1, BPV-2, and BPV-4) have been associated with cancer. BPV-1 and BPV-2 cause urinary bladder tumors, while BPV-4 causes cancer in the upper alimentary tract.

82.1.2 Genome Organization

The BPV viral structure follows a general pattern shared by all virus-like particles. It can be described as a 52–55 nm diameter icosahedral protein capsid composed of two protein types: a major protein structured in 72 oligomeric complexes and 12 copies of minor transcapsid DNA-bound protein, L1 and L2, respectively [25]. While L1 protein plays an essential role in viral particle anchorage [26], L2 minor capsid protein is necessary for viral morphogenesis [25]. This small and nonenveloped capsid has a size of 8 kb, and is a circular, double-stranded DNA genome, which includes a long-control region (LCR) and two gene groups, early (E) and late (L) [27]. The LCR is composed of 500–1000 nucleotides; although it does not comprise genes, it contains transcriptional regulatory and replication origin sites [28]. The E and L coding regions follow a time-dependent expression pattern during the virus cycle [29].

The E region in the PV genome usually contains six early genes, although the same genes may not be present in all the PVs and their sequences may not be conserved. The E1 protein has helicase activity and plays a role in the viral replication [30]. The E2 gene product is a transcriptional factor and is also involved in recognition and ligation to the replication origin. In addition, it has mitotic chromosome binding activity to ensure an equal distribution of the viral episomes among the daughter cells [31]. The E4 gene produces a small protein within the E2 gene but in a different reading frame. Without a clear function as described in the BPV infection, this small protein is found within profuse cytoplasm of keratinocytes during productive replication [32].

Two early proteins are necessary for the BPV-mediated carcinogenesis: E5 and E6 [3]. BPV E5 is a membrane-associated hydrophobic protein, which plays a role in disrupting cellular growth control. It has been shown that BPV-1 E5-expressing mouse fibroblast cell lines exhibited a transformed phenotype as well as nonimmortalized human foreskin fibroblasts [33–35]. In cultured cells and animals, the transforming activity of BPV-1 E5 can be assumed to be a consequence of its ability to bind and activate the cellular platelet-derived growth factor β receptor [36]. BPV E6 protein is known to have a large number of binding partners and activities in the virus life cycle [37–39]. In *Xipapillomavirus*, the E6 gene is replaced by an E5-like gene, which was initially defined as E8. However, when it was found that most of the functions of this protein are shared with BPV-1 E5, this prompted its redefinition as E5 [4]. Unlike oncogenic human papillomavirus (HPV) E7 protein, which has a great carcinogenic potential, BPV E7 protein just appears to be cooperating with E5- and E6-mediated cell transformation, since its expression only increases the transformation efficiency [40].

82.1.3 Transmission, Clinical Features, and Pathogenesis

The BPV group is responsible for a wide range of diseases, the clinical symptoms of which can be summarized as outcomes of diverse hyperproliferative lesions. However, each subgroup can be specifically associated with some particular lesions in its host, particularly, in bovines.

Deltapapillomaviruses, known as fibropapillomaviruses, cause fibropapillomas, which involve subepithelial fibroblasts, followed by epithelial acanthosis and papillomatosis, in a hyperproliferative process. Although these infected fibroblasts may harbor multiple episomal copies of the BPV genome (commonly, BPV-2), it is not usual to be able to detect a mature virus or its antigens from tumors in the upper alimentary tract [41]. Fibropapilloma persistence, which can be attributed to environmental cofactors, may also allow mesenchymal cancers to develop such as bladder cancer. BPV-1 has been found in teat and penile fibropapillomas, while BPV-2 is linked to cutaneous warts, alimentary fibropapillomas, and

urinary bladder tumors; all these are members of the fibropapillomavirus group [42].

Epitheliotropic BPVs (Xipapillomaviruses) induce epithelial papillomas without fibroblast involvement. BPV-3 causes general cutaneous papillomas. BPV-4 has been implicated with epithelial papillomas, which are located in the upper gastrointestinal tract. BPV-6 is often isolated from multiple teat papillomas. BPV-9 and BPV-10 are associated with epithelial squamous papillomas of the udder. Epsilonpapillomaviruses are involved in tumor development and are of both mesenchymal and epithelial origin. BPV-5 induces rice grain fibropapillomas, which are usually found in the udder, while BPV-8 causes cutaneous papillomas. Furthermore, the detection of two or more BPV types in the same animal may be a frequent event that has consequences for diagnosis and treatment. Coinfections by BPV-1 and BPV-2 [43] or even detection of different genera of BPVs in the same animal have already been reported [44,45].

In a similar way to the expression patterns exhibited by several PVs, BPV replication during acute infection is linked to the differentiation status of the infected cell. Papilloma development is preceded by infection of basal keratinocytes, where a set of early genes is expressed in the undifferentiated basal and suprabasal layers. BPV replication has only been detected in keratinocytes undergoing terminal differentiation to squamous epithelium, as well as L gene expression, where it corresponds to structural proteins. In the differentiating spinous and granular layers, new virus particles are encapsidated and released into the environment when the cells die. In fact, a complete viral cycle seems to be strictly performed in the epithelial component of the BPV-associated tumors and only at certain stages of its development. It should be noted that even in BPV-containing fibroblasts, virus replication has never been found in these cells, and the viral genome remains in a nonintegrated episomal form [46]. In addition to environmental cofactors, such as immune suppression by bracken fern ingestion, malignant transformation is an outcome of deregulated expression and is especially linked to the upregulation of the early viral genes (E5 and E6 genes), which results in an uncontrolled proliferation and delay or a lack of cell differentiation [47].

In general, transmission is made possible by the exposition of the basal layers, where viral particles may have access to primary keratinocytes and fibroblasts. Viral-bearing fomites, like contaminated milking equipment, halters, nose leads, grooming and earmarking equipment, rubbing posts, and wire fences, may provide the means of transmission between animals [48]. Since warts are rare in animals that are artificially inseminated, it can be postulated that sexual transmission of papillomatosis can occur among cattle [49]. Moreover, arthropods like flies are probably an aggravating factor in bovine papillomatosis transmission, not only between bovines but also between horses [50,51].

82.1.4 Diagnosis

Traditional methods for virus identification include electron microscopy, cell culture, inoculation studies, and serology [52]. Although these techniques were responsible for the identification of many of the viruses known today, they have some obvious limitations, including time-consumingness and variability. On the other hand, molecular techniques provide a sensitive and rapid means of virus detection and identification [53]. PCR-based methods include conventional PCR, degenerated PCR, sequence-independent PCR, and rolling circle amplification.

82.1.4.1 Conventional Techniques

A commonly employed technique to diagnose whether a cutaneous lesion is induced by PVs is to conduct a histological analysis of the collected tissue. Papillomas induced by BPV in bovine have two classical patterns depending on the type of BPV involved. The true papillomas are composed of multiple papillary fronds of varying width, the surfaces of which are covered with the multiple-layered keratinized epithelium. There are also acanthosis and parakeratosis of the epithelium, and active viral replication takes place during development, resulting in inclusion bodies that are visible in the nuclei of the infected cells.

The BPV-induced fibropapilloma follows different recognized stages. Initially, the tumor develops as a fibroma, either alone or plus acanthosis. Histologically, an active proliferation of anaplastic fibroblasts with large nuclei gives rise to a subcutaneous mass stretching of the overlying epithelium. Subsequently, proliferation of basal and keratinocyte layers of the epithelium spreads downward toward the mesenchymal mass. In the epithelium, the granular cell layer becomes thicker, and clear central areas in the nuclei appear. Viral replication takes place in the nuclei and, once the cells develop into more differentiated layers, the viral particles spread from the cells among the keratinized plates. Finally, the tumor is infiltrated by macrophages and lymphocytes as the regression phenomenon takes place.

82.1.4.2 Molecular Techniques

Since the virus cycle of the PVs requires keratinocyte differentiation to express all the genes, there are no conventional cell lines that allow the growth of these viruses [54]. Moreover, the PVs cannot be transmitted to laboratory animals [55]. Hence, molecular methods have been widely used to discover and characterize the genome of the new PVs as well as to carry out a diagnosis of the PVs that are clinically significant [56].

The most commonly used molecular method to study PVs through their genome is the PCR. This methodology has been widely used to detect a broad range of PV types in human and animals. The PCR-based method has been routinely used on account of its high sensitivity (with the capacity to detect a few copies of PVs, DNA, and viral load samples) and specificity [57,58].

At present, there are several molecular assays that use PCR methods to investigate PVs. These methodologies essentially differ in the extent to which the PV gene segment is amplified and in the number of primers used. For clinical studies of PV prevalence, the most frequently used primer

sets are MY9/MY11, FAP59/64, and PGMY9/ PGMY11. These consensus primer sets were designed to amplify a partial sequence of highly conserved PV L1 genes. In addition, these primers made use of degenerate nucleotides that increase the range of PV detection, although they may lower their sensitivity [59]. The MY9/MY11 primer set is the most common method used to detect HPV infection in cervical samples [60]. These primers amplify approximately 450 base pair fragments and allow amplification of 47 HPV DNA types. The PGMY9/PGMY11 primer set is an extended version of the MY9/11 primer set, which allows the sensitivity to be increased to detect HPV types [61]. Alternatively, the association of fixed nucleotide primers, such as GP5+/GP6+, with degenerate nucleotide primers may be employed to increase their sensitivity to HPV.

Another PCR assay using FAP59/64 primers also amplifies a broad spectrum of HPV types. Similar to the MY09/11 primer set, the FAP59/64 primers have degenerate nucleotides and were designed to amplify a partial sequence of highly conserved PV L1 genes [62]. The FAP59/64 primers allow the detection of 46 HPV types. Apart from HPV, FAP59/64 and MY09/11 can be used to identify a broad range of animal PVs DNA. For instance, Ogawa et al. [63] showed that MY09/11 primers make it possible to detect BPV-1 and BPV-3. Moreover, the FAP59/64 primers can detect 13 BPV types [64,65] as well as putative new BPV types [63]. Furthermore, the use of FAP59/64 primers made it possible to identify PVs in chimpanzees, gorillas, macaques, monkeys, lemurs, cows, and elks [20].

More recently, real-time PCR has been used to detect PVs as well as viral load assessment. This method is based on the release of fluorescent markers at each amplification cycle, which is directly proportional to the amount of amplicon generated. The real-time PCR has been used to detect and quantify the viral load of human and animal PV types, such as BPV-1, BPV-2, BPV-12 [66,67].

BPV DNA is detected by a variety of PCR-based techniques. These techniques often involve the detection of one or two BPV types by using degenerated or type-specific primers. Genotyping is performed either by real-time detection [68] or by sequence analysis [69] or restriction fragment length polymorphism analysis [70] of the generated PCR fragments. The discovery of putative new types, subtypes, and variants are usually made in works that employ consensus primers capable of identifying potentially more than two BPV types [63]. Previous studies that involved consensus primers detected about 31 putative new BPV types [14,20,62,63,65,71]. Thus, it is believed that there may be an underestimation of the extent of the spread of BPV. Only 13 BPV types have been described so far, despite the great diversity found in HPV, and the use of consensus primers is a very important means of increasing our knowledge of BPV diversity. The use of consensus primers is also of great value in the investigation of novel PV types and shows that there is a need for this technique.

PCR that uses a type-specific primer is widely employed in research studies and allows BPV DNA to be amplified from different tissues and cells, such as epithelium, blood, spermatozoa, and oocytes [64,72–74]. A comparison between these consensus primers and the BPV type-specific primers showed that the BPV type-specific primers are more sensitive than the consensus primers and are able to detect coinfection of BPV in the tissues [74]. Several epidemiological studies employed on the herd in recent years have revealed a large number of coinfections caused by BPV [65,75,76]. This shows the importance of using BPV type-specific primers to reveal the real diversity of BPV that infects the herd.

82.2 METHODS

82.2.1 Sample Collection and Preparation

BPV DNA can be detected in samples of papillomas and the blood of symptomatic and asymptomatic cattle. Papillomas should be collected by parallel incision from different areas of the skin surface of the animal, using a disposable sterile scalpel.

In general, the chosen papillomas should be neither too early nor too chronic. During the procedure, it is important to use local anesthesia subcutaneously with 1–2 mL of 2% lidocaine and restraint. The incision should be made after 5 min of local anesthesia. One fragment of the collected papilloma must be separated and fixed in 10% formalin for later histological analysis, and the another fragment must be cooled for molecular analysis.

The blood should be collected by jugular venipuncture using EDTA-containing tubes. About 200 μL of total blood is used for the DNA extraction.

Several methods have been used for the extraction of BPV DNA from clinical samples prior to PCR amplification. In addition, commercial DNA extraction kits introduced by various companies are widely used for BPV DNA isolation. The DNeasy® Blood & Tissue from Qiagen, Germany, allows the DNA from papillomas and cattle blood to be isolated.

Using this DNA isolation kit, the DNA is extracted from small fragments of papillomas and blood. Briefly, 25 mg of cut papillomas is mixed with buffer ATL and proteinase K and incubated at 56°C, until the tissue is completely lysed. It is important to note that the papillomas are keratinized tissue samples, so vortex should be used during the process. After this, the buffer AL is added to the sample and then the ethanol (96%–100%) is mixed with the sample. The resulting mixture is pipetted to the column and centrifuged for 1 min. The flow-through is discarded and two buffers (AW1 and AW2) are added to the column and centrifuged. Finally, the buffer AE is introduced onto the column and incubated for 1 min. To maximize the DNA yield, the buffer AE may be warmed before use on the column.

In isolating DNA from blood, the first step is to add proteinase K to 100 μL of blood plus 100 μL of PBS. Following this, the buffer AL is added to the mixture, and the sample is incubated at 56°C for 10 min. After this, the ethanol is added to the sample, and the mixture is placed in the column. The final stages are the same as with the previous protocol

described for the papilloma sample and involve the addition of buffer AW1 and AW2 and, in the final stage, the addition of buffer AE.

82.2.2 Detection Procedures

Recent molecular studies have been largely based on the amplification of a fragment of L1 BPV ORF with some exceptions (e.g., BPV-4 type-specific primer).

82.2.2.1 PCR Using Consensus Primers

The consensus primers FAP59/64 (Fw 5′-TAACWGTIGG ICAYCCWTATT-3′; Rev 5′-CCWATATCWVHCCATITC ICCATC-3′) and MY 11/09 (Fw 5′-GCM CAG GGW CAT AAY AAT GG-3′; Rev 5′-CGT CCM ARR GGA WAC TGA TC-3′) are very suitable for use in studies that are designed to detect a broad range of BPV types; however, it is necessary to perform the sequencing assay after the PCR technique to distinguish between the BPV types. These primers amplify a conserved fragment of L1 ORF. The conditions of the PCR when combined with these primers are described in the following.

82.2.2.1.1 Procedure

1. Prepare the PCR mix as follows: add 25 units/mL of Taq DNA polymerase, 200 μM dATP, 200 μM dGTP, 200 μM dCTP, 200 μM dTTP, 1.5 mM $MgCl_2$, and 0.25 μM of each oligonucleotide primer (FAP59/64 or MY09/11).
2. Homogenize by pipetting the mixture and then add 23 μL of the mixture to each PCR tube.
3. Add 2 μL of DNA samples at a concentration of 50 ng/μL and pipette the mixture until it is homogenized.
4. Add 2 μL of ultrapure water in a PCR tube to perform the nontemplate control (NTC).
5. Take the samples to a thermocycler to amplify the DNA fragments in accordance with the conditions outlined in Table 82.1.
6. Visualize the amplification products by using 1.5% Tris-acetate buffer (TAE) agarose gel electrophoresis and subsequent ethidium bromide staining.

82.2.2.2 PCR Using Type-Specific Primers

The BPV type-specific primers are very suitable for epidemiological studies because of their sensitivity. However, several rounds of amplifications are necessary to obtain a screening of the major BPV types from a set of samples. In the following, there is a description of the conditions and the primers required to amplify the 12 first BPV described in the literature (with the exception of BPV-7). Some of them can be used with the same thermal profile as the thermocycler, although since the amplicon has a similar fragment size, they cannot be used as multiplex PCR.

TABLE 82.1
PCR Thermal Profile Using Consensus Primers

Primer	Denaturation	Annealing	Extension	Number of Cycles
FAP59/64	94°C for 1 min	50°C for 1 min	72°C for 1 min	45
MY09/11	95°C for 30 s	48°C for 30 s	72°C for 1 min	35

82.2.2.2.1 Procedure

1. Prepare the PCR mix as follows: add 25 units/mL of Taq DNA polymerase, 200 μM dATP, 200 μM dGTP, 200 μM dCTP, 200 μM dTTP, 1.5 mM $MgCl_2$, and 0.25 μM of each oligonucleotide primer. Information about the primers is given in Table 82.2.
2. Homogenize the mixture by pipetting and then add 23 μL to each PCR tube.
3. Add 2 μL of DNA samples at a concentration of 50 ng/μL and pipette the mixture to homogenize.
4. Add 2 μL of ultrapure water in a PCR tube to perform the NTC.
5. Take samples to a thermocycler to amplify the DNA fragments in accordance with the conditions outlined in Table 82.3.
6. Visualize the amplification products by using 2% TAE agarose gel electrophoresis and subsequent ethidium bromide staining.

82.3 CONCLUSION AND FUTURE PERSPECTIVES

Although diseases caused by BPV have been known for a long time, new discoveries about BPV infection such as the classification of new variants, coinfection by multiple genotypes, and the spread of viruses through nonepithelial sites and heterologous infection have given them an increasing prominence. The lack of understanding of BPV biology suggests further need to study this subject and to employ control strategies against papillomaviruses. Hence, a knowledge of BPV diversity and epidemiology is of crucial importance to establish prevention strategies and obtain an understanding of the evolution of this group of viruses. The molecular strategies deployed in recent years have been tremendously helpful for farmers and veterinarians. These strategies have increased our knowledge of BPV biology and epidemiology to a great degree.

BPV infection in its natural host has become an important concern as the disease reduces the value of livestock in financial terms, impairs the quality of the leather, leads to a general decline in animal health, and, in severe cases, causes the death of the animal. Furthermore, the presence of this disease on a farm imposes a threat to neighboring farms, and thus, urgent action is required by the farmers involved or public agencies. In the case of bovine papillomatosis in particular, there is a lack of accurate information about the serious consequences of the disease, and thus, interventionist measures are needed to control its spread and mitigate its effects. Currently, there is a range of therapies with limited

efficacy for the treatment of BPV-infected animals. The surgical removal of the lesions is often recommended when the animal shows signs of having papillomas, or alternatively chemical treatment may be used. There has been a great demand for an effective product for the treatment of papillomatosis, due to the difficulties encountered in its control and the increasing incidence of the disease observed in recent years. In the case of equine sarcoid, besides being a locally aggressive tumor due to its infiltrative capacity, it is resistant to different forms of therapy.

The ultimate goal should be to develop an effective and affordable vaccine approach, in contrast with the current expensive and relatively ineffective strategies. Thus, there is a good deal of scope in the BPV field to identify and implement improved control, intervention, and treatment strategies, together with the development of highly protective vaccines.

83.1 INTRODUCTION

Adenoviruses are double-stranded DNA viruses with a nonenveloped icosahedral capsid. With a broad host range, adenoviruses have been isolated from members of every class of vertebrates, ranging from cartilaginous fish, birds, to humans [1–3].

The first avian adenovirus was isolated by accident at the end of the 1940s [4], and a clinical isolation was obtained from a quail bronchitis around the same time [5]. Human adenoviruses were isolated in the 1950s, at an attempt to produce tissue cultures from excised human adenoids. With some cells undergoing a spontaneous degeneration, the causing agent was named "adenoid degeneration agent," abbreviated as "A.D. agent" [2,3].

Adenovirus infection is rather common among birds, including both poultry [6–8] and wild species [9,10]. In most cases, the route of infection is fecal–oral or vertical through the egg. The infection is regularly subclinical; a coinfection or other immunosuppressive effect—for example, laying eggs—is needed for the clinical manifestation of the disease [11,12]. A chronic infection is established in the birds, which results in a continuous virus shedding and the vertical transmission of the infection [13]. But some types among poultry-infecting adenoviruses are primary pathogens, for example, the turkey hemorrhagic enteritis virus [14].

Adenoviruses usually exhibit strong host specificity; the natural host of one specific type is usually only one species or a group of closely related species. *In vitro*, most avian adenoviruses replicate in primary cell cultures originating from the embryonic liver or kidney of the host species. The reproduction of the virus takes place in the nucleus, and intranuclear inclusion bodies are very common both in the propagated cells and during the histopathological examination of animals [15].

Avian adenoviruses were traditionally diagnosed and classified using serological methods. As the number of different serotypes rose, serological approach that relies on the use of reference strains and sera has become increasingly cumbersome and impractical. Molecular methods circumvent this problem by comparing the samples to entries stored in publicly available databases, such as GenBank. Diverse molecular methods have emerged in the recent years. In this chapter a short summary of available methods is given with more details on a generally applicable one.

83.1.1 Classification

The family *Adenoviridae* currently consists of five established genera: while the genera *Mastadenovirus* and *Aviadenovirus* have been recognized long ago [16], the genera *Atadenovirus*, *Siadenovirus* [17], and *Ichtadenovirus* [1] represent more recent additions. A sixth genus is being proposed: *Testadenovirus* [18].

Initially, all bird-infecting adenoviruses were classified into the genus *Aviadenovirus* simply because of the host of the virus. However, it was observed that some virus types differ fundamentally (e.g., antigenically) from a majority of the genus members. This led to the establishment of three distinct groups within the genus: group I, II, and III avian adenoviruses [15]. Phylogenetic analyses accomplished later among members of the family proved that the only member of group II (turkey hemorrhagic enteritis virus) can be classified as a *Siadenovirus*, and the sole member of group III (egg drop syndrome virus) is an *Atadenovirus* [19–21]. Thus, birds can be infected by members of three different genera of the family *Adenoviridae*: *Aviadenovirus*, *Atadenovirus*, and *Siadenovirus*. The current phylogenetic classification, official species and type names, recommended abbreviations, and host species of bird-infecting adenoviruses are summarized in Table 83.1.

The species demarcation criteria are officially set for every genus in the family *Adenoviridae* by the International Committee on Taxonomy of Viruses [1]. The most important and up-to-date criterion for all genera is the phylogenetic distance based on the DNA polymerase gene (>5%–15%), but for some genera other features (e.g., the host range, genome organization, or restriction fragment length polymorphism analysis of the genome) can be used as well.

Unfortunately there are no generally accepted type demarcation criteria for adenoviruses. Although the serotype definition is still valid [1], the neutralization test [22–24] is rarely used nowadays. Novel avian adenovirus isolates are increasingly studied using molecular methods instead, and then classified into the existing serotypes [6,7,25–28]. Thus, the recommended term for strains classified using such methods is "type" rather than "serotype." Marek et al. [29] tried to redefine the classification and typing system of fowl adenoviruses (FAdVs) using only molecular methods, and the usage of "genotype" was proposed. The same topic caused a long and heated debate among human adenovirologists as well [30–33], and a general solution to this problem that can be applied hopefully to all genera of the virus family is really anticipated.

83.1.2 Morphology and Genome Organization

Adenoviruses are medium-sized (70–90 nm in diameter), nonenveloped viruses with an icosahedral capsid. The major capsid proteins are the hexon (numbered as II after protein electrophoreses), the penton base (III), and the fiber proteins (IV). The 20 facets of the capsid are assembled from 240 homotrimers of the hexon protein. The 12 vertex capsomeres are constituted from the basal homopentomer of the penton base proteins and the protruding, elongated homotrimer of the fiber proteins [34]. Most adenoviruses possess one piece of fiber per vertex, but aviadenoviruses possess two [35]. These can be a duplicate of the same fiber or two different ones [36].

The minor capsid proteins or cement proteins are either stabilizing the capsid (IIIa, VI, and VIII) or found within the capsid. Most of the latter ones are bound to the DNA (VII, μ, IVa2, and the terminal protein); the only nonassociated protein is the viral protease [37].

The genome of adenoviruses is a nonsegmented, linear, double-stranded DNA genome coding on both strands. The length of the genome varies between 26 and 45 kb; siadenoviruses tend to have the shortest genomes (~26 kb) among adenoviruses [38] and aviadenoviruses (~43 to 45 kb) the longest [39].

In every adenovirus, the genome ends code for the inverted terminal repeats, which are the longest among aviadenoviruses (duck adenovirus 2: 721 bp) [36]. The central region of the genome contains a gene cassette, conserved in every adenovirus, and codes for basic proteins needed for DNA replication, DNA encapsidation, formation, and structure of the virion. The flanking regions vary in size among the different genera and contain genus-, species-, or type-specific genes [40,41].

83.1.3 Epidemiology and Clinical Features

Adenovirus infections are commonly present in both domestic and wild avian species. As most of the adenovirus strains are opportunistic pathogens, they do not necessarily cause overt disease in the infected birds. Rather, in most cases, secondary immunosuppressive factors are responsible for the onset of an outbreak. The severity of the disease can be affected by the exact strain of the virus; different strains classified even into the same adenovirus type can differ in virulence. Other factors have influence as well: the age of the bird or the infective titer of the virus. Perhaps this can explain the often equivocal results of animal experiments [11].

Avian adenovirus infections can spread both vertically and horizontally. Vertical transmission occurs through the embryonated egg, while horizontal transmission occurs through the fecal–oral route involving the feces or other excretions. The birds often develop a persistent, chronic infection after recovering and can be virus carriers for their whole lives. The virus shedding reoccurs if any immunosuppressive stress effect takes place, for example, egg laying. This ensures maximum transmission of the virus again [11–14].

Avian adenoviruses are relatively resistant to chemical or physical treatment. As they do not possess a viral envelope, they are resistant not only to lipid solvents such as ether and chloroform, but also to variations in pH between 3 and 9. Some strains of aviadenoviruses can withstand 60°C or even 70°C for 30 min, but their stability is reduced in the presence of divalent cations, and they can be inactivated by a 0.1% formaldehyde solution [11]. The infectivity of the egg drop syndrome virus can be decreased by 50% if it is heated for

Italicized species names are officially accepted by the International Committee on Taxonomy of Viruses. Names of species officially not established yet are in roman style. Recommended abbreviations are given in parentheses.

30 min at 60°C [42]; a treatment using 0.5% formaldehyde or 0.5% glutaraldehyde is disinfecting [43]. The turkey hemorrhagic enteritis virus can be destroyed only by a 1 h treatment at 70°C or using a 0.0086% sodium hypochlorite solution [44]. Sodium lauryl sulfate, phenolic, and iodine-based disinfectants are also effective against this virus [45].

83.1.3.1 Aviadenoviruses

83.1.3.1.1 In Chickens

Chicken-infecting aviadenoviruses are called fowl adenoviruses. These are the most examined aviadenoviruses because of the economic value of their host and their worldwide distribution; FAdVs are ubiquitous in chicken populations. There are 12 different serotypes described among FAdVs; these serotypes are classified into five species: *Fowl aviadenovirus A–E*. There are several diseases of chickens associated with aviadenoviruses; most significant are the inclusion body hepatitis (IBH), the hydropericardium syndrome, and the gizzard erosion.

IBH occurs mainly in 3–7-week-old broilers. The disease starts with a sudden onset of mortality; sick birds take a crouching position and have ruffled feathers [46]. Pale, friable, swollen livers are found in the dead animals and intranuclear inclusion bodies in the hepatocytes during the histopathological examination [47,48]. Although almost every fowl adenovirus (FAdV) type was isolated already from diseased animals, the disease is mostly associated with species FAdV-D (FAdV-2, -3, -9, -11) and FAdV-E (FAdV-6, -7, -8a, -8b) strains [6,27,29,47,49].

The hydropericardium syndrome causes similar clinical and pathological signs to the IBH but the mortality (20%–80%) and the incidence of the hydropericardium is higher. The name of the disease is of course derived from its pathology: the pericardial sac is often filled with clear straw-colored fluid. Other pathological findings are pulmonary edema, swollen liver, and enlarged kidneys. The etiological agents of the disease are FAdV-4 strains (species FAdV-C) [11,12].

Pathogenic strains of the type FAdV-1 (species FAdV-A) can cause the gizzard erosion in chickens [6,13,50]. The disease has no clinical signs apart from the elevated level of mortality. During necropsy, the most common findings are erosions in the koilin layer and the inflammation of the mucosa. The gizzards might be dilated with bloody fluids. Pathogenicity of the Japanese strains was in connection with their fiber gene sequence [51], but European strains could not been differentiated using this method [52].

FAdV strains are sometimes associated with a fall in egg production, with decreased food consumption and depressed body weights, with respiratory diseases, or with tenosynovitis [53].

83.1.3.1.2 In Turkeys

There are multiple diseases in turkeys associated with adenoviruses. The strains, later classified into the types turkey adenovirus 1 and 2 (TAdV-1, TAdV-2) [54], were isolated first in Northern Ireland. TAdV-1 strains were found in birds suffering from conjunctivitis, nephritis, and airsacculitis [55]; a TAdV-2 strain was recovered from 1-day-old chicks with

IBH [56]. This latter strain caused suboptimal hatchability in experiments [57]. For historical reasons, a new strain of TAdVs was designated later as TAdV-1, originating from the trachea of 10-week-old turkeys showing respiratory signs [58], and the original TAdV-1 strains were reclassified as TAdV-4 [8]. Further strains—now regarded as type TAdV-5—were isolated from diseased fattening turkeys [8]. TAdVs were also isolated from diseased turkeys showing respiratory signs, but these isolates have not been typed [59–61].

83.1.3.1.3 In Geese

The first strains of goose adenoviruses were isolated in Hungary from unhatched eggs and fecal samples [62]. Later, other strains were classified into three types (goose adenovirus 1–3), but these were found to be apathogenic in animal infection studies [63]. Pathogenic strains of goose adenoviruses have caused IBH [64] occasionally combined with hydropericardium syndrome in young goslings [65].

83.1.3.1.4 In Other Birds

Adenoviruses can cause severe respiratory infections in young Muscovy ducks [66]. FAdV-1 can also cause severe respiratory infection, the so-called quail bronchitis in bobwhite quails and Japanese quails with up to 50% mortality [12,67]. Pigeons possess their own aviadenoviruses [36] but can be infected by FAdVs as well [68,69].

83.1.3.2 Atadenoviruses

The most important avian atadenovirus type from an economical point of view is the duck adenovirus 1, which causes the egg drop syndrome in chickens. The natural host of the virus is different species of ducks and geese, hence the official name of the virus type. But the virus is apathogenic in ducks, and the same is true in most of the cases for geese. In young goslings, some strains can cause a severe respiratory disease [70] or the so-called new type gosling viral enteritis [71]. Wild waterfowl species might play an important role in the spread of the disease.

Chickens of all ages are susceptible for the virus, which causes thin-shelled, soft-shelled, or shell-less eggs and a sharp decrease in egg production by up to 40%. Apart from these, the birds seem healthy. The virus replicates in the pouch shell gland; common pathological findings associated with the disease are the inactive ovaries, atrophied oviducts, edema of the uterine folds, and exudate in the pouch shell gland [72].

Atadenoviruses can be found in other bird species as well [73].

83.1.3.3 Siadenoviruses

Economically, the most important siadenovirus type is the TAdV-3. Strains belonging to this type cause the hemorrhagic enteritis in turkeys, the marble spleen disease in pheasants, and the avian adenovirus splenomegaly in chickens. Most important clinical sign of the hemorrhagic enteritis is the bloody droppings; blood-containing feces can be found on the feathers surrounding the cloaca. The average mortality is 10%–15% but may reach more than 60% during the 6–10 days of the disease. Dead poults are usually pale due to the blood loss; the small intestinal tract is usually distended, discolored, and filled with a bloody content; the spleen is enlarged, friable, and mottled [14].

The marble spleen disease in pheasants and the avian adenovirus splenomegaly in chickens are quite similar to each other in their clinical appearance and pathology, but the former one is more severe. In both cases the birds are depressed or might die suddenly. Mortality values may reach 5%–20% for the marble spleen disease but only 8.9% for the avian adenovirus splenomegaly. The spleens of dead or infected animals are enlarged and mottled (marbled); the lungs are edematous and congested [14].

Siadenoviruses are common among wild birds, too [10,74–76]. The raptor adenovirus 1 was diagnosed in three species of birds of prey: Bengal eagle owl, Verreaux's eagle owl, and Harris hawk. In the specimens of these birds, hepatic and splenic necroses were found together with ventricular ulceration and necrosis [77]. A siadenovirus was also found in Gouldian finches with depression and significant respiratory crackles [9].

83.1.4 Diagnosis

83.1.4.1 Conventional Techniques

Conventional techniques in the avian adenovirus research and diagnostics involve the virus isolation, microscopic and histological techniques, and immunological methods.

The sample source for virus isolation is the affected organs, mainly the liver, or the feces from diseased animals. The sample is homogenized in a cell medium containing antibiotics and seeded onto avian cells. The most permissive cell lines for FAdVs are usually primary chicken cells: chicken embryo liver cells, chicken embryo kidney cells, chicken kidney cells, or chicken embryo fibroblasts. Duck adenovirus 1, the causative agent of the egg drop syndrome, can be isolated on embryonated duck or goose eggs; the sample for the isolation attempt might be an altered egg or an affected pouch shell gland. The isolation of TAdV-3, the turkey hemorrhagic enteritis virus, requires either live turkeys or a special lymphoblastoid cell line (MDTC-RP19). Adenoviruses of other birds require usually cell lines originating from the host species; goose aviadenoviruses, for example, are propagated on goose embryonic liver cells [78]. This might be almost impossible for adenoviruses originating from wild, especially from endangered bird species [77]. The success of virus isolation can be confirmed by the occurrence of a cytopathogenic effect. The isolate can be identified as an adenovirus using immunological or molecular methods, an electron microscopic investigation, or a simple hematoxylin–eosin staining by the characteristic intranuclear inclusion bodies. Electron microscope or hematoxylin–eosin staining can be used in the histopathological examination of the animals as well; the same inclusion bodies are also characteristic, for example, in the IBH [47,48,65].

Immunological methods are either detecting the virus (the antigen) or the antibodies produced against adenoviruses. Agar gel precipitation (agar gel precipitin, agar gel immunodiffusion, double immunodiffusion) can be used for both purposes. Several enzyme-linked immunosorbent assays have been developed for adenovirus diagnostics, and immunofluorescence assays [54] are also useful. The immunohistochemistry (immunofluorescent or immunoperoxidase staining) might aid the histological examination. Duck adenovirus 2 agglutinates avian red blood cells, so hemagglutination tests are available for the identification of the virus, and also hemagglutination inhibition tests are available for serological diagnosis.

Serum neutralization tests were widely used for the serotyping of avian adenovirus isolates [22–24,79]. Such tests are rather tedious and time consuming, and for example for the proper serotyping of a FAdV isolate, the 12 standard reference antiserums are also needed. For the establishment of a new, officially accepted serotype, the 12 reference FAdV strains are needed as well, as "a serotype is defined as one that either exhibits no cross-reaction with others or shows a homologous/heterologous titer ratio greater than 16 (in both directions)" [1]. The evaluation of the results might be further complicated by the fact that different diagnostic institutes might use different reference or prototype strains of the same serotype [80] and that chickens are often infected by multiple serotypes of FAdVs [81,82].

83.1.4.2 Molecular Techniques

To aid the detection of avian adenoviruses and simplify the typing of these, numerous molecular methods have been developed. The restriction endonuclease analysis of the viral genomes was one of the first techniques used for such a purpose. Although this technique determines basically only a few nucleotides in the whole genome using the specificity of the restriction endonuclease, it was still sufficient for the genotyping of goose [63], turkey [57], and FAdV [83] strains. This classification of the FAdV types was retained later when the FAdV species were established [17], as phylogenetic analyses based on hexon sequences supported it [29,84,85]. Another molecular method used in the diagnostics of avian adenoviruses is the hybridization of labeled probes to the viral DNA either on the blotting membrane or *in situ*. But as the isolation of the virus strain and the extraction of the viral genomic DNA are still required for both the genomic restriction endonuclease analysis and the DNA hybridization (except the *in situ* hybridization), their usage became rather limited since the development of the polymerase chain reaction (PCR).

Using PCR, a specific fragment is amplified from the targeted genome using custom-made, specific oligonucleotides, the primers. Several PCR methods have been published for the diagnostics of adenoviruses infecting birds, targeting the hexon gene [84–88], the viral DNA polymerase gene [89–91], and other different genes [92,93]. More sophisticated techniques include real-time PCR [92,94] and the high-resolution melting curve analysis of the products [28,29,95], pyrosequencing [96], and loop-mediated isothermal amplification [97].

Chickens can be infected by FAdVs (genus *Aviadenovirus*), by duck adenovirus 1 (egg drop syndrome virus, genus *Atadenovirus*), and by TAdV-3 (turkey hemorrhagic enteritis virus, genus *Siadenovirus*). These viruses are evolutionarily distant, thus the available conserved gene stretches are scarce, limiting the possible locations for diagnostic primers. So beyond the PCR developed for FAdVs, separate PCR tests were designed for the detection of duck adenovirus 1 [85] and TAdV-3 [98]. More universal PCR systems were also published, but these were tested specifically on duck adenovirus 1, TAdV-3, and FAdV types only [86,99], and it is not certain at all whether these would be able to detect a new adenovirus infecting chickens. These PCRs were not tested either in the diagnostics of other adenoviruses like goose or turkey adenoviruses.

There is one PCR [90] which is regarded the pan-adenovirus PCR, possibly detecting all adenoviruses, as it was tested with multiple samples belonging to all known and proposed genera in the family *Adenoviridae* [10,18,47,74,77,91,100–104]. Thus, it simplifies the diagnostics of avian adenoviruses as it detects at- and siadenoviruses as well, not only aviadenoviruses. It enables the detection of hitherto unknown adenoviruses without the need of virus isolation, and as it is a nested PCR system, it ensures a high sensitivity.

However, every method has its limitations. The nested system also means double workload: two rounds of PCR and an enhanced risk for contamination. And also, it is not a real-time PCR system, so the agarose gel electrophoresis of the PCR products is needed for the detection of the results. But as it is a pan-adenovirus PCR, no other reaction is needed for the detection of any adenovirus. This exceptionally wide target range was achieved by highly degenerate consensus primers targeting the viral gene of the DNA-dependent DNA polymerase. The high level of degeneracy enhances the possibility of nonspecific results as well, therefore, the sequencing of the PCR products is essential in every case, even if they are of the right size. The determined partial polymerase gene sequence is so much conserved that it allows a preliminary, genus, and species classification only. For the intraspecies, type-level identification of avian adenoviruses, a hexon-targeting PCR can be recommended. The materials and methods needed for the DNA polymerase–targeting PCR is discussed in detail in the next section.

83.2 METHODS

83.2.1 Sample Preparation

For molecular diagnostics the adenoviral DNA is needed. This does not mean necessarily that the DNA must be extracted from the sample, for some PCR the diluted viral isolate might be applicable [6]. Obviously an extracted, pure DNA enhances the chance of a successful PCR. For the restriction endonuclease analysis of adenoviruses, the selective extraction of the viral genome is needed [105,106]. But for PCR applications a simpler, total DNA is appropriate. The source

of DNA extraction might be the isolated virus; an affected organ, mainly the liver; or, if diarrhea was observed, the feces.

For the DNA extraction, any commercially available DNA extraction kit gives sufficient result. Here a DNA extraction method based on guanidine hydrochloride according to Dán et al. [107] is presented.

83.2.1.1 Materials Needed

1. 1× TE (tris(hydroxymethyl)aminomethane-ethylenediaminetetraacetic acid) buffer
2. 10% sarkosyl (sodium lauroyl sarcosinate)
3. Proteinase K (20 mg/mL)
4. 8 M guanidine hydrochloride
5. 7.5 M ammonium acetate
6. Refrigerated (–20°C) absolute ethanol
7. Refrigerated (–20°C) 70% ethanol
8. Sterile, ultrapure water
9. Equipment: micropipettes; sterile scissors, scalpels; mortar and pestle, or other tissue homogenizer; 1.5 mL tubes; thermoshaker or water bath capable of 55°C; centrifuge (possibly refrigerated)

83.2.1.2 Procedure

1. Collect sample from an affected organ using uncontaminated sterile tools. The desired sample size is the size of a peppercorn.
2. Homogenize the sample in 200 µL TE buffer.
3. Transfer 100 µL of the homogenate to a 1.5 mL tube and add 10 µL sarkosyl and 4 µL Proteinase K.
4. Gently mix the content of the tube and incubate it on 55°C overnight.
5. Add 300 µL guanidine hydrochloride and 20 µL ammonium acetate, mix thoroughly, and incubate the tube on room temperature for 1 h. Shake the tube every 20 min.
6. Add 1 mL absolute ethanol and mix thoroughly.
7. Spin the tube (16,000 × *g*, 12 min, 4°C).
8. Discard the supernatant and add 1 mL 70% ethanol.
9. Spin the tube (16,000 × *g*, 5 min, 4°C).
10. Discard the supernatant and let the pellet dry on room temperature.
11. Reconstitute the pellet in 50 µL ultrapure water. If pieces of undigested tissue remain in the tube, transfer the supernatant to a new tube after a short spin.
12. Store the DNA sample on –20°C.

83.2.2 Detection Procedures

Here, the nested PCR targeting the adenoviral DNA polymerase gene [90] is described. Slight modifications are applied to the original publication.

83.2.2.1 Materials Needed

1. DNA samples
2. Primers for PCR amplification (see Table 83.2)
3. REDTaq DNA Polymerase (Sigma-Aldrich)
4. 10× reaction buffer (provided with REDTaq)
5. 10 mM deoxynucleotide mix: 10 mM dATP, 10 mM dCTP, 10 mM dGTP, 10 mM dTTP in ultrapure water
6. 25 mM $MgCl_2$
7. Sterile, ultrapure water
8. Adenovirus DNA solution for positive control
9. Agarose
10. TBE (tris(hydroxymethyl)aminomethane-boric acid-ethylenediaminetetraacetic acid) or TAE (tris(hydroxymethyl)aminomethane-acetic acid-ethylenediaminetetraacetic acid) electrophoresis running buffer
11. DNA-staining dye (ethidium bromide, GelRed [Biotium])
12. Equipment: micropipettes, PCR tubes, 1.5 mL tubes, ice, tube racks, gel electrophoresis apparatus, power supply, thermal cycler, and gel imaging system

TABLE 83.2
Polymerase Chain Reaction Primers Targeting Deoxyribonucleic Acid Polymerase Gene

PCR	Primer	Sequence (5′–3′)
First round	polFouter	TNMGNGGNGGNMGNTGYTAYCC
	polRouter	GTDGCRAANSHNCCRTABARNGMRTT
Second round	polFinner	GTNTWYGAYATHTGYGGHATGTAYGC
	polRinner	CCANCCBCDRTTRTGNARNGTRA

IUPAC nucleotide codes: N = G/A/T/C, M = A/C, R = A/G, W = A/T, S = C/G, Y = C/T, H = A/C/T, D = A/G/T, B = C/G/T.

83.2.2.2 Procedure

1. Thaw all reagents completely, vortex, and spin them briefly. Store them on ice. It is recommended to set up the reaction on ice.
2. Prepare a master mix according to Table 83.3. Do not forget to count the positive and the negative control

TABLE 83.3
Recipe for Polymerase Chain Reaction Targeting Deoxyribonucleic Acid Polymerase Gene

Component	Volume (per Reaction) (µL)
Sterile ultrapure water	37
10× PCR Buffer of the REDTaq DNA Polymerase	5
$MgCl_2$ (25 mM)	1
Deoxynucleotide mix (10 mM)	1.5
polFouter/polFinner primer (50 mM)	1
polRouter/polRinner primer (50 mM)	1
DNA sample	1
REDTaq DNA Polymerase	2.5
Total reaction volume	50

beyond the samples, and add 10% excess, too, to counterbalance any pipetting inaccuracies. The recipes of the two rounds are almost the same except the primers: use the outer primers for the first round and the inner ones for the second round.
3. Dispense 49 μL from the master mix to each marked PCR tube.
4. Add 1 μL ultrapure water to the negative control, 1 μL DNA sample to each sample tube, and 1 μL adenovirus DNA solution to the positive control.
5. Close the tubes properly, place them into a compatible thermal cycler, and run the program according to Table 83.4.
6. When the thermal cycler has finished, prepare the master mix of the second round, containing the inner primers.
7. Dispense 49 μL from the master mix to each marked PCR tube.
8. Transfer 1 μL from the ready reaction mixture of the first round to the tube of the second round.
9. Close the tubes properly, place them into a compatible thermal cycler, and run the same program again according to Table 83.4.
10. Prepare a 1.5% agarose gel and run 10 μL from the samples of both rounds. The product size of a positive reaction is 318–324 bp, but nonspecific bands of other sizes can be often observed.

Sequencing of the PCR products is essential in every case, even if they are of the right size. The PCR product needs to be purified for this purpose. If nonspecific bands are observable next to the specific product, the leftover 40 μL needs to be loaded onto a gel. The specific band needs to be excised using a sterile scalpel and purified from the agarose gel using a gel extraction kit. If only a specific band is observable, perhaps a commercial sequencing provider might be recommended for the purification and sequencing of the product. It is recommended to determine the nucleotide sequence of the PCR product on both strands.

TABLE 83.4
Thermal Cycling Conditions for Both Rounds of Polymerase Chain Reaction Targeting Deoxyribonucleic Acid Polymerase Gene

Step	Temperature (°C)	Duration
Denature template	96	5 min
45 cycles		
1. Denature template	96	30 s
2. Anneal primers	46	1 min
3. Extension	72	1 min
Final extension	72	3 min

Source: Wellehan, J. et al., *J. Virol.*, 78(23), 13366, 2004.

Birds are often infected by multiple strains of adenoviruses [6,81,82]. In this case the PCR amplifies its product from all the strains, resulting in a mixed product, and at the end also a mixed, undeterminable sequence. This still might provide enough data to prove the presence of adenoviruses in the sample. If exact species determination is needed, the molecular cloning of the PCR product is recommended [6].

83.2.3 Phylogenetic Analysis

For a phylogenetic analysis, molecular typing of the avian adenovirus strains, the resulting forward and reverse sequences of the PCR product need to be assembled to form a consensus sequence. The primer sequences must be omitted before submitting the consensus sequence to a BLAST (basic local alignment search tool) search [108] or to a phylogenetic analysis. A step-by-step description of a basic phylogenetic analysis using adenoviral sequences can be found in Harrach and Benkő [109].

83.3 CONCLUSION AND FUTURE PERSPECTIVES

As adenovirus infection is common in both domestic and wild birds and perfect diagnostic methods are not available yet, a continuous improvement of these methods is needed. An ideal diagnostic method for avian adenoviruses would detect any adenovirus belonging to different genera in a single closed-tube reaction with high sensitivity, specificity, and reproducibility possibly within a few hours from sample collection till the result. It would also enable the typing of the investigated strain, even if it happens to originate from a mixed infection, without the need for the reference strains. Preferably, it should also have an affordable cost. Current diagnostic methods are far from these goals.

Closest solutions to these goals nowadays are real-time PCR methods combined with the high-resolution melting curve analysis of the products [28,29,95]. But even these methods do not fulfill by far the above mentioned aims. High-resolution melting curve analysis methods used in avian adenovirus diagnostics are specific for FAdVs only, which are economically the most important, but there are numerous other avian adenoviruses as well. To use it for molecular typing, reference strains are needed to compare the samples to these. But even with all 12 fowl reference strains, it is questionable whether the high-resolution melting curve analysis can clearly classify FAdV field samples into the nowadays accepted types; the molecular classification of virus strains not necessarily mirrors the classical serotyping [29]. For a clear, safe result new type demarcation criteria are needed, which are based on molecular principles. The outdated type demarcation criteria need to be updated to meet the needs of the molecular age.

The greatest concern about molecular methods might be that they yield a positive result only with the organisms they are designed for. Molecular methods usually operate with a

specific oligonucleotide, thus missing any microorganism that they are not specific to. The method of virus isolation enables the discovery of new viruses, but with its tedious and time-consuming nature, it is not used routinely these days. This problem might be solved in the future by the increased usage of deep sequencing. As the cost of sequencing decreases continuously, it will definitely play a bigger role in future diagnostics. The high number of sequencing reads enables the identification of several microorganisms in a clinical sample without any prior cultivation [110].

84.1 INTRODUCTION

Members of the subfamily *Betaherpesvirinae* are characterized by host-specific infection and cell type–specific replication in culture. In general, these viruses are cell-associated and slow growing in culture. The site of latency in some members of the subfamily is monocytes. The genomes of viruses belonging to this subfamily are characterized by the presence of homologues of the *Human herpesvirus 5* (HHV-5) gene US22 [1].

The most well studied and characterized of the subfamily *Betaherpesvirinae* is HHV-5, more commonly known as human cytomegalovirus. The descriptive name of viruses belonging to the *Betaherpesvirinae* subfamily, "cytomegalovirus," is derived from the characteristic feature of the infection, which is enlarged cells, or cytomegalo. As with many other herpesviruses, HHV-5 is ubiquitous in the human population and largely asymptomatic. However, HHV-5 can be of concern in immunocompromised patients such as transplant recipients and those with acquired immunodeficiency syndrome. HHV-5 is also of concern to infected pregnant women as it may cross the placenta and have negative effects on the fetus. As a result, considerable effort has been placed on the development of a safe and effective vaccine for preventing transplacental infections in humans.

There are few well-studied betaherpesvirus that infect animals other than some species of primates and rodents. *Bovine herpesvirus 4* and *Equine herpesvirus 2* were initially placed within the betaherpesviruses; however, molecular data resulting in these viruses are being reclassified to the subfamily *Gammaherpesvirus* [2,3]. *Elephantid herpesvirus 1* has also been assigned to the betaherpesviruses and has emerged as an important infection of elephant populations [4].

Currently, the sole member of the subfamily *Betaherpesvirinae* known to infect livestock is the *Suid herpesvirus 2* (SuHV-2), which is also known as the porcine cytomegalovirus. The clinical disease in pigs caused by SuHV-2 is referred to as inclusion body rhinitis, which was first described in 1955 [5]. SuHV-2 has a widespread distribution and generally is only of clinical relevance in young swine. It has gained some interest in recent years as it represents a potential risk in xenotransplantation of porcine cells and tissues to humans [6]. This chapter focuses on the current status, biological properties, and diagnosis/detection of SuHV-2 infection in pigs.

84.1.1 Classification

Forming one of the three subfamilies (*Alphaherpesvirinae*, *Betaherpesvirinae*, and *Gammaherpesvirinae*) in the family *Herpesviridae*, the subfamily *Betaherpesvirinae* is currently divided into four genera (i.e., *Cytomegalovirus*, *Muromegalovirus*, *Proboscivirus*, and *Roseolovirus*). Although these genera share a common lineage within the subfamily, they clearly diverge from other viruses in the family *Herpesviridae*. The characteristic biological feature of the subfamily is the enlargement of virus-infected cells referred to as cytomegalic.

The genus *Cytomegalovirus* includes the type species HHV-5, *Panine herpesvirus 2* (chimpanzee cytomegalovirus), and other viruses that infect primates. The genus *Muromegalovirus* includes the two species that infect rodents, *Murid herpesvirus 1* and *Murid herpesvirus 2*, which

infect mice and rats, respectively. The viruses assigned to the *Cytomegalovirus* and *Muromegalovirus* generally have genomes that exceed 200 kb in length.

The genus *Proboscivirus* contains a single virus species, ElHV-1, which is associated with severe and fatal disease in elephants. The genome ElHV-1 is approximately 177 kb in length [7]. The inability to culture strains of ElHV-1 has hampered research efforts due to a complete reliance on material sourced from clinical infected animals and samples obtain at necropsy. The most recent molecular analyses of ElHV-1 genome and strains have led to a proposal that these strains not only represent a number of separate viral species but have also recommended the establishment of a new subfamily, *Deltaherpesvirinae*, within the family *Herpesviridae* [8,9]. This recommendation is yet to be ratified by the International Committee on Taxonomy of Viruses.

The fourth genus of the *Betaherpesvirinae* subfamily is *Roseolovirus*. Viruses assigned to this genus are generally characterized by smaller genomes compared to other genera with genomes less than 200 kb in length. The genus currently includes HHV-6 and HHV-7, which are distinct species although they are serologically related [10]. These viruses are the cause of roseola infantum in infants [11].

Unassigned species within the subfamily are *Caviid herpesvirus 2* and *Tupaiid herpesvirus 1*, which infect guinea pigs and tree shrews, respectively. The most well studied of the betaherpesvirus animal viruses, SuHV-2, has not been assigned to a specific genus. It was recently recommended that SuHV-2 be classified within the genus *Roseolovirus* based on the analyses using the complete viral genome sequence [12]. This recommendation has not been adopted yet by the International Committee on Taxonomy of Viruses.

84.1.2 Transmission, Clinical Features, and Pathogenesis

SuHV-2 is widely distributed and has been reported to be endemic in many swine herds. In countries where the virus has been investigated, the infection rate of herds can vary from 12% to 50% with up to 90% of animals serologically positive in some herds. Where the virus is endemic, it may persist in the absence of clinical signs. Expression of the disease is more likely to occur as a result of introduction, poor management, or coinfections.

SuHV-2 can be transmitted both vertically and horizontally [13]. The clinical presentation can vary depending on the age of the animals in question and the viral status of the herd. A SuHV-2 incursion into a susceptible herd will likely result in transplacental infection and horizontal transmissions, which can result to severe disease. Transplacental infections can result in fetal loss. Animals surviving to birth are likely to exhibit severe respiratory signs along with runting and poor production performance. Infection of young naïve animals, less than 10 weeks of age, can result in generalized clinical signs of rhinitis including ocular and nasal discharge. In very young animals, less than 2 weeks of age, more severe disease can develop where the nasal discharge becomes mucopurulent resulting in potential blockage of the nasal passages. Piglets with severe disease may be unable to suckle effectively and may die due to rapid loss of body condition.

In endemically infected herds, maternal antibody can prevent transplacental infections and suppress the development of severe disease resulting from horizontal virus transmission [14]. The most likely outcome of infection in these herds is subclinical disease expression.

There are few studies on the pathogenesis of SuHV-2 and the clinical significance of infections in older animals, an area that requires further investigation. An example of this is a comprehensive study on porcine respiratory disease complex (PRDC) reported by Hansen et al. [15]. This study explored the association of five viruses including SuHV-2 and seven bacterial species with PRDC cases by histopathology, pathogen culture, and pathogen detection. Of all the pathogens examined, SuHV-2 was more commonly associated with controls (43%) compared to cases (24%), although this association was not statistically significant. The study did conclude that in acute cases of PRDC, the presence of SuHV-2 was more common compared to subacute and chronic cases. While further research is required, the results suggested that when SuHV-2 was present, more severe diseases were observed.

84.1.3 Diagnosis

The diagnosis of SuHV-2 infection can be confirmed with a range of experimental methodologies.

84.1.3.1 Conventional Approaches

Serological methods have been described for the detection of SuHV-2-specific immunological responses following the infection of swine using virus-derived and recombinant antigens [16,17]. SuHV-2 can be readily grown in cell cultures from a variety of clinical samples. Histological examination of tissue sections or nasal scrapings with hematoxylin and eosin staining, particular tissues of the kidney, and nasal epithelia can be useful in diagnosis. The presence of cells with large, basophilic, intranuclear inclusions bodies exhibiting cytomegalia strongly suggests a SuHV-2 infection. Sekiguchi et al. [18] described *in situ* and immunohistochemistry methodologies for enhanced specificity in the detection of SuHV-2 in tissue sections. Electron microscopy has also been used to confirm the presence of SuHV-2 in glandular epithelial cells [19].

Molecular detection: Various molecular assays have been used to confirm the presence of SuVH-1 in samples and virus isolation experiments. Initially, the herpesviral consensus oligonucleotides designed using conserved motifs of DNA polymerase (*dpol*) provided the first sequence information of SuHV-2 PCR, and these data were used to develop a specific PCR assay [20–22]. After these initial reports, a number of conventional, semiquantitative and quantitative real-time PCR assays have been reported for the detection and quantitation

of SuHV-2 [21,23–25]. The impetus for most of these studies was not for the detection of SuHV-2 in clinical samples from pigs but rather in the risk management processes for xenotransplantation studies in primates as models for human transplants.

84.2 METHODS

84.2.1 Sample Collection and Preparation

Due to a commonality of clinical signs, the SuHV-2-associated disease may require a discriminated test. The possible confounding agents will depend on the status of the country in question but could include swine fever virus, porcine circovirus 2, porcine respiratory and reproductive syndrome viruses, porcine parvovirus, and porcine enterovirus. Lee et al. [26] have reported a multiplex conventional PCR assay for the detection of SuHV-1, porcine herpesvirus 1, and porcine circovirus.

The samples of choice from live animals for the isolation and detection of SuHV-2 are nasal swabs, nasal scrapings, or whole blood. Suitable samples collected at necropsy include turbinate mucosa and lung lavage samples for the isolation of pulmonary macrophages and kidney tissues. The virus may be more widely distributed in tissues of aborted fetuses, allowing for a more expansive list of tissues to be utilized for isolation.

84.2.2 Virus Isolation

Cells: SuHV-2 can be cultured in the laboratory although slow-growing SuHV-2 will reach modest titers ($\leq 1 \times 10^6$ $TCID_{50}$/mL) in primary cells established from swine testis, ovarian, and lung tissues. The virus can also be grown directly from or in porcine pulmonary macrophages recovered from lung lavage samples. The virus will also replicate efficiently in continuous porcine turbinate PT-K75 cells (ATCC CRL-2528) and porcine kidney epithelial PK-15 cells (ATCC CCL-33) to similar tires.

84.2.3 Molecular Detection

A number of molecular assays have been reported for the detection of SuHV-2 in clinical materials. The diagnosis of clinical disease to SuHV-2 should take into consideration the clinical presentation as well as the presence of the virus or viral genome. Two potential methodologies are outlined in the succeeding text for the specific detection of the SuHV-2 genome in extracts from various samples such as nasal scrapings, tissues, or cell culture supernatants.

84.2.4 Sample Extraction

Isolation of the SuHV-2 genomic DNA can be readily extracted from a suitable quantity of available tissue (20–30 mg) or serum (200 μL) or whole blood (200 μL) using a suitable commercially available kit such as the Qiagen blood and tissue extraction kit as described by the manufacturer. The integrity of the extracted DNA can be analyzed using standard gel electrophoresis, and the quantity can be estimated using UV spectroscopy. For most amplification-based detection methodologies, the integrity of the DNA is not critical with successful results being obtained from degraded samples. Despite this flexibility, a negative result in highly degraded samples should be interpreted with caution.

Some operators prefer to standardize the quantity of input DNA for amplification. This is not essential but can aid in determining the comparative viral load of particular samples where this is of interest. While the template concentration is not critical, care should be taken not to exceed 10 ng/μL of template; the standard working range for quantitative real-time PCR (qPCR) is between 2 and 5 ng/μL, which is suitable for most applications. Caution should be used in drawing conclusions based on viral loads with a pathogen qPCR assay alone from tissue samples. Ideally, if comparisons are required between tissues samples, a host gene should be consider as a calibrator/reference gene to account for variation in the starting quantity of the tissue.

84.2.5 Loop-Mediated Isothermal Amplification Assay

The presence or absence of SuHV-2 genomic DNA in extracted nucleic acids can be determined using loop-mediated isothermal amplification assay (LAMP) with minimal specialized equipment [27]. The LAMP reaction, targeting the *dpol*, uses the following combination of oligonucleotides.

Oligonucleotide	Sequence (5′–3′)	Nucleotide Position	Amplicon Size (bp)
F3 forward outer	TATCTGGTTCTG GCGGAC	46,356–46,373[a]	211
B3 backward outer	AGCATATTTCTCTT TCTAGTCTC	46,163–46,185	
FIP (forward inner primer)	TAGCAGATGCTTC CATATGGTAATT-GGGCAGATATTGT ATACAGGA	46,266–46,290	
		46,325–465,345[a]	
BIP backward inner	TTCTAAGTTGG CCTACTTGCCC-ATGAAGGATA CACGTGAACAC	46,243–46,264[a]	
LF loop forward	ACAACTCCTTAAC GATCACCGAA	46,186–46,206	
LB loop backward	ATCAGGAAGGTG ATAAATGATGGAC	46,218–46,242[a]	

[a] Complement to viral genome sequence.

84.2.5.1 Procedure

1. Thaw reaction components on ice. Once thawed, gently mix and pulse spin reagents to ensure homogeneity.

2. Prepare required reaction volumes in multiples of the following:

Reaction Component	Volume (μL)
F3 forward outer (20 μM)	0.25
B3 backward outer (20 μM)	0.25
FIP forward inner (20 μM)	1.0
BIP backward inner (20 μM)	1.0
LF loop forward (20 μM)	0.5
LB loop backward (20 μM)	0.5
dATP, dCTP, dGTP, dTTP (25 mM)	1.0
Betaine (25 M)	1.0
Isothermal amplification buffer (×10)[a]	2.5
Bst 2.0 WarmStart® DNA polymerase (8 U/μL)[a]	1.0
DNA/RNA-free water	15
Total	24

[a] Sourced from New England Biolabs.

1. Add 24 μL per reaction tube.
2. Add 1 μL of each nucleic acid extract sample (≤100 ng) to labeled reaction tubes. Include template-free reaction by adding 1 μL of water to one tube.
3. Close/seal tubes, gently mix, and pulse spin.
4. Place reactions at 65°C for 40 min.
5. Three methodologies can be used to determine the results of the LAMP assay:
   a. *Visual inspection*: As a result of the accumulation of the by-product magnesium pyrophosphate in the LAMP reaction, the reaction mixture will appear turbid in those reactions with sufficient quantities of starting SuHV-2 template DNA. Test reactions are compared to the controlled reaction (no template).
   b. *Agarose gel electrophoresis*: Standard agarose gel electrophoresis can be used to assess the amplification results. An aliquot (5 μL) of the reaction is run on 2% agarose gel with appropriate staining. Successful amplification is evident through the observation of multiple amplification products ranging in size from approximately 200 to 1000 bp. No amplification products should be in the reactions in the absence of added templates.
   c. *Addition of fluorescent dye*: The addition of a suitable DNA interchelating fluorescent dye, such as SYBR green, can be used to enhance the detection of LAMP-amplified products. This is performed by adding 1 μL of 1/1000 working solution, which can be added to each reaction. Positive reactions are expected to change to green in color. A 10-fold increase in sensitivity is expected compared to the evaluation of magnesium pyrophosphate accumulation alone.

Note: The LAMP amplification products result from the complex binding reaction of oligonucleotides and strand displacement activity of the *BSt dpol* (see review [28]). Alignment of SuHV-1 *dpol* sequences from GenBank suggests a variation within the primary LAMP amplicon (data not shown). A negative LAMP amplification result, where other observations such as clinical presentation and/or histopathology suggest a SuHV-2 infection, may require additional investigations such as consensus *dpol* PCR and amplicon sequencing [20]. Any subsequence redesign of the LAMP oligonucleotides should be performed using an appropriate software package for optimal performance.

84.2.6 Quantitative Real-Time Polymerase Chain Reaction

The presence or absence of SuHV-2 genomic DNA in extracted nucleic acids can also be determined using qPCR, which is the oligonucleotide combination of PCMVpolF, PCMVpolR, and PCMV probe dual labeled with 6-carboxyfluorescein (6FAM) and tetramethylrhodamine (TAMRA) [24]. The locations of the oligonucleotides in the SuHV-2 genome sequence are shown, which target *dpol* on the negative strand of the viral genome [12]. The reaction uses the following oligonucleotides:

Oligonucleotide	Sequence (5′–3′)	Nucleotide Position	Amplicon Size (bp)
PCMVpolF	GCTGCCGTGTC TCCCTCTAG	45,699–45,718[a]	82
PCMVpolR	ATTGTTGATAAA GTCACTCGTCTGC	45,637–45,661	
PCMV probe	6FAM-CCATCAC CAGC ATAGGGCGGGAC-TAMRA	45,670–45,692[a]	

[a] Complement to viral genome sequence.

84.2.6.1 Procedure

1. Thaw reaction components on ice. Once thawed, gently mix and pulse spin reagents to ensure homogeneity.
2. Prepare required reaction volumes in multiples of the following:

Reaction Component	Volume (μL)
Qantitect Master Mix (×2)	10.0
Primer PCMVpolF (0.2 μM)	0.2
Primer PCMVpolF (0.2 μM)	0.2
Dual-labeled probe PCMV-P (0.2 μM)	0.2
DNA/RNA-free water	7.4
Total	18.0

3. Add 18 µL per reaction tube.
4. Add 2 µL of each nucleic acid sample (≤100 ng) to labeled reaction tubes. Include template-free reaction by adding 2 µL of water to one tube.
5. Close/seal tubes, gently mix, and pulse spin.
6. Place in qPCR thermocycler and cycle as follows: 1 cycle of 95°C for 5 min; 40 cycles of 95°C for 15 s and 60°C for 75 s.
7. Fluorescent amplification signals are acquired using default instrument settings. Analyze experimental outputs with the proprietary instrument software provided according to the manufacturer's instructions.

Note: The sensitivity of the qPCR makes template control critical, and every effort should be made to prevent reaction contamination. Where possible, each step in the sample analysis process from collection, nucleic acid extraction, qPCR reaction setup, qPCR amplification, and any postamplification manipulations should be physically separated.

The reaction components, setup, and cycling described earlier are generally appropriate for the Master Mix QuantiTec® kit (Qiagen) with cycling conditions and data acquisition using a Rotor Q (Qiagen). The manufacturer has variations of these Master Mix reagents available that are compatible with a range of qPCR cyclers, and it is strongly recommended that the user consults the supporting documentation to ensure that the most suitable Master Mix is selected for the instrument to be used. It should also be noted that the manufacturer recommends reaction volumes of 50 µL. Reduced reaction volumes are used in the authors' laboratory for a wide range of qPCR assays to detect herpesvirus in various samples with no impact on the assay performance. For users new to the technology, it may be more appropriate to initially use the recommended reaction volumes before reducing assay volumes. The user should also ensure that the reduced reaction volume is compatible with the available qPCR instrument.

A comparison of the SuHV-2 *dpol* sequences available from GenBank demonstrated strain-dependent sequence variations within the qPCR 82 bp amplicon. While the primer and probe-binding sites were invariant, a variable nucleotide was identified in approximately half of the 16 sequences examined (data not shown). If any postamplification validations such as high resolution melt analyses are performed, the impact of these variations should be considered.

84.3 CONCLUSION

Given the ubiquity with which herpesviruses are distributed across vertebrate animal species, it is reasonable to conclude that there are many betaherpesviruses that infect livestock, which remain undiscovered. This likely reflects the homeostasis the virus and host have attained through coevolution. It is only when something perturbs this established relationship that the presence of these agents becomes apparent. Further, the lack of in-depth investigation in many veterinary disease episodes may also contribute to the underrepresentation of viral species infecting livestock in this subfamily. Exploratory studies in wild suid and bat species have reported evidence of novel betaherpesviruses [29,30]. The existence of undetected betaherpesviruses in livestock warrants further investigation.

As SuHV-2 is the most characterized of the animal betaherpesviruses, it will likely remain of interest due to the continued research on xenotransplantation between swine and humans. In pig–primate xenotransplant studies, reactivation of SuHV-2 has been demonstrated, and in the immunosuppressed setting of transplant recipients, it is of concern [6]. A benefit of these studies is that unlike many other herpesvirus infections of animals, the sensitivities of SuHV-2 to antiviral drugs have also been reported [23]. However, it is considered unlikely these would ever be used in pig production systems. Similarly, the capacity of SuHV-2 to be transmitted across the placenta and infections in piglets make it an ideal experimental model for testing of vaccination studies to prevent HHV-5 cross-placental infections in human [31].

While SuHV-2 is of importance in swine production, it can be effectively managed with the implementation and maintenance of on-farm biosecurity measures. Studies have been unable to establish links between the presence of SuHV-2 and porcine diseases with complex etiologies such as PRDC and porcine periweaning failure-to-thrive syndrome [15,32]. More recently, molecular investigations suggest novel and complex interactions between SuHV-2 and the porcine immune system resulting in immune suppression [33]. To resolve these issues, the continued surveillance for SuHV-2 using the outlined detection methodologies here will be important to more accurately assess its impact on production.

85.1 INTRODUCTION

Infectious laryngotracheitis (ILT), caused by infectious laryngotracheitis virus (ILTV) or gallid herpesvirus 1, is an economically important respiratory disease of chickens worldwide. The natural hosts include chickens, turkeys, and pheasants. Although all ages of chickens are vulnerable to ILTV, the most sensitive age is above 3 weeks [1,46]. In the virulent form of ILT, the clinical signs include gasping, coughing, bloody mucus in trachea, and dyspnea, which lead to suffocation. This form can result in 90%–100% morbidity and 5%–70% mortality. The signs of the mild form include nasal discharge, conjunctivitis, reduced egg production and shell quality, decreased weight gain, and increased condemnation rate. The mortality and morbidity of the mild form is about 5% [2]. Despite the availability of various vaccines (attenuated live, inactivated, recombinant), ILTV still causes significant economic losses.

ILT was first reported in the 1920s in the United States; however, this disease may have existed in chickens much earlier [3,4]. In the 1930s, the name infectious laryngotracheitis was formally used for this disease. The agent of ILT was verified as a herpesvirus in 1963 [4]. From then on, ILT become prevalent in chickens all over the world especially in countries with large poultry industries.

85.1.1 Classification, Morphology, Genome Organization, and Biology

85.1.1.1 Classification

The *Herpesviridae* family covers a large group of DNA viruses, with more than 200 different species identified in humans and animals. The *Herpesviridae* family can be separated into three subfamilies, *Alphaherpesvirinae*, *Betaherpesvirinae*, and *Gammaherpesvirinae*, which share similar basic biological features. The *Alphaherpesvirinae* consists of four genera, including the genera *Mardivirus* and *Iltovirus*, which are known to infect avian hosts. Specifically, avian Marek's disease viruses and herpesvirus of turkey belong to *Mardivirus*, while ILTV (or gallid herpesvirus 1) and psittacid herpesvirus 1 (PsHV-1) are members of *Iltovirus*. Several alphaherpesviruses cause important diseases in animals, such as pseudorabies virus (PrV), bovine herpesvirus 1 and 5, and equid herpesvirus 1 and 4 [5,6]. The DNA sequence of ILTV is different from those of other alphaherpesviruses [7].

85.1.1.2 Morphology

ILT viral particles, as herpes simplex virus (HSV), have icosahedral symmetry and are 200–350 nm in diameter. The spherical virion comprises core, capsid, tegument, and envelope.

The viral genome is packaged as a single, linear, double-stranded DNA molecule into a capsid. The nucleocapsid of ILTV contains 162 capsomers, which contain 150 hexons and 12 pentons, and the triangulation number (T) is 16. The major capsid proteins are constructed by six copies of hexons and five copies of pentons. The diameter of virion is about 195–250 nm. The envelope surrounding the nucleocapsid is a lipid bilayer, which is intimately associated with the outer surface of the tegument. It contains a number of integral viral glycoproteins [7]. The buoyant density of ILTV DNA in CsCl is 1.704 g/mL, and the molecular weight is 100×10^6 Da. The genome of ILTV is a linear 155 kb double-stranded DNA, which comprises long and short unique regions (U_L, U_S) and inverted repeat sequences (internal repeat, IR; terminal repeat, TR) that flank the U_S regions. The genome forms two isomers, which are different from the orientation of the U_S regions [8]. This genome structure is designated as type D herpesvirus genomes [9].

ILTV is enveloped and thus sensitive to the lipolytic solvents, such as ether and chloroform [10]. ILTV can be inactivated by ether after 24 h [11]. ILTV is also susceptible to heat. At 55°C for 10–15 min or 38°C for 48 h, this virus is readily inactivated. However, different strains of ILTV show varied resistance to heat [10], and the Belgian strain had partial infectivity after 56°C at 1 h. In chicken tracheae and chorioallantoic membranes (CAMs), ILTV can be destroyed in 44 h at 37°C or inactivated in 5 h at 25°C [3]. ILTV can be destroyed in 1 min by treating with 3% cresol or a 1% lye solution [10]. On the chicken farm, 5% hydrogen peroxide mist with fumigating equipment can completely inactivate ILTV. At a lower temperature, ILTV can maintain its infectivity for a long period. The virus can survive for 10–100 days in tracheal exudates and chicken carcasses at 13°C–23°C [2]. When stored at −20°C to −60°C, ILTV can be viable for several months to years. Storage media containing 50% glycerol or sterile skim milk can greatly increase the infectivity in tracheal swabs [16].

85.1.1.3 Genome Organization

ILTV genome is double-stranded linear DNA. By assembling 14 ILTV genome sequence data published by different laboratories, the ILTV genome was confirmed to be 148,687 bp in length, with a G + C content of 48.16% [13] (Figure 85.1). The ILTV genome consists of 77 predicted open reading frames (ORFs), 63 of which are homologous to HSV-1 genes, the prototype of alphaherpesviruses [5]. The U_L region may contain 62 genes, and the U_S region has 9 predicted genes. There are five ORFs (ORF A–E) located in U_L region, which were unique for ILTV and PsHV-1 [14,15]. In the other U_L region, upstream of the conserved UL1 gene, UL0 and UL (-1) were ILTV-specific genes [35]. They were expressed during the late phase of viral replication in cell culture, and both of their mRNAs are spliced with removing introns at the 5′ ends. These two gene products showed 28% homology, which indicated a duplication of ILTV evolution [16]. The ILTV genome contained internal inversion within U_L region from UL22 to UL44 genes, which were similar to the inversion from UL27 to UL44 genes

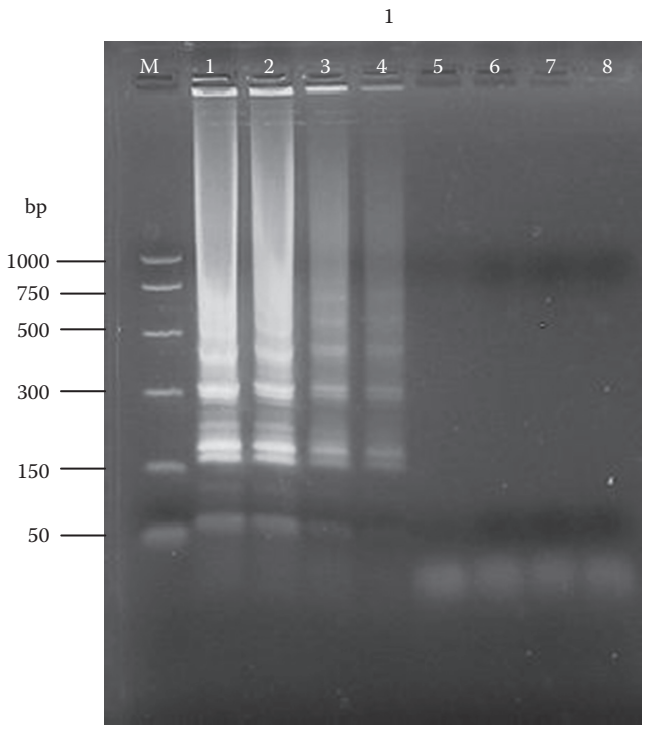

FIGURE 85.1 Sensitivity of the loop-mediated isothermal amplification assay for infectious laryngotracheitis virus detection. Electrophoresis photo of serial 10-fold dilutions of infectious laryngotracheitis virus (ILTV) ICP4. The ILTV-positive products showed many bands with different sizes and a smeared DNA between these bands. The bands smaller than 50 bp were primer dimmers. M: DNA marker (PCR Makers, Promega). Lane 1: 6×10^4 copies/μL; lane 2: 6×10^3 copies/μL; lane 3: 6×10^2 copies/μL; lane 4: 60 copies/μL; lane 5: 30 copies/μL; lane 6: 15 copies/μL; lane 7: 6 copies/μL; lane 8: negative control.

of PrV. The biological functions of these inversions were not clear [15,17]. The UL47 gene of ILTV changed to U_S region, and there was no UL16 homologous gene in ILTV genome [13,18,30]. ILTV had three viral replication regions (Ori), one located in the middle of U_L region (Ori_L) and two copies in the U_S region (Ori_S). There were 11 structural glycoproteins of ILTV homologous to HSV-1 (gB–gM), but between UL2 and UL3 of ILTV was an ORF, UL3.5, which was conserved in other alphaherpesviruses but not HSV-1 [19].

According to the phylogenetic analysis, comparative DNA, and amino acid sequences, researchers indicated that ILTV and PsHV-1 genes shared limited homology to other alphaherpesviruses and were distinct from the other two avian alphaherpesviruses, Marek's disease virus and herpesvirus of turkeys. Their studies revealed that ILTV was a separate branch in the phylogenetic tree and could be an early type of alphaherpesviruses [6,13].

There are many conserved ORFs in ILTV and other alphaherpesviruses genomes. In recent research, the PsHV-1 was the most similar virus to ILTV in gene arrangement and gene sequences. Therefore, PsHV-1 and ILTV were classified into *Iltovirus* (ILT-like) genus [13]. There are about 40 genes commonly found in all herpesviruses. These gene products

include capsid proteins, DNA replication proteins, DNA packing or cleavage proteins, and envelope glycoproteins. They are termed core genes for herpesviruses [20].

Herpesvirus genes can be classified into three groups: immediate early (IE), early (E), and late (L) genes. IE genes are transcribed immediately after infection and are viral genome regulators and activators. E gene products are involved in viral DNA replication and nucleic acid metabolism. Most of the L gene products are virion components, like capsid proteins, tegument proteins, and envelope glycoproteins. In ILTV, many viral proteins have been identified by monoclonal antibodies, monospecific antisera, or direct detected in viral particles. The function and the distributions of ILTV gene products are assigned by [13].

Glycoprotein B (*gB*): gB is identified in every herpesvirus, and it is the most conserved structural protein. According to amino acid analysis, protein sequence of ILTV gB is similar to other herpesviruses. Therefore, it might have the same function with its homologue [21,22]. The gB is an essential protein for virus attachment and penetration to host cells. It also involves cell-to-cell spread and syncytium formation [23,24]. Furthermore, gB induces humoral and cell-mediated immune response. An ILTV gB subunit vaccine protected chickens from presenting clinic signs and viral replication. Recombinated ILTV gB into fowl pox virus can protect chickens from ILT challenge [25]. gB might be a candidate for an ILTV recombinant or subunit vaccine. In ILTV-infected chicken embryo liver (CEL) cells, gB is synthesized as a 110 kDa monomeric precursor protein in the endoplasmic reticulum and then converted to homodimers, which are composed of two 100 kDa subunits. The mature ILTV gB is composed by two disulfide-linked 58 kDa subunits with N-linked glycohydrate chains and is secreted from the Golgi apparatus.

Glycoprotein C (*gC*): gC is a structural and nonessential protein for viral replication in cell culture. This glycoprotein involves viral attachment and virulence. In most alphaherpesviruses, gC mediates viral attachment by interacting with the cellular heparan sulfate receptor [26]. However, according to the gC sequence analysis and protein expression research, ILTV gC lacked about 100 amino acids at N-terminal end of the protein, which was the heparin-binding motif, but this did not affect ILTV infectivity. It indicated that ILTV used a different mechanism to attach to the host cells [27,38].

Glycoprotein E and glycoprotein I (*gE and gI*): gE and gI are nonessential ILTV proteins. They form a heterodimer with noncovalent binding. In HSV-1, gE and gI assists virus cell-to-cell spreading. The gE/gI heterodimer was used to promote cell-to-cell spreading by binding cellular receptor at cell junctions [28]. The gE/gI-deleted mutants of HSV-1, PRV, and bovine herpesvirus 1 reduced their ability to spread cell to cell [29]. In ILTV, gE/gI-deleted mutants showed reduced cell-t-ocell spread, and this gE/gI-deficient ILTV could not form plaques in cell culture. Thus, gE/gI plays a more significant role in cell-to-cell spread of ILTV than other alphaherpesviruses [29].

Glycoprotein G (*gG*): gG is nonessential and conserved in most of alphaherpesviruses. This glycoprotein is not assembled into virus particles but secreted from infected cells [9]. The gG of ILTV serves a virulence factor. The gG-deficient ILTV reduced their pathogenicity producing less clinical signs, less effect on weight gain, and less mortality [31]. Workers inoculated this gG-deficient ILTV into birds by eye drop, drinking water, and aerosol routes [31]. Results showed that eye drop and drinking water routes were safe and induced protection from virulent strain challenging. However, aerosol inoculation did not reach the estimated protection level. This gG-deficient ILTV had the potential to become a marker vaccine to quarantine vaccinated and naturally infected birds [31].

Glycoprotein J (*gJ*): The gJ is the product of ORF 5 gene located in U_S region, a nonessential and structural glycoprotein. This protein was named gp60 because it was identified as a 60 kDa glycoprotein [32]. This ORF 5 gene product was recognized by ILTV gJ monoclonal antibody. Therefore, it was identified as the gJ of ILTV. The ILTV gJ showed different protein forms by separating in different masses [32]. ILTV gJ contains *N*- and *O*-linked carbohydrate chains, and two different translation products are formed by nonspliced and spliced mRNA. The gJ-deficient ILTV has minor effects on cell-to-cell spread, but the virus replication rate was affected. Moreover, the gJ-deficient ILTV reduced their virulence, when compared with parent viral challenge. Therefore, the gJ-deleted ILTV might serve as a marker vaccine for serological differentiation between vaccinated and wild virus-infected birds [33].

Glycoprotein M and glycoprotein N (*gM and gN*): The gM and gN are gene products of UL10 and UL49.5 in ILTV. They are dispensable for viral replication of most alphaherpesviruses in cell culture [9]. The gM and gN form heterodimeric complex with each other by disulfide link. The gM and gN of many herpesviruses are *O*-glycosylated. However, in ILTV, the gM is not modified by glycosylation [18].

Thymidine kinase (*TK*): The TK gene is located in the U_L region of viral genome. It is not essential for virus growth in cell culture, but TK is a virulence factor of ILTV. TK-negative alphaherpesviruses reduced the rate of reactivation from latent infection [34]. Chickens, which received TK-deficient ILTV, showed reduced clinical signs and induced protection against virulent ILTV. TK-deficient ILTV may provide a direction for latent infection, reactivation, and as a vaccine candidate.

Other proteins: The UL50 gene of ILTV encodes dUTPase. This protein prevents uracil addition into DNA, when ILTV DNA replication occurs. In ILTV, this protein is nonessential in cell culture. The UL50-deleted ILTV did not attenuate viral pathogenicity. However, when green fluorescent protein (GFP) was inserted into UL50-deleted region, the virulence was readily decreased. The disadvantage was that this GFP-inserted recombinant was unstable [18]. The ILTV-specific UL0 gene can be deleted, and the recombinant virus was almost apathogenic for chickens. Although UL (-1) gene product was structurally homologous to UL0, UL (-1) was indispensable for ILTV [32]. The genes, ORF A–E, were unique in ILTV. They were not essential proteins, but the deficient mutants showed reduced virus titer and plaque size [35].

The gene products of ORF A–E might be important in virus replication [18]. The ILTV genome contains U_L and U_S regions and two inverted repeats (IR, TR). The IR and TR flank the U_S region.

85.1.1.4 Biology

Virus replication of ILTV was similar to that of other alphaherpesviruses, such as PrV and HSV [36]. At the beginning of infection, the virus attached to the receptors on the cell surface. The envelope fuses with the cell membrane, and virus nucleocapsid was released into the cytoplasm. Viral DNA was transported into the nucleus. Transcription of viral genome, replication of viral DNA, and assembly of new virion occurred in the nucleus [18].

The replication of ILTV DNA was highly regulated in a cascade function. After infecting the cell, viral linear DNA circularized rapidly, and the DNA was replicated by rolling circle mechanism producing concatemers. The DNA concatemers were cleaved into monomers and packaged into newly synthesized nucleocapsids within the nucleus. The viral DNA containing nucleocapsids were transported through the cytoplasm to become enveloped [18]. The enveloped virions were released by cell lysis or budding [18,37].

During ILTV replication, like HSV, protein expression is regulated strictly in a cascade function. The virus turns off host protein synthesis and expresses three groups of viral proteins. When the later viral genes are expressed, the prior genes are downregulated. ILTV uses host RNA polymerase II to transcribe all viral genes. At first stage, the viral α- or IE genes are expressed. The IE gene activation does not need prior protein synthesis. A virion tegument protein, α-transinducing factor, enhances α-genes transcription. The α-gene products stimulate β- or E gene expression. The β-proteins regulate DNA replication, nucleotide metabolism, and γ-gene stimulation. The β-gene expression starts infection and turns off after viral DNA replication. The γ-genes or L genes are divided into two groups based on their timing and requirement for viral DNA synthesis. The γ-genes encode structural components of the virion [18,36].

The capsid proteins are synthesized in the cytoplasm, and then transported into the nucleus for viral capsid assembly. The ILTV progeny DNA concatemers are cleaved into unit length monomers and packaged into capsids by recognizing the specific sequences as signals. After encapsulation of viral DNA, the nucleocapsids are budded into inner nuclear membrane and form primary enveloped virion in the perinuclear space. At primary envelopment steps, UL31 and UL34 proteins form part of primary virion, which is different from mature virus particles, which helps the nucleocapsid to become primary enveloped. The primary enveloped virion then fuses with the outer nuclear membrane and deenvelopes for releasing nucleocapsid into cytoplasm. After transportation into the cytoplasm, the nucleocapsid collects 15 tegument proteins and 10 envelope glycoproteins and is reenveloped by budding into endoplasmic reticulum–Golgi vesicle. This mature virus particle is released by fusing of the vesicle with the cell membrane [44,45].

85.1.2 Transmission and Pathogenesis

The chicken is the primary natural host of ILTV. All ages of chickens are affected, but chickens above 3 weeks old are more susceptible [1]. A report maintained that ILTV can also infect pheasants, pheasant–bantam crosses, and peafowl.

Turkeys can be infected with ILTV experimentally, but they might have an age-dependent resistance, since lesions are restricted in young age birds [39,40]. A natural infection of ILTV in turkeys was reported [40]. The clinical signs in turkeys were similar to that in chickens. Starling, sparrows, crows, pigeons, ducks, and guinea fowls were resisted to ILTV infection. Chicken and turkey embryo eggs were susceptible to ILTV, but guinea fowl and pigeon eggs were not [12].

ILTV can be propagated in chicken embryo eggs and several avian cell cultures. In chicken embryonating eggs, because of necrosis and proliferative tissue, ILTV forms plaques on the CAM. Plaques on the CAM can be observed in 48 h after infection, and embryo death might occur 2–12 days after infection. Different strains of ILTV showed different plaque size and morphology on the CAM [41].

ILTV can be propagated in primary avian cell cultures, such as CEL, chicken embryo kidney (CEK), and chicken kidney (CK) cell cultures [42,43]. Hughes and Jones [52] investigated the sensitivity of ILTV isolation and propagation in different culture methods. They found that CEL was the most sensitive for isolation, and CK was a second choice. The CEK, chicken embryo lung cells, and CAM inoculation were less sensitive [44]. It was reported that ILTV can be propagated in chicken leukocytes from the buffy coat cells [42]. Macrophages from bone marrow or spleen were susceptible to ILTV [45]. Chicken embryo fibroblasts, Vero cells, and quail cells were not satisfactory for primary isolation of ILTV. Other cell types, such as lymphocytes, thymocytes, and activated T cells were not sensitive to ILTV infection [43]. ILTV can also replicate in an avian liver cell line, LHM, which is chicken liver tumor cell induced by chemicals. In order for ILTV to multiply in LHM cells, it must be adapted.

Viral cytopathic effect (CPE) can be observed in cell culture in 4–6 h postinoculation (PI). Cytopathology contains increased swelling of cells, chromatin displacement, and rounding of the nucleoli. Cytoplasmic fusion produces multinucleated giant cells. The intranuclear inclusion bodies can be observed at 12 h PI. Large cytoplasmic vesicles develop in the multinucleated cells and become more basophilic as cells generate [2].

Natural transmission in birds is through the upper respiratory and ocular routes. The sources of ILTV transmission are clinically affected chickens, latent infected carrier chickens, contaminated dust, litter, and fomites that are contaminated with ILTV. Egg transmission is not verified [2,16]. Other sources of mechanical transmission included dog, crows, cats, and beetles [47]. One report investigated that wind-borne transmission as a critical for ILTV spread.

After infection, ILTV replicates in the epithelium of larynx and trachea. Virus particles are present in trachea tissue and secretion for 6–8 days PI. The virus may survive in trachea at

least 10 days PI [48]. Like other herpesviruses, ILTV establishes latent infections. The virus can be reisolated by tracheal swabs from 7 weeks after infection or 2 months after infection in tracheal homologized samples [48]. Trigeminal ganglion is the target for ILTV latency. After 4–7 days PI with ILTV in the tracheae, 40% of infected chickens showed that virus migrated to trigeminal ganglion [48]. After vaccination for 15 months, the latent ILTV from trigeminal ganglion could be reactive. Mature laying chickens challenged with wild ILTV DNA were detected in the trigeminal ganglion by polymerase chain reaction (PCR) at 31, 46, and 61 days PI [49]. When birds are stressed, such as onset of lay or rehousing, ILTV can respread from latent infected birds [44].

85.1.3 Clinical Features

Clinical signs appear 6–12 days PI. Experimental challenge with intratracheal route results in an incubation period of 2–4 days [50]. There are two clinical forms for ILT infection. The clinical signs of the severe form include dyspnea and bloody mucus. The severe form of ILT causes 90%–100% morbidity and 5%–70% mortality [2,49].

Clinical signs of the mild form include depression, reduction in egg production and weight gain, conjunctivitis, swelling of infraorbital sinuses (almond shaped eyes), and nasal discharge. The morbidity of the mild form is about 5% and mortality is 0.1%–2%. It takes 10–14 days for recovery, but with some strains, the clinical signs might extend to 1–4 weeks.

Gross lesions are most commonly observed in the larynx and trachea. With the severe form of ILT, the mucosa of the respiratory tract showed inflammation and necrosis with hemorrhage. A characteristic diagnostic feature was intranuclear inclusion bodies in epithelial cells, which might be observed about 3 days PI. These cells have a condensed nucleus surrounded by a halo and margining of chromatin. Inclusion bodies generally were present only for a few days at the early stage of infection before epithelial cells died. Epithelial cell hyperplasia induced multinucleated cells (syncytia), lymphocytes, histiocytes, and plasma cells, which migrated to the lamina propria. Lesions were followed by desquamation of the necrotic epithelium and loss of mucous glands. At that time, bloody mucus in the trachea was observed [51,52].

85.1.4 Diagnosis

85.1.4.1 Conventional Techniques

Laboratory diagnosis is required for ILT certification, because many respiratory diseases cause similar clinical signs and lesions, such as infectious bronchitis, Newcastle disease, avian influenza, mycoplasma, and infectious coryza. ILT infection can be confirmed with several methods. Virus isolation uses susceptible live hosts to propagate pathogens from samples and can be used for investigating the pathologic changes in these hosts. For ILTV isolation, the dropped CAM of 9–12-day-old embryo eggs and cell cultures is most commonly used. Samples from sick birds include trachea, conjunctiva, larynx, and lung, which are collected and inoculated on the CAM. The CAM route is the most sensitive method for ILTV isolation in embryos [43]. Plaques can be observed in 2 days PI; however, pocks usually develop on the CAM at 5–7 days PI. The plaque size and morphology on the CAM can be used to differentiate the virulence of different strains. The CEL and CEK cells are suitable for ILTV isolation. The typical CPE-multinucleated giant cells might be observed in 24 h PI in cell culture. At least two serial passages of virus isolation are often required to detect CPE [2].

Traditional antigen detection uses ILTV polyclonal or monoclonal antibodies to bind ILTV from clinical samples. Viral antigen can be detected by direct or indirect fluorescent antibodies (FA) in the tracheal smear or tracheal tissues [25]. A more sensitive method, immunoperoxidase (IP)-labeled monoclonal antibodies, was used as immunoprobes to detect ILTV in tracheal smears. This IP method can detect ILTV on the second day PI [54]. Agar gel immunodiffusion (AGID) used ILTV hyperimmune serum to detect antigen in tracheal samples, and it can quickly differentiate ILT from the diphtheritic form of fowl pox. However, the sensitivity of this method was relatively lower than other methods [11]. Antigen capture enzyme-linked immunosorbent assay (AC-ELISA) used ILTV monoclonal antibodies for antigen detection. The AC-ELISA was faster and more accurate than AGIP or FA [25].

There are several methods for detection of ILTV-specific antibodies in chicken serum including AGID, ELISA, virus neutralization (VN), and indirect FA. Among these antibody detection methods, ELISA was more sensitive than VN, and AGID was least sensitive. Both ELISA and IFA were quick and sensitive [55,56] and an ELISA method, which coated *Escherichia coli*–expressed ILTV gE and gp60 (gJ) for ILTV-specific antibody detection. This ELISA test was able to differentiate ILTV infected from noninfected chicken serum [56]. It is difficult to identify different strains of ILTV by serological methods, because the ILTVs have close genomic homology [57].

85.1.4.2 Molecular Techniques

ILT DNA detection methods emerged in recent years. The DNA detection methods can identify ILTV quickly, accurately, and sensitively. The molecular techniques for ILTV detection include cloned DNA probes for dot-blot hybridization [58,59], PCR and nested PCR [59], real-time PCR [60], multiplex PCR [61], *in situ* hybridization [62], and PCR followed by restriction fragment length polymorphism (RFLP) [63–66]. Work [49] compared the sensitivity of different ILTV detection methods and found that PCR was much more sensitive than virus isolation in cell culture and electron microscopy. PCR also detected ILTV samples, which were contaminated with other pathogens [49].

The most common and effective molecular method for ILTV differentiation is PCR-RFLP. PCR-PFLP analysis of single or multiple viral genome regions identified different strains from different geographic areas and vaccine from wild-type strains [8,14,65–68]. Restriction endonuclease analysis of ILTV DNA can also differentiate vaccine strains

from wild-type strains [52]. Moreover, PCR-RFLP analysis of partial ICP4 gene, gC gene, and TK gene distinguished wild strains from vaccines in Taiwan. In that investigation, some virulent isolates were from Taiwan poultry houses and could be separated from vaccine strains [69]. Analysis of multiple genes PCR-RFLP combined with DNA sequence analysis of gG gene and TK gene to separate vaccine and nonvaccine strains in Korea [69]. In Austria, researchers demonstrated that multiple gene PCR-RFLP was more reliable to identify the relationship between vaccine and wild strains [64].

In the United States, researchers [53,65] investigated ILTV isolates from commercial poultry samples between 1988 and 2005 using multiple gene PCR-RFLP analysis (ORFB-TK, ICP4, UL47/gG, and gM/UL9). ILTVs in the United States were separated into nine genetic groups. Group I and II were the USDA reference strain and tissue culture origin (TCO) vaccine strain. Group IV isolates were identical to chicken embryo origin (CEO) vaccine strains, whereas group V isolates, which had one PCR-RFLP pattern different from the CEO vaccine strains, were CEO-related isolates. Group VI isolates were different from CEO and TCO vaccine strains. In that report, most of ILTV commercial poultry isolates were closely related to vaccine strains [65]. Researchers [65] investigated 46 ILTV field isolates in the United States from 2006 to 2007. After multiple gene PCR-RFLP analysis, most of the isolates (63%) were closely related to vaccine strains (group III–V) [66]. According to these reports, most ILTV wild isolates in U.S. chicken farms were derived from vaccines.

In Europe, a research investigation collected 104 field isolates during 35 years from eight different countries and analyzed the viruses with PCR-RFLP from the TK gene. The results showed that ILTVs in these countries were separated into three genetic groups. Moreover, 98 field isolates had the same RFLP patterns with vaccine strains [67]. In Australia, PCR-RFLP was used to analyze ILTV gG, TK, ICP4, ICP18.5, and ORFB-TK genes. These isolates could be discriminated into five genetic groups. Some isolates could not be distinguished from vaccine strains [64].

PCR assays such as conventional PCR, nested PCR [67], real-time PCR [60], and multiplex PCR [61] offer a quick, accurate, and highly sensitive approach for ILTV DNA detection. However, PCR samples can show false-negative results, if heavily contaminated pathogens and organisms are present [49].

Due to its speed and sensitivity, reproducibility, and ability to quantify directly from clinical samples, real-time PCR has increasingly become a method of choice in clinical laboratories. The most widely used real-time PCR assays are the SYBR Green PCR melting curve analysis and TaqMan PCR [70,71], the latter of which has a detection limit of <100 genome copies. A sensitive SYBR green PCR assay, with an extended dynamic range of 7 orders of magnitude compared to 7 orders of magnitude reported for the TaqMan, was developed and validated [71].

A novel DNA amplification method, loop-mediated isothermal amplification (LAMP), has been used in disease diagnosis. LAMP method uses *Bst* DNA polymerase, which has strand displacement activity, and a set of two inner and two outer primers to recognize six regions of target sequences. The LAMP method amplifies DNA at isothermal conditions between 60°C and 65°C in 60 min. The LAMP assay provides a rapid, and low-cost, detection method in disease diagnosis. It has been widely used for viral and bacterial nucleic acid detection. In the present study, the LAMP assay and TaqMan® probe-based real-time PCR were developed and compared for ILTV DNA detection.

85.2 METHODS

85.2.1 Sample Preparation

Five commercial ILT vaccine strains: four chicken embryo origin (CEO) vaccines—AviPro® LT (Lohmann Animal Health Inc., Winslow, ME), LT Blen® (Merial Select Inc., Gainesville, GA), Laryngo-Vac® (Zoetis Animal Health, Raleigh, NC), Trachivax® (Schering-Plough Animal Health Corp., Kenilworth, NJ), and the TCO vaccine (LT-IVAX®) (Schering-Plough Animal Health Corp., Kenilworth, NJ). *Mycoplasma gallisepticum* (MG) vaccine (MycoVac-L®) (Intervet Inc., Millsboro, DE), fowl pox vaccine (Chicken –N-Pox™ TC) (Zoetis Animal Health), and Marek's disease serotype 3 vaccine (MD-Vac® CFL) (Zoetis Animal Health) were used for test specificity [71].

85.2.2 Detection Procedures

85.2.2.1 Real-Time PCR

ILTV DNA is extracted using Qiagen DNeasy® Blood & Tissue Kit (Qiagen, Valencia, CA) with slight modifications. Briefly, 200 µL of each sample is mixed with 20 µL proteinase K and 200 µL of Buffer AL. The mixture is mixed well and incubated at 56°C for 10 min. Then, 200 µL of 100% ethanol is added and vortexed. The mixture is transferred into the DNeasy mini spin column and centrifuged at 6000 × *g* for 1 min, and then the flow-through was discarded. The column is placed in a 2 mL collection tube, and 500 µL of Buffer AW1 was added. The tube is centrifuged at 6000 × *g* for 1 min, and the flow-through was discarded. The column is transferred into a 2 mL collection tube and 500 µL of Buffer AW2 was added. The tube is centrifuged at 20,000 × *g* for 3 min to remove excess reagents from the column membrane. Finally, the DNA is eluted in 100 µL of Buffer AE by centrifuging at 6000 × *g* for 1 min and stored at −20°C.

A segment of LT Blen ILTV ICP4 gene is amplified by PCR using the following primers: ICP4-F: 5′-CG CAGAGGACCAGCAAAGACCG-3′; ICP4-R: 5′-GAAGCAGA CGCCGCCGTAGGAT-3′. For PCR, 50 µL of reaction is set up as follows: 5 µL of 10× PCR buffer, 5 µL of 25 mM $MgCl_2$, 1 µL of 10 mM dNTP each, 1 µL of 100 µM ICP4-F, 1 µL of 100 µM ICP4-R, 0.25 µL of Taq DNA polymerase (5 U/µL; AmpliTaq® DNA polymerase, Applied BioSystems, Foster City, CA), 28.75 µL of water, and 5 µL of sample DNA. PCR steps were subjected to a 94°C initial denaturation for 2 min and 35 cycles of 94°C denaturation for 30 s, 55°C annealing for 30 s, and 72°C extension for 1 min, followed by 72°C final extension for 5 min.

PCR is conducted in GeneAmp® PCR System 9700 (Applied BioSystems, Foster City, CA). PCR products are detected with 2% agarose gel electrophoresis.

PCR products are purified by Wizard® PCR preps DNA purification system (Promega, Madison, WI). The cDNA is cloned into the pT7Blue-3 vector. A blunt-end cloning kit (Novagen, Darmstadt, Germany) is used according to the manufacturer's instructions. The plasmids are transformed into NovaBlue® Singles™ competent cells (Novagen, Darmstadt, Germany). Several clones are selected and the plasmid DNA extracted using Wizard Plus SV kit (Promega, Madison, WI), according to the manufacturer's directions. Clones containing the proper insert are verified by DNA sequencing. The concentrations of cloned plasmids are measured by the NanoDrop® ND-100UV-Vis Spectrophotometer (Wilmington, DE).

Copy number of ILT ICP4 cloned DNA is calculated with the following formula:

$$\text{ICP4 DNA}\left(\text{copies}/\mu\text{L}\right) = \frac{6.022\times10^{23}\left(\frac{\text{molecules}}{\text{mol}}\right)\times\text{concentration}\left(\frac{\text{g}}{\mu\text{L}}\right)}{\text{Weight}\left(\frac{\text{g}}{\text{mol}}\right)}$$

Weight in Daltons (g/mol) = (bp size of plasmid + insert) × (330 Da × 2 nucleotide/bp)

Real-time PCR amplification is performed in a LightCycler® (Roche, Applied Science, Indianapolis, IN) with a 20 µL reaction volume. For real-time PCR assay, each reaction contains 10 µL of 2× master mix (QuantiTect® Probe PCR kit, Qiagen, Valencia, CA), 0.5 µM of each primer, 0.1 µM of probe, 2.5 µL of water, and 5 µL of DNA template. Real-time PCR mixture is subjected to 95°C initial activation for 15 min, and 40 cycles for 95°C denaturation 0 s, and 60°C combined annealing and extension for 60 s.

Conventional PCR is performed in GeneAmp PCR System 9700 (Applied BioSystems, Foster City, CA) using the same primers with real-time PCR. Totally 50 µL of PCR reagents in a reaction tube contains 5 µL of 10× PCR buffer, 5 µL of 25 mM $MgCl_2$, 1 µL of 10 mM dNTP each, 1 µL of each primer in 100 µM, 0.25 µL of Taq DNA polymerase (5 U/µL; AmpliTaq DNA polymerase, Applied BioSystems, Foster City, CA), 28.75 µL of water, and 5 µL of sample DNA. The PCR steps are subjected to a 94°C initial denaturation for 2 min and 35 cycles of 94°C denaturation for 30 s, 50°C annealing for 30 s, and 72°C extension for 30 s, followed by 72°C final extension for 5 min. PCR products were detected with 2% agarose gel electrophoresis.

The LAMP assay is performed in 25 µL, which contained 1× ThermolPol buffer (New England Biolabs Inc., Beverly, MA). Each dNTP are used at a final concentration of 1.2 mM, inner primers to a final concentration of 1.6 µM, outer primers to a final concentration of 0.2 µM, loop primers to a final concentration of 0.4 µM, 1.0 M of butaine (Sigma, Saint Louis, MO), 1 µL of 8U *Bst* DNA polymerase (Large Fragment; New England Biolabs Inc., Beverly, MA), 4 mM of $MgSO_4$, and 5 µL of DNA template. To optimize the reaction, 60°C, 63°C, and 65°C temperatures are tested. Reaction times of 15, 25, 35, 45, 50, and 60 min were tested to optimize the LAMP. The reaction is stopped at 95°C for 3 min to terminate enzyme activity. After LAMP reaction, DNA products are verified by 2% agarose gel electrophoresis, stained with ethidium bromide, and visualized on a UV transilluminator (Fotodyne® Inc., Hartland, WI). In LAMP assay, 1.0 M of betaine is added to the reaction. During DNA amplification (PCR or LAMP), the betaine increased the yield and specificity. It also reduces secondary structure forming in GC-rich regions and eliminates the base pair composition dependence of DNA melting.

Primers and probe for real-time PCR and primers for LAMP are designed in the amplicon of ICP4F/R. The ICP4 gene sequences of four ILTV strains: CEO vaccine (GenBank accession number EU104900), TCO vaccine (accession number EU104908), ILTV-assembled total genome sequence (accession number NC_006623), and 2 ILTV vaccine strains (AviPro LT and LT Blen), are sequenced. They are aligned with AlignX® from vector NTI sequence analysis and data management software v10.3 (Invitrogen Co., Carlsbad, CA). Real-time PCR primers and probe, which generate a 125 bp product, are selected from the conserved regions of ICP4 gene. The target DNA sequence is compared with other sequences using the BLAST service in the GenBank database. Results indicate that the real-time PCR product is located in the ILTV ICP4 gene. Primers and probes are produced by Integrated DNA Technologies®, Inc. (Coralville, CA).

85.2.2.2 LAMP

The LAMP primers are designed using the conserved region of ILTV ICP4 gene in ICP4F/R amplicon using the Primer Explorer V4 software (Eiken Chemical Co., Ltd., Japan). For the end stability, the primer selection followed the rule that the free energy (ΔG) of 3′ end of F2/B2, F3/B3, LF/LB, and the 5′ end of F1c/B1c should be −4 kcal/mol or less. One set of primers is chosen. This primer set comprising two outer, two inner, and two loop primers recognized eight distinct regions in the target sequence. The forward inner primer and the backward inner primer each have two distinct sequences corresponding to the sense and antisense sequence. The DNA strands synthesized from the outer primers (F3 and B3) displace the primary strands. The forward loop primer (LF) recognizes the complementary strand corresponding to the region between F1 and F2, and the reverse loop primer (LB) annealed to the complementary strand corresponding to the region between B1 and B2.

To determine the sensitivity and detection limit for real-time PCR and LAMP, serial 10-fold dilutions of plasmid DNA from 10^9 to 10^0 copies/µL are analyzed. The real-time PCR assay is repeated four times. Standard curves indicating the linear relationships between the threshold crossing points (Cp) and the logarithms of initial ILTV ICP4 gene DNA count are constructed. The serial dilutions are repeated in the same run for evaluating the intraexperiment reproducibility.

To determine specificity, five ILTV strains, nontemplate negative controls, MG, fowl pox, and Marek's disease vaccines are tested. The detection limit and reproducibility of the real-time PCR assays are determined by four independent runs using 10-fold serial dilutions (10^9–10^0) of the ICP4 gene plasmids as template. A standard curve and equation are generated. The ILTV template copy number per amplification reaction is estimated using the standard curve equation. Serial dilution of the ICP4 gene plasmids from 6×10^4, 6×10^3, 6×10^2, 60, 30, 15, and 6 copies/μL is used to determine the sensitivity of the LAMP assay.

To determine viral titer, 50% embryonic infective dosage (EID_{50}) of the LT Blen vaccine is performed as follows. Nine serial 10-fold dilutions of viral stock are made in phosphate-buffered saline. Four 9-day-old specific pathogen-free (SPF) chicken embryonic eggs are used per viral concentration, and each embryonic egg was inoculated with 200 μL of viral dilution via CAM route. The inoculated CAMs are checked for pock formation after 7 days. The viral titer is calculated. The EID_{50} titrations are repeated three times and compared with the ILTV genome copy number with real-time PCR assay.

Both assays are positive for ILTV strains only. No fluorescent signal or positive patterns are detected with nontemplate control and non-ILTV pathogens. The LAMP assay produces stem-loop DNA structure with different length of inverted repeats and cauliflower-like structures of target sequence. Thus, when the LAMP products are analyzed with agarose gel electrophoresis, they show many bands with different sizes and a smeared DNA between these bands at each loading well.

Four repeats of real-time PCR tests generate standard curves, which have an average intercept of 38.28 ± 0.63 and an average slope of -3.14 ± 0.06. The standard curves display a significant correlation between Cp value and copy number with the square of the sample correlation coefficient (R^2) above 0.99 and an average efficiency of 2.063 ± 0.75.

The standard deviation (SD) of Cp value is low; therefore, these data indicate excellent reproducibility. The real-time PCR assay maintains linearity at 10 copies/μL, and the SD and standard error values are stable and low. Although the plasmid concentrations at 1 copy/μL are positive, the machine cannot define the Cp value above 35 cycles. The quantification limits are determined at 10 copies/μL, and the samples with the Cp value ≤ 35 are considered positive for ILTV. Comparing with real-time PCR, conventional PCR with the same primer set is able to detect 10^3 copies/μL. Therefore, real-time PCR is about 100 times more sensitive than conventional PCR.

Serial dilutions of plasmid are used to determine the sensitivity of the LAMP assay. The LAMP assay can detect ILTV DNA templates at 60 copies/μL. Therefore, the sensitivity of real-time PCR is sixfold higher than LAMP.

Viral titers of ILTV LT Blen are measured using 9-day-old SPF chicken embryonic eggs via CAM route. To check viral concentration in 1 dose of ILTV vaccine, the vaccine is diluted by the manufacture's direction to four doses and the copy number checked with real-time PCR. Results show that 1 EID_{50} was equal to $(2.1 \pm 1.3) \times 10^2$ ILT genomic copies, and 1 dose of ILTV vaccine is equal to $(6.9 \pm 0.85) \times 10^5$ copies. This viral vaccine titer is compatible with most manufacture results.

The LAMP reaction creates many DNA bands of different size in the target sequence region. The amplification with LAMP assay shows a ladder-like pattern upon agarose electrophoresis. The optimal temperature for *Bst* DNA polymerase is between 60°C and 65°C. The reaction temperature of 60°C, 63°C, and 65°C is performed to check the optimal efficiency. Results show that the LAMP assay products at 65°C are brighter and clearer than at other temperatures. Thus, 65°C is selected as the optimal temperature for this ILTV LAMP assay. Different reaction times also affect LAMP efficiency. Different reaction time intervals are performed to check the optimal reaction timed for the LAMP assay. Results show that the LAMP products can be easily observed with bright bands after the LAMP reaction is performed above 45 min.

The real-time PCR assay is highly sensitive and specific and can detect as few as 10 copies/μL of the ILTV DNA genome and was highly reproducible. Standard curves of multiple repeats are almost identical. According to the statistics analysis, the variation of slop (-3.14 ± 0.06) and intercept (38.28 ± 0.63) of regression equation is small. Thus, this real-time PCR assay is highly reproducible. Viral titers of field samples and vaccines are critical for vaccine production and efficacy experiments. Since the real-time PCR can determine the concentration of nucleic acids in the samples by estimating with standard curve, the viral titer in samples can be accurately predicted. The titers of 1 dose of vaccine determined in 9-day-old chicken embryo eggs (EID_{50}) are compared with the copy number of ILTV genome by real-time PCR. Results indicate that 1 EID_{50} is equivalent to $(2.1 \pm 1.3) \times 10^2$ ILT genomic copies (Table 85.1). One dose of ILTV vaccine is equivalent to $(2.1 \pm 1.3) \times 10^2$ ILT genomic copies. One dose of ILTV vaccine was equivalent to $(6.9 \pm 0.85) \times 10^5$ copies (Table 85.2).

The LAMP assay is highly specific and sensitive. However, the sensitivity of the ILTV LAMP assay (60 copies/μL) is slightly lower than real-time PCR (Figure 85.1). It provides a 10–100-fold higher sensitivity than regular PCR. It is a simple, rapid, and an easy detection method, in which the reaction is performed at 65°C for less than 1 h and does not require a thermal cycler. In addition, the reaction time is faster than real-time PCR. Furthermore, the reagents and equipment of LAMP assay are cheaper than real-time PCR and can be performed in most laboratories. The sensitivity of LAMP assay is less affected by contaminating components, feces, feed, and blood, which are contained in clinical samples, than PCR. Therefore, the DNA purification steps can be omitted.

The detection limit of real-time PCR and LAMP assays is higher than other prior methods. The sensitivity of nested PCR for ILTV gE gene detection reached 31.3–62.5 fg. The sensitivity of traditional PCR reaches 10^3 copies/μL using the same primers with real-time PCR. However, the real-time PCR (10 copies/μL) and LAMP (60 copies/μL) are more sensitive than conventional PCR. Another TaqMan real-time PCR for ILTV gE gene could detect 100 copies/μL [60]. Creelan et al. [60] used real-time PCR to detect ILTV ICP4 gene with SYBR Green I chemistry, and the sensitivity reached 140 copies/μL.

TABLE 85.1
Correlation between Infectious Laryngotracheitis Virus Viral Genomic Copy Number and 50% Embryonic Infective Dosage

	Titration1	Titration 2	Titration 3	Mean	SD
EID_{50}/mL	8.9×10^5	8.0×10^5	5.0×10^5		
Real-time PCR (copies/mL)	3.2×10^8	9.8×10^7	7.6×10^7		
Conversion factor (copies/EID_{50})	3.6×10^2	1.2×10^2	1.5×10^2	2.1×10^2	$\pm 1.3 \times 10^2$

1 $EID_{50} \approx (2.1 \pm 1.3) \times 10^2$ copies.

TABLE 85.2
Correlation between Vaccine Dosage and Infectious Laryngotracheitis Virus Viral Genomic Copy Number

	4 Doses of ILTV Vaccine				
Real-time PCR (copies/4 doses)	2.4×10^6	3.1×10^6	2.8×10^6	Mean	SD
Conversion factor (copies/dose)	6.0×10^5	7.7×10^5	7.0×10^5	6.9×10^5	$\pm 0.85 \times 10^5$

1 dose $\approx (6.9 \pm 0.85) \times 10^5$ copies to $(6.9 \pm 0.85) \times 10^5$ copies.

The ILTV ICP4 gene real-time PCR is the most sensitive detection method reported so far. As the binding of SYBR Green dye to double-stranded DNA molecules is nonspecific, the SYBR Green–based PCR can be affected by a number of factors, such as the formation of primer–dimmers, and sample concentration [72]. In addition, multiple SYBR Green dye molecules can bind to the same double-stranded DNA fragment. These disadvantages have limited the application of SYBR Green–based real-time PCR in quantitative detections. Although the nested PCR has similar sensitivity as real-time PCR and LAMP assay, it requires two rounds of PCR thermal cycles. Therefore, it is more time consuming, and the possibility of nucleic acid contamination is higher than for real-time PCR and LAMP assays. Since ILT-LAMP method uses six primers, which recognize eight distinct regions of the ILT ICP4 gene, the specificity of LAMP is high. However, the selection region of the LAMP primer designation is limited to the same region of real-time PCR. This could affect the sensitivity of LAMP assay. Designing LAMP primers of different genes or different region of ICP4 gene might increase the sensitivity.

The ILTV real-time PCR and LAMP assays are specific, sensitive, and reliable for ILTV detection (Figure 85.1) [73]. Although the sensitivity of LAMP is slightly lower than that of real-time PCR, it has a value for ILTV detection because of its speed, lower cost, and does not require a temperature cycler or more expensive real-time PCR equipment.

85.3 CONCLUSION AND FUTURE PERSPECTIVES

ILTV molecular detection methods continue to evolve. They provide faster results, increased sensitivity, and reproducibility. Starting with PCR about 15 years ago, they have further developed to nested PCR, multiplex PCR, real-time PCR, and loop-mediated PCR. On the near horizon will be novel automated methods for the rapid extraction of viral DNA. Real-time PCR systems using fast ramping combined with intuitive software packages. The recombinant polymerase amplification assay has been recently developed with a run time of 10 min, and including nucleic acid extraction from samples, results can be obtained in 30 min. The next-generation droplet digital PCR assay employs an emulsion-based endpoint to quantitate the amount of target DNA and is more robust than real-time PCR when analyzing sequence variations. This test could replace PCR and RFLP testing for differentiating vaccine from field viruses. Nanoparticle-assisted PCR is a novel method for the rapid amplification of DNA and has been used for the detection of virus. Rapid detection and characterization of ILTV field isolates will add in epidemiological studies, diagnosis, and development of more efficient vaccines for improved control and prevention of this important pathogen of poultry.

86.1 INTRODUCTION

Malignant catarrhal fever (MCF) is a clinically noticeable, lethal disease of cloven-hoofed, ruminant mammals that include bison, African buffalo, water buffalo, antelopes, gazelles, sheep, goats, domestic cattle, and deer [1–3]. This disease has also been reported in pigs [4]. The causal agents for MCF are members of the MCF virus (MCFV) group that belongs to the genus *Macavirus,* subfamily *Gammaherpesvirinae,* family *Herpesviridae* [5]. MCF has a worldwide distribution and occurs sporadically and rarely in outbreaks. Clinically, MCF is characterized by high fever, hemorrhagic diarrhea, corneal opacity, and swelling of lymph nodes, usually culminating in death of the susceptible species. Similar to members of the *Herpesviridae* family, MCFV produces lifelong infection with establishment of latency. This chapter focuses on the two most prevalent viruses, alcelaphine herpesvirus 1 (AlHV-1) and ovine herpesvirus 2 (OvHV-2), within the genus *Macavirus.*

86.1.1 Classification, Morphology, and Genome Organization

Gammaherpesvirinae is one of three subfamilies in the family *Herpesviridae* and consists of a large group of viruses that can infect humans as well as animals. After a recent taxonomical reorganization, gammaherpesviruses are now subdivided into four genera, two of which are newly established; *Macavirus* and *Percavirus*, and the other two are well-known *Lymphocryptovirus* and *Rhadinovirus* [6]. The *Lymphocryptovirus* genus contains Epstein–Barr virus and several other lymphocryptoviruses of primates. The *Rhadinovirus* genus contains herpesviruses that infect many mammalian taxa. All the MCF causing viruses belong to the genus *Macavirus* under the subfamily *Gammaherpesvirinae* in the family *Herpesviridae*. To date, 10 closely related but different viruses have been identified within the MCFV group and out of these 6 are associated with clinical diseases [7]. The two most prevalent macaviruses are AlHV-1, which causes wildebeest-associated MCF (WA-MCF), and OvHV-2, which is responsible for sheep-associated MCF (SA-MCF). AlHV-1 is endemic in wildebeest, but does not lead to clinical disease in this host [8]. Domestic and wild sheep are reservoirs for OvHV-2 [2,5]. In both forms of the disease, animals with clinical disease are not a source of infection as the viruses are only excreted by the natural hosts—wildebeest and sheep, respectively. Other MCFVs known to cause disease include caprine herpesvirus-2 (CpHV-2), which is endemic in goats [9], MCFV of unknown origin causing disease in white-tailed deer (MCFV-WTD) [10], ibex MCFV (MCFV-ibex) carried by ibex [11], and an AlHV-2-like virus carried by Jackson hartebeest [12]. The remaining four viruses carried by roan antelope, oryx, muskox, and aoudad have not yet been associated with disease [7].

Both AlHV-1 and OvHV-2 are about 140–220 nm in diameter containing a double-stranded DNA genome. The genomic DNA is enclosed in an icosahedral capsid, which is embedded in a complex amorphous layer composed of several proteins called the tegument. This complex structure is then enclosed by a lipid envelope [13,14]. AlHV-1 has been isolated and

sequenced completely. Its DNA genome encompasses 70 open reading frames (ORFs). Among these, 61 ORFs are homologous to other herpesviruses. There are some genes that are shared only by AlHV-1 and other gammaherpesviruses. About 10 specific ORFs (A1–A10) of AlHV-1 have been identified to encode proteins A1–A10 with different functions. Out of these, eight ORFs have clear homologues with OvHV-2 and there are no equivalents of A1 or A4 [5]. Protein A1 is believed to play a role in cell transformation and/or immunoregulatory function [13,15]. A2 and A6 are involved in activation of transcription while A3 is involved in suppression of tumors, immunoregulation, development of bones and heart, arthritis, and the growth of sensitive cones during embryogenesis [13,15–17]. While A4 has no assigned function, A5 is structurally similar to G protein and believed to be involved in cell proliferation [15,18]. A7 and A10 may be related with the virulence of the virus as there is 3′end deletion of A7 gene and modification of A10 ORF in attenuated AlHV-1 [19]. Glycoprotein A8 is responsible for the interaction of the virus and cell receptor. A9 proteins are homologous to Bcl-2 family, which regulates apoptosis [13].

OvHV-2 has never been isolated due to the lack of a compatible tissue-culture system. More recently, an OvHV-2 infected bovine T-lymphoblastoid cell line, BJ1035, that was derived from a clinically affected cow with SA-MCF [20] has been cloned and sequenced [21]. Sequence analysis showed that the unique region of the OvHV-2 genome consists of 130 kb with 73 ORFs. The organization of ORFs in the OvHV-2 genome is quite similar to that of other gammaherpesviruses but matches most closely with that of AlHV-1. Three ORFs are unique to OvHV-2, that is, Ov 2.5, Ov 3.5, and Ov 8.5, whereas 8 ORFs are common in AlHV-1 and OvHV-2, that is, Ov2, Ov3, Ov4.5, Ov6, Ov7, Ov8, Ov9, and Ov10 [21]. Ov2.5 contains five exons and encodes a homologue of cellular IL-10. Ov3.5 encodes a 163 aa long protein, which forms a signal peptide. This protein, therefore, is believed to be secreted from the infected cell. Ov2 contains two exons and encodes a protein with a basic leucine-zipper (bZIP) motif and is believed to be a transcription factor. Ov3 produces a signal peptide to residue 22 and is homologous to proteins of the semaphorin family. Ov3 is predicted to be involved in the modulation of the host response to OvHV-2. The Ov4.5 and Ov9 products promote survival of infected lymphocytes and the establishment of latency in the OvHV-2 infected cells. The Ov5 ORF is located downstream of ORF9/DNA polymerase and overlaps with ORF10. This ORF is predicted to encode a G proteincoupled receptor. In between ORF50 and ORF52 lie three ORFs: Ov6, Ov7, and Ov8. The product of Ov6 contains a leucine-zipper motif in its C-terminal region and plays a role in transcriptional activation. The product of Ov7 contains a predicted signal peptide and N-linked glycosylation motifs and is thus likely to be a viral glycoprotein, involved in receptor binding. The product of Ov8 contains a transmembrane anchor near the C terminus and N-linked glycosylation sites. Ov8.5 is predicted to encode a proline-rich (24%) 42 kDa peptide of unknown function. The predicted Ov10 protein has a potential transmembrane anchor at the C terminus and four consensus nuclear-localization signals, and thus the Ov10 protein may localize to the nucleus of infected cells [21].

86.1.2 Transmission

Ovine herpesvirus 2: All domestic sheep are infected with ovine herpesvirus-2 [22]. Transmission occurs mainly by nasal shedding of the virus from lambs that are above 3 months of age, especially from the adolescent lambs of age 6–9 months [23]. The viral DNA in nasal secretions shows a steep rise and subsequent fall within 24–36 h. In sheep, this occurs multiple times between the ages 6 and 9 months and then declines after 9 months of age. Adult sheep are less frequent shedders than adolescent lambs [24]. Unlike WA-MCF, shedding of the virus might not be associated with lambing and no seasonal trend in viral shedding from adult sheep has been identified [23]. Horizontal transfer between clinically ill cattle has neither been seen in field nor in any experimental observations [3]. Bali cattle, Asian swamp buffalo, the American bison, and some deer species are reported to be more susceptible to disease caused by OvHV-2 than *Bos taurus* and *Bos indicus* cattle species [25,26]. Death in bison occurs within 48 h of infection [27]. Cattle in general are less susceptible to disease caused by OvHV-2 than AlHV-1 [28].

Alcelaphine herpesvirus-1: WA-MCF occurs throughout natural distribution of its carrier host in Africa. It was earlier believed that the virus existed as a cell-associated virus and was later identified that it survived as cell-free virus also and could be transmitted to cattle by nasal secretions of wildebeest [29]. It can also be vertically transmitted to offspring transplacentally [30]. The main source of infection is the wildebeest. The virus has been isolated from the ocular and nasal secretions of young wildebeest less than 3 months of age, and virtually all animals are infected by 4 months of age. Viral shedding in adult wildebeest is quite low and occurs primarily during periods of stress or parturition [31]. AlHV-1 is not transmitted from one clinically susceptible host to another via natural means, as the virus secreted from nonhost animals is cell associated and therefore extremely labile [32,33]. As such, sick animals may be housed with healthy animals without fear of horizontal disease transmission [34]. All ages of cattle are susceptible to the disease though adults are more prone, particularly peripartuent females [35].

86.1.3 Clinical Features and Pathogenesis

Clinical features: The clinical features have been described in detail [36]. The incubation period in MCF infection is variable. It ranges from 3 to 8 weeks, and in case of experimental infection, it ranges between 14 and 37 days (22 days on an average). MCF is a multisystemic syndrome and is seen in a number of forms: (1) peracute form, (2) alimentary tract form, (3) common “head and eye” form, and (4) mild form; all of these gradations are based on appearance of clinical signs.

In serial transmissions with one strain of the virus, all of these forms may be produced. The most common manifestation is the *head and eye form*, which is characterized by a sudden onset of extreme dejection, anorexia, agalactia, high fever (40°C–43°C), rapid pulse rate (100–120 bpm), profuse mucopurulent nasal discharge, severe dyspnea with stertor due to obstruction of the nasal cavities with exudate, ocular discharge with variable degrees of edema of the eyelids, and congestion of sclera vessels. There is superficial necrosis seen in the anterior nasal mucosa and on the buccal mucosa. Discrete local areas of necrosis may be seen on the hard palate, gums and gingivae, dorsum of the tongue, or commissures of the mouth. At this stage, there is excessive salivation with ropy and bubbly saliva hanging from the lips. Opacity of the cornea is almost always seen, beginning as a gray ring at the corneoscleral junction and spreading centripetally with conjunctival and episcleral hyperemia. Hypopyon is observed in some cases. Lesions may occur at the skin-hoof junction of the feet, especially at the back of the pastern. The skin of the teats, vulva, and scrotum in acute cases may slough off entirely upon touch or become covered with dry, tenacious scabs. Nervous signs, like incoordination, muscle tremor, nystagmus, head-pushing, paralysis, and convulsions, may occur in the final stages. The superficial lymph nodes are visibly and palpably enlarged. In cases of prolonged illness, skin changes, including local papule formation with clumping of the hair into tufts over the loins and withers, may occur. In addition, eczematous weeping may result in crust formation, particularly on the perineum, around the prepuce, in the axillae, and inside the thighs. Infection of the cranial sinuses may occur with pain on percussion over the area. The *peracute and alimentary tract forms*: In the peracute form, the disease runs a short course of 1–3 days and characteristic signs and lesions of the "head and eye" form do not appear. There is usually a high fever, dyspnea, and an acute gastroenteritis. Symptomatically, WA-MCF resembles SA-MCF, except in alimentary tract form where there is marked diarrhea in SA-MCF whereas there is constipation in WA-MCF with only minor eye changes consisting of conjunctivitis rather than ophthalmia as seen in SA-MCF**.** The *mild form* is generally observed in experimental animals. There is a transient fever and mild erosions on the oral and nasal mucosae. This form may also be followed by complete recovery or recovery with recurrence or chronic MCF. A distinctive clinical feature in chronic MCF is persistent bilateral ocular leukomata. The disease in pigs is similar to the head and eye form in cattle and manifests with fever and tremor, ataxia, hyperesthesia and convulsions, and death [36].

*Pathogenesis***:** Infection of susceptible animal has an incubation period of about 10 days to 2 months, which is followed by febrile condition till death of the animal. Although the pathological changes that occur in MCF infections are marked, the pathogenesis still remains to be fully understood. The production of a bacterial artificial chromosome clone carrying the entire pathogenic AlHV-1 genome has been used in studying the pathogenesis of MCF [37]. This clone grew infectious AlHV-1 virus and produced MCF disease in rabbits, which was similar to the disease caused by the field virus. In rabbits, the disease was seen as a progressive T-cell hyperplasia involving local proliferation and infiltration of both lymphoid and nonlymphoid organs, associated with extensive vasculitis and the dysregulated cytotoxic lymphocytes that lead to tissue destruction [20,38]. The lesions caused by AlHV-1 were seen in peripheral lymph nodes whereas OvHV-2-associated lesions are more apparent in visceral lymphoid tissue. The AlHV-1-associated lesions contained less areas of necrosis than those of OvHV-2. However, in both viruses, lymphoid cell infiltrations consist of mainly T cells, of which CD8+ T cells predominate, with very few CD4+T cells. The presence of a small number of infected lymphocytes observed in lesions characterized by lymphocyte accumulation also suggests that MCF has an autoimmune-like pathology, caused by the cytotoxic action of uninfected cells under the influence of a small number of infected cells [20,38]. The presence of CD8+ OvHV-2-infected lymphocytes in brain and various tissue sites indicate a direct action of virus-infected dysregulated cytotoxic T cells at sites of lesions [39]. The other lesions like epithelial erosions and keratoconjunctivitis is mainly because of the involvement of the vascular adventitia. The lymph node enlargements occur due to atypical proliferation of sinusoidal cells. The cerebromeningeal changes observed are basically a form of vasculitis. There is synovitis, especially involving tibiotarsal joints and which is also associated with a lymphoid vasculitis. Thus, the pathogenesis of this disease is basically an outcome of virus–cell interactions and immune-mediated responses directed against infected cells.

86.1.4 Diagnosis

Diagnosis of SA-MCF poses significant challenges to veterinarians due to multisystemic involvement of the disease and symptomatic resemblance to many other diseases in the field. Symptomatically, MCF should be differentiated from bovine viral diarrhea caused by *pestivirus*, IBR caused by *bovine herpesvirus* 1, bluetongue caused by *Orbivirus*, and rinderpest caused by *morbillivirus* among viral diseases. It should also be differentiated from salmonellosis, coccidiosis, and besnoitiosis caused by protozoan *Besnoitia besnoiti* [40]. Clinically, only a tentative diagnosis of the disease is possible, and a laboratory confirmation is essential to arrive to a definitive diagnosis. A history of contact with sheep or wildebeest or with pasture recently grazed by either of these species is also a support for the tentative diagnosis. Earlier, histological identification of vasculitis, hyperplasia of lymphoid tissues, and accumulations of lymphoid cells in nonlymphoid organs was considered the gold standard for disease confirmation. However, with the development of molecular tests, an antemortem as well as early confirmatory diagnosis is now possible. Various methods used in diagnosis are enumerated below.

86.1.4.1 Conventional Techniques

Virus isolation: Plowright and associates first isolated AlHV-1 in cell culture and also obtained a cell-free virus of an isolate

WC11 [8,33]. Tissue cultures infected with AIHV-l exhibit a cytopathic effect (CPE), consisting of multinucleate cellular foci, which is characteristic of AlHV-1. Intranuclear, cytoplasmic, and extracellular herpes-like particles has been demonstrated by electron microscopy in AIHV-1-infected tissue cultures [41]. This virus isolate is still utilized today for the development of diagnostics. In case of OvHV-2, lymphoblastoid cells infected with OvHV-2 have been propagated from cattle, deer, and rabbits with SA-MCF [42,43], but cell-free virus has not yet been cultivated despite numerous attempts till date.

Virus neutralization assay: This assay was developed by Plowright in 1967, utilizing the WC11 virus isolate mentioned previously [44]. The virus neutralization assay in use today still employs the AlHV-1 virus as the target of neutralization, as cell-free virus has never been isolated from other strains. This assay works best for antibody against the alcelaphine group of herpesviruses and is used in studying the extent of natural gammaherpesvirus infections in wildlife. The virus neutralization assay is not used as a diagnostic test in clinically affected animals, as these animals are not able to produce virus neutralizing antibody [45]. Animals with SA-MCF do not produce virus neutralizing antibodies to AlHV-1 [46].

Indirect immunofluorescence assay (*IFA*): Although the IFA is not as specific as the virus neutralization assay, it is useful in detecting antibodies in AIHV-1-infected cell monolayers. This test is not very specific, as other herpesviruses such as bovine herpesvirus-4 and infectious bovine rhinotracheitis virus cross-react [47]. This assay alone cannot be reliably utilized to detect SA-MCF when this disease is suspected [45].

Enzyme-linked immunosorbent assay (*ELISA*): Many ELISA assays have been developed to detect antibody to MCFVs [48–50]. The most commonly accepted competitive inhibition CI-ELISA was developed in 1994 to detect antibody to OvHV-2 using a MAb (15-A) targeting an epitope on a complex of glycoproteins that are conserved among all MCFVs [51]. This indirect CI-ELISA utilized enzyme labeled antimouse immunoglobulins for antibody detection and was reformatted as a direct CI-ELISA in 2001 to increase sensitivity [52]. This direct ELISA showed high sensitivity and specificity. However, there were certain issues like uninfected lambs less than 4 months of age give positive results due to the presence of maternal antibodies and low doses of virus infection take longer than usual (almost 4 weeks) for antibody production. Therefore, paired sampling is required for conclusive identification, and moreover, ELISA, though specific, cannot differentiate between different MCFVs [52].

86.1.4.2 Molecular Techniques

Genomic detection of MCF virus: Detection of the viral nucleic acid is currently the accepted method of diagnosis for MCF. Recently developed molecular diagnostic assays have improved the detection and differentiation of MCF causative viruses. A number of different formats of PCR have been developed targeting various MCFVs since the first PCR for detection of AlHV-1 DNA was reported in 1990 [53]. However, among all the diagnostic tests, the one with the most significant impact is the PCR specific for detection of OvHV-2 DNA developed by Baxter et al. [54]. It is currently the only OIE (World Organisation of Animal Health) approved diagnostic test for detection of OvHV-2 infection. In this assay, the primers target a DNA fragment in the ORF75 of OvHV-2, a gene coding for a viral tegument protein. Two sets of primers are used for a nested OvHV-2 PCR assay: the outer set 556 (5′-AGTCTGGGGTATATGAATCCAGATGGCTCTC-3′) and 755 (5′-AAGATAAGCACCAGTTATGCATCTGATAAA-3′) in the first round and heminested PCR with inner set comprising of 556 and 555 (5′-TTCTGGGGTAGTGGCGAGCGAAGGCTTC-3′). The primers are specific to OvHV-2. The outer set of primers (556 and 755) amplifies a 422 bp fragment of OvHV-2 DNA. The nested primer set (556 and 555) amplifies a 238 bp fragment. The specificity of both of the fragments can be confirmed by restriction enzyme (RE) analysis with RsaI enzyme. The primers are specific and do not amplify DNA from BoHV-l, BoHV-2, BoHV-4, or AlHV-1. This PCR assay has been used in many studies to detect latent OvHV-2 infections in sheep. This nested PCR has high sensitivity and is validated for detection of OvHV-2 DNA in infected sheep as well as in animals with clinical MCF. This assay has been widely used in veterinary diagnostic laboratories and is considered as the gold standard [55]; however, its use as a routine method to detect OvHV-2 DNA for confirmation of clinical SA-MCF in diagnostic laboratories was problematic due to a high potential for carryover amplicon contamination leading to false positive results. In addition, it can only be used as a qualitative method for establishing infection in the *in vivo* model. As repeated attempts to isolate the virus had failed, a need to trace the agent in a quantitative manner along the time axis of a natural infection was felt, and the second important step in MCF diagnosis was the development of quantitative PCR or the real-time PCR for OvHV-2 DNA by Hussy et al. [56]. The OvHV-2-specific primer–probe set for the real-time PCR is based on the same sequence of genomic OvHV-2 DNA that had been used for the nested PCR (ORF75 gene) and is equally sensitive for clinical samples. The development of a multiplex PCR for detection and differentiation of MCF causing viruses was the next significant advancement in MCF molecular diagnostics, especially for mixed-species operations, such as zoos, wildlife parks, and game farms. The multiplex real-time PCR uses one pair of primer in conjunction with fluorescently labeled probes that target a polymorphic region in the viral DNA polymerase gene specific for OvHV-2, CpHV-2, MCFV-WTD, MCFV-ibex, and AlHV-1. This PCR has been optimized and validated for the identification of these pathogenic MCFVs in clinical samples using a single reaction. The assay is able to simultaneously detect and differentiate the viruses in clinical samples with high sensitivity and specificity [57]. Based on the analysis of several conserved genes of MCFV, it has been reported that the use of the glycoprotein region sequence provides an accurate phylogenetic relationship [58]. Sequencing of this region for studying the epidemiology of the virus has also been done indicating high similarity between various herpes viruses [59,60].

86.1.5 Treatment and Control

There is no commercial effective treatment or vaccines available; reduction of stress in subclinical or mildly affected animals is suggested. Nonsteroidal anti-inflammatory drugs may give some symptomatic relief. The prognosis of the disease is usually grave. The segregation of the susceptible hosts from the reservoir hosts is the most important step for control of the disease. If cattle and sheep are reared under natural flock conditions, the grazing areas should be separated. Grazing sheep in the morning hours and cattle in the evening hours on the same land patch may also help as the virus may be destroyed in the day's sun as it is very heat labile. Under natural flock conditions, lambs are not infected until after 2 months of age. If lambs are removed from contact with infected sheep prior to that age, they remain uninfected and can be raised virus-free [23]. This knowledge should be used by sheep producers and zoos to produce sheep free of OvHV-2. If certain flocks continue to be the source of infection, disposal of these flocks for slaughter should be considered. The introduction of carrier species from areas where the disease has occurred to farms with cattle should be avoided. Zoological parks also should introduce seronegative animals only and follow strict quarantine restrictions for newly acquired animals.

86.2 METHODS

86.2.1 Sample Collection and Preparation

Tissue samples intended for AlHV-1 virus isolation must be collected either before or shortly after the death of the animal. Collected tissues should be kept in sterile viral transport media containing antibiotics and antifungal agent and be transported under cold chain conditions to the diagnostic laboratory immediately. The probability of a successful isolation is higher when the time interval between collection and inoculation of the culture is minimized. Transport media containing tissue samples for virus isolation should never be frozen since virus cannot be recovered from frozen material [61].

Makeup of transport medium 199 as recommended by WHO is presented as follows:

1. Tissue culture medium 199 containing 0.5% bovine serum albumin (BSA).
2. To the above medium, add benzylpenicillin (2×10^6 IU/L), streptomycin (200 mg/L), polymyxin B (2×10^6 IU/L), gentamicin (250 mg/L), nystatin (0.5×10^6 IU/L), ofloxacin hydrochloride (60 mg/L), and sulfamethoxazole (0.2 g/L).
3. Sterilize by filtration and distribute in 1.0–2.0 mL volumes in screw-capped tubes.

For molecular diagnosis both in carrier and susceptible animals, 2–3 mL of peripheral blood in EDTA collected in vacutainers should be couriered to the diagnostic laboratory in ice pack. Widespread pathological changes are observed involving many organs in clinical cases of MCF. These include hemorrhages and erosions throughout gastrointestinal tract, enlarged lymph nodes, formation of diptheritic membrane, and erosions with catarrhal accumulations in respiratory tract. Echymotic hemorrhages are also often seen on the epithelial lining of urinary bladder [45]. Hence, for histopathological examination, different tissue samples including lymph node, brain, liver, adrenal gland, kidney, urinary bladder, salivary gland, and alimentary tract mucosa including pharynx, esophagus, rumen, and peyer's patch can be collected in 10% formalin and should be sent to a diagnostic laboratory.

86.2.2 Detection Procedures

86.2.2.1 Virus Isolation

Isolation of causative agent to confirm MCF could only be performed for AlHV-1 till date. Infectivity of the virus is strictly cell associated and hence can be isolated only from cell suspensions of affected tissues, lymph nodes, and peripheral blood leucocytes. Bovine thyroid cells are commonly used for isolation of AlHV-1 though most primary and low-passage monolayers of ruminant origin may prove to be suitable substrate for virus isolation. Monolayers inoculated with approximately 5×10^6 cells/mL of cell suspensions from affected tissue should be examined microscopically at 40× for CPEs. Characteristic multinucleate foci appear within the monolayers, which retracts progressively forming dense bodies. CPE seldom appears within 1 week and may take as long as 21 days. Since infectivity is cell associated, for further passage it must be ensured that cell viability is maintained [62]. In case of isolation of OvHV-2, several attempts have been made wherein lymphoblastoid cells infected with OvHV-2 have been propagated from cattle, deer, and rabbits [42,43], but cell-free virus has not yet been cultivated.

86.2.2.2 Genomic Detection

86.2.2.2.1 Peripheral Blood Leucocytes Separation

Peripheral blood leucocytes (PBL) are separated from the whole blood. Usually, cells from 1.5 mL blood are sufficient for DNA extraction. The blood is centrifuged at 5000 rpm for 5 min and the supernatant is discarded. About 1 mL of erythrocyte lysis buffer is added to the pellet, mixed with gentle tapping, and kept for incubation for 10 min at room temperature. The centrifugation is at least twice or until clear PBL pellet is visible. The pellet is washed with 1 mL of 1× PBS by vortexing twice and stored at −40°C for further use after resuspending in 250 µL 1× PBS.

Makeup of erythrocyte lysis buffer is presented as follows:

1. Dissolve 1.21 g of Tris base in 800 mL of double distilled water.
2. Adjust pH to 7.4 with conc. HCl.
3. Add 0.584 g of NaCl.
4. Add 8 mL of 1 M (0.76 g) of $MgCl_2$.
5. Make up the volume to 1000 mL with double distilled water and autoclave.

86.2.2.2.2 DNA Extraction

Use 200 μL of PBL suspended in PBS for DNA extraction by conventional method or any commercial kit available.

86.2.2.2.3 PCR

PCR is currently the OIE approved test for confirmatory diagnosis of OvHV-2 detection. Tegument region is unique for all the OvHV-2 so this region is targeted for diagnostic purpose. Amplification of OvHV-2 DNA is carried out by using OIE approved primers developed by Baxter et al. [54]. The Two-step PCR amplification uses the following primer sets: primer set 556 (5′-AGTCTGGGGTATATGAATCCAGATGGC TCTC-3′) and primer set 755 (5′-AAGATAAGCACCAGTTA TGCATCTGATAAA-3′) in the first step and primer sets 556 and 555 (5′-TTCTGGGGTAGTGGCGAGCGAAGGCTTC-3′) in the second step (nested PCR). The amplification reactions are performed in a 25 μL volume containing 10 mM Tris-HCl (pH 8.0); 2 mM $MgCl_2$; 200 mM (each) dATP, dCTP, dGTP, and dTTP; 20 pM (each) primer; and 2 U of Taq DNA polymerase. Thermal cycling conditions for both steps are 5 min at 95°C and then 35 cycles of 94°C for 1 min, 60°C for 1 min, and 72°C for 2 min; this is followed by a final 7 min at 72°C for extension. The expected size of the amplified product for positive samples in the outer PCR and the nested PCR are 422 and 238 bp, respectively. Agarose gel electrophoresis of the amplified product is performed by using 2% agarose gel.

86.3 CONCLUSION AND FUTURE PERSPECTIVES

MCF is widespread to a large part of the world and has become one of the emerging diseases of ruminants of significant economic, trade, and/or food security concerns. The two most prevalent forms are the alcelaphine herpesvirus infection and OvHV-2 infections. Wildebeest for AlHV1 and sheep and goats for OvHV-2 are asymptomatic carrier species for these two infections that transmit this fatal disease to the susceptible ruminant species. The disease is of particular significance in the context where mixed farming is a common practice with these species. The virus is transmitted by aerosol or by contact, and most lambs or wildebeest calves are infected shortly after birth and are capable of then infecting susceptible cattle. The clinically susceptible species either die within 24 h or usually undergo a conspicuous clinical course affecting any or all of these systems: respiratory system, gastrointestinal system, and nervous system. Due to its sporadic nature and overlapping clinical signs with many other diseases, the disease at places has not received the due attention of veterinarians, researchers, and policy makers; thus in most parts of the world, there is no national policy for disease control. There is no treatment and vaccine available for this disease to date. Although the pathogenicity of the disease has become much clearer now, the fact that the OvHV-2 infection agent has not yet been isolated worldwide has hampered the information influx. With development and continuing refinement of PCR-based assays, it has now become easier to recognize the status of this disease, and a confirmatory diagnosis can be made wherever the facility is available or the samples can be easily sent to the nearest testing lab. Countrywide survey of this disease coupled with molecular characterization of virus genome will provide new insights into epidemiology and economic losses associated with MCF and will help devise an effective control strategy.

87.1 INTRODUCTION

Marek's disease (MD) is known as the most important threat in commercial production of chickens, turkeys, and Japanese quail. The loss due to the disease reaches US$1 billion annually [1], with mortality up to 60% in affected chicken flocks prior to application of protective vaccination [2]. Apart from significant mortality, egg production may also be reduced [3,4].

MD was first described in 1907 by the Hungarian veterinarian József Marek who observed polyneuritis signs along with histopathological lesions in the brain and peripheral nerves of chickens [5,6]. Following this first conference report, the disease was noted in 1914 in the United States, the Netherlands, and Great Britain [1]. For many years, MD was sporadically observed among chickens and turkeys and was manifested by neurological signs and disorders of locomotor system [7]. A notable increase in mortality among commercial chickens was observed between 1920 and 1940. In the 1960s, the observed clinical signs were called by Dr. Biggs [8] as "Marek's disease" but the observed clinical signs and lesions were misdiagnosed as lymphoid leukosis (LL). Therefore, MD was assigned to avian leukosis group. The milestone in MD history was the description of clinical signs by Pappenheimer et al. [7] as lymphoproliferative lesions in the spatial ganglia and peripheral nerves. Subsequently, Churchill and Biggs [9] and Nazerian et al. [10] isolated an etiological agent that was herpesvirus and called it "Marek's disease virus" (MDV). However, early attempt to reisolate the virus was not successful, probably due to the strictly cell-associated nature of MDV and the lack of specific-pathogen-free (SPF) chickens.

MD has been subdivided into acute and classic forms. The classic form of the disease was observed in the 1950s but is seldom detected these days. Following the successful virus isolation, Clanek et al. [11] found that the cell-free virus particles are shed *via* feather follicle epithelium (FFE), which explained MDV contagious features and transmission. MD is also an example of successful disease prevention by prophylactic vaccination of chickens [12]. Additionally, vaccination against MDV was the first application of vaccine against tumoral disease, which paved the way for further research on cancer treatment. However, the attempts to verify the possible role of MD in cancerogenesis in humans failed indicating that the virus is not capable itself to replicate in humans [13].

87.1.1 Classification

The primary classification of MDV was confusing due to the different clinical signs observed during disease process [8]. Some of the virus strains were more or less virulent inducing lymphomas, neurological disorders, or both. MDV shares some lymphotropic features with gammaherpesviruses, but finally, the virus was assigned to *Mardivirus* genus of *Herpesviridae* family [4,14]. According to International Committee on Taxonomy of Viruses, the MDV is represented by three different serotypes (MDV-1, *Gallid herpesvirus 2*; MDV-2, *Gallid herpesvirus 3*; and MDV-3, *Melagrid herpesvirus* 1, or herpesvirus of turkey, HVT). All pathogenic strains fall into the serotype 1 of MDV; however, the most efficient vaccine against MD is based on attenuated CVI988/Rispens strain [2]. The MDV-2 serotype is represented by SB-1, $HPRS_{24}$, and 301B/1 strains or other field isolates that are nonpathogenic for chickens [15,16]. These strains are used in vaccines against MD, which are applied mainly in the United States and Asia. Application of MDV-2-based vaccines in Europe is limited due to the increasing incidence of leukosis (LL) among vaccinated chickens [14,17,18]. The MDV-3 (FC126) strain is also nonpathogenic for chickens. Meanwhile, the vaccine based on the FC126 strain of HVT has been applied since 1970 as a live cell-associated or lyophilized cell-free suspension. On the basis of MDV-1 oncogenicity and virulence, four pathotypes may be distinguished, that is, mildly virulent MDV (mMDV), virulent MDV (vMDV), very virulent (vvMDV), and very virulent plus strains (vv+MDV). The latter one is capable to override postvaccinal protection. The pathotyping of MDV isolates is however laborious and time-consuming as it is based on lesions onset in vaccinated 15 × 7 chickens according to Avian Disease & Oncology Laboratory [19]. An increase of MDV pathogenicity in field may be related to the common vaccination against MDV that leads to the emergence of more virulent strains [14].

87.1.2 Morphology and Biology

The MDV's particles observed under electron microscopy (EM) are enveloped and have a diameter between 150 and 160 nm. The hexagonal nucleocapsid measures 85–100 nm [4]. The amorphous virus particles can be also visualized in thin sections of feather epithelium cells [20]. The virion particles from different serotypes appear similar. The capsids of FC126 and HVT show a crossed pattern.

MDV genome consists of double-stranded DNA (dsDNA) with a unique long (U_L) and unique short (U_s) regions flanked by internal (IT_R) and terminal (T_R) repeats [21,22]. At the terminal ends of IT_R and T_R, the alpha (α-like) sequences specific for *Alphaherpesvirinae* subfamily are located [23,24]. These regions have a crucial role in the packaging of viral DNA into the capsids. All three MDV serotypes have genomes of different sizes (from 159 to 180 kb), with encoded homologous genes, as well as genes that are unique for the serotype [25]. As the density of viral DNA equals to approximately 1.70 g/mL, it is difficult to separate the virus from the cellular, chicken DNA.

The MDV genome encodes over 100 specific proteins that are specific for alphaherpesviruses and may be specific only to the particular serotype. The main oncoprotein of MDV is Meq with leucine zipper motif characteristic for all transcriptional regulators [26]. The Meq is present in two copies located within the TR_L region and between the junction of IR_L and IR_s. Other MDV genes taking part in replication and oncogenesis are ICP4 (immediately early promoter), pp38 (phosphoprotein from pp38 to pp24 complex), and latency-associated transcripts (LATs), which downregulate MDV replication during latency [27,28]. The complete clones of all three MDV serotypes have been constructed in the bacterial artificial chromosome, which facilitated further genetic manipulation on MDV and determination of a number of MDV gene functions [29]. The MDV DNA is integrated into the telomeric regions of the host chromosomes [30]. This feature may be linked to the sequences located at the terminal ends of virus genome. Therefore, MDV is strictly cell-associated and cell-dependent. However, it was still unclear how the viral DNA is maintained during latency stage [27,31]. The study conducted in tumor cell lines showed the virus may parallely replicate in infected cells while in other cells switch to transformation [31]. Another unique feature of MDV is the possibility of concurrent infection with virulent MDV-1 strain and nonpathogenic MDV-2 and HVT viruses. This may potentially lead to interactions between these three agents but the recombination between different MDV serotypes in the field is rare. The successful recombinant event between MDV-1 and MDV-2 was artificially achieved using MSB1-41C cell line [32,33]. Meanwhile, it has been shown that coinfection with MDV-1 and avian leukosis or reticuloendotheliosis (RE) virus leads to spontaneous insertion of long terminal repeat (LTR) regions into the MDV genome [34,35]. It has been also shown that MDV may interact during coinfections with other immunosuppressive agents especially fowl adenoviruses (FAdV) [36], chicken anemia virus (CIAV) [37], or infectious bursa disease virus. The recent *in vitro* study on the interactions between FAdV-7 and FC126 of HVT in chicken embryo fibroblasts (CEFs) indicated the role of FAdV in HVT replication inhibition. These results were confirmed during *in vivo* studies on SPF chickens [36].

The productive replication of MDV occurs in B lymphocytes. The virus replication initiates by MDV binding to the cellular receptors via glycoprotein B (gB) and other virus proteins [31]. The virus spreads to other cells by direct contact *via* intracellular bridges. Three glycoproteins of MDV called gE, gI, and gM are important in virus transfer from infected to noninfected cell. Replication rate differs between serotypes as well as virus passage level. During productive replication, the number of virus genome may reach 100–1000 copies per cell. In infected cells, the virus leads to the formation of inclusion bodies and cell lysis. Fully productive stage of infection that leads to shedding of the infectious particles undergoes in FFE [5,15]. Latency is an important stage during MDV infection. During this stage, the viral proteins are not expressed but MDV DNA may be detected at low levels. LATs encoded by MDV have been described to play an important role in mapping to antisense sequence of genes thus downregulating

protein expression [27]. However, in the case of MDV-1, it is impossible to separate latently infected from the transformed cells. Latency undergoes mainly in CD4+ cells but can be also associated with CD8+ and B cells. The viral copy number may reach below five copies per cell. The latency may then switch to transformation stage with expression of MD tumor-associated surface antigen (MATSA) [38]. Similarly, CD30 antigen is detected during lymphomas onset [31].

MDV is transmitted by direct contact between infected chickens or indirectly by virus particles present in feather debris and dust [20]. Vertical transmission of MDV does not exist. Additionally, MDV may be passively carried by litter mites, darkling beetles (*Alphitobius diaperinus*), or even mosquitoes [39]. The virus present in dust particles remains infectious up to several months in temperatures between 20°C and 25°C. It may persist for a longer time in lower temperatures.

87.1.3 Clinical Features and Pathogenesis

MDV infection may cause distinct clinical signs and anatomopathological lesions. The most common clinical signs include paralysis of legs, torticollis, stunting, and depression. Paralysis or torticollis occurs after 2–12 weeks post infection (PI). In field conditions, the outbreaks of MD occur in chicken aging over 3 weeks. The late MD outbreaks are observed in 8–9-week-old chickens [31]. The early mortality may occur after 8–16 days PI during infection with vMDV and vvMDV strains. Before the prophylactic vaccination was applied, the mortality reached from 20% to 60% but currently was considerably reduced [2].

The neurological signs are related to peripheral nerve dysfunction [14]. Frequently, celiac plexus as well as sciatic and brachial nerves is affected. These nerves lose the cross-striations and have yellowish appearance. The gross lesions may also be found in the ganglia and brain. Visceral lymphomas may occur in different organs including the liver, spleen, lungs, heart, intestines, kidneys, proventriculus, ovaries, testis, skin, and skeletal muscles [40]. The lesions are seen as the considerable enlargement of affected organs and the presence of nodular white or gray tumors. The surface of an organ with tumors is however smooth. The skin lesions are associated with infiltration of feather follicles [11]. The nodular erythematous tumors may be detected especially in feather tracts and are termed "Alabama Red Leg syndrome." Other less specific signs including diarrhea and anorexia may also be observed. Ocular lesions with infiltration of the iris and loss of pigmentation are not frequently observed.

87.1.4 Diagnosis

Diagnosis of MD on the basis of clinical signs or lesions may be difficult or confusing because of some similarities observed during LL or RE. Therefore, different techniques of classic virology and molecular biology are adapted to confirm the presence of MDV as the causative agent. As in the case of any infectious agent, the most important is virus isolation, then the presence of specific antibody or viral DNA in organs of infected birds.

87.1.4.1 Conventional Techniques

Virus isolation: MDV isolation is always conducted in order to confirm the presence and infectivity of the virus [6,9,10], as the presence of DNA alone does not indicate the virus presence. MDV may be isolated from organs of infected chickens as early as 1–2 days PI. Additionally, cell-free virus particles may be retrieved from skin or feather tips of infected chickens [11]. The infected lymphocytes may be separated from the peripheral blood as a "buffy coat." MDV may be isolated in primary cell cultures prepared from SPF chicken embryos or duck embryos. The best cell type for MDV isolation is duck embryo fibroblasts (DEF) prepared from 17- to 18-day-old duck embryos. The strains belonging to serotype 1 as well as 2 and 3 (HVT) show rapid growth in DEF with the presence of evident cytopathic effect (CPE) after 48–96 h PI. Similar good results are achieved when chicken embryo kidney cells (CEK) prepared from 18- to 19-day-old SPF chicken embryos are used. The good results are also obtained when trypsinized chicken kidney cells of MDV-infected chickens are used for virus isolation. In general, CEFs that are prepared from 11-day-old SPF chicken embryos are the good choice for isolation of MDV-2 and MDV-3 strains. These cells are less permissive for inoculation with MDV-1 field strains but after 3 virus passages, some strains are showing specific CPE.

Immunofluorescence assay: The confirmation of isolated virus purity may be examined using indirect immunofluorescence assay (IFA) using monoclonal antibodies targeting different antigens [41,42]. The antigens of MDV may also be detected in infected lymphoid tissues, FFE, and feather tips. The most frequent pp38, gB, and Meq proteins are the targets for monoclonal antibodies in immunofluorescent detection (Figure 87.1).

Electron microscopy: EM allows to confirm the presence of MDV particles in cell cultures and FFE during

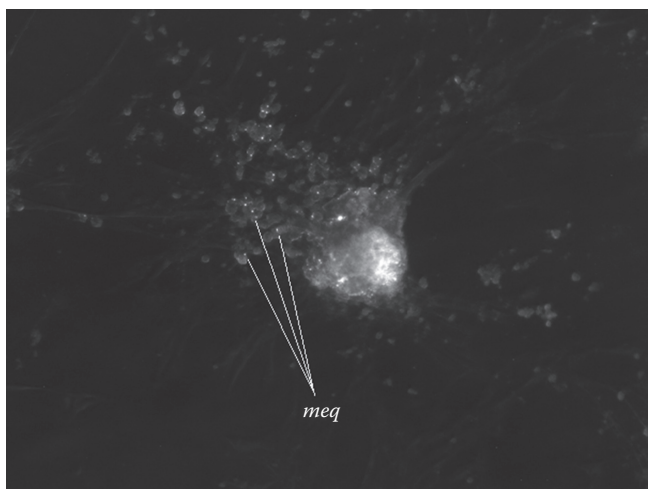

FIGURE 87.1 Indirect immunofluorescence assay. Chicken embryo fibroblasts infected with 31/07 Marek's disease virus isolate at third passage 56 h postinfection. Primary anti-*meq*-specific antibody and secondary antimouse Alexa 568 (Life Technologies, Delhi, India) were applied. Magnification 400×. The *meq* conglomerates in cell nuclei were indicated.

productive infection. Also, the sections of affected organs are used to identify the presence of enveloped icosahedral particles with a diameter between 150 and 160 nm. Due to the requirements of sophisticated equipment and experienced staff, this method cannot be considered as a routine technique for MD diagnosis.

Histopathology and immunohistopathology: The classic staining methods of tissue section collected from infected chickens are used to show the cytopathological changes caused by MDV. The tissues are fixed in formalin or frozen and embedded in paraffin to obtain ultra thin sections. The sections are stained with hematoxylin and eosin. The viral and cellular antigens can be detected in the thin sections of tissues using immunocytochemistry. The cells found in MDV tumor sections include infiltrations of large and small lymphocytes, macrophages, and lymphoblasts. The proportion of infected cells may be different, which also reflects the stage and severity of infection. The cells in MD tumors express MATSA and CD30 antigen [38]. Other antigens comprise of MHC class II antigen as well as CD4 and CD8 specific markers.

Specific antibody detection: The humoral immune response against MDV has a marginal role in MD prophylaxis but might be used to indicate the contact of chickens with the virus. In general, enzyme-linked immunosorbent assay (ELISA) and agar gel precipitation assay (AGID) are used to monitor the purity of SPF chickens from the control groups. Also, virus neutralization test may be used to determine the titer of the sera [43,44]. However, the MDV- or HVT-specific antibody is detected as early as 14–21 days PI and their level may decrease after 56 days PI.

Radial immunodiffusion assay: Radial immunodiffusion assay (RID) relies on detection of MDV antigen present in feather tips during the productive stage of infection [45]. The method is conducted in petri dishes covered with agar layer supplemented with sodium chloride and positive serum against MDV. The feather tips picked from the neckal route of infected chickens are put into the agar layer. The prepared dish is then incubated in a humid chamber at 37°C for 24–48 h. In case of the presence of MDV antigen, the whitish ring of precipitates around the feather tips is observed. The method is useful to monitor the productive stage of MDV infection; however, its application is very limited during latency stage.

87.1.4.2 Molecular Techniques

The classic methods including virus isolation and histopathological examination are still the "gold standard" in MDV identification. However, in spite of their advantages, they are time-consuming and laborious and require experienced laboratory staff or pathologist. The complete sequences of all three MDV serotypes allowed further development of molecular biology techniques including polymerase chain reaction (PCR) and real-time PCR as well as novel techniques of loop-mediated isothermal amplification (LAMP) [46–55]. These techniques facilitated quick and convenient detection of all MDV serotypes. However, molecular biology methods cannot be used as a sole evidence for the virus presence because the DNA detection is not equal to the presence of infectious virus.

87.1.4.2.1 DNA Hybridization

DNA hybridization is useful for confirmation of the presence of sequences specific for MDV. The specific probes targeting genes of MDV are labeled with radioisotope or fluorescent reporter dye. This technique may also be successfully applied for *in situ* hybridization to detect MDV-1 and MDV-3 (HVT) strains. Building on hybridization and use of labeled molecular probes, other molecular biology techniques including PCR and real-time PCR were developed.

87.1.4.2.2 PCR and Real-Time PCR

The primary PCR used 132 bp repeated region of MDV-1 to amplify tandem repeats of this sequence [45,46]. The vMDV has one or two copies of these repeats while the attenuated forms of MDV-1 including CVI988/Rispens have at least several repeats (Figure 87.2).

Similarly, based on a double nucleotide mismatch within the pp38 gene, it was possible to differentiate vMDV from CVI988/Rispens using a mismatch amplification mutation assay (MAMA-PCR) [53]. Other PCR targets include gB, *meq*, ICP4, and more specific MDV-1 genes [47–50].

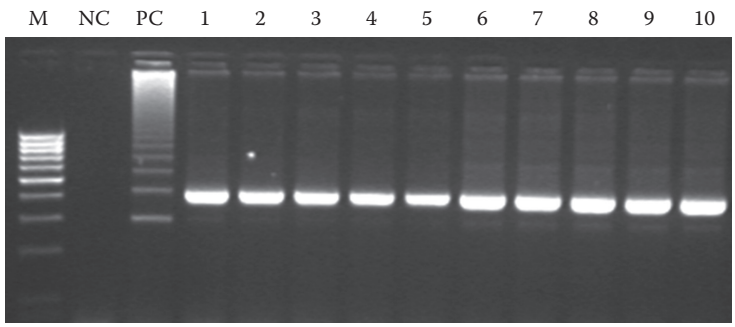

FIGURE 87.2 Polymerase chain reaction. Detection of 132 bp tandem repeats in samples collected from Marek's disease virus (MDV)-infected chickens. Descriptions: M, molecular length marker GeneRuler™ 100 bp DNA Ladder Plus (Thermo Scientific, Waltham, MA); NC, DNA template extracted from noninfected chicken embryo fibroblasts; PC, positive control (DNA of CVI988/Ripens strain isolated from commercial vaccine) (MSD Animal Health, Boxmeer, the Netherlands); 1–10 DNA templates extracted from liver of MDV-infected chickens. The obtained product length –434 bp indicates the presence of virulent MDV-1 DNA.

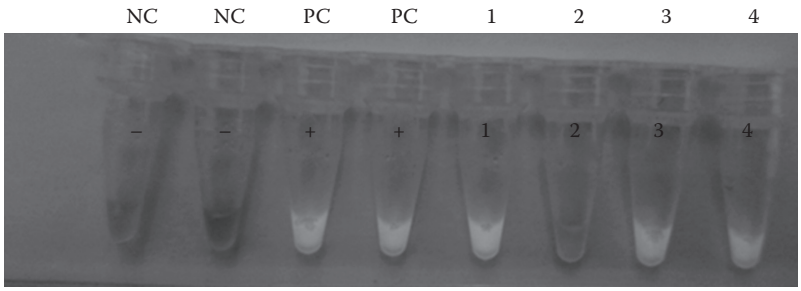

FIGURE 87.3 Loop-mediated isothermal amplification (LAMP): Detection of Marek's disease virus (MDV)-1 strains in chickens sent for Marek's disease (MD) examination. Visual LAMP detection of MDV under UV light after addition of SYBR Green® I dye. NC, DNA template extracted from noninfected chicken embryo fibroblasts; PC, positive control (DNA of $HPRS_{16}$ strain) (Houghton Poultry Research Station, Huntingdon, United Kingdom); 1–4 DNA templates extracted from liver of chickens sent for MD examination.

Given that HVT has nonhomologous genes including HVT068 (SORF1) and HVT070, it is also possible to differentiate this serotype from MDV-1 and MDV-3 strains. Due to the latent nature of MDV, its detection may be difficult because PCR detects approximately up to 100–1000 DNA copies. Taking into account the numbers below 10 copies of MDV DNA in latently infected cells, conventional PCR may produce false-negative results. The more sensitive alternative for PCR is real-time PCR with the use of SYBR Green® dye binding dsDNA products of fluorescently labeled probes (TaqMan®, Scorpion®, etc.). The sensitivity of real-time PCR may reach even a few copies of DNA and may be used to quantify the virus load in different tissues, FFE, or farm dust [54]. Using quantitative PCR (qPCR), it is also possible to detect and differentiate all three MDV serotypes. In the case of qPCR, an additional internal control represented by the "housekeeping" gene ensures the reliability of the obtained results. The DNA templates extracted from the blood or some organs including the spleen or liver may contain PCR inhibitors, thus additional internal control minimizes the risk of false-negative data. Additional advantage of qPCR is the possibility to apply it for the study on replication kinetics, expression patterns of different MDV serotypes and field isolates, or detection of nucleotide point mutations (SNPs).

87.1.4.2.3 Loop-Mediated Isothermal Amplification

Alternative methods to standard PCR or real-time PCR include nucleic acid sequence–based amplification, cross-priming amplification, helicase-dependant amplification, and LAMP [55]. LAMP uses two or three primer pairs specific to the chosen target under isothermal conditions. The main advantage of LAMP is its no absolute requirement to use PCR thermocyclers, electrophoresis chambers, or real-time PCR systems. LAMP is carried out in a water bath or dry heating block at different temperatures ranging from 59°C to 68°C. The method uses *Bst* or *Bsm* polymerases isolated from *Bacillus stearothermophilus* and *Bacillus smithi*, respectively. Other more effective and faster polymerases including *Gsp*SSD polymerase have been recently released. These enzymes have DNA strand displacement activity; therefore, LAMP may be conducted in isothermal conditions. The sequence of the target gene is separated into six fragments specific for the designed primers [55]. Forward inner primer (FIP) and backward inner primer (BIP) are needed to initiate the reaction. The FIP sequence consists of F1c fragment and the F2 fragment complementary to F2c region in target (e.g., *meq*, ICP4, or HVT070) sequence. BIP consists of the B1c fragment complementary to B1 sequence and B2 fragment. The outer primers B3 and F3 mediate displacement of the new DNA strands amplified from FIP and BIP primers. The initial steps of LAMP lead to the formation of a dumbbell-like structure, which is the prerequisite for complexes of stem-loop DNA and autocycling DNA synthesis and subsequent addition of new loops. LAMP is capable of amplifying a few copies of DNA in 30–120 min. The final products are cauliflower-like structures with multiple overhangs and loops; therefore, the method is called "loop-mediated isothermal amplification." LAMP was successfully applied to detect and differentiate all three MDV serotypes [51,52]. Recently, LAMP was used to specifically detect U_L49 fragment of attenuated CVI988/Rispens strain. However, due to its high sensitivity, the method is prone to incidental contamination as it is also observed in very sensitive qPCR methods (Figure 87.3).

87.2 METHODS

87.2.1 Sample Preparation

The ideal material for MD diagnosis and MDV detection originates from live chickens showing MD clinical signs. It is especially important for successful virus isolation, which is strictly cell-associated. The "buffy coat" layer of infected lymphocytes collected from the peripheral blood of chickens gives the best results for virus isolation or molecular detection. The chicken sera without the signs of hemolysis may also be used to detect the presence of specific antibody in ELISA or AGID assays [43,44]. The good source of the virus is 10% V/w homogenates of the spleen, kidney, ovaries, and liver. The virus may also be isolated from freshly collected feather tips. This material is also recommended for RID [45]. As transportation of whole chickens is sometimes difficult logistically, DNA cards with immobilized "buffy coat" drops, blood, or stamp from the affected organ provide a reliable alternative for PCR diagnosis of MD. However, it should be noted that

such kind of material may be used only for the confirmation of DNA of MDV not the infectious virus presence. Both PCR and LAMP facilitate detection of MDV DNA in poultry dust. In the case of LAMP, direct detection of viral DNA in dust particles without DNA extraction is also possible [56].

87.2.2 Detection Procedures

87.2.2.1 Virus Isolation

The optimal cell monolayer for infection should have approximately 1×10^6 cells/mL. After incubation for 24–48 h at 37°C, the virus-free cell monolayer is ready for inoculation. Especially for MDV-1 field strains, the inoculated cell cultures should be incubated for 24 h, and then the inoculum should be washed off. The typical CPE is observed after 72–96 h PI. MDV strains may be propagated up to six passages in CEF or CEK cells but normally three passages are enough to show CPE typical for MDV. Moreover, an excessive passaging of field MDV isolates may lead to loss of its pathogenicity and attenuation. In such case, the back-passaging of MDV isolate in SPF chickens may recover the initial virus features. On the basis of the plaque size, it is also possible to distinguish the three MDV serotypes. The largest plaques are produced by MDV-3 (HVT), while the smallest by MDV-1 strains. The field MDV-1 isolates should be purified from the possible contaminants with vaccine strains using specific antiserum. The CIAV may be eliminated by serial passaging of field isolate. It may also be achieved by specific MDV-1 plaque purification assay. Purification is important to eliminate the vaccine strains that may mask the true pathogenicity of MDV-1 in infected chickens. The purified virus stocks should be gradually frozen then stored in liquid nitrogen at –196°C. An addition of 10%–15% dimethyl sulfoxide protects the cells from the disruption during freezing. The virus stocks collected from liquid nitrogen after long storage should be checked for their titer because of its possible change.

87.2.2.2 Agar Gel Immunodiffusion

AGID is applied to detect specific anti-MDV antibody or the antigen. The test is conducted on glass slides with 2–3 mm layer of 1% agar in phosphate-buffered saline containing 8% sodium chloride. The holes in the gel are cut using a template to obtain six wells in equal distance. The antigen is placed in the center well while the exterior wells with examined sera. The slide is then incubated at 37°C for 24–48 h in a humid chamber to mediate diffusion of sera and antigen. The assay may be used to examine antigens with the standard serum. The MDV antigen may originate from the infected cell cultures or as an extract of feather tips or skin. The results are observed using lamp in a darkened room. The presence of precipitation lines between standard antigen and examined sera is considered as positive.

87.2.2.3 Radial Immunodiffusion Assay

The 1% solution of agar with 8% sodium chloride should be prepared. The whole solution should be heated to 56°C and then 20% of standard positive serum against MDV with the titer 1:8 is added. Petri dishes are then covered with 3 mm agar layer. The feather tips taken from examined birds are put into the agar layer each in the distance of about 10 mm away from the other wells. Petri dishes should be incubated in a humid chamber at 37.0°C for 24–48 h. The presence of ring precipitates around the feather tips is meant to be the positive result for the viral antigen presence.

87.2.2.4 Polymerase Chain Reaction

PCR for MDV-1 is conducted using a pair of specific primers complementary to one of the specific targets comprising of *meq*, ICP4, pp38, or 132 bp tandem repeated sequence that allows differentiation between virulent and attenuated strains [46–50,53,54]. For MDV-3 (HVT), the primers specific to HVT068 (SORF1) region are applied. Real-time qPCR is known to be a useful tool for quantification of the virus load and measuring dynamics of its replication *in vitro* and *in vivo*. Detection of all serotypes is possible using DNA extracted from internal organs of infected chickens, peripheral blood, feather tips, or dust of poultry houses [49,50,54].

87.2.2.5 Loop-Mediated Isothermal Amplification

The protocol for MDV-1 detection in feather samples along with the differentiation of all MDV serotypes has been previously described [51,52]. The successful attempts to selectively detect CVI988/Rispens strain using U_L49 fragment have been also conducted. Other LAMP primers may be designed using Primer Explorer version 4 (Net Laboratory, Tokyo, Japan, http://primerexplorer.jp/e/). LAMP is conducted with the application of two or three sets of specific primers in 15–25 μL using *Bsm* DNA polymerase kit (Thermo Scientific Fermentas, Vilnius, Lithuania) or Isothermal Mastermix Kit (OptiGene, Horsham, United Kingdom). The latter kit has preoptimized the concentration of *Gsp*SSD isothermal DNA polymerase with partial reverse transcriptase activity. Using the *Bsm* polymerase optimization of $MgSO_4$, *Bsm* and polymerase concentration is recommended. Additional parameters that should be optimized prior to the routine testing of field samples are concentration of inner, outer, and loop primers. The working concentrations of primers in LAMP for MDV are 50 pmol each of inner primers FIP and BIP, 10 pmol each of outer primers F3 and B3, and additionally 25 pmol each of loop primers LF and LB. The reaction mixture is supplemented with 1 μL of 1:10 dilution per reaction of 10,000× concentrated SYBR Green or GelRed™ (Biotum, Delhi, India). The primer sequences used for the detection of three different MDV serotypes and CVI988/Rispens are listed in Table 87.1.

Reaction tubes may be incubated in the broad temperature range from 59.0°C to 68.0°C, but the optimum temperature for most of the isothermal polymerases is 63°C. LAMP reaction time may range from 30 to 90 min and is dependent on not only initial DNA concentration in MDV templates but also the usage of two or three sets of primers. The final results are registered under UV light illumination. In case when too

The primers are specific for the serotype MDV-1, MDV-2, MDV-3, or attenuated Rispens strain. The nucleotides in FIP and BIP primers written in italics are thymidine linkers.

high background of fluorescence is observed in negative control, an additional glass or plastic mat may be placed between UV light source and the tubes with LAMP mixtures.

87.3 CONCLUSION

MD remains a continuous problem in worldwide production of chickens and turkeys. The disease discovered over 100 years ago seems to evolve through the different clinical forms as well as models of pathogenesis. The prophylactic vaccination against the disease onset considerably reduced the loss caused by the mortality of birds or reduced egg production. The unique ability of MDV to avoid host immune system and to transform infected cells complicates the study on this virus. Application of effective vaccines is critical for the control of MD, although vaccination has been implicated in indirect increase of pathogenicity of field MDV isolates. The use of rapid and reliable diagnostic techniques such as PCR or LAMP for MD is equally important to avoid virus transmission to the further flocks of birds. Given the strictly cell-associated character of MDV, the classic methods of virology including virus isolation should not be neglected. Indeed, following molecular detection, confirmation of the virus infectivity using virus isolation is highly valuable.

88.1 INTRODUCTION

Cypriniviruses largely affect common and koi carp (*Cyprinus carpio*), goldfish (*Carassius auratus*), Prussian carp (*Carassius gibelio*), and crucian carp (*Carassius carassius*). In particular, cyprinid herpesviruses 1 (CyHV-1) and 3 (CyHV-3) are important pathogens of *C. carpio*, while CyHV-2 affects *C. auratus*, *C. gibelio*, and *C. carassius*. These host species belong to the family *Cyprinidae*, the largest family of freshwater fishes in the world with over 2000 species in 210 genera.[1] Native species occur in all tropical and temperate regions except Australia, New Zealand, Madagascar, and South America. However, cyprinids have even been introduced to each of these previously free locations. While common carp are an important food source for humans in Asia, Europe, and Israel,[2] koi carp and goldfish are almost purely ornamental fish, albeit sometimes being very expensive. By contrast, in many regions of the world (e.g., Australasia and North America), carp are regarded as an environmental pest species.[3]

Anguillid herpesvirus 1 (AngHV-1) is the fourth known member of the cypriniviruses. Much less work has been done on this virus compared with the other three cypriniviruses, and therefore, only basic comments will be made where appropriate.

88.1.1 Classification

There are four genera in the family *Alloherpesviridae*[4] (herpesviruses of fish and amphibians; see Table 88.1): (1) the *Cyprinivirus* genus containing CyHV-1, CyHV-2, CyHV-3 (type species), and AngHV-1; (2) the *Batrachovirus* genus containing the ranid herpesviruses; (3) the *Ictalurivirus* genus; and (4) the *Salmonivirus* genus.

Within the genus *Cyprinivirus*, genomes of all four viruses have been fully sequenced, and genome maps have been proposed for each.[4] The cyprinid herpesviruses are most closely related to each other, and they share a genome structure—a central unique (U) region flanked by direct terminal repeats. Within the U region of these three viruses, there is a central section (open reading frames [ORFs]28–113) where conserved genes are arranged in an equivalent manner. On the other hand, 18 ORFs are unique to CyHV-1, 13 to CyHV-2, and 21 to CyHV-3.[4] ORF134, which encodes an interleukin (IL)-10-related protein, is one of the ORFs unique to CyHV-3 and AngHV-1,[5] while ORFs encoding the JUNB family of proteins (oncoproteins) are unique to CyHV-1 and have never been reported in herpesviruses previously.

Phylogenetic analysis for viruses in the order *Herpesvirales* can be inferred from full-length deduced amino acid sequences of the concatenated DNA polymerase and

TABLE 88.1
Classification of Cypriniviruses

Taxonomy and Scientific Name	Abbreviation	Common Name	Host	Genome Size (bp)	Accession No.
Order *Herpesvirales*					
Family *Alloherpesviridae*					
Genus *Cyprinivirus*					
Cyprinid herpesvirus 1 (unassigned virus)	CyHV-1	Cyprinid herpesvirus (CHV), Herpesvirus cyprini, Carp pox herpesvirus	*Cyprinus carpio*	291,144	NC_019491
Cyprinid herpesvirus 2 (unassigned virus)	CyHV-2	Goldfish hematopoietic necrosis herpesvirus (GFHNHV)	*Carassius auratus* *C. gibelio* *C. carassius*	290,304	NC_019495
Cyprinid herpesvirus 3	CyHV-3	Koi herpesvirus (KHV)	*Cyprinus carpio*	295,146	NC_009127

terminase (Figure 88.1). It shows monophyly of the fish and amphibian herpesviruses (*Alloherpesviridae*), separated from invertebrate herpesviruses (*Malacoherpesviridae*) and herpesviruses of mammals, birds, and reptiles (*Herpesviridae*). Within the genus *Cyprinivirus*, CyHV-2 and CyHV-3 are more closely related to each other than either is to CyHV-1 or to AngHV-1.[4,6]

88.1.2 Morphology, Biology, and Epidemiology

88.1.2.1 Morphology

Of the cypriniviruses, the most comprehensive morphological studies have been conducted on CyHV-3.[7–9] It was concluded that the development of virions *in vitro* was the same as for mammalian herpesviruses.[7] A capsid is formed in the cell nucleus and buds into the lumen between the inner and outer nuclear membrane. As it does so, it acquires a primary envelope (derived from the inner nuclear membrane). The enveloped capsid then enters the cytoplasm by fusion of the primary envelope with the outer nuclear membrane. As a result, a naked capsid is released into the cytoplasm. From this point, the capsid acquires a layer of tegument proteins and then acquires a mature envelope by budding into Golgi-derived cytoplasmic vesicles. When the vesicles fuse with the cell membrane, mature infectious virus is released from the cell. *In vivo*, viral particles with typical herpesvirus morphology have been observed in the tissues of CyHV-3-infected fish.[10] The inner capsid was 100–110 nm in diameter, while the envelope increased the size to 170–230 nm.[11]

While the morphology of CyHV-1 and CyHV-2 is similar to CyHV-3 (Figure 88.2), the sizes of the former are slightly different. The diameters of enveloped virions and icosahedral nucleocapsids of CyHV-1 are 157–190 nm and 109–113 nm, respectively,[12,13] whereas the equivalent values for CyHV-2 are 170–200 nm and 95–110 nm, respectively.[14]

88.1.2.2 Biology and Epidemiology

88.1.2.2.1 CyHV-1

CyHV-1, also known as cyprinid herpesvirus, Herpesvirus cyprini, or carp pox herpesvirus, affects *C. carpio* but generally only kills young fish up to 2 months old.[13,15] The disease is seasonal, and clinical signs associated with this acute form of the disease develop when water temperature is around 15°C.[13] CyHV-1 has been reported worldwide including in most European countries, the United States, Russia, Israel, and in some Asian countries.[16]

CyHV-1 is also the cause of "carp pox,"[13] and up to 60% of fry surviving the acute form of the disease may develop epidermal tumors/hyperplastic papillomas, also known as herpesvirus epidermal proliferation in carp (HEPC).[12,15,17] The prevalence of HEPC on carp farms ranges from <1:10,000 to over 70%.[17] It appears with low to moderate water temperatures (from late winter to early summer). HEPC can be transmitted to carp and to carp–goldfish hybrids.

88.1.2.2.2 CyHV-2

While CyHV-1 and CyHV-3 seem to affect *C. carpio* alone, CyHV-2 occurs in *C. auratus*, *C. gibelio*, and *C. carassius*, but not *C. carpio*.[18–21] In *C. auratus*, CyHV-2 is commonly known as goldfish hematopoietic necrosis herpesvirus.

The virus appears to be widespread in goldfish populations throughout the world. It was first reported as a severe pathogen in Japan in 1995.[19] Subsequently, there were a number of outbreaks in other countries, including the United States,[22,23] Taiwan,[24] Australia,[25] the United Kingdom,[26] and China.[20] Disease outbreaks usually occur in spring and autumn when water temperatures are between 15°C and 25°C.[19] Mortality due to the disease varies from 60% to 100%.[19]

88.1.2.2.3 CyHV-3

CyHV-3 causes a severe systemic disease with high mortality in *C. carpio*. It was first described in 1997 in Germany,[27] and from Israel and the United States in 1998.[10] However, there

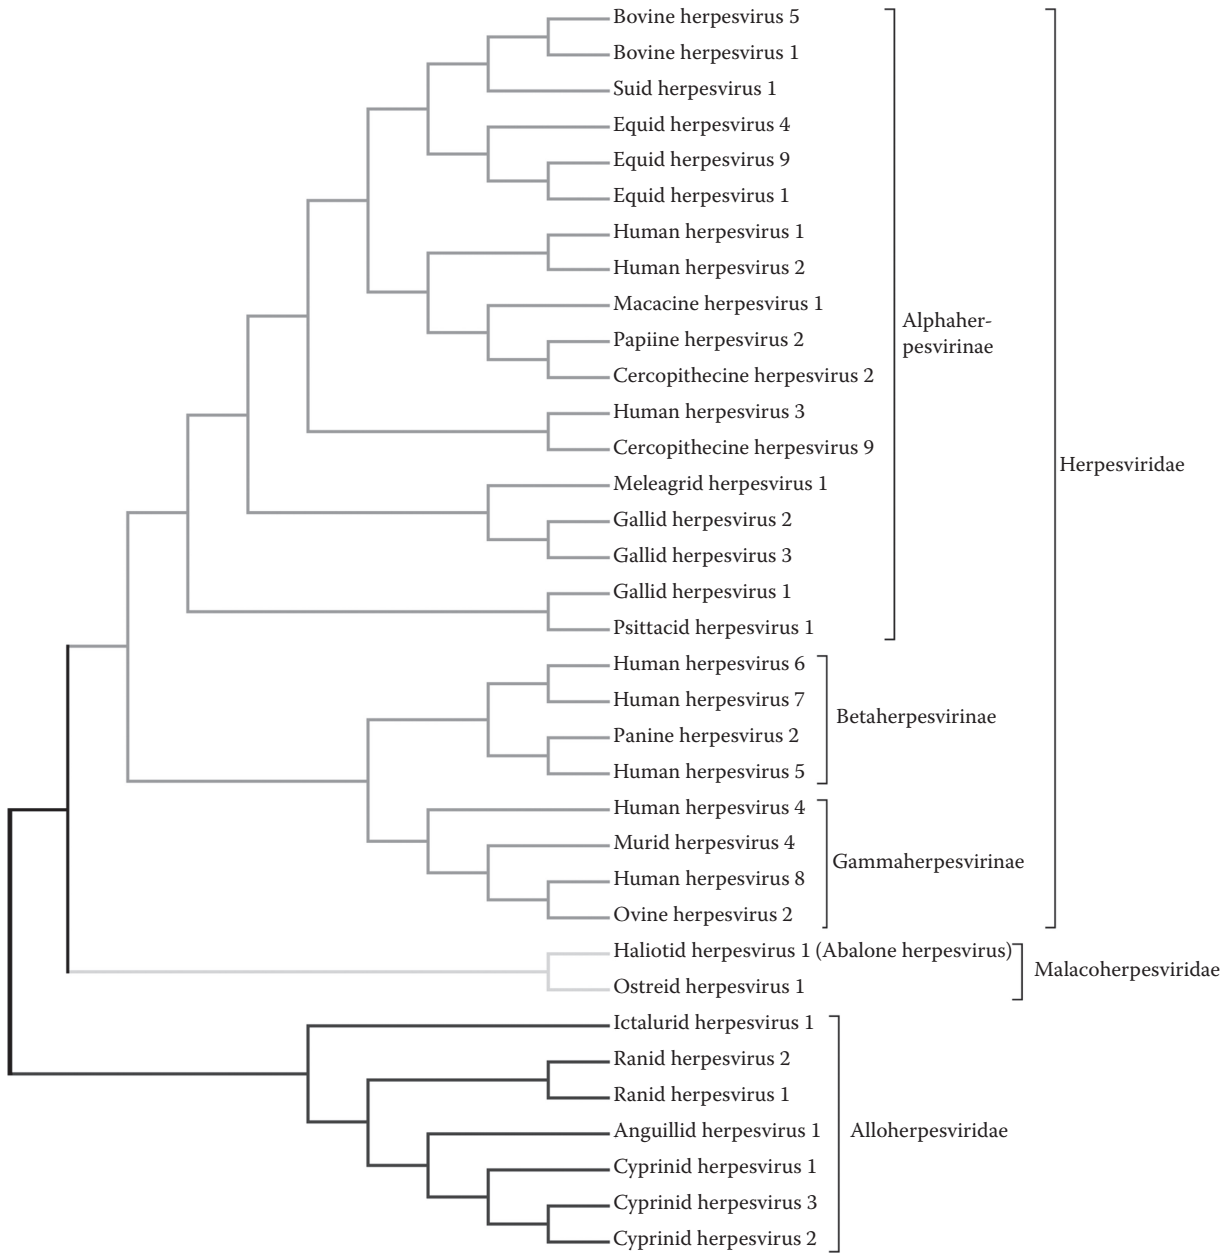

FIGURE 88.1 Molecular phylogenetic analysis of the order *Herpesvirales*. The DNA polymerase and terminase full-length protein sequences were concatenated; then, Mega6 was used to align them with Muscle and infer the evolutionary history using the minimum evolution method (see Figure 94.1 for further details).

is evidence that CyHV-3 may have been present in carp in the United Kingdom in 1996.[28] It has since spread to many other countries around the world and is now considered to represent a significant worldwide threat to the important carp industry.[29]

From sequence analysis, there appear to be two clear genotypes of CyHV-3, Asian and European, the former having two variants and the latter having seven.[30] The variants can be differentiated by a number of methods: a sequence from the C-terminal region of the thymidine kinase gene[30]; an examination of sequences from ORF25 to ORF26, which encode membrane glycoproteins[31]; a duplex PCR based on differences in three variable domains within two genetic markers[32,33]; or a variable number tandem repeat analysis.[34] However, new isolates, wherever they are found, need to be characterized because Asian isolates may readily be introduced to Europe,[35] and vice versa.[36] The recent PCR discovery of three variants of CyHV-3[37] may portend modifications to the classification of CyHV-3 genotypes, but first they need to be cultured and fully sequenced.

It was hypothesized that CyHV-3 had spread globally as a result of intensive fish culture, koi shows, and local and

international trade.[2] On the whole, these activities tend to occur without any restrictions or inspections. It was also predicted that movements of live carp were likely to be the main means of transmission of CyHV-3 between locations (in this case, in England and Wales).[38] Although the transmission of the virus by fomites (such as fishing gear) was considered to be of low probability, the high frequency of the use of fishing equipment suggested that there would, nevertheless, be a risk with this activity.[38] Alternatively, the stocking of imported ornamental fish appears to constitute a high-risk activity for the introduction of CyHV-3. Carrier fish represents an important issue in terms of developing control measures. At an International Koi Herpesvirus Workshop in 2004, it was recommended that fish be held in quarantine at 23°C–28°C for 2–4 weeks followed by a PCR check for CyHV-3.[39]

The outcome of the infection is very dependent on environmental temperatures. Mortality occurs when water temperatures range from approximately 16°C to 28°C, with the optimal range being 18°C–25°C.[2,40–42] Survival of the infectious virus in water is up to 3 days within this temperature range,[43] although it may survive longer in fish feces and in mud.[44,45] In different parts of the world, natural disease outbreaks tend to occur in the spring, as water temperatures are warming,[10] or in the spring and autumn, corresponding to the times when water temperatures are in the optimal range.[46]

While many studies have shown that juvenile and adult *C. carpio* are susceptible to CyHV-3.[46–48] Ito et al.[49] demonstrated that while larvae larger than 2 cm were, in general, 100% susceptible, larvae between 1 and 2 cm were of mixed susceptibility (66%), and larvae/fry less than 1 cm were generally insusceptible. The virus could not be detected by PCR in the larvae, suggesting that the larval resistance was to the infection rather than to the disease.

While *C. carpio* are well known for their susceptibility to CyHV-3, the susceptibility of other species of fish is a more contentious issue. The susceptibility of at least 22 species of fish has been tested,[27,46,50,51] and in all cases, there has been no evidence of the disease in these other species. While CyHV-3 DNA was detected in 10 out of 15 species of fish that were exposed to acutely or latently infected carp, only a small proportion of each species was infected, but none showed clinical signs of the disease, and only low copy numbers of CyHV-3 DNA were found.[50] In no case was there an attempt to demonstrate CyHV-3 RNA (as an indicator of virus replication).

Yuasa et al.[52] developed a reverse transcription-polymerase chain reaction (RT-PCR) for CyHV-3 and then commented on the work of various groups that had tried to demonstrate that *C. auratus* (and other species) may carry CyHV-3. Even though one study[53] used an RT-PCR to "demonstrate" that CyHV-3 replication took place in *C. auratus*, their work was slightly flawed in that neither primer in their PCRs was designed over a splice junction nor in separate exons. Therefore, it was possible that they were simply detecting DNA from a contaminant virus. In fact, Yuasa et al.[54] subsequently provided the most compelling evidence that *C. auratus* are not infected by CyHV-3; rather, they simply act as mechanical vectors of the virus.

Due to the high mortality, and specificity, of CyHV-3 for *C. carpio*, the virus is also regarded as a potential biological control agent in those parts of the world where *C. carpio* are regarded as a pest species.[55]

88.1.3 Clinical Features and Pathogenesis

88.1.3.1 Clinical Features

Water temperature directly affects the body temperature of fish, which, in turn, affects viral infections of fish (1) directly, by affecting the rate of viral replication, and (2) indirectly, by affecting the host immune response.[2] These are important considerations in understanding the clinical signs and the pathogenesis of the Cypriniviruses.

88.1.3.1.1 CyHV-1

The severity of the acute phase of a CyHV-1 infection is temperature and age dependent.[15,56,57] At 20°C, mortalities over 80% were reported in 2-week-old carp, 20% in 4-week-old carp, and 0% in 8-week-old carp.[15] Other work has shown that mortality is highest at 15°C and decreases with increasing temperature. For example, it was reported that CyHV-1 caused up to 60%, 16%, and 0% mortality in juvenile carp at water temperatures of 15°C, 20°C, and 25°C, respectively.[56] Clinical signs of the disease depend on the age of the fish and may include abnormal behavior such as spiral swimming, occasional immobility on the bottom, loss of appetite, a distended abdomen, exophthalmia, darkened pigmentation, and hemorrhages on the operculum and abdomen.[15]

Fish that survive the acute infection may develop white, mucoid papilloma-like lesions at 5–6 months postinfection.[13] They usually occur in caudal areas, including the caudal fin, but they may also occur on the mandible and, indeed, anywhere on the skin.[58] Eventually, the tumors are sloughed, but they may recur in the same season in subsequent years.[57]

88.1.3.1.2 CyHV-2

There are no consistent clinical signs of the disease, although affected fish may exhibit pale gills, and there may be yellowish discoloration of, and white patches on, the skin.[26] Fish tend to be inappetent and listless, and they sit at the bottom of the pond.[19]

88.1.3.1.3 CyHV-3

Experimental infections of *C. carpio* with CyHV-3 reveal a disease course ranging from 3 to 23 days, the duration being inversely related to both water temperature and virus dose.[2,10] The clinical course of the disease, however, is most frequently 24 h, although it can last up to 3 days.[27] The range of signs is relatively consistent: inappetence; lethargy; gasping in shallow water; excess, followed by decreased, cutaneous, mucus production resulting in pale patches on the skin ("sandpaper-like"); swollen, irregularly colored gills also with excess mucus; and occasionally nervous signs such as uncoordinated movements and erratic swimming.[9,10,29,59]

88.1.3.2 Pathogenesis

88.1.3.2.1 CyHV-1

The acute form of the disease is characterized by necrosis in the liver, kidney, and lamina propria of the intestinal mucosa (reviewed in Fijan[17]). Viral antigen and genome have been demonstrated by indirect fluorescent antibody tests and *in situ* hybridization (ISH), respectively, not only in these tissues but also in gills.[15] Following the acute phase, there is a phase in which virus cannot be isolated nor can viral antigens be detected in any tissues. However, the viral genome may be demonstrated by ISH, and it is presumed that the virus becomes latent in the cranial nerve ganglion, spinal nerves, subcutaneous tissue, and sometimes in gills.[57] These same tissues are also associated with reactivation of the virus, and it is thought that it is this recrudescent virus that results in the induction of the skin tumors (also known as HEPC, see Section 88.1.2.2) at 11–20 weeks postinfection. During this reactivation phase, the viral antigen can once again be detected in developing tumors, and the virus may also be isolated in the early stages of tumor formation, but not in the later stages. Generally, tumors are prevalent in the late fall and winter as ambient temperatures decrease, and they regress in the spring as water temperatures increase above 20°C or 25°C.[12,57,60] As viral antigen can be detected in recurrent tumors, it is speculated that following tumor regression, the virus becomes latent in the cranial nerve ganglion and spinal nerves once again and is reactivated when the temperature becomes permissive in the following year.[15]

Light microscopic examination of the affected skin revealed that epithelial hyperplasia was the primary lesion leading to proliferative papilloma-like tumors.[12,13,17] Within these proliferative lesions, the nuclei of affected cells are enlarged with marginated chromatin. Some cells have Cowdry type A intranuclear inclusion bodies (IBs), and mitoses may be frequent. By electron microscopy, particles with typical herpesvirus morphology may be observed in infected cells. Proliferating cells are not invasive. After the skin tumors slough off, scar tissue may develop, but mortality is rare.[12,15,17]

88.1.3.2.2 CyHV-2

C. auratus of all sizes are susceptible to infection with CyHV-2.[19] While the portal of entry of the virus is unknown, an infected fish can transmit the virus horizontally through

the water, and there is also evidence for vertical transmission.[61] The most severe gross changes in the infected fish are swollen kidneys, an empty intestine, and splenomegaly with white nodular lesions in the spleen.[19,26] Histologically, the most severe lesions are necrosis of the hematopoietic tissue of the kidney and spleen.[19] Affected cells may have enlarged nuclei with margination of chromatin and the presence of intranuclear IBs.[26] Viral DNA may be detected for lengthy periods in healthy *C. auratus* brood stock suggesting that latency may be a feature of CyHV-2.[61]

88.1.3.2.3 CyHV-3

Within the optimal temperature range of CyHV-3, *C. carpio* are susceptible to extremely low concentrations of the virus, with most fish dying following bath exposure to 12 or even 1.2 $TCID_{50}$/mL of virus.[2] Pikarsky et al.[9] stated that the early lesions in the gills of carp suggested that these were the portal of entry of the virus, but it was later demonstrated, through the use of bioluminescence studies, that the skin, and later the oral mucosa, may, in fact, be the major portals of entry.[62,63] However, ISH studies[64] and direct *per-gill* infection of carp[8,65] continue to support a role for gills in the infection.

Although the cell receptor for the virus has not yet been identified, it is known that following infection, CyHV-3 spreads rapidly throughout the body of the fish. Viral DNA is found in the blood and kidneys by 1 day postexposure[9] and then progressively spreads to other tissues such as the brain, liver, and spleen.[59] A great deal of work has been conducted on both the innate and adaptive immune responses (IRs) of the host (reviewed by Adamek et al.[66]), including the acute phase response.[67] Both arms of the adaptive IR have been dissected, in particular, the humoral[68,69] and the cell-mediated IRs. For the latter, resistant and susceptible lines of *C. carpio* have been especially useful in understanding the dynamics of the expression of various immune-related genes.[70]

In addition, a number of potentially important immunosuppressive molecules have been identified in the viral genome.[66,71] A viral homologue of the host IL-10 gene (khvIL-10) is likely to be very influential in the pathogenesis of the disease,[72] although this could not be confirmed in one study.[73] Interestingly, a viral IL(vIL)-10 gene is also present in AngHV-1.[5] Although AngHV-1 is closely related to CyHV-3, there is a little sequence homology between the respective vIL-10s. CyHV-1 and CyHV-2 both lack a vIL-10.[4] While the latter observation may indicate an important role for khvIL-10 in the pathogenesis of CyHV-3 infection,[74] clearly much remains to be learned about the function of khvIL-10.[75]

Depending on the water temperature, infected fish may shed virus for days before mortality begins,[41] suggesting the potential for a high risk of transmission from fish that show no clinical signs of the disease. It has been proposed that the loss of osmoregulatory function in the gills, kidney, gut, and skin (all of which contain virus) account for the death of fish.[59]

The histological lesions associated with infection by CyHV-3 are consistent with the pathogenesis of the disease. In the gills, there may be an early mixed inflammatory cell infiltrate, followed by complete effacement of the gill structure characterized by a severe inflammatory response, hyperplasia, and hypertrophy of epithelial cells and fusion of the secondary lamellae.[40] Intranuclear IBs may be present in epithelial cells. Subepithelial inflammation and congestion of the gill rakers, with focal sloughing of the surface epithelium, is often a more consistent finding.[40] Multifocal necrosis of the hematopoietic tissue, and in some fish the tubular epithelium, of the kidney may be prominent.[40] Multifocal necrosis, occasionally with IBs, may also be seen in the oral epithelium, spleen, pancreas, and liver, while a mild to moderate enteritis and a focal meningitis have also been reported.[9,40]

In fish that survive infection with CyHV-3, persistent (possibly latent) infections may develop, and, in this case, B cells have been identified as at least one site of latency.[76]

88.1.4 Diagnosis

A tentative diagnosis of the infection by any of the Cyprinivirus may be based on the use of a number of conventional techniques (clinical signs, gross and histopathology, electron microscopy, virus isolation, immunochemistry, serology, immunochromatography). However, to make a definitive diagnosis, specific molecular techniques (PCR, sequencing) are required. Loop-mediated isothermal amplification (LAMP) and ISH are other molecular techniques. LAMP has some advantages over PCR, but like ISH, it is unable to provide a definitive diagnosis.

88.1.4.1 Conventional Techniques

The clinical, pathological, and electron microscopic diagnoses of infection by CyHV-1, CyHV-2, and CyHV-3 have been discussed earlier (see Sections 88.1.2.2 and 88.1.3.1, respectively).

CyHV-1: Davison et al.,[4] in their sequencing studies on cyprinid herpesviruses, cultured CyHV-1, CyHV-2, and CyHV-3 on koi fin-1[10] (KF-1) cells. CyHV-1 was passaged by using an infected cell culture medium.

CyHV-2: CyHV-2 is difficult to isolate in cell culture. The virus has been isolated from the spleen and kidney of infected fish using FHM, EPC, and TO-2 cyprinid cell lines.[19] The virus induced cytopathic effect (CPE) in infected cells, including vacuolation and pyknosis followed by aggregation of rounded cells. However, the virus was lost after four passages. Therefore, the diagnosis of CyHV-2 was based on the presence of histological lesions and electron microscopic isolation of the virus. Davison et al.[4] cultured CyHV-2 on KF-1 cells by passaging infected cells (rather than cell culture supernatant). Difficulty in detection of the virus may be masking the true distribution and significance of the virus in goldfish populations.

CyHV-3: For isolation of CyHV-3 in cell culture, the earliest, and most commonly used, cell lines are the KF-1 and common carp brain[77] lines. A number of others have subsequently been described (e.g., Dong et al.[78]). The gill, kidney, and spleen are the best tissues for virus isolation, but it is often difficult to isolate the virus from fish that have been dead for a few hours, or fish that have been frozen.[59] It

appears that CyHV-3 in the kidney is more stable than in the gills[79] possibly because bacteria in the gills degrade the virus. While Hedrick et al.[10] stated that uninfected cells should be cultured at 25°C, but that virus isolation attempts should be conducted at 20°C, Gilad et al.[2] found that optimal growth of CyHV-3 in KF-1 cells was at temperatures between 15°C and 25°C. Sunarto et al.[80] found that maximum virus titers in the supernatant fluid of a KF-1-infected culture at 25°C were between 4 and 6 dpi. There have been reports of CyHV-3 being cultured on various other cyprinid and salmonid cell lines,[10,27,81–83] but results are often difficult to reproduce with other strains of CyHV-3.

CyHV-1, CyHV-2, and CyHV-3 all share some common antigens,[84] but various polyclonal and monoclonal antibodies have also been reported[29,85] that can be used in immunocytochemical or immunohistochemical assays for the detection of CyHV-3.

Ronen et al.[83] developed an ELISA for the detection of anti-CyHV-3 antibodies. For fish that survived the infection, an elevated titer was first observed at 14 dpi with the peak titer occurring at 21 dpi. The titer remained elevated until at least 51 dpi. Subsequently, another antibody-detection ELISA was developed[84] that could detect specific antibodies to CyHV-3 for up to 1 year after the last known exposure of fish to the virus. While this appears to be the serological test of choice, even this test is said to be more useful in identifying the antibody status of a population of fish rather than any individual within the population.

An immunochromatographic lateral flow device (LFD) for the detection of CyHV-3 antigen has been developed for pondside use as a diagnostic tool.[86] Gill swabs are the preferred site for sampling. The LFD is capable of detecting CyHV-3 up to 2 days prior to mortality, and up to 100% of infected fish can be detected at 7–9 dpi. The test takes about 15 min, and, while being very useful, it certainly does not have the sensitivity of a PCR test.

In general, CyHV-1 and CyHV-3 can be differentiated by (1) differences in cell-line specificity (CyHV-1 grows on EPC and FHM cyprinid cell lines), (2) type of CPE, (3) antigenic properties (Hedrick et al.[10] demonstrated that anti-CyHV-1 antiserum recognized CyHV-1-, but not CyHV-3-infected cells), and (4) timing of lesions (CyHV-1 lesions occur when water temperatures are declining[12]).

88.1.4.2 Molecular Techniques

Conventional PCR, with sequencing of specific products, or quantitative PCR (qPCR) are the most common molecular techniques for the definitive diagnosis of a *Cyprinivirus* infection.

CyHV-1: There is limited information available on conventional PCRs,[87] and none on qPCR, for the diagnosis of CyHV-1.

CyHV-2: A conventional PCR[23] and a quantitative real-time PCR[88] have been developed for the detection of CyHV-2.

CyHV-3: For CyHV-3, PCR is commonly used for diagnosis, and it is much more sensitive than virus isolation for detection of the virus.[29,89] Numerous one-step, and nested, conventional PCRs have been developed for CyHV-3, two of the early ones being based on noncoding regions of the genome.[89,90] Considering the possibility that conserved regions of the genome might yield a more reliable PCR (both in terms of detection of regional variants of CyHV-3)[29] and the reduced likelihood for mutations that could upset the efficacy of the PCR primers,[91] another conventional PCR was based on the thymidine kinase gene.[91] Although two of these PCRs[90,91] have been adopted by the World Organization for Animal Health,[92] work continues toward a single recommended protocol for the detection of CyHV-3 by a conventional PCR.[93,94] A widely used quantitative TaqMan real-time PCR was also developed for CyHV-3.[59] This test is not only more sensitive than a one-step conventional PCR, but it also dramatically reduces the risk of false-positive results due to inadvertent contamination problems.

Early LAMPs were developed for the detection of CyHV-3.[95,96] It was noted that while the speed and the absence of expensive equipment to run the test were the great advantages of LAMP, the test was no more sensitive than a one-step PCR.[97] However, a later commercial test claimed to be more sensitive.[98] Other LAMP tests for CyHV-3 have also been reported.[99–101]

The use of ISH as a diagnostic tool for CyHV-3 has been reported only infrequently.[94,102,103] Lee et al.[104] used the technique on paraffin-embedded sections to make a retrospective diagnosis of CyHV-3 in common carp in Korea. They showed, in 2012, that an outbreak of the disease in 1998 was, in fact, due to CyHV-3.

88.2 METHODS

88.2.1 Sample Preparation

Given that, of the molecular tests available, only conventional and qPCRs are capable of providing a definitive diagnosis, this section will be devoted to these tests.

Identification of the viral genome by ISH in the gills, kidney, liver, and intestine[105] indicates that these are the tissues of choice for PCR diagnosis of an acute CyHV-1 infection. By contrast, the cranial nerve ganglia, spinal nerve, and subcutaneous tissue are the tissues of choice during latent infections.[57]

The gill, kidney, and spleen are the tissues of choice for PCR diagnosis of CyHV-2.[19]

In acute CyHV-3 infections, the gill, kidney, and spleen are the tissues of choice, regardless of whether samples are collected from clinically normal fish in a suspect population, or from moribund or dead fish. Even decomposed fish may be tested,[90] although, in this case, primers that result in short PCR products are more likely to be useful. For suspected subclinical or persistent infections, the gut and brain are recommended.[92]

For the diagnosis of any *Cyprinivirus* infection, whole fish, or specific tissues, should be sent to the laboratory, either on ice or frozen (assuming that only a PCR diagnosis is being attempted). Alternatively, small tissue samples may be submitted in 80%–100% alcohol (at a tissue:fixative ratio of 1:10), or in RNAlater (Ambion Cat #: AM70),

which preserves both RNA and DNA). Viral DNA (and, if necessary, RNA) may be extracted from tissues through the use of a variety of commercially available nucleic acid extraction kits that produce high-quality nucleic acid. The latter can then be held at −20°C or −80°C for short-term or long-term storage, respectively.

88.2.2 Detection Procedures

Ideally, water and equivalent tissues from uninfected *C. carpio* should be used as negative controls, while tissues from known infected fish act as positive controls. Due to the sensitivity of PCR tests, care at every step of sample preparation must be taken to ensure that cross-contamination of diagnostic samples does not occur. Thus, all instruments and sample containers must be clean and uncontaminated. Wherever possible, it is recommended that disposable reagents and plasticware are used.

88.2.2.1 Conventional PCR

1. In a virus-free room, prepare the Master Mix. This consists of the following reagents for a single sample: 9.5 μL of nuclease-free water, 12.5 μL of HotStar Taq Master Mix (QIAGEN Cat #: 203443), 0.5 μL of the forward primer (18 μM), and 0.5 μL of the reverse primer (18 μM). Calculate reagent amounts for the number of samples required, including positive and negative controls plus extras to account for pipette error. Aliquot 23 μL of Master Mix into each PCR tube. Primers for the required PCR are shown in Table 88.2.
2. In a separate extraction room, tissue samples (including blood) and other specimens containing cells are homogenized at approximately 10% w/v in water, and then frozen and thawed. Samples are then microfuged (approximately 13,000 × *g* for 20–30 s), and the cell-free supernatant fluid is collected. Nucleic acid (including viral DNA) is obtained from cell-free samples using the QIAamp viral RNA extraction kit (QIAGEN Cat #: 52904). The manufacturer also recommends this kit for extraction of DNA viruses.
3. Moving to a separate template room, 2 μL of extracted DNA is then added to each sample of Master Mix, resulting in a total volume of 25 μL.
4. The mixture is then incubated in an automatic thermal cycler that is programmed appropriately for each PCR (Table 88.3).
5. At the completion of conventional PCR, specific PCR fragments of the correct size are identified by agarose gel electrophoresis. The negative control sample must have no evidence of specific amplified products, while a positive control sample must yield a specific CyHV-3 fragment. Amplified fragments of the correct size are then eluted from the gel and used to determine the DNA sequence (by using the PCR primers as sequencing primers).

TABLE 88.3
Cycling Conditions for Cyprinivirus Polymerase Chain Reaction Tests

Virus	PCR	Cycling Conditions
Conventional PCRs		
CyHV-1	Lievens et al. [87]	1 cycle, 94°C for 2 min; 35 cycles, 94°C for 45 s, 59°C for 30 s, and 72°C for 45 s; 1 cycle, 72°C for 10 min
CyHV-2	Goodwin et al. [23]	1 cycle, 94°C for 1 min; 30 cycles, 94°C for 30 s, 45°C for 30 s, and 72°C for 3 min
CyHV-3	Bercovier et al. [91]	1 cycle, 94°C for 15 min; 35 cycles, 94°C for 30 s, 52°C for 30 s, and 72°C for 1 min; 1 cycle, 72°C for 7 min
	Yuasa et al. [90]	1 cycle, 94°C for 15 min; 40 cycles, 94°C for 30 s, 63°C for 30 s, and 72°C for 30 s; 1 cycle, 72°C for 7 min
Quantitative PCRs		
CyHV-1		None published
CyHV-2	Goodwin et al. [88]	1 cycle, 95°C for 2 min; 35 cycles, 95°C for 30 s, 58°C for 45 s, and 72°C for 45 s; 1 cycle, 72°C for 2 min
CyHV-3	Gilad et al. [59]	1 cycle, 50°C for 2 min; 1 cycle, 95°C for 10 min; 40 cycles, 95°C for 15 s and 60°C for 1 min

Note: An apparently specific PCR product only provides a tentative diagnosis. *The PCR product must be sequenced to make a definitive diagnosis.* Sequence identity and genotype are determined by a BLAST search of the GenBank database. An assay is valid only when all controls yield the expected results.

88.2.2.2 Quantitative PCR

1. In a virus-free room, prepare the Master Mix. The PCR mixture for a single sample (1 well only) consists of the following reagents: 3 µL of nuclease-free water, 12.5 µL of TaqMan 2× Universal PCR Master Mix (Applied Biosystems, Cat #: 4304437), 1.25 µL of the forward primer (18 µM), 1.25 µL of the reverse primer (18 µM), 1.25 µL of the TaqMan probe (5 µM), 1.25 µL of the forward 18S primer (5 µM), 1.25 µL of the reverse 18S primer (5 µM), and 1.25 µL of the TaqMan 18S probe (5 µM). For multiple samples (and if more than 1 well per sample is required), the volumes are multiplied appropriately. Aliquot 23 µL of Master Mix into each well of a 96-well plate.
2. The primers and probes for Cyprinivirus qPCR tests, which are designed to be multiplexed with 18S ribosomal RNA (rRNA) qPCR, are shown in Table 88.2. The 18S rRNA gene (Applied Biosystems) is used to validate the nucleic acid presence and integrity, and the absence of PCR inhibitors. qPCR is performed using 96-well plates with samples, and positive and negative controls, tested in duplicate or triplicate.
3. In a separate extraction room, tissue samples (including blood) and other specimens containing cells are homogenized at approximately 10% w/v in water, and then frozen and thawed. Samples are then microfuged (approximately 13,000 × *g* for 20–30 s), and the cell-free supernatant fluid is collected. Nucleic acid (including viral DNA) is obtained from cell-free samples using the QIAamp viral RNA extraction kit (QIAGEN Cat #: 52904). The manufacturer also recommends this kit for extraction of DNA viruses.
4. Moving to a separate template room, 2 µL of extracted DNA is then added to each well of Master Mix, resulting in a total volume of 25 µL. Transfer the plate to the qPCR thermal cycler that is programmed appropriately for each PCR (Table 88.3).
5. For the assay and test results to be accepted, the following criteria must be fulfilled. The no template control and/or negative sample control must have no evidence of specific amplification curves. Each positive control must yield a specific amplification curve and mean C_T values within the acceptable range according to quality control data. Each sample must have an 18S-specific amplification curve. Test samples with characteristic amplification curves and C_T values are considered test positive.

88.3 CONCLUSION AND FUTURE PERSPECTIVES

Despite their taxonomic similarities, individual cypriniviruses exert vastly different impacts on farmed and wild fish throughout the world. These differences account for the variation in methods, and effort, to control each of the viruses.

As mentioned earlier, CyHV-1 can cause mortality in young cyprinids[13,15] and also causes HEPC[17] in up to 60% of fry surviving the acute infection.[12,15] Control of this disease involves increasing the water temperature, to speed up sloughing of tumors, isolation of the diseased fish, and good husbandry practices to prevent further spread of the disease in a population.[87]

CyHV-2, on the other hand, appears to be restricted to *C. auratus*, *C. gibelio*, and *C. carassius* where it may be associated with low to severe mortality.[25] Control methods, where invoked, would include standard control practices based on isolation of the affected fish, sanitation measures, and good husbandry to prevent spread.[23]

CyHV-3 is considered to represent a significant worldwide threat to the important carp industry.[29] As a consequence, there has been great interest in a variety of potential control methods including the development of vaccines and "natural" vaccination,[65,83,106–110] disinfection of water,[111,112] crossbreeding for resistance,[113–115] RNA interference,[116] and the institution of standard control practices for any infectious disease.[48] Undoubtedly, the importance of the disease will continue to drive advances in many of these approaches. In addition, given that subclinical persistent infections are likely very important in the spread of CyHV-3 both locally and globally, it is critical that we continue to develop a much better understanding of persistent/latent infections for this virus.

Finally, it should be noted that while the specificity for, and high mortality in, *C. carpio* makes CyHV-3 a scourge for farmed carp, these same factors mean that the virus offers great potential as a biological control agent for *C. carpio* in those countries where this fish is regarded as a pest species.[55]

ACKNOWLEDGMENT

We thank Dr. Keith W. Savin (Department of Environment and Primary Industries, AgriBio Centre, Bundoora, Victoria 3083, Australia) for the use of Figure 94.1 in this chapter (as Figure 88.1).

89.1 INTRODUCTION

Ictalurid herpesvirus 1 (IcHV1), commonly known as channel catfish virus, is the first identified and characterized herpesvirus of fish [1]. This virus causes channel catfish virus disease (CCVD), a severe hemorrhagic viremia in young channel catfish (*Ictalurus punctatus*). Given that losses to CCVD can exceed 90% of the affected population within a 2-week period, this disease is of concern to aquaculturists that produce channel catfish. This virus is easily identified in acutely infected individuals, but latent IcHV1 infections can be difficult to detect. A related alloherpesvirus designated *Ictalurid herpesvirus* 2 (IcHV2) has been detected in Italy from another North American freshwater catfish, the black bullhead (*Ameiurus melas*) experiencing hemorrhagic viremia similar to CCVD [2]. The distinction between the two virus species is important in diagnostic evaluation because the channel catfish may be extremely sensitive to IcHV2 [3] and it is not known to occur in North America where the largest stocks of wild and aquacultured channel catfish occur.

89.1.1 Classification

IcHV1 is the type species of the *Ictalurivirus* genus, family *Alloherpesviridae,* order *Herpesvirales* [4]. Apart from *Ictalurivirus,* the family *Alloherpesviridae* also includes the genera of *Batrachovirus*, *Cyprinivirus,* and *Salmonivirus.* Currently, the *Ictalurivirus* genus contains three recognized species: IcHV1, IcHV2, and *Acipenserid herpesvirus* 2 (AciHV2). AciHV2 was isolated from white sturgeon (*Acipenser transmontanus*) in California [5]. Classification within the *Ictalurivirus* genus was based on sequencing portions of the genomes of IcHV2 and AciHV2 and comparing them to the genome sequence of IcHV1 [6–8].

89.1.2 Morphology, Genome Organization, Biology, and Epidemiology

Initial electron microscopic characterization of negatively stained IcHV1 particles and infected cells demonstrated that IcHV1 morphology and assembly processes are similar to other herpesviruses [1]. The IcHV1 virion has a buoyant density of 1.15 g/mL [9] and consists of an electron-dense staining core, a capsid, an amorphous tegument, and a lipid bilayer envelope [1]. The enveloped virion is 175–200 nm in diameter, while the capsid is 100 nm in diameter. It has icosahedral symmetry containing 162 capsomeres. The genome replication, capsid assembly, and capsid packaging take place in the nucleus. The complete nucleocapsids are seen budding out of the nucleus and budding into cytoplasmic vacuoles [1]. It is assumed that the nucleocapsids exit the nucleus by budding out of the inner nuclear membrane, and then they lose this nuclear-derived envelope by fusing with the outer nuclear membrane. These cytoplasmic nucleocapsids acquire the tegument components and then acquire the final envelope by budding into cytoplasmic vacuoles and are transported out of the cell by exocytosis [10].

Early electron microscopic analysis, sucrose density gradient sedimentation, reassociation kinetics, and restriction fragment analysis demonstrated that the packaged genome of IcHV1 is a single linear, nonpermuted ~130 kb dsDNA molecule with 18 kb direct repeats [11,12]. There are genetic differences between strains [13] and that the virus loses one copy of the direct repeats and becomes endless in the infected cells

(concatemeric or circular) [14]. In 1992, Davison sequenced 134,226 bp linear genome of IcHV1 and predicted that it contained 79 open reading frames (ORFs) encoding 76 genes (the DNA polymerase gene ORFs 57 and 58 and terminase gene ORFs 62, 69, and 71 are spliced) [8]. This was the first fish herpesvirus sequenced, and the lack of gene sequence homology to mammalian herpesviruses indicated a very distant relationship. When compared to other members of *Alloherpesviridae* that have been sequenced, the IcHV1 genome is the smallest. It is less than half of the size and encodes less than half of the genes of *Cyprinid herpesvirus* 3. The purified IcHV1 genome was also shown to be infectious and efficiently undergo homologous recombination allowing for trait and mutation analysis by marker rescue/marker transfer [15]. These studies and, more recently, the ability to efficiently generate recombinants in *Escherichia coli* using overlapping genomic fragments cloned into bacterial artificial chromosomes have opened the way for efficiently evaluating IcHV1 genes by reverse genetics [16].

Proteomic analysis of differentially fractionated preparations from purified virions demonstrated that 11 of the predicted genes encode structural proteins, one on the envelope (gene 59 product—major glycoprotein), two tegument proteins (gene 11 and gene 65 products), four tegument-associated proteins (gene 15, gene 72, gene 73, and gene 74 products), and four capsid proteins (gene 28, gene 27, gene 39, and gene 53 products) [17]. The quantitative data of the capsid proteins was used in conjunction with cryoelectron microscopy and three-dimensional image reconstruction to deduce the detailed morphology and makeup of the capsid [18]. The structure of the IcHV1 capsid is remarkably similar to that of *Human herpesvirus* 1 (HHV1—herpes simplex virus 1). It is composed of 150 hexamers and 12 pentamers. The capsomers have 9 nm (IcHV1) compared to 11 nm (HHV1) chimney-like protrusions with an axial channel through each capsomer, and the gene 39, gene 53, and gene 27 products are structural orthologs of HHV1 VP5, VP19c, and VP23, respectively.

Other characterized gene products include the gene 50 product. It has been shown to be a secreted mucin [19,20]; the product of gene 10 was identified as an envelope protein using antibodies [21] and the thymidine kinase product of gene 5, which can activate nucleotide analogs including acyclovir [22]. The thymidine kinase gene is likely derived from the host deoxycytidine kinase gene [23]. High-throughput mass spectroscopy with probabilistic proteogenomic mapping demonstrated the expression of 37 of the predicted genes and identified the products of 17 novel protein–coding regions [24].

In 1980, Dixon and Farber evaluated the temporal profile of virus protein expression in IcHV1-infected cells and found that the genes are temporally regulated much like the more intensely studied members of *Herpesviridae*. Of 32 identified infected cell proteins, 8 were expressed within 2 h of infection (immediate-early candidates), 8 were expressed 2–4 h after infection (early candidates), and 16 were expressed after 4 h postinfection (late candidates). Furthermore, like other herpesviruses, some of the immediate-early protein candidates were expressed at higher levels following the release from protein synthesis inhibitor, cycloheximide, and the synthesis of late protein candidates was inhibited by ara-C, an inhibitor of DNA synthesis [11]. Similar temporal expression assays were performed on various transcripts coded by the direct repeat regions. However, accurately evaluating of mRNA expression is challenging because some genes utilize the same termination/polyadenylation signals resulting in overlapping transcription [25,26]. Also, when trying to differentiate immediate-early genes from early genes using cycloheximide blocking, some early genes are apparently leaky, and these early gene transcripts can build up to high levels over time [27,28]. The reason for "leaky" early gene transcription is not known, but among the 14 genes in the direct repeats, genes 1 and 3 are clearly immediate-early genes [28].

CCVD-affected populations of catfish may experience high mortality, reduced growth, and a predisposition to bacterial diseases [29]. The severity of a CCVD epizootic is significantly enhanced by environmental stress and crowding. Outbreaks of CCVD are sporadic in heavily stocked channel catfish fingerling ponds. Although older fish can be affected [30], natural outbreaks almost exclusively occur in young-of-the-year channel catfish during the warm summer months. In experimental challenge trials, very young fish are more resistant to the virus and become more sensitive as they age to 60 days posthatch. Furthermore, the resistance was correlated to the maternal parent's IcHV1-neutralizing antibody titer suggesting that the maternal transfer of antibodies may influence early susceptibility [31]. The optimum temperature for disease progression is 27°C or higher [32]. In the catfish-producing region of the United States, these temperatures occur from July through September when fingerlings are less than 4 months of age. Under these conditions, over 90% of the population may die in less than 2 weeks from the first signs of disease, yet most IcHV1 endemic populations will experience no obvious CCVD. Losses due to CCVD on fingerling production operations can vary substantially from year to year without obvious environmental cues, changes in management, or genetics of the stock.

IcHV1 appears to be maintained in a population by vertical transmission. IcHV1-specific PCR on recently hatched fry from five representative fingerling operations demonstrated latent carrier status of 10%–20% in each population [33]. These farms represented approximately 20% of the commercial catfish fingerling production. Therefore, it can be assumed that IcHV1 is endemic in most aquaculture populations of channel catfish in the Southeastern United States. Furthermore, evaluating incidence of latent IcHV1 in endemic fingerling populations over time showed an increase even though no CCVD was detected. This indicates that horizontal transmission occurs in the populations without overt disease [33]. By using PCR to detect and eliminate carrier brooders, it was noted that numbers of carrier offspring were reduced, but vertical transmission to the subsequent generation was not eliminated [33].

89.1.3 Clinical Signs and Pathogenesis

During a CCVD outbreak, IcHV1 is highly contagious and spreads quickly through the population. In experimental exposures, clinical signs appear 2–3 days postinfection and include erratic swimming, exophthalmia, a distended abdomen, and hemorrhages in the fins (Figure 89.1). Internal gross pathology includes yellow ascites, swollen spleen, and posterior kidney.

The posterior kidney, the most severely affected organ during acute CCVD, typically displays extensive edema, inflammation, and necrosis of hematopoietic tissue and tubules. This is followed by focal necrosis, hemorrhage and edema of the liver and gastrointestinal tract, and necrosis of pancreatic tissue, congested spleen, and focal areas of hemorrhage in musculature [34,35].

Acute CCVD usually occurs in young fingerlings. More chronic CCVD can occur in older fingerlings. This form is associated with less kidney necrosis and inflammation but a higher incidence of secondary bacterial infections, most commonly external infections with *Flavobacterium columnare*. Although rare, IcHV1 can cause disease in yearlings, and IcHV1 has been isolated from adult fish during winter months [36].

A study using radioisotope labeled IcHV1 in immersion challenges indicated that the virus was taken up by the gills and caudal fin. After this, the virus DNA increased in the liver, gallbladder, and gut [37]. Cell culture titrations and quantitative PCR (qPCR) performed on the posterior kidney, gill, blood, skin, intestine, spleen, and liver of immersion-exposed catfish fingerlings demonstrated that the highest levels of virus develop in the posterior kidneys with peak virus production occurring 3–4 days postinfection, and this correlates well with the period of peak mortality [38]. The next highest concentration of virus occurs in the gills. Analysis of water demonstrated detectable shedding on days 2–5 postinfection with day 4 being the peak [38].

FIGURE 89.1 Photograph of a channel catfish fingerling displaying abdominal swelling and exophthalmia due to channel catfish virus disease.

89.1.4 Diagnosis

The identification of IcHV1 infection to diagnose CCVD is easily accomplished and most often done using traditional cell culture techniques. This virus replicates rapidly in cell culture, producing distinctive cytopathic effect (CPE) within 24 h from heavily infected samples. Molecular methods are also effective for detecting the virus in tissues from CCVD-affected fish. However, detecting latent IcHV1 infection is more problematic and requires the use of sensitive DNA-based detection methods.

Conventional techniques: IcHV1 is somewhat host specific in cell culture. It has been shown to replicate in a variety of catfish cells but does not replicate in most cell lines derived from noncatfish species. For diagnostic purposes the virus replicates very well and shows distinctive CPE in the channel catfish ovary (CCO) cell line [39] and the brown bullhead (BB) cell line [1,40]. Also, either cell line can be used for the primary isolation of IcHV2 and causes similar CPE, but IcHV2 can replicate in the bluegill (BF2) cell line, which is refractive to IcHV1. Thus, the use of CPE on the catfish cells but no CPE on BF2 cells has presumptive diagnostic value. These cell lines are available from the American Type Culture Collection. Although conventional cell culture method is effective for diagnosing CCVD, it will not detect latent virus. Thus, it is of little use for inspecting populations of fish for IcHV1 carrier state. The use of IcHV1-specific antibody screening has some value in detecting populations that have CCVD. However, the amounts of antibody can decrease to undetectable levels over time, as antibody levels subside over the winter [41] and many carriers never develop detectable antibody titers.

Molecular techniques: Published nucleic acid–based techniques for detecting IcHV1 include gene-specific PCR [33,42–44] and degenerate PCR followed by sequencing of a fragment of the DNA polymerase gene [45]. A hydrolysis probe (TaqMan)-mediated qPCR method has also been published that is specific for IcHV2 [46], and a sensitive TaqMan qPCR method has been developed in the author's lab for IcHV1 that can distinguish between two observed genomovars and will not detect IcHV2. Conventional PCR and TaqMan PCR are sensitive enough to detect latent IcHV1, but the level of virus is often close to the sensitivity limit. Samples from whole processed sac fry give a relatively strong signal, but most samples from tissues of adult fish are very low, and it is suggested that for highest sensitivity, at least three PCR assays be run per tissue sample evaluated.

89.2 METHODS

89.2.1 Sample Preparation

Virus culture: The best samples for disease diagnostic cases are fish that are displaying signs of disease or are freshly dead from the epizootic. If clinically affected fish are available, three of them should be evaluated. Alternatively, if diseased fish cannot be sampled, a minimum of 10 randomly sampled fish from a population of fish that is experiencing

an epizootic can be evaluated for culturable virus. Small fish (2 cm or less) are evaluated in entirety or with the yolk sac removed from sac fry. The trunk portion (anterior to the anal fin) is evaluated in 2–3 cm fish, and the viscera can be taken on 3–5 cm long fish. Larger fish are dissected and posterior kidney and spleen sampled. These samples are suspended in the homogenization medium (serum free cell culture medium, pH 7.4–7.6, with 800 IU/mL penicillin, 800 µg/mL streptomycin, and 7.5 µg/mL amphotericin B) at approximately 1:10 tissue to medium and can be stored at 0°C–4°C for up to 48 h. To process the samples, the tissues are simply homogenized using a tissue homogenizer or mortar and pestle. Then the cellular debris is then removed by centrifugation at 1500 × *g* for 10 min. This tissue supernatant is then filtered through a 0.45 µm syringe filter to remove bacterial and fungal agents. The filtrate is then diluted to a final concentration of 1:100 (tissue to medium) in cell culture medium with serum for use as the cell culture inoculum. As an alternative protocol, the homogenate may be decontaminated by the incubation overnight at 4°C in the high concentration of antibiotics in the homogenization medium, and the supernatant from the centrifugation step (diluted as stated earlier) can then be used directly as the cell culture inoculum. For disease diagnosis, in general, up to 1/3 of the inoculum is used fresh to inoculate cells, 1/3 is stored at 4°C for up to 48 h, and 1/3 is archived at –70°C.

Molecular assays: Samples for PCR analysis can be the tissue pellet from processing described earlier or separate samples. Approximately 100 µg of tissue is processed. DNA can be isolated using a commercial kit such as DNeasy Tissue Kit (Qiagen, Maryland, Delaware). To evaluate latent carriers, a noninvasive biopsy can be taken from the caudal fin using a 3 mm diameter biopsy punch. After extraction, the quality and quantity of the DNA can be assessed using a NanoDrop spectrophotometer.

89.2.2 Detection Procedures

89.2.2.1 Cell Culture Isolation

Case samples should be inoculated on to CCO or BB cells and BF2 cells. The fish cell lines are cultured in Dulbecco's modified minimal essential medium (DMEM) containing γ-irradiated 10% fetal bovine serum and 25 mM HEPES buffer (Table 89.1). The maintenance medium has no antimicrobial or antimycotic agents. These cells are incubated at 20°C–30°C and may be cultured without the use of CO_2. In this case, no bicarbonate is used in the medium. Cell lines are routinely split when cultures reach confluency using 0.25% trypsin/EDTA. All media are prepared using commercially available certified endotoxin-free cell culture water. Each cell line is handled separately during subculturing procedures, and each has separate designated culture solutions. All procedures are performed in laminar flow HEPA filter hoods, using sterile, disposable plastic pipettes, centrifuge tubes, filters, and culture vessels. Countertops in the hoods are swabbed with 70% ethanol between culture procedures with various cell lines. All cell lines in the culture facility are evaluated for mycoplasma contamination every 6 months using a commercially available kit, and any contaminated cultures are discarded.

TABLE 89.1
Reagents Used for Cell Culture and Virology

Reagent	Source[a]	Description
DMEM powder	Sigma D1152	DMEM powder (makes 1 L at 1×) with 4500 mg/mL glucose, L-glutamine, and 25 mM HEPES without sodium bicarbonate
Tissue culture water	Sigma W3500	Cell culture water, ultrapure endotoxin-free
L-Glutamine	Gibco 25030	L-Glutamine 200 mM (100×) in water
Penicillin–streptomycin	Gibco 15140-122	10,000 IU/mL penicillin and 10,000 µg/mL streptomycin
Fungizone	Gibco 15290-018	250 µg/mL amphotericin B, 205 µg/mL sodium deoxycholate
Trypsin/EDTA	Gibco 15140-054	(0.5% trypsin, 5.3 mM Na_4EDTA) 10× liquid
FBS	Gibco 10438-026	Fetal bovine serum—qualified and heat inactivated—making 30 mL aliquots to avoid freezing and thawing repeatedly

[a] Company and catalog number, equivalent reagent from another source may be substituted.

89.2.2.1.1 Procedure

1. To prepare cells for virus culture, a confluent monolayer is split 1:3 into a 24-well plate or a 12.5 cm^2 flask and incubated at 30°C the day before virus inoculation to produce cells at 80%–90% confluency the next day.
2. To inoculate with the case sample, the medium is removed, and the cells are overlaid with 0.2 mL per well of a 24-well plate or 1.5 mL per flask of inoculum and incubated at 30°C for 30 min.
3. The cultures are then fed 1 mL/well or 6 mL/flask of cell culture medium containing 200 UI/mL penicillin and 200 µg/mL streptomycin. If using a 24-well plate, inoculate at least two wells with each sample. Also a noninfected control flask or set of wells (inoculated with homogenization medium alone) should accompany each case.
4. Observe the cultures daily by microscopic examination at 40–100× total magnification for 10 days. The use of a phase contrast microscope or similar contrast enhancement facilitates the recognition of early cytopathology. The CPE produced by IcHV1 is extensive and rapidly progressing by 48 h postinoculation in cultures from overtly diseased individuals.

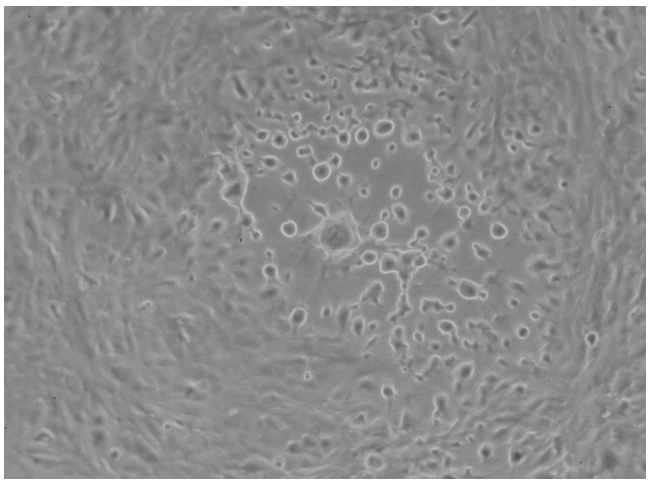

FIGURE 89.2 Photograph of channel catfish ovary cells displaying typical cytopathic effect caused by *Ictalurid herpesvirus* 1 infection (40× total magnification).

This CPE consists of cell fusion (syncytium) formation and contraction leaving cytoplasmic spindles irradiating from the syncytium to points on the flask surface where the cells were originally attached (Figure 89.2). Cultures from chronic or subclinical infections may show CPE later than this.

5. Blind passage is recommended from negative cultures at 7–10 days postinoculation. Some cultures may show signs of stress or unusual growth due to toxicity or growth factors in the cell extract; these samples should be passaged to fresh cells as well. This blind passage consists of inoculating fresh cells with the medium from the original culture wells/flask as described earlier. These passaged cells are observed for at least 7 more days. Cultures that show CPE can be harvested and stored short term (up to 4 days) at 4°C or archived at –70°C.
6. The observation of characteristic CCVD clinical signs and pathology in channel catfish fingerlings and the characteristic CPE in catfish cell lines is a presumptive diagnosis of CCVD. Confirmation requires the use of IcHV1-specific antibody-based analysis or a specific molecular assay.

89.2.2.2 Antibody Neutralization

The use of neutralizing monoclonal antibody (NAb) produced by Arkush et al. [47] provides the specificity to distinguish IcHV1 from IcHV2 [3]. Polyclonal antibodies are also useful, but IcHV1 in general is poor at inducing neutralizing antibodies in immunized rabbits. None of these diagnostic antibodies are commercially available.

89.2.2.2.1 Procedure

1. Seed and incubate at least two 96-well tissue culture plates to provide 80%–90% confluence as described earlier.
2. Collect the culture medium of the cell monolayers exhibiting CPE and centrifuge at 2000 × *g* for 15 min at 4°C to remove cell debris.
3. Dilute virus-containing medium from 10^{-2} to 10^{-5} in 200 µL aliquots.
4. Mix 100 µL aliquots of each virus dilution with equal volumes of an antibody solution specific for CCV, and similarly treat 100 µL aliquots of each virus dilution with cell culture medium.
5. In parallel, other neutralization tests must be performed against the following:
   a. The type isolate of IcHV1 or other confirmed samples (positive neutralization test)
   b. A heterologous virus (negative neutralization test)
6. Incubate all the mixtures at 25°C for 1 h. Then bring the volume up to 1 mL with cell culture medium.
7. Aspirate the medium off of at least 6 wells per dilution per sample and transfer 100 µL aliquots of each of the aforementioned mixtures on to the cell and then incubate at 30°C.
8. Microscopically observe all cell cultures daily for CPE and note the dilution and time of first detectable CPE and then note positive and negative wells at 96 h postinfection. Then calculate the titers of the virus sample treated and untreated using the proportional distance calculation of Reed and Muench [48] or Karber [49].
9. The tested virus is identified as IcHV1 when the sample virus titer is reduced by treatment with the IcHV1-specific antibody, when compared to the same sample given the medium alone treatment. If the IcHV1 NAb does not reduce the titer, the suspect sample should be evaluated using IcHV1- and IcHV2-specific nucleic acid–based assays. When cell culture supernatant of the monoclonal NAb 95 [47] was used undiluted on IcHV1 case isolates, it demonstrated a 10–100 fold reduction in titer of 90% of the samples.

89.2.2.3 PCR

Latent infections of IcHV1 are not associated with infectious virus, and the genome concentrations in the infected individual are very low. PCR is the only method sensitive enough to detect latent virus reliably. Also these assays are easy to perform and thus are often the method of choice for confirming a presumptive diagnosis of CCVD by IcHV1 isolation in cell culture. There are three types of PCR methods that are of diagnostic value for IcHV1, which are described in the following text: conventional PCR, TaqMan-based qPCR, and degenerate primer PCR. When using PCR assays in a diagnostic laboratory, there must be constant vigil against contamination. The most common source of DNA contamination that causes false-positive results is the product of a previous assay. Given the contamination risk, the use of nested PCR should be avoided in diagnostic assays whenever possible. Other sources of high levels of target DNA are tissues from a CCVD-affected fish

and infected cell cultures. Therefore, all labs that use PCR assays must have separate physically isolated areas and pipettors for PCR reagent preparation, and reagents are usually dispersed into inconvenient single assay aliquots. Also assay setup is done in separate areas from where PCR product evaluation is done. To minimize potential for contamination, all sample preparation and reaction setup should be done with aerosol-preventing pipette tips. Each assay must have relevant positive and negative controls to assure that the assay is functioning well and to monitor for contamination problems. The best negative control is a known negative sample that is similar to the test sample that is extracted and prepared using the same reagents in parallel with the test sample. Also, a water blank control is often run. In the positive control, the target sequence should be diluted to the level of sensitivity desired in the assay. A third type of control that helps assure the quality of individual sample results is the use of an internal control. This can be an assay for a host genomic sequence, a spiked modified target [38], or a commercially available exogenous internal control. The internal control will indicate PCR failure or inhibition due to inhibitors in the sample or errors in setup.

89.2.2.3.1 Cell Culture Confirmation–Extraction Procedure

A cell culture sample that displays CPE typical of IcHV1 can be easily tested either by conventional PCR or qPCR. The DNA can be extracted using a commercially available kit or simply proteinase K treated as described here:

1. Collect 1–0.5 mL of cell culture supernatant from the affected wells into a 1.5 mL microcentrifuge tube.
2. Centrifuge at maximum speed in microfuge (18,000–20,000 × *g*) for 30 min.
3. Discard supernatant and resuspend the pellet in 10 µL proteinase K buffer (50 mM KCl, 15 mM Tris-HCl pH 8.3, and 0.5% Nonidet P-40) containing 0.5 mg/mL proteinase K, and incubate at 55°C for 1 h.
4. Heat-inactivate the proteinase K at 95°C for 10 min. Centrifuge at maximum speed for 10 s. Use 3 µL per PCR.

Other standard DNA extraction methods may be used.

89.2.2.3.2 Conventional PCR

The conventional PCR assay described here is sensitive and does not rely on nested PCR procedures [33]. It uses modified primers (Table 89.2) of the original described PCR method [42] and can use the described internal control [38] to evaluate PCR sensitivity in individual assays.

1. Make the master mix. Prepare at least one extra aliquot for each 10 reactions planned. Include a positive and a negative (water blank or negative cell culture extract) control for every reaction.

Per sample:

Distilled water	33.6 µL
10× buffer	5.0 µL
Upper primer (50 pmol/µL)	0.4 µL
Lower primer (50 pmol/µL)	0.4 µL
dNTPs (2.5 mM each)	2.0 µL
25 mM $MgSO_4$	5.0 µL
Internal control (0.025 pg/µL—optional)	0.3 µL
Taq polymerase (5 U/µL)	0.3 µL

2. Add 47 µL per reaction tube.

TABLE 89.2
Primers, Probes, and Amplification Parameters for *Ictalurid herpesvirus* 1 Quantitative Polymerase Chain Reaction Assays

Assay, Primers, and Probes	Sequence[b]	Cycle Parameters
IcHV1 PCR		30 s at 60°C, 30 s at 72°C, 30 s at 90°C
Upper primer	TCATCCGAATCCGACAACTGA	
Lower primer	CCAAGATCGCGGAGAAAC	
IcHV1 TaqMan		60 s at 64°C, 15 s at 72°C, 15 s at 95°C
Upper primer	CTCCGAGCGATGACACCAC	
Lower primer	TGTGTTCAGAGGAGCGTCG	
IcHV1a Probe[a]	FAM-CCCATCCCTTCCCTCCTCCCTG-BHQ-1#	
IcHV1b Probe[a]	FAM-CCCATCCTTCCCCTCCTCCCTG-BHQ-1	
IcHV2 TaqMan [46]		45 s at 59°C, 45 s at 72°C, 30 s at 95°C
Upper primer	ATACATCGGTCTCACTCAAGAGG	
Lower primer	TAATGGGTATTGGTACAAATCTTCATC	
Probe	FAM-CGC+CTG+AGA+ACC+GAGCA –BHQ-1	

Source: Latorra, D. et al., *Mol. Cell. Probes*, 17, 253, 2003.

[a] Probe IcHV1a detects genome type A; Probe IcHV1b detects genome type B. Both assays use the same primers and reaction conditions.

[b] FAM designates 6-FAM fluorescent dye, BHQ-1 indicates black hole quencher, and + indicates use of locked bases to increase its melting point [50].

3. Add 3 µL (up to 1 µg total DNA) of sample or negative control.
4. Run the reaction. Incubate at 95°C for 5 min to activate the polymerase followed by 30 cycles of 90°C for 30 s, 60°C for 30 s, and 72°C for 30 s. After the last cycle, the samples are incubated at 72°C for 5 min.
5. Electrophorese 10 µL of the product on a 10% polyacrylamide gel with a 100 bp size ladder. Stain the gel with ethidium bromide. Observe and photograph under UV transillumination.
6. Evaluate the results. The internal control produces a 149 bp product. CCV produces a 136 bp product. Expect a 149 bp band within the negative control and on negative samples. Expect a 136 bp product and a 149 bp product on CCV-positive samples. If CCV is present at a high level, the 136 bp band will be very strong, and the 149 bp band may be missing. If no bands are present, the PCR did not work indicating a failure of one of the PCR components or an inhibitor in the sample. If the negative control shows a 136 bp product, then there is a contaminant in the PCR setup, and the assay must be redone. To confirm that the PCR product is from CCV, the PCR can be redone using no internal standard, and the product can be directly sequenced. The sequence can then be evaluated using basic local alignment search tool (BLAST) on the National Center for Biological Information internet site (http://blast.ncbi.nlm.nih.gov/Blast.cgi) to identify sequences with high homology. The PCR amplifies the region from 107,827 to 10,7962 of the CCV genome (GenBank accession M75136) representing a portion of ORF 73 [8]. Expect at least 95% identity to this sequence.

A modification to the aforementioned protocol includes the use of 40 cycles to detect low-level genomes such as in latently infected fish [33]. If 40 cycles are used, additional larger nondiagnostic bands may be present in the gel.

89.2.2.3.3 TaqMan PCR

The use of TaqMan qPCR increases the specificity of the PCR assay due to the use of the internal probe. The quantitative analysis assists in evaluating the clinical relevance of a positive result. Also because there are no steps that involve manipulating the products, there is less chance of product contamination of reagents or samples. There are three TaqMan qPCR assays that are of use for *Ictalurid herpesvirus* diagnosis: IcHV2-specific qPCR [46] and two IcHV1-specific qPCR assays that differentiate two identified genome sequences of IcHV1. The two IcHV1 assays use the same primers and reaction conditions so they can be run on the same plate.

89.2.2.3.3.1 Procedure

1. To prepare for the qPCR, dilute the DNA sample to 0.1 µg/µL. For fin tissue extractions using the Gentra Kit, rehydrating using 20 µL/mg of tissue will give you approximately 1 µg/µL.
2. Make a CCV control containing 0.1 µg/µL of CCO DNA and 0.001 µg/µL of positive control virus DNA.
3. Plan an experiment using at least three positive control wells and three negative (water) control wells per plate. Make up a master mix for the plate. Calculate the volume for at least one more well than you will use for every 20 wells.

   Reaction makeup for one sample, volumes in µL

Water	8.8
10× PCR buffer	2.5
$MgSO_4$	1.5
dNTPs	0.5
20 µM primer U	0.5
20 µM primer L	0.5
10 µM probe	0.5
Platinum Taq	0.2
Total	15

4. Add 15 µL of master mix per well of real-time plate that will be used. (Make sure the qPCR thermocycler is warmed up).
5. Add 10 µL of fish DNA or positive or negative control sample.
6. Seal plate using real-time plate sealer.
7. Spin at 1200 rpm for 3 min.
8. Real-time PCR is performed using an iCycler BioRad or similar qPCR thermocycler.

Stage 1—1 cycle at 95°C for 3 min 30 s
Stage 2—45 cycles as indicated in Table 89.2
The real-time reaction takes approximately 2 h to run.

The plate can be saved for polyacrylamide gel electrophoresis to see if the product is generated if you get unusual results. The IcHV2 assay will not detect IcHV1. The IcHV1a assay will not detect IcHV2 and is specific for IcHV1 genomotype A, which represents 72% of the CCVD diagnostic cases in Mississippi. The IcHV1b assays will not detect IcHV2 and is specific for IcHV1 genomotype B, which represents 18% of the CCVD diagnostic cases. Due to the high specificity of these assays, some genomic variants may be overlooked. If so and PCR product is produced by the primers, direct sequencing can be used to characterize these variants. The positive control can be generated using cloned genomic DNA containing the target sequence or purified viral DNA. If the DNA is extracted from the extracellular-packaged IcHV1, each genome will have two copies of the IcHV1 qPCR target, because the target is in the direct repeat region. In the author's lab, the 10 fg control sample has a threshold cycle (CT) of 32. Given the 84 MD molecular mass of the mature genome, this represents 71 genome copies, and the theoretical CT value for one copy would be 38. Using 1 µg of sample DNA, most latently infected fish give a CT value of 33–38, whereas extracts from fish with CCVD and cell culture give CT values of less than 27. Modifications to the aforementioned protocol that are used in the author's lab include the use of a

commercially available Exogenous Internal Positive Control Reagents (VIC probe) (Life Technologies) in each sample as described by the manufacturer. This provides an assessment of the individual variation in qPCR efficiency. If a sample has a CT value of over two cycles more than the standards, the sample is reanalyzed.

89.2.2.3.4 Degenerate PCR and Sequencing

The use of degenerate PCR followed by sequencing of a fragment of the DNA polymerase gene [45] is useful for evaluating virus isolates that show unexpected host range, culture characteristics, antigen profile, or PCR results. The concept is based on the use of two regions in the DNA polymerase gene that are conserved. The upstream primer is 5′cggaattctaGAYTTYGCNWSNYTNTAYCC3′ with the upper case being specific for the DNA pol target (Y = C or T, N = ACG or T, W = C or G) and the lower primer being 5′cccgaattcagatcTCNGTRTCNCCRTA3′ (R = A or G). Furthermore, the use of DNase to remove host sequences from virion pellets can be used before DNA purification to increase the effectiveness of the degenerate PCR. This method is most effective on virus from cell cultures but also can be used on productively infected tissues.

89.2.2.3.4.1 Procedure

1. Disrupt the cells/tissue to release the virions. The virus from infected cell cultures in 25 cm^2 flasks is released from the cells by three serial freeze–thaw cycles or by sonication.
2. Pellet the cellular debris by centrifugation at 1000 × *g* for 5 min.
3. Filter the supernatant through a 0.45 μm syringe filter.
4. Concentrate the virus from the filtrate by centrifugation at 21,000 × *g* for 30 min.
5. Resuspend the pellet in 80 μL of water, add 20 μL of 10× buffer and 100 μL of RQ1 DNase (buffer and enzyme from Promega), and incubate at 37°C for 2 h. This is followed by the addition of 20 μL of stop buffer (20 mM EGTA, pH 8.0) and a 10 min incubation at 65°C to inactivate the DNase.
6. Extract the DNA using the Puregene genomic DNA isolation system (Qiagen, Maryland, Delaware, United States).
7. Run degenerate PCR: PCR consists of approximately 100 ng of template DNA, 20 pmole of each primer, 4 μL 10 mM dNTP, 5 μL 10× buffer, and 2.5 U Taq polymerase mix (Fisher Scientific) in 50 μL reactions. The reaction conditions are 93°C, 1 min for 1 cycle, followed by 93°C, 30 s; 45°C, 2 min; and 72°C, 3 min for 35 cycles, and then a single cycle at 72°C for 4 min. Product is then evaluated by electrophoresis on 1.5% agarose gels followed by staining with ethidium bromide or a similar stain and UV transillumination. Bands of interest are then excised from the gel, and the DNA was recovered using GenElute Agarose Spin Columns (Supelco, Bellefonte, PA).
8. Clone predominant bands of the appropriate size using the TOPO TA Cloning Kit (Invitrogen) or a similar rapid cloning system. The sizes for large DNA viruses range from 450 to 800 bp; IcHV1 produces a band of 465 bp. Selected candidate clones are evaluated for a DNA insert of the appropriate size using colony PCR. Then plasmid is purified for sequencing from 1 mL cultures using the QIAQUICK Plasmid Purification Kit (Qiagen).
9. Sequence the products and use BLASTx to compare the translated sequence to deduce amino acid sequences in GenBank.

Variations that are helpful are (1) to use larger amounts of cells or tissues in samples that are suspected of having low numbers of virions and (2) to run a negative control of noninfected tissue when multiple weak bands are produced to distinguish cellular products from virus product candidates.

89.3 CONCLUSION AND FUTURE PERSPECTIVES

Ictalurid herpesviruses are important fish pathogens that have impacted aquaculture. As the *Ictalurivirus* genus is smaller and simpler than other alloherpesviruses, it offers a useful model for evaluating the molecular basis of how an alloherpesvirus infects, persists, and causes disease in fish. The alloherpesviruses studied to date are very host specific. The *Ictalurivirus* genus has been detected causing disease in North American catfish and sturgeons, which are genetically distant fish hosts. Therefore, in the future, as more types of fish are cultured at high densities, the recognitions of more members of this genus as pathogens are likely. Detecting new members for this genus using traditional cell culture may be difficult if appropriate cell lines are not available. Therefore, the use of molecular methods such as degenerate primer PCR or next-generation sequencing will likely facilitate the discovery of new *Ictalurid* viruses and allow the establishment of efficient, specific molecular diagnostic assays.

Many regional and federal agencies restrict the importation of catfish that may harbor IcHV1. However, most commercially produced populations of channel catfish carry the virus, and the current diagnostic tests are not sensitive enough to detect all carriers. This virus is efficiently vertically transmitted from parent to offspring. Also the disease outbreaks only occur in very young fish, held at high density at high temperatures. Therefore, many populations of channel catfish are endemic with the pathogen even if they have no history of CCVD. The PCR assays in use are very sensitive, near the one copy threshold per reaction. Therefore, the development of an assay that could evaluate larger amounts of host tissue would be beneficial for screening brood stock. Currently used methods are reliable enough to detect most carrier populations, but higher sensitivity is needed for screening individuals with confidence.

90.1 INTRODUCTION

Abalone were first farmed in Japan and China in the 1950s. However, it took until the 1990s before aquaculture of various abalone species began to expand significantly in various countries, including the United States, Mexico, Chile, South Africa, Australia, New Zealand, Japan, China, Taiwan, Korea, Ireland, and Iceland [1]. While the fishery in Tasmania in southern Australia is the predominant world supplier of wild abalone (approx. 2500 tons per annum), China is the largest producer of farmed abalone, with annual production of mostly Taiwan abalone (jiukong; *Haliotis diversicolor supertexta*) in the order of 50,000 tons per annum. As abalone aquaculture has expanded, various parasitic (e.g., perkinsosis [2]), bacterial (e.g., vibriosis [3], withering syndrome [4]), and viral diseases [5–7] have emerged. Of the viral diseases, the most recent to emerge in 2003 in Taiwan was a herpes-like virus associated with mass mortality of farmed *H. diversicolor supertexta* [8]. Diseased abalone displayed necrotic lesions with hemocytic infiltrations in nerve tissues, and the presence of a viral infection was confirmed by electron microscopic examination. Virion ultrastructural and morphogenesis were indicative of a herpesvirus. In 2005, mass mortalities also occurred in greenlip (*Haliotis laevigata*) and blacklip (*Haliotis rubra*) abalone being farmed in Victoria, Australia [9]. As observed in the *H. diversicolor supertexta* [8], diseased abalone exhibited ganglioneuritis pathology, and electron microscopic examination of virions purified from nerve tissues confirmed the presence of a herpes-like virus [10]. Subsequently, in 2008, abalone herpesvirus (AbHV) was discovered to be the cause of mortality of wild abalone being held in a live-holding system at a processing plant in Tasmania, Australia [11].

Upon DNA genome sequence information being acquired for the Victorian strain of AbHV (AbHV-Vic), various deduced protein sequences were identified that were most similar (amino acid similarity ranging from 19% to 53%) to homologs deduced from the ostreid herpesvirus 1 (OsHV1) genome sequence [12,13], revealing the abalone and oyster herpesviruses to be distantly related [14]. Based on this genetic relatedness, it has been proposed that AbHV be classified alongside OsHV-1 in the family *Malacoherpesviridae*, order *Herpesvirales* [15]. Comparison of three genomic regions of AbHV-Vic and AbHV-Taiwan has confirmed their nucleotide homology of between 92.4% and 96.6%. Complete genome sequences assembled recently indicate that a number of AbHV genotypic variants occur in wild abalone populations inhabiting coastal regions around Tasmania [16].

In Australia, the known host range for AbHV includes *H. laevigata*, *H. rubra,* and the hybrids of these species [9]. Clinical signs consistent with abalone viral ganglioneuritis (AVG), the disease caused by AbHV infection, have not been reported in other molluscan species inhabiting areas where AVG has decimated wild abalone populations. In Taiwan, disease was also not reported among Japanese black abalone (*H. discus*) cohabitating farms at which ganglioneuritis and mortality of *H. diversicolor supertexta* occurred due to acute herpes virus infection [8].

90.1.1 Classification

The International Committee on Taxonomy of Viruses (http://www.ictvonline.org/virusTaxonomy.asp) has formally named AbHV as Haliotid herpesvirus 1 (based on the genus of the host and for consistency with OsHV1), as the type species of a newly created genus, *Aurivirus* (based on the abalone shell shape), which together with the genus *Ostreavirus* (type species OsHV-1) comprises the family *Malacoherpesviridae* within the order *Herpesvirales*. Genome sequence analysis of *Chlamys* acute necrobiotic virus, a herpesvirus found recently to infect the Chinese scallop, *Chlamys farreri*, has indicated it to be an OsHV-1 variant [17]. A phylogenetic tree illustrating the evolutionary relatedness of viruses classified within each genus of the *Herpesviridae*, *Malacoherpesviridae*, and *Alloherpesviridae* families comprising the *Herpesvirales* determined for concatenated amino acid sequences of the DNA polymerase and DNA packaging terminase is shown in Figure 90.1.

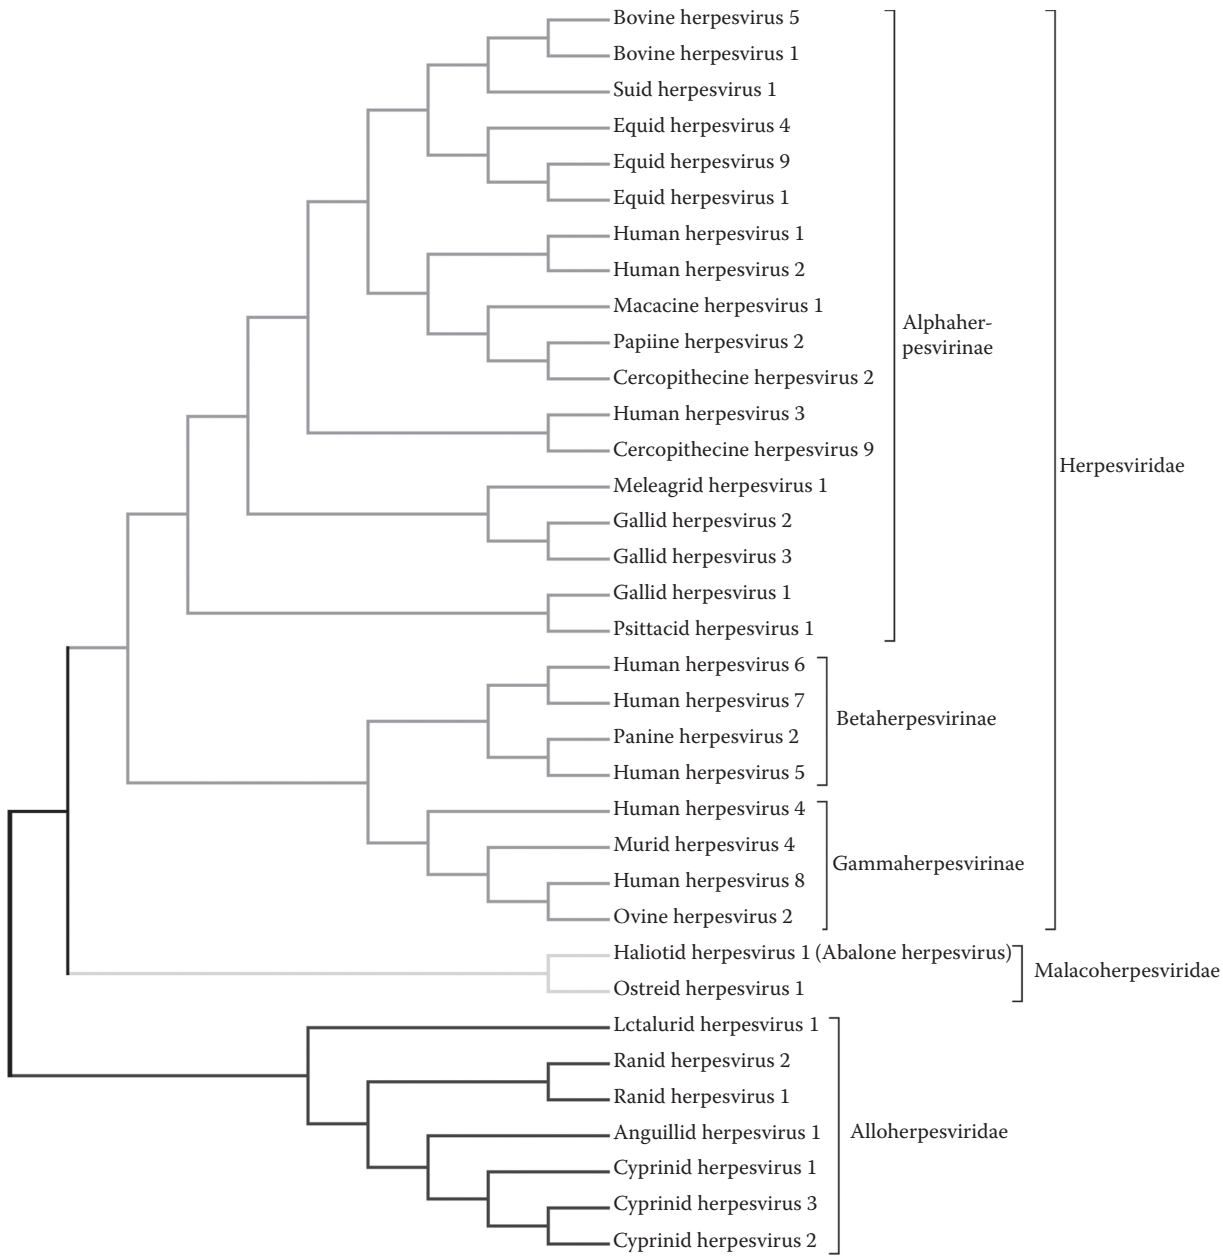

FIGURE 90.1 Molecular phylogenetic analysis of the *Herpesvirales*. The DNA polymerase and terminase full-length protein sequences were concatenated, and then Mega6 [18] was used to align them with muscle and infer the evolutionary history using the minimum evolution method (ME) [19]. The bootstrap consensus tree was inferred from 500 replicates [20]. The evolutionary distances were computed using the number of differences method [21]. The ME tree was searched using the close-neighbor-interchange algorithm [21] at a search level of 1. The neighbor-joining algorithm [22] was used to generate the initial tree.

90.1.2 Morphology, Biology, and Epidemiology

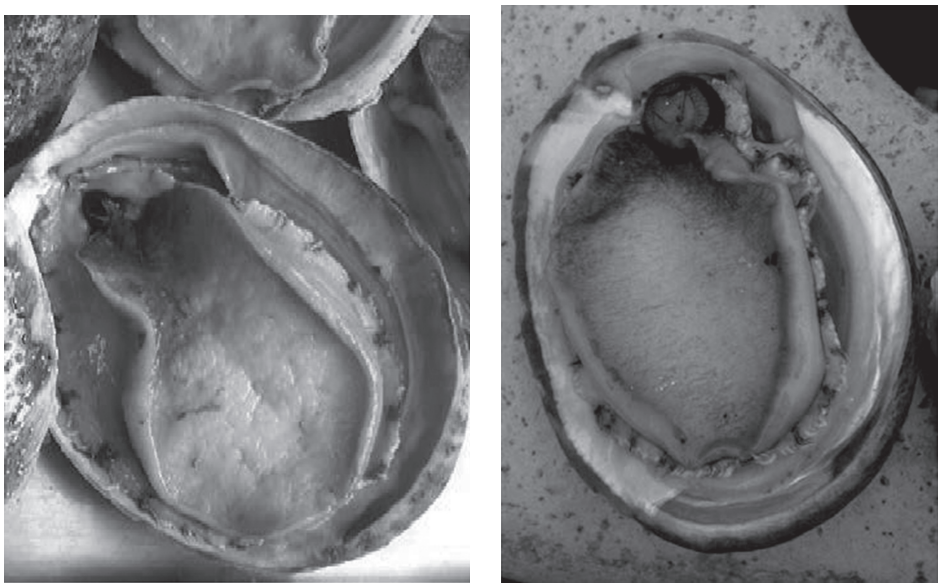
Morphology and physicochemical properties: Transmission electron microscopy of negatively stained AbHV particles purified from AVG-affected abalone demonstrated virions comprising an icosahedral capsid (92–109 nm diameter) surrounded by an envelope (~150 nm diameter) decorated with numerous projecting spikes [10]. Particles similar in morphology have been detected in ultrathin sections of cells within the pleuropedal ganglion of AbHV-infected abalone [23]. When ultracentrifuged to equilibrium in either caesium chloride or isopycnic potassium tartrate density gradients, AbHV particles have a buoyant density of 1.17–1.18 g/mL. The morphology and buoyant density of AbHV particles are typical of those described for other members of the *Herpesviridae* family [24].

Biology and epidemiology: In AVG outbreaks occurring in abalone cultured in Taiwan, in 16°C–19°C water, mortalities began to accumulate 3 days after the appearance of gross signs of disease, and both adults and juveniles suffered 70%–80% cumulative mortality [8]. In Australia, AVG outbreaks in both farmed and wild abalone have similarly been associated with rapid disease onset in all age classes and up to 90% cumulative mortality [25]. In experimental infections undertaken in Taiwan (water temperature 17°C–20°C) and Australia (water temperature 15°C–18°C), gross signs and pathology consistent with AVG have been reproduced typified by a 1–3 day preclinical period and 100% mortality within 5–7 days post-exposure [8,23,26].

Horizontal transmission has been demonstrated experimentally either by exposing healthy abalone to water containing diseased abalone using tank systems in which direct contact between the diseased and healthy abalone could not occur or by placing healthy abalone in water that previously contained diseased abalone [8,23,26]. An important epidemiological finding from one study [23] was that AbHV DNA and histological lesions could be demonstrated in infected abalone before the onset of clinical signs of disease. This suggests that preclinical excretion of virus may occur in infected abalone, a finding of great importance in developing control programs for this disease.

90.1.3 Clinical Features and Pathogenesis

In Australia, and similarly in Taiwan, AVG outbreaks have been typified by rapidly increasing mortality and abalone dying within a day of displaying gross signs of disease (e.g., curling of the foot). There have been limited studies on the pathogenesis of the disease. Whereas Hooper et al. [9,27] simply reported lesions in dead and moribund abalone, Chang et al. [8], Corbeil et al. [23], and Crane et al. [28] used bath immersion and time-course studies to gain some preliminary insights into pathogenesis. Based on all of these studies, lesions in infected abalone are largely restricted to neural tissues, possibly occurring first in those around the buccal cavity. In particular, the cerebral, pleuropedal, and circumoesophageal ganglia may be affected in addition to the pedal nerve cords, the transverse commissures linking these nerve cords, and the associated peripheral nerves. The constant histological lesion is necrosis and/or apoptosis of neurons in the gray matter of the ganglia and nerve cords. This is associated with edema and increased cellularity in affected areas possibly due to proliferation of glial cells or infiltration by hemocytes. Observation of a leucopenia in affected abalone [27] may support sequestration of hemocytes into the neural tissue. Increased cellularity of the white matter of the ganglia and cords is also observed, together with disruption of the perineural sheath investing these sites. As the clinical course continues, the severity of these lesions increases until there is almost complete effacement of normal neural architecture in the ganglia and nerve cords [23]. It has been reported that, occasionally, intranuclear inclusion bodies may be seen in neurons [9].



90.1.4 Diagnosis

AVG caused by AbHV infection can be diagnosed by a combination of methods. Typical disease gross signs associated with rapidly increasing mortality are suggestive, but not pathognomonic, of AVG. Biopsies of nerve tissue can allow AbHV DNA to be detected rapidly by conventional or real-time polymerase chain reaction (PCR) methods [25]. Tissues preserved for histology, *in situ* hybridization (ISH), and electron microscopy can assist in confirming AVG, particularly in circumstances when the PCR tests might not detect a particular AbHV genotype. In the absence of cell lines suitable for virus isolation and amplification, PCR methods provide the only current means of reliably detecting subclinical AbHV infection [25].

90.1.4.1 Conventional Techniques

Gross signs of AVG in abalone resulting from AbHV infection are characterized by irregular elevation of the foot, swollen and protruding mouth parts, eversion of the radula (Figure 90.2), restricted movement of the pedal muscle, excessive mucus production, reduced pedal adhesion to substrates, and an inability to right themselves if turned onto their back. AVG-affected wild blacklip abalone examined from disease episodes at Tasmanian processing plants have also exhibited "hard foot" or tetany, excessive mucus production, abnormal spawning, and "bloating" [11]. Similar gross signs have been reported in herpesvirus-infected abalone in Taiwan [8]. However, compared to outbreaks of AVG in farmed or wild abalone in Victoria, the onset of gross signs and mortality was slower; morbidity and mortality rates were lower and appear to be influenced by environmental conditions under which abalone were held. In some cases, it was noted that blacklip abalone infected with the virus were apparently normal, suggesting that subclinical carriage can occur [11].

Moribund abalone exhibiting loose attachment to the substrate due to pedal muscle weakness or abnormalities should be sampled for AbHV diagnosis. Tissue samples containing neural tissue (see Figure 90.3 for location) should be fixed for histological examination.

(a) (b)

FIGURE 90.2 Photographs of a healthy greenlip abalone (a) and a greenlip abalone affected by abalone viral ganglioneuritis (b). Note the curling of the foot, the swollen and protruding mouth parts, and the eversion of the radula in the abalone with AVG. (Photographs provided by Kevin Ellard, DPIPWE, and Abalone Farms Australia.)

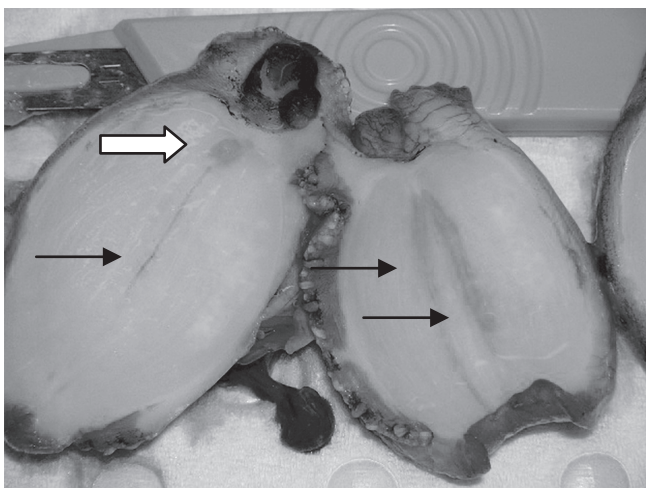


FIGURE 90.3 Photograph of a dissected abalone. A longitudinal cut through the foot muscle reveals the pleuropedal ganglion (white arrow) and nerve cords (black arrows). (Photograph provided by CSIRO AAHL.)

As detected by histopathology, AVG is characterized by increased necrosis/apoptosis of neurons in the gray matter of ganglia and nerve cords with concomitant proliferation of glial cells and infiltration by hemocytes [9,23].

While tissues can also be fixed for electron microscopy, viral particles often occur in relatively low numbers difficult to detect even in cases of acute disease [23]. The intranuclear location of AbHV particles and their ultrastructure [23] are the characteristic of members of the *Herpesviridae* family [24].

90.1.4.2 Molecular Techniques

The complete genome sequence of the AbHV-Vic strain has been reported [14] and used to develop conventional and real-time PCR tests [25] as well as ISH probes [23,29] to detect, quantify, and localize AbHV infection in abalone with either clinical or subclinical infections [30]. Conventional PCR tests targeted to variable genome sequences have also been established to identify AbHV genotypic variants [16]. The ISH test is particularly useful in tracking disease progressing in target organs and in associating AbHV infection with tissue lesions evident by histopathological examination.

90.2 METHODS

90.2.1 Sample Preparation

Tissues of live moribund individuals should be sampled when abalone exhibit gross signs of AVG (i.e., abnormal behavior, loose attachment to the substrate, sudden onset of mortality). For screening of healthy farmed abalone, representatives of all class ages should be sampled. For histopathology, dissected tissue pieces (<1 cm^3) containing nerves should be fixed for 24 h in 10% formalin prepared in filtered seawater at a tissue: fixative ratio of at least 1:10, processed for embedding in paraffin wax and tissue sections cut and stained with hematoxylin and eosin using standard methods. For optimal ISH detection of AbHV DNA, tissues should not be fixed for longer than 24 h in formalin before being transferred to alcohol (where they may be held for extended periods).

For electron microscopy, small pieces (<0.1 cm^3) of fresh tissue containing nerves should be fixed in 2.5% glutaraldehyde prepared in filtered seawater at a tissue: fixative ratio of

at least 1:10. Following fixation, ultrathin tissue sections can be cut and negatively stained for electron microscopy using standard methods.

For PCR, dissected tissue pieces (<1 cm^3) containing nerves should be preserved in 95% ethanol at a tissue: preservative ratio of at least 1:10. As PCR is extremely sensitive, in situations where sample cross contamination could compromise data interpretation, this should be prevented by either using disposable tissue dissection instruments or decontaminating instruments thoroughly between individuals.

If fixatives are not available, either whole abalone or dissected tissue pieces should be kept on ice or refrigerated and processed at a diagnostic laboratory within 24 h of collection. While freezing of diagnostic specimens is acceptable for PCR analysis, frozen tissue is not suitable for processing for histopathology or electron microscopy.

For PCR, DNA is extracted from ethanol-preserved tissue ideally trimmed to primarily contain pleuropedal ganglion and/or pedal nerve cords using the QIAamp® DNA Mini Kit (QIAGEN) or equivalent. Briefly, ~20 mg tissue is digested overnight and DNA bound to a column is eluted in 100 µL Buffer AE (~100 ng/µL DNA concentration) provided in the kit. For larger sample numbers, 50 µL tissue digests can be used to extract total nucleic acid (DNA/RNA) using the MagMAX-96 Viral RNA Isolation Kit and an AB MagMAX Express-96 Magnetic Particle Processor (Applied Biosystems) or equivalent system. DNA should be stored at −80°C until further processing

90.2.2 Detection Procedures

AbHV has been detected in abalone in Taiwan and in Victoria and Tasmania in Australia, with genotypic variants identified in abalone affected by AVG in Tasmania [16]. Of various TaqMan real-time quantitative PCR (qPCR) tests that have been developed, two tests targeted to ORF49 and ORF66 have proved useful for detecting AbHV genomic variants when used in parallel [31]. Plasmid DNA is available for use as a positive control for each test and negative controls should include water and DNA extracted from naïve abalone. Negative controls should not demonstrate any amplification.

90.2.2.1 TaqMan qPCR

Primer and probe sequences used in the AbHV-ORF49 and AbHV-ORF66 TaqMan real-time qPCR tests designed to be multiplexed with an 18S rDNA TaqMan qPCR test are described in Table 90.1. The 18S rDNA PCR test (Applied Biosystems) is used to validate nucleic acid extraction and integrity and the absence of PCR inhibitors. qPCR tests are performed using 96-well PCR plates with diagnostic samples and positive and negative controls being tested in either duplicate or triplicate.

90.2.2.1.1 Procedure

1. PCR primer, probe, and reagent concentrations and volumes used in the PCR tests are detailed in Table 90.2. Master mixes are prepared as for the real-time PCR tests.
2. Briefly vortex and pulse-centrifuge the master mix, dispense 23 µL into each 200 µL PCR tube or plate well, and transfer the tubes/plate to a refrigerator in a dedicated template addition laboratory.
3. Add 2 µL template DNA or water (no template negative control) to each well first and then 2 µL/well of quantified positive control plasmid DNA (20,000 and 200 DNA copies/reaction).
4. Pulse-centrifuge and transfer tubes/plate to an ABI 7500 thermal cycler or equivalent in a dedicated real-time PCR laboratory.
5. Thermal cycling conditions are 95°C for 59 s followed by 50 cycles of 95°C for 3 s and either 62°C for 30 s (AbHV-ORF49 PCR) or 60°C for 30 s (AbHV-ORF66 PCR).
6. At the completion of PCR, fluorescence data are analyzed at threshold value of 0.1.

TABLE 90.1
Primer and Probe Sequences Used in TaqMan qPCR Tests for AbHV and 18S rDNA

Test	Primers/Probe	Sequence
AbHV-ORF49	ORF49F1	5′-AACCCACACCCAATTTTTGA-3′
	ORF49R1	5′-CCCAAGGCAAGTTTGTTGTT-3′
	49Prb1	5′-6FAM-CCGCTTT CAATCTGATCCGTGG-TAMRA-3′
AbHV-ORF66	ORF66F1	5′-TCCCGGACACCAGTAAGAAC-3′
	ORF66R1	5′-CAAGGCTGCTATGCGTATGA-3′
	66Prb1	5′-6FAM-TGGCCG TCGAGATGTCCATG-TAMRA-3′
18S rDNA	18S Forward	5′-CGGCTACCACATCCAAGGAA-3′
	18S Reverse	5′-GCTGGAATTACCGCGGCT-3′
	18S VIC probe	5′-VIC-TGCTGGCA CCAGACTTGCCCTC-TAMRA-3′

TABLE 90.2
Reagent Volumes Required per Sample in TaqMan Real-Time qPCR Tests Multiplexed with a TaqMan Real-Time 18S rRNA qPCR

Reagent	Stock Conc. (µM)	Volume per Reaction (µL)	Final Conc. (µM)
Deionized water	—	8.46	—
TaqMan Universal PCR Master Mix	—	12.5	—
AbHV F1 primer	20	0.38	0.3
AbHV R1 primer	20	0.38	0.3
AbHV Prb1	5	0.51	0.1
18S Forward primer	20	0.13	0.1
18S Reverse primer	20	0.13	0.1
18S VIC probe	5	0.51	0.1
Total volume		23.0	

Note: For samples with characteristic amplification curves and C_T values to be considered positive for AbHV DNA, PCR test results must be validated by

1. There being no evidence of specific amplification curves with the no template and/or negative sample controls
2. Each positive control yielding a specific amplification curve and mean C_T value within the acceptable QC (quality control) range
3. The sample generating specific amplification curve for 18S rDNA

90.2.2.2 Conventional PCR

Real-time PCR results can be confirmed by conventional PCR (AbHV1617 test) utilizing the primers AbHV-16 (5′-GGCTCGTTCGGTCGTAGAATG-3′) and AbHV-17 (5′-TCAGCGTGTACAGATCCATGTC-3′).

90.2.2.2.1 Procedure

PCR primer and reagent concentrations and volumes used in the AbHV1617 PCR test are detailed in Table 90.3.

1. Briefly vortex and pulse-centrifuge the master mix, dispense 23 µL into each 200 µL PCR tube or plate well, and transfer the tubes/plate to a refrigerator in a dedicated template addition laboratory.
2. Add 2 µL template to the appropriate wells. Include the appropriate positive controls and no template control.
3. Pulse-centrifuge briefly and transfer tubes/plate to a thermal cycler in a dedicated PCR laboratory.
4. Thermal cycling conditions are 95°C for 15 min followed by 40 cycles of 94°C for 30s, 52°C for 30 s, and 74°C for 45 s and a final extension at 72°C for 7 min and 4°C hold.
5. Amplified DNA is detected using a blue-light transilluminator following electrophoresis in a 1.5% agarose-TAE gel containing SYBR Safe dye or equivalent.
6. DNA sequence analysis is recommended to confirm that AbHV DNA was amplified.

TABLE 90.3
Reagent Volumes Required for per Sample in the AbHV1671 PCR Test

Reagent	Stock Conc. (µM)	Volume per Reaction (µL)	Final Conc. (µM)
Deionized water	—	9.50	—
HotStar Taq Master Mix	—	12.50	—
AbHV Forward primer	18	0.50	0.36
AbHV Reverse primer	18	0.50	0.36
Total volume		23.0	

Note: For samples generating DNA bands to be considered positive for AbHV DNA, PCR test results must be validated by

1. There being no evidence of specific DNA products being amplified with the no template and/or negative sample controls.
2. Each plasmid positive control DNA yielding a DNA product 522–588 bp in length depending on the AbHV genotype used to prepare the plasmid.
3. Test samples generating amplicons in the 522–588 bp size range depending on the AbHV genotypes detected, with DNA authenticity confirmed by sequence analysis of the purified amplicon.

90.2.2.3 *In Situ* Hybridization

The ISH procedure described here uses a digoxigenin (DIG)-labeled DNA probe to detect AbHV DNA in formalin-fixed, paraffin-embedded tissue sections. The following reagents are required:

20 × standard saline citrate (SSC) pH 7.0 (store at room temperature) (made up of 175.32 g/L NaCl, 88.23 g/L sodium citrate)

100 × Denhardt's solution (store at –20°C) (made up of 2% bovine serum albumin (Fraction V), 2% Ficoll 400, 2% polyvinylpyrrolidone)

Hybridization buffer (store at –20°C) (made up of 25 mL formamide, 10 mL 20 × SSC, 2.5 mL 100 × Denhardt's solution, 10 mL 50% dextran sulfate in distilled water, 500 µL 10 mg/mL herring sperm DNA made to 50 mL with Milli-Q water)

10 × Tris-buffered saline (TBS) (store at room temperature) (made up of 23.6 g/L Tris base, 127 g/L Tris-HCl, 87.66 g/L NaCl [pH 7.5])

90.2.2.3.1 Procedure

1. The DIG-labeled probe is prepared by PCR amplification of AbHV plasmid DNA or DNA extracted from AbHV-injected abalone using the modified ORF66 primers AbHVORF66f1 (5′-TCCCGGACACCAGTAAGAAC-3′) and AbHVORF66r2 (5′-GCCGGTCTTTGAAGGATCTA-3′) and reagents in the PCR DIG Probe Synthesis Kit (Roche Cat. No. 11-636-090-910) according to the manufacturer's instructions.
2. Thermal cycling conditions 95°C for 5 min followed by 30 cycles of 95°C for 30 s, 57°C for 30 s, and 72°C for 60 s followed by a final extension at 72°C for 10 min, with 4°C hold.
3. Place tissue sections (3 µm thickness) cut from paraffin block onto Superfrost Plus slides (Menzel Catalogue No. SF41296SP) and allow to dry.
4. Heat sections at 65°C for 30 min and deparaffinize in two changes of xylene.
5. Rehydrate tissue sections by placing slides in absolute ethanol (2 min) followed by 90% ethanol (2 min) and 70% ethanol (2 min) and then into distilled water.

6. Place slides in 0.2 N HCl for 20 min and rinse in distilled water for 5–10 min.
7. Apply 50–100 µL of 100 µg/mL proteinase K in TBS and incubate at 37°C for 30 min.
8. Rinse with 0.2% glycine for 2 min and wash in running water for 10 min.
9. Dehydrate sample in 70% ethanol (2 min), 90% ethanol (2 min), and 100% ethanol (2 min) and allow slides to air-dry.
10. Make 100 µL hybridization solution per tissue section containing ~5 ng/L DIG-labeled DNA probe.
11. Heat the hybridization solution to 95°C–100°C for 5 min to denature the DNA and place on ice until used.
12. Apply sufficient hybridization solution to cover the section (~50 µL) and gently cover with a glass coverslip.
13. Using either a PCR heating block or a specialist hybridization block, heat the slides to 95°C for 5 min to denature the nucleic acid in the tissue specimen.
14. Place the slides in a humidified chamber preheated to 37°C and incubate at 37°C overnight (12–16 h).
15. Remove coverslips by immersing slides in 2 × SSC at room temperature, place slides in a rack, and immerse in 2 × SSC at room temperature.
16. Wash, with gentle rocking/shaking, in 0.5 × SSC at 37°C for 15 min.
17. Wash slides briefly in TBS at room temperature.
18. Incubate slides in blocking solution (0.5% skim milk powder in TBS) for 30 min at room temperature.
19. Cover sections with 100–200 µL alkaline phosphatase conjugated sheep anti-DIG antibody (Roche Cat. No. 1093274) diluted 1:100 in blocking solution and incubate at room temperature for 1 h.
20. Wash (3 × 3 min) in TBS buffer.
21. Equilibrate in Solution II (either a solution of 0.1 M Tris-HCl (pH 8.0), 0.5 M NaCl, and 0.1 M $MgCl_2$ with final pH 9 or a solution made up of 0.1 M Tris-HCl (pH 8), 0.05 M, and $MgSO_4 \cdot 7H_2O$ with final pH 9.5) for 3 min at room temperature.
22. Cover the sections with NBT/BCIP diluted in Solution II (25 µL/mL), cover with a coverslip, and incubate in the dark for 3–4 h in a humidified container, making sure that the slides do not dry out.
23. Periodically monitor for color development in tissue using a light microscope. For additional color development, slides incubation in the dark at room temperature can be continued overnight.
24. To stop color development, remove the coverslip by immersing the slides in distilled water and wash the slides under running water for 5 min.
25. Counter stain the sections for 1 min with 0.5% Bismarck brown or equivalent.
26. Mount the slides with mounting medium (DAKO Cat. No. S3023) and a coverslip.
27. Examine by light microscopy for specific dark blue-black intracellular staining indicating the presence of AbHV DNA.

90.3 CONCLUSION AND FUTURE PERSPECTIVES

AbHV is an emerging viral pathogen of abalone that has caused disease outbreaks associated with high mortality rates in farmed abalone in Taiwan and wild and farmed abalone in Victoria, Australia. It has also caused mortality among wild-captured abalone being held in recirculating live-holding facilities at processing premises in Tasmania, Australia. In this latter case, mortality has been reported to be lower and varying dependent upon where abalone were sourced and the conditions under which they were held. Of interest, genotypic variation has been detected among the Taiwanese, Victorian, and Tasmanian AbHV strains and among AbHV strains identified as the cause of AVG outbreaks occurring at different Tasmanian premises between 2008 and 2011.

As there are no effective treatments for AVG, control methods in Australia currently rely on surveillance, biosecurity systems at farms and processing premises, zoning and restrictions on the movement of live abalone, and rapid response and decontamination systems to contain disease occurrences. Farm disease outbreaks are managed through the destruction and safe disposal of affected abalone, disinfection of water and equipment, and following procedures to effectively prevent recurrences. The use of sentinel abalone at previously affected farms and premises has been proposed as a means of ensuring the absence of infectious AbHV prior to restocking. These practices are consistent with many used to control and eradicate viral diseases of other aquatic species [32,33]. As an example, rigorous surveillance, culling, and decontamination processes have resulted in viral hemorrhagic septicemia (VHS) of rainbow trout being eradicated successfully from farms in the United Kingdom in 2006 [34] and farms in Norway in 2007 [35]. More recently in Denmark, >400 affected farms were declared free from VHS after 45 years of surveillance and control [36].

In cases where abalone might harbor subclinical, possibly persistent, AbHV infections, reduced handling and other potential stressors in farms or processor live-holding facilities (e.g., poor water quality, high stocking density, and poor feed quality) will assist in preventing acute infection from arising that can result in rapid horizontal transmission of disease to cohabitating abalone. The virus has been shown to persist in biofilters of recirculating systems and reemerge when tanks hold infected abalone previously restocked. Strict hygiene measures applied between tanks and between batches of abalone have been shown to provide some degree of effective controls in Tasmania. Another important issue for control of the disease is the early detection of abalone with low-level infections. Current DNA-based PCRs cannot differentiate truly infected abalone from uninfected abalone acting as fomites or cross contamination during laboratory studies [28]. Therefore, a reverse transcription polymerase chain reaction (RT-PCR) capable of detecting AbHV mRNA (similar to that used for CyHV-3, [37]) should be developed in order to identify genuinely active infections.

With aquaculture of species including various molluscs expanding globally and tighter restrictions on the use of

chemicals to control disease, there is mounting interest in understanding defense mechanisms that can be stimulated to protect hosts against pathogen challenge. In salmon, carp, and channel catfish, as examples, understanding of their pathogen defense systems [38] has guided the development of experimental and commercial vaccines [39]. Similar investigations are now aiming to better understand the mechanisms underpinning pathogen defense in shrimp [40], oysters [41,42], and abalone [43–45]. In addition to understanding antiviral responses in abalone [46,47], better understanding of persistent infections (which are possibly associated with spread of the disease) and potential protective roles for RNA interference [48] and genetic selection strategies [49,50] to generate disease-resistant abalone may also offer opportunities to minimize environmental and commercial impacts of AVG.

91.1 INTRODUCTION

African swine fever virus (ASFV) is an intracytoplasmically replicating DNA virus that is responsible for African swine fever (ASF). Maintained in warthogs and bushpigs and transmitted by soft ticks of the *Ornithodoros* genus, ASFV infection in domestic pigs leads to high fever, loss of appetite, hemorrhages in the skin and internal organs, and death (with mortality rates as high as 100%) [1].

First described in Kenya in 1921, ASF is endemic in sub-Saharan African countries. The disease spread beyond Africa to Portugal in 1957 and Spain in 1960. In subsequent years, sporadic outbreaks of ASF occurred in Belgium, Italy, Malta, Sardinia, and Holland, and the virus reached the Caribbean (Cuba, Dominican Republic, and Haiti) and Brazil in the 1970s. Apart from Sardinia in Italy, most European countries have managed to eradicate the disease in domestic pigs by the late 1990s. However, with the reintroduction to Georgia in the Caucasus region in 2007, ASF quickly traveled to Armenia, Iran, Azerbaijan, and Chechnya. By 2014, ASF outbreaks have been reported in Ukraine, Belarus, Lithuania, Latvia, and Poland [1].

Being a highly contagious, fatal disease of domestic pigs, ASF contributes to significant losses in pig farming industry and increases economic burdens on both ASF-affected and disease-free countries with trade bans and eradication costs. As such, ASF is listed as a reportable disease by the World Organization for Animal Health (OIE) Terrestrial Animal Health Code.

91.1.1 Classification

ASFV is a double-stranded DNA virus classified in the genus *Asfivirus*, family *Asfarviridae*, which derived its name from ASF and other related viruses.

As the sole member of the family *Asfarviridae*, ASFV demonstrates several distinct features from other viruses. First of all, while ASFV is capable of stimulating host antibody production in natural infection, the resulting antibodies do not seem to consistently neutralize the virus [2]. Second, despite the existence of antigenic variations among ASFV isolates, it has been practically impossible to serotype these viruses. Third, being the only known DNA arbovirus, ASFV is remarkably adaptable. Besides circulating between warthogs and bushpigs (natural host) and *Ornithodoros* soft ticks (vector), ASFV is able to maintain its life cycle in domestic pigs through contaminated feed, without further input from tick vector. Further, free-ranging domestic pigs may acquire the virus by feeding on infected carcasses of warthogs and bushpigs or via tick bites [3].

On the basis of sequence variations in the C-terminal region of the *B646L* gene encoding the major capsid protein VP72, ASFV is distinguished into 22 genotypes (I–XXII) [4]. While genotypes I–XXII are found in eastern and southern Africa, genotype I (the so-called ESAC-WA genotype) is present in Europe, South America, the Caribbean, and western Africa, and genotype II ASFV is identified in Madagascar, the Caucasus region, and Russia [5].

In addition, phylogenetic analysis of the central variable region (CVR) within the *B602L* open reading frame (ORF) detects 12 differently sized products within the ESAC-WA genotype and separates this genotype into 19 subgroups. Moreover, a combined B646L–CVR assessment identifies eight lineages within genotype VIII, and an examination of *E183L* gene encoding the inner envelope transmembrane protein P54 permits finer differentiation within genotype IX [6,7].

Thus, sequencing analysis of the variable 3′ end of the *B646L* gene encoding the major capsid protein p72 provides a valuable approach for genotyping ASFV isolates. Further subtyping of ASFV *B646L* (p72) genotypes into subgroups is facilitated by sequencing the complete *E183L* gene encoding the p54 protein, and analysis of the nucleotide sequence of the CVR as well as the tetramer amino acid repeats within the CVR of the *B602L* gene encoding the J9L protein [8–12].

91.1.2 Morphology and Genome Organization

ASFV is a large, enveloped, icosahedral DNA virus of 175–215 nm in diameter. Extracellular virions are composed of five concentric layers, including the central nucleoid, the core shell, the inner envelope, the icosahedral capsid, and the lipid envelope layer, which is acquired when the virion buds from the plasma membrane.

The genome of ASFV consists of a linear, double-stranded DNA of 170–190 kb in length. Variation in the genome size among ASFV isolates is mainly due to the length heterogeneity (resulting from insertions and deletions of members of different multigene families [MGFs] such as MGFs 100, 110, 300, 360, and 505/530 and family p22) in the regions that flank a central conserved region (CCR) of approximately 125 kb. The left variable region ranges from 38 to 47 kb and the right variable region ranges from 13 to 16 kb. Additionally, minor length variations in the CCR also impact the overall genome size [13–15].

Within the DNA genome of ASFV, between 150 and 167 ORFs are identified. Closely spaced and read from both DNA strands, these ORFs encode 54 structural proteins including the antigenically stable virus protein VP72 and enzymes that are required for transcription and replication of the virus genome such as elements of a base excision repair system. Other ASFV-encoded molecules include factors involved in evading host defense systems and modulating host cell function and proteins that inhibit apoptosis of infected cells to facilitate production of progeny virions [14,15].

91.1.3 Biology and Epidemiology

Similar to other viruses causing viral hemorrhagic fevers, ASFV targets monocyte and macrophage lineage for replication. Following the uptake by the host, ASFV enters the host cell through receptor (dynamin) binding and clathrin-mediated endocytosis. Macropinocytosis also plays a part in the internalization of ASFV into the cells [16]. Inside the cytoplasm, the virus replicates in a highly orchestrated process with at least four stages of transcription—immediate-early, early, intermediate, and late. This activity mostly occurs in discrete, perinuclear regions of the cell called virus factories. The newly assembled progeny virions are then transported to the plasma membrane along the microtubules for a release via budding or actin-propelled cell-to-cell spread [17–22].

ASFV naturally occurs in wild pigs such as warthogs (*Phacochoerus aethiopicus* and *Phacochoerus africanus*), bushpigs (*Potamochoerus porcus*), and giant forest boars (*Hylochoerus meinertzhageni*), in which no clinical signs are apparent, although ASFV-infected wild boar (*Sus scrofa*) and feral pigs often show similar clinical signs and mortality to domestic pigs [23–25].

Soft ticks of the genus *Ornithodoros* (particularly, *O. moubata*, *O. erraticus*, *O. porcinus domesticus*, and *O. porcinus porcinus* and possibly, *O. coriaceus*, *O. turicata*, *O. parkeri*, *O. puertoricensis*, *O. savignyi*, *O. sonrai*, and *O. tholozani*) function as a vector for the virus as they are able to retain the virus for long periods and transmit it to susceptible hosts. In addition, tick-to-tick transmission through transstadial, sexual, and transovarial routes allows the virus to persist in the absence of viremic hosts [26,27].

ASFV is present in all tissues and body fluids of infected pigs with highest concentrations in the blood and the spleen [28]. Blood shedding during necropsies or pig fights and bloody diarrhea from infected pigs are main sources of contamination. The virus remains viable for long periods in the blood, feces, and tissues, with half-lives in the feces or blood ranging from >2 years at temperature up to 12°C to 15 days at temperatures of 30°C and in the tissue samples ranging from 1.7 to 7.4 days at 20°C. In addition, ASFV survives for 30 days in pepperoni and salami sausages and for >100 days in Iberian-cured pork products and Parma hams. ASFV also maintains infectivity to domestic pigs for 3 days in contaminated pigpens in the tropics.

ASFV is transmitted via three cycles: the sylvatic cycle, domestic pig cycle, and wild pig–to–domestic pig cycle. In the *sylvatic cycle*, warthogs become infected and develop a transient viremia lasting 2–3 weeks after biting by resident *O. moubata* ticks harboring the virus. Ticks feeding on viremic warthogs acquire the infection, completing the sylvatic cycle of infection. The sylvatic cycle mainly occurs in eastern and southern Africa [29]. In the *domestic pig cycle*, pigs acquire the virus from other infected/recovered pigs through ingestion of infected pig carcasses or pork products, or exposure to the blood and body fluids during fighting or mating. Ticks may or may not be involved in the transmission. The domestic pig cycle is seen in both west and east Africa [30]. In the *wild pig–to–domestic pig cycle*, free-ranging domestic pigs may acquire the infection through feeding on ASFV-contaminated wild pig carcasses or feces or tick bites during foraging [31].

Endemic in most sub-Saharan Africa including Madagascar, ASFV commonly occurs in feral pigs in Sardinia, Italy. After its reintroduction into the Caucasus in 2007, ASFV has become endemic among wild boars in the region, causing outbreaks among domesticated swine in the Republic of Georgia, Armenia, Azerbaijan, Russia, and other countries in the region [32–37].

91.1.4 Clinical Features and Pathogenesis

With an incubation period of 5–19 days after direct contact with infected pigs or <5 days after exposure to ticks, ASFV infection in domestic pigs may induce peracute, acute, subacute, or chronic disease depending on the virulence of virus strains, age, and immune status of the host [1].

Peracute disease is caused by highly virulent ASFV strains and usually occurs in a naïve pig population. Individual pigs are often found dead without showing apparent clinical symptoms [1].

Acute disease due to a highly virulent ASFV often shows fever (40°C–42°C) by 48 h postinfection. This is followed by loss of appetite, depression, dyspnea, anorexia, lethargy, leg weakness, recumbence (with shivering and coughing), erythema, cyanotic (blue-purple color), skin blotching (on the nose, ears, tail, lower legs, or hams), abdominal pain, constipation or diarrhea (initially mucoid and later bloody), viremia (appearing from 3 days postinfection and rising to a peak of over 10^8 hemadsorption units $[HAD]_{50}$/m), hemorrhages (on the ears and flanks and the internal organs), vomiting, nasal and conjunctival discharges, neurologic signs, abortion, coma, and death (up to 100% within 7–10 days). The infected pigs develop an acute hemorrhagic fever with viremia appearing from 3 days postinfection and rising to a peak of over 10^8 HAD_{50}/mL. Mortality of approaching 100% occurs within 8–12 days postinfection. In this form of the disease, the death rate is generally lower in adult swine, but may still be very high in very young animals [1].

Subacute or chronic disease caused by moderately virulent strains produces milder symptoms that may take several weeks to spread through the herd. Clinically, subacute disease is characterized by intermittent low fever, loss of appetite, depression, coughing, diarrhea, vomiting, emaciation, stunting, swollen joints, ulcers, reddened or raised necrotic skin foci over body protrusions, thrombocytopenia, and transient leukopenia. The infected pigs usually die (70%–80% in young pigs but less than 20% in older animals) or recover within 3–4 weeks [1].

Subacute disease due to moderate to highly virulent strains is characterized by intermittent low fever (lasting 30–45 days), anorexia, loss of appetite, coughing, dyspnea, depression, diarrhea, vomiting, emaciation, stunting, swollen joints, ulcers, reddened or raised necrotic skin foci over the body protrusions, abortion, thrombocytopenia, and transient leukopenia. The infected pigs usually die (30%–70% in young pigs but less than 20% in older animals) or recover within 3–4 weeks. This form of disease is also seen in herds with previous exposure [1].

Chronic disease due to strains of low to moderate virulence often occurs in previously exposed herds. Clinical signs include weight loss, unthriftiness, growth retardation, loss of hair, irregular febrile conditions, undulating respiratory peaks, lameness (arthritis), secondary infections, and low-grade perpetual sickness, with mortality (up to 30%). However, conjunctivitis is absent [1].

Asymptomatic infections or mild disease is usually seen in warthogs and bushpigs, while wild boar may develop clinical disease similar to domestic pigs.

At postmortem, pigs with peracute or acute disease may show bluish-purple discoloration and/or hemorrhages in the skin; bloody diarrhea; internal hemorrhages (in the spleen, lymph nodes, kidneys, and heart); large, friable, and dark red to black spleen; swollen and hemorrhagic lymph nodes (especially the gastrohepatic and renal lymph nodes); petechiae on the cortical and cut surfaces of the kidneys and in the renal pelvis; perirenal edema; hydropericardium with hemorrhagic fluid; petechiae and ecchymoses (in the urinary bladder, lungs, heart, stomach, and intestines); congestion or edema (in the liver, gall bladder, or lungs); straw-colored or blood-stained fluid (in the pleura, pericardium, and peritoneum); and congested, edematous, or hemorrhagic brain and meninges. Aborted fetuses are anasarcous, with a mottled liver, petechiae, or ecchymoses in the skin and myocardium as well as in the placenta [38].

Pigs with subacute or chronic disease may have emaciated carcass, enlarged but nonfriable spleen with a normal color, enlarged and hemorrhagic lymph nodes, slight petechiation on the kidneys, focal areas of skin necrosis, skin ulcers, consolidated lobules in the lung, caseous pneumonia, nonseptic fibrinous pericarditis, pleural adhesions, generalized lymphadenopathy, and swollen joints [39].

The pathogenesis of acute ASF reflects the capacity of ASFV to generate a series of molecules that interfere with host signaling pathways controlling the transcription of cytokines and modulate host cell function in relation to the apoptosis, inflammation, and immune responses. For example, ASFV A276R, A528R, and I329L genes are involved in the inhibition of IFN and NF-κB induction via the TLR3, cytosolic, or type I interferon (IFN) signaling pathways. This helps ASFV to evade host immune surveillance and overcome host innate and adapted immunity against the invading virus, leading to its unhindered replication and spread within/between host cells [40,41].

After gaining entry into the host via oronasal route, ASFV migrates to the tonsils or dorsal pharyngeal mucosa, then the mandibular/retropharyngeal lymph nodes, and finally the hematogenous system, leading to viremia as early as 8 h postinfection in newborn piglets and subsequent spread to other body organs within a day of postinfection. ASFV replication in these cells/organs results in pronounced depletion of lymphoid tissues, apoptosis of lymphocyte subsets, impairment of hemostasis and immune functions, extensive necrosis, destruction of endothelial membrane, and hemorrhages (in melena, epistaxis, erythema, renal petechiae, and lymph nodes) [42].

The pathogenesis of subacute/chronic ASF relates to the inability of nonvirulent ASFV strains to completely deplete host CD8(+) lymphocytes and to the increased host natural killer cell activity. This reduces the severity of the disease and protects the host from succumbing to the disease. At the same time, this enhances host autoimmune activity, leading to increased deposition of immune complexes in tissues (the kidneys, lungs, and skin) [42].

Thus, most lesions seen in ASF are attributable to cytokine-mediated interactions triggered by infected and activated

monocytes and macrophages, rather than by virus-induced direct cell damage [38,43].

91.1.5 Diagnosis

Pigs displaying fever together with a very large, friable, dark red to black spleen and greatly enlarged and hemorrhagic gastrohepatic and renal lymph nodes at necropsy may be suspected of ASF.

Differential diagnoses include classical swine fever (hog cholera), acute porcine reproductive and respiratory syndrome, porcine dermatitis, nephropathy syndrome, erysipelas, salmonellosis, pasteurellosis, eperythrozoonosis, actinobacillosis, Glasser's disease (*Haemophilus parasuis* infection), Aujeszky's disease (in young animals), thrombocytopenic purpura, warfarin poisoning, heavy metal toxicity, and other generalized septicemic or hemorrhagic conditions.

Laboratory diagnosis of ASF is mainly reliant on virus isolation, detection of viral antigen, antiviral antibody, and viral nucleic acids [44].

Virus isolation: ASFV from the blood (heparin or EDTA) or tissues (the spleen, kidney, tonsils, and lymph nodes) are isolated on the porcine leukocyte, bone marrow, alveolar macrophages, and blood monocyte cultures. ASFV virulent isolates tend to induce hemadsorption of pig erythrocytes to the surface of infected cells (the so-called a hemadsorption "autorosette" test), while avirulent isolates do not. This offers a sensitive approach to isolate ASFV from the blood, spleen, lymph nodes, tonsil, and kidney, but its usefulness is limited by its requirement of regular supply of fresh primary bone marrow cells or pig leukocytes [45,46].

Antigen and antibody detection: ASFV antigens are detected in tissue smears, cryostat sections, or buffy coat by fluorescent antibody test. Anti-ASFV antibodies may be detected from the serum, lymph nodes, or spleen of an infected pig with enzyme-linked immunosorbent assay (ELISA), immunoperoxidase test, immunoblotting, counter-immunoelectrophoresis, etc. [47]. A commercial-blocking ELISA (INGEZIM PPA Compac 11.PPA.K3, INGENASA) targeting VP73 viral protein is recommended by the OIE [48].

Nucleic acid detection: ASFV nucleic acids may be detected by hybridization probes and, more recently, by PCR and other amplification techniques (isothermal amplification assays) [49–65]. Real-time PCR assay targeting a highly conserved structural protein p72 has been shown to be extremely useful for detecting ASFV in samples of unknown origin. A commercial reverse transcription polymerase chain reaction (RT-PCR) Tetracore® assay (Tetracore Inc.) may be also used to detect ASFV DNA. Furthermore, fluorogenic probe hydrolysis (TaqMan) PCR allows specific, one-step, single-tube detection of ASFV in <2 h.

91.1.6 Treatment and Prevention

In the absence of specific treatment, control and prevention of ASF center on quarantine, stamping out (slaughter), and eradication [66,67].

In the event of an ASF outbreak, stamping out may be applied to the affected individual farms or the areas within 5 km surrounding the affected farms. The key quarantine and eradication measures include slaughtering of infected and in-contact animals, proper disposal of carcasses (by burying, rendering, or burning), movement control, chemical disinfection (with sodium hypochlorite, 2% sodium hydroxide, 1% formalin, 4% anhydrous sodium carbonate plus 0.1% detergent, 10% crystalline sodium carbonate plus 0.1% detergent, and 1% phosphorylated iodophors, chloroform, and cresol), and control of tick vectors with acaricides. In addition, proper cooking of swill fed to pigs, that is, heating unprocessed meat at 70ºC for 30 min and heating serum and bodily fluids at 60ºC for 30 min, may help inactivate the virus.

Prevention in countries free of the disease requires stringent import policies to ensure proper disposal of waste food from aircraft, ships, or vehicles coming from infected countries. Application of state-of-the-art diagnostic technologies is also important for early detection and prompt implementation of control measures.

Although vaccination represents the most effective approach to prevent virus diseases, past attempts to develop vaccines against ASF have not had much success. Preliminary data suggest that partial protection of pigs is possible with low-virulence isolates from the field or obtained by passage in tissue culture or by deletion of genes involved in virulence. Further research in this area is warranted [66,67].

91.2 METHODS

91.2.1 Sample Preparation

Suitable samples for ASFV diagnosis are the blood, lymph nodes, and spleen. Ticks are collected and placed in small plastic boxes containing a wet piece of filter paper for tick survival. In the laboratory, ticks are stored at −80°C until analysis.

Total DNA is purified from 200 μL of a sample (cell culture supernatant, serum, blood treated with EDTA, or tissue homogenate in 10% phosphate-buffered saline) by using the High Pure PCR Template Preparation Kit (Roche Molecular Biochemicals), DNeasy Blood and Tissue Kit (Qiagen), or QIAamp Viral RNA Mini Kit (Qiagen). The extracted DNA is eluted in a 50 μL volume and stored at −20°C.

91.2.2 Detection Procedures

91.2.2.1 Conventional PCR

Aguero et al. [68] developed a PCR for ASFV detection with primers from the *B646L* gene encoding the major capsid protein p72. Use of the primer set PPA1 (5′-AG TTATGGGAAACCCGACCC-3′) and PPA2 (5′-CCCTGA ATCGGAGCATCCT-3′) allows amplification of 257 bp.

PCR mixture (25 μL) is made up of 2 μL of sample DNA, 1× PCR buffer II (50 mM KCl, 10 mM Tris-HCl), 2 mM $MgCl_2$, 0.2 mM concentrations of the 4 deoxynucleoside triphosphates (Roche Molecular Biochemicals), and 0.2 μM

concentrations of both primers (PPA-1/2 and 0.625 U of Taq Gold polymerase; Applied Biosystems).

Amplification is carried out with (1) incubation at 95°C for 10 min; (2) 40 cycles of 95°C for 15 s, 62°C for 30 s, and 72°C for30 s; and (3) incubation at 72°C for 7 min.

Amplification products are analyzed by electrophoresis on a 2% agarose gel containing 0.5 μg of ethidium bromide per mL.

Note: The PCR using primer set PPA1 and PPA2 appears to be more sensitive than the OIE-recommended primer set (primer 1: 5′-ATGGATACCGAGGGAATAGC-3′; primer 2: 5′-CTTACCGATGAAAATGATAC-3′), which corresponds to a 278 bp region in the central portion of the p72 gene [48].

91.2.2.2 Real-Time PCR

91.2.2.2.1 Protocol of Haines et al. [69]

Haines et al. [69] described a real-time PCR assay for ASFV identification with primers and probe from the 3′ end of the VP72 gene (Table 91.1). The inclusion of IC-RNA-specific primers EGFP1-F and EGFP2-R and TaqMan probe EGFP1-HEX allows monitoring the efficiency of sample preparation and amplification (Table 91.1).

PCR mixture (25 μL) is composed of 8.4 μL nucleic acid extract, 12.5 μL 2× reaction mix, a final concentration of 5 mM $MgSO_4$, 5 U RNAsin, 50 nM ROX, and 0.5 U Superscript III Reverse Transcriptase/Platinum Taq mix. EGFP1-F and EGFP2-R primers are at a concentration of 200 nM and EGFP-HEX probe is at 100 nM. Primers ASFVp72IVI_L and ASFVp72IVI_R are at a concentration of 900 nM and the ASFV-Cy5 is at 200 nM.

Amplification and detection are conducted in Mx3005P qPCR System (Agilent Technologies) with the following conditions: RT at 50°C for 15 min, followed by incubation at 95°C for 2 min, then 50 cycles of denaturation at 95°C for 15 s, and annealing and extension at 60°C for 1 min. After amplification, a threshold cycle (C_T) value is assigned to each sample.

Note: Samples are considered ASFV positive if the ASFV probe results in a (CY5) C_T value ≤35. Samples are classed as ASFV negative if the IC-RNA probe (HEX) gives C_T values ≤38 but for which no C_T values for FAM or CY5 are obtained. In the event where a sample does not meet the aforementioned criteria, the sample is classified as "inconclusive."

91.2.2.2.2 Protocol of Zsak et al. [70]

Zsak et al. [70] designed a one-step real-time PCR assay for ASFV, with primers and TaqMan probe from ASFV gene encoding a highly conserved structural protein p72. Specifically, the forward primer starts at base position 1466 (5′-CCTCGGCGAGCGCTTTATCAC-3′); reverse primer starts at base position 1528 (5′-GGAAACTCATTCACCAAATC CTT-3′); probe starts at base position 1486 (5′-CGATGC AAGCTTTAT-3′). The TaqMan probe is labeled with a 5′ reporter dye, 6-carboxyfluorescein, and 3′ minor groove binder nonfluorescent quencher (PE Biosystems).

The PCR mixture (25 μL) is made up of 5× buffer solution, 5 mM Mn_2-acetate, 0.3 M concentration of each primer, 0.1 mM dATP, dCTP, or dGTP, 0.2 mM dUTP, 0.1 U of recombinant *Tth* DNA polymerase per μL (EZ-RT-PCR, PE Biosystems), 0.1 μg of bovine serum albumin per μL, and 0.5 M trehalose. The PCR mixture is dried within the reaction tubes (Fisher Scientific) and stored at room temperature for at least 1 year. For sample testing, the dried reagents are rehydrated with 22.5 μL of 1× buffer and 2.5 μL of DNA sample material.

Cycling parameters include 45 amplification cycles (95°C for 2 s and 60°C for 30 s) using the SmartCycler (Cepheid, Inc.).

Note: The real-time PCR assay displays a higher sensitivity with tonsil scrapings (95.4%) and nasal swabs (92.8%) than that with the blood (89.7%).

91.2.2.3 Phylogenetic Analysis

Atuhaire et al. [71] employed primers p72-U/p72-D from the C-terminal region of the p72 gene (478 bp), PPA722/PPA89 from the complete gene encoding the P54 protein (676 bp), and CVR-FL1/CVR-FL2 from the CVR located in the B602L gene for phylogenetic analysis of ASFV isolates (Table 91.2).

TABLE 91.1
Identity of Real-Time Polymerase Chain Reaction Primer and Probes

Target	Primer/Probe	Sequence (5′–3′)
ASFV	ASFVp72IVI_L	GAT GAT GAT TAC CTT YGC TTT GAA

TABLE 91.2
Identity of Primers for Phylogenetic Analysis of African Swine Fever Virus

Gene	Primer	Sequence (5′–3′)	Product (bp)
p72 gene	p72-U	GGCACAAGTTCGGACATGT	478
	p72-D	GTACTGTAACGCAGCACAG	
P54 gene	PPA722	CGAAGTGCATGTAATAAACGTC	676
	PPA89	TGTAATTTCATTGCGCCACAAC	
CVR (B602L gene)	CVR-FL1	TCGGCCTGAAGCTCATTAG	Variable size
	CVR-FL2	CAGGAAACTAATGATGTTCC	

PCR mixture (100 μL) is made up of 10–50 ng of sample DNA, 1× PCR buffer II (50 mM KCl, 10 mM Tris-HCl), 2.5 mM $MgCl_2$, 0.2 mM concentrations of the 4 deoxynucleoside triphosphates (Roche Molecular Biochemicals), 0.2 μM concentrations of the primers, and 0.625 U of Taq Gold polymerase (Applied Biosystems).

Amplification is carried out in the Perkin–Elmer thermal cycles with (1) denaturation at 95°C for 5 min; (2) 40 cycles of 95°C for 30 s, 50°C for 30 s, and 72°C for 1 min; and (3) incubation at 72°C for 10 min.

PCR products are separated in a 2% agarose gel; bands of the correct size are excised and purified by Gel Extraction Kit (BIORON®) and sequenced.

The resulting sequences are submitted to the Basic Local Alignment Search Tool in order to identify their similarity with sequences obtained from the GenBank. Sequence alignment is performed using the CLUSTAL W with manual adjustments. For phylogenetic analysis, the MEGA 5.0 program is used to construct the neighbor-joining trees with 1000 bootstrap replications. The trees are drawn to scale, with branch lengths in the same units as those of the evolutionary distances used to infer the phylogenetic trees. The evolutionary distances are computed using the p-distance method and are in the units of the number of base differences per site. Codon positions included are 1st + 2nd + 3rd + noncoding. All ambiguous positions are removed for each sequence pair.

91.3 CONCLUSION

ASF is a hemorrhagic, fatal disease of pigs, resulting from infection with ASFV. Due to its remarkable ability to perpetuate in wild pigs, soft ticks, and/or domestic pigs, ASF has spread from sub-Saharan Africa in the 1960s to Europe and subsequently to the Caribbean. Following its reintroduction to the Caucasus in 2007, this disease is associated with a number of outbreaks in eastern Europe and southern Russia, with huge economic impact. In the absence of effective vaccines, control and prevention of ASF are dependent on the application of reliable laboratory diagnostic methods for early detection and monitoring, adoption of stamping out policy, implementation of quarantine and disinfection measures, and prevention of ASF incursion from infected areas to ASF-free areas.

92.1 INTRODUCTION

As a recently identified genus in the family *Iridoviridae*, *Megalocytivirus* contains several double-stranded DNA (dsDNA) viruses that are pathogenic to a wide variety of freshwater and marine fishes, with a significant negative impact on ornamental and food fish aquaculture worldwide [1–5]. The first outbreak of megalocytivirus-induced disease was recorded in cultured red sea bream (*Pagrus major*) in Japan in 1990, and the causative agent was designated as red sea bream iridovirus (RSIV) [6]. Thus far, RSIV disease has been documented in 31 cultured seawater fish in Japan [7,8]. In China, a molecular epidemiology study indicated that over 50 species of cultured and wild seawater fish were infected by megalocytiviruses [9]. More than 10 species of cultured marine fish with iridovirus infection were reported in Taiwan [10–12,68]. In Korea, megalocytiviruses were reported in 10 freshwater ornamental fish species and 7 cultured fish species [13–15]. In addition, the farmed Murray cod (*Maccullochella peelii peelii*) and dwarf gourami (*Colisa lalia*) were observed to be infected in Australia [16]. Since 2007, a systemic megalocytivirus infection in three-spine stickleback (*Gasterosteus aculeatus*) was described in Canada [17]. Given the wide host range and geographic distribution of megalocytivirus, phylogenetic analysis using the major capsid protein (MCP) and ATPase gene has been performed for multiple isolates. This chapter focuses on the classification, morphology, clinical features, pathogenesis, and diagnosis of megalocytivirus. Developments in various vaccines and RNA interference (RNAi) techniques for preventing megalocytivirus infection in fish are also discussed.

92.1.1 Classification

According to the Eighth Report of the International Committee on Taxonomy of Viruses, the family *Iridoviridae* currently consists of five genera: *Iridovirus*, *Lymphocystivirus*, *Chloriridovirus*, *Ranavirus*, and *Megalocytivirus,* with *Megalocytivirus* being the latest addition to the family [4].

Megalocytivirus is composed of several members, including infectious spleen and kidney necrosis virus (ISKNV) and RSIV. ISKNV was first identified in a high-mortality outbreak among cultured mandarin fish (*Siniperca chuatsi*) in China [18]. RSIV, another crucial member of the genus, was listed by the World Organisation for Animal Health, or the Office International des Epizootic (OIE), as a pathogen and isolated from cultured red sea bream (*P. major*) [6]. Since 1992, increasing numbers of megalocytivirus strains genetically similar to these two species have been identified in food and ornamental fish and were assigned with host-derived names such as the sea bass iridovirus [19], rock bream iridovirus (RBIV) [20], Murray cod iridovirus [16], dwarf gourami iridovirus (DGIV), African lampeye iridovirus [21], large yellow croaker iridovirus (LYCIV) [22], orange-spotted grouper iridovirus (OSGIV) [23], Taiwan grouper iridovirus (TGIV) [10],

spotted knifejaw iridovirus (SKIV-ZJ07) [56], and turbot reddish body iridovirus (TRBIV) [24].

Sequence analysis of megalocytiviruses revealed high nucleotide and amino acid sequence identities in many open reading frames (ORFs) [25]. The viral putative MCP, vascular endothelial growth factor, mRNA capping enzyme, tumor necrosis factor receptor-associated protein, and ATPase genes have been used to classify new megalocytivirus isolates [26]. Among these genes, the MCP and ATPase genes are suitable targets for phylogenetic studies because they are highly conserved in the iridovirus [27].

Analyses of the MCP and ATPase genes show that the genus *Megalocytivirus* can be divided into three clusters represented by RSIV, ISKNV, and TRBIV, which could be considered distinct viral species [1,28–30]. The megalocytiviruses on the RSIV cluster can be further divided into two subclusters: genotype I, of which RSIV Ehime-1 is a representative, and genotype II, which includes other RSIV strains found in Japan, Korea, Taiwan, China, and Southeast Asia. The host ranges for RSIV clusters are extremely wide and have been associated with a mass mortality epizootic in the crucial maricultured fish species [29].

The second cluster is represented by ISKNV and related viruses and exhibits less genetic variation than the RSIV cluster does as well as different biological characteristics. ISKNV, originally isolated from the mandarin fish (*S. chuatsi*) raised for food in China, also resulted in an epizootic of more than 10 species of fresh ornamental fishes. A second ISKNV genotype was recently recognized following disease episodes in ornamental and food fish species, including the Banggai cardinalfish iridovirus, isolated from a marine ornamental fish, and marbled sleepy goby iridovirus, isolated from a freshwater species cultured for food in China [31,32]. The host range and geographical distribution of ISKNV are relatively broad, but freshwater and brackish water fish species are the predominant species affected.

The third cluster, TRBIV, has primarily been associated with diseases in a cultured Asian flatfish species, *Scophthalmus maximus* (turbot) [24,33]. The cluster includes flounder iridovirus and other viruses from the bastard halibut (*Paralichthys olivaceus*); the viral hosts belong mainly to the order Heterosomata [34].

Except for slight differences in nucleotide sequence among the three clusters, variations also exist in their biological characteristics. For example, the marine isolates of the ISKNV group of viruses are easier to propagate in cell cultures than those of the RSIV group of viruses. Mortality is observed in experimental infections with ISKNV between 25°C and 34°C, optimal replication of the RSIV group of viruses is observed at 20°C or 25°C, and an outbreak of TRBIV disease in South Korea occurred at 17°C–18°C [1].

Recently, a fourth cluster of TSIV (i.e., three-spine stickleback iridovirus) was proposed by Waltzek et al.; the virus was isolated from an epizootic that occurred in three-spine stickleback fish in Canada [17]. Due to the impact of megalocytiviruses on aquaculture, further collection of new virus strains from affected species is crucial. Continual monitoring of the iridovirus genotype, with strains being contributed to a worldwide database, may improve the understanding of local viral genotype shifts and their relationship with worldwide epidemiology.

92.1.2 Morphology, Biology, and Epidemiology

Iridoviruses are large cytoplasmic dsDNA viruses with an icosahedral capsid of approximately 120–240 nm in diameter. Complete virions consist of three layers: the outer layer is an icosahedral capsid, the intermediate layer is a thick translucent space, and the inner spheroid core is a homogeneously electron-dense nucleoid [2,3,24]. The viral genomes are both circularly permuted and terminally redundant, which are unique features among the eukaryotic virus genomes [35]. The entire genomes of seven megalocytiviruses have been sequenced: ISKNV, RSIV, RBIV, OSGIV, TRBIV, RBIV-C1, and LYCIV (accession no. AY 779031) [23,36–40]. The genome lengths range from 110104 to 112636 bp, with putative ORFs from 115 to 124. The GC content of megalocytiviruses ranges from 53% to 55%. On the basis of the complete genome sequences, megalocytiviruses were suggested to be more similar to ranaviruses than to viruses in other iridoviral genera [41]. Genes encoding large and small subunits of ribonucleotide reductase (RNRS) are found in all iridoviruses except for megalocytivirus, in which only a small subunit is present [1].

Megalocytiviruses can propagate in cell cultures; a fibroblast cell line (CRF-1) derived from the tail fin of red sea bream (*P. major*) susceptible to RSIV infection was developed. RSIV-infected CRF-1 cells showed typical morphological changes that were associated with apoptosis according to EGFP–annexin V staining. Serial viral passages were successful in CRF-1 cells according to an MTT assay [42]. In Taiwan, a similar cell line derived from the dorsal fin of red sea bream was also established (i.e., RSBF-2 cells). The RSBF-2 cell line was susceptible to RSIV but produced only round and refractory cells and was then subcultured to generate a persistently infected cell line [43]. In addition, a GBC4 cell line susceptible to giant seaperch iridovirus (GSIV) was developed, and the virus titers approached 10^9 $TCID_{50}$/mL. The suitable temperature for GSIV growth was 15°C–30°C [44]. A continuous cell culture derived from the mandarin fish fry (MFF-1) was developed [45]. MFF-1 could produce high titers of ISKNV through continuous viral passages, and these titers were confirmed through indirect immunofluorescence (IF) assay and real-time polymerase chain reaction (quantitative PCR [qPCR]) analysis. In addition, the TK and TF cell lines derived from the kidney and fin of turbot were found to be susceptible to the TRBIV isolate [46,47]. Using cell culture testing, RSIV was determined to be sensitive to acid (pH 3), chloroform, and ether. The virus was unstable when exposed to heat but stable when subjected to ultrasonic treatment, repeated freezing, and thawing *in vitro* [48]. Experimental infection in mandarin fish showed that ISKNV could be inactivated at pH 11 and with UV irradiation and chemicals (e.g., sodium hypochlorite and potassium

permanganate) but that iodine was not effective for viral inactivation [49].

Megalocytiviruses have caused mass mortality in various marine and freshwater fish species throughout Asia, indicating that these viruses have a broad host range and geographical distribution [8–11]. The viruses have spread internationally through the translocation of live fish. Recently, a growing number of megalocytiviruses have been identified. As fish are transported worldwide for commercial and ornamental use, one or more species may be the vehicle by which megalocytivirus is introduced to a new host or environment [30,50,51]. In addition, megalocytivirus (RBIV) in Pacific oysters (*Crassostrea gigas*) and blue mussels (*Mytilus edulis*) inhabiting the area around rock bream farms was identified in Korea. Cohabitation of mussels with megalocytivirus-infected rock bream results in the presence of viral particles in the gills, mantle, and digestive gland of mussels. The virus can be retained in the digestive gland for 28 days, regardless of water temperature. Infection with megalocytivirus derived from the digestive gland of cohabitating mussels has led to 100% cumulative mortality in rock bream [52].

92.1.3 Clinical Features and Pathogenesis

Megalocytivirus-infected fish may exhibit nonspecific clinical signs including lethargy, anorexia, hyperpigmentation, exophthalmos, skin lesion, unusual swimming behavior, gulping, severe anemia, and white feces [18,22,24,53]. The characteristics of affected fish are systemic formation of enlarged cells and basophilic intracytoplasmic inclusion bodies in multiple organs including the spleen, kidney, liver, heart, brain, gill, intestine, eye, and hematopoietic tissues. Electron microscopy reveals viral particles in an inclusion body within the cytoplasm of infected cells. The heterochromatins of the affected cells are marginated and aggregated to one side of the nuclei during the early stages of infections. The surrounding cytoplasm of infected cells is compressed and contains fragmented organelles and degenerated mitochondria. The viroplasm generally occupies a large proportion of the cytoplasm. Inside the viroplasm, virus particles are assembled around either a ring or disc-shaped virogenic stroma [18,21,22,24,53,56,60].

The pathogenicity of RSIVs isolated from various cultured marine fishes to the red sea bream has been examined through experimental infection. The different megalocytivirus isolates proved to be of high virulence leading to 60%–90% mortality in red sea bream, as the original RSIV isolates [54]. In Australia, an outbreak of high mortality in Murray cod fingerlings caused by megalocytivirus infection was reported. A hypothesis that the outbreak arose through the induction of a virus into an ornamental dwarf gourami (DGIV) imported from Southeast Asia underwent testing. Intraperitoneal injection of Murray cod fingerlings with DGIV resulted in 90% mortality. Mortality was also induced by cohabitating Murray cod fingerlings and dwarf gourami, with researchers speculating that the virus spread between the two species through water [55]. Similar experiments were performed in Korea. The megalocytivirus was isolated from freshwater pearl gourami (*Trichogaster leeri*; PGIV-SP) and the pathogenicity of seawater rock bream (*Oplegnathus fasciatus*; IVS-1) was examined, showing a cross infection between these two fish species. Comparisons of the stability of the two megalocytiviruses showed that both viral genomes decreased much faster in seawater than in freshwater after 4 days of incubation at 25°C. In addition, healthy rock bream that cohabitated with the PGIV-SP-challenged rock bream showed 100% cumulative mortality, implying the potential for megalocytivirus transmission from freshwater ornamental fish to marine fish even in a marine environment [50]. In addition, a new marine megalocytivirus isolated from spotted knifejaw was designated as SKIV-ZJ07. Twenty proteins of SKIV-ZJ07 were found to match proteins derived from RBIV, OSGIV, and ISKNV. Challenge tests showed that SKIV-ZJ07 was highly virulent in freshwater mandarin fish [56].

In another experiment, the megalocytivirus disease progressed more rapidly at higher water temperatures. When the water temperature for fish infected with the megalocytivirus by intramuscular injection was shifted from 13°C to 25°C, the fish experienced rapid onset of the disease, with a cumulative mortality of 100% [57]. In addition, asymptomatic RSIV-infected carriers of fingerling rock bream showed a high cumulative mortality caused by elevated water temperature. However, no morality was observed and no RSIV DNA was detected using PCR in yearling rock bream [58]. Using a two-step PCR method, a high level of asymptomatic iridovirus infection in various marine cultured fish was reported in Korea. The proportion of iridovirus-positive fish varied from month to month, but the overall prevalence was approximately 37.2% and differed depending on the fish species (i.e., rock bream, rockfish, seaperch, and red sea bream) [59]. A zebrafish (*Danio rerio*) model for ISKNV infection was established, and the experimental conditions were characterized. The mortality of adult zebrafish infected with ISKNV through intraperitoneal injection exceeded 60%. ISKNV can be passed stably in zebrafish for over 10 passages. Histological and real-time reverse transcription polymerase chain reaction (RT-PCR) analyses confirmed that ISKNV is replicated in fish. The establishment of a zebrafish model of ISKNV provided a valuable tool for studying the interactions between ISKNV and its host [60].

92.1.4 Diagnosis

Several methods are used for diagnosing megalocytivirus infection in fish, including histopathology, transmission electron microscopy (TEM), cell culture tests, IF tests, immunohistochemistry enzyme-linked immunosorbent assay (ELISA), dot blot assay, *in situ* hybridization (ISH), PCR, nested PCR, multiplex PCR, qPCR, and loop-mediated isothermal amplification (LAMP) (Table 92.1). PCR and DNA sequence analysis are widely used for detecting megalocytivirus infection and identifying the genotype of the virus.

92.1.4.1 Conventional Techniques

Giemsa-stained impression smears of splenic cells have been commonly used for the rapid diagnosis of RSIV in

The following are the viruses with their corresponding abbreviations used: red sea bream iridovirus (RSIV), rock bream iridovirus (RBIV), infectious spleen and kidney necrosis virus (ISKNV), dwarf gourami iridovirus (DGIV), African lampeye iridovirus (ALIV), large yellow croaker iridovirus (LYCIV), Taiwan grouper iridovirus (TGIV), spotted knifejaw iridovirus (SKIV-ZJ07), three-spine stickleback iridovirus (TSIV), and turbot reddish body iridovirus (TRBIV).

fish in Japan. However, this method provides only a presumptive diagnosis; the sensitivity and accuracy of this method are poor [1]. In addition, isolation of the virus in cell cultures by using susceptible cell lines is time-consuming and requires exquisite manipulation by highly trained technicians; the drawbacks are similar to those of histopathological and TEM observation. Therefore, these three methods for diagnosing megalocytivirus infection are impracticable in field tests. A monoclonal antibody (MAb) M10, which is a RSIV-specific polypeptide (180–230 kDa), was established and used to develop a method for rapidly diagnosing RSIV by using an indirect IF test [61]. The rate at which infected fish were detected by using the IF test with MAb was much higher than that obtained using Giemsa-stained impression smears [62]. The use of MAb M10 is described in the manual *Diagnostic Methods for Aquatic Animals* published by the World Organisation for Animal Health (OIE) and applicable to both RSIV and ISKNV.

In addition, an RBIV-specific polyclonal antibody was produced using a recombinant RBIV-049L fusion protein with glutathione *S*-transferase in mice. One-step PCR with a dot blot–indirect ELISA combination detection system by using the ORF-49L protein and its antiserum showed high sensitivity and specificity for RBIV [63]. In the zebrafish ISKNV infection model, polyclonal mouse sera against viral protein VP23R can be used to mark the infected cells through immunohistochemistry. Specific staining of the plasma membrane with the anti-VP23R antiserum shows that ISKNV-infected hypertrophic cells are present in different organs of moribund zebrafish. Using a double-stained immunofluorescent assay, VP23R signals were found in an equal number of enlarged cells in zebrafish and mandarin fish, indicating that ISKNV can infect zebrafish as effectively as it infects mandarin fish [60].

92.1.4.2 Molecular Techniques

On the basis of the nucleotide sequences of megalocytiviruses genomes, several specific and sensitive detection methods have been developed for diagnosing iridoviral disease outbreaks. Among these methods, ISH can successfully show the distribution and kinetics of the viral DNA–containing cells of infected fish. Digoxigenin-labeled probes were cloned from parts of the viral genome, and the sections of various tissues were hybridized with specific probes. The results of ISH showed the megalocytivirus-specific DNA located in most of the basophilic but not eosinophilic enlarged cells of various infected organs. Nuclei of infected cells were labeled during an early stage of infection, and the nuclei and cytoplasm were labeled during later stages [53]. Viral DNA was also found in the cytoplasm of leucocytes in blood smears by using the ISH method. The results suggested that virus-infected cells can migrate to the connective tissues of various organs from the blood [64].

Conventional diagnosis of megalocytivirus is based on histopathological, electron microscopic observation, or immunoassays. However, using the increased amount of information available on the genomic regions of megalocytivirus, PCR amplification has been developed to provide a rapid, simple, and sensitive method for detecting virus-specific nucleic acids. Several PCR-based methods have been established for detecting and quantifying megalocytivirus infection. Primer sets employed in PCR have been designed to detect target regions of different viral genes and can detect both ISKNV and RSIV-like megalocytivirus genotypes (Table 92.2). In 1996, a small subunit of the RNRS gene of RSIV was cloned. Subsequently, PCR was used to amplify virus-specific nucleic acids with a primer set based on the RNRS gene [65]. In addition, four oligonucleotide primer sets were synthesized on the basis of the ATPase gene, DNA polymerase (DPOL) gene, and a *Pst* I–restriction fragment of RSIV genomic DNA. A PCR- and nested PCR-based diagnostic system were developed for detecting RSIV infection in various species of affected fish, and none of the PCR products were obtained from frog virus 3 or lymphocystis disease virus [66]. Using the designed primers from the *Pst* I–restriction fragment of RSIV genomic DNA, four species of cultured fish showing clinical signs of RSIV diseases were identified to have megalocytivirus infection by using PCR in Korea. Nucleotide sequence analysis revealed that these viruses were the same as RSIV or had a slight variation in RSIV DNA sequences [67]. Nested PCR was also developed for detecting grouper iridovirus infection in cultured hybrid grouper, giant seaperch, and largemouth bass in Taiwan. The PCR results and sequence analyses of the amplicons suggested that the etiological agents infecting giant seaperch and largemouth bass might be the same and related to but distinct from TGIV [68]. Considering that variants of RSIV have been found in different species, countries, and years, it is yet to be determined whether PCR primers that have been published in different reports are suitable for their detection. Multiplex PCR with all four primers derived from two variable and two conserved positions in the *Pst* I–restriction fragment of RSIV was developed. Three RSIV strains isolated in Korea could be distinguished according to the sizes of the PCR amplicons [69]. The presence of multiple viral strains among genus *Megalocytivirus* has caused problems in designing primers for diagnostic PCR. By using genomic DNA sequence information for the viral MCP gene, new PCR primers for discriminating among the three viral species–RSIV, ISKNV, and TRBIV, of the genus *Megalocytivirus*–can be developed. The specifics of the primer sets for RSIV and ISKNV have been confirmed; however, those of the TRBIV primer sets remain unknown [1].

qPCR is suitable for use in large research studies because it is a rapid test, enables quantifying a viral load, and is more sensitive compared with conventional PCR. Requiring less time and having a lower risk of contamination, qPCR is an attractive alternative because only one round of amplification is performed and analysis through gel electrophoresis is not necessary. Of the chemicals used to detect PCR products during qPCR, the inexpensive dsDNA-binding dye SYBR Green I is desirable because it eliminates the need for costly probes linked to fluorescent molecules. In addition, many conventional PCRs can be used in a real-time format with few modifications. Thus far, several reports have detailed the development of qPCR assays for megalocytiviruses. In 2003, a novel qPCR detection and quantification method for RSIV was developed using the MCP gene. The detection method is two orders of magnitude more sensitive than conventional PCR. The MCP gene was also shown to be specific to RSIV (i.e., it did not react with hirame rhabdovirus, viral hemorrhagic septicemia virus, or DNA samples from apparently healthy red sea bream). The viral loads of dead juvenile red sea bream experimentally challenged with RSIV were determined using qPCR to have MCP gene copy totals ranging from 2.4×10^5 to 5.4×10^7. The highest viral load was obtained in the heart, whereas the lowest copy total was detected in the blood [70]. Based on the nucleotide sequence of the MCP gene, real-time PCRs that involve using SYBR Green and molecular beacon assays were developed to specifically target gourami iridovirus. The analytical sensitivities

For virus abbreviations see Table 92.1.

of the SYBR Green and molecular beacon assays are 10 and 100 fg, respectively. The analytical specificity of real-time PCR determined that the assays can detect all megalocytiviruses with no cross-reaction, nontarget viruses, and aquatic bacterial species being observed [71]. In addition, a qPCR assay for detecting DGIV and other megalocytiviruses was developed in Australia. The limit of detection for this qPCR assay was 100 copies, and the assay did not cross-react with ranaviruses or other aquatic viral pathogens tested. DNA extraction using the magnetic bead or spin column–based methods had no effect on the sensitivity of the qPCR assay. Compared with the sensitivity of OIE reference PCR protocol, the sensitivity was improved by approximately 3–4 logs. The OIE reference PCR protocol detected only 8% of the samples identified to be positive through qPCR [72]. A qPCR targeting the *Pst* I–fragment gene of RSIV was developed. The quantitative detection limit of the assay was $10^{3.5}$ genomes/mg, corresponding to 100 genomes per reaction. After RSIV inoculation of rock bream, the viral genome was detected in fish at 10 days by using qPCR [73]. The qPCR detection method was employed to investigate the kinetics of RSIV in fish. The results of measurements of the viral DNA of several organs from experimental fish infected using the immersion method showed that the spleen is the target organ of RSIV in Japanese amberjack [74].

PCR-based methods are time-consuming and require expensive equipment and reagents, rendering them unsuitable for use in field tests. LAMP, a novel nucleic acid amplification method, was developed and involved employing a *Bst* DPOL with strand displacement activity and four primers that recognize a total of six distinct sequences on the target DNA. In the LAMP method, target DNA can be amplified from a few copies to 10^9 copies within 1 h under isothermal conditions (60°C–65°C), by using a simple incubator such as a water bath or a thermostat block. At the end of the reaction, the presence or absence of the target DNA is judged visually according to the appearance of a white precipitate magnesium pyrophosphate. The presence of multiple bands of varying sizes during agarose gel electrophoresis of the LAMP reaction products indicates that they are composed of a mixture of stem-loop DNAs with various sizes of stem and cauliflower-like structures with multiple loops induced through annealing between alternatively inverted repeats of the target sequence in the same strand. A LAMP procedure was established to detect the genomic DNA molecule of RSIV targeting the *Pst* I–fragment gene. The method was at least 10 times more sensitive than conventional PCR in detecting the presence of RSIV [75]. A 20 min LAMP amplification of the DPOL gene of ISKNV by using a biotin-labeled primer combined with lateral flow dipstick (LFD) chromatography was developed. The detection limit of LAMP–LFD in detecting ISKNV is 10 copies of the viral genome. The method has higher sensitivity and speed and less dependence on equipment than standard PCR in specifically detecting low levels of ISKNV DNA; this method can be used in the field as a routine diagnostic tool for megalocytiviruses [76].

92.2 METHODS

92.2.1 Sample Collection and Preparation

Moribund or dead fish displaying signs of megalocytivirus infection can be obtained from cultured fish farms or ornamental fish shops. The spleens and kidneys of infected fish are collected and stored at −80°C until used. Several methods have been employed for extracting of megalocytivirus DNA from clinical specimens prior to conventional PCR, nested PCR, or qPCR. These methods include conventional DNA extraction by using phenol/chloroform, extraction by using magnetic beads, and the spin column–based method. Recently, highly sensitive and reproducible DNA extraction kits have been developed by various commercial companies and are prevalently used for genomic DNA extraction in megalocytiviruses. The procedures for extracting DNA by using phenol/chloroform and the spin column–based method (Wizard Genomic DNA Purification System; Promega) are described in the following two sections.

92.2.1.1 DNA Extraction by Using Phenol/Chloroform

92.2.1.1.1 Procedure

1. Homogenize samples of approximately 30–50 mg of tissues from megalocytivirus-infected fish in a 500 μL lysis buffer (50 mM Tris–HCl, pH 8.0; 20 mM NaCl, 3% SDS; 10 mM EDTA, pH 8.0; proteinase K at 100 μg/mL) by using a small homogenizer. Incubate the mixture in a 1.5 mL microcentrifuge tube at 65°C for 1–3 h.
2. Add an equal volume of saturated phenol to the mixture. Mix the phases through vortexing for approximately 10 s. Resolve the phases through microcentrifugation for 2 min. Carefully remove and transfer the upper aqueous phase to a fresh tube by using a micropipettor. If a heavy interface is present, repeat this procedure until the excessive interface is no longer present.
3. Add an equal volume of chloroform. Mix. Resolve the phases through centrifugation for 2 min in a microcentrifuge. Transfer the upper aqueous phase to a fresh tube.
4. Add 1/10 volume of 3 M sodium acetate (pH 7.0) and 2.5 volume of 95% ethanol. Mix through vortexing or repeated inversion. Incubate the mixture on ice for 10 min, or at −20°C for 4 h to overnight (i.e., for small amounts of DNA). Collect the precipitate through microcentrifugation for 15–20 min at 13,000–16,000 × *g*.
5. Decant the supernatant. Add 1 mL 75% ethanol to the tube containing the pellet. Mix. Collect the pellet through centrifugation for 15–20 min at 13,000–16,000 × *g*. Decant the ethanol and dry the pellet in an oven until all residual ethanol is evaporated.
6. Dissolve the pellet in 100 μL of either sterile water or a TE buffer. The DNA can be used directly in the PCR step or stored at −20°C for future use.

92.2.1.2 DNA Extraction by Using Spin Column

92.2.1.2.1 Procedure

1. Add 10–20 mg of fresh or thawed tissues to 600 µL of a chilled nuclei lysis solution and homogenize the mixture for 10 s by using a small homogenizer. Incubate the lysate in a 1.5 mL microcentrifuge tube at 65°C for 15–30 min.
2. Add 3 µL of RNase solution to the nuclear lysate and mix the sample by inverting the tube 2–5 times. Incubate the mixture for 15–30 min at 37°C. Allow the sample to cool to room temperature for 5 min before proceeding.
3. To the room-temperature sample, add 200 µL of protein precipitation solution and vortex vigorously at high speed for 20 s. Chill the sample on ice for 5 min. Centrifuge it for 4 min at 13,000–16,000 × *g*. The precipitate protein will form a tight, white pellet.
4. Carefully remove the supernatant containing the DNA and transfer it to a clean 1.5 mL microcentrifuge tube containing 600 µL of room-temperature isopropanol. Gently mix the solution through inversion until the white threadlike strands of DNA form a visible mass.
5. Centrifuge the mixture for 1 min at 13,000–16,000 × *g* at room temperature. Carefully decant the supernatant. Add 600 µL of room-temperature 70% ethanol, and gently invert the tube several times to wash the DNA. Centrifuge for 1 min at 13,000–16,000 × *g* at room temperature.
6. Carefully aspirate the ethanol by using either a drawn Pasteur pipette or a sequencing pipette tip. Invert the tube on clear absorbent paper, and air dry the pellet for 10–15 min.
7. Add 100 µL of a DNA rehydration solution, and rehydrate the DNA by incubating it at 65°C for 1 h. Alternatively, rehydrate the DNA by incubating the solution overnight at room temperature or at 4°C. The DNA can be used directly in the PCR step or stored at −20°C for future use.

92.2.2 Detection Procedures

The genomic diversity of megalocytiviruses in fish is evidenced by the identification of three genotypes (RSIV, ISKNV, and TRBIV) within the genus *Megalocytivirus*. Several molecular diagnostic methods have been developed and used to detect these three genotypes. The following protocols (conventional PCR, nested PCR, and qPCR) have been modified from previous reports.

92.2.2.1 Conventional PCR

92.2.2.1.1 Procedure

1. Remove all aliquots of PCR reagents (nuclease-free water, 10× PCR buffer, dNTP mix, *Taq* DPOL, 25 mM $MgCl_2$, primer pairs, and temple DNA) from the freezer and store on ice. Vortex and spin all reagents before opening the tubes.
2. Prepare 25 µL of a PCR mix in a 0.2 mL PCR tube as follows:

Component	Volume (µL)
Nuclease-free water	16.5
10× PCR buffer	2.5
dNTP mix (10 mM of each dNTP)	1.0
Taq DPOL (5 units/µL)	0.5
25 mM $MgCl_2$	1.5
Forward primer (1F) (20 pmol/µL)	1.0
Reverse primer (1R) (20 pmol/µL)	1.0
Template DNA (100 ng)	1.0
Total	25.0

3. Spin the sample tubes in a microcentrifuge for 30 s at room temperature. Turn on a thermocycler and preheat the block to 94°C. Place the sample tubes in the thermal cycler for 40 cycles at 94°C for 0.5 min, 58°C for 1 min, and 72°C for 1 min, followed by an extended period of 10 min at 72°C after the last cycle.
4. Following the amplification, the samples are ready for electrophoresis or to be stored frozen at −20°C. Analyze the PCR products through agarose electrophoresis using 1% agarose gel in a TAE buffer at 100 V for 30 min.
5. Stain the gel with ethidium bromide and then observe the samples under a UV light source.

Note: Negative control is concurrently included along with the test samples to monitor for possible contamination during the PCR procedure. The presence of a 570 bp product is indicative of RSIV genomes in the samples. However, different primer pairs can be used to detect and discriminate three viral species of the genus *Megalocytivirus*: RSIV, ISKNV, and TRBIV (Table 92.2).

92.2.2.2 Nested PCR

Reaction conditions are the same as those described for conventional PCR amplification. However, the primer set is replaced by 1F and 2R with 848 bp amplicons in the first-round PCR assays. The amplified products are diluted 1:100 in nuclease-free water and subjected to reamplification. The second round of amplification is performed using primers 2F and 1R (Table 92.2), and the 248 bp products are amplified. An alternative nested PCR is also performed using the C1105/C1106 primer set for the first amplification and C1073/C1074 primer set for the second PCR (Table 92.2). The amplified products are 430 bp and 167 bp, respectively. The temperature and conditions for the PCR assays are listed as follows: 1 cycle at 95°C for 3 min and 35 cycles at 95°C for 0.5 min, 55°C for 0.5 min, and 72°C for 1 min, followed by an extended period of 5 min at 72°C after the last cycle.

92.2.2.3 Real-Time PCR

92.2.2.3.1 Procedure

1. Remove all aliquots of qPCR reagents (nuclease-free water, SYBR Green Master Mix, primer pairs, template DNA) from the freezer and store on ice. Vortex and spin all reagents before opening the tubes.
2. Prepare 25 µL of a PCR mix in 0.2 mL of qPCR for 8 tubes (or 12 tubes) as follows:

Component	Volume (µL)
Nuclease-free water	9.75
SYBR Green Master Mix	12.5
Forward primer (C1073) (100 pmol/µL)	0.125
Reverse primer (C1074) (100 pmol/µL)	0.125
Template DNA (100 ng)	2.5
Total	25.0

3. Place the sample (8 tubes or 12 tubes) in the qPCR system for 1 cycle at 95°C for 15 min and 40 cycles at 95°C for 0.5 min, 62°C for 0.5 min, and 72°C for 0.5 min.
4. Standard curves are produced through 10-fold serial dilution of the plasmid-containing target region in Molecular Grade Water to establish template concentrations of 1×10^7 to 1×10^0 copies per reaction. Standard curves, which are generated using the mean data from experiments performed in duplicate, indicate a satisfactory linear relationship between the threshold cycle (Ct) value and the logarithmic plasmid concentration. Positive and no template controls are included in each run.
5. Quantifications of the viral DNA are interpolated from the plasmid DNA standard curve, based on the Ct value determined after 40 cycles of the unknown sample.

92.3 CONCLUSION AND FUTURE PERSPECTIVES

Over the past two decades, epizootic iridoviral disease has caused serious economic losses in aquaculture worldwide. In particular, megalocytivirus infections represent one of the most consequential diseases in cultured fish. The availability of rapid, specific, and sensitive pathogen detection methods is crucial to monitor the disease status, evaluate viral kinetics, reduce virus transmission, and minimize the economic and environmental impact of viral diseases in aquaculture.

To control and prevent megalocytivirus infections, formalin-inactivated RSIV vaccine was developed [77–80]. The vaccine is efficient for protecting red sea bream (*P. major*), yellowtail (*Seriola quinqueradiata*), and other fish species but is not effective for fishes belonging to the genus *Oplegnathus*. This injectable vaccine is now commercially available in Japan, and a similar megalocytiviral vaccine has been developed in Taiwan for grouper iridoviral disease [1]. A formalin-killed cell (FKC) vaccine was also prepared using ISKNV propagated in the MFF-1 cell line, and more than 90% of fish immunized with the vaccine were protected against ISKNV virulence [81]. An FKC vaccine used to immunize cage-cultured mandarin fish was also shown to be efficient in preventing RSIV infection in field trials [82]. Recombinant subunit vaccines with the RSIV and ISKNV MCP gene have been developed and induced protective immunity against iridovirus disease in fish but have not been commercialized [83,84]. In addition, DNA vaccines based on the RSIV MCP gene and seven genes of RBIV-1 were separately constructed. The results demonstrated that DNA vaccines are able to induce robust protection in fish against RSIV infection and a cellular immune response, as shown by the upregulation of the MHC class I transcript, which may be associated with such protection, after vaccination [85]. The protective effects of RBIV-1 DNA vaccines were examined in a turbot model. The results indicated that pCN 86, which expresses an equivalent of the RSIV 351R gene, is a highly effective DNA vaccine that may be used in controlling megalocytivirus-associated diseases in aquaculture [86].

Given the high level of manual labor and stress to fish caused by injection, oral vaccines based on the MCP gene of megalocytivirus have been developed by using cell-surface display system technology in yeast [87,88]. However, the protective efficiency of the oral vaccines requires further confirmation through field trials. Recently, RNAi has been shown to have activity against a wide range of virus infection and is considered a potential antiviral tool. In aquaculture, relatively few studies have reported on the use of RNAi for protection from megalocytivirus infection. Thus far, the results have only shown that MCP-targeted siRNA and miRNA can effectively and specifically inhibit the expression of the target gene and hinder RSIV replication in a cell culture system [89,90]. The precise mechanism of the RNAi employed in preventing the megalocytivirus infection is not fully understood.

Although commercial vaccines are available in Japan for preventing RSIV infection, the existence of other virus strains in the genus *Megalocytivirus* weakens the protective effect and application of the vaccines. Thus, prevention of exposure, together with the adoption of rapid and accurate diagnostic technologies, remains the most effective method for controlling diseases caused by megalocytivirus.

93.1 INTRODUCTION

Avipoxviruses (APVs) are large, complex DNA viruses that belong to the subfamily *Chordopoxvirinae* of the family *Poxviridae* [1]. APVs can naturally infect over 278 species in 23 orders of birds [2] and the effects of APV infection on wild bird species can be severe, which may even cause extinction of species. Undisputed examples come from the Hawaiian Islands, where extinctions of endemic forest birds are attributed to avian pox and avian malaria transmitted from introduced species [3]. The virus is transmitted via biting insects and aerosols and is usually named on the basis of bird species from which the virus was first isolated. The highly visible, wart-like lesions associated with the featherless areas of birds have facilitated recognition of avian pox since ancient times. The disease is characterized by proliferative lesions of the skin and diphtheric membranes of the respiratory tract, mouth, and esophagus of avian species [4]. APV infection in wild birds may produce several negative effects including elevated predation among affected birds [5], trauma, secondary infection, reduced male mating success [6], and death. Avian pox occurs worldwide, but little is known about its prevalence in wild bird populations. The increased frequency of reported cases of this highly visible disease and the involvement of new bird species during recent years suggest that avian pox is an emerging viral disease. Outbreaks are commonly reported at aviaries, rehabilitation centers, and other places where confinement provides close contact among birds. The disease can spread rapidly when avian pox is introduced into such facilities. Avian pox has rarely been reported in wild waterfowl.

Although wild birds can be infected by APV year round, disease outbreaks have been associated with the environmental conditions, the emergence of vector populations, and the habits of the species affected. Environmental factors such as temperature, humidity, moisture, and protective cover all play a role in the occurrence of this disease by affecting virus survival outside the bird host. APVs can withstand considerable dryness, thereby remaining infectious on surfaces or dust particles. Mosquitoes that feed on birds are the most consistent and efficient transmitters of this disease.

Fowlpox is a slow-spreading virus disease of chickens and turkeys caused by the fowlpox virus (FWPV), the prototype species of the genus *Avipoxvirus*. The disease results in significant economic losses to the poultry industry due to decreased egg production, reduced growth rate, blindness, and increased mortality. The mortality rate may go up to 50% particularly in young birds in the diphtheritic form of the disease. Our knowledge of the molecular and biological characteristics of APV is largely restricted to FWPV and canarypox virus (CNPV) for which full genome sequences are available [7,8].

93.1.1 Classification

From the beginning, APVs and other poxviruses have been classified on the basis of original host, growth, and morphological characteristics in the chorioallantoic membrane

(CAM) of embryonated eggs or cell cultures and on clinical manifestations of the disease in different host species [9,10]. These criteria, rather than genetic identity, form the basis for subsequent classification of APVs despite the development of new molecular tools capable of resolving the species identity of APV. All avian poxviruses are assigned to the genus *Avipoxvirus* in the subfamily *Chordopoxvirinae* of the *Poxviridae* family, indicating their shared biological features with other poxviruses. Despite the large number of host species, currently only 10 recognized species exist within the genus *Avipoxvirus*: FWPV, CNPV, *Juncopox virus*, *Mynahpox virus*, *Psittacinepox virus*, *Sparrowpox virus*, *Starlingpox virus*, *Pigeonpox virus*, *Turkeypox virus*, and *Quailpox virus*, according to the International Committee on Taxonomy of Viruses (http://ictvonline.org/). The exact number of avipoxvirus species, strains, and variants is unknown, since new isolates continue to be identified from a wide variety of avian species. These new isolates vary in virulence and host specificity, highlighting the need to further investigate and characterize APVs.

93.1.2 Morphology, Genome Structure, Replication, and Epidemiology

Morphology: The morphology of APVs is like that of other viruses in the *Poxviridae* family. The mature virus (elementary body) is brick shaped and measures about 330 × 280 × 200 nm. The virion consists of an electron-dense centrally located biconcave core or nucleoid with two lateral bodies in each concavity and surrounded by an envelope. The outer coat is composed of random arrangements of surface tubules visible in negative-stained (phosphotungstic acid [PTA]) preparations under electron microscope [11]. APV particles have generally been shown to be resistant to ether, but sensitive to chloroform treatment.

Genome structure: APVs possess a single, linear, double-stranded DNA genome of 260–365 kb in size with low G + C content (30%–40%). The ends of the DNA are covalently closed by hairpin loops. The central region of the genome is flanked by two identical inverted terminal repeats and contains several hundred closely spaced open reading frames [7]. The central region contains about 90–106 homologous genes that are involved in basic replication mechanisms, including viral transcription and RNA modification, viral DNA replication, and proteins involved in structure and assembly of intracellular mature virions and extracellular enveloped virions [8]. In general, genes located in this region have common molecular functions and are relatively conserved among poxviruses. This is in contrast to the more variable, terminally located genes that have been shown to encode a diverse array of proteins involved in host range restriction. Complete genomes of two APVs (a virulent and an attenuated FWPV, and a virulent CNPV) have been sequenced [7,8,12]. Although nucleotide and amino acid sequences for these two viruses are known, the functions of some putative genes and proteins remain to be fully assigned. Virulence genes, which influence the pathological profile of virus in an infected host, are generally nonconserved in nature and in infected host, and play an important part in viral evolution.

Replication and morphogenesis: APVs are believed to replicate only in avian cells, notably chicken embryo fibroblasts (CEFs). However, recent studies have shown that APV can replicate in mammalian cell cultures, such as embryonic bovine tracheal cells [13] and baby hamster kidney cells [14] that are defined by the presence of infectious viral particles and cytopathic effects (CPE). CEF cells have a good split ratio compared to other cell lines and are thus useful for large-scale propagation of virus for vaccine production or diagnostic tools. APVs have also been shown to replicate in chicken embryo kidney, chicken embryo dermis, and quail cell lines, such as QT-35.

After the virus binds to the cellular membranes, a fusion step, which is generally poorly understood, results in the release of the virion core into the cytoplasm of the cell. The core, which contains the viral RNA polymerase and transcription factors, initiates the transcription of early viral genes. This is followed by the uncoating stage, the release of viral DNA into the cytoplasm where it serves as a precursor for viral DNA replication as well as the source of intermediate and late viral gene transcription. As late viral gene product accumulates, the virus undergoes assembly and morphogenesis of infectious virus particles. During morphogenesis, APVs induce the formation of inclusion bodies in the cytoplasm of infected cells. The inclusions, which may also be termed viral factories, viroplasms, or viral replication complexes, are generally believed to be the sites of active viral replication and particle assembly within infected cells. Assembled virus is released by budding, cytolysis, or exocytosis.

Epidemiology: During avipox outbreaks, mortality can reach 80%–100% in canaries and other finches. This is in contrast to a generally lower mortality seen in chicken and turkey affected by FWPV. The virus is present in large numbers in lesions and usually transmitted by contact through a break in the skin. Aerosols generated from infected birds, or the ingestion of contaminated food or water have also been implicated as a source of transmission. Skin lesions (scabs) shed from recovering birds in poultry houses can become a source of aerosol infection. Mosquitoes and other biting insects may serve as mechanical vectors. Transmission within flocks is rapid when mosquitoes are plentiful. The disease tends to persist for extended periods in multiple-age poultry complexes because of slow spread of the virus and availability of susceptible birds. APVs are resistant and may survive in the environment for extended periods in dried scabs. Photolyase and A-type inclusion body protein genes in the genome of FWPV appear to protect the virus from environmental insults.

93.1.3 Clinical Features and Pathogenesis

Avipox is a slow-spreading disease. In chicken and turkey, it is known as fowlpox and turkeypox, respectively. The disease is most commonly characterized by development of cutaneous proliferative lesions (cutaneous form—dry pox), ranging from small nodules to spherical wart-like masses on the skin

of unfeathered areas, such as comb, wattle, legs, feet, eyelids, and the base of the beak (Figure 93.1). Scars are usually visible after recovery and healing of skin lesions. The mortality in wild birds is usually low, depending on the number and size of the proliferative lesions. However, if infection occurs with secondary bacterial infection, mortality may be high. The other and less common form of APV infections is the diphtheritic form (wet pox) where slightly elevated white opaque nodules develop on the mucous membranes. They rapidly increase in size to become a yellowish diphtheritic membrane. Lesions occur on mucous membranes of the upper respiratory tract (larynx or trachea), mouth, and esophagus. Diphtheritic form generally has a higher mortality than the cutaneous form [15]. In some instances, birds display both cutaneous and diphtheritic forms and in those cases, mortality rates are often higher compared to the cutaneous form alone. Despite the variety of hosts and virus strains, associated pathology remains the same in infected domestic birds, although clinical signs vary depending on the virulence of the virus, susceptibility of the host, distribution, and type of lesions.

APV infections are associated with significant levels of morbidity and mortality in domestic and wild bird populations. It is difficult to address the pathogenicity of different APVs in different bird species as most of the investigations and reported cases are based on single APV isolates. Chickens are commonly used to determine the pathogenicity of new isolates, but they may not be the ideal host, since APVs from wild birds may not multiply in chickens. Pathogenicity studies of APVs in turkeys, pigeons, and canaries have been reported. Canaries are highly susceptible to CNPV, but show resistance to turkeypox virus, FWPV, and pigeonpox virus [4]. Pigeonpox virus produces mild infection in chickens and turkeys, but it is more pathogenic for pigeons [16]. Despite the worldwide prevalence of APV infections, experimental infection studies in birds using APVs have centered on few viral isolates especially on FWPV termed the prototype of the genus.

FIGURE 93.1 Fowl pox lesions on the head of a chicken.

FWPV and reticuloendotheliosis virus (REV): In the poultry industry, prophylactic measures against FWPV are achieved primarily by vaccination with live FWPV or antigenically similar pigeonpox virus strains produced in chicken embryo or CEF cells. In the past two decades, numerous outbreaks have been reported in vaccinated flocks, suggesting that vaccines used against the disease were not effective. In the United States, a commercial FWPV vaccine was shown to be contaminated with REV and caused lymphoma among broiler chickens [17]. Reticuloendotheliosis is a tumorigenic and immunosuppressive disease. REV strains have been reported to cause diseases characterized by chronic lymphoma, nonneoplastic lesions, and a runting-stunting syndrome in chickens, turkeys, and quails [18,19]. It has been shown that sequences of REV have been integrated into the DNA of FWPV vaccines as well as in FWPV field isolates [20–24]. The integration site is constant, while the size of the integrated fragments differs between various isolates and strains. Two types of integrated sequences are reported: long terminal repeats (LTRs) with size of approximately 200–600 bp and the near full-length REV provirus of about 8000 bp [21,24,25]. Most vaccine strains carry only an LTR remnant, while most FWPV field isolates carry the near full-length provirus. Singh et al. [20], however, detected REV LTRs of various lengths in the genome of two commercial FWPV vaccine strains and four field isolates, while several studies have shown that the source of REV infection was REV-contaminated FWPV [17,26] and herpesvirus of turkeys vaccines [27]. There exists a relationship between FWPV and REV and it is plausible that the presence of REV provirus in FWPV may exacerbate disease progression. Integration of near-full-length REV provirus in FWPV genome has been seen in a recurring fowlpox infection, which suggests that REV integration may modulate disease progression and contribute to disease slowdown into a chronic form [28]. The mechanisms of disease progression following REV provirus integration into the FWPV genome remain unresolved. The presence of REV in FWPV vaccines and the failure of currently used FWPV vaccines to evoke high level immunological protection against field challenge of FWPVs are of major concern to the poultry industry [29], which emphasizes the need for research into alternative vaccines.

93.1.4 Diagnosis

Clinical diagnosis is based on the presence of multiple skin lesions varying from papules to nodules in infected birds. Gross lesions in both the cutaneous and the diphtheritic forms, seen on birds and during necropsy, are usually sufficient to suspect APV infection. However, these signs are inadequate to provide a definitive diagnosis of APV infection as other agents, such as papilloma virus, scaly leg mites, and mycotoxins, may produce similar lesions in the skin, and conditions like candidiasis, capillariasis, and trichomoniasis may give lesions in the oral cavity similar to the diphtheritic form of APV infection. Laryngeal and tracheal lesions in chickens must be differentiated from those of infectious laryngotracheitis, which is caused by a herpesvirus. It is therefore crucial to

secure samples and confirm the viral etiology of the condition in the laboratory.

93.1.4.1 Conventional Techniques

Histopathology and electron microscopy: FWPV multiplies in the cytoplasm of epithelial cells with the formation of large intracytoplasmic inclusion bodies (Bollinger bodies) that contain smaller elementary bodies (Borrel bodies). The inclusions can be demonstrated in sections of cutaneous and diphtheritic lesions by the use of hematoxylin and eosin, acridine orange, or Giemsa stains. Transmission electron microscopy can be used to demonstrate typical APV particles morphology in ultrathin sections of infected tissues or in fluid (cell culture isolate, pustule) by negative staining with 2% PTA.

Virus isolation: Demonstration of infectious virus by inoculation of homogenates of clinical samples of typical APV skin lesions onto the CAMs of embryonated hen's eggs is the gold standard method for the diagnosis of APV, although some strains of APV do not grow readily on chicken embryos [30]. Primary CEFs, chicken embryo kidney cells, chicken embryo dermis cells, or the permanent quail cell line QT-35, can also be used to propagate FWPV.

Serological tests: Although both cell-mediated immunity (CMI) and humoral immunity play an important role in APV infections, routine use of the CMI test is not convenient. Therefore, serological tests, such as virus neutralization (VN), agar gel immunodiffusion (AGID), passive hemagglutination, and fluorescent antibody tests as well as the enzyme-linked immunosorbent assay (ELISA), are used to measure specific humoral antibody responses. The conventional serological techniques of VN and AGID are in continued global use for surveillance and disease control efforts in domestic poultry species despite the availability of modern molecular and immunoassay techniques.

1. *VN*: After virus/serum interaction, the residual virus activity may be assayed in embryonating chicken eggs or in cell cultures. This technically demanding test may not be convenient for routine diagnosis. Only some selected strains of the virus have plaque-forming ability in chicken embryo cells. Neutralizing antibodies develop within 1–2 weeks of infection.
2. *AGID*: Precipitating antibodies can be detected by reacting test sera against viral antigens. The test is less sensitive than the ELISA or the passive hemagglutination test.
3. *Passive hemagglutination*: Passive hemagglutination is more sensitive than the AGID. The test will give cross-reactions among avian poxviruses. Tanned sheep or horse red blood cells are sensitized with a partially purified fowlpox viral antigen.
4. *Fluorescent antibody tests*: Direct or indirect immunofluorescence tests will reveal specific intracytoplasmic fluorescence in infected cells. The latter test is commonly used and involves two steps: the antibody against FWPV is reacted with the antigen in infected cells and followed by a secondary fluorescein isothiocyanate-labeled antibody against chicken gamma globulin (e.g., goat anti-chicken). In this regard, formalin-fixed tissue sections can be used effectively for fluorescent antibody test.
5. *Immunoperoxidase*: Specific staining of cytoplasmic inclusions is achieved when horseradish peroxidase-conjugated specific polyclonal antibody against fowlpoxvirus is reacted with hydrated sections of APV-infected fixed tissues (CAM and skin) or cell culture. Similar results are obtained when either polyclonal or monoclonal antibodies are used in an indirect test. An advantage of the technique is that the sections can be examined with the light microscope and can be stored for an extended period.
6. *Immunoblotting*: Antigenic variations between strains of APV can be evaluated by means of immunoblotting or western blotting. In this method, viral antigens separated by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) are reacted either with polyclonal or monoclonal antibodies against the virus. This method is not convenient for routine diagnosis.
7. *ELISA*: ELISA has been described as a non-species-specific test for birds. It is a faster and easier method to detect antibodies against APV, particularly when large numbers of sera are to be screened. The technique is also more sensitive than the neutralization test [31]. ELISA protocols have also been developed to test the efficacy of FWPV vaccines in commercial and wild bird species where AGID is ineffective due to lack of precipitating antibodies [32].

93.1.4.2 Molecular Techniques

APVs are increasingly being detected and characterized by polymerase chain reaction (PCR), restriction fragment length polymorphism (RFLP), Southern blot hybridization, and cycle sequencing, directed at specific genes such as the 4b core protein gene [33,34]. RFLP analysis has been used for comparison of field isolates and vaccine strains of FWPV [35,36]. However, this procedure is not used in routine diagnosis. Cloned genomic fragments of FWPV have been used effectively as nucleic acid probes for diagnosis of fowlpox. Viral DNA isolated from lesions can be detected by hybridization with either radioactively or nonradioactively labeled genomic probes. This method is especially useful for differentiation of fowlpox from infectious laryngotracheitis when tracheal lesions are present [37].

APV or FWPV genomic DNA sequences of various sizes can be amplified by the PCR using specific primers [38]. PCR amplicons could be cloned and sequenced or directly sequenced and amplicon sequence allows a rapid search for homologous sequences in gene databases, to verify and identify the virus in question and to address phylogenetic relationships. This technique is useful when there is only an extremely small amount of viral DNA in the sample. Detection by

real-time PCR has been used to identify recombinant APV from individual plaques [39] or to identify mixed genotype in the blood [40].

93.2 METHODS

93.2.1 Sample Collection and Preparation

Samples may be collected from live or dead affected bird. From the live bird, samples should be collected by cutaneous scarification of the scab or lesions on comb or other places in a sterile vial. Blood should also be collected for demonstration of neutralizing or precipitating antibody in serum. Diphtheritic lesions should be collected from the upper respiratory and digestive tract of dead bird. For virus isolation, samples should be collected in phosphate buffered saline (PBS) with no preservative and transported to laboratory on ice. This may be kept preserved in −80°C for a long time. Lesion or tissue should be preserved in formaldehyde for histopathology.

93.2.2 Detection Procedures

93.2.2.1 Demonstration of Elementary Bodies (Borrel Bodies)

APVs multiply in the cell with the formation of large intracytoplasmic inclusion bodies (Bollinger bodies) that contain smaller elementary bodies (Borrel bodies). The elementary bodies can be detected in smears from lesion by a simple staining technique [41]. Briefly, on a clean slide a drop of distilled water and the lesion (cutaneous or diphtheritic) are placed. A thin smear is prepared by pressing the lesion with another clean slide and rotating the upper slide several times. The smear is air died and gently fixed over a flame and stained for 5–10 min with freshly prepared basic fuchsin. After washing, the slide is counterstained with malachite green for 30–60 s. Following a wash and drying, the slide is examined under oil immersion. The elementary bodies appear red and are approximately 0.2–0.3 μm in size.

93.2.2.2 Agar Gel Immunodiffusion

Precipitating antibodies can be detected by reacting test sera against viral antigens. The antigen can be derived from infected skin or CAM lesions as well as infected cell cultures after proper treatment. Gel-diffusion medium is prepared with 1% agar, 8% sodium chloride, and 0.01% thimerosal. The viral antigen is placed in the central well and the test sera are placed in peripheral wells. It is important to include a positive and negative control serum. The plates are incubated at room temperature. Precipitation lines develop in 24–48 h after incubation of the antigen with antibody to homologous or closely related strains.

93.2.2.3 Virus Isolation

APVs and specifically FWPV virus can be isolated by inoculation of suspected material into embryonated chicken eggs. Approximately 0.1 mL of tissue suspension of skin or diphtheritic lesions is inoculated on to the CAMs of 9–12-day-old developing chicken embryos. These are incubated at 37°C for 5–7 days, and then examined for focal white pock lesions or generalized thickening of the CAMs. Histopathological examination of CAM lesions will reveal eosinophilic intracytoplasmic inclusion bodies following staining with hematoxylin and eosin. Primary CEF cells, chicken embryo kidney cells, chicken embryo dermis cells, or the permanent quail cell line QT-35 can be used for isolation of virus directly from the suspected material. A 10% suspension of the suspected material is made in PBS, which is filtered through 0.45 μm membrane filter. Virus in the filtrate is adsorbed onto the preformed layer of the cell for 1 h at 37°C and then washed with media. The infected cells are then incubated in an appropriated medium at 37°C. This results in the formation of CPE within 4–6 days postinoculation, depending on the virus isolate and on the multiplicity of infection. The isolated virus is then confirmed by molecular techniques.

93.2.2.4 Enzyme-Linked Immunosorbent Assay

ELISA can detect humoral antibodies to FWPV 7–10 days after infection [31]. FWPV antigens are prepared from either infected primary or permanent cell (QT-35 cell) monolayers or CAM lesions. Infected cells are pelleted (700 g for 10 min at 4°C), washed with isotonic buffer followed by lysis in hypotonic buffer or sonication. Nuclei and cellular debris are removed by low-speed centrifugation and the resulting supernatant is used as a source of FWPV antigens for ELISA or immunoblotting. To isolate viral antigen from CAM lesions, initial grinding of the lesions with subsequent detergent treatment is required.

Wells of microtiter plates are coated with 1 μg of soluble FWPV antigen in 100 μL of coating buffer (15 mM Na_2CO_3, 35 mM $NaHCO_3$, pH 9.6) and incubated overnight at 4°C. Each well is then rinsed once with wash solution (0.29 M NaCl, 0.05% Tween 20) and then blocked with PBS (pH 7.4) containing 3% bovine serum albumin (BSA) for 1 h at 37°C. After one wash, serial dilutions of the test sera in PBS containing 1% BSA are added to the wells. After rocking for 2 h at 37°C, wells are washed three times prior to the addition of 100 μL/well horseradish peroxidase-conjugated goat anti-chicken IgG antibodies at a recommended dilution in PBS. After 2 h incubation at 37°C and three subsequent washes, 100 μL of the peroxidase substrate tetramethylbenzidine (TMB) is added to each well. Reactions are terminated by the addition of 1 M phosphoric acid and absorbance at 450 nm is recorded using an ELISA plate reader.

93.2.2.5 Polymerase Chain Reaction

APVs are increasingly being detected and characterized by PCR, targeting specific genes such as the 4b core protein gene [38]. PCR allows for sensitive and specific detection of viral nucleic acids when compared to cell culture. From a small amount of suspected tissue material or infected cell or CAM, DNA is isolated by using commercial kits. DNA can also be isolated following the conventional method of treating the tissue with detergent and proteinase K and extraction

with phenol–chloroform. Tissue materials (scab and pharyngeal lesions) are triturated and homogenized to make a 10% suspension in PBS. About 0.5 mL of the tissue homogenate is treated with SDS (sodium dodecyl sulfate) (1% final concentration) at 37°C for 30 min and then digested with proteinase K (1 mg/mL final concentration) in a buffer (0.01 M Tris-HCl, 0.1 M NaCl, 0.001 M EDTA, pH 7.6) at 56°C for 2 h. DNA is extracted using equal volume of phenol–chloroform mixture and precipitated by 2.5 volume of ethanol. After washing and drying, DNA is dissolved in 20 µL of TE buffer (10 mM Tris-HCl, 1 mM EDTA, pH 8.0) and used in PCR. PCR is carried out in a total volume of 50 µL, containing 10 mM Tris-HCl, pH 8.8, 50 mM KCl, 0.08% Nonidet P40, 1.5 mM $MgCl_2$, 200 µM each dNTP, 5 µL DNA, 0.2 µM each primer, and 1.5 units of Taq DNA polymerase. Amplification is done in a PCR thermal cycler under the following conditions for 30 cycles: initial denaturing at 94°C for 5 min, subsequent denaturing at 94°C for 1 min, annealing at 60°C for 1 min, and extension at 72°C for 1 min. The final extension is carried out at 72°C for 15 min to ease cloning in TA cloning vector. A volume of 5 µL of the PCR products is separated on 1.2% agarose gel electrophoresis. The size of the amplified DNA fragment using primers designed by Lee and Lee [38] is expected to be 578 bp long (Figure 93.2). For authentication of the amplified fragment, it may be directly sequenced or sequenced after cloning in a plasmid vector. The sequence allows a rapid search for homologous sequences in gene databases, to verify and identify the virus in question and to address phylogenetic relationships.

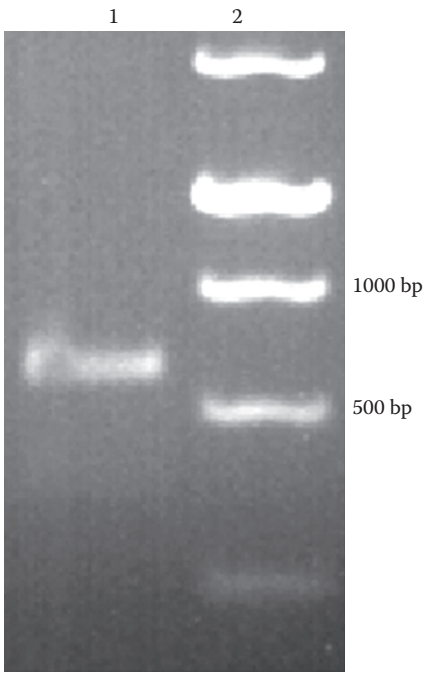

FIGURE 93.2 Polymerase chain reaction amplification of fowlpox virus (FWPV) 4b gene. Total DNA was extracted from scab arterial of a chicken affected with fowlpox and FWPV 4b gene was amplified (lane 1) using the primers described by Lee and Lee [38] with an expected size of 578 bp. Lane 2:100 bp DNA molecular weight marker.

93.3 FUTURE PERSPECTIVES

APVs cause disease in poultry, pet, and wild birds. It is of great economical importance for the poultry industry and thus prophylactic measures, such as vaccination, will always be required. There are very effective vaccines and they have undoubtedly contributed immensely to the prevention of the disease in commercial poultry farming. However, there is a need for more efficient and safe vaccines. It is known that fowlpox vaccines often get contaminated with REV. It has been shown that sequences of REV have been integrated into the DNA of FWPV as well as in field isolates. The reactivation of REV often causes disease in vaccinated birds although the FWPV vaccine virus is attenuated. Therefore, FWPV vaccines should be made from virus strains or isolates free from integrated REV DNA. Field strains of FWPV are known to contain integrated near-full-length REV provirus DNA and to achieve a REV-free FWPV; the integrated sequence has been deleted through the application of modern biotechnological approaches. The recombinant FWPV, thus prepared from a field strain, could be considered a safe candidate for vaccine preparation. Live modified vaccines have been developed mainly to prevent APV infection in chickens, turkeys, pigeons, and quails. There is seldom any vaccine for APV infections in other species of birds. Many APVs have been isolated from a wide range of bird species and only a few isolates have been characterized and so, it has been difficult to develop vaccines for all species. More knowledge of epidemiology, pathology, and molecular biology of these viruses is necessary to develop vaccines that can effectively protect a wide range of bird species.

The traditional vaccine technology based on live viruses has given rise to a wide range of effective vaccines against infectious agents, both in veterinary and human medicine. However, the emergence of new deadly human pathogens and cancers have proven less amenable to the application of traditional vaccine platforms, indicating the need for new approaches. The use of a live virus vector represents novel way to deliver and present vaccine antigens that may provide advantages over traditional platforms. Currently, representatives of a wide range of virus families are under intensive investigation as vaccine vectors for human or veterinary use. Of these, FWPV and CNPV appear to be very promising as vectors, and some veterinary APV-vectored vaccines are already licensed and in commercial use in North America, South America, and Europe. One of the main advantages of APVs as vaccine vectors is its large genome that can accommodate many heterologous genes, such as genes coding for antigens, cytokines, and other immunomodulating factors. The major safety argument for using APVs rather than vaccinia virus or other mammalian viruses as vectors is that APVs are not zoonotic and are unable to conduct a full replication cycle in mammals. However, it was recently shown that FWPV was able to replicate and produce progeny virions in some established mammalian cell lines. This is certainly a matter of concern that requires a good understanding of the molecular properties of APVs for development of safe APV-vectored vaccines.

94.1 INTRODUCTION

Capripoxviruses are classified within the family *Poxviridae* and are the etiological agents of sheeppox (SPP), goatpox (GTP), and lumpy skin disease (LSD) of cattle. The causative viruses, sheeppox virus (SPPV), goatpox virus (GTPV), and lumpy skin disease virus (LSDV), are responsible for a generalized pox disease characterized by pyrexia, generalized skin lesions, ulcerative lesions in the mucous membranes of the mouth and nasal cavities, and lymphadenopathy.[1–4] Due to their transboundary capacity, capripoxvirus infections could become emerging diseases; the Office Internationale des Epizooties (OIE), or the World Organization for Animal Health, have to be notified of outbreaks. In endemic areas, they are of great economic significance to farmers and have a major impact on international trade in livestock and livestock products. The morbidity and mortality of SSP and GTP are very high and can reach 100% in naïve animals. In contrast, LSD is an occasionally fatal disease with morbidity averaging 10% and mortality 1% in affected herds, although mortality rates over 75% have been recorded.[5]

Initially, the distribution of capripoxviruses differed geographically from the current distribution. SPPV and GTPV mainly occurred in Africa north of the equator while LSDV was originally identified south of the equator and also in regions free of SPPV and GTPV. These viruses, expanding their distribution and LSD, has now spread to almost the entire Africa and the Middle East with outbreaks reported in 2013 and 2014 from previously disease-free countries such as Turkey, Iraq, Iran, and Azerbaijan. SPP and GTP spread to Asia and as far east as China but inexplicably only recently south of the equator. The spread of capripoxviral diseases is predominantly associated with illegal animal movement through trade.[6,7]

Capripoxviruses are morphologically and serologically indistinguishable, share a group-specific antigen, and have varying degrees of cross-protection. They have a close relationship genomically but differ phylogenetically.[8–11] The availability of sequence data from all three viruses led to the development of molecular laboratory techniques like PCR assays and improves the diagnosis of these diseases.

94.1.1 Classification

The *Poxviridae* family, one of the largest virus families, is divided into two subfamilies: poxviruses affecting insects (*Entomopoxvirinae*) and those affecting vertebrates (*Chordopoxvirinae*). The subfamily *Chordopoxvirinae* consists of at least eight genera: *Avipoxvirus*, *Capripoxvirus*, *Cervidpoxvirus*, *Crocodylipoxvirus*, *Leporipoxvirus*, *Molluscipoxvirus*, *Orthopoxvirus*, *Parapoxvirus*, *Suipoxvirus*, and *Yatapoxvirus*, of which *Orthopoxvirus* and vaccinia virus are the prototypes of the family and the genus, respectively.[12,13] LSDV, SPPV, and GTPV represent the only known members of the genus *Capripoxvirus*. SPPV was first studied during the nineteenth century (cited by Bhanuprakash and coworkers)[14] and SPPV is the type species. The prototype of LSDV is the Neethling strain, which was isolated in South Africa in 1944.[15]

94.1.2 Morphology, Genome Organization, Biology, and Epidemiology

Morphologically, members of the subfamily *Chordopoxvirinae* are very similar and it is difficult to differentiate capripoxviruses from orthopoxviruses on the morphological criteria alone.[16] With the largest virions (measuring 320–260 nm in size) of animal viruses, capripoxviruses are ovoid or brick-shaped.[3,17] They are characterized by the presence of three major structures: an outer coat (the envelope), two lateral bodies, and the inner dumb-bell shaped core, containing the double stranded DNA genome.[16] The virion consists of over 100 polypeptides. The core of the viruses contains proteins that include a transcriptase and several other enzymes.[16] Poxviruses exist with, or without an envelope in the intracellular space and are enveloped in the extracellular space.[16] Both forms are infectious and have the same core and genetic material. The mature virions,[18] also called intracellular mature virions,[16] are surrounded by a single lipid membrane with irregular arrangements of tubular nonglycosylated viral proteins on the surface. The extracellular enveloped virion has an additional outer membrane.[19] All strains of capripoxvirus share a group-specific antigen,[20] and recovery from infection with one strain provides immunity against all other strains.

Comparative DNA sequence analysis of SPPV and GTPV genomes from isolates including pathogenic field isolates and attenuated vaccine viruses revealed that genomes are approximately 150 kb and are strikingly similar to each other, exhibiting 96% nucleotide identity over their entire length. Wild-type genomes share at least 147 putative genes, including conserved poxvirus replicative and structural genes, and genes likely involved in virulence and host range. Not many genomic changes are evident in SPPV and GTPV vaccine viruses compared to their respective field strains. SPPV and GTPV genomes are very similar to LSDV, sharing 97% nucleotide identity, but phylogenetic reconstructions have shown that these viruses can be segregated into three different lineages according to their host origins: the SPPV, GTPV, and LSDV lineages.[9–11,21] In addition, a 21-nucleotide deletion found in all individuals within only the SPPV group allows for diagnostic differentiation of SPPV from GTPV.[21] All genes present in SPPV and GTPV are present in LSDV[11] but nine LSDV genes with possible virulence and host range functions are disrupted, including a unique LSDV gene (LSDV132). The absence of these genes in SPPV and GTPV suggests involvement in the bovine host range. The close genetic relationship among capripoxviruses suggests that SPPV and GTPV are distinct and likely derived from an LSDV-like ancestor.[11]

DNA analysis using restriction endonucleases on both field samples and vaccine strains showed 80% homology between strains of capripoxviruses.[22] Species-specific molecular assays have been developed by sequencing the host-specific G protein-coupled chemokine receptor or the 30 kDa RNA polymerase subunit genes. These genes also enable differentiation and phylogenetic grouping of capripoxviruses.[23–26]

SPPV and GTPV strains are not totally host-specific and some cause disease in both sheep and goats, while others may cause disease in only one species. The severity of SPP is influenced by several factors like host (age, sex, breed, nutritional and immunological status), agent (strain, virulence, pathogenicity), environment (micro and macro), poor management and scarcity of feed. Although the severity varies with age, all age groups of sheep are affected. The disease is more severe in young lambs (4–8 months) than adult sheep and newborn lambs[27] (cited by Bhanuprakash and coworkers[14]).

LSD is, however, specific for cattle of all breeds and sexes. Experimental infection of LSDV in sheep and goats only caused a local erythematous swelling at the site of inoculation.[3] Evidence of infection has been reported in some wildlife species but no clinical disease has been observed in nature.[28–30] These studies do not confirm that wildlife species play a significant role in the spread or maintenance of capripoxviruses and no strong evidence of a wildlife reservoir for these viruses exists. Studies by Hosamani and coworkers[31] indicating that molecular markers for host specificity of capripoxviruses can be determined if sufficient virus strains and genes are analyzed.

The host range also reflects the different geographical distribution of these viral diseases. LSD was known to exist in the central African territories for many years[32] before the disease was reported in Northern Rhodesia (Zambia) in 1929,[2,32,33] and by the 1940s, the disease had spread across southern African countries, affecting large numbers of livestock.[32] The disease then slowly spread northward and is currently present virtually throughout the entire African continent, including Madagascar (World Animal Health Information database, OIE WAHID Interface). The only African countries still disease-free are Libya, Algeria, Morocco, and Tunisia. The disease was first reported in Egypt in 1988, and in August 1989, the disease spread for the first time out of Africa into Israel.[34] In 2006–2007, after an apparent absence of 17 years, LSD reoccurred in Egypt and Israel.[35] LSD is endemic in the Horn of Africa from where many Middle Eastern countries import live cattle and frozen meat.[36] According to the OIE WAHID and Handistatus II Database, LSD has been reported in Kuwait (1991), Yemen (1995), the United Arab Emirates (2000), Bahrain (2009), and Oman (2013). The presence of LSDV in Saudi Arabia (1992) has not been confirmed.[29] Between 2012 and 2013, several outbreaks of LSD occurred in Israel (ProMed 20120728.1218484), Lebanon (ProMed 20130118.1505118), Jordan (ProMed 20130612.1768278), and the West Bank (ProMed 20130311.1581763). No data are available from Syria but due to the LSDV outbreaks in the Golan Heights in Israel and southern Lebanon, which is in close proximity of Syrian borders, it is highly likely that the disease is present in that country.[37] Incursions of the disease to Turkey (ProMed 20130831.1915595) and Iraq (ProMed 20130718.1831781) were reported in the last part of 2013. In July 2014, the disease spread further to Iran (ProMed 20140623.2561202) and Azerbaijan (ProMed 20140719.2621294) (Figure 94.1a).

LSD is most prevalent in the wet season or summer and along water courses[38–40] although outbreaks may also occur

FIGURE 94.1 (a) Occurrence of lumpy skin disease. (b) Occurrence of sheeppox and goatpox.

in the dry season.[1,39] In endemic areas, LSD has a tendency to disappear during the dry and cold months.[4,41]

SPPV infections were studied during the nineteenth century, and during the mid-twentieth century, the disease was reported from African, Asian, and European countries. Many SPP outbreaks occurred during 1847–1866 in Great Britain and eradication was achieved in 1866. The disease persisted in other parts of Europe, however, due to extensive trade between other foreign countries. The disease has been eradicated from many countries, but is still present in Africa (cited by Bhanuprakash and coworkers).[14] SPP and GTP currently mainly occur in Africa north of the equator, but suspected cases were reported in Zambia in 2012 (OIE WAHID and Handistatus II databases 2012). The diseases occur throughout West Asia, (Russia, Kazakhstan, and Kyrgyzstan), India, Turkey, Mongolia, Greece, and as far east as China and Bangladesh (Figure 94.1b) (OIE WAHID and Handistatus II databases, 2012, 2013).[42] Recent cases were reported in 2012 and 2013 in Russia (OIE, RFI 20121010.1335877; OIE, RFI 20131019.2009540 and Promed 2012 20131023.2017272), 2013 in Bulgaria (RFI 20131227.2138858), and 2013 and 2014 in Greece (OIE 20131221.2128611; OIE 201).

SPP occurs throughout the year depending on season, climate, agent, and the different breeds of sheep[43] but outbreaks associated with unusual winters[44] and drought[45] have been reported. In many countries, sheep are exposed to various geoclimatic conditions due to migration; this causes stress, which aids in spreading the disease.[14]

94.1.3 Clinical Features and Pathogenesis

Capripoxviruses cause severe acute diseases that have major impacts on small ruminants (SPP and GTP) and cattle (LSD) production in countries, where the disease is endemic, due to reduced milk yields, damage to hides, and mortalities.[46] The severity of clinical disease is variable depending on the host species, the breed and age of the susceptible host, and the virus isolate. Mortality rates for SPPV and GTPV reach up to 100%, whereas mortality rates in LSDV infections are usually much lower with morbidity averaging 10% and mortality 1% but 75% in affected herds have been reported (reviewed in reference 42). Different isolates can behave differently in sheep and goats, with most isolates more virulent in either sheep or goats, while others are pathogenic in both species.[47] LSDV, however, will only cause disease in cattle. A number of diseases may show symptoms similar to SPP and some of them warrant differential diagnosis, that is, bluetongue.[14]

Generally, poxviruses are epitheliotropic and cause localized cutaneous (orf and pseudocowpox viruses) or systemic diseases (LSDV and SPPV) involving the skin and many organs and tissues. The incubation period for LSDV under experimental conditions is 4–14 days.[48] Under natural conditions, it may take between 2 and 4 weeks.[3] Early signs include a fever of 40°C–41.5°C, which will last between 4 and 14 days. During this time, the animal will manifest inappetence, salivation, lacrimation, and mucoid to mucopurulent nasal discharge.[49–51] The superficial lymph nodes especially the prescapular and precrural become markedly enlarged.[51–55] Conjunctivitis develops and may be followed by corneal opacity and eventual blindness.[1,15,55] Characteristic circumscribed intradermal, mostly eruptive, skin nodules develop. They are firm, raised, round, about 10–50 mm wide, and are readily seen in animals with short hair unlike in long haired animals. Ulcerative lesions may develop in the conjunctiva, nostrils, muzzle, and mucous membranes of the mouth, larynx, trachea, reproductive, and alimentary tracts, especially the abomasum.[3,48,49,51] The number of lesions may vary from

a few in mild cases to multiple lesions covering the entire body in severely infected individuals. Subclinical infections are common in the field. In severe cases, nodules may erupt leaving a raw surface of the muscles. Nodules in the skin of the udder and teats may lead to mastitis. Subcutaneous swelling of the legs may occur, leading to lameness. Abortions or prolonged anoestrous as well as intrauterine infection may occur. Temporal sterility in infected bulls may be observed and secondary complications like pneumonia caused by the virus itself or secondary bacterial infections may develop.[51]

After infection of SPPV and GTPV, fever develops concurrently with the generation of macules in the skin. Rhinitis, conjunctivitis, and excessive salivation occur, and macules enlarge and develop into papules and then scabs. The distribution of pox lesions in the skin can be widespread with over 50% of the skin surface affected. More commonly in endemic areas, however, the lesions are restricted to a few nodules under the tail and are thus only detected on close examination.[42]

New biochemical and microscopic findings led to a better understanding of poxvirus entry and membrane fusion. Four viral proteins associated with the mature virus/virion membrane facilitate attachment by binding to glycosaminoglycans or laminin on the cell surface, whereas enveloped viruses attachment proteins have not yet been identified.[19] Host cell entry of vaccinia virus, the prototypic poxvirus, revealed a membrane fusion event with delivering of the viral core and two proteinaceous lateral bodies into the cytosol[18] where they undergo two stages of uncoating and multiplication. Uncoating of viral cores is poorly characterized, and the composition and function of lateral bodies remain unclear.[56]

After multiplication at the site of entry, the virus enters and multiplies in local draining lymph nodes followed by a primary viremia.[57,58] Draining lymph nodes are often enlarged following infection; however, lymphadenopathy is not associated with high viral replication/load in the nodes.[59] Internal organs such as the lung and stomach also develop characteristic pox-like lesions. In severely affected animals, respiratory distress occurs, followed by death. Like smallpox, capripoxvirus disease pathogenesis is associated with both viral and host factors.[60]

In experimental LSDV-infected animals, the first viremia has been detected as early as day 2–7 postinfection.[48,61,62] Infection also spreads to internal organs especially the lungs, liver, spleen, rumen, and abomasum.[4,42] There is infiltration of epithelial and endothelial cells, pericytes, and fibroblast causing lymphangitis and vasculitis with concomitant thrombosis and infarction, which leads to edema and necrosis.[51,63] The virus has been demonstrated in saliva, semen, nasal secretion, skin lesions, kidneys, abomasum, and rumen but not in urine and feces.[3,51,61]

Viremia of SSP and GTP viruses is cell-associated,[64] starts at the time of lesion occurrence, and clears within 2–3 weeks postinoculation in their respective hosts. This coincides with the time of seroconversion when host antibodies can neutralize the virus. Peak shedding of viral DNA and infectious virus in nasal, conjunctival, and oral secretions occurred between 10 and 14 days postinoculation and persisted at low levels for up to an additional 3–6 weeks. Although gross lesions developed in multiple organ systems, the highest viral titers were detected in skin and in discrete sites within oronasal tissues and the gastrointestinal tract confirming that the greatest viral replication occurs in the skin.[59,65]

Infective mature viruses are released from the host cells by cell eruption.[16] The majority of extracellular enveloped viruses remain attached to the host cell surface and mediate efficient cell-to-cell spread of the virus. The other enveloped viruses are free in extracellular space and responsible of long-range dissemination of the virus within a host.[16] The envelope is fragile and breaks easily outside the cell, particularly during freeze and thaw cycles.[16]

94.1.4 Diagnosis

Although experienced veterinarians can initially diagnose capripoxvirus infections based on animal host origin and clinical signs including overt skin lesions, laboratory confirmation is still necessary. Low virulence strains and the absence of skin lesions present problems for differential diagnosis, and laboratory confirmation is therefore necessary when studying epidemiology, for example.[14]

94.1.4.1 Conventional Techniques

In the past, laboratory confirmation for identification of virus in clinical material relied on classical laboratory techniques including animal transmission, pathology and histopathology, electron microscopy,[66] and virus isolation in cell cultures.[48,67,68]

Histopathology has been used to determine changes in cells using hematoxylin and eosin staining,[51,55,69] while immunohistochemistry confirms infection by demonstrating the viral antigen in the tissues.[63,70] A monoclonal antibody was developed from the LSDV core protein (ORF 057) expressed in *E. coli*.[61] An immunohistochemical method was successfully used in the diagnosis of LSDV during an outbreak in Egypt[70] and to confirm the presence of LSDV in testes of experimentally infected bulls.[63] It was also used to demonstrate the presence of the virus in macrophages and hair follicle epithelium.[61] Immunohistochemistry has also been used in the diagnosis of SPPV.[43,71]

Electron microscopy is technically simple and provides a rapid method for detecting viruses in tissue samples on the basis of their morphology[72] and can therefore not distinguish between capripoxviruses. Negative contrast staining or positive staining of thin sections as well as immune-staining can be used.[72] A disadvantage of this technique is that the limit of detection for negative staining is 10^6 virus particles per mL but it can improve to between 10^4 and 10^5 for ultrathin sections.[73]

Capripoxviruses can be grown in a variety of sheep, goat, and cattle cells[74] and primary lamb kidney, lamb testis cells,

or bovine dermis cells are used.[48,67,75,76] These viruses grow slowly in cell cultures and may require several passages for cytopathic effects to be observed.[15] The presence of the virus in cell cultures is demonstrated by cytopathic changes and intracytoplasmic inclusion bodies.[3]

Currently, tests used to distinguish a specific virus are made according to the infected host species from which the virus was isolated, complemented by sequencing and phylogenetic analyses.

Until the late 1990s, the only capripoxvirus-specific antibody tests available were based on immunofluorescence and the virus neutralization test (SNT) using cell cultures. The SNT is considered the gold standard serodiagnostic method for detecting neutralizing antibodies to capripoxviruses.[42] This method has been used as a screening test to confirm infection with LSDV[48,62] and to carry out serological surveys on LSD.[77,78] However, the test cannot differentiate between GTPV, SPPV, and LSDV.[22,64] As immunity to LSDV is mostly cell-mediated, the sensitivity of this test is low and it cannot detect the low level of circulating antibodies in animals.[62] SNT is also difficult to interpret, is time-consuming, and is not available in countries where the viruses are not endemic.

The availability of sequence data led to the study and expression of specific open reading frames, which inspire/stimulate the development of different ELISA tests. Although there is currently no validated ELISA for the detection of capripoxviruses, many attempts have been made to develop different formats of the assay. Antigen trapping and recombinant antigen ELISAs were developed by Carn and coworkers.[79,80] An ELISA was developed based on the envelope protein P32 of LSDV expressed in *Escherichia coli*.[79,81] The 3.7 kb viral DNA fragment of SPPV, which contained open reading frames homologous to the vaccinia virus J6R, H1L, H2R, H3L, and H4L genes, was cloned and sequenced. The vaccinia virus H3L homolog was identified as the capripoxvirus P32 antigen. The P32 proteins of SPPV and LSDV were expressed in *Escherichia coli* as a fusion protein and used as a trapping antigen in an ELISA, but this test had limitations due to the instability of the recombinant protein.[82] Whole inactivated sucrose gradient-purified SPPV as a coating antigen[82] has also been used in an indirect ELISA but has the disadvantage of being too costly to produce in bulk.[83] An indirect ELISA was developed using the virion core proteins ORF095 and ORF103, which were able to detect capripoxvirus antibodies in both acute and convalescent phase sera.[83]

Western blotting assays, although difficult to perform and interpret, can be used and are specific and sensitive.[84]

94.1.4.2 Molecular Techniques

The complexity of capripoxvirus differentiation emphasizes the need to develop more reliable tools for the identification of these viruses. The analysis of genome sequences of capripoxviruses has shown that SPPV, GTPV, and LSDV are genetically distinct.[11] The availability of sequence data initiate the development and validation of several molecular techniques, that is, PCR methods, some of which were refined to detect either vaccine strains or only a specific species of virus. These assays provide a rapid and sensitive diagnostic technique for capripoxvirus genome detection and have the advantage of using internal reaction controls. If used as a diagnostic assay, however, results should be confirmed by at least one additional test.

Conventional PCRs have been used and reported,[48,81,85–89] and real-time PCR has been reported by several authors.[21,25,59,61,69,90–92] A multiplex PCR using species-specific primers was used to detect capripoxvirus strains in Russia and with modification to distinguish vaccine strains.[88] A PCR assay has been developed to identify both capripoxviruses and orf virus (parapoxvirus) in the same procedure.[91,93] A single-tube duplex PCR for the detection of SPPV and GTPV is useful where herds are affected with both viruses.[94]

The development of different platforms for sequencing, that is, next-generation sequencing, although not in general always feasible to use as a diagnostic tool, led to a better understanding of the origin and geographical distribution of strains of capripoxviruses.

94.2 METHODS

94.2.1 Sample Preparation

Samples for virus isolation and antigen-detection ELISA should be taken during the first week of symptoms, before neutralizing antibodies have developed. Samples for PCR, blood (EDTA), and/or skin lesions can be collected after this time. In live animals, biopsy samples of skin nodules or lymph nodes can be used for virus isolation and antigen detection. Scabs, nodular fluid, and skin scrapings may also be collected, specifically also for electron microscopy (EM). The virus can be isolated from blood samples (collected into heparin or EDTA) during the early viremic stage of disease; virus isolation from blood is unlikely to be successful after generalized lesions have been present for more than 4 days. Samples of lesions, including tissues from surrounding areas, should be submitted for histopathology. Acute and convalescent sera are collected for serology. At necropsy, samples for fixation in formalin should be taken of skin lesions and lesions in the respiratory and gastrointestinal tracts, and fresh samples should be taken and treated as described above.[48,51,95]

Tissue or clinical samples are generally homogenized as 10% suspensions in sterile water or phosphate buffer saline and used for extraction of total genomic DNA and stored at –20°C until use.[96] In a method used by Ireland and Binepal,[85] one gram of tissue was ground up with sterile sand and approximately 1 mL of tissue culture medium containing serum and antibiotics in a glass tissue grinder; the mixture was then transferred to a 1.5 mL microcentrifuge tube. The suspension was clarified by centrifugation at full speed for 5 min in a microfuge and stored at 4°C until needed for ELISA or PCR.[85]

94.2.2 Detection Procedures

94.2.2.1 Extraction Methods

Although the use of traditional phenol chloroform extraction methods has recently been reported for scabs and cell culture material,[94] commercially available extraction kits are currently mainly used to obtain nucleic acids from diagnostic samples. DNA was extracted from tissue samples using the DNeasy Blood and Tissue Kit (QIAGEN, USA). After complete lysis of the specimens by ATL buffer and proteinase K, absolute ethanol was added, then the mixture was transferred to a spin column according to the manufacturer's protocol.[97] The Qiagen AllPrep DNA/RNA extraction kit (Qiagen, Hilden, Germany) was used to extract viral DNA by Lamien and coworkers.[25] Homogenates of infected tissues (10% weight/volume in PBS), or infected cell culture supernatants were mixed with the kit lysis buffer, RLT plus (200 µL sample + 800 µL buffer). The DNA was extracted according to the manufacturer's instructions and eluted in 50 µL of elution buffer included in the kit.

Tuppurainen and coworkers[48] used an extraction method containing a lysis buffer with 60% guanidine thiocyanate and digestion by proteinase K at different time periods, following the use of Trizol (Roche products, Mannheim, Germany) for nucleic acid extraction. Briefly, 200 µL of specimen was added to 100 µL of lysis buffer containing 0.378 g KCl, 1 mL Tris (1.0 M, pH 8), 0.5 mL Tween 20%, and 60% guanidine thiocyanate (Roche products, Mannheim, German). To digest proteins, 10 µL of proteinase K (Roche products, Mannheim, Germany) were added to the mixture and incubated at 56°C for 2 h. This was done for blood, saliva, and VI supernatants, and at least 16 h were used for tick homogenates.[48,98,99] The mixture was then heated to 90°C for 10 min to stop enzyme activity. Then, 300 µL of Trizol, a solution of phenol/chloroform/isoamyl alcohol (Roche products, Mannheim, Germany), was added, mixed by vortexing, and incubated at room temperature for 10 min before centrifuging at 13,000 rpm (Centrifuge 5417R, Eppendorph International, Germany) at 4°C for 15 min. The supernatant (200 µL) was collected in a 2 mL tube and DNA precipitated.

94.2.2.2 Amplification Methods

A PCR to detect capripoxviruses in tissue material reported by Ireland and Binepal[85] is widely used. The primers for the attachment gene are

5′ d tccgagctcTTTCCTGATTTTTCTTACTAT 3′
5′ d tatggtacctAAATTATATACGTAAATAAC 3′

And the primers from viral fusion protein encoding gene are

5′ d actagtggatccATGGACAGAGCTTTATCA 3′
5′ d gctgcaggaattcTCATAGTGTTGTACTTCG 3′

The extra sequences shown in lower case letters were added to allow for cloning the PCR products. A 50 mL reaction volume was used that contained 16 mM $(NH_4)_2SO_4$, 67 mM Tris–HCl (pH 8.8 at 25°C), 2.5 mM $MgCl_2$, 0.2 mM dNTPs, 5 units of Taq polymerase, 0.25 mM of each primer for either the attachment gene or fusion gene, 0.1% Tween-20, and 5 mL of cell culture or biopsy supernatant plus 20 mL of GeneReleaser or 20 mL of cell culture, or biopsy supernatant. The PCR had an initial cycle of 94°C for 5 min, 50°C for 30 s, 72°C for 1 min followed by 34 cycles of 94°C for 1 min, 50°C for 30 s, 72°C for 1 min, and a final elongation step of 72°C for 5 min. The reaction products were visualized using a 1.5% agarose gel containing ethidium bromide. To distinguish between capripox-, orthopox-, and parapoxviruses, the PCR products were confirmed by restriction enzyme analysis, using 20 units of *Eco*RI (attachment gene) or *Dra*I (fusion protein encoding gene).

A capripoxvirus-specific PCR assay was developed that differentiated between SPPV and LSDV on the basis of unique restriction sites in the corresponding PCR fragments.[81]

Real-time PCRs based on hydrolysis probe chemistry (TaqMan probes) have been developed and used to study capripoxvirus shedding in sheep, goat, and cattle,[59,61,100] and for a rapid preclinical diagnosis of capripoxvirus.[90] However, these methods were not used for strain discrimination. The method of Balinsky and coworkers[90] used reagents from an EZ-RT PCR kit (Applied Biosystems, Branchburg, NJ) according to the manufacturer's guidelines. The final 25 µL assay mix included an EZ buffer solution, 5 mM manganese acetate, 0.2 mM dNTPs, and 0.1 U of recombinant *rTth* DNA polymerase. A forward primer (5′-GGCGATGTCCATTCCCTG-3′) (200 nM), reverse primer (5′-AGCATTTCATTTCCGTGAGGA-3′) (500 nM), and fluorogenic minor groove-binding TaqMan probe (5′-CAATGGGTAAAAGATTTCTA-3′, labeled with 6-carboxyfluorescein and a nonfluorescent quencher) (200 nM), were included in each reaction mix. Sample template (2.5 µL) was added to the reaction mix in a SmartCycler (Cepheid, Sunnyvale, CA) 25 µL reaction tube. Cycling conditions consisted of an initial denaturation at 95°C for 120 s, followed by 45 amplification cycles (95°C for 2 s and 60°C for 60 s). The assay was run on a Cepheid SmartCycler (Cepheid, Inc., Sunnyvale, CA).

Genotyping can be performed by real-time PCR by using a dual hybridization probe assay (also known as fluorescence resonance energy transfer probe or FRET).[101,102] With this method, PCR chemistry is combined with fluorescent probe detection of the amplified product in the same reaction vial. In this assay, the acceptor probe is designed where differences exist between strains to be able to differentiate between them. The melting point temperature of the probe and its target will therefore differ between different strains. The melting peaks obtained after fluorescence melting curve analysis serve to differentiate the strains. This procedure has been used to discriminate between different species of orthopoxviruses.[103–105]

Recently, a species-specific real-time PCR was reported based on unique molecular markers that were found in the G-protein-coupled chemokine receptor gene sequences of capripoxviruses and that use dual hybridization probes for their simultaneous detection, quantitation, and genotyping. This PCR method described by Lamien and coworkers[26] can be used effectively for differentiation between SPPV and GTPV. Differences in the melting point temperature and fluorescence melting curve analysis were also used to differentiate between capripoxvirus strains.[26] Primers were developed to allow the

amplification of a 200 bp target at position 7015–7214 within conserved regions of the G-protein-coupled chemokine receptor gene after alignment of 58 capripoxvirus isolates as target sequences. A pair of dual hybridization probes (donor and acceptor) was designed to bind within the amplicon. The acceptor matched 100% with GTPV sequence but showed 3 and 5 mismatches, respectively, with LSDV and SPPV sequences. The donor (Cp-LNA-FAM1) was labeled at the 3′ end with the blue dye 6-carboxyfluorescein (6-FAM) and further modified by incorporating Locked Nucleic Acid (LNA) into it. The acceptor (Cp-Cy5) was labeled at the 5′ end with a red cyanine dye, Cy5 (KPL, Gaithersburg, MD), and its 3′ end was blocked with a phosphate moiety. All primers and probes were synthesized by VBC-BIOTECH (Vienna, Austria) (Table 94.1).

An iCycler (BioRad, Hercules, CA) thermocycler was used using a volume of 20 μL containing template DNA, 100 nM forward primer, 300 nM reverse primer, 300 nM of each of the dual hybridization probes, and the iQ Supermix (BioRad, Hercules, CA). Reaction cycles proceeded at 95°C for 3 min followed by 40 cycles of 95°C for 10 s, 46°C for 30 s, and 72°C for 30 s. Fluorescence was measured at the end of each annealing step (46°C). Subsequent fluorescence melting curve analysis involved an initial denaturation at 95°C for 1 min and cooling at 40°C for 1 min and then heating to 90°C with a ramping rate of 1°C each 10 s.[25]

A loop-mediated isothermal AMPlification assay for the detection of capripoxvirus DNA was developed using loop primers from the conserved region of the P32 gene. This DNA-dependent amplification method uses a combination of four to six primers targeting six to eight genomic regions, while utilizing the activity of a strand-displacing DNA polymerase. The assay could detect SPPV, GTPV, and LSDV and did not cross-react with other mammalian poxviruses.[106]

A multiplex PCR and phylogenetic analysis were used to detect and characterize the first description of SPPV in a recent outbreak in Saudi Arabia. Primers from the KS-1 DNA fragment and the inverted terminal repeats described by Mangana–Vougiouka and coworkers[87] were used for screening samples and the P32 gene for sequence analysis.[97] The primers used in the PCR assays were KS-1.5/KS-1.6 and InS-1.1/InS-1.1/ for SPPV screening and B68/B69 primers for partial sequencing of the P32 gene are indicated in Table 94.2.

The presence of SPPV was detected by a multiplex PCR using a HotStartTaq® Plus Master Mix Kit (QIAGEN, USA). 2 μL sample of each purified genomic DNAs were amplified in 20 μL of the final volume of a 2× HotStartTaq Plus Master Mix containing 1.5 mM $MgCl_2$, 200 μM of each dNTP, and 1 unit HotStartTaq Plus DNA polymerase and 10 μM of each KS-1.5/KS-1.6 and InS-1.1/InS-1.1/primers. Thermocycling conditions were enzyme activation and initial denaturation at 95°C for 5 min followed by 35 cycles of 94°C for 30 s, 43°C for 30 s, 72°C for 30 s, and a final extension step at 72°C for 10 min. The amplified PCR products were visualized using a 5% agarose gel stained with ethidium bromide and documented using ultraviolet gel documentation system.

94.3 CONCLUSION

Capripoxviral diseases are economically important diseases of small ruminants and livestock. The spread of the diseases into various geographical areas has been alarming during the past 4 years, with SPP and GTP spreading into South Asia and the Far East and LSD into the Middle East. The threat now is spreading into Europe where naïve animal populations would suffer high morbidity and mortality.

Control of the diseases is possible through vaccination and strict movement control, which is not possible in all countries. An attenuated strain of any capripoxvirus should theoretically protect against all SPPV, GTPV, and LSDV strains. The use of attenuated capripoxvirus virus as a heterologous vaccine has been described but is not used in SPP- and GTP-free areas where a LSDV-specific vaccine is normally used (reviewed by Boshra and coworkers[7]).

The success of control programs needs to be monitored by active serosurveillance. In endemic countries, it is difficult to differentiate between naturally infected and vaccinated animals. Seroconversion to capripoxviruses is also not always detectable using existing laboratory tests. In many countries, socioeconomic and political stability as well as logistics and veterinary support make it difficult to implement surveillance and vaccination programs.

The development of molecular-based assays has made a significant difference to the diagnosis of capripoxviruses enabling rapid genotyping and gene-based classification of viral strains and

different isolates. This facilitates rapid responses to outbreaks, improved monitoring of capripoxviruses in endemic regions, and detailed investigation of the epidemiology of the diseases.

95.1 INTRODUCTION

95.1.1 Classification

As the type species of the *Leporipoxvirus* genus in the *Chordopoxvirinae* subfamily, *Poxviridae* family, myxoma virus (MYXV) is a large, double-stranded DNA virus that replicates in the cytoplasm of infected cells. MYXV causes the generalized, frequently lethal disease, myxomatosis, in European rabbits (*Oryctolagus cuniculus*). Other leporipoxviruses include hare fibroma virus, rabbit fibroma virus (also called Shope's fibroma virus), and squirrel fibroma virus, which naturally infect various leporid and squirrel species.

95.1.2 Morphology, Genome Organization, Biology, and Epidemiology

95.1.2.1 Morphology

Electron microscopic images of shadowed MYXV or negatively stained particles show a brick or oval-shaped virus with dimensions of 286 × 230 × 75 nm.[1,2] The MYXV virion is indistinguishable from more intensively studied poxviruses such as *Vaccinia virus* (VACV).[1,3] More recent structural studies of VACV have suggested that poxviruses resemble a flattened ellipsoid or possibly barrel shape depending on the imaging method (reviewed in reference 4).

As with other poxviruses, there are two infectious forms of MYXV[5]: an intracellular mature form (MV; also called intracellular mature virus [IMV]), released by cell lysis, and an enveloped extracellular form (EV; also called extracellular enveloped virus [EEV]), which is produced by wrapping MV with a double membrane, probably derived from the Golgi or endoplasmic reticulum,[5] forming an intracellular wrapped virion. This contains virus-encoded proteins that are not present in the MV form. The outer of the double membrane layer is lost by fusion with the cell plasma membrane as the virus is exocytosed to produce the final EV.[4] EV may be retained attached to the cell membrane (CEV) or released into the extracellular fluid.

By convention, the outer component of the MV form is referred to as the viral membrane although the structure is much more complex than a typical lipid bilayer; negative-stained electron micrographs show an unstructured array of spicules termed surface tubular elements. This membrane

surrounds a peanut-shaped core containing the viral genome complexed with virion structural proteins and proteins needed for early gene expression. By thin section electron microscopy, lateral bodies are seen on either sides of the core concavity, filling the space between the core and the membrane.[4]

No specific cellular receptor has been identified, and it seems likely that MYXV is able to enter cells by binding to common cell membrane molecules followed by uptake in vesicles.[6] VACV can enter cells by direct fusion at the cell membrane or by triggering uptake by macropinocytosis or endocytosis. For EV, rupture of the EV envelope, triggered by binding to molecules such as cell surface glycosaminoglycans, is needed to allow the MV membrane to either fuse with the cell plasma membrane or trigger uptake.[7–9]

Replication of poxviruses occurs entirely within the cytoplasm. Early genes are transcribed from within the virus core by virus-encoded RNA polymerase. Uncoating of the virus core is followed by DNA synthesis and intermediate and late gene expression. Virus assembly occurs in "factories" within the cytoplasm. The replication cycle of MYXV in cell culture takes approximately 16 h.[5]

95.1.2.2 Genome Organization

The genome of the Lausanne reference strain of MYXV (GenBank AF170726.2) consists of 161,777 nucleotides of double-stranded DNA with closed single-stranded hairpin termini and terminal inverted repeats (TIRs) of 11,577 nucleotides.[10,11] There are 158 unique open reading frames (ORFs) annotated, 12 of which are duplicated within the TIRs.[10,11] By convention, genes are numbered from the left-hand end of the genome with the direction of transcription indicated by L (left) or R (right); genes within the TIR are indicated by L/R since the direction of transcription is reversed in the L and R TIR, for example, *M001L/R*, proteins are indicated by omitting the direction of transcription, M001. Like other poxviruses, genes encoding replication and structural proteins tend to be in the center of the genome and conserved with other poxviruses, while genes encoding the large number of proteins involved in immunosuppression or host-range functions tend to be toward the termini and are less conserved.

95.1.2.3 Natural History

MYXV naturally infects the South American tapeti or forest rabbit (*Sylvilagus brasiliensis*), in which it induces a cutaneous fibroma at the inoculation site. Virus adheres to the mouthparts of biting arthropods, such as fleas and mosquitoes, probing through the virus-rich epidermis overlying the fibroma and is mechanically transmitted by these vectors; the virus does not replicate in the vector, and there is no vector specificity.[12] MYXV appears to be present throughout the natural range of the tapeti in South America and into Central America.[13] Although largely innocuous in its natural host, in European rabbits, MYXV causes the lethal, generalized disease termed myxomatosis.

European rabbits probably evolved in the Iberian Peninsula and Southern France but were subsequently spread around Europe as semidomesticated stock, some of which reverted to the wild.[14–16] The breeds of domestic rabbit farmed for meat and fur, the various pet breeds, the rabbits used in laboratories, and wild rabbits are all *Oryctolagus cuniculus*. European rabbits were introduced to other countries such as Australia and New Zealand following European settlement where they established and became destructive pests.[15] Although European rabbits are not native to the Americas, (native leporids, such as cottontails and jackrabbits, belong to the *Sylvilagus* and *Lepus* genera) domestic breeds were introduced following European settlement and in some countries, such as Chile and Argentina, have established widespread feral populations that have attained serious pest status.[15]

Myxomatosis was first described as a novel disease occurring in laboratory rabbits, at the Institute of Hygiene in Montevideo, Uruguay, in 1896. It was one of the earliest animal diseases ascribed to a filterable virus. MYXV would have had limited significance, except as an occasional cause of disease in domestic rabbits in the Americas, but, in 1950, a South American strain of MYXV was experimentally introduced into the wild European rabbit population of Australia to evaluate its potential as a biological control.[17] The subsequent unprecedented spread and lethality of myxomatosis in Australian rabbits prompted a landholder to introduce a separate strain of South American MYXV into wild rabbits in France in 1952.[16,17] From this introduction, MYXV spread into the wild rabbit populations throughout Europe, Ireland, and Britain and into farmed European rabbits across the continent. MYXV is now endemic in Australia and Europe and has also been introduced and become established in feral European rabbit populations in Chile and Southern Argentina (outside the natural range of the tapeti).

A leporipoxvirus, closely related to MYXV, albeit with significant sequence divergence,[18] occurs in the brush rabbit (*Sylvilagus bachmani*) on the west coast of North America and Mexico. This Californian MYXV (Cal MYXV) also causes lethal myxomatosis in European rabbits but only a cutaneous fibroma in brush rabbits.[19] Another leporipoxvirus, *rabbit fibroma virus* (Shope's fibroma virus), occurs in the eastern cottontail (*S. floridanus*) in the eastern and central parts of the United States.[20] This virus induces an innocuous cutaneous lesion in immunocompetent European rabbits and has been used extensively as a heterologous live vaccine to protect rabbits from myxomatosis. More generalized disease may occur in very young rabbits or in experimentally immunosuppressed rabbits infected with rabbit fibroma virus.

95.1.2.4 Transmission of MYXV

In European rabbits, MYXV can be spread both by biting arthropods and by direct contact. It is mechanically transmitted on the mouthparts of biting arthropods, usually mosquitoes or various species of flea, which pick up the virus by probing through the virus-rich cutaneous lesions and sites such as the base of the ears and eyelids where virus replicates to high titers.[13] Other biting arthropods such as *Culicoides* midges or simuliids (black flies), lice, and mites are also potential vectors. Virus is shed in ocular and respiratory discharges and from the eroded surface of cutaneous lesions and

is readily inoculated into the nasal passages, conjunctivae, or epidermis during social interactions or fighting. The virus is not normally infectious orally, and natural aerosol transmission is inefficient.[21] Sexual transmission has been recorded and the virus may be present in semen.[22]

MYXV is only able to infect and transmit from a narrow range of leporids.[21,23] Apart from *S. brasiliensis* and *O. cuniculus*, MYXV can be transmitted by mosquitoes from experimentally infected *S. nuttalli* (mountain cottontail), *S. audubonii* (desert cottontail), and, occasionally, *S. floridanus* (eastern cottontail). The brush rabbit (*S. bachmani*) can be infected, but MYXV does not reach transmissible titers in this species.[24,25] Of these American species, only *S. floridanus* potentially overlaps with the distribution of MYXV. European hares (*Lepus europaeus*) and mountain hares (*L. timidus*) have occasionally been reported with natural myxomatosis, but this is unusual. Cal MYXV also appears to have a very restricted host range.[26,27]

95.1.2.5 Coevolution of MYXV and European Rabbits

The viruses released in Australia (standard laboratory strain, SLS) and Europe (Lausanne strain, Lu) were highly lethal with estimated case fatality rates (CFRs) up to 99.8% in both wild and domestic rabbits.[13,28] The subsequent host–pathogen coevolution has became the classic model for what happens when a novel pathogen shifts into a completely naïve host species.[29–33] Over relatively short time periods, virus strains that were moderately attenuated, albeit, still with CFRs of 75%–90%, became predominant in the field.[31] These slightly attenuated viruses allowed the infected rabbit to survive longer, thus increasing the probability of transmission. At the same time, there was intense selection pressure for rabbits with some degree of resistance to myxomatosis. This may have been aided by the emergence of moderately attenuated viruses and, in Australia, by very hot summer weather, which ameliorates the clinical disease in rabbits infected with attenuated viruses, especially if these rabbits have some genetic resistance.[34] At one study site, CFRs in wild rabbits, tested under controlled laboratory conditions with the same strain of virus, decreased from 90% to 26% within 7 years, representing seven generations of selection.[35,36]

Field isolates of MYXV were classified into five (later extended to six) virulence grades based on CFR and average survival times in small groups of laboratory rabbits infected with low doses of virus (Table 95.1). Grade 1 viruses were of the same virulence as the originally released strains with essentially 100% CFR, whereas grade 5 viruses had CFR of <50% and were never common in the field, probably because the rabbit immune system could quickly reduce titers in the skin lesions below the threshold for efficient mosquito transmission.[28,31] Grade 3 viruses became the most prevalent in both Australia and Europe[31,37]; however, the ongoing selection for resistance in the wild rabbit population may also be selecting for a higher prevalence of more virulent viruses.

It is important to recognize that MYXV strains of different virulence grades and symptomatology are circulating in wild and domestic rabbits and that the clinical signs and disease outcomes will depend on both the virulence of the infecting virus and the genetic resistance of the rabbit. In addition, apparent virulence will be influenced by biotic factors such as age of the rabbit, nutritional status, intercurrent disease, and parasite load and abiotic factors such as environmental temperature. The clinical disease in highly resistant wild rabbits may be quite different to that in unselected domestic rabbits (see Section 95.1.3). In addition, infections with attenuated strains of MYXV in farmed rabbits can be confused with bacterial upper respiratory tract disease so that infected rabbits are not recognized and isolated, allowing ongoing transmission.[38,39]

TABLE 95.1
Virulence Grades of Myxoma Virus

Virulence Grade	Case Fatality Rate (%)	Average Survival Time (Days)[a]
1	>99	≤13
2	95–99	13–16
3A	90–95	17–22
3B	70–90	23–28
4	50–70	29–50
5	<50	n/a

[a] Survival time (ST) was transformed as $\log_{10}$(ST-8) for each rabbit; average survival times were calculated using the transformed data and then back-transformed.[13,28]

95.1.3 Clinical Features and Pathogenesis

95.1.3.1 Clinical Features

Three general forms of clinical disease can be recognized in European rabbits following infection with different strains of MYXV: cutaneous myxomatosis, amyxomatous myxomatosis, and peracute disease.

95.1.3.1.1 Cutaneous Myxomatosis

This is the classic form of the disease. Two to three days after intradermal inoculation, a cutaneous swelling develops at the inoculation site (primary lesion; also termed myxoma or tumor), which, over time, may become as much as 4 cm in diameter and 0.5–2 cm high. This is followed, over the next 2–3 days, by gradually increasing redness and swelling of the eyelid margins and swelling of the head and ears. By around 10–12 days, infected rabbits have a markedly swollen head, sometimes described as leonine; swollen ears, especially the base of the ear; blepharoconjunctivitis with swollen, closed eyelids; and copious mucopurulent discharge, and there may be hair loss from around the head (Figure 95.1). Rhinitis, with profuse mucopurulent discharge obstructing the nasal passages, causes respiratory distress characterized by stertor and gasping with the mouth open and the head and neck extended. Intense swelling of the anogenital region and, in males, of the scrotum and testes is typical. Cutaneous secondary lesions are present over the head, body, and legs (these may merge

FIGURE 95.1 Domestic rabbit with severe myxomatosis. Note the very swollen head with hair loss and swollen eyelids and ears. This rabbit has the amyxomatous form of the disease.

to form a solid mass). Ears may become so swollen that they droop rather than being upright. Erosion, weeping, and scabbing of the surface of the primary cutaneous lesion occur late in infection. Palpable lymph nodes, such as popliteal, can be enlarged. Rectal temperatures are frequently above 40°C from around 4–5 days after infection but may drop below normal prior to death.

Rabbits infected with more attenuated strains of the virus may exhibit milder clinical signs and, depending on the virulence of the virus, have a prolonged disease course often complicated by secondary bacterial infections. These rabbits can lose 15% or more of their body weight and have elevated temperatures for weeks. In survivors, gradual resolution of the clinical disease occurs over a month or so, but rabbits may be left with chronic respiratory problems. The disease in genetically resistant wild rabbits tends to resemble that in domestic rabbits infected with attenuated viruses, but resolution can be surprisingly rapid.[40–42] In some cases, the main clinical finding is multiple gray, hairless, raised fibromas.

95.1.3.1.2 Amyxomatous Myxomatosis

Infected rabbits have the swollen head and ears, blepharoconjunctivitis, rhinitis, nasal obstruction, and discharge together with anogenital swelling that are typical of myxomatosis. However, there are no, or very few, cutaneous lesions apart from the primary inoculation site, but this is absent if the rabbits were infected intranasally or conjunctivally.

Virus strains causing this amyxomatous type of disease were originally described in France and Belgium[43–47] and are reported as common in rabbit production units in Spain and Italy.[22] Some Australian field strains, characterized from the 1990s onward, cause a similar disease in domestic (nonresistant) rabbits. It has been speculated that amyxomatous strains of MYXV are adapted to respiratory transmission because of the absence of cutaneous lesions; however, this has not been demonstrated.[43,46] Whether titers of virus in the swollen base of the ears and eyelids are compatible with vector transmission has not been reported. As with the cutaneous form of the disease, viruses of very different virulence grades are present in the field, and secondary bacterial infection may be important in the pathogenesis and outcome of the infection.[46,47] Prolonged incubation periods, up to 20 days, have been reported with some strains of amyxomatous viruses. This may allow transmission of virus to uninfected rabbit farms by transfer of apparently healthy rabbits or vaccinated stock that were incubating the disease prior to vaccination.[48,49]

95.1.3.1.3 Peracute Disease

Rabbits are found dead or moribund with minimal clinical signs of myxomatosis 7–12 days after infection. There may be slight to moderate swelling of the head and base of the ears and some swelling of the eyelids and anogenital region, but generally there is little or no ocular or nasal discharge. The lesion at the inoculation site is flat, poorly differentiated from the surrounding skin, and often barely visible; on sectioning it may be only 2–4 mm thick, usually white in color; sometimes the overlying epidermis forms a visible red line. Convulsions at or around death may be seen, and death is often due to pulmonary edema. Rectal temperatures are very variable, sometimes elevated around day 4–6 but only for a short period. Genetically resistant wild rabbits infected with these strains tend to develop more typical myxomatosis.[41] Very young rabbits infected with cutaneous strains of MYXV die with minimal clinical signs of myxomatosis. Cal MYXV strains can cause peracute death in both laboratory and genetically resistant wild rabbits.[28,50]

95.1.3.2 Pathogenesis

Detailed pathogenesis studies of MYXV infection in European rabbits have been done with virulent cutaneous virus such as SLS, the Lu strain, attenuated cutaneous virus, the Cal MYXV MSW strain, and many single-gene knockout viruses derived from Lu[40,50–54]; reviewed in references 32, 33, 55, and 56. There have also been studies on amyxomatous viruses.[43,44,46,47]

Virus inoculated intradermally initially replicates in major histocompatibility complex (MHC)-II-positive cells at the epidermal/dermal interface and then spreads to the overlying epidermis inducing epidermal hyperplasia and hypertrophy with loss of architecture and disruption of the underlying dermis, forming the raised primary lesion. This can be apparent from 2 to 4 days after inoculation depending on the virus strain and the genetic resistance of the rabbit. At the same time, virus spreads to the draining lymph node where it can be demonstrated in the cells of the subcapsular sinus and then in lymphocytes of the cortex.[40,53,54] From here, virus disseminates in lymphocytes to the spleen and lymph nodes, mucocutaneous sites such as eyelids and nasal mucosa, and cutaneous sites, particularly the base of the ears, but secondary cutaneous lesions can be found all over the body. Virus is also found in the liver, lungs, and testes and, at low titers, in the central nervous system.[57,58] Cal MYXV has been reported to reach high titers in brain[28] but this was not observed in another study.[50]

MYXV causes profound immunosuppression of European rabbits with loss of lymphocytes from the lymphoid tissues and anergy in the surviving lymphocytes together with downregulation of macrophage responses.[59–61] Specific viral proteins stimulate cell growth and disrupt intercellular and intracellular inflammatory and antiviral pathways, including type I and type II interferon responses, tumor necrosis factor (TNF), chemokine signaling, NFκB signaling, MHC-1 presentation, inflammasome signaling, and cell death pathways.[32,55,56] Death typically occurs 10–14 days after infection with highly virulent virus. The direct cause of death is unclear as there is no critical pathology in any of the major organs.

95.1.4 Diagnosis

Presumptive diagnosis of myxomatosis can be made on clinical examination, potentially combined with gross autopsy data and supported by histological evaluation. Definitive diagnosis relies on demonstration of virus or viral DNA in samples from clinically affected animals or demonstration of specific IgM or a rising IgG titer (Table 95.2).

TABLE 95.2
Diagnostic Procedures for Myxomatosis

Procedure	Interpretation/Limitations
Clinical examination/autopsy	Indicative in cutaneous form; may be equivocal in amyxomatous or peracute cases.
Histopathology	Epidermal cell hyperplasia, hypertrophy, and degeneration with disruption of underlying dermis in cutaneous form. Eosinophilic inclusions may be present in cytoplasm of epidermal cells.
Immunostaining (immunofluorescence, immunoperoxidase, biotin/streptavidin/peroxidise, etc.)	Specific antiserum required; confirmatory on histological sections or impression smears.
Negative staining electron microscopy	Indicative on extracts from tissues; does not differentiate from other poxviruses.
Agar gel immunodiffusion (AGID)	Confirmatory on tissue extracts; requires specific antiserum.
Polymerase chain reaction (PCR)	Confirmatory on total DNA from tissues or conjunctival swabs.
Virus isolation	Typical cytopathic effect is indicative; confirmation by PCR, immunostaining, or AGID.
Serology (ELISA, immunofluorescence assay [IFA], plaque reduction neutralization assay [PRNA], AGID, complement fixation assay [CFA])	IgM (I-ELISA or C-ELISA) or rising antibody titer by ELISA, IFA, or PRNA together with clinical signs or history. AGID and CFA have low sensitivity.

95.1.4.1 Conventional Techniques

95.1.4.1.1 Clinical Diagnosis

Diagnosis is relatively straightforward in typical cutaneous forms of myxomatosis where the disease has progressed sufficiently for the raised skin lesions, swollen head, and anogenital edema to be apparent, and there is a history of potential exposure either from contact with infected rabbits or by insect transmission.

Differential diagnosis: Amyxomatous forms of the disease are readily confused with bacterial respiratory disease or blepharoconjunctivitis. Peracute forms of the disease need to be differentiated from other causes of acute death such as clostridial infections, bacterial septicemia, and rabbit hemorrhagic disease.[62] Infection with *leporid herpes virus 4* is also a potential differential diagnosis because of the acutely swollen head, conjunctivitis with closed eyelids, skin lesions, anogenital swelling, and respiratory difficulty caused by this virus.[63] *Rabbitpox virus* (an orthopoxvirus derived from VACV) can cause acute death or a more protracted disease with skin rash, blepharoconjunctivitis, and orchitis. Historically, outbreaks of rabbitpox have occurred in laboratory rabbits, but it should now only be seen following experimental infection. Poisoning with sodium fluoroacetate or anticoagulants such as pindone are potential causes of acute death in wild rabbits in countries where lethal control is practiced.

95.1.4.1.2 Autopsy Findings

Swollen head, ears, eyelids, and anogenital swelling are typical. If cutaneous lesions are present, these are firm on sectioning with color ranging from red to white depending on the virus strain and stage of infection. Classic cutaneous forms have very glistening cut sections due to the mucinous nature of the swollen dermis. Lymph nodes can be grossly enlarged 3–5× their normal size and range from firm to flaccid and watery on cut section; the spleen is frequently very enlarged often 2–4× normal size. Testes and epididymides may be swollen or atrophied, depending on the stage of disease, and granulomata may be present. Other internal tissues often appear normal; however, the lungs may show evidence of pneumonia due to secondary bacterial infections, particularly with amyxomatous strains. In chronic cases, there is often complete wastage of the fat depots around the kidneys. Pulmonary edema may cause peracute deaths; massively enlarged, wet lungs with froth and fluid filling the trachea and bronchi are obvious at autopsy.

95.1.4.1.3 Histopathology

Hematoxylin- and eosin-stained sections from the cutaneous lesions or eyelids of rabbits with the cutaneous form of the disease show hyperplasia, hypertrophy, and degeneration of the epidermal cells often with vesicle formation in the cutaneous lesions. There is disruption of the underlying dermal collagen fibers and massive thickening of the dermis and subdermis by the acellular mucinous material.[51,52,54] The small blood vessels are frequently disrupted by large stellate or elongated cells termed "myxoma cells," which may also be seen throughout the dermis. Eosinophilic cytoplasmic inclusions may be

present in degenerating epidermal cells; although these are reported as best seen with fixatives such as Bouin's solution,[44] they can also be seen in formalin-fixed sections. These inclusions are distinct from the eosinophilic A–type inclusion bodies formed by some orthopoxviruses. Large numbers of heterophils (neutrophils) may be present in the underlying tissues, sometimes only in deep tissues, but lymphocytes are normally absent unless the virus is very attenuated.

Cutaneous lesions may not be identifiable in the amyxomatous forms of the disease, but when these are sectioned, the epidermal hyperplasia and degeneration are not as pronounced as in the cutaneous form and the underlying dermis may only be disrupted directly under the epidermis. In amyxomatous cases, typical proliferative and degenerative changes in epidermis and mucosa can often be seen in sections from the eyelids.

Lymph nodes may be completely or partially devoid of lymphocytes with destruction of B cell follicles and loss of cortical lymphocytes. In some cases, proliferation of reticular cells may completely fill the node; in other cases, there may be very large numbers of heterophils present. Similar changes can occur in the spleen. Proliferation of reticular cells in lymphoid follicles has been described in the lungs together with varying degrees of pneumonitis, but frequently the lungs appear histologically normal. Proliferation of connective tissue elements and hepatic necrosis have also been described in the liver.[52]

95.1.4.1.4 Immunohistochemistry

Virus antigen can be demonstrated by immunostaining using impression smears made from primary lesions or conjunctivae or in histological sections using either frozen sections or antigen retrieval on fixed and paraffin-embedded sections[22,50,54,64] (Figure 95.2). Nonspecific autofluorescence, especially around hair follicles, can be a problem, so it is important to use appropriate controls.

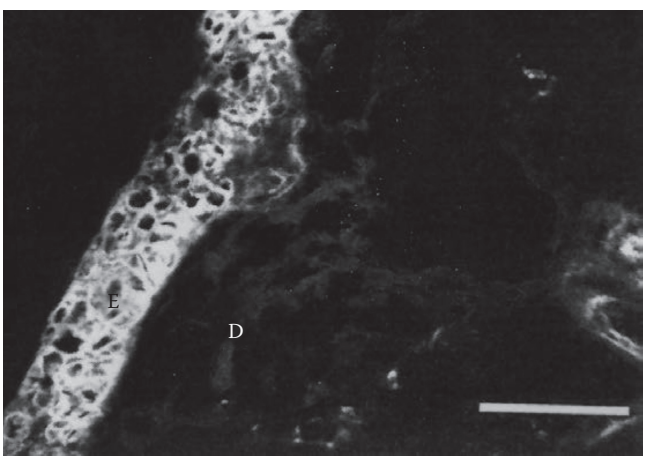

FIGURE 95.2 Immunofluorescent demonstration of MYXV antigen in the epidermis of a primary cutaneous lesion; E: epidermis; D: dermis; scale bar 100 μm. (Reproduced from *Virology*, 277, Best, S.M., Collins, S.V., and Kerr, P.J., Coevolution of host and virus: cellular localization of myxoma virus infection of resistant and susceptible European rabbits, 76–91. Copyright 2000, with permission from Elsevier.)

95.1.4.1.5 Electron Microscopy

Poxvirus particles can be demonstrated by negative staining of extracts from cutaneous tissues[22] or in thin sections from infected tissues. These cannot formally be differentiated from rabbitpox virus or rabbit fibroma virus without further immunological or DNA-based procedures.

95.1.4.1.6 Virus Isolation and Culture

MYXV can be readily isolated from tissue samples collected at autopsy or from clinical samples (see Section 95.2.1). Despite its narrow host range, MYXV replicates in cell lines derived from a number of species including: monkey (Vero, CV-1, BGMK), human (Hela), avian (chick embryo fibroblasts), and rabbit (RK-13, SIRC). It can also be grown and titrated on the chorioallantoic membrane of fertile hen eggs. The cytopathic effect (CPE) seen depends somewhat on the cell line and multiplicity of infection (MOI). At low MOI on RK-13 cells, proliferative raised foci develop 24–48 h after infection. At later times, or at high MOI, multinucleate syncytia may be the most prominent feature with progression to cell death and loss of monolayer integrity. The virus is strongly cell associated, and the spread in the culture is mostly to adjoining cells. Some strains may take up to 7 days to show CPE.[22] Confirmation of MYXV can be achieved by immunostaining, polymerase chain reaction (PCR; see Section 95.1.4.2), or purification of viral DNA and restriction endonuclease digest to show the typical MYXV restriction profile.[65,66] Viral antigen can also be demonstrated by the formation of specific precipitin bands using agar gel immunodiffusion (AGID) of cell extracts against specific antiserum. Detailed methods for preparing MYXV stocks, including gradient purification of virus, are given in reference 67. MYXV can be titrated by plaque assay (Vero cell monolayers) or focus assay (RK-13 cell monolayers).

95.1.4.2 Molecular Techniques

PCR and real-time PCR have been used for the molecular diagnosis of MYXV DNA from tissue materials such as lesions from eyelids, ear, internal organs, nasal and conjunctival swabs, or semen.[41,68–70] PCR is highly sensitive and very specific if the primers are designed properly. The high sensitivity can cause false positives unless stringent steps are taken to avoid contamination with MYXV DNA from other sources during sample preparation and setting up the reaction mix. Some live vaccines used in Europe, for example, the Borghi strain, are derived from the MSD strain of Cal MYXV, which means that oligonucleotide primers for MYXV may not work for these viruses. Specific sequences are available.[18,69] The French SG33 vaccine strain has a large deletion, and primers need to be designed to avoid this, plus there has been recombination between this strain and a Cal MYXV strain.[18,71] Specific primers for these strains are available.[22] Real-time PCR assays have also been published.[68,70] DNA sequence analysis can be used to confirm the identity of PCR products.

Restriction endonuclease analysis of purified genomic DNA has been used for epidemiological analysis of MYXV,[66,72] and PCR amplification of strain-specific restriction fragment length polymorphisms has been used for field epidemiological studies.[41,66,73,74] Genomic sequencing and phylogenetic analysis are now becoming readily available for evolutionary studies.[75,76]

95.2 METHODS

95.2.1 Sample Collection and Processing

MYXV can be readily cultured from cutaneous lesions or eyelids collected from clinical cases at autopsy. For field collection, samples should be taken into sterile 5 mL screw-cap plastic vials containing 1:1 (v/v) glycerol/phosphate-buffered saline (PBS; pH 7.2) (antibiotics/antifungals can also be included). The virus is relatively robust, but samples need to be kept cool, preferably frozen, prior to further processing. Tissues from the liver, lung, testis, lymph node, and spleen may also be used for MYXV isolation and have the advantage that they can be collected using sterile technique; virus titers can be quite low in these tissues and secondary bacteria can be present.

To release the virus, tissues are washed with PBS and hair removed using sterile scissors. Impression smears can be taken for immunohistochemistry at this stage, and small subsamples (10–20 mg) of the virus-rich epidermis collected for DNA extraction for PCR diagnosis. Extracts of the virus-rich epidermis can also be used for AGID against specific antiserum to demonstrate virus antigen or for electron microscopy. For virus isolation, the tissues are minced with scissors and can be ground with sterile sand, disrupted using a magnetic bead beater, or simply minced finely and then freeze–thawed two to three times or sonicated to disrupt cells. This is followed by low-speed centrifugation to clarify the supernatant. Passing the clarified supernatant through a 0.45 μm filter can reduce bacterial and fungal contamination; a 0.22 μm filter is effective at removing contaminants but will exclude a large proportion of the virus.

Virus isolation can be attempted from whole blood or, preferably, buffy coat, but virus titers may be very low. Cells need to be freeze–thawed or sonicated to release the virus; there is little or no virus in serum.

For nonlethal clinical sampling, conjunctival or nasal swabs are probably the simplest samples to collect; using a saline-moistened swab causes minimal distress to the animal. It is important to actually collect mucosal cells onto the swab not just the mucopurulent discharge. For processing, cut off the swab tip into a 1.5 mL capped plastic centrifuge tube containing approx 1 mL of minimal essential medium (MEM) or PBS plus 5× antibiotics/fungizone (penicillin 500 U/mL, streptomycin 500 μg/mL, fungizone [amphotericin B] 1.25 μg/mL, 5× P/S/F), vortex vigorously, or squeeze the swab with an applicator stick. Then centrifuge for 5 min in a microcentrifuge at high speed to pellet cells, remove the swab (but retain for further processing if necessary) and either freeze–thaw or sonicate the cell pellet, and then vortex, centrifuge briefly to clarify, and inoculate the supernatant into cell culture. DNA can also be extracted from the cell pellets for PCR diagnosis.[41] Punch biopsy of cutaneous lesions or needle biopsy of eyelids can be used for virus isolation or PCR (or AGID), and as noted earlier, buffy coat could be used, particularly in the acute phase of the disease, but it is less reliable.

95.2.2 Detection Procedures

95.2.2.1 In Vitro Culture of MYXV from Primary Samples

The following procedure is for RK-13 cells; however, other cell lines (Vero, SIRC, BGMK, CV-1) can be used for the isolation of MYXV using the same method. Seed cells in a T25 flask at approximately 1.4×10^6 cells to allow it reach 95% confluence after 24 h. Cells are cultured in MEM containing 10% fetal calf serum (FCS) at 37°C in an atmosphere of 5% CO_2/95% air.

Remove the medium from the cell monolayer and add 1–2 mL of the sample supernatant in 5× P/S/F and allow to adsorb for 60 min in the incubator. While not essential, removing the inoculum and washing the monolayer twice with PBS after adsorption can help to reduce contamination. Add 5 mL MEM + P/S/F and incubate at 37°C with 5% CO_2 (MEM supplemented with as little as 2% FCS can be used for maintenance once monolayers are confluent; RK-13 cells will tolerate at least 5× P/S/F). An uninfected control monolayer is also useful. On RK-13 cell monolayers, small proliferative, raised foci can be seen as early as 24 h after infection and should be readily seen by 48–72 h. With low-virus concentrations, there may be very few foci. With very high-virus concentrations, large syncytia may be seen instead of foci. Note that normal, uninfected RK-13 cells spontaneously form small syncytia as they age. If no CPE is observed after 5–7 days, a blind passage is usually performed: freeze–thaw the cells twice and centrifuge the suspension at $1500 \times g$ for 5 min and use 1–2 mL of the supernatant. It can be worthwhile reprocessing the original sample, and repeating the infection as the concentration of viable virus in poorly handled samples or samples collected late in the course of the disease may be very low. If bacterial or fungal contamination is a problem in the cell culture, it is often possible to rescue the virus by washing the monolayer several times with PBS + 5× P/S/F, freezing/thawing in PBS + 5×P/S/F to rupture the cells, centrifuging ($3000 \times g$, 10 min, 4°C) to remove debris, and then passing the supernatant through a 0.45 μm filter; use the filtered supernatant to infect cells as mentioned earlier using MEM + 5× P/S/F. Other antibiotic combinations can also be used.[22]

Virus identification should be confirmed by immunohistochemistry, AGID, PCR, or DNA purification.

95.2.2.2 Immunohistochemical Detection of MYXV Antigen

Immunohistochemistry to detect MYXV antigen can be performed on fixed tissue sections, frozen sections, impression smears, or on cells grown in culture. Antisera can be from

rabbits immunized against MYXV or, preferably, mouse monoclonal antibody, which has the advantage of high specificity and low background. The following protocols are for immunofluorescence assay (IFA). Protocols for immunoperoxidase staining of cultured cells, antigen retrieval on fixed tissue sections, and streptavidin–biotin–peroxidase staining have been published.[22,50]

95.2.2.2.1 Sample Preparation

Frozen sections: Slices of tissue are embedded in OCT compound (Tissue-Tek) and frozen in liquid N_2 or dry ice and stored at −80°C. Sections are cut at 4–7 μm, using a cryostat, onto poly-L-lysine treated glass slides; fixed in formol calcium (10% v/v formalin, 10% v/v 1 M $CaCl_2$, 80% v/v water), dipped in cold acetone and then chloroform/acetone 1:1 (v/v) for 5 min at −20°C, dipped in cold acetone, washed twice in PBS, and stored frozen at −80°C.[54] At least two sections for each tissue should be prepared: one for specific primary antibody, one for normal serum control; a no antibody control is also useful.

For cell culture samples, cells are grown on sterile glass cover slips in 24-well plates and infected with MYXV for 24–48 h. The cells are fixed in cold methanol or methanol/acetone 1:1 (v/v) for 5 min, washed with cold PBS (pH 7.4), and stored at −20°C prior to staining. Subsequent washing and staining can be done in the 24-well plate.

Impression smears from lesions can be made onto clean glass slides, air-dried, then fixed in methanol/acetone for 2 min at room temperature. These can be stored in the refrigerator or freezer prior to processing.

95.2.2.2.2 Immunofluorescence Procedures[54]

Thaw the slides for 20 min at room temperature and add 100 μL of blocking buffer (3% bovine serum albumin (BSA) w/v in PBS). Incubate for at least 30 min at room temperature or overnight at 4°C to reduce nonspecific staining. Wash with 1% BSA in PBS: (PBS-B).

Add 100 μL of the MYXV-specific antibody diluted in PBS-B (dilutions will need to be determined for each antiserum) onto the slide and incubate at room temperature for at least 2 h in a humidified chamber or at 4°C overnight. Wash slides with 0.01% Tween 20 v/v in PBS three times.

Apply fluorophore-labeled secondary antibody at dilution recommended by the manufacturer and incubate in the dark for 1 h at 37°C.

Wash slides with Tween 20-PBS three times and mount the slide with an antifade mounting medium. Visualize the signal using a fluorescence microscope.

95.2.2.2.3 Result Interpretation

Check the negative control sample first. If the sample with only secondary antibody but not with primary antibody gives low-background fluorescence, the signal from the sample with anti-MYXV antibody indicates the presence of MYXV in the cells or tissues.

95.2.2.3 Serological Determination of Rabbit's Immune Status

Following infection with MYXV, specific IgM antibodies are detectable as early as 6 days and have largely disappeared by 30–40 days; IgG antibodies are present from 10 to 15 days after infection and can be detected for at least 2 years.[40,77] Neutralizing antibodies can be detected by day 10 after infection in laboratory rabbits and as early as 6 days in resistant wild rabbits.[40]

Serological assays to determine the immune status to MYXV include ELISA, IFA, plaque reduction neutralization assays (PRNA), complement fixation test (CFT), and AGID. Due to the low sensitivity, CFT and AGID are not recommended.[22] Two types of ELISA are routinely used to detect MYXV-specific antibodies in rabbits: indirect ELISA (I-ELISA) and competition ELISA (C-ELISA). Alternative ELISA protocols[78] and protocols for IFA, CFT, and AGID are given in reference 22. It should be noted that when using these ELISAs, each laboratory should further optimize them according to the available antigen and the secondary antibody.

95.2.2.3.1 I-ELISA[77]

95.2.2.3.1.1 Preparation of Standard Sera Standard negative sera: Collect blood from rabbits that have never been exposed to MYXV and have not been vaccinated with rabbit fibroma virus. Confirm that the sera are negative prior to pooling the sera from all the rabbits. Aliquot and store at −20°C.

Standard positive sera: Vaccinate adult rabbits with live MYXV vaccine (this can be the heterologous rabbit fibroma virus or one of the commercial live homologous viruses) and challenge the rabbits with a virulent strain of MYXV 30 days later. Collect a blood sample 20–30 days after challenge to confirm that titers are high before bleeding the rabbits. Pool the sera, measure the specific antibody titer, aliquot, and store at −20°C.

95.2.2.3.1.2 Preparation of Virus Antigen The international reference MYXV strain (Lu, ATCC code VR-115) or another suitable strain can be used to prepare antigen. This antigen detects antibodies to Cal MYXV as well as MYXV.[27,50]

Infect 6–12 T175 flasks of RK-13 cells at a MOI of 0.2–0.5 and culture the cells in MEM. At this MOI, virus should be ready to harvest at 48–72 h after infection. When uniform CPE is observed, tip off the culture medium and wash the cell monolayers twice with PBS (pH 7.2), and then scrape the cells from the flask and pellet by centrifugation (800 × *g* for 10 min at 4°C). Resuspend pellets in 5 mL PBS and sonicate the cells for 2 min to release virus. Alternatively, cells can be Dounce homogenized to release the virus. Digest with DNase 1 (25 μg/mL—Sigma DN-25) and RNase A (50 μg/mL—Sigma R-4875) at 37°C for 30 min with frequent agitation. Pellet the virions by centrifugation (250,000 × *g*, 20 min at 4°C) through a step gradient formed by overlaying 10% of T10 dextran over the same volume of 36% sucrose,

both solutions in TE (10 mM Tris, 1 mM EDTA, pH 8.0). Resuspend the pellet in 1 mL PBS. Repeat the gradient centrifugation step. Resuspend the pellet in 0.5–1.0 mL PBS, aliquot, and store frozen at –20°C as antigen stock. Virus titers in the antigen should be around10^9 pfu/mL.

To establish the dilution at which to use the antigen in the ELISA, the antigen stock is titrated against a positive reference serum to produce an optical density (OD) of 1.0 at a serum dilution of 1/100.

95.2.2.3.1.3 ELISA Protocol This protocol was optimized with horseradish peroxidise (HRP)–conjugated secondary antibody and using ABTS (2,2-azino bis 3-ethylbenzthiazoline sulfonate) as the chromagen. Other chromagens could be used as per the manufacturer's specifications.

Diluted MYXV at pretitrated dilution in 50 µL of PBS (pH 7.2) is added into each well of 96-well plates and incubated for 2 h at 37°C, followed by three washes with 5% (w/v) skim milk powder in PBS (PBS/M). Block plates with PBS/M overnight at 4°C.

Centrifuge rabbit sera at 13,000 × *g* in a microcentrifuge for 5 min then serially dilute in PBS/M. Add 50 µL per well at minimum dilution of 1/50. Standard positive and negative sera should be included in each assay. Empirically, the centrifugation step reduced background in the assay.

Incubate plates for 2 h at 37°C, wash three times with PBS/T (PBS with 0.05% v/v Tween 20). Add 50 µL of HRP-conjugated antirabbit IgG or antirabbit IgM (for detection of IgM antibody) diluted in PBS/M (as previously optimized) and incubate for 30 min at 37°C.

Wash plates six times with PBS/T. Add 100 µL of ABTS (2,2-azino bis 3-ethylbenzthiazoline sulfonate, 1 mg/mL) mixed with H_2O_2 (0.06%) in 0.1 M citrate–phosphate buffer (pH 4.0).

Incubate at room temperature for 20 min and read absorbance at 405 nm on a microplate reader. The reading on wells containing only antigen and substrate is set as zero.

95.2.2.3.1.4 Result Interpretation Results can be reported as either the OD_{405} nm at a dilution of 1:100 or as a titer (the last dilution reciprocal to a positive reading) for each serum. In the original work, the OD_{405} nm cutoff value for negative serum was set at 0.13 based on the results with a large number of negative sera and positive at 0.28 based on the results with known positive sera. Values between 0.13 and 0.28 were regarded as equivocal.[77]

95.2.2.3.2 Competition ELISA[22]

The OIE Reference Laboratory for Myxomatosis uses a C-ELISA. The Reference Laboratory can supply the main reagents for the MYXV C-ELISA in a kit format that includes detailed methods and interpretation.

95.2.2.3.3 Plaque Reduction Neutralization Assay

The PRNA is considered to be the "gold standard" for detecting and measuring antibodies to MYXV.[22]

95.2.2.3.3.1 Procedure[77]

Seed Vero or RK-13 cells in 6-well plates and allow to grow up to 90%–100% confluence as for a standard plaque assay. The same procedure can be used in a 12-well-plate format.

Rabbit serum is heated at 56°C for 30 min to inactivate complement then diluted in twofold intervals from 1/10 to 1/640. Mix 150 µL of each antibody dilution with an equal volume of MYXV diluted to contain approximately 300 pfu. This can be done in a 96-well plate. Incubate at 37°C for 1 h. Controls are incubated with normal serum at 1:10 and 1:100 dilution or no serum.

After removing medium from the 6-well plates, add 100 µL aliquots of each dilution onto duplicate monolayers and adsorb for 60 min at 37°C, 5% CO_2; 2.5 mL of medium is added to each well and the cells are incubated for 4–5 days at 37°C 5% CO_2 (MEM + 2% FCS can be used to overlay the confluent monolayers; 1.5% carboxymethyl cellulose can be added to the overlay medium but is not required). Foci can be readily seen by eye by around 4 days.

Remove medium from the plates and add approximately 1 mL of 0.1% crystal violet in 15%–20% ethanol into each well (stain can be made up using Sigma HT901, 2.3% crystal violet in 20% ethanol: 20 mL crystal violet plus 70 mL ethanol plus 410 mL water). Allow to stain for 15–60 min; gently wash the wells with tap water and air-dry. Count plaques/foci by eye or with a dissecting microscope. Vero cells tend to produce small clear plaques; RK-13 cells produce foci.

95.2.2.3.3.1 Result Interpretation Titer of each serum is calculated as the reciprocal of the last dilution of serum reducing plaque numbers by >50% compared with controls. Some workers prefer to report 80% neutralization titers.

95.2.2.4 PCR Amplification of MYXV DNA

95.2.2.4.1 Preparation of MYXV DNA

Extraction of total DNA from tissues or virus-infected cells can be readily achieved with commercial DNA purification kits following the manufacturer's instructions or using sodium dodecyl sulfate (SDS)–proteinase K digestion followed by phenol–chloroform extraction and ethanol precipitation.[22,41] Extracted DNA is stored at –20°C.

95.2.2.4.2 PCR Procedure

The *M080L* gene (nucleoside triphosphatase) is highly conserved, with no mutations in MYXV isolates sequenced to date[76]; the following primers work in both conventional and real-time PCR and amplify a 126 bp product: M080F: 5′-TATCAAACAACCTCCGCATACC-3′; M080R: 5′-CTCCCATAACGCTTCCGAC-3′.

PCR mixture: 10× PCR buffer, 2.5 µL; 10 mM dNTPs, 0.5 µL; 10 µM forward primer, 0.5 µL; 10 µM reverse primer, 0.5 µL; 50 mM $MgCl_2$, 0.25 µL; template DNA, 100–250 ng; Taq DNA polymerase, 0.25 µL; add H_2O to 25 µL. Gently mix the reaction. Collect all liquid to the bottom of the tube by brief centrifugation. Use H_2O instead of DNA template in the negative control tube and MYXV DNA as positive control.

PCR cycle: Initial denaturation at 98°C for 30 s; 30 cycles of 98°C for 10 s, 55°C for 30 s, and 72°C for 2 min; final extension at 72°C for 10 min and hold at 4°C.

Gel electrophoresis: Take 10 µL of PCR product and mix with 2 µL of 6× loading dye and load onto a 1% agarose gel containing a suitable DNA stain (e.g., GelRed or SYBR Green). A suitable size ladder should also be run (e.g., 100 bp ladder). Electrophorese for 20 min at 80 V and examine with an appropriate UV source to detect the specific viral band. Gels can be poststained if preferred.

95.2.2.4.3 Result Interpretation

There should be no specific band in the negative control sample. By using a DNA ladder as standard marker, a band of 126 bp in the samples is indicative of MYXV DNA.

95.2.2.4.4 Preparation of Genomic DNA from MYXV

The following protocol is adapted from reference 79; it yields 2–5 µg of clean viral DNA suitable for next-generation sequencing or restriction enzyme analysis and has the advantage of being simple to perform without requiring ultracentrifugation. An alternative protocol is given in reference 65. Detailed protocols for gradient purification of MYXV are provided in reference 67.

Infect 4× T175 flasks of 90%–100% confluent RK-13 cells at an MOI of 0.2. Incubate until confluent CPE is present but before large numbers of cells are lost. This usually takes 2–4 days. [Some field isolates appear to spread poorly in RK-13 cells, for these viruses, using a higher MOI (0.5–1) will often yield sufficient virus.]

Tip off the medium from the flasks into 10% bleach solution (or other suitable disinfectant), and gently wash the monolayers 2–3× with PBS (pH 7.4). Scrape the cells from the plastic and transfer to a sterile 50 mL centrifuge tube, then pellet the cells by centrifuging at 2000× *g* for 10 min at 4°C. Tip off the supernatant, and drain the tube. Resuspend the cells in 9 mL of 10 mM Tris (pH 7.5). Leave on ice for 20 min and then rupture the cells by pipetting up and down with a 10 mL pipette 50–100 times.

Centrifuge at 2000 × *g* for 10 min at 4°C. Carefully remove the supernatant into a clean 50 mL centrifuge tube, add 1 mL 10× DNase I buffer (100 mM Tris pH 7.5, 25 mM $MgCl_2$, 5 mM $CaCl_2$), 200 µL DNase I (2.5 mg/mL: Sigma DN-25), and 50 µL RNase A (10 mg/mL; Sigma R-4875). Vortex the tube briefly and incubate at 37°C for 1–2 h with occasional mixing. Total virus levels of $>10^9$ pfu should be obtained from the preparation.

Add 2 mL 10 mM Tris (pH 7.5) and 3 mL of 40% (w/v) polyethylene glycol in PBS. Vortex to mix thoroughly and leave at 4°C for 1–2 h or overnight. Centrifuge at 3000 × *g* at 4°C for 60 min to pellet the virus. Carefully tip off the supernatant and drain the tube—it is important to remove as much of the polyethylene glycol (PEG) as possible.

Resuspend the pellet in 150 µL of 1× DNase I buffer (if necessary can use 300 µL but will need to then split into two tubes for subsequent steps) and transfer the suspension to a sterile 1.5 mL tube. Add 20 µL DNase I, vortex briefly to mix and incubate at 37°C for 60 min. Heat the tube at 75°C–80°C for 10–15 min to inactivate the DNase I then cool on ice.

We then extract DNA using the Masterpure DNA kit (Epicorp) but proteinase K/SDS digestion followed by phenol/chloroform extraction and ethanol precipitation can also be used.

95.3 CONCLUSION AND FUTURE PERSPECTIVES

Myxomatosis remains a significant disease of rabbit production and wild rabbits in Europe and of wild rabbits in Australia. It also affects domestic European rabbits and feral rabbits in countries where it is endemic or has been established. MYXV has also become a model for understanding immunology: the virus encodes multiple proteins that manipulate cells and inflammatory and immune responses.[32,55,56] Some of these proteins have been demonstrated to have potential as inflammatory modulators in clinical models.[80,81]

Like other poxviruses, MYXV is readily engineered to express foreign proteins and can induce an immune response to these proteins in rabbits[82] and other species in which it does not replicate.[83] It has been investigated as a means of delivering immunocontraceptive antigens to rabbits as means of population control.[84] Recombinant MYXV expressing the rabbit hemorrhagic disease virus capsid protein have been developed and tested in the field and commercialized as a combined live vaccine against myxomatosis and rabbit hemorrhagic disease.[85,86] A further area of active research is the possible use of MYXV in human cancer therapy.[87]

The coevolution of MYXV with the European rabbit has formed the bedrock of much of the thinking on host-pathogen evolution over the last 50 years.[29,30] MYXV has now been evolving in European rabbits for 65 years. Different forms of the disease have become apparent but whether these have altered transmission mechanisms has not been clearly demonstrated. Genomic sequencing studies indicate that in these large complex DNA viruses there are multiple pathways to virulence and attenuation.[75,76] Further evolutionary studies should be aimed at teasing out the molecular basis of the adaptations that have occurred in the rabbits and the virus.

96.1 INTRODUCTION

There have been some reports on the emergence of human infections by pox viruses since smallpox was eradicated globally in 1979 [1]. However, different pox viruses such as cowpox virus (CPXV), buffalopox virus (BPXV), and vaccinia virus (VACV) (genus *Orthopoxvirus* [OPV]) and orf virus, bovine papular stomatitis, and pseudocowpox (genus *Parapoxvirus*) can cause very similar lesions in cattle and animal handlers [2]. In general, OPVs carrying genes responsible for host immune evasion pose a threat to livestock and humans as potential biowarfare agents.

As type species of the genus *Orthopoxvirus*, VACV causes only mild complications in humans. Given that VACV and variola virus (VARV), the causative agent of smallpox, are mutually immunogenic, VACV was used as a vaccine against smallpox worldwide by mass immunization strategy promoted by the World Health Organization, which led to the eventual eradication of smallpox.

Camelpox is considered as an emerging public health threat during this decade due to increased cases and outbreaks in animals and humans [3–5]. Camelpox is a contagious, often sporadic, and notifiable skin disease of camelids and is socioeconomically significant as it incurs considerable loss in terms of morbidity, mortality, loss of weight, and reduction in milk yield and confined to camel-rearing belts particularly in developing countries [6]. The camelpox virus (CMLV) is genetically closely related to VARV and has gained much attention from researchers due to its recent emergence in humans [3].

Cowpox is a zoonotic OPV infection caused by CPXV, which is closely related to VACV. It is most commonly found in animals other than bovines such as rodents and cats. Clinically, cowpox is similar but milder than smallpox and transferrable to humans causing mild localized skin lesions. CPXV was used initially to control smallpox and remains prevalent in Europe [7,8].

Buffalopox is another emerging and reemerging OPV infection due to BPXV. Being a close relative of VACV, BPXV causes mild to severe skin lesions in buffaloes, cows, and humans [9]. Monkeypox is yet another zoonotic OPV infection caused by monkeypox virus (MPXV). It has been confined to West and Central Africa for several decades where the rodents and squirrels act as reservoirs [10]. However, the

disease recently emerged in the United States through imported wild rodents from Africa. Monkeypox is clinically very similar to that of ordinary forms of smallpox, including flu-like symptoms, fever, malaise, back pain, headache, and characteristic rash [11].

Globally, emergence and reemergence of vaccinia-like viruses (VLVs) in Brazil, and BPXV in Egypt, Indonesia, India, Nepal, and Pakistan constitute a public health risk [2,12]. Recent outbreaks of zoonotic camelpox and buffalopox in developing countries like India are of particular concern [2–5]. The nature of occurrence, mode of transmission by contact, difficulty in detection, and identification make OPV as potential biological or bioterror weapon like smallpox virus, creating panic and fear among common people [13]. The phylogenetic relationships, ecology, and host range of OPVs such as smallpox (VARV), MPXV, CPXV, VACV, and CMLV as well as the pattern of their evolution suggests that a VARV-like virus could emerge in the course of natural evolution of modern zoonotic OPVs [14].

OPVs have gained much attention from researchers due to close genetic relatedness to VARV and carrying genes responsible for host immune evasion mechanisms. Effective control of any infectious disease warrants diagnostic, epidemiological, and prophylactic studies. Although the disease can be diagnosed based on clinical features, the similar confusing skin lesions necessitate identification, detection, and differentiation of the different OPV infections (CMLV, BPXV, CPXV, MPXV infections, etc.) by molecular techniques. Further, novel highly sensitive and specific techniques would be useful in the identification of emerging and reemerging viruses, thereby therapeutic, prophylactic, preventive measures would be applied on proper time to curtail further spread of OPV infections like other zoonotic diseases. There is an obvious need to coordinate international control efforts over the outbreaks to zoonotic OPV infections in various countries. This will help provide a rapid response and prevent OPV infections from evolving into epidemics.

In this chapter, a comprehensive note on camelpox, cowpox, buffalopox, and other OPVs with particular reference to their classification, biology, epidemiology, pathogenesis, diagnosis, and prevention will be presented.

96.1.1 Classification, Morphology, and Physico-Biochemical Properties

The genus OPV is one of the eight genera in the subfamily *Chordopoxvirinae*, family *Poxviridae* [15]. Members of the genus include several pathogens of veterinary and zoonotic importance—VACV, CPXV, CMLV, VARV, MPXV, BPXV (a variant of VACV), ectromelia virus, rabbitpox virus, taterapox virus, North American OPVs (volepox virus, raccoonpox virus [RCNV], and skunkpox virus)—and an unclassified OPV species, Uasin Gishu disease virus [16,17]. Recently, pox-like infections caused by VACV-like agents affecting cattle and humans, Cantagalo [18] and Aracatuba viruses [19], were also reported from Brazil [12].

Morphologically, OPVs are enveloped brick-shaped large viruses (350 × 270 nm). The average size of the virion estimated by electron microscopy (EM) is 224 × 389 nm [15,20]. The size of BPXV isolates BP Giza 72 (Egyptian) and BP4 (Hisar, India) was reported to be 270 × 700 × 100 Å [9]. There were no differences in appearance between Indian and Egyptian isolates neither of BPXV nor between BPXV and VACV.

An orthopox virion consists of an envelope, outer membrane, two lateral bodies, and a core. It is brick-shaped and the outer membrane is covered with irregularly arranged tubular proteins. The different OPV species cannot be distinguished by means of EM.

OPVs are ether resistant but chloroform sensitive, whereas it is sensitive to both acidic (pH 3–5) and alkaline (pH 8.5–10) conditions [21]. The virus can be destroyed by either autoclaving or boiling for 10 min and ultraviolet rays in a few minutes [22]. In general, it is well recognized that poxvirus virions show high environmental stability (strong tolerance to high temperatures, pH, and chemicals) and can remain contagious over several months. This feature is enhanced by the materials (crusts, serum, blood, and other excretions) in which the virus is released [23].

96.1.2 Genome, Biology, and Epidemiology

96.1.2.1 Genome

The OPV genome contains a single, linear, double-stranded DNA molecule with a size of approximately 200 kb, the ends of which are connected by covalent links (terminated by a hairpin loop) and replicates in the cytoplasm [15]. The genome is AT-rich (66.9%) having cross-links that join the two DNA strands at both ends. The end of each DNA strand has long inverted tandem repeats that form single-stranded loops. The central region of the genome contains genes that are highly conserved among all sequenced OPVs [24]. The OPV genes are tightly packed with little noncoding sequences. The genome of the poxviruses encodes 150–200 different proteins. Most genes at each terminus within 25 kb of the genome are transcribed outward toward the terminus and are variable in nature coding for host range, virulence, and immunomodulation, whereas the genes within the center of the genome transcribed from either DNA strands are of highly conserved and code for proteins involved in viral replication like RNA transcription, DNA replication, and virion assembly.

Molecular details about the genome structure and phylogenetic analyses of some selected genes indicate that CMLV is clearly distinct from VARV and VACV. Among the OPVs, CPXV possesses the largest genome (~224–228 kb) [25] and possibly infects the widest range of host species [26]. The extensive phylogenetic analysis showed that CPXV strains sequenced clearly cluster into several distinct clades, some of which are closely related to VACVs while others represent different clades in a CPXV cluster. Particularly, one CPXV clade is more closely related to CMLV, taterapox virus, and VARV than to any other known OPVs [25]. CPXV is rodent

borne with a broad host range and contains the largest and most complete genome of all poxviruses, including parts with high homology to VARV (smallpox).

BPXV is closely related to VACV vaccine strains by sequence and phylogenetic analyses based on structural protein genes including H3L, A27L, D8L, B5R, and nonstructural protein (H4L) homologue genes [9]. It showed that among OPVs, BPXV shared 97.2%–98.9% and 94.6%–98.7% sequence similarity with VACV at the nucleotide and amino acid levels, respectively. Other VLVs reported from Brazil also showed that they are closely related to VACV than other OPVs. Aracatuba virus showed 95.7%–96.4% identity with VACV, in comparison to 97.2%–98.9% sequence identity of BPXV isolates with VACV strains. However, BPXV isolates appeared to be more closely related to VACV than Aracatuba virus to VACV [9].

96.1.2.2 Biology

Unlike other DNA viruses, poxviruses replicate in the cytoplasm of infected cells in so-called virus factories (Guarnieri inclusion bodies). Originally, four different infectious virus particles can be distinguished during OPV replication: intracellular mature enveloped virus particles, intracellular enveloped virus particles, cell-associated enveloped virus particles, and extracellular enveloped virus particles. Both intracellular and extracellular viruses play an important role for pathogenesis. Intracellular and cell-associated viruses are involved in the spreading of the virus from cell to cell, whereas viruses released from the cell enable the dissemination within the infected organism. The growth kinetics of CMLV in human embryonic lung fibroblast cells indicates that CMLV is different from VACV and CPXV [27]. CMLV appears to share biological features with other OPVs, mainly VARV. Both CMLV and VARV are restricted to a single host and induce a similar disease course [20,28]. CMLV was first regarded as an own OPV species in the mid-seventies, sometime before phylogenetic analyses were conducted [29]. Earlier, CMLV was shown to share strong similarities with VARV as both had a narrow host range and were indistinguishable in terms of pock formation on chorioallantoic membrane (CAM) in embryonated eggs, growth in cells, and low or absence of pathogenicity in various animal models [30,31]. Camels have been used as animal models of camelpox infection, mainly for evaluating the efficacy of vaccines [32–34]. Most of CMLV strains produce white pocks, flat in shape, with sizes varying between 0.5 and 1.5 mm diameters at 37°C. Most of the CMLV strains did not induce pock proliferation, necrosis, or hemorrhage, in contrast to what was observed with VACV or CPXV [35–37]. In general, cells derived from camel, lamb, calf, pig, monkey, chicken, hamster, and mouse enable the propagation of CMLV strains [35]. Other than camels, the species that have been infected successfully are monkeys and infant mice [29].

So far, most CPXV cases have occurred individually in unvaccinated animals and humans and were caused by genetically distinguishable virus strains. The ability of CPXV to infect a wide range of mammalian host is likely due to the fact that, among the OPVs, CPXV encodes the most complete set of open reading frames (ORFs) expected to encode immunomodulatory proteins. This renders CPXV particularly interesting for studying poxviral strategies to evade and counteract the host immune responses [26].

Serological studies demonstrated the cross-antigenicity among VACV, VARV, CPXV, and CMLV, but not with parapoxviruses (PPVs) and avipoxvirus infections [21,29]. The serological relationship of BPXV with VACV and CPXV has been studied by different methods and it indicated that a pattern of cross-reaction in agarose gel immunodiffusion (AGID) and immunoelectrophoresis is indicative of a closer relationship of BPXV with VACV than CPXV [9].

96.1.2.3 Epidemiology

Reports on human poxvirus infections have been rare since smallpox eradication. The main OPVs that infect humans include VARV and MPXV infections as seen in Congo and the United States, CPXV in Europe, VLVs in Brazil, and BPXV (Vaccinia variant) and CMLV infections in India. Camelpox is one of the most common contagious OPV diseases of the Old World (both *Camelus dromedarius* and *Camelus bactrianus*) and the New World camelids [17]. CMLV is considered to solely naturally infect Old World camelids [28]. The disease occurs throughout the camel-breeding areas of Africa, north of the equator, the Middle East, and Asia, as the camels are used for nomadic pastoralism, transportation, racing, and production of milk, wool, and meat purposes [38]. Of note, camelpox has never been reported in Australia, even though camel farming is practiced [28], and has not been seen in feral camels in Australia, in wild Bactrian camels in China and Mongolia, or in New World camelids [16]. The disease has been reported initially in Punjab and Rajputana (India) [39] and later from many other countries. It has been reported in the Middle East (Bahrain, Iran, Iraq, Saudi Arabia, UAE, and Yemen), in Asia (India, Afghanistan, and Pakistan), in Africa (Algeria, Egypt, Kenya, Mauretania, Niger, Somalia, Morocco, Ethiopia, Oman, and Sudan), and in the southern parts of former USSR, where the disease is endemic [6,40]. Camelpox has been reported for the first time in two provinces named Hama and Duma in Syria [41]. In general, young camels (calves) under the age of 4 years and pregnant females appear more susceptible to camelpox [41,42]. In the recent past, the first conclusive evidence of zoonotic CMLV infection in humans (unvaccinated smallpox individuals) associated with outbreaks in dromedarian camels in northwest region of India has been reported in three human confirmed cases [3].

CPXV is distributed in Europe, west former USSR, and adjacent areas of Northern and Central Asia, with an increasing number of reports in Europe [7]. Human CPXV infections are commonly described in relation to contact with diseased domestic cats and rarely from rats [43]. Human infections usually remain localized and self-limiting but can become fatal in immunosuppressed and eczematous patients particularly children. CPXV infections in captive exotic animals have been reported to be transmitted by rodents [7]. CPXV has also been reported to infect elephant [43], llama [44], and

banded mongooses and jaguarundis [8]. However, the list of animals known to be susceptible to CPXV is still growing. Thus, the likely existence of unknown CPXV hosts and their distribution may present a risk for other exotic animals but also for the general public [8].

Buffalopox was first recorded in Lahore during 1934 in undivided India [45]. Later, regular outbreaks have been reported from different states of India [46]. It affects primarily buffaloes and occasionally cows and humans [9,40]. The disease outbreaks are reported from India, Pakistan, Egypt, Nepal, and Bangladesh. In the recent past, analysis of samples collected from cows suffering with pox-like disease in India revealed that cows suffered mostly from BPXV than CPXV based on sequence and phylogenetic analysis of HA gene [47].

VLVs are reported from Brazil. Their origin in Brazil is hypothesized to account for the usage of VACV strains during the smallpox eradication campaign and may be related to outbreaks of bovine vaccinia, namely, Cantagalo and Aracatuba viruses in cattle and humans [18,19]. Until 2010, these infections were limited to cattle and humans. However, there was an evidence of seropositivity with OPV antibodies in buffaloes, which again hypothesized to account for exposure to VACV, the only OPV known to be circulating in Brazil [48].

Human monkeypox was first identified in humans in 1970 in the Democratic Republic of Congo. Since then, the majority of cases have been reported in rural regions of the Congo Basin and western Africa, particularly in Congo [49]. In Midwest of the United States, the first confirmed report of monkeypox cases outside of the African continent has been documented during 2003. Later, it has been reported in Unity state, Sudan [50]. In Africa, human infections have been documented through the handling of infected monkeys, Gambian rats, or squirrels [51].

96.1.3 Clinical Features and Pathogenesis

CMLV and VARV cause illness in a single host species and both viruses are distinguishable. CMLV has rarely caused disease in man. Similarly, VARV is unable to cause disease in camels, although camels immunized with VARV are resistant to subsequent infection with CMLV [31]. The clinical manifestation of camelpox ranges from mild, local, and inapparent infection confined over the skin to less common but severe systemic disease, depending on the CMLV strains involved in the infection [28]. The incubation period of the disease varies from 4 to 15 days with an initial rise in temperature followed by enlarged lymph nodes and skin lesions with development of papules on labia, vesicles, pustules, and scabs [52]. In the generalized form, pox lesions may cover the entire body and even multiple pox-like lesions can be found on the mucous membranes of the mouth, respiratory, and digestive tracts [28]. In contrast to smallpox, in which pustules occur only on the skin and the squamous epithelium of the oropharynx, severely ill camels also develop proliferative poxviral lesions in the bronchi and lungs [53].

The CMLV enters commonly through the skin. However, the oronasal infection is also reported. After local replication and development of a primary skin lesion, the virus spreads to local lymph nodes leading to a leukocyte-associated viremia, which may be associated with pyrexia. Widespread secondary skin lesions appear a few days after the onset of viremia, and new lesions continue to appear for 2–3 days, at that time the viremia subsides. Like other OPVs, CMLV encodes multiple genes that antagonize or affect the antiviral host immune response by interfering with the interferon response, key proinflammatory cytokines (interleukin [IL]-1b, IL-18, and tumor necrosis factors [TNFs]), chemokines, and complements [16].

Cowpox causes skin eruptions with lesions occurring principally on the udder and teats in milking cattle. Human infection may occur while milking an infected animal and also from rats and mice bite [54]. In humans and nonhuman primates, lesion develops facial swelling, gingivitis, and vesicopapules followed by scabs with an incubation of 1 week. In herbivores, it develops pustules and swellings in the skin and gingiva, pox lesions on the vulva, penis, trunk, anal mucosa, gingiva, and tongue, and detached sole horn and stillbirth after an incubation period of 15–22 days [54].

BPXV is associated with severe disease outbreaks among buffaloes [9], cattle [47], and humans in contact with these animals [4,5]. Most human BPXV infections occur in animal attendants and milkers [9]. However, in Pakistan, buffalopox has caused a nosocomial infection in humans [55]. The incubation period in animals is comparatively shorter (2–4 days) than in humans (3–19 days) [56]. The disease may be localized or generalized with mild to severe disease associated invariably with mastitis in almost 50% of the affected animals. The skin lesions are more common on the udder, the base of the ear, and other less hairy areas like the inguinal region. Otitis has also been reported due to secondary bacterial complications [9]. The lesions are mainly confined to the hands, forehead, face, buttocks, and legs [9]. Occasionally, lymphadenopathy has also been recorded. Human-to-human transmission has not been reported so far.

Monkeypox is a rare but potentially serious viral illness, characterized by blister-like rashes that resemble smallpox [49]. However, unlike smallpox, monkeypox causes lymphadenopathy. Humans contract monkeypox by having close contact with animals or other infected people. Primates (monkeys, apes), rodents, and rabbits are known to carry the MPXV including most warm-blooded animals. Monkeypox illness in humans usually starts about 12 days after exposure to MPXV. The illness begins with fever, headache, muscle aches, backache, swollen lymph nodes, a general feeling of discomfort, and exhaustion. Within 1–3 days (sometimes longer) after the appearance of fever, the patient develops a papular rash (i.e., raised bumps), often first on the face [57].

96.1.4 Diagnosis

The diagnosis of OPV infection can be done based on the history of contact with infected animals and clinical manifestations in affected animals and humans in zoonotic cases.

Following the appearance of clinical signs of the disease, tissue samples (skin or organ biopsies) are most useful to identify the infectious agent [6,16]. However, the confounding signs caused by contagious ecthyma (orf [parapox] virus), herpesvirus infections, papillomatosis, and insect bites demand OPV infections to be differentiated from these infections using laboratory-based diagnostic methods. Initially, the diagnosis and differential diagnosis of the OPV infections has been performed by inoculation of suspected clinical material on the CAM and identification of different OPVs based on cultivation at distinct temperature, pock morphology, and histology characteristics [14,58]. It is necessary to apply more than one method for confirmatory diagnosis. Few complementary techniques are required for the diagnosis of OPV infections like transmission electron microscopy (TEM), virus isolation, immunohistochemistry, demonstration of neutralizing antibodies by immunoassays and PCR assays. However, the identity of the causative agent as OPV must be confirmed by TEM, PCR, and/or sequencing.

96.1.4.1 Conventional Techniques

Generally, most of the conventional serological tests are time consuming (less rapid), laborious, less sensitive, and therefore not suitable for primary diagnosis but useful in secondary confirmatory testing and retrospective epidemiological studies.

TEM and restriction enzyme analysis can be used to differentiate CMLV from other infections caused by OPV and PPVs [24,41]. TEM is a rapid primary diagnostic allowing first morphological characterization of pathogens [16]. It is a reliable and rapid method to demonstrate the presence of OPVs in scabs or tissue samples, although a relative high concentration of the virus in the sample is required. This technique enables the morphological differentiation between OPVs, which are brick-shaped, and PPVs, which are ovoid-shaped [20], and also from herpesviruses and *Bacillus anthracis*, which causes comparable type of skin lesions [14].

OPVs including CMLV antigen in infected scabs and pox lesions can be identified by immunohistochemistry [28], antigen-capture ELISA [58], and immunoblot [59]. Similarly, OPV infection can be diagnosed by the presence of specific IgM antibodies in acute infection using ELISA. However, these serological methods are less sensitive than PCR and not useful in the differentiation of OPVs as they are antigenically closely related to each other. The hemagglutination, hemagglutination inhibition, neutralization [60], complement fixation, fluorescent antibody, and indirect ELISA assays/tests are available to detect CMLV antibodies [6,40]. Although various serological assays have been developed for the diagnosis of buffalopox including AGID, counterimmunoelectrophoresis (CIE), serum neutralization test (SNT), ELISA, and immunoperoxidase test, these tests fail in the accurate diagnosis of the disease because of antigenic cross-reactivity [9]. Conventional biological and serological methods have limitations in the identification and differentiation of OPVs.

Most of the OPVs can be cultured in suitable cell cultures. The isolation of the virus using embryonated eggs and various cell lines (HeLa, GMK-AH1, WISH, Vero [29], MA104, and BHK21 cells) as well as primary cell cultures (lamb testis and kidney, camel kidney, calf kidney, and chicken embryo fibroblast [21]) could be of gold standard diagnostic procedure. However, cell lines of monkey and human origin are mostly preferred. Blood, serum, and homogenized scab or tissue samples can be used to infect cell cultures. The infected cells should be monitored for cytopathic effects (CPE) for 10–12 days. CPE includes the formation of multinucleated syncytia, rounding, ballooning, and syncytia with degenerative changes. CAMs can also be used for the growth of CMLV and other OPVs [36], but it is important to consider that pocks produced by VARV and CMLV are indistinguishable [29]. In case of BPXV, it produces characteristic "rosette" or "sunflower" like hemadsorption with 0.4% fowl erythrocytes [46]. The infected cell culture can be identified by known polyclonal or monoclonal OPV antibodies in the immunofluorescence technique [58,59].

96.1.4.2 Molecular Techniques

To overcome the drawbacks associated with conventional diagnostic techniques, molecular techniques like PCR, real-time PCR, and loop-mediated isothermal amplification (LAMP) assays have been used for the rapid and sensitive detection of OPV DNAs from clinical samples. DNA can be extracted from cell cultures, clinical scab samples, or tissue material using numerous commercial kits. Recently, a reliable low-cost two-step extraction method has been developed for isolating CMLV DNA from skin samples [61]. It can be modified for other OPV samples as a cost-effective method.

PCR assays are available for the identification and differentiation of OPV species and for differential diagnosis of OPVs from other viruses such as varicella zoster virus and herpes simplex virus, but also of bacteria such as *Bacillus anthracis* [58]. Human OPV infections should be given careful attention due to their high transmission to humans. Therefore, OPV species are to be differentiated using validated PCR detection methods and also sequencing and phylogenetic analyses of several genome regions in order to achieve reliable classification of these viruses. In case of suspected OPV infection in humans, it can be verified by means of virological or microbiological and molecular methods [14].

PCR-based assays have been described for the diagnosis and differentiation of OPVs like VACV, VARV, MPXV, and CPXV, based on inclusion and HA genes [18,62,63]. PCR using primers CoPV-3 and CoPV-4 has been used for the diagnosis of OPVs including CPXV, CMLV, MPXV, RCNV, VACV [64,65], and BPXV [9]. Amplification of full-length A-type inclusion (ATI) gene using CoPV-1 and CoPV-2 primer set [64] has been used in differentiation of OPVs (CMLV, CPXV, and BPXV). Primer pair ATI-up and ATI-low, which amplifies a fragment of the inclusion gene, is also used for differentiation of OPVs [62,66]. PCR assays in combination with restriction endonuclease (RE) or RE viral DNA analysis enabled differentiation of OPVs [66,67]. But, it needs virus isolation and genomic DNA (gDNA) extraction, which is time consuming and laborious. Further, PCR strategies targeting HA gene [63] and B2L gene [68] have been developed for

detection of CMLV and its differentiation from OPV and PPV infections in camels.

Similarly, a PCR assay based on the C18L gene (encoding ankyrin repeat protein) specific for CMLV has been developed [69], which differentiates CMLV from other OPVs, PPVs, and capripoxviruses in both cell culture and clinical samples. Further, a duplex PCR based on the C18L and DNA polymerase (DNA pol) genes for specific and rapid detection and differentiation of CMLV from BPXV has also been developed [69,70]. These assays have the advantage of avoiding an extra step of restriction analysis. As an improvement over conventional PCR approaches, the real-time PCR techniques targeting A36R gene using fluorescence resonance energy transfer (FRET) method [71], A13L, RPO18, and viral early transcription factor (VETF) genes [72,73] using melting curve analysis have been in use for rapid, highly sensitive, and specific detection and quantitation of VARV and CMLV and their differentiation from related OPVs.

Further, C18L gene specific real-time PCR based on SYBR green [69] and TaqMan hydrolysis probe [74] chemistry have been optimized for specific detection of CMLV in clinical samples. A TaqMan-based assay targets the OPV DNA pol gene and detects Eurasian OPVs other than variola. A hybridization assay, utilizing a 3'-minor groove binder (MGB) probe, targeting an envelope protein gene (B6R) specifically detects MPXV in human clinical samples [75]. Further, a quantitative real-time PCR assay targeting ATI gene of MPXV has been described for specific detection and differentiation of MPXV Congo basin and West African strains [76,77] and will be helpful in differential diagnosis of MPXV infections from other rash illnesses. As there is an increase in the number of human infections of cowpox, the real-time PCR for specific detection of CPXV has been reported [78]. A SYBR green- and probe-based real-time PCR assays have been reported for detecting and/or typing DNA of OPV from clinical samples as VARV, MPXV, CPXV, and VACV [79] as alternatives to PCR detection methods for clinical diagnosis of human pathogenic OPV infections in laboratories. Likewise, many real-time PCR assays in either single or multiple format/s for species specific identification of VARV and/or other OPVs and also their differentiation among them had been described [80–85].

LAMP, a simple, rapid, specific, highly sensitive, novel, and pen-side or field disease diagnostic laboratory test, has

been developed to target C18L [86] and HA genes [87] for rapid detection of CMLV and BPXV, respectively, in the clinical samples. A real-time quantitative MPXV genome amplification system targeting D14L and partial ATI genes has been developed using LAMP technology for specific diagnosis and discrimination of Congo basin and West African strains [88], and this tool would be useful for the assessment of MPXV infections. In general, LAMP assays appear to be potential as rapid and sensitive diagnostic tools for their application in less equipped rural disease diagnostic laboratories. Different molecular diagnostics targeting different genes of OPVs along with the primer set for detection and differentiation are summarized in Tables 96.1 and 96.2.

96.2 METHODS

Different techniques for detection of OPVs and diagnosis of OPV infections in terms of antigen, antibody, and nucleic acid in clinical samples are described here particularly for BPXV and CMLV. Suspected clinical samples from OPV-infected cattle, buffaloes, camels, and humans in the form of dry scab or skin lesions in 50% phosphate glycerol saline and blood in case of viremic stage and paired sera collected at 14 days interval should be sent for diagnostic purposes.

96.2.1 Sample Preparation

The clinical samples either collected from field outbreaks or submitted to reference laboratory for disease investigation and confirmation should be processed as described in the following text. A 10% (w/v) suspension of scab material is prepared using phosphate-buffered saline (PBS; pH 7.4) and after freezing and thawing for three times, the homogenate suspension is clarified at 1500 × *g* for 10 min. The clarified suspension is used for viral antigen identification by CIE. Antibiotics such as penicillin (10,000 IU/mL) and streptomycin (100 µg/mL) as well as antifungal agent (mycostatin 50 IU/mL) is added to the supernatant and filtered through 0.45 µm membrane filters. The filtrates so obtained can be aliquoted and stored at −80°C for further use for either extraction of DNA or isolation of virus in the cell culture system [5,69].

Alternatively, for isolation of the virus, the triturated suspension is repeatedly freeze-thawed thrice at −80°C and then subjected to sonication for 2 min at an amplitude of 30% with a pulse frequency of 0.9 s duration with 9.9 s to extrude virus particles from cells. The suspension is clarified at 5000 × *g* for 5 min and the supernatant is filtered using 0.45 µm membrane filters and inoculated onto 48 h old confluent cell monolayers. Infected Vero and primary lamb testes (PLT) cells in 25 cm^2 tissue culture (TC) flasks showing 80%–90% CPE is harvested after decanting the media and the pelleted cells are resuspended in 250 µL of PBS (pH 7.2) for gDNA extraction.

The blood samples collected from infected animals and humans with anticoagulant are used as such or diluted with PBS and used for gDNA extraction or virus isolation. The sera collected at 2 weeks interval (paired sera) from ailing animals are inactivated at 56°C for 30 min before use in SNT

and immunohistochemical test or it can be used as such for any other antibody detection procedures like CIE and indirect ELISA.

96.2.2 Detection Procedures

96.2.2.1 Antigen and Antibody Detection

CIE test is being used to identify either unknown soluble antigen in suspected pox lesions or antibody present in the serum samples using standard/reference hyperimmune serum or antigen, respectively, as the case may be [89]. This method can be used for initial screening of OPV suspected clinical samples. The collected samples will be processed as 10% homogeneous suspension in PBS as described earlier and used for the detection of viral antigen. The test is quick as well as more sensitive than the agar gel precipitation test. The positive samples can be further subjected for virus isolation in a suitable cell culture system for definite identification. CIE can also be performed to identify the precipitating antibodies present in serum collected from suspected animals and humans of OPV infections. Identification of specific antibodies is carried out by using specific precipitin antigen prepared from cell culture infected with OPV or skin lesions collected from diseased animals during outbreaks.

96.2.2.2 Virus Isolation in Cell Culture System and Its Identification

Most of OPVs are known to grow in monkey and human cell lines such as Vero and HeLa. For isolation of the virus, the triturated suspension is inoculated onto 48 h old confluent Vero cell monolayers and incubated at 37°C for 1 h with intermittent shaking to allow the virus to adsorb onto cells. After decanting the virus inoculum, infected cells are washed three times with serum-free eagle's minimum essential medium (EMEM) and fed with medium containing 2% bovine calf serum. Infected flasks are incubated further at 37°C and are regularly observed for the appearance of CPE. OPVs (CMLV and BPXV) produce rounding, clumping, increase in refractivity, and detachment of cells in 24–48 h postinfection [5,40]. The identity of the virus isolates is further confirmed by virus neutralization test (VNT), which checks the ability of the virus to neutralize the virus-specific serum antibodies [89]. For VNT, the virus is titrated both in the presence and in the absence of hyperimmune serum and the difference in the virus titer gives the neutralization index.

96.2.2.3 Electron Microscopy

TEM can be used for primary diagnosis of OPV infections and its differentiation from PPV infections based on virion morphology. Here, the methodology of TEM is exemplified using BPXV present in infected Vero cells [90]. Vero cells grown in TC flask until attaining confluency for 48 h is infected with cell culture–isolated BPXV at 0.05 multiplicity of infection. The cells are observed for the appearance of CPE at 24 h interval and, at 80%–90% CPE, cells should be harvested using cell scraper and pelleted by centrifugation at 800 × *g* for 10 min. Cell pellet should be washed in chilled PBS (0.1 M) and suspended in a fixative (2.5% glutaraldehyde +, 2% paraformaldehyde, in 0.1 M sodium phosphate buffer, and pH 7.4) for 12 h at 4°C. On fixation, cells are washed once again and resuspended in PBS before processing and viewed under TEM.

96.2.2.4 Immunohistochemistry

Indirect immunoperoxidase technique is performed to identify OPVs in infected cells or specific antibodies in the serum from infected animal using antiserum against OPV or known OPV in cell culture. Briefly, Vero cells showing CPE suspected to any of OPVs in cell culture plates containing cover slips are selected. Cover slips exhibiting characteristic CPE (rounding, ballooning, and syncytia) at 36–48 h postinfection are rinsed gently with PBS and fixed in acetone for 30 min at –20°C. Acetone-fixed cover slips are then washed four times with phosphate-buffered saline containing 0.005% Tween-20 (PBST) and processed as described earlier [3]. The endogenous peroxidase is inactivated by methanol with 3% hydrogen peroxide at 37°C for 20 min followed by blocking with 4% skimmed milk at 37°C for 1 h. Thereafter, cells are incubated at 37°C upon addition of antiserum raised against OPV after diluting in PBST containing 4% skim milk. Subsequently, infected cells are washed four times with PBST and incubated with peroxidase-labeled anti-species IgG diluted (varies from 1:500 to 1000) in 4% skim milk powder. Finally, cells are washed and treated with 3,3-diaminobenzidine tetrahydrochloride for 8–12 min, followed by counter staining with 20% Harris hematoxylin for 2 min. The cover slips are mounted on glass slides and examined microscopically for the presence of antigen antibody reaction, which is exhibited in the form of reddish-brown color in infected cells.

96.2.2.5 Serum Neutralization Test

The serum samples were subjected to SNT for detecting antibodies against BPXV following the method described earlier [91]. Briefly, serum samples (in duplicate rows) are diluted in EMEM in twofold dilution series from 1:2 to 1:64 in flat-bottomed 96-well TC plates (M/s Nunc, Germany). The reference BPXV-BP4 virus suspension (50 µL/well) with a titer of 100 $TCID_{50}$ in 50 µL is added to each serum well and the mixture is incubated for 1 h at 37°C in a humidified CO_2 incubator. An aliquot of 50 µL of Vero cell suspension (≈ 1.5×10^6/mL) is added to each well and incubated. Control wells like serum, virus, and cells are included in the test. The plates should be observed for CPE after 72–96 h. The highest dilution of serum inhibiting the CPE of virus at the 50% endpoint is taken as the neutralizing titer of the serum sample.

96.2.2.6 Diagnostic PCR Assay

The sensitivity and reliability of PCR, real-time PCR, and sequencing for diagnostic and research purposes require efficient unbiased procedures of extraction and purification of nucleic acids. Extraction of DNA is often an early step in many diagnostic processes used to detect OPVs in the environment as well as in clinical samples.

DNA extraction from the suspension of the material could be carried out using commercial gDNA extraction kit following the manufacturer's protocol or conventional nucleic acid isolation method following phenol–chloroform extraction system or simplified nonenzymatic fast DNA extraction protocol are described [61]. These methods can be used to extract total gDNA from the purified virus, virus-infected cells, and clinical samples, and eluted gDNA are stored at −80°C until use.

Clinical scab materials from buffaloes, cows, camels, and humans collected from suspected cases of OPV infections during different outbreaks can be employed for C18L gene–based single PCR and duplex PCR in combination with DNA pol gene and confirmed as camelpox and buffalopox infections with simultaneous differentiation [70]. The primers used for these diagnostic PCRs are shown in Table 96.1. In brief methodology, the total gDNA extracted from clinical samples or infected cells after virus isolation will be used in standard protocol along with positive and negative controls. OPV primers (BPXV C18L F and R2) will produce a 368 bp fragment in BPXV, whereas primer pairs (CMLV C18L F and R) will amplify 243 bp PCR fragment in CMLV suspected samples. For simultaneous detection and differentiation, a duplex PCR (BPXV C18L F and R2 with DNA Pol FP1 and RP1) will produce two bands (368 and 96 bp) in BPXV and only one (96 bp) in CMLV suspected clinical samples [70].

Quantitative PCR (qPCR) or real-time PCR assay targeting DNA Pol gene using TaqMan probe has been reported for rapid and sensitive detection and quantification of CMLV or BPXV as OPV infections. Further, C18L gene–based qPCR has been developed for specific detection and differentiation of these viruses using two different primer pairs with specific probes [70,74].

96.2.2.7 LAMP Assay

Loop-mediated isothermal amplification (LAMP) is quite simple, requiring only a conventional water bath or heat block for incubation under isothermal conditions. The LAMP assay based on C18L gene described earlier is valuable due to its simple plot, rapid reaction, and trouble-free detection of CMLV DNA from infected camels and humans [86]. A negative control containing no template is included in each assay. The positive LAMP reaction produces a ladder-like pattern with a set of bands of different sizes consisting of several inverted repeat structures. LAMP products are separated electrophoretically in 2% agarose gel using standard protocol and visualized under UV light using ethidium bromide. Alternatively, addition of SYBR green I or hydroxyl naphthol blue (HNB) to LAMP reaction will identify positive cases by change in color (orange to apple green in SYBR green I or violet to sky blue in case of HNB). Similar kind of rapid nucleic acid detection method has also been reported for detection of MPXV [88] and BPXV [87] in clinical samples.

96.3 CONCLUSION AND PERSPECTIVES

OPV infections were considered inconsequential till recently and have emerged as an important public health problem during this decade and due to increased cases and outbreaks in camels and buffaloes. In this context, particular attention should be given to camelpox and buffalopox outbreaks, as well as to the identification of any human infections associated with it. Effective prevention and control measures can be achieved through the use of proper diagnostic and prophylactic aids to curtail further spread of these infections as described for most of the zoonotic diseases. In general, several factors related to human activities, environmental changes, and virus could be the determinants of incidence and prevalence of the diseases. To safeguard the public health from pathogens of zoonotic infections, application of skills, knowledge, and resources of veterinary public health is essential. Due to frequent outbreaks of OPV zoonotic infections in different parts of the world, a directed attention is essential on understanding the virus ecology and epidemiology, the identification of potential reservoirs, the transmission pattern, and the immune response upon natural infection in order to control the zoonotic infection onslaughts in the near future. Further, the control measures for emerging and reemerging pathogens are demanding, as there is population explosion. Novel highly sensitive and specific techniques comprising genomics and proteomics along with conventional methods would be useful in the identification of emerging and reemerging pathogens or viruses; thereby, therapeutic/prophylactic/preventive measures would be applied on proper time. Intensified surveillance should be implemented to detect and restrain the spread of these zoonotic infections. Research should focus on molecular biology of these viruses so as to develop diagnostics and prophylactics in a modern way to combat these infections.

97.1 INTRODUCTION

The *Parapoxvirus* (PPV) genus of the *Poxviridae* family includes four worldwide-distributed viral species that mainly infect domestic and wild ruminants (e.g., sheep, goat, and cattle). PPV species are transmissible to humans and, for this reason, are considered zoonotic agents of veterinary and public health relevance [1,2]. The fact that PPV infection has been reported in an even broader host range (including camels, seals, and deer species) highlights the emerging importance of this genus [1,3,4]. PPVs are epitheliotropic viruses whose clinical manifestations include exanthematic lesions as painful pustules and vesicles. Clinical diagnosis of PPV infection is often made difficult by both the absence of pathognomonic signs and the great similarity in the symptoms to either different *Poxviridae* infections or unrelated exanthematic diseases, such as cutaneous anthrax, foot-and-mouth disease, blue tongue, and bovine viral diarrhea. In addition, subclinical infections have been recorded. Thus, improvement of molecular analyses and epidemiological studies is considered an urgent priority in order not only to avoid unnecessary treatment due to misdiagnosis but also to lessen the economical impact of PPV diseases and to implement strategies for the limitation of this infection. Clinical evidence and restriction analysis have been traditionally used to diagnose and characterize PPV diseases. Nevertheless, the historical relevance of the *Poxviridae* family has increased the availability of genomic data in scientific databases. This further facilitates the use of the molecular diagnostic approach for improved diagnosis of PPV infection.

97.1.1 Classification, Morphology, and Genome Organization

The PPV genus belongs to the subfamily *Chordopoxvirinae* (ChPV), family *Poxviridae*. The genus comprises four zoonotic viral species that cause localized skin nodules mainly in domestic and wild ruminants: *Bovine papular stomatitis virus* (BPSV), *Pseudocowpox virus* (PCPV), the genus prototype species *Orf virus* (ORFV), and the newest characterized species *Parapoxvirus of red deer in New Zealand* (PVNZ) [5–7]. PPVs are primarily classified on their natural host range and viral DNA restriction enzyme analyses, while the extensive serological cross-reactivity makes neutralization tests and immunofluorescence useless to differentiate viral species [8].

Viral particles are large, enveloped, and oval shaped, with variable size ranging from 260 nm × 160 nm in ORFV to 300 nm × 190 nm in PCPV. Tubular filiform structures surround virions and can be used to discriminate PPV particle

from others poxviruses, such as orthopoxviruses (OPV) by electron microscopy (EM) [9,10]. PPV virions enclose a typical *Poxviridae* genome, consisting of linear double-stranded DNA of approximately 140 kb, composed by one central region and two flanking inverted terminal repeats (ITR) terminally linked by a hairpin structure that allows cross-hybridization between isolates of the same species. High intraspecific variability has been found at either genomic level, by viral DNA restriction pattern analyses, or protein level [8,11–16].

PPV genome contains approximately 130 open reading frames organized in a conserved central core and two external regions. ChPV conserved genes are essential for viral replication and morphogenesis and encode transcription and replication machineries. Nonessential variable genes, conversely located along ITRs, are mainly responsible for pathogenesis and virulence and, in some cases, are genus specific [10,17,18]. *B2L* gene encodes PPV major envelope antigen of approximately 42 kDa. This gene is the homologue of *F13L* gene of *Vaccinia virus* (VACV) and has been widely used in PPV diagnosis and characterization, as well as vascular endothelial growth factor gene (*VEGF*) and virus interferon resistance (*VIR*) genes, which are common targets of phylogenetic analyses. For differential diagnosis, a polymerase chain reaction (PCR) assay targeting the *A32L* gene, which encodes a 34 kDa ATPase protein involved in DNA packaging, has also been developed [19–26]. Like other poxviruses, PPV replicates in the cytoplasm of host cells, exploiting their own machinery for DNA transcription and replication. Notably, PPV shares with the *Molluscipoxvirus* genus the peculiar genome feature of high guanine and cytosine (G+C) content. In fact, conversely to a majority of other poxvirus genomes that enclose approximately 25%–35% of G+C, PPV genome contains about 65% of G+C [12,27,28].

97.1.2 Transmission, Clinical Features, and Pathogenesis

PPV infections occur primarily in ruminants such as sheep, goats, and cattle. Infections in wild species, such as grey seals, serows, cervids, and gazelle, have also been described. Furthermore, PPV infections have been reported in cats expanding the range of the identified hosts [6,29–34]. PPV infections are zoonoses, and their transmission is facilitated by contact with lesions or fomites. Zoonotic transmission to humans represents an occupational hazard that mainly affects either milkers or particular risk category workers like veterinarians, farmers, and butchers, who directly handle infected mammals. Additionally, transmission from wild animals is also possible at low frequency. Often, the presence of painful lesions impairs milking and breastfeeding, and the infected animals become unproductive resulting in economical losses in outbreak-affected farms [35–37]. Finally, the reported cases of human-to-human transmission have highlighted the importance of developing a thorough understanding of the chain of transmissional events [38–44].

The clinical outcome in human manifestations consists of painful lesions on hands and less frequently on the face [9,45,46], while the main clinical signs observed in infected animals are papular lesions around the mouth and in the oral mucosa, skin, and teats. Lesions in the esophagus, stomach, and intestine have been reported with less frequency. Lesion progression is characterized by formation of macules and papules, followed by vesicles and pustules. Disease progression and resolution generally occur over the course of 1–2 months concomitantly with an accumulation of neutrophils, T and B cells, and dendritic cells in proximity to infected epidermal cells. Keratinocytes are the major multiplication site that is characterized by eosinophilic cytoplasmic inclusions and irregularly shaped nuclei.

97.1.2.1 Orf Virus

ORFV is the prototype species of the PPV genus and the causative agent of contagious ecthyma (CE), also known as orf, a zoonosis that primarily affects domestic sheep and goats, although some cases have been also described in wild animals [34,47,48]. CE can decrease the fitness of infected hosts leading to severe economic losses, as well as public health problems, according to the zoonotic potential of this disease [49–52].

Since the first identification of a human ORFV by Newsom and Cross in 1934 [53], several human cases caused by occupational or household exposures have been reported [54–56]. CE is characterized by epidermal proliferative lesions (vesicles) mainly localized in the lips, mouth, nostrils, gums, and tongue. Less frequently, lesions can be observed in the esophagus, stomach, and intestine, while among sheep, the lesions are commonly localized at the teat and udder. Genital lesions have also been described. However, asymptomatic ORFV infections can occur. In addition, when lesions in the mouth, lips, and udders prevent infected animals from feeding, the consequences can be even more severe leading to a rapid weight loss and increased mortality rate [57]. Incubation period in sheep ranges from 3 to 14 days, while in humans is shorter (2–4 days). Based on the clinical symptoms only, CE can be frequently misdiagnosed, leading to unnecessary treatments. Furthermore, cases of coinfection between poxviruses of different genera have been reported, reinforcing the need to apply molecular assay for the differential diagnosis [36,48,52,58]. In human, ORFV causes skin lesions and occasionally malaise and lymphadenopathy, while immunodeficient individuals can develop even severe infection. In such cases, even though the treatment had resulted in successful outcome, no therapeutic options have been yet characterized [59–61]. Studies have shown that the mortality rate in kids can reach 93%; nevertheless, the disease is considered mild by some authors. ORFV transmission is typically associated to animal direct contact (Figure 97.1), and the importance of preventive measure (e.g., wearing gloves and appropriate hand hygiene) is pivotal in order to limit the zoonotic transmission of CE, especially in rural areas where the risk of human-to-human transmission can be very high.

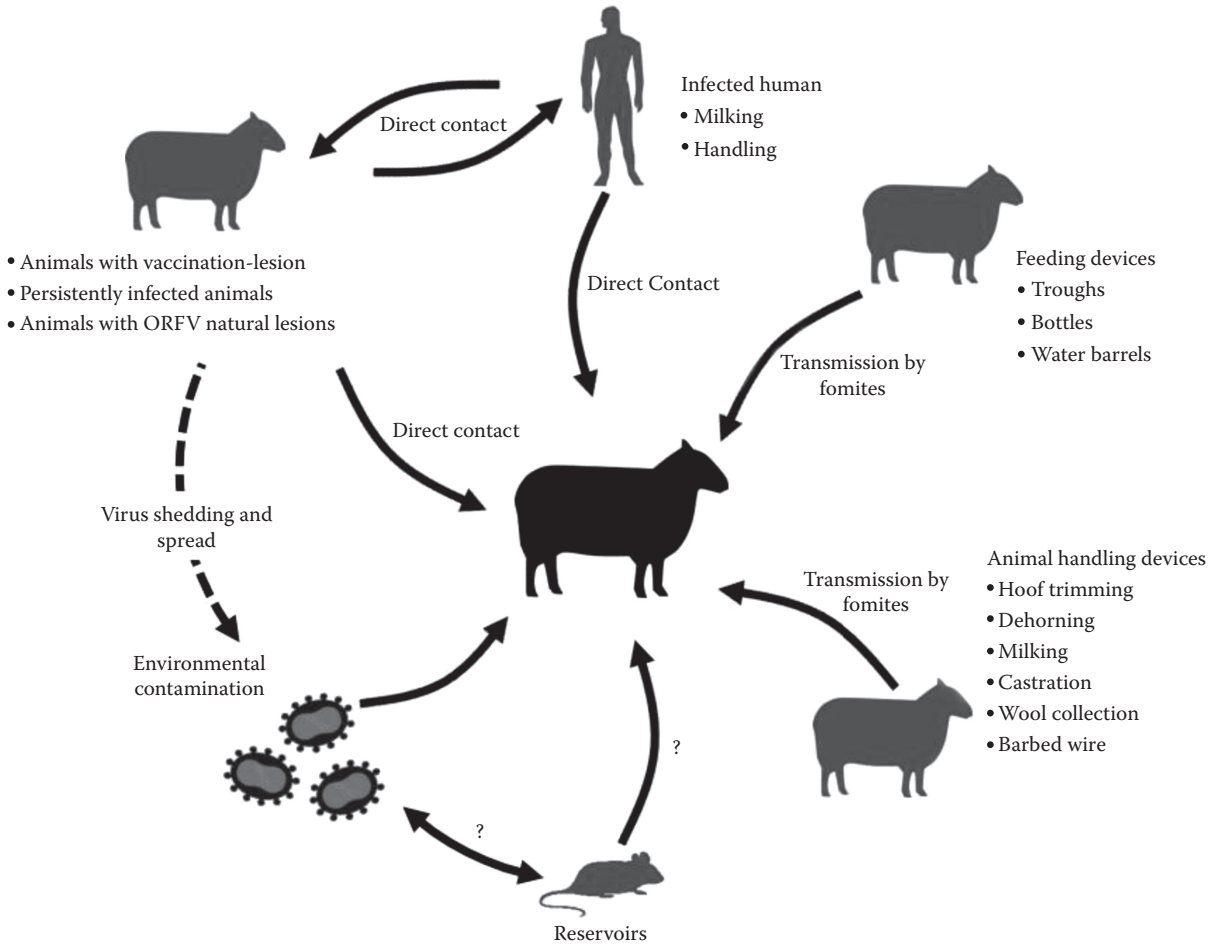

FIGURE 97.1 *Orf virus* hypothetical transmission cycle.

In human, lesions generally appear on the hands and face, but some patients develop ulcerating lesions on oral mucosa, in particular at the level of the upper lip [22,57,62–65]. A case of human-to-human transmission was reported from father to daughter via the common use of tweezers. Despite being uncommon, human-to-human infection reveals new questions concerning the transmissional chain of the ORFV [44]. Like other poxviruses, ORFV contains immune modulatory genes primarily located in terminus of the viral genome. Among them, granulocyte macrophage colony-stimulating factor (GM-CSF) inhibitory factor gene (*GIF*) encodes for an inhibitor of both GM-CSF and viral gene encoding an interferon resistance factor orf virus interferon-resistance gene (OVIFNR). These genes have been used in genetic variation studies of ORFV [66–69].

Immunohistological studies of the skin of infected sheep have shown that there is an accumulation of neutrophils, dendritic cells, and T cells. CD4+ are the predominant T cells in lesions. Reinfection can occur, but smaller lesions are observed, which resolve usually in 3 weeks. For this reason, the disease is most severe in those animals, such as lambs, that have never been exposed to the virus [66,70,71]. In some countries, vaccination with attenuated vaccine is practiced. The virus was attenuated through serial passages on primary chicken embryo fibroblast tissue cultures. A field study was conducted to confirm the efficacy of the vaccine and demonstrated that vaccination was able to block the normal course of the disease and induce rapid recovery. Thus, the ORFV vaccine can limit the severity of the disease [72]. In short, CE is an emerging zoonosis, with an increasing number of outbreaks reported worldwide. It not only has a significant impact on livestock but also poses a public health threat. Further studies and epidemiologic surveys are warranted in order to improve our knowledge on this viral disease [51,63,73–75].

97.1.2.2 Bovine Papular Stomatitis Virus

BPSV infection is characterized by exanthematic lesions mainly localized on the muzzle, around the mouth, oral mucosa, and less frequently in the esophagus and forestomach of calves and udders of cows. In general, lesions begin with papules formation progressing to pustules and vesicles that regress approximately 12–16 days after the onset. Calves usually develop the classical disease outcome, whereas BPSV is the cause of severe esophagitis in adult bull [76–78]. The exanthematic lesions typically resemble those of foot-and-mouth disease, highlighting the importance of differential diagnosis. Commonly, acute forms of disease are described, but chronic forms of bovine papular stomatitis in young cattle have been also demonstrated [79]. Recently, a molecular

analysis has identified a new viral strain, revealing the existence of genetic variability in the BPSV envelope gene [80]. Reinfections by BPSV are commonly observed, indicating that this virus does not confer permanent immunity, as it has been shown for other viruses of the family, such as *VACV*, which cause repeated outbreaks of bovine vaccinia mainly in Brazil and ORFV in sheep and goats. BPSV has a worldwide distribution, and infection of calves and cows is of economical importance as it leads to a decrease in milk production [81–84]. Furthermore, since it is a zoonosis, human cases have a significant public health impact. Human transmission usually occurs by direct contact with lesions causing nodules and pustules on the hands and less frequently on the face; occasional cases may develop severe lesions [46]. In this way, milkers and other livestock workers are exposed to infection [41].

97.1.2.3 Pseudocowpox Virus

First isolation of *PCPV*, the causative agent of milker's nodule disease, dates back to 1963, and it was obtained from lesions of cows and calves [85]. Nowadays, PCPV infections are currently worldwide distributed affecting cows and calves and representing a zoonotic threat to human health [86–89]. Moreover, infection in hosts such as camels in the Arabian Peninsula, reindeers, and cats has also been described [90–92]. The virus is usually transmitted by direct contact with infected animals. Once infected, milking cows develop proliferative lesions on teats and udders in a clinical course of approximately 10–15 days. As observed for ORFV and BPSV, cases of reinfection can occur in herds. In addition, chronic lesions may occur. PCPV diagnosis is complicated not only by virion morphology but also by clinical symptoms, which are similar with other poxvirus infections that affect bovine, such as VACV and BPSV. Moreover, cases of PCPV human coinfection with different *Poxviridae* species have been described [93]. Therefore, the correct diagnosis of PCPV infection in cattle mainly relies upon the identification of the viral agent by molecular assays [94].

97.1.2.4 Parapoxvirus of Red Deer in New Zealand

PVNZ has been classified as new PPV species due to its distinct restriction enzyme patterns [5]. PPV in red deer have been firstly reported in New Zealand and, more recently, in Italy among wild ruminants. In red deer, the disease is characterized by lesions mainly located in the muzzle, lips, ears, and neck. Infections are more common in younger animals, with morbidity often reaching 100%. Diagnosis is generally made on clinical signs alone, but histology, EM, and molecular tests have also been used [95,96].

97.1.3 Diagnosis

Diagnostic methods for PPV infection include clinical diagnosis based on the history of contact with animals and the clinical appearance of the lesion. However, PPV infections may be misdiagnosed due to the great similarity in symptoms with other vesicular–pustular diseases. In these cases, the diagnosis can be established by histopathology and EM; serological methods, such as ELISA, immunofluorescence assay (IFA), agar gel immunodiffusion (AGID), and neutralization test (NT); viral growth in cell cultures and molecular assays as restriction fragment length polymorphism (RFLP); and conventional PCR, multiplex PCR, and real-time PCR (qPCR). Among the available methods, molecular approaches and nucleic acid sequence analysis are widely used for detection and identification of PPV infections.

97.1.3.1 Conventional Techniques

PPV infection can be identified by histopathological analysis that usually shows vascular degeneration of keratinocytes, the primary viral target [97]. PPV infection of keratinocytes is also characterized by eosinophilic cytoplasmic inclusions and irregularly shaped nuclei [34,97]. The diagnosis can be enhanced by negative-stain EM, which identifies the viral particles within infected cells, discriminating PPV genus from OPV [34,97]. However, EM requires morphologically intact clinical samples with high viral load (approximately 10^6 particles per mL), as well as trained personnel [98,99]. High viral load is usually obtained from fresh lesions and crusts of infected individuals and/or animals, whereas in case of low viral load or not correctly processed samples, EM may produce false-negative results with high probability. In this case, virus isolation can also be performed using primary ovine or bovine cell culture. Although once regarded as the gold standard method for detection of poxviruses, virus isolation is not attempted routinely in clinical laboratories [17,100–103].

Determination of serum titers during the acute and convalescent phase of disease is also useful. The presence of specific antibodies can be confirmed by AGID and IFA. In these techniques, Madin–Darby bovine kidney–infected, fetal bovine muscle–infected, and bovine fetal testicle–infected cells with known PPV strains can be used as antigen after lysis or sonication treatments [104–106]. Moreover, ELISA for IgM and IgG determination has also been employed, according to the direct correlation between fast healing of lesions and rise in antibody levels during the infection [58,104,105,107]. Furthermore, NT assays are also applied. Although neutralizing antibodies are associated with protective status, all PPV are immunologically related and cannot be distinguished in NT [108,109]. Western blot analysis is usually confirmatory and has demonstrated that the produced antibodies in response to infection are directed against the viral surface tubule protein [99,102].

97.1.3.2 Molecular Techniques

Traditional diagnostic laboratories rely on conventional culture and serological methods for the confirmation of several viral infections. The access to reliable diagnostic laboratory testing methods is limited, due to the requirement of well-qualified personnel, standard and automated products, and equipments. The identification and characterization of an already isolated viral pathogen is mainly assessed by molecular techniques that represent a rapid tool for the diagnosis of fresh clinical specimens. Indeed, molecular techniques generally in use for PPV diagnostic include RFLP, nucleic acid

hybridization, and, especially nowadays, conventional PCR and qPCR. These methods, and in particular PCR, are well recognized to be more rapid, sensitive, and specific than conventional techniques for the identification of target viruses.

In RFLP analysis, viral DNA is digested with one or more restriction enzymes (e.g., EcoRI, HindIII, BamHI), and the resulting restriction fragments are separated according to their size by electrophoresis, generating distinct restriction fragment profiles and allowing species and strains differentiation [5,15,34,80,110,111]. Multiplex PCR can be useful for clinical differential diagnosis as rapid approach for simultaneous detection of coinfections with different *Poxviridae* genera, such as PPV and OPV [112,113], and PPV and capripoxvirus [114].

The PCR assay that has traditionally provided the most valuable approach to identify PPV infections targets the conserved major envelope protein gene (*B2L*), which is the homologue of *VACV* envelope protein antigen-p37K [26]. Besides, *B2L* gene has been widely used in the molecular characterization and phylogenetic analysis, representing the main molecular marker for PPV genetic analysis. Other PPV-specific genes have been described as target of PCR amplification, such as interferon-resistant protein (*VIR*) [101,115], ATPase (*A32L*), dsRNA-binding protein (*E3L*) [116], and GM-CSF/interleukin-2 inhibitory factor (*GIF*) genes [111]. These genes have been extensively used for phylogenetic studies in order to investigate on epidemiology and evolution of PPVs [21,24,75, 93,101,111,112,115,116].

Finally, qPCR assays have further improved the diagnosis of PPV infections due to their high efficiency and sensitivity. These features are required for the analysis of human clinical samples, which often have a low viral load and/or poor DNA quality. Different qPCR methods for PPV DNA detection in clinical specimens have been developed [23,116–118]. These methods target ORFV major envelope antigen *B2L* and can be used either in the diagnosis and quantification of ORFV [23,117] or in the diagnosis of several PPV species including PCPV and BPSV [23].

97.2 METHODS

97.2.1 Sample Collection and Virus Isolation

Biopsies of lesions are the most frequent and suitable clinical samples collected for the diagnosis of PPV-associated infections. For virus isolation, 1%–10% (weight–volume) of biopsy suspension is prepared in pH 7.4 phosphate-buffered saline (PBS) or nuclease-free water, both supplemented with gentamycin to eliminate bacterial contamination, then clarified by centrifugation at 2000 × *g* for 3 min to eliminate larger debris. The supernatant is collected and submitted to DNA extraction [119] or, in order to isolate viruses, is directly used to infect cell cultures. There are some permissive cell lines useful for PPV isolation, such as ovine organotypic skin culture, ovine fetal turbinate (OFTu) cells, and Madin–Darby ovine kidney cells [120,121]. Besides, primary bovine lineage esophageal cells (KOP, cell culture collection Friedrich Loeffler Institute, Riems, Germany), bovine lung, or kidney fibroblasts can be used. OFTu cells, which are the most frequently used for PPV isolation, are cultured in minimal essential medium (Hyclone) with 10% fetal bovine serum (Hyclone), 2 mM of L-glutamine, 100 U of penicillin, 100 µg of streptomycin, 20 µg of nystatin per mL at 37°C, and 5% of CO_2 [121]. In this system, the cytopathic effect (CPE) is usually detected 1–2 days postinfection, according to the starting viral load, and is characterized by cell rounding, pyknosis, and cell detachment. When 50%–75% of CPE is observed, cell cultures are subjected to one cycle of freeze–thawing. The virus-containing supernatants are then clarified by centrifugation, aliquoted, and frozen at –70°C [34,99].

97.2.2 Detection Procedures

97.2.2.1 DNA Extraction

DNA from macerated sample supernatant, serum, and virus-infected cells is extracted by commercial kits and phenol–chloroform–isoamyl alcohol, or in some cases, samples can be submitted to PCR with no previous DNA extraction step [112].

97.2.2.2 qPCR Detection of PPV

One of the first diagnostic qPCR for PPV detection was developed by Nitsche and colleagues in 2006. Before that time, the diagnosis of PPV infections had been traditionally performed by EM and/or conventional PCR. The following protocol describes the qPCR currently used for detection of PPV. We have used this protocol in our lab successfully. To date, this assay is capable of specifically amplifying DNA from all PPV species. A conserved region into the major envelope protein gene (*B2L*) was chosen for the design of two primers and one 5-nuclease minor groove-binder (MGB) probe [23].

Primer	Target Gene	Sequence (5′–3′)	Expected Product (bp)	Reference
PPV up	B2L	TCGATGCGGTGCAGCAC	95	[23]
PPV do		GCGGCGTATTCTTCTCGGAC		
PPV TMGB		GTCGTCCACGATGAGCAG		

The reaction is performed into a mix solution containing 1× PCR buffer, 5 mM of $MgCl_2$, 1 mM of deoxynucleotide triphosphate mixture with dUTP, 1 µM of ROX, 1 U of platinum Taq p polymerase (Invitrogen), 7.5 pmol of each primers, 2.5 pmol of the MGB probe, and 5 µL of DNA template [23].

Cycle condition
Incubation at 95°C for 5 min
↓
40 cycles
Denaturation (95°C, 15 s)
Annealing (60°C, 30 s)

This reaction has a linear detection range from 10^6 to 10^1 copies per reaction, with a correlation (R^2) of 0.99 and an amplification efficiency of 97%. Its limit of detection is 4.7 copies per assay (95% confidence interval, 3.7–6.8 copies/reaction). The assay variability is <30% for yield close to the detection limit (10^2 copies) and <15% for higher DNA amount (10^4 and 10^6 copies). The assay specificity has been tested against several viral DNA, such as OPV (*vaccinia*, *cowpox*, *monkeypox*, *ectromelia*, and *camelpox virus*), *Molluscum contagiosum virus*, *Yaba-like disease virus*, human herpesviruses types 1–8, and adenoviruses, and no amplifications were detected [23].

In 2013, Zhao and colleagues have validated a new robust and specific qPCR assay, which amplifies the conserved RNA polymerase gene of all PPV species.

Primer	Target Gene	Sequence (5′–3′)	Reference
Forward primer	PAPV J6R	CGCGGTCTGGTCCTTG	[118]
Reverse primer		CAGCATCAACCTCTCCTACATCA	
Probe		CCACGAAGCTGCGCAGCAT	

PCR protocol is as follows.

Component	Concentration	Thermocycle
PPV primers	0.4 μmol/L	Incubation at 95°C for 2 min
FastStart TaqMan Universal PCR Master Mix (Applied Biosystems, Foster City, CA)	1×	45 cycles
TaqMan probe	200 nmol/L	Denaturation (95°C, 5 s)
Template	2 μL	Annealing (62.5°C, 20 s)
Total volume	**25 μL**	

97.2.2.3 Nested PCR Detection of PPV

Abrahão and colleagues in 2009 designed a nested–multiplex PCR to detect orthopox–parapox coinfections. In addition, the reaction was successfully used to specifically detect PPV, with high sensitivity. An adapted nested PCR protocol developed to detect exclusively PPV in scabs is as follows. Clinical sample is prepared by maceration of the scab in PBS (pH 7.4) (0.1 g scab/0.9 mL PBS) and clarification by centrifugation at 2000 × *g* for 3 min. Supernatant is collected and directly amplified by PCR targeting the gene ORFV011–*B2L* gene (viral envelope antigen). As previously stated, the *B2L* gene is the most common target used for diagnosis and phylogenetic studies of PPV. The technique described in the following has been previously reported [24,26,75,93,112], and here, we proposed an adaptation. It is worth mentioning that all known PPV species are detected by this reaction.

Primer	Target Gene		Sequence (5′–3′)	Expected Product (bp)	References
OVB2LF1	B2L	First step	TCCCTGAA GCCCTATTA TTTTTGT	1206	[26]
OVB2LR1			GCTTGCG GGCG TTCGGA CCTTC		
PPP-1		Nested step	GTCGTCCAC GATGA GCAG	592	[24]
PPP-4			TACGTGGGA AGCGCC TCGCT		

Prepare the mix of the first step and perform the reaction in a thermal cycler following the protocol:

Component	Concentration	Thermocycle
PPV primers	0.8 mM	Incubation at 95°C for 9 min
dNTPs	10 mM	↓
$MgCl_2$	2.0 mM	30 cycles
Bovine serum albumin (BSA)	500 ng	Denaturation (94°C, 1 min)
Taq DNA Polymerase (Promega, Madison, the United States)	2 U	Annealing (45°C, 1 min)
DEPC-treated water q.s	18 μL	Extension (72°C, 1 min)
Template	2 μL	↓
Total volume	**20 μL**	Final extension (72°C, 10 min)

Notes: For the nested step, the same chemical and thermal conditions must be used, but using internal PPV (PPP-1 and PPP-4–0.8 mM) primers. The final PCR products may be electrophoresed on 2% agarose or 8% PAGE gels in parallel with standard DNA, as described elsewhere [119].

97.2.3 Sequencing and Phylogeny of PPV

In order to discriminate the PPV species detected by PCR, the amplified products are usually sequenced and subjected to phylogenetic analysis. Sequencing is usually performed using the primers described earlier and those by Hosamani et al. [26] and Inoshima et al. [24]. In addition, other targets have been described for characterization as shown in the following:

Primer	Target Gene	Sequence (5′–3′)	References
PPV011-F	ORF 011 (B2L)	GTG CGC GAA GGT GTC GTC CA	[103]
PPV011-R		ATGTGGCCGTTCTCCTCCATC	
PPV032-F	ORF 032	CGA GCT TTA AAT AGT GGA AAC ACA GC	
PPV032-R		GCA CCA TCA TCC TGT ACT TCC TC	
D27F	VEGF	AAT GTA AAT WMT AAC GCC	[122]

(*Continued*)

11R		AAC CCA GAA ACG TCC CGC TAC	
D2R		CGT TTG GAT MTG CGG TCC	
VIR1	VIR	TTA GAA GCT GAT GCC GCA G	[34]
VIR2		ACA ATG GCC TGC GAG TG	
FP	A32L	GTG TTG ATC ATC GAA GAC TCG GTG	[123]
RP1		GTC GCC CTT GTC GCC CTT AGT CTC	
RP2		CCG CCG TCA GAG TCG ACG TCG CCC T	

[a] VEGF, vascular endothelial growth factor;
[b] W, A/T. M, A/C;
[c] VIR, virus interferon resistance.

In 2014, Friederichs and colleagues developed a pan-PPV PCR reaction using primers that encompasses all PPV strains, designed on *B2L* gene [103]. They also described a further PCR protocol, targeting a more variable region within the ORF 032. For the ORF 032 gene, the same B2L-PCR protocol must be used, but the annealing temperature is set to 67°C. PCR conditions for B2L and ORF 032 are the following:

Component	Concentration	Thermocycle
PPV primers (B2L/ ORF 032)	0.5 μM	Incubation at 98°C for 30 s
dNTPs	200 μM	↓
Q5 reaction buffer	1×	35 cycles
Q5 high GC enhancer	1×	Denaturation (98°C, 10 s)
Q5 high fidelity DNA polymerase (New England Biolabs, MA)	1 U	Annealing for B2L (65°C, 30 s) Annealing for ORF 032 (67°C, 30 s)
DEPC-treated water q.s	49 μL	Extension (72°C, 30 s)
Template	1 μL	↓
Total volume	**50 μL**	Final extension (72°C, 2 min)

Other genes that encode nonstructural proteins—*VEGF* and *VIR*—have been previously described to characterize PPV isolates [122,124]. Worth of note, high variability in *VEGF* gene of PCPV has been reported, suggesting that particular attention is required in choosing this target for PCR diagnosis. PCR conditions for *VEGF* and *VIR* are the following:

Component	Concentration	Thermocycle
PPV primers VEGF/VIR	0.2 μM	Incubation at 95°C for 5 min
DNTPsmix	800 μM	↓
Tris-HCl (pH 8.3)	10 mM	35 cycles
KCl	50 mM	Denaturation (94°C, 30 s)
$MgCl_2$	1.5 mM	Annealing for VEGF(40°C, 30 s)
AmpliTaq Gold DNA polymerase (Applied Biosystems, CA)	1 U	Annealing for VIR (55°C, 30 s)
DEPC-treated water q.s	49 μL	Extension (72°C, 30 s)
Template	1 μL	↓
Total volume	**50 μL**	Final extension (72°C, 7 min)

The PPV strains can be genotyped using a differential PCR for the *A32L* gene, as described previously [123]. This process is based on the polymorphisms among PPV isolates, and the PCR conditions for the *A32L* are described as follows.

Component	Concentration	Thermocycle
FP primer	1 μM	Incubation at 95°C for 9 min
RP1primer	0.4 μM	↓
RP2 primer	0.4 μM	35 cycles
dNTP mix	800 μM	Denaturation (94°C, 30 s)
Tris-HCl (pH 8.3)	10 mM	Annealing (63°C, 30 s)
KCl	50 mM	Extension (72°C, 30 s)
$MgCl_2$	1.5 mM	↓
AmpliTaq Gold DNA polymerase	1 U	Final extension (72°C, 7 min)
Extracted DNA	3 μL	
Total volume	**50 μL**	

The expected gene fragments are amplified by the protocols mentioned earlier and electrophoresed on 2% agarose gels. The amplicons are purified, cloned, and sequenced. The obtained sequences are compared with the available sequences in the National Center for Biotechnology Information GenBank database, The European Molecular Biology Laboratory, or DNA Data Bank of Japan.

With these results, phylogenetic and molecular evolutionary analyses have been performed. Several studies have traditionally inferred PPV phylogeny by amplification and sequencing of *B2L* gene [15,24,26,96]. However, Friederichs and colleagues recently proposed to include ORF 032 in phylogenetic analyses of PPV. ORFV phylogenetic tree based on *B2L* gene, as well as on ORF 032, shares a similar basic structure and reveals three distinct clusters with high bootstrap support, each representing one of the PPV species: ORFV, PCPV, and BPSV. In particular, ORF 032–derived phylogenetic tree shows a highly diversified branching and consequently provides an improvement in the analysis of PPV phylogeny [103].

As previously reported, *B2L* gene has been extensively used in phylogeny. In 2010, Inoshima and colleagues have reported a highly conservative profile among *B2L* sequences from Japanese's ORFs. Then, they have proposed additional analysis using three nonstructural protein genes, such as *VEGF*, *VIR*, and *A32L*. These additional analyses are suitable to phylogeny allowing the proper clustering of PPV isolates into regional clades [103]. Interestingly, *B2L*, *VIR*, and *VEGF* genes of Brazilian ORFV isolates have been recently analyzed, showing a high variation degree among them, indicating a multiple introduction source of ORFV in Brazil from different sources, such as European countries, Asia, North America, and/or Oceania. The cocirculation of allochthonous-derived isolates may have led to this polytomous phenomenon observed among Brazilian ORFV isolates [21].

Virus isolation, molecular detection, and whole genome sequencing are useful tools for the diagnosis of PPV infections. The genome-wide studies can support the understanding about the origins, evolution, and epidemiology of ORFVs. All of these concerns are of great importance in the veterinary, economy, and public health fields.

97.3 CONCLUSION

The emergence of zoonotic poxviruses has highlighted the importance of molecular techniques in the diagnosis of PPV infections. In recent years, improvement in molecular assays has enhanced the accuracy of pathogen identification and yielded insights into PPV genomic organization and phylogeny. Further refinement of molecular diagnostic techniques in relation to test turnaround time and automation will not only contribute to the discovery of new pathogens but also assist researchers and clinicians in the implementation of effective intervention (e.g., vaccines and drugs) and management strategies for PPV infections.

98.1 INTRODUCTION

White spot syndrome virus (WSSV) is a double-stranded DNA (dsDNA) virus that has emerged as a significant threat to wild and farmed shrimp worldwide. Although WSSV is infective to a wide range of crustaceans (such as salt and brackish water penaeids, crabs, lobsters, freshwater prawns, and crayfish), its impact on penaeid shrimp is nothing short of extraordinary. Besides developing lethargy, emaciation, white spots on the carapace, and reddish discoloration of the body, nearly 100% of shrimp succumb to white spot disease (WSD) within 3–10 days of infection. Clearly, prompt and accurate diagnosis is vital to limit the spread of infection and reduce its impact on aquaculture, which is currently dominated by two shrimp species: the black tiger shrimp (*Penaeus monodon*) and the white Pacific shrimp (*Litopenaeus vannamei*) [1].

98.1.1 Classification

WSSV is a dsDNA virus classified in the genus *Whispovirus*, family *Nimaviridae*. As the sole member of the family *Nimaviridae*, WSSV was regarded as baculovirus prior to 2005, on the basis of its cylindrical morphology and the histological lesions it induces that resemble those of nonoccluded baculoviruses. The other former names for WSSV include hypodermal and hematopoietic necrosis baculovirus, rod-shaped nuclear virus of *Penaeus japonicus*, Chinese baculovirus, systemic ectodermal and mesodermal baculovirus, penaeid rod-shaped DNA virus, and white spot baculovirus (WSBV) [2].

First identified in 1992 from cultured penaeid shrimp in China and Taiwan, WSSV has quickly spread to other parts of Asia; the Middle East; North, Central, and South America; Africa (Mozambique), and other shrimp farming countries of the world. For the penaeid shrimp, WSSV is responsible for a highly lethal disease (WSD) with a mortality of nearly 100% within 7 days. However, in other aquatic species, such as crayfish, crabs, and bivalves, WSSV causes only subclinical infection. These aquatic species act as a reservoir of WSSV [1].

Previous restriction fragment length polymorphism analysis indicated that WSBV isolates from various geographical regions display limited genomic differences and appear to be closely related to each other [3]. With the whole genome sequences of several WSSV isolates becoming available recently, detailed examination of their genetic differences is possible. Indeed, despite sharing an overall sequence identity of >99%, WSSV genomes contain several variable genomic loci that offer useful targets for genotype identification and epidemiologic trait determination. These include the ORF14/15 region (which is prone to recombination), the ORF23/24 region (which is prone to ~13 kb deletions), and the variable number of tandem repeats (VNTRs) within the coding regions of ORF75, ORF94, and ORF125 [4]. In fact, deletions associated with the ORF23/24 and ORF14/15

variable regions are of evolutionary significance, as WSSV genotypes with smaller genomic size (and larger deletion in the ORF23/24 and ORF14/15) are fitter and thrive better than those with larger genomic size [5–10]. Within the ORF94 and ORF125, perfect repeat units (RUs) of 54 and 69 bp, respectively, are identified, and a compound RU of 45 bp interspersed by a 57 bp unit is found in the ORF75 region [11,12]. It appears that for general epidemiological studies of WSSV strains, ORF94 is a better marker than ORF125 and ORF75 due to its maximum variation. In fact, a recent study separated WSSV isolates from India into 31 different genotypes on the basis of ORF94 VNTR [13,14].

98.1.2 Morphology and Genome Organization

Morphologically, WSSV is an enveloped nonoccluded, elliptical to rod-shaped particle of 210–380 nm in length and 70–167 nm in width, with a tail-like appendage at one end. Inside the trilaminar envelope is the nucleocapsid core of 180–420 nm in length, 54–85 nm in width, with a 6 nm thick external wall. Encasing the viral genome, the nucleocapsid core has a crosshatched appearance and is formed by stacks of rings (about 14 in total), which are in turn formed by regular-spaced globular subunits of about 8 nm in diameter, arranged in two parallel rows [15–17].

The genome of WSSV is a monopartite, circular, supercoiled, dsDNA of approximately 300 kb (ranging from 292,967, 295,884, 305,107 to 307,287 bp in isolates originated from Thailand, Korea, China, and Taiwan, respectively) [18,19]. Sequence analysis on the WSSV-TH, WSSV-KR, WSSV-CN, and WSSV-TW genomes reveals a total of 684, 515, 531, and 507 putative open reading frames (ORFs), respectively, of which only 184 (WSSV-TH) and 181 (WSSV-CN) may encode functional proteins [20]. These include at least 39 structural proteins (of which 22 are envelope proteins), as well as enzymes for the nucleotide metabolism, DNA replication, and protein modification [21].

Five major structural proteins (i.e., viral protein [VP] 15, VP19, VP24, VP26, and VP28, with molecular masses of 15, 19, 24, 26, and 28 kDa, respectively) are found in the WSSV particle. Present in the nucleocapsid core, VP15 is a highly basic, histone-like, dsDNA-binding protein with no hydrophobic regions. VP19 and VP28 are associated with the virion envelope. VP26 acts as a tegument protein that links the nucleocapsid associated proteins VP15 and VP24. In addition, about 40 WSSV encoded minor virion proteins are identified from WSSV virions [22,23].

It is notable that VP28 (encoded by ORF 421 or *wsv421*, of 204 amino acids in size) is a major envelope protein of WSSV [24]. VP28 acts as a viral attachment protein to the shrimp cells and interacts with host cellular proteins such as PmRab7, heat shock cognate protein 70, and signal transducer and activator of transcription. The crystal structure of VP28 comprises 12 copies of the protein assembled into four trimers, with each monomer exhibiting a single β-barrel and a α-helix protruding from the β-barrel architecture. The predicted N-terminal transmembrane region of VP28 may anchor on the viral envelope membrane [21].

The nucleocapsid core encasing the viral genome consists mainly of proteins VP15, VP24, VP26, and VP664. Of these, VP664 (with a molecular mass of around 664 kDa) is the major core protein responsible for the striated appearance of the nucleocapsid core [25].

98.1.3 Biology and Epidemiology

98.1.3.1 Biology

WSSV replication initially takes place in the nucleus, and virus morphogenesis begins with the formation of viral envelopes in the nucleoplasm followed by a generation of extended, empty, long tubules, which break up into fragments of 12–14 rings to form empty nucleocapsid shells. The empty capsids are then surrounded by the envelope leaving an open for nucleoproteins and the viral DNA to enter. After the narrowing of the open end, mature virions produce a taillike extension of the envelope and move out of the cell either by budding or by rupture of the nuclear envelope or cell membrane of an infected cell [17].

WSSV persists for a long period in the environment, remains intact in pond soil after 10 months of storage at room temperature, and maintains infectivity in the seawater up to 40 days.

98.1.3.2 Host Range

WSSV is infective to a large variety of aquatic animal species, including penaeids (*P. monodon*, *P. vannamei*, *P. indicus*, *P. japonicus*, *P. chinensis*, *P. penicillatus*, *P. aztecus*, *P. merguiensis*, *Farfantepenaeus duorarum*, *P. stylirostris*), freshwater prawns, crayfish, crabs, marine and brackish water crustaceans, squillas, aquatic arthropods/decapods, copepods, and planktons [26,27]. In farmed shrimp and many other aquatic animals, WSSV is a deadly pathogen, while in some hosts (polychaete worms, microalgae, and rotifer eggs), it causes subclinical infection, which is attributed to viral latency (involving three WSSV ORFs 366, 151, and 427) [28,29]. Animals with asymptomatic infections (including 93 species of arthropods) may act as carriers or reservoirs for WSSV [30,31].

98.1.3.3 Transmission

WSSV is transmitted by both horizontal and vertical modes. Horizontal transmission occurs between individuals of the same host species or between different host species, usually after ingestion of dead infected shrimp or exposure (mainly through the gills and other body surfaces) to water containing infected animals or free virus particles. Various factors may influence the efficiency of horizontal transmission, including biological (host ages, aggression/predation and density, and virulence potential of virus strains) and physiological (water temperature, dissolved oxygen, and salinity) factors [32]. Vertical transmission takes place between mother (shedding virus particles at the time of spawning) and offspring (ingesting virus particles at first feeding). In addition, there is evidence for vertical transmission from infected brood stock to larvae and from adult rotifer (*Brachionus urceus*) to its eggs.

In infected shrimp, WSSV viral particles are present in the connective tissue layer surrounding the seminiferous tubules in testes and in follicle cells, oogonia, oocytes, and connective tissue cells in the ovary [33,34].

98.1.3.4 Geographic Distribution

Since its first emergence in China and Taiwan in 1992, outbreaks of WSD have been recorded across major shrimp farming regions of East Asia, Southeast Asia, Indonesia, and India within a few short years [35–38]. In 1995, WSSV was detected in Texas and South Carolina in the United States. Early in 1999, WSSV spread to Central and South America including Brazil and Argentina [16,39–41]. In 2002, the virus traveled to Europe (France) and the Middle East (Saudi Arabia) and then to Iran and Madagascar. To date, Australia is the only shrimp farming country free of WSSV [42]. Apparently, WSSV transmission between countries is facilitated by the import and export of both live and frozen uncooked shrimp, as well as brood stock [34,42].

98.1.4 Clinical Features

A typical outbreak of WSD in cultured shrimp starts 1 or 2 days after the introduction of the virus or virus-infected shrimp. Clinical signs of WSSV infection include lethargy, anorexia, lack of appetite, swimming near the surface of ponds, formation of white spots (a few mm to 1 cm in diameter) on the exoskeleton especially on the inside surface of the carapace, and finally abdominal segment, loose cuticle, reddish to pink body discoloration, and high mortality (up to 100% within 2–5 days of onset of clinical symptoms [2]).

At the early stages of infection, WSSV is located in the stomach, gills, and cuticular epidermis, and the connective tissue of the hepatopancreas gets infected. At later stages of infection, the virus is found in the lymphoid organ, antennal gland, muscle tissue, hematopoietic tissue, heart, hindgut and parts of the midgut and eventually reaches to the nervous system and the compound eyes. Destruction of ectodermal and mesodermal tissues by WSSV leads to lesions in the infected tissues and organs, with homogeneous hypertrophied/enlarged nuclei containing basophilic central inclusions (called Cowdry A-type inclusions) surrounded by marginated chromatin. The pathognomonic enlarged nuclei containing reddish basophilic inclusions surrounded by unstained cytoplasm are particularly evident in the subcuticular epithelium of the stomach [2,43].

98.1.5 Diagnosis

Although white spots are typically associated with WSD, they may also be caused by bacterial infection (possibly *Bacillus subtilis*) or environmental conditions (such as high alkalinity). Therefore, accurate diagnosis of WSSV infection requires the use of laboratory tests based on histopathological, serological, and molecular principles.

Histopathological examination is useful for the detection of WSSV. In combination with clinical signs, observation of histological changes in affected tissues from moribund prawns provides a presumptive diagnosis of WSD. Typically, live moribund prawns from a suspected WSSV outbreak are fixed by injection with highly acidic Davidson's fixative, which decalcifies the tissues for easy processing and sectioning. For ISH, specimens are transferred from Davidson's fixative after 24–48 h to 70% ethyl alcohol. Then, the specimens are embedded in paraffin wax and processed using standard methods. Observation of inclusion bodies in target tissues is suggestive of WSSV infection.

Further histological details may be obtained by using electron microscopy [44]. Subcuticular tissues, gills, and pleiopods are ideal for this purpose. These specimens may be first screened by rapid-stain tissue squashes or histology to show signs of hypertrophied nuclei and Cowdry A-type inclusions or marginated chromatin surrounding a basophilic inclusion body. Tissues are fixed in a 10:1 fixative to tissue volume of 6% glutaraldehyde at 4°C and buffered with sodium cacodylate or phosphate to pH 7.0 for at least 24 h. For long-term storage, glutaraldehyde concentration is reduced to 1%. The tissues are then fixed in 1% osmium tetroxide and stained with uranyl acetate and lead citrate. WSD virions are rod shaped to elliptical with a trilaminar envelope and measure 80–120 × 250–380 nm.

WSSV may be isolated from infected shrimp using primary cultures of lymphoid or ovary cells [45,46]. A recent report showed that mud crab hemocyte culture also supports WSSV replication in vitro [47]. Collected from live animals, hemocytes are grown in double-strength L-15 medium (2× L-15) prepared in crab saline, supplemented with 5% fetal bovine serum and antibiotic–antimycotic solution (penicillin 100 U/mL, streptomycin 100 µg/mL, and amphotericin B 0.25 µg/mL) with osmolality adjusted to 894 mOsm/kg. The hemocytes adhere within 2 h after seeding and show proliferation up to 72 h. After inoculation with WSSV, the cultured hemocytes display cytopathic effects such as detachment, rounding of cells, and clear areas of depleted cells in 48 h [47,48].

Serological assays employing polyclonal or monoclonal antibodies raised against the virus and native or recombinant viral structural proteins (such as VP28 and VP18) have been proven useful for the diagnosis of WSD. The most common serological testing platforms include indirect fluorescent antibody test, immunohistochemistry, enzyme-linked immunosorbent assay, Western blot, and immunodot assay. These techniques are rapid, convenient, and applicable to field use, but their limited specificity can be a drawback [49,50].

Molecular techniques represent recent additions to diagnostic arsenal for microbial infections including WSD. A range of nonamplified and amplified approaches have been explored with excellent outcomes [51–54]. In particular, PCR and its derivatives (e.g., nested, multiplex, and real time) have been widely adopted in clinical laboratories for WSSV identification, due to their high sensitivity, specificity, speed, and amenability for automation [55–72]. Several commercial PCR assays for WSD diagnosis have been marketed (EBTL, DiagXotics, IQ2000, BIOTEC). The nested PCR described by Lo et al. [73] utilizes the primers 146F1 and 146R1 for

amplification of a 1447 bp fragment in the first round and the primers 146F2 and 146R2 for amplification of an internal fragment of 941 bp in the second round. This assay has an overall sensitivity of 18–180 target molecules for nondegraded DNA and has been recommended by the OIE for routine detection of WSSV [74].

98.1.6 Treatment and Prevention

Currently, no specific treatment is available for WSSV infection, and control and prevention are dependent on implementing measures that reduce virus exposure and enhance host immune status. These include removal of diseased shrimp, filtering intake water into the pond (with 250 μm or smaller mesh filters), screening stocked animals for the presence of the virus, use of nonspecific immune stimulants and fortified mineral and vitamin diets to increase stress tolerance, and increasing acclimation times before stocking.

Vaccine strategies that have been explored to protect shrimp against WSSV include inactivated WSSV vaccines; recombinant protein vaccines expressing VP19 and/or VP28; DNA vaccines containing VP15, VP28, VP35, and/or VP281 genes; and dsRNA vaccines with specificity for VP26, VP28, and VP281. As envelope structural proteins are crucial for viral entry, assembly, and budding processes, they offer useful targets for WSSV vaccine development. In particular, VP28-based vaccines confer protection or increase survival rate of shrimp against WSSV challenge. Given the lack of diversified molecules or memory cells in invertebrates, the current vaccine preparations generally provide short-term protection against WSSV. Further research is needed to extend the efficacy of the vaccines, including the use of *specific immune priming* protocol [75].

98.2 METHODS

98.2.1 Sample Preparation

Viruses in the water samples are concentrated by microfiltration (MF) followed by ultrafiltration (UF). Water samples are prefiltered using 5 μm cartridge filter to remove particulate matter and then subjected to MF using TFF system (QuixStand™ Benchtop system, GE Healthcare Bio-Sciences Corp) fitted with a 0.2 μm pore size TFF cartridge (CFP-2-E-4MA with a surface area of 420 cm^2 or CFP-2-E-9A with a surface area of 8400 cm^2) to remove bacteria and particulate matter. The permeate is then subjected to UF for concentration of viruses with a 100 kDa MWCO TFF cartridge using either a UFP-100-C-4MA with a surface area of 650 cm^2 or a UFP-100-C-9A with a surface area of 1.15 m^2. As a consequence, 20–100 L of water samples is concentrated to 200–1000 fold. After every use, the filter system is sanitized with 200 ppm of free chlorine and 0.5 M sodium hydroxide solution.

Gill tissues from infected shrimp are homogenized in TN buffer (0.2 M Tris–HCl, 0.4 M NaCl, pH 7.4), followed by centrifugation at 5000 × *g* for 20 min. The supernatant is filtered through a 0.45 μm filter and stored at −80°C for later use.

Total DNA is extracted from ~50 μg of gill tissue. The tissue is homogenized using a disposable rod in a 200 μL of 5% (w/v) Chelex X-100 resin (Bio-Rad) solution, 16 μL of 20 mg/ml proteinase K (Promega) in 50 mM Tris–HCl pH 8.0 is then added, and the mixture is incubated at 56°C for at least 6 h to overnight, followed by 95°C for 10 min to inactivate the proteinase K. The mixture is microcentrifuged at 13,000 rpm for 5 min and the supernatant containing DNA is stored at −20°C. Alternatively, total DNA may be extracted by using the Qiagen DNA purification kit.

98.2.2 Detection Procedures

98.2.2.1 Conventional PCR

Dieu et al. [36] described the use of the primers VP26F (5′-ATGGAATTTGGCAACCTAACAAACCTG-3′; nt 228,835–228,809) and VP26R (5′- GGGCTGTGACGGTAGAGA TGAC-3′; nt 228,532–228,553) for specific amplification of a 304 bp fragment from the WSSV VP26 gene.

PCR mixture (50 μL) consists of 1 μL of gill DNA solution and Taq DNA polymerase from Promega. The cycling parameters include denaturation at 94°C for 3 min, 40 cycles at 94°C for 30 s, 52°C for 30 s, and 72°C for 50 s and an extension at 72°C for 7 min. The resulting product is separated on 1.5% agarose gel containing ethidium bromide and visualized under UV light.

Note: A nested PCR developed by Lo et al. [73] may be performed if a higher sensitivity is desired. While the first-round PCR primers, 146F1 (5′-ACT-ACT-AAC-TTC-AGC-CTA-TCTAG-3′) and 146R1 (5′-TAA-TGC-GGG-TGT-AAT-GTT-CTT-ACG-A-3′), amplify a 1447 bp product; the second-round PCR primers, 146F2 (5′-GTA-ACT-GCC-CCT-TCC-ATC-TCC-A-3′) and 146R2 (5′-TAC-GGC-AGC-TGC-TGC-ACC-TTG-T-3′), produce a 941 bp fragment. This assay is recommended by OIE for WSSV diagnosis [OIE 2012].

98.2.2.2 Real-Time PCR

Mendoza–Cano and Sánchez–Paz [69] reported a SYBR green-based real-time PCR (qPCR) for the detection and quantitation of WSSV, with primers (VP28-140Fw, 5′-AGG-TGT-GGA-ACA-ACA-CAT-CAA-G-3′; VP28-140Rv, 5′-TGC-CAA-CTT-CAT-CCT-CAT-CA-3′) targeting a 141 bp fragment from a highly conserved region of the VP28 gene. This 141 fragment corresponds to the segment of the protrusion emanating outside the viral envelope (VWNNTSRKINITG MQMVPKINPSKAFVGSSNTSSFTPVSIDEDEVG), which plays an essential role in the initial interaction with host receptors.

The qPCR mixture (14 μL) is composed of 1 μL of DNA, 7.5 μL of 2× iQ SYBR® Green Supermix (Bio-Rad), 0.5 μL of each primer (10 pmol), and 4.5 μL of nuclease-free water.

Amplification and detection are carried out in a Rotor-Gene 3000 real-time rotary thermal cycler (Corbett Life Science), with the following parameters: denaturation at 95°C for 5 min; 30 cycles at 94°C for 30 s, 61°C for 30 s, and 72°C for 30 s; and a final extension step at 72°C for 5 min.

Fluorescence measurements (510 nm) are taken at the end the elongation phase for each cycle. Melting curve analysis, to detect the occurrence of primer-dimer formation or the amplification of other nonspecific products, is performed immediately after amplification by slow heating of the samples from 60°C to 99°C with a 0.3°C/s ramping rate and stepwise fluorescence detection at 0.3°C interval. The melting curves are converted to melting peaks by plotting the negative derivatives of fluorescence against temperature (−dF/dT). All reactions are done in triplicate, and the quantification cycle (C_q) values are automatically calculated with the Rotor-Gene software version 6.1. The qPCR reaction efficiency and linearity are calculated from the standard curve.

Note: This one-step real-time PCR provides a rapid and sensitive tool for detection and quantitation of WSSV in both penaeid and nonpenaeid crustacean species (e.g., *P. stylirostris*, *P. vannamei*, *Farfantepenaeus paulensis*, *Farfantepenaeus brasiliensis*, *P. monodon*, *P. indicus*, *Lysmata californica*, *Palaemon ritteri*, *Calanus pacificus*, *Macrobrachium rosenbergii*, and *Petrolisthes edwardsii*).

98.3 CONCLUSION

WSSV is an enzootic organism with common occurrence in >98 wild and cultured aquatic animal species throughout the world. Transmitted both vertically and horizontally, WSSV causes a highly contagious, lethal disease known as WSD, most common in cultured shrimp. In the absence of therapeutic treatments and vaccines, control and prevention of WSD rely on good management practices including the use of highly sensitive and specific PCR for disease diagnosis and certification of WSSV-negative shrimp stocks. Further research is warranted in the area of WSSV pathogenesis in order to develop effective, tailor-made control strategies against WSD.

99.1 INTRODUCTION

Prion diseases, or transmissible spongiform encephalopathies (TSEs), are fatal neurological diseases that include Creutzfeldt–Jakob disease (CJD) in humans, scrapie in sheep and goats, bovine spongiform encephalopathy (BSE) in cattle, chronic wasting disease (CWD) in cervids, transmissible mink encephalopathy in minks, feline spongiform encephalopathy in cats, and exotic ungulate encephalopathy in zoo animals such as the kudu, nyala, gemsbok, eland, and oryx. The prion agent of each disease is named after the disease itself (e.g., CJD agent in CJD, scrapie agent in scrapie). A key event in the development of prion diseases is the conversion of the cellular, host-encoded prion protein (PrP^{C}) to its abnormal isoform (PrP^{Sc}) predominantly in the central nervous system (CNS) of the infected host [1]. This chapter will introduce the molecular detection of BSE as well as the fundamental aspects of the disease.

99.1.1 Classification

To understand the causative pathogens, information on their chemical composition will provide important clues. Reports published in 1980 indicated that the scrapie agent was inactivated by proteases [2,3] or by treatment with modified or denatured proteins [4,5]. These studies demonstrated that the scrapie agent required a protein but did little to discriminate it structurally from other infectious particles [6]. The knowledge that a protein was involved undoubtedly motivated scientists to improve both the method for purifying the scrapie agent and techniques for identifying agent-specific proteins. The discovery of PrP^{Sc} and PrP^{C} initiated a period of remarkable progress in this field by providing physical and diagnostic markers for prion diseases [7]. Numerous compelling observations made over the last three decades support the notion that PrP^{Sc} is the main component of prion agents [8].

99.1.2 Morphology and Biology/Epidemiology

99.1.2.1 Morphology

The discovery of scrapie-associated fibrils (SAFs) [9] provided the first ultrastructural observation that achieved some degree of consensus as a prion-specific agent. SAFs were verified by several laboratories and found to be similar, though not identical, to prion rods, which were identified shortly afterward [10,11]. A consensus on the issue of SAF/prion rod identity was not achieved because the theoretical perspective of the respective research groups significantly shaped their interpretation of the observations. Some research groups viewed SAFs as filamentous scrapie viruses or later as components of a tubulofilamentous nemavirus structure [12], whereas others viewed SAFs as part of the pathology. Another research group considered SAFs and prion rods to be either related forms of the same phenomenon (i.e., aggregate of PrP^{Sc} [13]) or unrelated structures [14]. However, in both cases, these structures were considered unnecessary for prion biological activity. This is because neither rods nor SAFs are present after sonication or in liposome preparations although high protein titers and PrP^{Sc}

remained [15]. In contrast, reports identifying specific virus particles or nucleoprotein complexes [16] have not been reinforced by other reports in terms of a plausible prion agent.

99.1.2.2 Biology

Three biological criteria are used to define strains of prion agents: incubation time, distribution of vacuoles throughout the brain, and distribution of amyloid or PrP^{Sc}. As the existence of more than one prion agent phenotype in a single genetically identical host can be accepted, there should be little doubt that different prion isolates exhibit distinct phenotypes.

Structural differences in PrP^{Sc} conformations can explain the different strains. Specific examples to support this hypothesis have been reported in the literature [17]. Critics of the protein hypothesis cite the existence of at least 20 distinct strains and argue that different conformations of PrP^{Sc} cannot account for all of these variations. These statements could be counteracted by the following two arguments. First, most of the strains cited have not been characterized in a single inbred host, and thus, the actual number of unique strains remains unknown. PrP^{Sc} is actually a population of molecules having at least 400 different glycosylation variants. Therefore, combinations of protein conformation and different patterns of glycosylation could (at least numerically) account for all the strains known at this time.

99.1.2.3 Epidemiology

The BSE agent is believed to have originated from the scrapie agent. Scrapie was considered a disease of sheep that did not infect humans, although the tissues of infected animals were known to contain an infectious agent. As there were no other known natural TSEs, when BSE first appeared, it was immediately considered to be derived from scrapie. Meat originating from sheep had been fed to cattle as part of the food they consumed to increase milk yield. Under the direction of the British Ministry of Agriculture, Fishery, and Foods (MAFF), a change occurred in the way that this meal was prepared in the United Kingdom in the early 1980s. This change in policy coincided with the original infection in cattle.

A small farm in Surrey in the United Kingdom reported the development of a strange neurological disease in multiple cows. The cattle were immediately killed and their brains removed for examination. When it was found that the cattle had developed a previously unrecognized disease, the farmer wanted to publish the data, but he was advised against this by MAFF. It is currently estimated that approximately 100 cattle may have developed BSE symptoms prior to 1987.

In 1987, Wells et al. published data illustrating that a cow developed a spongiform encephalopathy [18], although few extra details were provided. MAFF soon realized that this was no straightforward disease and devised a committee to advise them on what action should be taken to avoid any risk to humans and cattle.

In April 1988, the UK government established the Southwood Committee to investigate the outbreak of BSE. In the same year, the committee published a report stating that there would be minimal risk to humans, because all infected cattle would be slaughtered. The response to the BSE crisis was to prevent all bovine material from entering the meal fed to cattle. This strategy was implemented in July 1988. The feed manufacturers were warned several months in advance of the change in *policy*. The reporting of cases of BSE to MAFF was made obligatory, and farmers were compensated with half the value of a nonsick animal.

Since its first appearance in 1986, BSE has been registered at a clinical level in more than 180,000 bovine cattle in the United Kingdom (Figure 99.1), and it is believed that as many as 1 million undiagnosed infected cattle would have entered the human food chain [19]. This transmissible prion disease was transmitted from bovine tissue through the consumption of contaminated meat-and-bone meal (MBM) [20]. MBM is used as animal feed in various proportions throughout most of the developed world. However, only a few European countries described cases of BSE originating from within their borders following the initial outbreak in the United Kingdom. Epidemiological analysis revealed many years later that almost all European countries were affected by BSE (Table 99.1). Between November 1986 and October 2014, 184,624 cases of BSE were confirmed in the United Kingdom.

This table is based on information on the OIE website as of October 12, 2014.

[*1] The data for the United Kingdom (as of October 2, 2014) and the other countries were those reported in 2013 or 2014.

[*2] One case was detected in the United States.

[*3] The total number of cattle tested in Canada included one imported cattle and the first reported case in the United States (December 2003).

[*4] One animal with BSE was found in Romania.

Since 1989, a relatively small number of cases of BSE (6028 in total) have also been reported in native cattle in Austria, Belgium, Brazil, Czech Republic, Denmark, Finland, France, Germany, Greece, Ireland, Israel, Italy, Japan, Liechtenstein, Luxembourg, the Netherlands, Poland, Portugal, Slovakia, Spain, and Switzerland. Since the introduction of monitoring programs to detect BSE in dead and slaughtered cattle, 12 countries have reported their first native case (Austria, Czech Republic, Finland, Germany, Greece, Israel, Italy, Japan, Poland, Slovakia, Slovenia, Spain). A small number of cases have also been reported in Canada, the Falkland Islands (Islas Malvinas), and Oman, but these cases occurred solely in animals imported from the United Kingdom. In the absence of large-scale studies, whether many non-European countries are actually BSE-free remains unknown [21].

In 1996, the British government announced several cases of a new form of CJD in young patients [22] called variant Creutzfeldt–Jakob disease (vCJD) that was caused by a BSE agent entering the body through the oral route. As of June 2014, 229 cases of vCJD have been confirmed (including 177 in the United Kingdom). Many parameters, including the infective dose, susceptibility, and duration of the incubation period, remain unknown. Mathematical models have been developed to analyze the likely spread of the disease, but these remain imprecise. The initial models estimated that the number of cases of vCJD ranged between 100 and more than 100,000. However, more recent models suggest that a total of a few hundred to a few thousand cases of vCJD occurred in the United Kingdom due to the direct contamination of humans through the consumption of beef products [23]. Moreover, the risk of secondary transmission between humans must be considered. Proteinase K (PK)-resistant prion protein (PrPres), the disease-specific biochemical marker that is believed to be the infectious agent [24], has been found in peripheral lymphoid organs (e.g., tonsils, appendix) of patients with vCJD [25]. The theoretical risk of iatrogenic transmission, *via* blood transfusion, organ transplantation, or contaminated surgical tools, could be higher than that for sporadic CJD [26].

To prevent new cases of vCJD, the first measure has been to stop the consumption of the potent infectious organs of cattle (the CNS and some immune organs) [27], which are termed specified risk materials and which correspond to 99% of the total infectivity. The clinical signs of BSE appear late in the course of the disease, and the clinical diagnosis is complicated by the absence of pathognomonic signatures. Consequently, an infected animal could still enter the human food chain and present a risk to human health. For example, the spinal cord could be incompletely removed, and dorsal root ganglia may be retained in the vertebrae. Moreover, improvements in slaughtering practices did not prevent the contamination of healthy materials by infected tissue. Therefore, the development of sensitive detection and efficient inactivation methods for prion is important.

99.1.2.4 Atypical BSE

The large-scale testing of livestock nervous tissues for the presence of PrP^{Sc} has led to the recognition of two molecular signatures that are distinct from BSE. These were termed H-BSE and L-BSE (or BASE) (Table 99.2). The L-type is also referred to as "bovine amyloidotic spongiform encephalopahy" or BASE.

TABLE 99.2
Number of Cases of Atypical Bovine Spongiform Encephalopathy Worldwide (as of July 2014)

Summarized by the Department of Epidemiology of Animal Health Institute of Italy (the 71st Prion Expert Committee Material 3 [May 29, 2012] was partially revised).

Updated from the report of OIE (World Organisation for Animal Health).

Their PrP^{Sc} molecular signature differed from that of the classical BSE in terms of the protease-resistant fragment size and glycopattern [28]. The experimental transmission of these cases to different lines of bovine prion protein (PrP) transgenic mice unambiguously demonstrated their infectious nature and confirmed their unique but distinctive strain type as compared to the classical BSE [29,30]. These uncommon cases have been detected in aged asymptomatic cattle during systematic testing at slaughterhouses. In France, a retrospective study of all TSE-positive cattle identified through the compulsory EU surveillance program (2001–2007) was conducted [31]. This study revealed that all cases of H-BSE and L-BSE detected by rapid tests were observed in animals over 8 years of age in either the fallen stock surveillance stream or the abattoir. The frequencies of H-BSE and L-BSE are 0.35 and 0.41 cases per million adult cattle tested, respectively, but it increases to 1.9 and 1.7 cases per million, respectively, in animals more than 8 years of age.

The origin of these atypical BSE cases in cattle is currently unknown, as is the performance of the current active surveillance system for detecting H-BSE- and L-BSE-affected animals. Consequently, there is uncertainty concerning the true prevalence of these conditions within the stock of cattle. All atypical cases of BSE identified in the EU occurred in animals born before the extended or real feed ban that was passed into law in January 2001. Hence, as observed with classical BSE, exposure of these animals to contaminated feed with low titers of TSE agents cannot be excluded. Equally, additional origins for these TSE forms cannot be ruled out at this stage. In particular, the unusually old age of all animals affected by H-BSE and L-BSE and their apparent low prevalence in the population could suggest that these atypical BSE forms arise spontaneously.

There are some data related to the peripheral distribution of the L-BSE agent in cattle experimentally challenged *via* the intracerebral route. In a Japanese study, infectivity and PrP^{res} were detected in many peripheral nerves tested from midincubation onward. PrP^{res} was not detected in lymphoid tissue [32]. In an Italian study, PrP^{res} was not detected in peripheral nerves [33], but the presence of infectivity in skeletal muscle, presumably linked to nervous structures, of natural cases was described [34].

Both L-BSE and H-BSE agents can propagate in experimentally challenged foreign species such as mice, sheep, voles, primates, and hamsters and in transgenic mice expressing heterologous (i.e., nonbovine PrP) sequences. It is notable that the transmission barrier observed for the L-BSE agent was lower than that for classical BSE. The transmission of an H-BSE isolate originating from France and Poland to bovine PrP transgenic mice has recently been reported [35].

99.1.3 Clinical Features and Pathogenesis

BSE, which is also called "mad cow disease," causes progressive and invariably fetal neurodegeneration in cattle. The clinical signs of BSE include tremors; gait abnormalities, particularly of the hind limbs (ataxia); aggressive behavior; apprehension; and hyperreactivity to stimuli [36]. Weight loss and decreased milk production are occasionally observed. The incubation period for BSE is 2–8 years, and most cases of BSE were found in 4–5-year-old dairy cattle [37].

Early studies during the 1980s indicated that the BSE agent can only be found in the brain, spinal cord, and retinal tissue of BSE-diseased cattle [38]. An infectivity assessment in several tissues from orally inoculated cattle, using a bioassay based on RIII mice [39], revealed the presence of BSE infectivity in the CNS, optic nerve, retina, cervical, thoracic, trigeminal ganglia, and facial and sciatic nerves, as well as in the distal ileum. The skeletal muscle, spleen, and other lymphatic tissues were demonstrated to be free from detectable infectivity. More recently, infectivity was discovered on the tonsils of cattle killed 10 months after the oral BSE challenge by intracerebral inoculation in cattle [40]. These results consistently indicate that BSE infectivity after oral uptake only propagates poorly in some intestinal lymphatic tissues (mainly Peyer's patches) and from there spreads to the CNS, probably by an intraneural route *via* the peripheral nervous system [41].

These findings contrast to the manner in which the scrapie agent spreads in infected sheep, mice, and hamsters. In this case, the scrapie agent spreads *via* tissues such as the spleen, other lymphatic tissues, and muscles, even during the

preclinical stage [42–45]. However, the BSE agent can be found in the lymphoreticular system and other peripheral tissues when transmitted to sheep or primates [46].

99.1.4 Diagnosis

Several biochemical methods have been used to diagnose BSE. These include enzyme-linked immunosorbent assay (ELISA), western blotting, and immunohistochemistry (IHC) (Figures 99.2 and 99.3). As an index of prion infection, representative changes in the brain were detected in these assays. Using ELISA and western blotting, protease-resistant PrPs, which are accumulated in the brain and form deposits, were biochemically detected after treatment with PK. In the case of ELISA for BSE, a homogenate is usually prepared from the brain obex and treated with PK. The treated sample is applied to a microtiter plate for absorption and then reacted with an anti-PrP antibody. This method is commercially exploited in the Bio-Rad TeSE BSE Kit (Bio-Rad, France), Enfer TSE Kit (Abbott Laboratories, United States), and FRELISA BSE Kit (FUJIREBIO Inc., Japan) (Table 99.3). Although the extensively employed ELISA is a sensitive and high-throughput method, the large frequency of false-positives remains a problem. Therefore, if a result is positive, ELISA must be repeated to validate the finding. If a positive result is obtained again, western blotting and IHC are performed. Western blotting uses a membrane to absorb PK-treated proteins separated by sodium dodecyl sulfate (SDS) polyacrylamide gel electrophoresis (PAGE) (Figure 99.2). After the absorption, PK-resistant PrP (PrP^{res}) in the membrane-bound proteins is detected with an anti-PrP antibody. Importantly, western blotting provides information on both prion infections and the mobility of peptides, which is influenced by the host genotype and prion strains [47]. In the case of IHC, the indices for BSE are neuronal cell loss, astrocytosis, and vacuolation in addition to PrP accumulation (amyloid plaques) (Figure 99.3). In IHC-based analyses of brain sections, these changes are examined by light microscopy. Although vacuolation is also used as an index of prion infection, various combinations of prion strains with

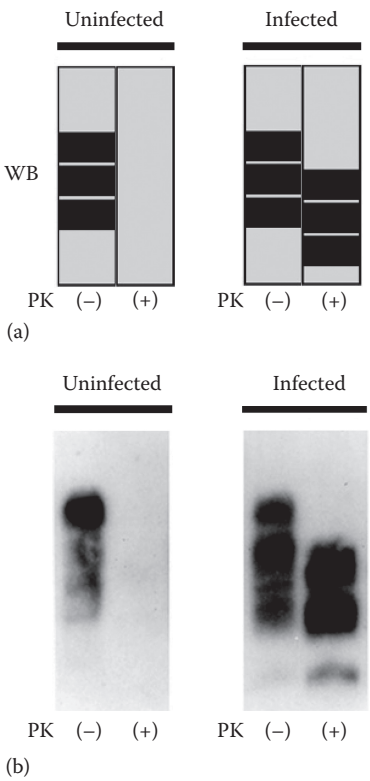

FIGURE 99.2 Western blotting for diagnosing prion diseases. Brain tissue is used for the definitive diagnosis of prion diseases. Therefore, the diagnosis is basically postmortem. Most methods for diagnosing prion diseases are based on the characteristics of the abnormal isoform of a prion protein (PrP^{Sc}), which is resistant to proteinase K (PK). PK completely degrades the cellular isoform of prion protein (PrP^{C}) but only partially digests PrP^{Sc} because the latter forms protease-resistant aggregates. After the treatment, western blotting with antiprion protein (PrP) antibody detects PK-resistant PrP (PrP^{res}) when PrP^{Sc} is included in the sample. As the N-terminal region of PrP^{Sc} is digested with PK (+), PK-resistant PrP displays a shift to a lower molecular weight compared to untreated PrP (–) in western blotting. (a) Schematic presentation and (b) the data of western blotting for PrP in the brains of prion-infected and uninfected mice before (–) and after (+) PK treatment. (Modified from Fig. 1 in the study by Inoue, Y. et al., *Jpn. J. Infect. Dis*., 58, 78, 2005. After permission from Japanese Journal of Infectious Diseases.)

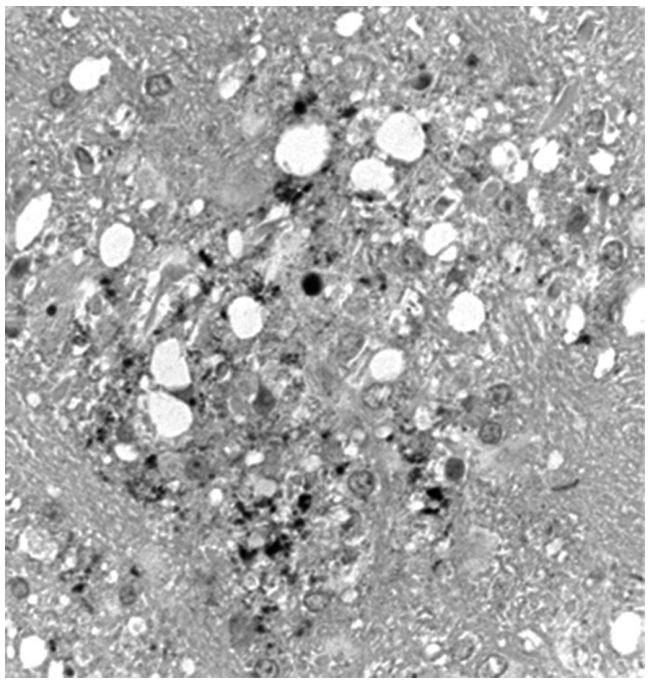

FIGURE 99.3 Immunohistochemistry (IHC) for the diagnosis of prion diseases. IHC is usually used for the definitive diagnosis of prion diseases. In IHC, vacuolation and prion protein (PrP) deposits in brain are usually used as indices of prion diseases. IHC of the brains of terminally prion-diseased mice infected with Obihiro-1 prions is shown. PrP was detected by an anti-PrP antibody (6H4). (Vacuolation and PrP deposits were observed courtesy of Dr. Yuji Inoue, Department of Virology, Center for Infectious Disease Control, Research Institute for Microbial Diseases, Osaka University, Osaka, Japan.)

TABLE 99.3
Representative BSE Kit

Kit[a]	Company	Methods
Beta Prion BSE EIA Test Kit	Roboscreen	Sandwich ELISA (colorimetric)
Bio-Rad TeSeE BSE	Bio-Rad	Sandwich ELISA (colorimetric)
Bovine Spongiform Encephalopathy Antigen Test Kit, IHC	VMRD	IHC (for BSE, formic acid + heat-treated brain specimen for the detection of accumulated PrP)
BSE PLUS TEST—a presymptomatic test for BSE	Altegen	Detection of antiprion antibody, which is produced at an early stage of prion infection
CediTect BSE	Cedi Diagnostics	Filter assay for the measurement of denatured/undenatured PrP (chemiluminescence)
Enfer TSE Kit v2.0	Abbott Laboratories	Direct ELISA (automation, chemiluminescence)
Frelisa BSE	Fujirebio	Sandwich ELISA (colorimetric).
IDEXX HerdCheck BSE Antigen Test Kit	IDEXX Laboratories	Direct ELISA (no PK treatment, colorimetric)
Inpro CDI Kit	Beckman Coulter	CDI for the measurement of denatured/undenatured PrP (concentration by PTA precipitation)
NipplBL BSE Test Kit	Nippi	Sandwich ELISA (colorimetric)
PAD-Beads Seprion-PAD	Microsens Biotechnologies	Concentration of abnormal aggregated PrP including PrP^{Sc} (binding of aggregated protein by Seprion ligand)
Platelia BSE Detection Kit	CEA (Bio-Rad)	Sandwich ELISA (colorimetric)
Prion Protein EIA Kit	SPI Bio	Sandwich ELISA (no PK treatment, PrP detection, colorimetric)
Prionics-Check LIA	Prionics	Sandwich ELISA (chemiluminescence)
Prionics-Check PrioSTRIP	Prionics	Immunochromatography (for BSE)
Prionics-Check WB	Prionics	Western blotting (for BSE)
PrionScreen	Roche Applied Science	Sandwich ELISA (colorimetric)
Priontype postmortem	Labor Diagnostik Leipzig	Sandwich ELISA (no PK treatment, colorimetric)
Speed'it BSE	Institut Pourquier	Sandwich ELISA (chemiluminescence)

BSE, bovine spongiform encephalopathy; CDI, conformation dependent immunoassay; ELISA, enzyme-linked immunosorbent assay; IHC, immunohistochemistry; PK, proteinase K; PrP, prion protein; PrP^{Sc}, abnormal prion protein; PTA, phosphotungstic acid; TSE, transmissible spongiform encephalopathy.

[a] Modified and new versions of kits have been developed by each company.

host species result in the accumulation of PrP without vacuolation in brain sections [48]. Many new diagnostic methods for prion diseases have recently been developed (Table 99.4). Most of these methods use PrP^{res} as the index of prion infection. Among them, the protein misfolding cyclic amplification (PMCA) method is the most promising for a sensitive diagnosis [49]. In this method, the ability of PrP^{Sc} to convert PrP^{C} into PrP^{Sc} is used. This enables the *in vitro* amplification of PrP^{res} from a small quantity of PrP^{Sc} as seed *via* sequential cycles of incubation and sonication. The levels of PrP^{res} amplified by this method correlated with the prion infectivity titer [50]. Furthermore, PMCA could detect prions in blood [51]. Thus, PMCA may be used to diagnose both terminally diseased hamsters and prion-infected presymptomatic hamsters [52]. This method has the highest sensitivity when compared with any of the methods used for detecting PrP^{res} reported to date. Recently, PMCA has been modified, leading to recombinant PrP-PMCA [53] and its combination with the quaking-induced conversion reaction [54], as well as the real-time quaking-induced conversion for quantitative analysis [55].

In other diagnostic methods, capillary gel electrophoresis is combined with a competitive antibody-binding assay that uses a fluorescein-labeled synthetic PrP peptide and PrP [56]. The free peptide and antibody-peptide peaks are separated by capillary electrophoresis and used for diagnosis. In fluorescence correlation spectroscopy, single fluorescently labeled molecules in solution are detected [57]. Using this method, PrP^{Sc} can be labeled by the anti-PrP antibody or by conjugation with labeled recombinant PrP for diagnosis. In Fourier transform infrared spectroscopy, the difference of the infrared spectra of samples between prion-infected and uninfected animals is used for diagnosis [58]. A detection tool for PrP^{Sc} was recently developed. Some antibodies and aptamers can distinguish PrP^{Sc} from PrP^{C}. Antibodies having a conformational epitope of PrP^{Sc} were obtained by immunization with a Tyr-Tyr-Arg peptide [59]. The antibodies 15B3, V5B2, mAb132, 3B7, 2C4, 1B12, and 3H6 can also recognize PrP^{Sc}-specific epitopes [60]. PrP^{C}- and/or PrP^{Sc}-specific binding aptamers, which are RNA or DNA molecules that are specifically binding to a target protein, were reported [61]. PrP^{Sc}-specific antibodies and aptamers might both serve as a diagnostic or analytical tool for investigating prion diseases and facilitate the development of useful therapeutic agents, that is, if they are found to inhibit the accumulation of PrP^{Sc}.

There are many genes and proteins with differential abundances in prion diseases [62]. These changes can be used as markers of prion diseases. Examples of deregulated genes associated with prion diseases include adenosine triphosphate (ATP)-binding cassette, amyloid beta (A4) precursor-like protein 1, apolipoprotein D and E, beta-2-microglobulin, CD9 molecule, clusterin, cystatin C, cathepsin S, glial fibrillary acidic protein, osteonectin, bone sialoprotein I, and early T lymphocyte activation 1 [63]. Differentially expressed protein biomarkers for prion diseases include vitronectin, α1-acid glycoprotein, α1-antichymotrypsin, apolipoprotein B100, apolipoprotein E, cathelicidin antimicrobial peptide, clusterin, complement C3 and C4, complement factor

CDI, conformation dependent immunoassay; DELFIA, dissociation-enhanced lanthanide fluorescent immunoassay; ELISA, enzyme-linked immunosorbent assay; MRM, multiple reaction monitoring; PCR, polymerase chain reaction; PET, paraffin-embedded tissue; PK, proteinase K; PMCA, protein misfolding cyclic amplification; PrP, prion protein; PrP^{C}, cellular isoform of PrP; PrP^{res}, PK-resistant PrP; PrP^{Sc}, abnormal isoform of PrP; PVDF, polyvinylidene difluoride; SDS, sodium dodecyl sulfate; SOFIA, surround optical fiber immunoassay.

[a] Protein A binds an antibody.

B and H, haptoglobin α-2 chain, histidine-rich glycoprotein, Ig gamma-2 chain C region, transthyretin, uroguanylin, vitronectin precursor, and α2-macroglobulin [63–67]. Changes in response to prion infection have recently been employed as an index for the diagnosis of prion diseases. For example, the level of urinary α1-antichymotrypsin was drastically increased in the urine of patients with sporadic CJD and other animal models of prion diseases [68]. Moreover, increases of S100β, cystatin C, and heart fatty acid–binding protein levels in the blood of patients with CJD has been reported [67,69]. In particular, 14-3-3 [70], erythroid-specific marker [71], plasminogen [72], tau, phosphor-tau, S100β, and neuron-specific enolase are promising surrogate markers for prion diseases [62].

Taken together, prion diseases can usually be diagnosed by methods such as ELISA, western blotting, and immunohistochemical analysis [73]. Recently, there have been drastic improvements in sensitive diagnostic methods for prion diseases. Nonetheless, further developments of analytical methods to specifically and reliably detect prions are urgently needed.

99.2 METHODS

As an example of a diagnostic method for prion diseases, the materials and methods used for western blotting are presented. In particular, several precautions that should be monitored during the procedures are emphasized.

99.2.1 Reagents and Equipment

99.2.1.1 Reagents

- Dithiothreitol (Promega, Madison, WI)
- *N*-tetradecyl-*N*,*N*-dimethyl-3-ammonio-1-propanesulfonate and sulfobetaine (Calbiochem or Sigma)
- *N*-lauroyl-sacrosinate (Sigma), protease inhibitors (Roche)
- RNase A (from bovine pancreas, protease-free) and DNase I (Calbiochem or Roche)
- Protein concentration assay kit (Pierce)

99.2.1.2 Equipment

To avoid cross contamination between different scrapie strains, we recommend the use of new glassware and instruments or single-use materials for animal inoculations, the dissection of brains from affected animals, and the purification of PrP^{Sc}. This is particularly important if the isolates are to be used in animal bioassays. Avoid blood contamination during the dissection of brains, rinse excised brains in phosphate-buffered saline (PBS), flash freeze the specimens in liquid nitrogen, and store the dissected brains at −70°C. All solutions must be filtered (0.2 μm) and placed in lint-free vessels previously rinsed with distilled or deionized water. All procedures should be performed in a laminar flow biosafety cabinet in an appropriate laboratory according to governmental regulations. Personal protection equipment (lab coat, gloves, and face mask) should be used, and gloves should be changed frequently.

99.2.2 Sample Preparation and Detection Procedures

PrP^{Sc} was prepared using a modified version of the procedure described by Sakudo et al. [74]. PrP^{Sc} from a TSE-affected brain tissue has been successfully purified in several species including humans with CJD and vCJD, sheep with scrapie, cattle with BSE, and cervids with CWD. Numerous experiments have used PrP^{Sc} isolates purified by this procedure, allowing detailed analyses of several different aspects of TSEs. Typically, the PrP^{Sc} yield from the hamster 263 K strain is 50–100 μg/g brain. The described method yields PrP^{Sc} preparations with a total protein content of between 60% and 90%. Non-PK-digested preparations are usually less pure than PK-digested preparations because nearly all other proteins are digested by PK. However, a significant protein contaminant identified in these preparations is ferritin, which survives even with PK treatment [75]. Variations in purity may depend on the TSE strain, the stage of the disease, the manner in which the brain is excised and stored, and the expediency of the purification. In addition to contamination by other proteins, the final PrP^{Sc} sample most likely contains trace quantities of lipids, nucleic acids, carbohydrates, and ions (e.g., copper, iron, calcium).

Tissues or cells are solubilized in radioimmunoprecipitation assay buffer containing 10 mM Tris–HCl (pH 7.4), 1% deoxycholate, 1% Nonidet P-40, 0.1% sodium dodecyl sulfate (SDS), and 150 mM NaCl and then sonicated at 4°C for 10 min. Then, the protein concentration of the supernatants is measured using a Bio-Rad DC protein assay (Bio-Rad, Hercules, CA). Afterward, the sample (120 μg of protein) is treated with PK at 20 μg/mL for 30 min at 37°C. An equal volume of 2× SDS gel-loading buffer (90 mM Tris–HCl pH 6.8, 10% mercaptoethanol, 2% SDS, 0.02% bromophenol blue, and 20% glycerol) is added and heated at 100°C for 10 min to terminate the reaction prior to western blotting. Samples treated as described previously excluding the digestion by PK should also be included as controls. For protein detection, proteins in the samples are separated by conventional SDS-polyacrylamide gel electrophoresis (PAGE) (15%) as described previously. Then, the proteins are transferred to polyvinylidene difluoride (PVDF) membranes (Amersham Biosciences, Piscataway, NJ) using a semidry blotting system (Bio-Rad). The membranes are blocked with 5% skim milk for 1 h at room temperature. The blocked membranes should then be further incubated for 1 h at room temperature with anti-PrP antibody, which recognizes the C-terminal half of PrP, in PBS-Tween (0.1% Tween 20) containing 0.5% skim milk.

Note: Anti-PrP antibodies recognizing the C-terminal half of PrP such as SAF83 and 6H4 (Prionics AG) should be used for the detection of PrP^{Sc} in this western blotting system, whereas those recognizing the N-terminal half of PrP such as SAF32 (SPI bio) cannot be used. This is because the C-terminal half of PrP^{Sc} is resistant to PK, whereas the N-terminal half is susceptible to PK.

After washing the membranes thrice for 10 min in PBS-Tween, they are incubated with horseradish peroxidase-labeled antimouse immunoglobulin secondary antibody in PBS-Tween containing 0.5% skim milk for 1 h at room temperature. The membranes are further developed with an enhanced chemiluminescence (ECL) reagent (Amersham) for 5 min. Blots are exposed to ECL Hypermax film (Amersham). Films are processed in an x-ray film processor.

The results obtained by western blotting using prion-infected and uninfected mouse brain are shown in Figure 99.2. Uninfected brain produces PrP^{C} but not PrP^{Sc}, whereas prion-infected brain produces both PrP^{C} and PrP^{Sc}. Therefore, PrP in uninfected mouse brain is digestible with PK, whereas that in prion-infected mouse brain is partially resistant to PK. It is obvious that western blotting of PrP using the anti-PrP antibody detects PrP in prion-infected brain but not in uninfected brain after digestion by PK. PK treatment causes a shift in the molecular weight of PrP from 33–35 kDa to 27–30 kDa in prion-infected brain, whereas PK treatment completely degrades PrP in uninfected brain.

99.2.3 Inactivation Methods

Prion agents are highly resistant against various treatments. Since prion has no associated nucleic acid [75], it cannot be inactivated by conventional sterilization procedures such as autoclaving (121°C, 20 min) or exposure to UV or γ-ray irradiation [76]. Treatment with alcohols, such as 70% ethanol, has no effect on prions. Inactivation of prions involves the use of an autoclave under severe conditions (134°C, 18 min), NaOH (1 N, 20°C, 1 h), SDS (30%, 100°C, 10 min), and NaOCl (20,000 ppm, 20°C, 1 min). Fixation using aldehyde slightly decreases the prion titer, but this is insufficient. Therefore, to treat tissue sections from prion-infected animals, formic acid is recommended. The following procedures for prion inactivation are currently recommended by the Society for Healthcare Epidemiology of America [77]: (1) washing with appropriate detergents + SDS treatment (3%, 3–5 min), (2) treating with alkaline detergents (80°C–93°C, 3–10 min) + autoclaving (134°C, 8–10 min), (3) washing with appropriate detergents + autoclaving (134°C, 18 min), and (4) washing with alkaline detergents (at a concentration and temperature according to instructions) + vaporized hydrogen peroxide gas plasma sterilization. Although these methods can be used for apparatuses or instruments, there is no applicable treatment to inactivate prions in food.

99.3 CONCLUSION

BSE was first diagnosed in the United Kingdom in 1986. Since that time, the disease has occurred in many European countries as well as Japan, Brazil, Canada, Israel, and the United States. Most of the reported cases of BSE (95%) have occurred in the United Kingdom.

Most cattle are infected when they orally ingest prion-contaminated "ruminant" MBM. This dietary supplement has been banned from feed since 1999. BSE is a fatal but typically slow developing disease. Infected cattle appear normal for 2–8 years. As the disease develops, the brain is affected. Symptoms such as trembling, stumbling, swaying, and behavioral changes (e.g.,

nervousness, aggression, or frenzy) are observed. Weight loss and a drop in milk production may be noted.

Humans who eat BSE-contaminated beef products could develop vCJD. The initial signs of vCJD include behavioral changes and abnormal sensations. As the disease progresses, incoordination and dementia develop, followed by coma and death. There is no cure for vCJD. Most people die within a year after the signs occur. Most cases have been observed in people who lived in the United Kingdom during the BSE outbreak in the late 1980s. Recent UK research using appendix biopsy reported 16 carriers of vCJD per 32,441 individuals [78]. This rate implies the presence of 30,000 vCJD carriers with no symptoms in the United Kingdom. Therefore, appropriate global countermeasures are urgently needed with careful monitoring of patient numbers.

Recent experimental evidence demonstrated that a low level of TSE infectivity can be present in blood or blood fractions derived from experimental rodents and sheep models. In addition, three cases of vCJD were observed after the transfusion of contaminated blood in the United Kingdom. Of primary interest is the potential for plasma and biotechnological processes to remove the human form of prion agents.

Prion agents are present in the blood at extremely low levels, thus making them difficult to use for analysis. Thus, most studies attempting to remove prion agents from blood or blood products have been performed using blood spiked with animal brain-derived prion agents as a model system. Moreover, owing to the biochemical similarities between animal and human prion agents, PrP^{Sc} from both species could be expected to partition in the same manner during fractionation. However, there is no evidence that blood PrP^{Sc} has the same or similar properties as brain PrP^{Sc} in addition to species differences between prion agents. Thus, applying sensitive assays for detecting PrP^{Sc} in blood is critical in identifying the plasma and biotechnology manufacturing processes capable of removing animal and human PrP^{Sc} in real systems. Recent developments in diagnostic methods such as PMCA have the potential to facilitate sensitive detection. In addition, further developments of inactivation methods for prion agents are also important in reducing the risks of secondary infection with prion diseases.

100.1 INTRODUCTION

100.1.1 Classification

Chronic wasting disease (CWD) belongs to a group of fatal neurodegenerative diseases in cervids and is an example of a transmissible spongiform encephalopathy (TSE). An extraordinary feature of CWD is its relatively high incidence in wild animals, despite its capability to affect both captive and free-living cervids. CWD infection in the wild appears to be limited to mule deer (*Odocoileus hemionus*) [1], white-tailed deer (*Odocoileus virginianus*) [2], Rocky Mountain elk (*Cervus elaphus nelson*) [3], and Shiras moose (*Alces alces shirasi*) [4]. Within endemic areas, transmission occurs intraspecifically (among deer of the same species) and interspecifically (among cervids of different species) through direct or indirect contact with infected cervids.

100.1.2 Biology and Epidemiology

CWD was first described as a wasting and progressive disorder in mule deer caught for nutritional research near Fort Collins, Colorado, in 1967 [1]. It has since been classified as an example of TSE, because the disease leads to typical vacuolation in the brain [1], prion protein (PrP) accumulation [5], and infectivity [6]. The original epidemic appeared to be confined to northern Colorado and southern Wyoming, but it soon spread in both captive and free-ranging populations across 22 U.S. states and 2 Canadian provinces, as well as the Republic of Korea. Initially, CWD was limited to the captive mule deer and elk but was later identified in captive and free-ranging wapiti, mule, white-tailed deer, and moose. The prevalence of CWD in affected areas between 1996 and 1999 was estimated to be about 5% in mule deer, 2% in white-tailed deer, and <1% in elk [7]. However, a study published in 2005 reported a high prevalence rate (30%) of CWD in some areas of Colorado [8]. A more recent survey in Colorado covering the period of 2006–2009 indicated that the incidence of CWD varied from <1% to 14.3% among mule deer, from <1% to 2.4% among elk, and <1% among moose [9]. By contrast, the European Food Safety Authority reported no CWD epidemic in the European Union [10]. Currently, CWD testing in other countries is limited, although active surveillance in Japan has not detected the disease [11]. Nevertheless, less than 30 million deer are believed to be infected with CWD in North America [12].

CWD is thought to be horizontally infected at a high rate among cervids [13]. Oral transmission of CWD-infected brain homogenate derived from mule deer to elk has been reported, which is further supported by the finding of CWD-infected free-ranging moose [14]. However, the origins of the disease remain unclear. Since saprovores (such as buzzard and jackal) and other animals (such as mountain lion, fox, raccoon, coyote, and eagle) prey on deer and elk, CWD may potentially spread among a variety of animals. Indeed, experimental infections in the laboratory setting suggest CWD-susceptible animals include not only cervids but also ferret [15], raccoon [16], squirrel monkey [17], cattle [17], sheep [8], goat [18], hamsters [15,19], bank voles [20], mink [21], meadow voles [20], red-backed voles [20], white-footed mice [20], and deer mice [20]. This highlights the potential of CWD to breach the species barrier.

100.1.3 Clinical Features and Pathogenesis

An abnormal isoform of PrP (PrP^{Sc}) in cervids, termed PrP^{CWD}, is generated from cervid cellular PrP (PrP^{C}). PrP^{CWD} accumulates in brain tissue causing neurological symptoms and ultimately death. At an early stage of the disease, PrP^{CWD}

localizes in the tonsils, gut-associated lymphoid tissue, and enteric nervous system. For example, orally CWD-infected brain homogenate of mule deer induces PrP^{CWD} accumulation in intestine-associated lymphatic tissues, such as retropharyngeal lymph nodes (RLNs), tonsils, Peyer's patch, and ileocecal lymph nodes, as early as 42 days postinfection [22]. However, it should be noted that PrP^{CWD} depositions in lymphoid tissue of elk are less than those of deer [23]. Thereafter, the distribution of PrP^{CWD} expands to the central nervous system (CNS) [24,25]. Finally, PrP^{CWD} is present in the brain, spinal cord, tonsils, skeletal muscle, lymph nodes, spleen, adrenal glands, peripheral nervous system, antler velvet, and pancreas (Figure 100.1). Significantly, the report using CWD-infected deer showed the presence of PrP^{CWD} in skeletal muscle and its seeding activity even when there were no associated clinical signs [26]. In addition, prion infectivity of TSE-associated PrP has been detected in the heart muscle of CWD-infected cervids [27]. These findings imply that muscle is a source of infection. Furthermore, akin to bovine spongiform encephalopathy (BSE), PrP^{CWD} agent can also be found in the retina of infected deer. Indeed, CWD prions have been detected in the saliva [28], urine [28], feces [29], and blood [30] of infected animals. Therefore, it has been proposed that the CWD agent is transmitted *via* saliva or in the stools of deer [22].

The clinical symptoms of CWD, which appear at least 18 months after infection, include weight loss, emaciation, excessive salivation, teeth grinding, fever, anorexia, polyposia, excessive urination and impaired motor coordination, and respiratory distress [8,31]. However, there is no immune response in CWD-infected deer. As these symptoms are not CWD specific, additional biochemical and pathological analysis is required to verify the diagnosis. After the development of these symptoms, most animals survive for a few weeks up to 3–4 months. Furthermore, most deer displaying symptoms

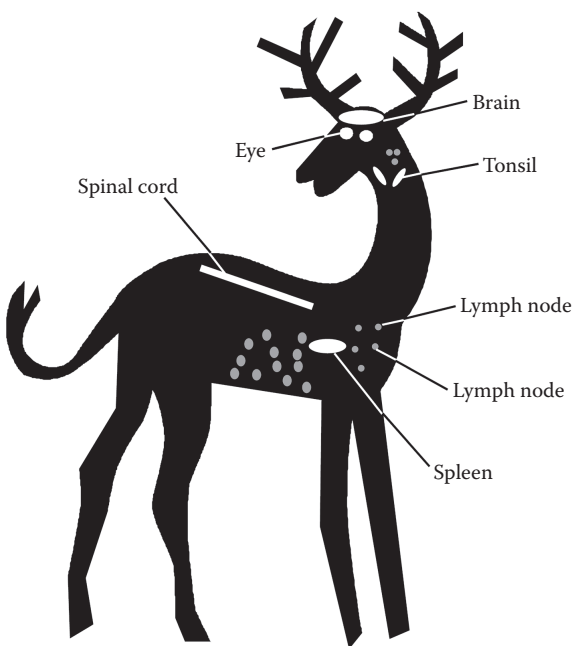

FIGURE 100.1 The distribution of PrP^{CWD}.

of CWD are between 3 and 7 years of age, probably developing CWD within 3 years of infection [32]. Experimental transmission to deer showed that CWD has a minimum incubation period of approximately 15 months, and the mean time from oral infection to death is about 23 months (20–25 months). CWD-infected elk developed the disease rapidly 12 months after oral inoculation compared to CWD-infected mule deer (16 months) [13].

It remains unclear how CWD is spread, although potential mechanisms include horizontal and environmental transmission. Unlike BSE, there is evidence that CWD could be transmitted horizontally among cervids [13]. Indeed, experimental model experiments using transgenic mice expressing the normal cervid PrP support the horizontal transmission of CWD [33]. Recently, maternal transmission was also shown to occur in cervids [34]. Experimental maternal transmission of CWD was demonstrated in the Reeves's muntjac deer model (*Muntiacus reevesi*) and PrP^{CWD} was found in the maternal placenta and mammary tissue of the dam [35].

The transfer of infection in saliva and stools are currently considered a likely means of transmission. For example, a carcass put into a field successfully transmitted CWD to experimental mule deer [22], suggesting a contaminated CWD environment can result in the spread of CWD. It has been demonstrated that hamster-derived PrP^{Sc} can adhere to soil minerals [36]. Moreover, some clay components of soil efficiently bind CWD prions [36]. In addition, binding to soil enhances oral transmissibility of hamster-adapted mink prions [37]. Water in areas where CWD is prevalent is known to be contaminated by CWD prions, which can be detected by serial protein misfolding cyclic amplification (sPMCA) [38]. It should be noted that aerosols and nasal exposure can also result in the transmission of CWD in cervid PrP–expressing transgenic mice [39]. A recent study using white-tailed deer confirmed the aerosol transmission of CWD to deer [40].

Some polymorphism in cervid PrP may affect susceptibility to CWD. Polymorphism at codon 95 (glutamine [Q] or histidine [H]) [41], codon 96 (glycine [G] or serine [S]) [41,42], and codon 116 (alanine [A] or glycine [G]) [43] in white-tailed deer has been reported. While all major genotypes were found in deer with CWD, the Q96, G96, A116 allele (QGA) was more frequently found in CWD-affected deer than the QSA allele [41,44]. In addition, some polymorphism of cervid PrP, such as the G96S in white-tailed deer [45] and S225F in mule deer [46], is suggested to reduce susceptibility. The elk PrP also displays polymorphism at codon 132, encoding either methionine (M) or leucine (L) [44,47], corresponding to the polymorphism of human PrP at codon 129. Statistical investigation of wild free-ranging and farm-raised elk [48] and experimental results using elk with all the three genotypes (MM132, ML132, LL132) suggest that the ML132 or LL132 genotype might offer better protection against CWD compared to MM132. Moreover, the inhibitory effect of L132 was supported by a study using transgenic mice [49]. This study showed that transgenic mice expressing cervid PrPL132 failed to develop the disease following challenge with CWD prions, while those expressing cervid PrPM132 were susceptible to infection [49].

Although several TSEs, such as scrapie and BSE, show similar symptoms, there are no relationships between such TSEs and CWD. Transgenic mice overexpressing deer PrP were resistant to BSE from cattle, whereas red deer–adapted BSE prion, which was produced after intracerebral inoculation of European red deer with BSE agent from cattle, could transmit the disease to mice [50].

Similarly, there is no evidence that CWD can transmit to humans, while squirrel monkeys can be infected with CWD prion [17,51]. By contrast, macaques remained healthy after intracerebral inoculation of CWD prion. This resistance of humans against CWD is supported by the fact that transgenic mice expressing human PrP did not show any hallmark symptoms of CWD 600 days after intracerebral inoculation with CWD prions [12]. These findings indicate the presence of a barrier that makes interspecies transmission unlikely, especially between species as diverse as humans and deer [12]. By comparison, the incubation time, which indicates the period required for displaying symptoms after intracerebral infection with CWD prions, using transgenic mice that had been "cervidized" was between 118 and 142 days [12]. Moreover, an *in vitro* assay showed that PrP^{CWD}-mediated conversion of human PrP to a protease-resistant form is very inefficient, suggesting a species barrier at the molecular level that limits the susceptibility of humans to CWD [42].

Recent studies indicate the presence of conformational variants or strains may exist. Based on bioassay studies, including passage of CWD into ferrets, hamsters, and cervidized mice, at least two putative strains of CWD agents have been proposed (e.g., CWD1 and CWD2, $SghaCWD^{md\text{-}f}$ and $SghaCWD^{md\text{-}s}$, CWD-CSU and CWD-WI) [19,52–54]. Further evidence comes from the observation that sequential passage of a single mule deer CWD isolate using hamster or hamster PrP–expressing transgenic mice causes two distinct disease phenotypes [19,20]. In addition, LaFauci et al. have reported that elk PrP–expressing transgenic mice developed phenotypically divergent diseases when inoculated with either mule deer or elk CWD, which was suggestive of different strains among cervids [55].

100.1.4 Diagnosis

Western blotting, enzyme-linked immunosorbent assay (ELISA), and immunohistochemistry (IHC) are useful for PrP^{CWD} detection (Figure 100.2). The procedures for detecting PrP^{Sc} in both animal and human prion diseases are similar. While ELISA provides an effective screening approach for CWD, Western blotting and IHC are valuable for confirming the diagnosis [56]. In Chapter 99 of this book, we introduced a diagnostic method for BSE and described an experimental procedure (Western blotting) that is also applicable to CWD.

Although the diagnostic procedures for prion diseases are commonly applicable among animals, it should be noted that the methodology depends on the reactivity of the antibody in each animal. Therefore, it is important to determine if the species of PrP is recognized by the antibody used in the immunoassay (e.g., ELISA, Western blotting, IHC).

To date, reliable diagnoses of CWD can only be performed by postmortem analysis using lymphoid or brain tissues [57]. However, antemortem diagnosis has been attempted using tonsillar or rectal biopsy of live cervids during the incubation stage. The detection of PrP in body fluids (such as blood, cerebrospinal fluid (CSF), and urine) and peripheral tissues (such as lymphatic tissues and peripheral nerves) has also been studied. In this chapter, we firstly describe the detection of PrP by Western blotting, ELISA, and IHC. We then describe the recent development of a CWD diagnosis method using ELISA.

While the amino acid sequence of cervid PrP^{C} and PrP^{CWD} is identical, these two protein forms are different in terms of the following biochemical characteristics: (1) protease resistance, (2) secondary structure (PrP^{C} has a high alpha-helix content; PrP^{CWD} is rich in beta-sheet), (3) half-life, and (4) solubility (Table 100.1). PrP^{CWD} is the main component of the CWD agent and can be detected in prion-infected cervids. Therefore, most diagnostic methods of prion diseases rely on an index of the difference between PrP^{CWD} and cervid PrP^{C}. The most commonly used index relies on protease sensitivity and solubility. These methods depend on the fact that PrP^{CWD} aggregates and is therefore resistant to both denaturing reagents and proteases. In the case of IHC, an autoclaving step is usually incorporated to remove PrP^{C}. After exposure of the epitope in PrP^{C} following pretreatment by autoclaving, IHC using anti-PrP antibody can be used to detect PrP^{CWD}. Furthermore, proteinase K (PK) can degrade PrP^{C}, whereas PrP^{CWD} is resistant to this protease. Thus, Western blotting and ELISA can be used detect PrP^{CWD} after PK treatment. Furthermore, guanidine hydrochloride (GdnHCl) reveals the epitope of PrP^{CWD} because this form of the protein is aggregated, whereas the denaturant does not cause any change in the epitope of PrP^{C} because PrP^{C} is solubilized. Thus, the reactivity of antibody against PrP^{C} is unchanged after GdnHCl treatment. Residual PrP after PK treatment is termed PrP^{res} (PK-resistant PrP). Hence, PrP^{CWD} can be separated from PrP^{C} on the basis of PK resistance and then subjected to Western blotting and ELISA for detection.

The gold standard for CWD diagnosis is IHC. Fixed and paraffin-embedded tissues are usually subjected to IHC for diagnostic testing. The quantity of accumulated PrP^{CWD} is different among tissues. Generally, medullary obex and lymphatic tissues, such as tonsils and RLNs, are used for the analysis. Since the brain contains the highest quantity of PrP^{CWD}, this tissue is usually used as sample material. However, it should be noted that the quantity of accumulated PrP^{CWD} differs in different regions of the brain. Therefore, it is preferable to use an appropriate tissue region for analysis.

IHC is a method for observing tissue sections stained with anti-PrP antibody using light microscopy. This methodology has merits in terms of its high level of both sensitivity and specificity. In addition, IHC can be used to verify whether the tissue distribution of PrP^{CWD} is as anticipated. Other methods for CWD diagnosis include ELISA and Western blotting. ELISA is used to detect PrP adsorbed on plates after treatment of brain homogenate with PK. Western blotting detects PrP absorbed on a membrane after an electroblotting procedure.

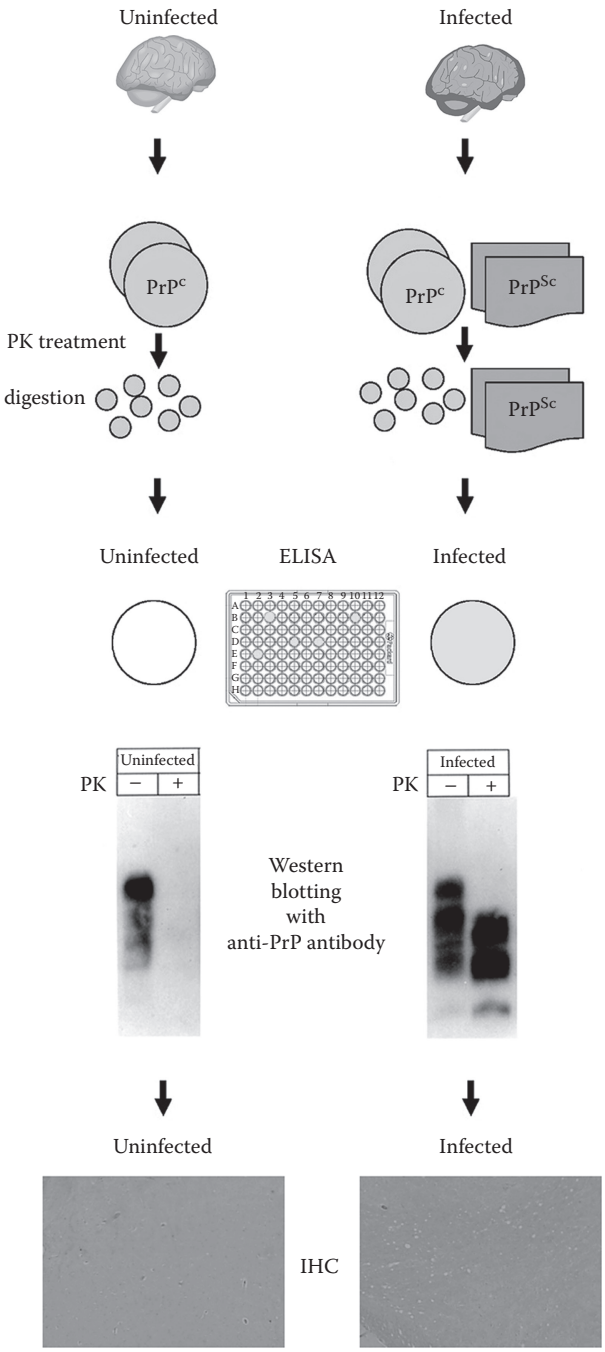

FIGURE 100.2 Diagnostic methods for chronic wasting disease (CWD). Early diagnosis of CWD based on clinical signs is unreliable because clinical symptoms are mild and nonspecific. However, at the late stage of the disease, there is extensive and progressive weight loss followed by hypersalivation, ataxia, polydipsia, and development of various abnormal behaviors. Positive diagnosis of CWD is carried out postmortem using brain tissue (i.e., obex region). Most methods of diagnosing prion diseases are based on the characteristics of PrP^{Sc}, which is resistant to proteinase K (PK). PK completely degrades PrP^{C} but only partially digests PrP^{Sc}, because PrP^{Sc} forms protease-resistant aggregates. After PK treatment, Western blotting and enzyme-linked immunosorbent assay with anti-PrP antibody can be used to detect PK-resistant PrP, when PrP^{Sc} is included in the sample. As the N-terminal region of PrP^{Sc} is digested with PK (+), PK-resistant PrP (27–30 kDa) shows a shift to a lower molecular weight compared to the untreated PrP (–) (33–35 kDa) in Western blotting. Immunohistochemistry (IHC) can be used for definitive diagnosis. In IHC, vacuolation and PrP deposits in brain are usually used as an index of CWD. Given the wide distribution of CWD prions in the animal body, antemortem sampling and testing of lymphatic tissues such as tonsils, retropharyngeal lymph nodes, and rectal biopsy materials have been attempted, and the results gave successful predictions of pre- and subclinical animals in the case of IHC [74]. Unfortunately, however, the sensitivity of this procedure is low compared to tests using brain tissue [74]. Recently, a PrP^{Sc} amplification method, protein misfolding cyclic amplification (PMCA), has been developed for potential antemortem diagnosis of CWD using body fluids such as blood, cerebrospinal fluid (CSF), saliva, and urine. (From Henderson, D.M. et al., *PLoS One* 8, e74377, 2013; Elder, A.M. et al., *PLoS One* 8, e80203, 2013.).

TABLE 100.1
Differences in Biochemical Characteristics between PrP^{C} and PrP^{Sc}

	PrP^{C}	PrP^{Sc} [a]
Protease resistance	Low	High
Rate of secondary structure	α-helix 42%, β-sheet 3%	α-helix 30%, β-sheet 43%
Half-life	3–6 h	>24 h
Solubility	High	Low
Cellular distribution	Cell surface	Intracellular
GPI anchor	Yes	Yes
Release from cell surface by PIPLC	Yes	No
Infectivity	No	Yes

PIPLC, phosphatidylinositol-specific phospholipase C; GPI, glycosylphosphatidylinositol.

[a] In the case of CWD, abnormal PrP (PrP^{Sc}) is sometimes termed PrP^{CWD}.

Priontype postmortem	Labor Diagnostik Leipzig	Sandwich ELISA
TeSeE SAP detection kit	Bio-Rad	Sandwich ELISA

CDI, conformation dependent immunoassay; ELISA, enzyme-linked immunosorbent assay; PrP^{Sc}, abnormal prion protein; TSE; transmissible spongiform encephalopathy.

[a] Modified new version of kits have been developed in each company.

ELISA is usually preferable for screening, because the technique allows rapid analysis. However, Western blotting facilitates more detailed biochemical analysis, such as the determination of the molecular weight of PrP. Such information may be used to help identify the prion source and strains. Western blot analysis of glycoform patterns of PrP^{CWD} suggest that CWD in deer and elk must be considered a single disease [58]. However, recent studies suggest that there are at least two strains of CWD agent.

There are currently several tests for CWD, which include recently modified kits. Most kits use lymphoid tissue, preferentially RLN or tissue from the CNS, ideally from the brainstem. In United States, a CWD kit, which uses RLN as test tissue, has been licensed for three different species of cervids, that is, white-tailed deer, mule deer, and elk. In addition, most of these tests were designed for TSE, so it can be applicable to CWD as well as BSE, scrapie, and other TSEs.

Most currently available CWD kits detect PrP^{CWD} by sandwich ELISA in which PrP is captured on an anti-PrP antibody-coated 96-well microplate and detected using a different anti-PrP antibody (Table 100.2). Alternatively, the Enfer TSE Kit employs a direct ELISA system, which involves the immobilization of PrP^{CWD} onto microplates. A dot blot ELISA is essentially the same as a direct ELISA except the procedure uses polyvinylidene difluoride membranes instead of microplates. Most of the other tests are based on the use of a sandwich immunoassay. This methodology requires two anti-PrP antibodies recognizing different epitopes. ELISA is preferably used for screening or surveillance of CWD. Positive hits from the ELISA screening should be verified by IHC and Western blotting to confirm a definitive diagnosis of CWD.

More recently, a new method for prion diagnosis has been developed known as protein misfolding cyclic amplification (PMCA). This method can amplify PK-resistant PrP by sequential incubation and sonication using a mixture of PrP^{C} source and PrP^{Sc} seed. PMCA can detect PrP^{CWD} in the urine of presymptomatic deer [59]. Recently, Hoover et al. successfully amplified PrP^{CWD} using brain homogenate of noncervids (ferret and hamster) [60]. Using this method, Hoover et al. attempted to amplify PrP^{CWD} using brain homogenate derived from various rodents. The results indicated successful amplification using PrPs derived from bank vole and field mouse but failed using those from prairie dog and coyote [60]. In addition, this method can amplify PK-resistant PrP derived not only from cervids [61] but also from various other species including hamster, mouse, sheep, and human [33]. Moreover, a transgenic mouse expressing cervid PrP [6] and CWD-susceptible cell lines [62,63] have been developed. These powerful research tools will be invaluable to CWD research in helping to reveal the molecular basis of the disease. In particular, these tools will be used to develop bioassays for CWD infectivity in tissues and fluid from CWD-infected cervids [64]. Further development of PMCA enables an estimation of the quantity of prion infectivity in tissues, such as the obex, left ventricle, pancreas, jejunum, and spleen, as well as body fluids, such as saliva and urine, by real-time quaking-induced conversion (RT-QuIC) [65]. Such an assay will contribute to the risk assessment of deer tissues, biological fluids, excreta, or environmental samples obtained from CWD-endemic areas.

Recent developments in detecting CWD have enabled antemortem diagnosis using IHC of tonsil tissue. Generally,

sample preparation for IHC is not a high-throughput procedure, and the paraffin-embedded tissues are not readily applicable to further biochemical analysis. Nonetheless, methods have been developed that allow these samples to be examined by Western blotting and ELISA. Continuous warming and freezing separates the tissue from the paraffin, which can then be sonicated and subjected to biochemical analysis (i.e., Western blotting and ELISA).

100.2 METHODS

The detection procedures for CWD are essentially common to those described for BSE. The procedure for the detection of PrP^{Sc} by Western blotting can also be used to detect PrP^{CWD}. Thus, to avoid redundancy, we introduce ELISA as an alternative method for detecting PrP^{CWD} in tissue samples. Fundamentally, the current procedures can be commonly used for all TSE including BSE and scrapie as well as human prion diseases such as Creutzfeldt-Jakob disease (CJD). There are two types of ELISA; direct ELISA and sandwich ELISA. In the direct ELISA method, PrP in the sample adheres to the microplate and is subsequently detected using an anti-PrP antibody. By contrast, in the sandwich ELISA method, anti-PrP antibody is coated onto the microplate to facilitate capture of PrP in the sample, which can then be detected using a different anti-PrP antibody. Sandwich ELISA is recommended because it is both sensitive and reliable. Thus, in this section, we introduce sandwich ELISA for PrP detection.

100.2.1 Reagents and Equipment

100.2.1.1 Reagents

- Anti-PrP antibodies. Anti-PrP antibodies are now available from several companies such as Bertin Pharma (SPI -Bio; Montigny le Bretonneux, France), Prionics (Schlieren, Switzerland), Roboscreen GmbH (Leipzig, Germany), VMRD Inc. (Pullman, Washington), R-Biopharm AG (Darmstadt, Germany) DakoCytomation Denmark (Glostrup, Denmark), and Alicon AG (Zürich-Schlieren, Switzerland).
- Streptavidin-HRP (horseradish peroxidase).
- Lysis buffer (10 mM Tris-HCl [pH 7.4] containing 100 mM NaCl, 10 mM EDTA, 0.5% NP40, 1% sodium deoxycholate).
- Bovine serum albumin (BSA).
- Protein Assay Kit (e.g., DC Protein Assay Kit, Bio-Rad [Hercules, California]).
- EIA buffer (phosphate-buffered saline [PBS] containing 0.1% BSA).
- Washing buffer (PBS containing 0.05% Tween20).
- PK.
- Recombinant PrP.
- Tetramethylbenzidine (TMB) solution containing 3,3′,5,5′-TMB and hydrogen peroxide (Thermo Scientific, Waltham, Massachusetts).
- Stop solution (sulfuric acid or hydrochloric acid).

100.2.1.2 Equipment

- 96-well microplate
- Microplate spectrophotometer

To avoid cross-contamination, we recommend the use of new glassware and instruments or single-use materials. Precautions must be taken to avoid contamination of solutions with highly concentrated reagents. Avoid blood contamination during the dissection of tissues, rinse excised tissues in PBS, flash-freeze the specimens in liquid nitrogen, and store the dissected brains at −70°C. All procedures should be performed in a laminar flow biosafety cabinet in an appropriate laboratory according to governmental regulations. Personal protection equipment (lab coat, gloves, and facemask) should be used, and gloves should be changed frequently. Avoid drying out the microplates. Repeated freeze–thaw cycles of solutions containing recombinant PrP, antibody, or streptavidin-HRP can adversely affect their activity and should be avoided. Thus, the corresponding solutions should be aliquoted and kept at −20°C or −80°C.

100.2.2 Sample Preparation and Detection Procedures

The tonsils, RLN, and brainstem at the obex (with intact dorsal motor nuclei of vagus) were thought to be the best tissues for PrP^{Sc} testing [5,8,56,66,67]. It should be noted that in the case of elk, elk younger than 8.5 years should be used for testing of rectal biopsies, because the number of lymphoid follicles in the recto-anal lymphoid tissues decreases with age [68].

As an example of a diagnostic method for prion diseases, the materials and methods used for ELISA are presented. In particular, several precautions that should be undertaken when carrying out this procedure are emphasized. As described earlier, an index for prion diseases can be generated by analysis of samples for PK-resistant PrP. In addition, as PrP is a glycosylphosphatidylinositol (GPI)-anchored protein on the cell membrane, it must be extracted from tissues using buffer including detergents such as lysis buffer as described earlier. This is also the case for the ELISA detection system.

Before starting ELISA, anti-PrP antibody used in the experiments should be carefully selected by checking information on the species specificity of the antibody recognizing PrP. For example, anti-PrP antibody 3F4 binds human and hamster PrP but not mouse, sheep, deer, and bovine PrP. Anti-PrP antibodies recognizing the C-terminal half of PrP, such as 6H4 (Prionics AG), should be used for the detection of PrP^{Sc} in this Western blotting system, whereas those recognizing the N-terminal half of PrP cannot be used. This is because the C-terminal half of PrP^{Sc} is resistant to PK, whereas the N-terminal half is susceptible to PK. 6H4 can be used for the detection of PrP^{CWD} because it recognizes epitopes of human PrP at amino acid residues 143–153 and cross-reacts with bovine, ovine, and cervine PrP. In addition, epitopes of PrP recognized by capture anti-PrP antibody and detection anti-PrP antibody should not

be near the region of PrP. Detection anti-PrP antibody should be labeled with biotin by a standard protocol. Furthermore, the optimum concentration of capture and detection anti-PrP antibodies must be determined before the assay is performed by adjusting nonspecific binding and intensity of PrP-related signals. In addition, optimum protein concentration of the sample for assay should be used.

1. Homogenate tissues or cells (10% w/v) in lysis buffer.
2. Syringe using 18G needles followed by 22G needles to mechanically break tissues or cells combined with sonication or breakage by violent agitation with beads.
3. Transfer samples to 1.5 mL Eppendorf tubes and centrifuge for 5 min at 10,000 rpm.
4. Discard the pellet, and aliquot the supernatant, which is then subjected to a protein assay, such as Bio-Rad DC Protein Assay (Bio-Rad) for measuring protein concentration. Store the samples at −20°C or −80°C until analysis.
5. Add PK solution to a final concentration of 20 μg/mL and incubate for 30 min at 37°C.
6. Mix the solution with 8 M urea to a final concentration of 4 M urea.
7. Heat at 100°C for 10 min to denature proteins.
8. Recombinant PrP can be used to generate a standard curve of PrP by diluting with lysis buffer.
9. Dilute all samples at 10-fold in EIA buffer before performing ELISA.
10. Wash a microplate, which has been coated with an anti-PrP antibody overnight at 4°C, using wash buffer (three times).
11. Dispose samples or standards of diluted recombinant PrP.
12. Incubate for 2 or 3 h at room temperature.
13. Wash the microplate three times with wash buffer.
14. Add biotin-labeled anti-PrP antibody that is different to the anti-PrP antibody coated on the microplate.
15. Seal the microplates with an adhesive cover sheet and incubate for 2 or 3 h at room temperature.
16. Wash the microplate with wash buffer three times.
17. Add streptavidin-HRP.*
18. Incubate for 2 h at room temperature.
19. Wash the microplate three times with wash buffer.
20. Add TMB solution.
21. Allow the enzymatic reaction to proceed at 37°C for 30 min–1 h in darkness.
22. Add stop solution to quench the reaction.
23. Measure absorbance at 450 nm using a microplate reader.
24. Calculate the concentration of PrP^{Sc} by comparison of absorbance with a standard curve generated using diluted recombinant PrP.

* When using streptavidin-AChE (acetylcholine esterase) as an alternative to streptavidin-HRP, Ellman's reagent (0.75 mM acetylthiocholine and 0.5 mM 5,5′-dithiobis[2-nitrobenzoic acid] in 100 mM phosphate buffer pH 7.4) should be used for the colorimetric substrate AChE. In this case, absorbance at 414 nm should be measured. If HRP-labeled reagents are used, it is essential to remove sodium azide from all buffers, because sodium azide inhibits the activity of HRP. Sodium azide should be replaced by thimerosal.

100.3 CONCLUSION AND FUTURE PERSPECTIVES

CWD is one of the prion diseases that show clinical symptoms such as progressive weight loss, abnormal behavior, and excessive salivation. Incidents have been reported in North America and Korea. Efficient transmission by horizontal infection may occur *via* contact with saliva or feces. Infectivity of the skeletal muscle from diseased deer has been observed, suggesting meat could be a potential source of infection. Recently, possible transmission of CWD to fishes has been reported. However, at the moment, CWD transmission to humans is thought to be very unlikely.

Several modified methods for PrP detection have been developed involving concentration, amplification, and sensitive detection. The most important recent advances in PrP^{CWD} detection have been the development of PMCA and related methods such as RT-QuIC [69,70]. Moreover, enrichment of PrP^{Sc} by phosphotungstic acid enhances sensitivity [69]. RT-QuIC enables the detection of PrP^{Sc} in the urine and feces of presymptomatic deer [71]. In addition, the production of CWD-susceptible transgenic mice [6,66] and cell lines [63,72] may enable the calculation of CWD infectivity more easily.

Despite these recent advances in diagnostic technologies, currently no treatments or vaccines are available for CWD or any other TSE [73]. In addition, the zoonotic potential of CWD agents, which appear to have various strain types, remains unclear. Thus, further studies of CWD transmission using primate and transgenic mouse models are required to assess the zoonotic potential of CWD agents.

VETERINARY MEDICINE, MICROBIOLOGY

MOLECULAR DETECTION OF ANIMAL VIRAL PATHOGENS

Molecular Detection of Animal Viral Pathogens presents expert summaries on state-of-the-art diagnostic approaches for major animal viral pathogens, with a particular emphasis on identification and differentiation at the molecular level.

Written by specialists in related research areas, each chapter provides a concise overview of an individual virus or group concerning its

- Classification
- Morphology
- Genome organization
- Epidemiology
- Clinical features
- Diagnosis
- Sample collection and preparation procedures
- Molecular detection protocols

Each chapter also discusses future prospects or further research requirements for streamlining the identification and epidemiological tracking of the virus concerned.

With broad coverage presented in a concise format, *Molecular Detection of Animal Viral Pathogens* is an essential reference for both beginning and experienced laboratory scientists as well as students of virology. It also offers an indispensable guide applicable to medical, veterinary, and industrial settings that are dependent on speedy turnarounds, extreme sensitivity, and exquisite specificity of virological testing for decision making and disease prevention.
