INTRODUCTION

Rabbits serve not only as an important animal species for biomedical research but also as a common food source for people throughout the globe. Over the past

several decades, great attention has been paid to controlling and eliminating the parasitic diseases of rabbits with the goal of making them more suitable animals for the laboratory environment as well as to increase their meat production capacity. Maintaining excellent levels

of hygiene is especially critical with treating, controlling, and/or preventing parasitic infections in rabbits. The use of non-solid flooring, along with proper sanitation, has been noted to decrease the level of fecal-borne parasites in rabbits today compared to other housing systems (Patton et al., 2008).

Given the increase of the rabbit in popularity as a pet in the United States, laboratory animal practitioners should be cognizant of pet rabbits that facility staff may have at home or visit at other locations (e.g. pet stores, fairs) that may not be free of common rabbit parasites. Items supplied from pet stores or other areas such as treats, hay, and toys, may also be potentially contaminated with parasites. Inattentive personnel and contaminated items can introduce parasites into specific pathogen-free (SPF) colonies of laboratory rabbits.

Commercial vendors of SPF, research-exclusive rabbits in North America are mostly located in the eastern United States and Canada. Therefore, many laboratory animal facilities in other parts of North America use non-SPF rabbits alongside SPF rabbits. Parasites would be among some of the first organisms that could be transmitted from non-SPF to SPF rabbits. Great control needs to be exercised in such facilities to prevent such pathogen spread.

PROTOZOA

Apicomplexa (Sporozoa)

Eimeria

Coccidiosis is considered to be one of the most important diseases of rabbits worldwide, affecting wild rabbits and domestic rabbits used for research, meat production, and companionship. The genus *Eimeria* contains 65 species which are considered to be host-specific (Kvicerova et al., 2008). Eleven *Eimeria* species make up the coccidia species known to infect *Oryctolagus cuniculus* under natural conditions. Other *Eimeria* species may be found in related non-*Oryctolagus* species such as cottontails (*Sylvilagus*), hares (*Lepus*), and pygmy rabbits (*Brachylagus*) (Duszynski et al., 2005). Research is ongoing for evaluating diagnostic methodologies, treatment regimens, identification methods, preventative measures, and characterization of new variants. Out of several rabbit coccidia species, one infects the liver (hepatic coccidiosis) while the remaining ten infect different areas of the intestinal tract with varying pathogenicity (intestinal coccidiosis). All follow the fecal-oral route of transmission (Figure 15.1).

Due to the severity of some coccidial infections, many countries require that imported rabbits are coccidia free. While this is targeted more towards hepatic coccidia, importation restrictions may extend to the more pathogenic species of intestinal coccidia as well.

HEPATIC COCCIDIA

BACKGROUND Hepatic coccidiosis, caused by *Eimeria stiedae*, was first identified over 100 years ago and is considered to be a devastating disease for rabbit colonies resulting in high morbidity and mortality (Kvicerova et al., 2008). Its pathogenicity is considered to be mild to severe (Kvicerova et al., 2008). The agent is still found in rabbitries throughout the world but is rare in laboratory animal facilities (Baker, 1998; Pakes and Gerrity, 1994).

ETIOLOGY/ETIOLOGIC AGENT *Eimeria stiedae* oocyst size is approximately $30\text{--}41 \times 15\text{--}24\text{mm}$ (average $36.9 \times 19.9\text{mm}$) in size with an ellipsoid shape (Kvicerova et al., 2008). Younger animals (around weaning age) are more susceptible to infection than older ones (Gomez-Bautista et al., 1987).

EPIZOOTIOLOGY Transmission is by the fecal-oral route. Experimental infection by other routes (intravenous, intraperitoneal, and intramuscular) can also result in disease but in a milder form compared to oral transmission (Pakes and Gerrity, 1994). Contaminated feed and water are primary sources of infection (Patton et al., 2008). The non-infective (un-sporulated) oocysts are shed in the feces of infected animals and become infective (sporulate) in the environment usually within about 3 days (Baker, 1998; Patton et al., 2008). Prepatency is 14–18 days while patency is 21–37 days (Schoeb et al., 2007). *E. stiedae* migrates from the intestinal tract, through the intestinal wall, either hematogenously or through the lymphatic system, into the bile ducts where its reproductive cycle takes place (Baker, 1998; Patton et al., 2008). Prevalence in populations can reach 100% with carrier adult animals serving as a source of infection for young animals although these adults may have lower body masses and fecundity when compared to non-infected individuals (Lello, 2005; Wang and Tsai, 1991). Experimental infection in mice resulting in a similar disease course as that of rabbits has been reported following immunosuppression with dexamethasone (Aly, 1993). Co-infection with intestinal coccidia is common. Proper hygiene is important in the control and elimination of this disease.

CLINICAL MANIFESTATIONS Clinical pathological findings have been reported with active hepatic coccidiosis. Gomez-Bautista et al. (1987) reported alanine aminotransferase (ALT) increases with no other enzymatic elevations. No enzymatic elevations were reported by Abdel-Ghaffar et al. (1990). Decreased fibrinogen and increased bilirubin and alkaline phosphatase (AP) have also been observed (Cam et al., 2006; Sherkov et al., 1986).

Anorexia, wasting, a “pot belly” appearance from ascites and/or hepatomegaly, icterus, diarrhea, constipation,

FIGURE 15.1 Life cycle of *Coccidia* in rabbits. (from Patton, N.M., K.W. Hagen, J.R. Gorham, and R.E. Flatt. 2008. *Domestic Rabbits: Diseases and Parasites*. PNW 310. Corvallis, OR: Oregon State University Extension Service. © 1986, 1998 Oregon State University. Used with permission)

death, and other clinical signs consistent with liver failure can be seen (Baker, 2008; Pakes and Gerrity, 1994; Patton et al., 2008; Schoeb et al., 2007). Death is more commonly seen in younger animals, in particular those around 2–3 months of age. Many animals may exhibit no clinical signs (Pakes and Gerrity, 1994).

An enlarged liver and gall bladder may be noted on radiographs (van Praag, 2009).

PATHOLOGY Both gross and microscopic lesions are well-defined. The liver is the major organ affected with diffuse, multi-focal white nodules on the surface

that range in size from 0.1–2 cm (Schoeb et al., 2007; Wang and Tsai, 1991) (Figure 15.2). Enlargement of the liver, gall bladder, and bile duct may be seen at necropsy (van Praag, 2009). A dark, green mucoid exudate has been described in the intestinal lumen (Wang and Tsai, 1991). Hyperplasia and cystic enlargement of the bile duct epithelium (Figure 15.3) results in the white nodules seen on the hepatic surface (Pakes and Gerrity, 1994; Wang and Tsai, 1991). Various life cycle stages of the organism may be seen histopathologically with oocysts in bile duct lumina (Figure 15.4) and inflammatory cell infiltration (lymphocytes and plasma cells

and potentially neutrophils and macrophages) around the ducts (Pakes and Gerrity, 1994; Schoeb et al., 2007; Wang and Tsai, 1991). Alternatively, organisms may be seen with an impression smear of the liver at the time of necropsy (van Praag, 2009). Bile duct enlargement may lead to rupture, granulomatous reactions, and fibrosis (Pakes and Gerrity, 1994). Fibrosis will increase with the chronicity of active disease (Schoeb et al., 2007). Other organs are not affected by *E. stiedae*, however, secondary bacterial infections may result (van Praag, 2009; Wang and Tsai, 1991).

PATHOGENESIS Excysting oocysts within the duodenum travel to the liver via the bloodstream or lymphatics and infect the epithelial cells of the bile ducts. The resulting inflammatory reactions along with an “obstructive jaundice due to oocyst shedding” in the bile ducts result in disease signs (Omata et al., 2001a).

DIAGNOSIS Diagnosis can be made by identification of the oocyst in the feces through fecal direct smear, fecal flotation or, more preferably, centrifugation (Pakes and Gerrity, 1984). Oocysts may also be found in bile duct aspirates. *Eimeria stiedae* can be differentiated from other *Eimeria* species through size and morphology.

Gross and microscopic lesions, previously described, can provide a diagnosis of active disease.

Other diagnostic methods described in the literature include antibody detection in serum and complement fixation (Omata et al., 2001b; Pakes and Gerrity, 1994).

PREVENTION AND THERAPY Several anti-hepatic coccidial treatments have been described, especially within the past 30 years. Due to rabbits serving as popular meat animals in many parts of the world, certain medications in the feed and/or water may be illegal depending on local and federal legislation. Some feed companies will not mix medication into feed due to these regulations or the adverse effects the medications may have on a species that could occur through contamination at the feed mill (e.g. ionophore toxicosis in horses). Additionally, not all medications can be found in the United States as approved medications for rabbits are more common in Europe and other parts of the world. Treatments reported in the literature include:

1. Robenidine, a non-ionophore synthetic drug (guanidine), has been used as a coccidiostat for several decades. The compound can be mixed into feed and dosages of 100 parts per million (PPM) have been shown to be effective (Peeters and Halen, 1980). Robenidine wafers are also available. It is approved for use against hepatic coccidia in rabbits in some countries where the dosage recommendation is 50–66 mg/kg in the feed even though robenidine

- is less effective against *E. stiedae* than the intestinal coccidia species (EFSA, 2008; Peeters et al., 1988; Polozowski, 1993).
2. Several sulfa-based antibiotics have been reported to be efficacious in preventing and treating coccidiosis.
 - a. Sulfamerazine at 0.02% in the drinking water (Pakes and Gerrity, 1994).
 - b. Sulfadimethoxine and pyrimethamine (10:3) have been used as prophylaxis against *Eimeria stiedae* infection (Gomez-Bautista and Rojo-Vazques, 1986).
 - c. Sulfamethoxine in the feed for 7 days at 75 mg/kg of body weight (Pakes and Gerrity, 1994). Sulfaquinoxaline, 0.025% in the feed for 3 weeks (Patton et al., 2008) or 0.03% (Pakes and Gerrity, 1994). In drinking water, the dose is 0.05% (Pakes and Gerrity, 1994).
 3. Toltrazuril, a coccidiostat and triazinetrione derivative, decreases oocyst shedding and prevents clinical signs when used at 10–15 ppm in water and up to 25 ppm during parasite reproduction (Peeters and Geeroms, 1986). Ivermectin combined with toltrazuril has been shown to be highly effective in reducing oocyst shedding and keeping liver lesions to minimal or non-existent levels in experimentally infected animals (Cam et al., 2008).
 4. Diclazuril can be used as both a prophylactic or therapeutic agent. Prophylactic doses are 0.5, 1, and 2 mg/kg and the treatment dose is 4 mg/kg. These doses are associated with decreased oocyst shedding and organism numbers in liver in experimental infections (Pan et al., 2008).
 5. Lasalocid is a coccidiostat and is used at levels of 90 or 125 ppm in the feed (Polozowski, 1993).
 6. Monensin, an ionophore, may be used at 20 ppm in feed (Polozowski, 1993).
 7. Narasin, another ionophore and coccidiostat, reduces oocyst output and prevents clinical signs when dosed at 12–24 ppm in the feed (Peeters et al., 1981). This drug is also known as salinomycin.
 8. Garlic has been used as a non-traditional treatment which resulted in decreased oocyst shedding and near-normal histopathology of hepatic tissue (Toula and Al-Rawi, 2007).

Practical measures for laboratory animal veterinarians focus on ensuring that rabbits supplied to research facilities are free of hepatic coccidia. Good hygiene practices of individuals handling animals, vermin control, and separation of sick young from older animals is important (Pakes and Gerrity, 1994).

Positive results have been preliminarily obtained from research into vaccination of rabbits with *E. stiedae* antigens. Organism shedding and inflammatory reactions have been decreased, resulting in little to no

disease after experimental vaccination (Hanada et al., 2003; Abdel Mageed et al., 2005).

INTESTINAL COCCIDIA

BACKGROUND As previously described, coccidia in rabbits are described as either hepatic or intestinal. Some authors have attempted to portray intestinal coccidia of rabbits as a singular group of pathogens responsible for diarrhea in weanling rabbits without discussion of the individual species involved. However, intestinal coccidia vary greatly in terms of pathogenicity from highly pathogenic resulting in high morbidity/mortality to non-pathogenic. Over two dozen intestinal coccidia species have at one time or the other been described to inhabit the gastrointestinal tract in rabbits, in many cases due to one species being given multiple names. There are ten accepted, well-characterized species of intestinal coccidia that will be described here that affect *Oryctolagus cuniculus*. They have different pre-patent periods, pathogenicity levels, and target areas within the intestines for causing disease. Co-infection is seen (Baker, 1998; de Almeida et al., 2006; Li and Ooi, 2008). *Eimeria perforans* has generally been considered the most common and least pathogenic intestinal coccidia species for laboratory rabbits (Pakes and Gerrity, 1994). Intestinal coccidia can still be common among SPF laboratory rabbit breeders. The three most common species encountered are *E. perforans*, *media*, and *magna*. Rabbits, including SPF laboratory rabbits, are commonly co-infected with these three species of intestinal coccidia.

ETIOLOGY/ETIOLOGIC AGENT Several species of *Eimeria* are considered to make up the intestinal coccidia infecting *O. cuniculus*. Speciation is done primarily through morphological criteria of oocysts identified in fecal or intestinal content preparations, and it is reported that the sporulated oocysts provide the best stage for identification (Licois, 2004). Other mechanisms for identification include the area of intestines affected as well as genomic profiles (Cere et al., 1996, 1997; Licois, 2004). Table 15.1 summarizes information from several sources (Kvicerova et al., 2008; Licois, 2004; Saxonet, 2005; Schoeb et al., 2007; van Praag, 2009) with respect to oocyst size and shape, pre-patent period, pathogenicity, and intestinal areas affected, listed in order of species pathogenicity.

EPIZOOTIOLOGY The *Eimeria* species described here are considered species-specific for the rabbit. Transmission is fecal-oral. Contaminated food, water, caging, as well as other fomites all serve as common means of spreading intestinal coccidia. Adult carriers often serve as a source of infection for newborns with rabbits aged 2–3 months being most susceptible to intestinal coccidiosis (Licois, 2004; Sherkov et al., 1986). Since *Eimeria* are monoxenes (having only one host),

TABLE 15.1 Summary of Common Rabbit *Eimeria* Species

Species	Oocyst Shape	Oocyst Size (μm)	Intestinal Areas Affected	Pathogenicity	Pre-Patent Period (days)
<i>E. intestinalis</i>	Ellipsoid, piriform, or ovoid	21–36 × 15–21 average 26 × 18	Jejunum and/or ileum	High	5–10
<i>E. flavescens</i>	Ovoid or broad ellipsoid	25–37 × 14–24 average 30 × 21	Cecum and/or proximal colon	High	9
<i>E. media</i>	Ellipsoid to ovoid	19–37 × 13–22 average 31 × 17	Jejunum and/or ileum	Mild	4–5
<i>E. magna</i>	Ovoid to ellipsoid	27–41 × 17–29 average 31 × 18	Jejunum and/or ileum	Mild	5–6
<i>E. irresidua</i>	Ovoid to ellipsoid	31–44 × 19–28 average 38 × 23	Jejunum and/or ileum	Mild	9
<i>E. piriformis</i>	Piriform	25–33 × 15–21 average 29 × 18	Colon	Mild	9
<i>E. vejdoskyi</i>	Ovoid	25–38 × 16–22 average 31 × 19	Ileum	Slight	10
<i>E. perforans</i>	Ellipsoid	15–30 × 11–20 average 21 × 13	Duodenum and/or proximal jejunum	Slight	5–6
<i>E. exigua</i>	Ovoid to spherical	10–21 × 10–18 average 15 × 13	Ileum	Slight	7
<i>E. coecicola</i>	Ovoid to ellipsoid	23–40 × 15–22 average 29 × 18	Cecum (GALT/vermiform appendix)	None	9

there are no other hosts involved with the life cycle (Licois, 2004). The number of young animals affected in colonies can vary greatly, but has been documented at 100% in some instances (Nosal et al., 2009).

CLINICAL MANIFESTATIONS The severity of clinical disease is dependent on the amount of infective agent present, the susceptibility of the animal, and the pathogenicity of the agent. Subclinical infections can exist with no clinical signs (Schoeb et al., 2007). Diarrhea is the main clinical sign of disease associated with all of the intestinal coccidia species. Undigested blood may be seen in the diarrhea and positive fecal occult blood test results may be obtained, depending on the species infecting the rabbit (Baker, 1998; Li and Ooi, 2009; van Praag, 2009). Due to inhibition of cellular function, impaired intestinal motility, and villous atrophy clinical signs including malabsorption, electrolyte imbalances, anemia, hypoproteinemia, dehydration, and even death (usually within just a few days after clinical onset) can be seen (Baker, 1998; Licois, 2004; van Praag, 2009). Additional clinical signs include a rough coat, anorexia, and weight loss (van Praag, 2009). A 20% weight loss has been associated with death within 24 hours (van Praag, 2009).

PATHOLOGY The diarrhea observed is usually dark and watery, possibly with mucus, accompanied

by a foul odor (Baker, 1998; Pakes and Gerrity, 1994). Intestinal bleeding and ulceration plus intussusceptions may be seen (Baker, 1998; van Praag, 2009). Epithelial sloughing has also been reported (Patton et al., 2008). Microscopically, villous atrophy, cellular congestion and edema, epithelial necrosis, leukocytic exudates, along with the different stages of the reproductive cycle may be visualized (Baker, 1998; Licois et al., 1992). Affected cells can become hypertrophied (van Praag, 2009).

PATHOGENESIS Once excreted in the feces, the oocyst undergoes sporogony and sporulates, becoming infective. After ingestion, the oocyst wall is destroyed in the stomach and spores are released (van Praag, 2009). Spores infect the epithelial cells of the intestinal walls, having a specificity for certain areas of the intestinal tract as expressed in the above table. Reproduction of *Eimeria* occurs in these cells (schizogony and gamogony), devastating them and causing disease. Oocysts are then shed in the feces to infect other rabbits. Surviving rabbits develop activity immunity, going on to become asymptomatic carriers (Licois, 2004). Concurrent microbial infections (e.g. *E. coli*) can exacerbate clinical signs, delay the formation of immunity, and lead to higher mortality and morbidity (Licois, 2004; Pakes and Gerrity, 1994). There is no cross-immunity between the intestinal

coccidia species and immunity is cell-mediated, meaning that passive immunity from dam to offspring does not occur (Baker, 1998; Licois, 2004).

DIAGNOSIS Diagnosis is customarily made based on the identification of oocysts in fecal preparations (direct smears, flotations, and centrifugations). Samples from intestinal preparations (e.g. smears, histopathology) may also be used (Pakes and Gerrity, 1994). It is recommended that veterinarians ask for the identified coccidia to be speciated in order to determine the significance of the finding to the individual rabbit as well as the colony (Licois, 2004). Finding oocysts in the feces, but not in histopathological samples from the intestines, or vice versa, is not uncommon given the reproductive cycle of the parasite or a “very heavy primary infection” (Pakes and Gerrity, 1994). Therefore, it is preferable to examine both to determine the presence of intestinal coccidia. Multiple animals in a colony may also need to be scrutinized to ascertain all *Eimeria* species involved (since co-infection can frequently occur) and level of infection in the colony.

PREVENTION AND THERAPY Prevention is primarily through acquiring only coccidia-free animals and maintaining good sanitation. Treatment can be carried out at the individual and colony level.

1. Sulfa drugs (e.g. sulfadimethoxine (0.8%), sulphaquinoxaline (0.025–3%)) have historically reported good results (Licois, 2004). Sulphaquinoxaline at 0.025% fed in the feed for 2–3 weeks will reduce parasite load (Patton et al., 2008).
2. As with *E. steidae*, robenidine has also been used successfully as a prophylaxis (at 66 ppm) and treatment for decades (Licois, 2004; Peeters and Halen, 1980; Peeters et al., 1983). However, reports of robenidine resistance exist in the literature (Licois, 2004; Peeters et al., 1987).
3. Salinomycin (narasin), an ionophore, is also used as a food additive to prevent intestinal coccidiosis at 20 ppm (Licois, 2004) although lower levels have been reported at 8–12 ppm (Peeters et al., 1981).
4. Diclazuril can be used in both prophylactic or therapeutic regimens. Prophylaxis can be achieved at 0.5, 1, or 2 mg/kg while the therapeutic dose is 4 mg/kg. Decreased oocyst shedding and organism numbers in the liver in experimental infections have resulted from these treatments (Pan et al., 2008; Vanparijs et al., 1989).
5. Toltrazuril is a coccidiostat and triazinetrione derivative which decreases oocyst shedding and prevents clinical signs when dosed 10–15 ppm in water. Up to 25 ppm may be used during parasite reproduction (Peeters and Geeroms, 1986).
6. Research is active in the area of creating a vaccination for rabbits against intestinal coccidia but all work is currently in the experimental stages (Drouet-Viard et al., 1997; Licois, 2004).

CRYPTOSPORIDIUM

BACKGROUND Many parasitologists consider *Cryptosporidium* more closely related to a group of Apicomplexa known as the gregarines than to coccidia (Carreno et al., 1999). Replicating stages of *Cryptosporidium* are located within the microvillus border of the host cell and protrude above the surface which is different than the typical coccidia location in the cytoplasm beneath the cell surface (Schoeb et al., 2007). Cryptosporidia infections have been reported in laboratory rabbits and a cottontail rabbit in the United States though the prevalence in laboratory rabbits is presumed to be low (Schoeb et al., 2007).

ETIOLOGY/ETIOLOGIC AGENT. Cryptosporidia were first described in the rabbit by Tyzzer in 1929, however the species found in lagomorphs remains unnamed and minimally described (Schoeb et al., 2007). In some reports, the agent is referred to as *Cryptosporidium cuniculus* (Pakes and Gerrity, 1994). Most research and investigation has been conducted with the species *C. parvum* (Schoeb et al., 2007).

EPIZOOTIOLOGY

The life cycle of the *Cryptosporidium* species in rabbits has not been described. It is thought, however, that it is similar to that of *C. parvum* which has been extensively studied and will be described here (Schoeb et al., 2007). Oocysts are ingested and release sporozoites which invade intestinal epithelial cells in the lower half of the small intestine (Bowman, 2009; Schoeb et al., 2007). Once in the intestinal epithelial cells, sporozoites undergo two generations of merogony. Second-generation merozoites develop into sexual stages which fuse to produce zygotes and mature into unsporulated oocysts. Oocysts undergo two internal divisions to form four sporozoites each. The oocyst wall develops while still in the parasitophorous vacuole. About 20% of the oocysts are thin-walled and are capable of autoinfection which is believed to allow the organism to persist in the host. The remaining thick-walled environmentally resistant oocysts are shed in the feces and are infectious for new hosts when ingested (Schoeb et al., 2007). Oocysts remain viable in the environment for months unless exposed to extreme temperature (below 0°C, above 65°C), desiccation, or concentrated disinfectants (Bowman, 2009). Sporozoites of another species, *Cryptosporidium muris*, have a similar life cycle, however they invade the microvillous border of the gastric glands instead of the small intestine (Bowman, 2009).

Cryptosporidium is considered a zoonotic concern and there is a report from the United Kingdom of transmission of the rabbit *Cryptosporidium* to humans (Chalmers et al., 2009).

CLINICAL MANIFESTATIONS Inapparent infections of cryptosporidia in rabbits are common. Infection has also been found in rabbits with diarrhea but other etiologic agents were also present leaving the role of *Cryptosporidium* questionable (Schoeb et al., 2007). Immunocompromised animals may develop a life-threatening hyperinfective form of cryptosporidiosis (Bowman, 2009).

PATHOLOGY

Intestinal lesions in most host species follow a pattern which includes loss of enterocytes and villus atrophy and fusion accompanied by lamina propria edema and infiltration by inflammatory cells which can be mixed or primarily mononuclear (Schoeb et al., 2007). In rabbits, changes in the intestinal mucosa are minimal and include a slightly decreased villus to crypt ratio, loss of microvilli from enterocytes where the organisms attached, and slight lamina propria edema.

PATHOGENESIS

Most infections result in no clinical signs. Diarrhea may be caused due to damage to the intestinal epithelium.

DIAGNOSIS

Cryptosporidium oocysts are difficult to find on fecal slides because they are colorless, transparent and small, but they may be found in wet mounts when numerous. Concentrated sucrose solution is the flotation medium of choice for concentrating oocysts. Special stains may enhance visibility of oocysts. Immunofluorescent techniques, enzyme-linked immunosorbent assay (ELISA), and polymerase chain reaction (PCR) methods have been developed to assess exposure to *Cryptosporidium*. The diagnosis in laboratory rabbits is usually based on histologic examination of the intestine (Bowman, 2009; Schoeb et al., 2007).

PREVENTION AND THERAPY

Prevention is achieved by adhering to strict sanitary practices to interrupt fecal-oral transmission. Waterborne transmission is a significant risk since only a small number of oocysts are necessary to establish infection (Schoeb et al., 2007). Currently no known treatment exists. However, since most cases are subclinical, treatment is generally not warranted. Supportive care should be offered in the face of clinical disease to maintain hydration and electrolyte balance (Schoeb et al., 2007).

Hepatozoon cuniculi

Very little is written about *Hepatozoon cuniculi*, also known as *Leukocytoegregarina cuniculi*. It was described by Sangiorgi in 1914 in domestic rabbits in Italy. Sangiorgi described gametocytes in leukocytes and schizonts in the spleen. The intermediate host was not identified although fleas were suspected (Pakes and Gerrity, 1994). Another source reports that asexual stages occur in the liver or other visceral organs of a vertebrate host, gametes develop in erythrocytes or leukocytes, and fertilization and sporogony occur in hematophagous arthropods (Levine, 1985a, 1985b).

Toxoplasma gondii

BACKGROUND

Toxoplasma gondii has been identified in rabbits worldwide, but its ability to cause disease as well as its significance is inconsistent (Cox et al., 1981; Schoeb et al., 2007). Its discovery in rabbits in 1908 coincided with its discovery in rodents (de Souza et al., 2009; Pakes and Gerrity, 1994). In the United States, some laboratory rabbit vendors include *T. gondii* on their pathogen exclusion list while others do not, thus its prevalence in laboratory rabbits would be unknown and variable, although likely quite low. Even though there are only rare reports of *T. gondii* causing natural disease in *Oryctolagus cuniculus*, serological prevalence in some domestic colonies can approach 50% while it can be higher in wild *O. cuniculus* (Dubey et al., 1992; Hughes et al., 2008; Ishikawa et al., 1990; Pakes and Gerrity, 1994; Patton et al., 2008).

Rabbits serve as a model of ocular toxoplasmosis characterized by a retinochoroiditis, a disease seen in immunodeficient humans (Garweg et al., 1998; Rollins et al., 1982).

ETIOLOGY/ETIOLOGIC AGENT

This protozoal agent is typically associated with cats who act as the definitive host.

EPIZOOTIOLOGY

Transmission is by ingestion of the sporulated oocyst. It is thought that exposure to the agent comes from animal handlers, the environment, feed, water, or fomites being contaminated with cat feces. Cats are the definitive host species for the agent while rabbits can serve as an intermediate host (Schoeb et al., 2007). Placental transmission from pregnant does to their offspring is another route of infection (Patton et al., 2008). Breeding facilities may consider limiting animal handler exposure to cats to decrease the potential for introduction into the colony. Conversely, infected rabbits may serve as a source of infection for cats (Pakes and Gerrity, 1994). Recent reports have postulated that a sexual route of transmission could exist since experimentally infected bucks can shed *T. gondii* in their sperm

FIGURE 15.5 Tachyzoite form of *Toxoplasma gondii* inside a host cell as seen by transmission electron microscopy. In this longitudinal section some of the main features of its ultrastructure can be observed, such as the apical complex composed by the conoid (arrows), the club-shaped rhoptries (R) converging to it, and profiles of the micronemes (arrowheads). Dense granules (dg) are also secretory structures that are distributed without specific location in the host cell. The Golgi complex (GC) lies above the nucleus (N) and next to it, the apicoplast (a). Profiles of the single mitochondrion (m) are also seen. Notice the three-layered pellicle (circle). Several other parasitophorous vacuoles with other parasites are also seen. Bar: 500 nm. (photo courtesy of Paredes-Santos T.C., Attias M., DeSouza, W.)

within a week of inoculation (Liu et al., 2006a, 2006b). Trophozoites may also be found in the blood of experimentally infected animals (Liu et al., 2006a). Anatomical structures of *T. gondii* can be seen in the transmission electron micrograph shown in Figure 15.5.

T. gondii is a recognized zoonotic pathogen and animals carrying the agent can represent a human health hazard. Rabbits can be considered a major source of infection for humans when dealing with intensive breeding operations (Sroka et al., 2003). Several documented cases of direct transmission between rabbits and humans exist (Sroka et al., 2003).

CLINICAL MANIFESTATIONS

When clinical signs appear, they are considered to take place in two phases (Patton et al., 2008):

1. Acute: Anorexia, fever (greater than 104°F), lethargy, increased respirations, ocular and nasal discharges,

and central nervous signs are seen (ataxia, paralysis, seizures) (Percy and Barthold, 2007; Pakes and Gerrity, 1994). Death occurs a week after the onset of clinical signs. Because of these acute signs, *T. gondii* is considered a differential diagnosis for rabbits with neurological clinical signs (Müller et al., 2009; Sroka et al., 2003).

2. Chronic to latent: Asymptomatic, intermittent signs that appear with stress (such as from research procedures), or progressive clinical signs including emaciation that result in paralysis and/or death (Pakes and Gerrity, 1994).

Cervicofacial lumps in infected pet rabbits have been observed (Ishikawa et al., 1990). Death from experimental infection may occur (Garweg et al., 1998; Liu et al., 2006b).

Recovery from active infection has been reported (Schoeb, 2007).

PATHOLOGY

Lesions in the acute form usually include necrosis of lymph nodes and the liver, spleen, heart, and lung (Pakes and Gerrity, 1994; Patton et al., 2008; Schoeb, 2007). The organs may be enlarged with small white foci (Patton et al., 2008). Organisms may be found in microscopic sections of the various organs plus skeletal muscle (Gustafsson et al., 1997; Patton et al., 2008). Gross lesions are less likely in the chronic form and the organism may only be found in the CNS at that time (Schoeb et al., 2007; Patton et al., 2008). Reticuloendothelial hyperplasia may be seen in the lymph nodes, spleen, liver, and the CNS (Pakes and Gerrity, 1994). Generally, the chronic form is usually seen in older rabbits (Pakes and Gerrity, 1994; Schoeb, 2007).

PATHOGENESIS

After ingestion, the parasite will take up residence in organs and tissues previously noted. The organism reproduces (multiplies) in these locations, which causes disease. Organismal replication will continue until the infected animal dies or develops immunity (Schoeb et al., 2007).

DIAGNOSIS

Diagnosis is through serology (antibody detection tests). ELISA, immunofluorescent antibody (IFA), and Multiplexed Fluorometric ImmunAssay™ (MFIA) methods are all utilized, depending on the diagnostic laboratory (Ise et al., 1985). Histopathological and gross necropsy findings can also be used (Waller and Bergquist, 1982). Identification of the organism can also be accomplished through immunohistochemistry and PCR (Schoeb, 2007).

PREVENTION AND THERAPY

Prevention is achieved through good sanitation as well as eliminating the possibility of contamination of the rabbit area with cat feces. Rabbits should be physically separated from cats in laboratory animal facilities (Pakes and Gerrity, 1994). Sulfadiazine, pyrimethamine, sulfones, tetracyclines (e.g. minocycline), spiramycin, and 1,2-dihydrotriazones have all been used to treat toxoplasmosis in laboratory animals (Pakes and Gerrity, 1994; Rollins et al., 1982). Treatment of infected rabbits is generally not considered warranted (Schoeb, 2007).

Sarcocystis cuniculi

BACKGROUND

Sarcocystis was first described in rabbits by Manz in 1867 in Germany. Brumpt identified the protozoan in 1913 in the European Hare and named it *Sarcocystis cuniculi*. A year later *Sarcocystis leporum* was described by Crawley in the cottontail rabbit in the United States (Pakes and Gerrity, 1994).

ETIOLOGY/ETIOLOGIC AGENT

Sarcocystis cuniculi infections are common in wild rabbits worldwide but have not been reported in laboratory rabbits (Schoeb et al., 2007). The cyst may be septate and the wall contains radial spines, cytophaneres (Pates and Gerrity, 1994). Mature cysts are curved and fusiform in shape and contain bradyzoites which are 11–16 µm by 4–6 µm. Immature cysts contain round metrocytes which are 4–6 µm in diameter.

EPIZOOTIOLOGY

Cats are the definitive hosts for *S. cuniculi*. Rabbits become infected by consuming the feces of cats which contain infective oocysts. Within 3 months, infective sarcocysts develop within the striated muscle of the intermediate host (Schoeb et al., 2007). Transmission to the definitive host is by consumption of infected muscle tissue of rabbits.

CLINICAL MANIFESTATIONS

Sarcocystosis infections in the rabbit are generally asymptomatic, however heavy infestations may result in lameness due to the lesions and inflammation described below.

PATHOLOGY

Infections result in the formation of cysts that can be 5 mm long and visible within the muscle tissue. Gross lesions are generally seen in cardiac and skeletal muscle of the loins, flank, and hind limbs (Levine, 1973). Heavily infected tissue may appear grossly as white streaks oriented in the direction of the myofibers. Microscopically, intact cysts may be visible within muscle tissue with no inflammatory component.

PATHOGENESIS

Ruptured cysts can cause an inflammatory response resulting in severe focal myocarditis and myositis characterized by an infiltration of lymphocytes, plasma cells, macrophages, and eosinophils with subsequent mineralization of myofibers (Pakes and Gerrity, 1994). Healed lesions result in scarring.

DIAGNOSIS

Diagnosis is generally made by histopathological examination, however visualization of white streaks paralleling the muscle fibers at gross exam can be diagnostic in heavily infected animals (Pakes and Gerrity, 1994). Fresh muscle tissue smears can be examined for *Sarcocystis* using phase microscopy or Giemsa stain. The sarcocysts are usually septate and have radial spines in the wall.

PREVENTION AND THERAPY

There are no effective methods for treatment of *Sarcocystis*. Good sanitation can serve to prevent disease by minimizing exposure to cat feces.

Microsporidia

Encephalitozoon cuniculi

BACKGROUND

Microsporidia are intracellular, obligate, spore-forming eukaryotic organisms to which all mammalian species are susceptible to infection. *Encephalitozoon cuniculi* was first described in young rabbits with granulomatous encephalitis resulting in motor paralysis in 1922 (Wright and Craighead, 1922). It was later named by Levatiditi et al. in 1923, whose group identified the protozoal agent from the tissue of rabbits with the same pathology (Pakes and Gerrity, 1994). The organism is currently considered a highly derived fungus (Keeling and Fast, 2002), but is included here due to its historical classification as a parasite.

Based on the variation in ribosomal RNA and karyotypes, *E. cuniculi* has been divided into three strains (Schoeb et al., 2007). Each strain has a distinct host distribution. Strain I (karyotypes A, B, and C) is considered the “rabbit” strain and infects humans, mice, and rabbits. The “mouse strain”, strain II (karyotype F), infects mice and blue foxes. Strain III (karyotypes D and E) infects both humans and dogs and is considered the “dog” strain.

ETIOLOGY/ETIOLOGIC AGENT

The mature spore is oval, measures 1.5 × 2.5 µm and is encased by a thick cell wall. Each spore contains an eccentric nuclei and a polar filament coiled within the inner wall which is characteristic of Microsporidia. This

polar filament is extruded by the spore when it comes in contact with the host cell membrane and inserts a sporoplast into the cell. The sporoplast proliferates within a vacuole giving rise to meronts which become sporonts and ultimately mature spores. This vacuole may rupture the host cell releasing mature spores into the vascular system which may further disseminate. Mature spores are shed via excreta.

EPIZOOTIOLOGY

Natural infections in rabbits occur primarily through the ingestion of mature spores in urine. Experimental modes of transmission include intranasal, tracheal, and parenteral routes (Pakes and Gerrity, 1994). Intrauterine transmission has also been reported though it is not considered a major mode of transmission (Csokai et al., 2009).

Encephalitozoon cuniculi is considered a life-threatening opportunistic pathogen in immunocompromised human patients (Weber et al., 1997). Though no known cases of direct zoonotic transmission exist between rabbits and humans, one should still consider *E. cuniculi* as a potential zoonotic organism.

CLINICAL MANIFESTATIONS

In rabbits, most *E. cuniculi* infections are subclinical though acute disease does occur sporadically. Neurological signs prevail in acute disease and include torticollis, ataxia, paresis, opisthotonos, and convulsions. Chronic renal failure and phacoclastic uveitis may also result from chronic infection (Kunzel et al., 2007). *E. cuniculi* is generally considered to be a top differential diagnosis of neurological clinical signs in all rabbits. *T. gondii*, space-occupying masses, and other infectious agents such as *Pasteurella multocida* are also common differential diagnoses.

PATHOLOGY

The classic pathological lesion of encephalitozoonosis in rabbits is pyogranulomatous encephalitis (Figure 15.6) with perivascular and leptomeningeal lymphoplasmocytic cuffing. The cerebrum is the most frequent site of infection with less frequent infection in the cerebellum and vestibular cores (Csokai et al., 2009). Gross lesions of the kidneys are common and present as multiple, white pinpoint, slightly depressed foci (often called “pitting”) randomly scattered on the capsular surface (Figure 15.7). Microscopically, evidence of necrosis exists with pyogranulomatous, lymphoplasmocytic inflammation. Interstitial nephritis was identified in 52% of pet rabbits evaluated for histopathological changes in one study (Csokai et al., 2009).

PATHOGENESIS

The clinical signs and granulomatous lesions seen in *E. cuniculi*-infected rabbits are the result of

FIGURE 15.6 Photomicrograph of granulomatous encephalitis with perivascular accumulation of lymphocytes. The arrow points to *E. cuniculi* organism. (photo courtesy of James G. Fox)

FIGURE 15.7 Pitting of the kidney surface (right side) resulting from infection with *E. cuniculi*, demonstrated on two halves of a rabbit kidney. (from Patton, N.M., K.W. Hagen, J.R. Gorham, and R.E. Flatt. 2008. *Domestic Rabbits: Diseases and Parasites*. PNW 310. Corvallis, OR: Oregon State University Extension Service. © 1986, 1998 Oregon State University. Used with permission)

inflammation caused by spore release from ruptured cells. Seroconversion occurs within 30 days of infection and precedes renal shedding (Cox et al., 2007). It has not been clearly elucidated which organs the spores infect first once ingested. However in the acute stage of experimental infection of rabbits with *E. cuniculi*, spores were identified in the lung, kidney, and liver but not the brain or gut. During chronic infection however the heart, brain, and kidney were the only organs involved (Cox et al., 2007).

FIGURE 15.8 Photomicrograph of Gram-positive (purple) spores of *E. cuniculi* in the brain.

DIAGNOSIS

Current serologic testing modalities include ELISA, IFA, and MFIA. Results using MFIA are generally more sensitive than those based on ELISA. PCR can be conducted on fresh urine, fecal, fresh or fixed tissue or cultured cells though this method is not routinely used for screening. However, a recent study reported that PCR failed to detect parasite DNA in urine or cerebrospinal fluid from pet rabbits displaying clinical signs of encephalitozoonosis (Kunzel et al., 2007).

Gross pathological signs can lead to a presumptive diagnosis. A definitive diagnosis is readily made post-mortem when organisms are identified in tissue using special staining techniques. *E. cuniculi* spores are “strongly” Gram-positive, stain dark purple with Goodpasture’s carbol fuschin, and are acid fast trichrome positive (Figure 15.8) (Harcourt-Brown, 2008).

PREVENTION AND THERAPY

Commercial SPF rabbit colonies exist to provide *E. cuniculi*-free animals for research purposes. Screening panels are also available through commercial laboratories and should be routinely performed to monitor SPF status. Maintaining adequate husbandry techniques will help to minimize exposure from contaminated excreta. Spores are resistant to standard environmental conditions, however they are readily susceptible to routine disinfectants and autoclaving. It should be noted that anecdotally the presence of histopathological lesions (both in the CNS and kidney) can result in misinterpretation of findings in toxicological studies utilizing rabbits, causing concern. Therefore, it is recommended that rabbits from *E. cuniculi*-free sources be used for toxicity testing.

Treatment success depends on whether an infection is chronic or acute. Acute infections can be treated with fenbendazole at 20mg/kg orally every 24h for 28 days

with some success (Suter et al., 2001). Acute neurological signs can be treated with steroids (0.5–1 mg/kg dexamethasone with further doses at 0.2 mg/kg if needed) (Harcourt-Brown, 2008). Chronic cases generally present with neurologic symptoms and if cell damage is severe treatment is usually not successful (Meredith, 2008). Preventive regimens of fenbendazole are used in areas of the world where both wild and domestic rabbits are of the species *O. cuniculus* (e.g. United Kingdom and Europe) (Harcourt-Brown, 2008).

Flagellates and Amoebae

Chilomastix cuniculi

Chilomastix cuniculi is a non-pathogenic organism observed in the cecum of the rabbit. The trophozoite is pyriform with three anterior flagella, a large cytosomal groove near the anterior end and an anterior nucleus. The trophozoite ranges in length from 3–20 μm (Pakes and Gerrity, 1994). Diagnosis is by microscopic evaluation of cecal contents or fecal smear.

Giardia duodenalis

Giardia is a bilaterally symmetrical flagellate organism with two axostyles, two anterior nuclei and four pairs of flagella. Trophozoites of *G. duodenalis* measure approximately $16 \times 9 \mu\text{m}$ (Hegner, 1922) and contain cysts with two to four nuclei which are shed via feces. *G. duodenalis* is occasionally found in the anterior intestinal tract of laboratory rabbits, however infection is generally not known to be pathogenic (Levine 1957, 1985a). Several cases of diarrheal disease have been attributed to this flagellate, some with successful treatment using metronidazole in drinking water (Schoeb et al., 2007). This organism is zoonotic, however there is no known evidence of rabbit-to-human transmission. Rabbits have been used to cultivate *Giardia* spp. for experimental purposes (Pakes and Gerrity, 1994).

Monocercomonas cuniculi

Monocercomonas cuniculi (Tanabe, 1926) (synonyms *Eutrichomastix cuniculi*, *Trichomastix cuniculi*) is a flagellate organism found within the cecum of the rabbit that is apparently non-pathogenic. Trophozoites range in length from 5–14 μm and are pyriform with three anterior and one posterior flagellum. A slender axostyle protrudes from the posterior of the body (Kulda and Nohynkova, 1978; Morgan and Hawkins, 1952).

Retortamonas cuniculi

Retortamonas cuniculi (Collier and Boeck, 1926) is a relatively uncommon, non-pathogenic flagellate organism found in the cecum. Flagellates measure approximately 7–13 by 5–10 μm (Pates and Gerrity, 1994). Cysts are oval

FIGURE 15.9 Light microscope image of *Trypanosoma nabiasi* in rabbit blood. (photo courtesy of Hamilton, PB)

and measure 5–7 by 3–4 μm (Collier and Boeck, 1926; Kreir, 1978).

Trypanosoma nabiasi

Trypanosoma nabiasi is a hemoflagellate organism that has been identified occasionally in wild *Oryctolagus cuniculi* in Europe and domestic rabbits outside Europe (Hamilton et al., 2005). Recently, the first identification of the organism in wild *O. cuniculi* was made in Australia (Hamilton et al., 2005) (Figure 15.9). There are no published reports of *T. nabiasi* in laboratory rabbits. The rabbit flea, *Spilopsyllus cuniculi*, is the vector for *T. nabiasi* (Hoare, 1959). The hemoflagellate measures 24–28 μm long and develops in the gut of the intermediate host *Spilopsyllus cuniculi* (Pakes and Gerrity, 1994). Hemoflagellates appear in the bloodstream within 5–12 days after infection (Grenwal, 1956). Infection of the rabbit likely occurs during grooming via consumption of fecal material from the flea (Hamilton et al., 2005). Rabbits are subsequently immune to reinfection (Grenwal, 1956). Furthermore, experimental evidence suggests that *T. nabiasi* is host-specific (Hamilton et al., 2005).

Entamoeba cuniculi

Entamoeba cuniculi is a non-pathogenic amoeba found in the cecum and colon of rabbits. The trophozoites measure 10–30 μm in diameter and the cysts are oval with eight nuclei that measure 7–21 μm in diameter (Hoare, 1959). *Entamoeba cuniculi* is morphologically similar to the rodent amoeba, *Entamoeba muris* (Baker, 2007).

Other

Pneumocystis

BACKGROUND

Pneumocystis oryctolagi is an extracellular non-mycelian fungal organism specific to the lagamorph host. However, because it was previously believed to be a parasite, information on the organism is included here as well as in Chapter 17. Previously this organism was unclassified and named *Pneumocystis carinii*. To date, five *Pneumocystis* species have been identified: *P. wakefieldiae* and *carinii* in the rat, *P. murina* in the mouse, *P. oryctolagi* in the rabbit, and *P. jirovecii* in the human (Beck and Cushion, 2009).

ETIOLOGY/ETIOLOGIC AGENT

The organism exists in two forms, a trophic and cystic form. The trophic form can range in size from small, ellipsoid, and 1–2 μm in length to rather large, irregular and 4–8 μm in length with filopodia. The cystic form is round, 5 μm in diameter, and possesses a thick wall (Dei-Cas et al., 2006). Filopodia are rare. Each cyst contains a maximum of eight spores.

EPIZOOTIOLOGY

Immunocompromised animals are most susceptible. Transmission is generally horizontal from other animals harboring the fungal organism.

CLINICAL MANIFESTATIONS

Disease is rare as infection is often subclinical. Pneumonia was reported in a group of weanling rabbits that resolved in most animals within 2–3 weeks (Soulez et al., 1989).

PATHOLOGY

Lesions include pneumonitis, vascular congestions, edema, and an inflammatory infiltrate of the alveolar walls. Infiltrate is made up of macrophages and lymphocytes with occasional plasma cells (Pakes and Gerrity, 1994).

PATHOGENESIS

All identified *P. oryctolagi* life cycle phases occur in the lungs (Dei-Cas et al., 2006), specifically the type I alveolar cells that line the air sacs. Inflammation caused by the fungal organisms within the lungs results in pneumonitis or pneumonia.

DIAGNOSIS

Diagnosis is often made by the presence of organisms in tissue at necropsy. Lung tissue can be stained with silver stains or toluidine blue O (TBO) to visualize the organism histologically. PCR can be used to identify

DNA from rabbit nasal and lung wash samples (Dei-Cas et al., 2006).

PREVENTION AND THERAPY

No definitive treatments have been described. Rederivation may be an option, however vertical transmission has not been ruled out.

ARTHROPODS

Arachnids

Psoroptes cuniculi

BACKGROUND

This mite affects domestic rabbits worldwide but is rare in wild rabbits (Schoeb et al., 2007). The parasite used to be very prevalent in laboratory rabbit colonies but improved husbandry and use of specific pathogen-free rabbits has greatly reduced the prevalence over the years (Schoeb et al., 2007).

ETIOLOGY

The mite (Figure 15.10) has also been called by different names throughout history including *Dermatodectes cuniculi*, *Psoroptes longirostris* var. *cuniculi*, *Psoroptes*

communis var. *cuniculi* and *Psoroptes equi* var. *cuniculi* (Hofing and Kraus, 1994). Within this genus, mites identified from various hosts (including goat, horse, mule, domestic sheep, white-tailed deer, mule deer, and black buck antelope) are morphologically and behaviorally similar and cross-infection of these mites to rabbits is possible (Hofing and Kraus, 1994).

Psoroptes may be distinguished from other mites such as *Chorioptes* by the jointed pedicels of the tarsal suckers (Schoeb et al., 2007).

EPIZOOTIOLOGY

Psoroptes cuniculi is a non-burrowing parasite which primarily lives on the inner surface of the pinna. Some sources report lesions caused by the parasite on other areas of the body (Hofing and Kraus, 1994). All life cycle stages can be found on the host where they feed on tissue fluids exuding from inflamed surfaces or obtained by piercing the epidermis. Epidermis and sebaceous secretions may also be ingested (Schoeb et al., 2007). The life cycle requires about 3 weeks and eggs hatch about 4 days after being laid. Mites can survive off the host for up to 3 weeks at low temperature and high humidity, but survive a much shorter time at high temperature and low humidity (Smith et al., 1999).

FIGURE 15.10 *Psoroptes cuniculi*. A is male B is female. Viewed from the underside. Farmers Bulletin 1568, revised 1931. (from Canestrini 1894. Used with permission from the University of North Texas Libraries, Digital Collection)

CLINICAL MANIFESTATIONS

Infestation with this mite results in otocariasis, also known as psoroptic mange, ear mange, ear canker, or psoroptic scabies (Hofing and Kraus, 1994). A copious, brown exudate builds up on the inner aspect of the ear. Exudate covering the entire inner surface of the ear may be seen and the underlying tissue may be red and inflamed. Alternatively, infested animals can be clinically normal until placed under stress (Bowman, 2009).

PATHOLOGY

The main microscopic lesion is chronic proliferative dermatitis. Early lesions have a dry whitish-gray to tan crusty exudate which thickens with disease progression to 2 cm or more. Exudate consists of desquamated epithelial cells, serum, inflammatory cells, mite feces, and adult mites. The skin surface is moist and red, may be odoriferous and very painful when touched (Hofing and Kraus, 1994). Histologically the epidermis is hyperplastic and parakeratotic and the dermis and epidermis are infiltrated with lymphocytes, eosinophils, and heterophils (Schoeb et al., 2007).

PATHOGENESIS

Due to intense pruritus, affected rabbits may shake or scratch at their ears. Pruritus may lead to excoriation and self-mutilation and secondary bacterial infections (Hofing and Kraus, 1994; Schoeb et al., 2007). An allergic response to the mites may play an important role in pathogenesis (Schoeb et al., 2007).

DIAGNOSIS

Adult mites may be seen upon visual or otoscopic examination of the ear. Observing the exudate, even from afar, can be considered pathognomonic. Samples of exudate from affected ears examined underneath a microscope usually reveal numerous mites (Hofing and Kraus, 1994).

PREVENTION AND THERAPY

Careful selection of vendors when acquiring laboratory rabbits is necessary to prevent ear mite infestations. Quarantine and prophylactic treatment of animals whose history is unknown is recommended. Historically, topical application of mineral oil in the ears was used as a preventive measure (Hofing and Kraus, 1994).

Treatments include subcutaneous administration of ivermectin, topical selamectin, oral moxidectin, and topical imidacloprid plus moxidectin (Beck, 2007; Schoeb et al., 2007; McTier et al., 2003; Wagner and Wendlberger, 2000). Many treat, either prophylactically or therapeutically, the ears with one drop each of concentrated ivermectin solutions with success.

Experts are torn when it comes to the removal of the exudate. Older texts recommend the removal of the

exudate in order to decrease the parasite load while more recent advice indicates that the removal of the exudate may be traumatic to the rabbit and could potentially result in necrosis of the thin and delicate structures of the pinna. Bleeding from the fragile ear veins and arteries could also result. In this case, treatment would proceed in the face of exudate and as the mite population decreases, the exudate would naturally clear or be removed with mineral oil when sufficiently diminished.

Notoedres and Sarcoptes scabiei

BACKGROUND

Notoedres cati is primarily a parasite of cats but can infect rabbits (Soulsby, 1982). Both *N. cati* and *S. scabiei* are found throughout the world but are not frequently reported in rabbits (Hofing and Kraus, 1994).

ETIOLOGY

Notoedres cati is referred to in older literature sources as *Notoedres minor cuniculi*. *Sarcoptes scabiei* (Figure 15.11) is also known as the itch or scab mite (Hofing and Kraus, 1994). It is thought that *S. scabiei* from different host species are separate varieties, however this is still being debated (Schoeb et al., 2007). It is also thought that host specificity has arisen in the parasite so that, for example, *S. scabiei* infecting a human would spread more readily to another human. Interspecies transmission does still occur, however resulting dermatitis may be atypical and transient (Bowman, 2009).

EPIZOOTIOLOGY

The life cycle is described from human infestations, however, the life cycle on the rabbit is presumed to be similar (Soulsby, 1982). The adult female mites burrow in the epidermis and lay eggs which hatch in 3–5 days. Six-legged larvae develop into eight-legged protonymphs then deutonymphs (Schoeb et al., 2007). Females, eggs, and young larvae are found in burrows in the epidermis. Older larvae, nymphs, and adult males are found on the surface (Hofing and Kraus, 1994). Mites develop into mature males and females about 17 days after hatching. All forms feed on epithelial cells and tissue fluid. Transmission is by contact with organisms on the skin surface. Adult mites are very susceptible to drying and only live a short time off the host (Hofing and Kraus, 1994).

CLINICAL MANIFESTATIONS

Disease caused by *Notoedres cati* is clinically and pathologically indistinguishable from that caused by *Sarcoptes scabiei*, although it is usually less severe (Schoeb et al., 2007). Early lesions consist of partial alopecia, hyperemia, and oozing of serous fluid which progresses to a yellow-white or gray-white crust of epidermal cells and dried serum. Lesions are very pruritic and rubbing and

FIGURE 15.11 *Sarcoptes scabiei*. A is male and B is female. Viewed from the underside (from *Farmers Bulletin* 1568, revised 1931; from *Canestrini* 1894. Used with permission from the University of North Texas Libraries, Digital Collection)

scratching by the rabbit may increase severity and allow for secondary bacterial infections to develop. Lesions usually first appear on the nose and lips and extend to the eyes, forehead, face, and occasionally other body areas such as the external genitalia (Hofing and Kraus, 1994). Extensive lesions on individual animals can be severe, leading to general debilitation, emaciation, anemia, leukopenia, and death within weeks (Hofing and Kraus, 1994).

PATHOLOGY

Lesions are characterized microscopically by epidermal hyperplasia with orthokeratotic and parakeratotic hyperkeratosis and an overlying layer of keratinic and proteinaceous debris (Schoeb et al., 2007). Mite and mite tunnels can be found in the debris and outer epidermis. The dermis contains inflammatory cell infiltrate, primarily lymphocytes, and eosinophils. A suppurative response may also be seen with secondary bacterial infections (Schoeb et al., 2007).

PATHOGENESIS

An immunologic hypersensitivity reaction to the mites is thought to be the major pathogenic mechanism of the dermatitis and pruritus (Schoeb et al., 2007). Pruritus may lead to excessive scratching and rubbing leading to secondary traumatic injuries.

DIAGNOSIS

Identification of mites in deep skin scrapings is the main diagnostic method for identification. *Notoedres cati* is slightly smaller than *Sarcoptes scabiei* and the position of the anus is dorsal in *N. cati* versus terminal in *S. scabiei* (Schoeb et al., 2007). Additionally, the dorsal dentate spines of *Sarcoptes* are significantly larger than *Notoedres* (Hofing and Kraus, 1994).

PREVENTION AND THERAPY

Limiting exposure to *Sarcoptes*- and *Notoedres*-affected individuals is necessary to prevent transmission. This includes the education of animal handlers with regards to the potential of disease transmission from humans to rabbits. Various sources recommend ivermectin, doramectin, or selamectin to treat infections (Kurtdele et al., 2007; Schoeb et al., 2007; Voyvoda et al., 2005).

Cheyletiella parasitovorax

BACKGROUND

There are several species of the fur mite *Cheyletiella* that occur with wide geographic distribution. Several species affect rabbits, with *C. parasitovorax* being the most commonly identified and described and thus classically associated with rabbits. However, the mite also infests dogs and cats and has been labeled one of the most common dermatological zoonosis of those species even though it is also considered under-diagnosed (Jeromin, 2006; Moriello, 2003). Laboratory animal veterinarians should take this into account when planning for biosecurity measures in the vivarium.

ETIOLOGY/ETIOLOGIC AGENT

C. parasitovorax is described as having a “distinctive” appearance with the adults having “large, curved palpal claws” (Schoeb et al., 2007). Other aspects of the mite include a semicircular dorsal shield, legs that reach out well beyond the body that have feathered bristles and terminal tarsal combs. As adults, males are up to 320µm long and 160µm wide and the females are larger measuring up to 500µm long and 200µm wide (Schoeb et al., 2007). Some authors have suggested that

the prevalence of *C. parasitovorax* in laboratory rabbit populations is now “rare” (Schoeb et al., 2007). In the experience of one author of this chapter, multiple research rabbit populations have been identified with the pathogen within a short time period. Obtaining rabbits from non-SPF sources and contact with potentially infested dogs and cats would be considered risk factors for introducing or maintaining mite infestations in rabbit colonies.

EPIZOOTIOLOGY

This fur mite does not burrow. Staying on the skin surface, it feeds on “tissue fluid” (Schoeb et al., 2007). Eggs will be attached to hair shafts approximately 2–3 mm above the skin surface (Hofing and Kraus, 1994; Schoeb et al., 2007). No other hosts are involved in the life cycle and transmission is by direct contact. Fomite transmission may also occur as adult female mites have been known to live for up to 10 days off the host (Bowman, 2003; Paterson, 2006). *C. parasitovorax* can also temporarily infest humans (Cohen, 1980).

Co-infections with other mites and lice have been reported (Flatt and Wiemers, 1976; Kim et al., 2008b).

CLINICAL MANIFESTATIONS

Clinical manifestations are variable, with some animals displaying no clinical signs with subclinical infections. The main clinical sign is excessive flakes and scales on the skin, especially in the scapular region, but this has been also reported on the face and ventrally (Cloyd and Moorhead, 1976; Richardson, 2000; Schoeb et al., 2007). Some cases result in layers of dead skin flakes building up on the skin surface. Areas of alopecia may be seen. Inflammation and pruritis are usually not observed. Skin flakes may move around on the skin surface due to mite movement with *C. parasitovorax* infestation or the mite might be visualized with the naked eye, giving the infestation the name “walking dander” (Bowman, 2003; Hess, 2004). Caution should be taken to ensure that cheyletiellosis is not misdiagnosed as ringworm. At least one author has suggested that clinical signs may be more pronounced in immunocompromised animals (Paterson, 2006).

PATHOLOGY

Gross findings include the excessive amount of skin scales and flakes when present. Mild epidermal hyperkeratosis along with dermal inflammatory cell infiltrate with neutrophils, lymphocytes, plasma cells, and eosinophils may be seen microscopically (Hofing and Kraus, 1994; Schoeb et al., 2007).

PATHOGENESIS

The skin exfoliates in response to the fur mite residing on the skin surface and penetrating the skin with its

“needle-like mouth parts” resulting in the clinical signs (Paterson, 2006).

DIAGNOSIS

Multiple methods exist for diagnosing and identifying *C. parasitovorax*. Perhaps the simplest method is to apply clear adhesive tape to the affected areas, or scapular region, remove it and then examine the tape on a slide with a microscope (Richardson, 2000). Performing a skin scrape and brushing the epidermis with a stiff bristled brush can also be used to find organisms (Hofing and Kraus, 1994; Patton et al., 2008). Debris gathered by these methods can be examined using a dissecting scope. Identification of the mite is considered easy given its characteristic structures. Eggs can also be detected using these diagnostic methods.

PREVENTION AND THERAPY

Prevention is best accomplished by acquiring rabbits from a source known to be free from *C. parasitovorax*. Good biosecurity control is also needed so that potentially infested dogs, cats, and fomites do not serve as a source of infection. Preventive treatments may be considered for incoming rabbits from non-SPF vendors.

Ivermectin has been described as an efficacious treatment for *C. parasitovorax* infestations in rabbits, dogs, and cats and is easy to administer. Because the mites have a life cycle of 14–21 days, multiple treatments are needed. The basic dose is 400 µg/kg delivered subcutaneously once every 10–14 days for three consecutive treatments (Paterson, 2006).

Topical selamectin, permethrin, and carbaryl products may also be used as treatments (Fisher and Shanks, 2008; Hess, 2004; Mellgren and Bergvall, 2008; Paterson, 2006). Selamectin in particular has been noted to be efficacious and safe, even at a single dose of 12 mg/kg (Kim et al., 2008b; Mellgren and Bergvall, 2008).

At the time of the first treatment, the animal’s caging, room environment, and items that could serve as fomites should be sanitized and/or treated with flea products such as 5% carbaryl dust (Hess, 2004; Jeromin, 2006; Paterson, 2006). All animals with potential contact with infested animals should be treated (Paterson, 2006).

Listrophorus gibbus (Also Known as *Leporacarus gibbus*)

BACKGROUND

Listrophorus gibbus, also called *Leporacarus gibbus* in the veterinary literature, is considered to be a clinically silent disease in rabbits. This mite has been reported in both wild and domestic rabbits in North America, Europe, Australia, and New Zealand (Hofing and Kraus, 1994; Schoeb, 2007).

ETIOLOGY/ETIOLOGIC AGENT

Since the mite does not generally reside on the skin, it is found on hair shafts. Its dark brown appearance comes from dense chitin (Hofing and Kraus, 1994). Adult males measure $240\mu\text{m} \times 440\mu\text{m}$ and females measure $310\mu\text{m} \times 560\mu\text{m}$ (Hofing and Kraus, 1994). In addition to having short legs, the body is “compressed laterally” or oval and there is a projection that extends out over the mouthparts (Hofing and Kraus, 1994).

EPIZOOTIOLOGY

The mite does not burrow and is described as feeding on sebaceous secretions, epithelial scales, and hair debris (Hofing and Kraus, 1994; Paterson, 2006). Rabbits are the mite’s necessary host and all life stages are completed on the animal.

Co-infections with *Cheyletiella* and other ectoparasites have been reported (Kim et al., 2008a; Pinter, 1999). Rare reports of human cases exist (Paterson, 2006; Schoeb et al., 2007).

CLINICAL MANIFESTATIONS

No clinical signs have been reported with infestations with *L. gibbus* only, even with heavy infestations (Paterson, 2006).

PATHOLOGY (GROSS AND MICROSCOPIC FINDINGS)

No pathological findings have been reported with infestations of *L. gibbus* only. The mite can be found on hair specimens.

PATHOGENESIS

This is not applicable.

DIAGNOSIS

Even though the mite causes no clinical signs, it can be easy to find. Fur plucks, brushings, or combing can be used to find the organism (Schoeb, 2007). Optimal areas for looking for the mite include the scapular region and rump. Fur can be placed on dissecting scopes or underneath clean cellophane and examined with a regular microscope. The mite can be identified by its characteristic anatomical features along with the lack of clinical manifestations.

PREVENTION AND THERAPY

As with other ectoparasites, ensuring that rabbit sources are free of the mite is important. The same ivermectin treatment used for *C. parasitovorax* parasitism can be used to effectively treat *L. gibbus* infestations (Schoeb et al., 2007). Some authors recommend against treatment but this parasite is generally considered to be unacceptable within the laboratory animal facility (Paterson, 2006).

Demodex cuniculi

Demodex cuniculi is a follicle mite that is found as a normal resident of rabbit skin. *D. cuniculi* is similar in morphology to *Demodex canis*. Rabbits can be treated with a 0.01% solution of amitraz or a biweekly subcutaneous injections of ivermectin at $500\mu\text{g}/\text{kg}$ body weight until infestation clears (Schoeb et al., 2007).

Trombiculid Mites

The mites of the family *Trombiculidae* (chiggers, red bugs, harvest mites) are found on wild and domestic rabbits which are exposed to vegetation. However, these mites have not been reported in rabbits maintained in modern laboratory facilities (Schoeb et al., 2007). Several species have been found on rabbits including *Trombicula autumnalis*, *T. cavicola*, *T. irritans*, and *T. microti* (Pates and Gerrity, 1997). These mites are not host-specific.

Adult mites are free-living within the soil. Only the larvae are parasitic. Larvae can survive up to 30 days without a host. Once a host is found, the larvae attach to the skin surface and release a highly irritating and pruritic salivary secretion. This secretion results in the destruction of the epithelium and creation of a tubular structure, stylostome, from which the larvae feed on tissue fluid of the host. Once engorged, the larvae fall off the host and enter a period of quiescence in the soil, then molt into non-parasitic nymphs. Unfed larvae are a deep red in color and approximately $210\mu\text{m}$ long. Fully fed larvae are pale yellow in color and approximately $400\mu\text{m}$ long (Pates and Gerrity, 1997).

Larvae are most commonly found on feet, ears, medial canthi, and perineum (Keay, 1937). The saliva released during the feeding process causes intense pruritus (Alexander, 1984) and the development of macules and pustules. Humans are parasitized in a similar fashion as rabbits.

Pentastomids

Linguatula serrata

Lagomorphs are one of the many natural intermediate hosts for the pentastomid, *Linguatula serrata* (James and Harwood, 1969; Soulsby, 1968). The rabbit becomes infected upon consumption of eggs shed by respiratory excretions of the definitive hosts which include dogs and occasionally humans (Schoeb et al., 2007). Upon hatching, larvae will migrate from the intestine to mesenteric lymph nodes, undergo six to nine molts, and become infective nymphs. Nymphs are curved, flattened ventrally, white, 4–6 mm long and contained within small cysts. Infected rabbits have no evidence of clinical disease. Nymphs are often an incidental finding at necropsy.

Ticks

Wild rabbits serve as the host for a multitude of hard (ixodid) and soft (argasidae) tick species. These ticks serve as vectors for several zoonotic diseases including tularemia, lyme disease, and rickettsial diseases. Ticks that feed on wild rabbits rarely bite humans (Schoeb et al., 2007). Ticks rarely infest domestic rabbits but laboratory rabbits may serve as animal models to study tickborne diseases (Hofing and Kraus, 1994).

FAMILY ARGASIDAE (SOFT TICKS)

Otobius lagophilus *Otobius lagophilus* is considered the most common soft tick to affect rabbits (Pates and Gerrity, 1994). The ticks are parasitic in the larval and lymph stages and are found on the face of the affected rabbit. Adult ticks are often found in the nesting areas. Adult female ticks will lay eggs that hatch in 3–8 weeks. *Otobius megnini*, *Ornithodoros parkeri*, and *Ornithodoros turicata* are additional argasid ticks that can affect rabbits (Schoeb et al., 2007).

FAMILY IXODIDAE (HARD TICKS)

Haemaphysalis leporis-palustris *Haemaphysalis leporis-palustris* is a common ixodidae tick that is found on both domestic and wild lagomorphs in North America (Pates and Gerrity, 1994). This tick requires three hosts to complete its life cycle and the rabbit can serve as a host for all three stages. Each stage requires departure from the host to the ground for feeding, thus prohibiting domestic rabbits maintained under proper husbandry conditions from fulfilling the role of a three-host animal. Larvae and nymphs usually attach to the head, especially the ears, and feed from 4–11 days (Soulsby, 1982). A heavy tick burden can lead to anemia and even death in wild rabbits. Diagnosis is made by accurate identification of the tick and treatment requires manual removal of the parasites. Maintaining adequate biosecurity minimizes exposure of domestic rabbits to both infected wild animals and infested vegetation.

Insects

Lice

Haemodipsus ventricosus (Figure 15.12) is the louse of *O. cuniculus* and is reported rarely in pet rabbits (Paterson, 2006). Other species of *Haemodipsus* infest other rabbit species (Durden and Rausch, 2007; Schoeb et al., 2007). The organism and its eggs may be seen with the naked eye. Heavy parasite loads can be associated with anemia, weight loss, alopecia, pruritis, and papules (Hess, 2004). Ivermectin, by subcutaneous injection at 4mg/kg, can be used to treat lice (Hess, 2004; Paterson, 2006). Topical imidacloprid has also been suggested as a treatment (Paterson, 2006).

FIGURE 15.12 *Haemodipsus ventricosus*. (from *Farmers Bulletin* 1568, revised 1931. From Railliet 1895. Used with permission of the University of North Texas Libraries, Digital Collection)

Laboratory rabbits are used in human louse research where the transmission of *Rickettsia* and immunization against human lice as a protective mechanism against infection are studied (Ben-Yakir et al., 1994; Houhamdi and Raoult, 2006; Mumcuoglu et al., 1997).

Fleas

Multiple flea species infect rabbits throughout the world. *Spilopsyllus cuniculi*, known as the rabbit flea (Figure 15.13), is the most frequently mentioned and studied although pet infestations with the dog and cat fleas (*Ctenocephalides canis* and *felis*, respectively) are becoming more commonly noted (Hamilton et al., 2005; Hess, 2004). Other species include *Cediopsylla simplex* (common eastern rabbit flea), *Odontopsylla multispinosus* (giant eastern rabbit flea), *Hystrichopsylla talpae*, *Caenopsylla laptevi*, *Xenopsylla cunicularis*, *Echidnophaga iberica* and *gallinacea*, and *Pulex irritans* (Bowman, 2003; Cooke, 1999; Osacar et al., 2001; Osacar-Jimenez et al., 2001; Schoeb, 2007; Visser et al., 2001). Seasonal variations exist in the population and parasitic potential for these flea species.

FIGURE 15.13 *Spilopsyllus cuniculi*. Cranial portion. (from *Farmers Bulletin* 1568, revised 1931. From Railliet 1895. Used with permission of the University of North Texas Libraries, Digital Collection)

A large concern with rabbit flea infestations is the transmission of pathogenic agents which use the fleas as vectors. Myxoma virus infection, endemic in many populations of *Sylvilagus* and devastating to *O. cuniculus*, is transmitted by fleas along with plague, Rocky Mountain spotted fever, and *Trypanosoma* species (Hamilton et al., 2005; Lowell et al., 2005; Reglero et al., 2007; Merchant et al., 2003a, 2003b, Schoeb et al., 2007; Stanford et al., 2007; von Reyn et al., 1976). Heavy flea infestations have been associated with outbreaks of rabbit hemorrhagic disease (calicivirus) (Lugton, 1999).

Fleas can be diagnosed by direct visualization of them and/or their feces in the fur. Pruritis, alopecia, excoriations, and other signs of trauma can be observed in affected animals. The face and ears are the main areas for clinical signs (Hess, 2004). Imidocloprid (0.4ml topical solution for rabbits weighing less than 4kg and 0.8ml in rabbits weighing greater than 4kg), selamectin, and lufenuron have all been reported to be effective against fleas in rabbits (Bowman, 2003; Hess, 2004). Rabbit environments should also be treated (Hess, 2004).

Flies (Dipterans)

FLIES

None of the parasites in the Order *Diptera* are considered important parasites of laboratory rabbits, however they may be considered relevant in outdoor-raised rabbits (Pates and Gerrity, 1994). Frequently occurring in wild lagamorphs in the western hemisphere are Botflies

FIGURE 15.14 Rabbit bot, *Cuterebra*. (from *Farmers Bulletin* 1568, revised 1931. From Osborn, 1896. Used with permission of the University of North Texas Libraries, Digital Collection)

or Warble flies of the genus *Cuterebra*. Commonly occurring species of *Cuterebra* in wild rabbits include *Cuterebra buccata*, *C. cuniculi*, *C. leporivora*, *C. abdominalis*, *C. jellisoni*, *C. ruficrus*, and *C. lepusculi* (Schoeb et al., 2007). Female flies, which can be up to 20mm long (Soulsby, 1992), deposit eggs near the nesting areas of wild rabbits. Upon hatching, the larvae penetrate the skin of the host directly or enter the host directly via natural orifices or wounds within the skin. The method of host entry is species-dependent. The larvae (Figure 15.14), which can be up to 25mm long (Schoeb et al., 2007), complete a quiescent phase and begin to migrate towards the subcutis. The resulting lesions consist of 2–3cm subcutaneous masses with a painful fistula. Occasionally there is aberrant migration of the larvae such as to the eye (Pates and Gerrity, 1994). Once the larva is ready to pupate it will drop to the group leaving behind a substantial hole in the host skin that should resolve without complication. Infection with multiple *Cuterebra* larvae can be debilitating to the host rabbit which may result in death. Controlling the fly population near any outdoor animal housing can serve to prevent *Cuterebra* infestation. Larvae can be removed from the animal using topical administration of iodine followed by manual extraction of the larvae using forceps (author's experience).

HELMINTHS

Nematodes

Obeliscoides cuniculi

BACKGROUND

The species *Obeliscoides cuniculi* is considered to be two subspecies based on whether it occurs in hares; *O. cuniculi cuniculi* or in cottontail rabbits; *O. cuniculi multistriatus* (Measures and Anderson, 1983). Experimental infection can occur with either species in the domestic rabbit. *O. cuniculi* has a worldwide distribution in wild and domestic rabbits (Schoeb et al., 2007). In experimental settings, guinea pigs are susceptible to infection (Alicata, 1932). There is only one report of an infection in a laboratory rabbit (Jensen et al., 1980) so this nematode is not considered of major importance in laboratory animal settings.

ETIOLOGY/ETIOLOGIC AGENT

Obeliscoides cuniculi is a member of the family Trichostrongylidae. Adult worms are pink and lack a buccal capsule. Females are 546 μ m wide and 15–18 mm long. Males are 230 μ m wide and 10–15 mm long. Eggs measure 75–91 by 42–53 μ m and are thin-shelled and oval (Alcata, 1932).

EPIZOOTIOLOGY

Rabbits become infected by consuming third-stage larvae. Ingested larvae penetrate the gastric mucosa within one day and by 3 days have developed into fourth-stage larvae. A final molt then occurs resulting in adult larvae that emerge on the surface of the gastric mucosa with females capable of dispensing eggs 16–20 days post infection (Alcata, 1932). The prepatent period is 16–20 days. Larvae are capable of maintaining a state of arrested development within the gastric mucosa and may continue development upon loss of adult worms (Schoeb et al., 2007).

CLINICAL MANIFESTATIONS

Clinical disease is generally not associated with natural infections, however heavy parasitemia can result in weight loss, anemia, and diarrhea (Schwartz and Shook, 1928). Similar clinical signs were noted in experimentally infected animals using a large volume of larvae. Animals returned to normal within 1–2 weeks of infection (Pakes and Gerrity, 1994).

PATHOLOGY

Gross pathologic change occurs in the stomach, resulting in a mucosal thickening with a finely granular “cobblestone” appearance with mucous and occasional petechial hemorrhages. The gastric mucosa appears thickened histologically due to glandular hyperplasia,

presence of larval parasites, and an inflammatory infiltrate comprised primarily of lymphocytes and eosinophils (Pates and Gerrity, 1994).

PATHOGENESIS

Infiltration of larvae and adult worms within the gastric mucosa result in glandular hyperplasia and inflammation which may impede the ability of gastric function.

DIAGNOSIS

Observation of *O. cuniculi* eggs within fecal samples can provide a clinical diagnosis. Gross identification of the adult nematode from gastric mucous scrapings can be made at necropsy.

PREVENTION AND THERAPY

Information pertaining to efficacy of treating *O. cuniculi* is limited. A variety of anthelmintic regimens have been used with some success including thiabendazole at 110 mg/kg four times a day on day one followed by eight additional doses at 70 mg/kg (Watkins et al., 1984) and fenbendazole at 50 ppm offered in feed for 5 days (Worley, 1963). Prevention is aimed at minimizing exposure to fecal matter and larvae through effective husbandry.

Trichurids

Trichuris leporis and *Sylvilagus*

BACKGROUND These two whipworms are found in hares (*Lepus* spp.) and cotton tails (*Sylvilagus*), as well as wild rabbits in Europe and the United States (Clemons et al., 2000; Hofing and Kraus, 2004; Schoeb, 2007).

ETIOLOGY/ETIOLOGIC AGENT Adult worms (Figure 15.15) and ova are the same size in both *T. leporis* and *T. sylvilagus*. Adult males measure 19–21 mm long and adult females measure 17.4–20.9 mm long while ova measure 60–65 μ m $\times$ 29 μ m with bipolar plugs (Schoeb et al., 2007).

EPIZOOTIOLOGY Adult whipworms are found in the cecum and large intestines. The mucosa is pierced by the anterior end (Schoeb et al., 2007). Eggs are passed by the animal's feces and become infective approximately 3 weeks later (Schoeb et al., 2007). Transmission is fecal-oral and larvae enter through the small intestinal mucosa eventually making their way to the cecum and large intestines (Schoeb et al., 2007). Several surveys of wild rabbits in the United States have demonstrated prevalence rates of 4–29% for *T. leporis* and *sylvilagus* (Andres and Davidson, 1980; Clemons et al., 2000; Strohlein and Christensen, 1983; Wiggins et al., 1980).

CLINICAL MANIFESTATIONS Weight loss has been associated with high parasite loads of *Trichuris* in snowshoe hares (Keith et al., 1986). Higher worm loads were

FIGURE 15.15 *Trichuris leporis*. (from Farmer Bulletin 1568, revised 1931. Enlarged. A is female and B is male. Used with permission of the University of North Texas Libraries, Digital Collection).

also reported in juveniles compared to adult snowshoe hares in the same epidemiological study (Keith et al., 1986).

PATHOLOGY There are no reports of lesions associated with these two trichurids (Andrews and Davidson, 1980).

PATHOGENESIS This is not applicable.

DIAGNOSIS Whipworm eggs can be identified in fecal preparations and adults can be found in the intestines at necropsy.

PREVENTION AND THERAPY Treatment regimens for these parasites have not been fully described. Ivermectin was reported as ineffective against *T. leporis* in snowshoe hares in Canada (Sovell and Holmes, 1996). As with other fecal-oral pathogens, good hygiene and eliminating contact with wild lagomorphs are important to controlling these parasites.

Filarids

Dirofilaria scapiceps and *uniformis*

BACKGROUND All members of the Superfamily Filarioidea are transmitted by blood-sucking insects.

Infection can be common among outdoor-housed rabbits (Schoeb et al., 2007). Rabbits can also be an aberrant host for the dog heartworm, *Dirofilaria immitis* (Hofing and Kraus, 1994).

ETIOLOGY/ETIOLOGICAL AGENT Members of this superfamily tend to be rather long and thin white-to-cream-colored worms without marked cuticular ornamentation or lips and have almost no buccal capsule (Bowman, 2003).

EPIZOOTIOLOGY Several species of mosquitoes serve as the intermediate host for these parasites. Mosquitoes become infected with microfilariae as they ingest a blood meal from an infected host. Microfilariae develop into infective third-stage larvae in the mosquitoes and are transmitted to a new host as the mosquito feeds. Larvae migrate to the subcutis, usually in the trunk area, where they mature into fifth-stage larvae. The fifth-stage larvae migrate to their tissue of choice and develop into the adult stage and begin to produce microfilaria. The prepatent period is 137–234 days (Hofing and Kraus, 1994; Schoeb et al., 2007). Adult *Dirofilaria scapiceps* live in the tendon sheaths of the hock joint and less frequently the fascia around the stifle joint (Hofing and Kraus, 1994). Adult *Dirofilaria uniformis* are found in the connective tissue of the trunk.

CLINICAL MANIFESTATIONS Infection is usually subclinical, though it may result in chronic tenosynovitis (Schoeb et al., 2007).

PATHOLOGY Adult forms may be found at necropsy. *D. scapiceps*-infected animals may exhibit chronic proliferative tenosynovitis with fibrinous exudate, hyperplasia, and hypertrophy of the synovial membrane and infiltration of lymphocytes and plasma cells (Hofing and Kraus, 1994).

PATHOGENESIS Infestations with these parasites are typically subclinical. Inflammatory responses to *D. scapiceps* adults in the tendon sheaths have the ability to cause localized disease.

DIAGNOSIS Adults can be identified at necropsy. Circulating microfilaria can be found in the blood.

PREVENTION AND THERAPY Prevention is via indoor housing and/or eliminating exposure to mosquitoes. Treatment has not been reported.

Brugia lepori

BACKGROUND Information on *Brugia lepori* is limited. The original published report is from cottontail rabbits (*Sylvilagus aquaticus* and *floridanus*) in Louisiana

(Eberhard, 1984). Infection of cottontail rabbits in the northeastern United States has also been reported (Eberhard et al., 1991).

ETIOLOGY The etiology is a filarial nematode, *Brugia lepori*.

EPIZOOTIOLOGY The details of the life cycle of *B. lepori* have not been reported. It is thought, however, that like for other members of this superfamily, mosquitoes are an intermediate host (Hofing and Kraus, 1994). Adults are found in abdominal lymphatics and subcutaneous tissue (Hofing and Kraus, 1994).

CLINICAL MANIFESTATIONS No clinical manifestations have been reported.

PATHOLOGY Adult organisms can be found at necropsy. Microfilaria are found in circulating blood.

PATHOGENESIS None reported.

DIAGNOSIS Adult organisms can be found at necropsy. Microfilaria can be found in circulating blood.

PREVENTION AND THERAPY If mosquitoes do serve as an intermediate host, prevention of exposure to infected mosquitoes should offer reasonable prevention of infection. No therapy is reported.

Metastrongylids

Protostrongylus boughtoni

BACKGROUND *Protostrongylus boughtoni* (Goble and Dougherty, 1943) is a metastrongylid parasite of the respiratory tract that occurs primarily in wild rabbits and hares of the northern regions of North America (Hofing and Kraus, 1997).

ETIOLOGY/ETIOLOGIC AGENT Both male and female worms possess six small lips on the anterior end. Male worms are 13–26 mm by 160–250 µm with a copulatory bursa and spicules that measure 260–320 µm. Female worms are larger than males measuring 21–36 mm in length by 200–300 µm in diameter with the vulva located at the abrupt narrowing of the body, 200 µm from the distal end.

EPIZOOTIOLOGY Wild hares and rabbits become infected by consuming an intermediate gastropod host, such as the small land snail *Vallonia pulchella*, while feeding (Hofing and Kraus, 1997). Adult worms inhabit the bronchi where eggs hatch and develop into first-stage larvae. These larvae are coughed up, swallowed, and leave the body via feces.

CLINICAL MANIFESTATIONS Clinical disease has not been adequately described.

PATHOLOGY Pulmonary lesions appear grossly as small, firm, discrete, yellow to gray nodules. Histopathology can reveal peribronchitis and bronchitis which is often more severe in hares than in cottontail rabbits (Goble and Dougherty, 1943).

PATHOGENESIS Infiltration of adult worms within the bronchi can cause inflammation and the formation of parasitic nodules.

DIAGNOSIS *P. boughtoni* larvae can be identified in feces using Baermann floatation methods.

PREVENTION AND THERAPY There have been no reported cases of infection in domestic rabbits. Prevention relies on proper husbandry methods. Ivermectin was reported not to be as effective against nematodes in snowshoe hares compared to other domestic and laboratory animals (Sovell and Holmes, 1996).

Oxyurids

Passalurus ambiguus

BACKGROUND Oxyurids are commonly known as pinworms. *P. ambiguus* is also known as *Oxyuris ambigua* and is the most common pinworm in rabbits in the United States and is distributed in rabbits worldwide (Hofing and Kraus, 1994; Schoeb et al., 2007). Pinworms are uncommonly encountered in SPF rabbits today (Schoeb et al., 2007).

ETIOLOGY/ETIOLOGIC AGENT *P. ambiguus* ova have the typical pinworm appearance being elongated, measuring 93–105 µm long by 43 µm wide (Schoeb et al., 2007). They are flattened on one side (Schoeb et al., 2007). Adults (Figure 15.16) are generally 0.5–1 cm in length (Richardson, 2000; Schoeb et al., 2007).

EPIZOOTIOLOGY The pinworm life cycle is direct and transmission is fecal–oral. Adult worms reside in the cecum and large intestine. Migrating worms may be stuck around the anal area (Richardson, 2000). A viewpoint of some authors is that pinworms should now be thought as normal inhabitants of the rabbit intestines as they are typically non-pathogenic (Richardson, 2000).

CLINICAL MANIFESTATIONS Reports in the veterinary literature note that pinworms are generally non-pathogenic. Granulomatous appendicitis and lymphadenitis and poor reproduction (Düwel and Brech, 1981) have been described in rabbits infected with *P. ambiguus* (Schoeb et al., 2007). Heavy worm

FIGURE 15.16 *Passalurus ambiguus*. (from *Farmers Bulletin* 1568, revised 1931. Enlarged 8 times. A is female and B is male. Used with permission of the University of North Texas Libraries, Digital Collection)

burdens have been associated with perianal pruritis with self-inflicted trauma, and rectal prolapse (Hess, 2004).

PATHOLOGY Limited pathological changes, as previously described, have been noted in animals infested with the pinworms. *P. ambiguus* juveniles can be found in microscopic intestinal sections with normal staining (Schoeb et al., 2007).

PATHOGENESIS Due to the rarity of clinical manifestations, the pathogenesis of the organism and associated disease has not been well described.

DIAGNOSIS Ova, and sometimes adult worms, can be found in fecal samples. At necropsy, adult worms may be seen in the cecum and large intestines (Schoeb et al., 2007). A perianal cellophane tape test could be used to find adults stuck to the anal region (Stein and Walshaw, 1996). Molecular diagnostic approaches (PCR) have been developed (Feldman and Bowman, 2007). Afternoon and evening hours appear to be the best times for fecal collection for the identification of *P. ambiguus* (Rinaldi et al., 2007).

PREVENTION AND THERAPY Main treatments for eradicating pinworm infestations include fenbendazole and ivermectin. Fenbendazole is dosed at 10–20 mg/kg and repeated in 2 weeks (Richardson, 2000). For entire

colonies, fenbendazole at 50 ppm for 5 days in the feed has been reported as efficacious (Düwel and Brech, 1981). The ivermectin dose is the same as for other parasites at 0.4 mg/kg (Richardson, 2000). This ivermectin treatment regimen was described ineffective in ridding snowshoe hares of *P. ambiguus*, however, a recent report of a combined therapy of albendazole (20 mg/kg orally once a day for 14 days) and ivermectin was 100% effective at eradicating *P. ambiguus* in a small colony of New Zealand Red rabbits meant as breeding stock for a laboratory animal vendor (Pritt et al., 2009). Piperazine is reported as a treatment for both young and adult rabbits (Hess, 2004; Schoeb et al., 2007). The anal region should be cleaned at the time of treatment initiation (Hess, 2004).

Good hygiene and ensuring that incoming animals are free of the parasite are important control measures. Due to the shedding of adults and ova that are immediately infective, decontamination of the environment is encouraged when treating for this agent (Hess, 2004).

Dermatoxys veligera

Very little is reported on *Dermatoxys veligera*. It is known to occur in wild rabbits in the United States and infection of domestic rabbits has been reported. Adult parasites live free in the lumen of the cecum and do not attach to the mucosa. Pathology is not reported in conjunction with adult parasites. Fourth-stage larvae attach to the cecal mucosa by hooks and small ulcers may form at the attachment sites. Female parasites are 16–17 mm in length and 600 µm in diameter. Males are 8–11 mm in length and 435 µm in diameter. Eggs are 50 µm by 110 µm with one side slightly flattened (Hofing and Kraus, 1994; Schoeb et al., 2007).

Ascarids

VISCERAL LARVA MIGRANS/CEREBROSPINAL NEMATODIASIS

BACKGROUND Rabbits are not a definitive host but are an aberrant host for ascarid species infecting carnivores. Rabbits have been used to study host immune responses to *Toxocara canis* and the tissue migrating larval stages of the bovine ascarid *T. vitulorum* (Hofing and Kraus, 1994). *T. canis* is an important zoonotic disease of humans, however it is not transmitted by rabbits.

ETIOLOGY *Baylisascaris procyonis*, with the raccoon as its definitive host, is the main causative agent of visceral larval migrans in rabbits. Other sources report *Baylisascaris columnaris* (definitive host is the skunk) and *Toxocara canis* (definitive host is the dog) (Hofing and Kraus, 1994).

EPIZOOTIOLOGY Adult ascarids live in the small intestine of the definitive host and produce eggs which

are shed in the feces. Eggs become infective about 30 days after being passed. Eggs are very resistant to environmental extremes and can remain infective in soil for many years (Bowman, 2009). Rabbits become infected by ingesting infectious eggs. The eggs hatch in the intestine and the larvae migrate throughout the organs and tissues. Because the rabbit is an aberrant host, the migration is not completed and the larvae do not mature (Hofing and Kraus, 1994; Schoeb et al., 2007).

CLINICAL MANIFESTATIONS Clinical signs vary depending upon the location of the parasite migration. The most pronounced clinical signs occur with migration in the central nervous system and include torticollis, ataxia, ear droop, and circling (Hofing and Kraus, 1994).

PATHOLOGY The migrating stage may be seen grossly and, due to its size, one larva can do a significant amount of damage. Histologically, granulomas may be seen along the path the larva has migrated, particularly in the viscera (Hofing and Kraus, 1994; Schoeb et al., 2007). Central nervous system lesions may include necrosis, hemorrhage, and a mixed inflammatory response of lymphocytes and polymorphonuclear cells (Schoeb et al., 2007).

PATHOGENESIS The pathogenesis of the disease is primarily due to damage caused by migrating larva but also to inflammatory response of host.

DIAGNOSIS Visceral larval migrans is typically diagnosed at necropsy via identification of ascarid larvae in tissues.

PREVENTION AND THERAPY Prevention of exposure of definitive host (raccoon, skunk, dog) to caging, bedding, and feed is essential. Treatment with mebendazole (100 mg/kg) for 3 days is reported to be effective against migrating larvae (Cuellar et al., 1990).

Cestodes

Anoplocephalids

BACKGROUND

Anoplocephalids are characterized by lacking a rostellum or hooks (Hofing and Kraus, 1994). Tapeworm infestation in rabbits is considered rare (Richardson, 2000).

ETIOLOGY/ETIOLOGIC AGENT

Several species within the anoplocephalid group have been described as inhabiting rabbits. *Cittotaenia variabilis*, *Mosgovoyia pectinanta americana*, *Mosgovoyia perplexa*, *Monoecocestus americana*, and *Ctenotaenia*

ctenoides have been reported in domestic and wild rabbits in North America (Hofing and Kraus, 1994). Other texts outline the scolex sizes, adult worm length, and approximate number of proglottid for the above species (Hofing and Kraus, 1994; Schoeb, 2007).

EPIZOOTIOLOGY

These cestodes are all located in the small intestines. Oribatid mites are the usual intermediate hosts and rabbits are the definitive hosts, although the life cycles for all anoplocephalid species of rabbits have not been completely documented (Hofing and Kraus, 1994; Schoeb et al., 2007). Transmission is fecal-oral where the rabbit ingests a mite with cysticercoids (Hofing and Kraus, 1994).

CLINICAL MANIFESTATIONS

Enteritis along with emaciation, intestinal perforation, and obstruction has been associated with anoplocephalid infestation (Hofing and Kraus, 1994; Patton et al., 2008). Usually the infestation does not produce clinical signs of disease (Schoeb, 2007).

PATHOLOGY

Clinical signs are associated with higher worm loads. Gross pathological findings would be associated with physical factors involving the number of anoplocephalids present.

PATHOGENESIS

The effects of anoplocephalids are based on the physical presence of excess numbers of organisms.

DIAGNOSIS

Anoplocephalids can be diagnosed in rabbits based on egg identification in the feces and or the gross presence of proglottids.

PREVENTION AND THERAPY

Good pest control combined with keeping infected animals out of research colonies prevent anoplocephalid infestations. Due to the need for an intermediate host, it is unlikely that anoplocephalid infection could continue in rabbits housed in typical laboratory animal facilities (Hofing and Kraus, 1994).

Treatment can be achieved with praziquantel at 5 mg/kg which is repeated in 10 days (Hofing and Kraus, 1994; Richardson, 2000).

Railletina

Several species of *Railletina* occur in wild rabbits, however natural infection of domestic rabbits is not reported (Schoeb et al., 2007). Very little is reported on *Railletina* in general. The species found in wild rabbits

FIGURE 15.17 *T. pisiformis* (adult) and life cycle. (from Patton, N.M., K.W. Hagen, J.R. Gorham, and R.E. Flatt. 2008. *Domestic Rabbits: Diseases and Parasites*. PNW 310. Corvallis, OR: Oregon State University Extension Service. © 1986, 1998 Oregon State University. Used with permission)

include *Raillietina salmoni* (also known as *R. stilesiella*/*R. stilesiella*), *R. selfi*, *R. loeweni*, and *R. retractalis* and are thought to be similar to other members of their class, Cestoda. Members of this class lack an alimentary tract with food absorption and gaseous exchange occurring through the cuticle. The rabbit is the definitive host for members of the genus *Raillietina* (Hofing and Kraus, 1994). *Raillietina loeweni* are known to use ants as intermediate hosts and are transmitted to rabbits via ingestion of cysticeroid-infected ants (Bartel and Hansen, 1967). Most tapeworm infections are subclinical, however large numbers of organisms can result in enteritis, intestinal obstruction, and perforation of the gastrointestinal tract. Adult cestodes are found in the small intestine.

Taenia pisiformis

BACKGROUND

Taenia pisiformis is the most common taeniid tapeworm of dogs in the United States and is also found in foxes and less frequently in other carnivores. Rabbits serve as an intermediate host. *T. pisiformis* is not known to infect humans (Schoeb et al., 2007). Until the middle of the nineteenth century the larval stage and the adult stage were thought to be separate species (Bowman, 2009).

EPIZOOTIOLOGY

Definitive hosts (typically dogs) pass the egg-laden proglottid phase in their feces (Figure 15.17). Rabbits

are infected with the eggs via ingestion of materials contaminated with fecal material from infected animals. Once ingested, the egg hatches and the hexacanth embryo enters the wall of the intestine and migrates to its organ of choice via the portal veins (Bowman, 2009; Schoeb et al., 2007). *Taenia pisiformis* typically prefers the liver and other viscera. The hexacanth embryo grows, cavitates, and differentiates to form the second larval stage which consists of a fluid-filled bladder with a scolex called a cysticercus. This second larval stage is also often called bladderworm and forms 2–4 weeks following ingestion (Bowman, 2009; Schoeb et al., 2007). The cysticercus stage encysts on the liver capsule (Figure 15.18) or other abdominal serosal surfaces and is ingested by the definitive host when it consumes the intermediate host (Schoeb et al., 2007).

CLINICAL MANIFESTATIONS

Infestation is usually asymptomatic. Severe infections, more typical of experimental inoculations, can cause severe hepatitis with chronic wasting or death (Soulsby, 1982).

PATHOLOGY

Liver migration can result in focal granulomatous inflammation and fibrosis. Cysticercus forms can be seen on liver capsule and serosal surfaces of other viscera.

FIGURE 15.18 Liver with cysticerci (arrow). (from Patton, N.M., K.W. Hagen, J.R. Gorham, and R.E. Flatt. 2008. *Domestic Rabbits: Diseases and Parasites*. PNW 310. Corvallis, OR: Oregon State University Extension Service. © 1986, 1998 Oregon State University. Used with permission)

PATHOGENESIS

Typically asymptomatic; severe infections cause disease due to liver damage from migration and resulting inflammation from host response.

DIAGNOSIS

Typically diagnosed at necropsy as an incidental finding. Peri-mortem diagnosis is possible with imaging techniques such as radiography and ultrasound (Schoeb et al., 2007).

PREVENTION AND THERAPY

Prevention is via proper husbandry to prevent contamination of feed, caging, and environment with feces from infected animals. This includes proper washing of fresh foods. Insect control is important also, as some sources report mechanical transmission by blowflies (Lawson and Gemmell, 1990). Treatment with mebendazole is reported to kill both the mature and immature cysticerci (Heath et al., 1975). Other sources recommend praziquantel or the combination of febantel/pyrantel embonate/praziquantel as effective against cestode infections (Mencke, 2007).

Taenia serialis

BACKGROUND

Taenia serialis is less widely distributed and less common than *T. pisiformis* (Schoeb et al., 2007). Rabbits serve as an intermediate host. This agent causes rare cases of human coenurosis but it is not transmitted from rabbits.

EPIZOOTIOLOGY

Definitive hosts (typically dogs) pass the egg-laden proglottid phase in their feces. Rabbits are infected with the eggs via ingestion of materials contaminated with fecal material from infected animals. Once ingested, the egg hatches and the hexacanth embryo enters the wall of the intestine and migrates to its organ of choice via the portal veins (Bowman, 2009; Schoeb et al., 2007). *T. serialis* typically prefers the subcutaneous tissues or viscera. The hexacanth embryo grows, cavitates, and differentiates to form the second larval stage which consists of a fluid-filled bladder with multiple scolices called a coenurus. Each scolex in the coenurus is capable of developing into a mature tapeworm (Bowman, 2009). This second larval stage is also often called bladderworm and forms 2–4 weeks following ingestion (Bowman, 2009; Schoeb et al., 2007). The coenurus stage encysts in the subcutaneous tissue primarily but can also occur in the musculature, abdomen, or brain (Hofing and Kraus, 1994). The coenurus stage is ingested by the definitive host when it consumes the intermediate host (Schoeb et al., 2007).

CLINICAL MANIFESTATIONS

Subcutaneous coenuri usually are asymptomatic. Coenuri in the musculature may affect mobility (Schoeb et al., 2007). Coenuri in atypical locations, such as the brain, may cause neurologic disturbances (Bowman, 2009).

PATHOLOGY

Liver migration of the worm can result in focal granulomatous inflammation and fibrosis. Coenurus forms can be seen in the subcutaneous tissues.

PATHOGENESIS

While infection is typically asymptomatic occasionally severe cases are described as noted above.

DIAGNOSIS

Infection is diagnosed at necropsy usually as an incidental finding. Peri-mortem diagnosis is possible with imaging techniques such as radiography and ultrasound (Schoeb et al., 2007).

PREVENTION AND THERAPY

Prevention is via proper husbandry to prevent contamination of feed, caging, and environment with feces from infected animals. This includes proper washing of fresh foods. Insect control is important also as some sources report mechanical transmission by blowflies (Lawson and Gemmell, 1990). Some sources recommend praziquantel or the combination of febantel/pyrantel embonate/praziquantel as effective against cestode infections (Mencke, 2007).

Trematodes

Hasstilesia tricolor

BACKGROUND

Hasstilesia tricolor is an intestinal fluke which infects wild rabbits in the United States (Hofing and Kraus, 1994).

ETIOLOGY/ETIOLOGIC AGENT

This fluke is small, measuring 350–640µm long and 480–1200µm wide with ventral and oral suckers and a spinous cuticle (Schoeb et al., 2007). Its name stems from three color shades seen on living organisms (Schoeb et al., 2007). *H. tricolor* ova look like typical operculated trematod ova and dimensions of 20–22µm in length by 13–15µm in width (Hofing and Kraus, 1994; Schoeb et al., 2007).

EPIZOOTIOLOGY

Wild rabbits are the definitive host while land snails are the intermediate hosts (Schoeb et al., 2007). Snail or metacercariae ingestion by rabbits results in infestation (Hofing and Kraus, 1994; Schoeb et al., 2007). Prevalence rates in wild rabbit populations range from 1 to 41% (Jacobson et al., 1974).

CLINICAL MANIFESTATIONS

Infestation with *H. tricolor* can result in diarrhea, enteritis, gross hemorrhage in the feces, emaciation, and death (Jacobson et al., 1974). A lack of other descriptions of clinical findings leads many to believe that infections are largely subclinical (Schoeb et al., 2007).

PATHOLOGY AND PATHOGENESIS

When clinical signs are present, infecting flukes destroy intestinal villi and also exhibit fluke-to-fluke attachment through ventral suckers (Jacobson et al., 1974). Physical pressure may be exerted on the intestinal mucosa with heavy infestations (Jacobson et al., 1974).

DIAGNOSIS

Eggs can be observed in fecal samples while adults may be seen in the intestines.

PREVENTION AND THERAPY

Treatment regimens have not been documented. To prevent infection, rabbits should not have access to snails or metacercariae (Schoeb et al., 2007).

Fasciola hepatica

BACKGROUND

Fasciola hepatica is a parasite of herbivorous mammals and humans. Distribution is worldwide and is dependent upon lymnaeid snails as an intermediate

host. These snails require neutral soil which remains moist throughout the year and tend to do better in areas with moderate winters which allow the eggs and juvenile stages to survive (Bowman, 2009). Due to the habitat requirements of the intermediate hosts, distribution may be patchy. The rabbit has been used as a research model for studying *Fasciola hepatica* infection and the host response to infection (Hofing and Kraus, 1994).

ETIOLOGY/ETIOLOGIC AGENT

Fasciola hepatica is a member of the Order Digenea. Members of this order undergo indirect development with sexual and asexual stages parasitizing alternate hosts. (Bowman, 2009).

EPIZOOTIOLOGY

Infection is via ingestion of the metacercaria cyst stage found on the surface of plant material. Following ingestion the cyst is digested in the small intestine to release a young fluke called a marita. The marita penetrates through the wall of the intestine and travels through the peritoneal space to penetrate the liver. The marita travels throughout the liver (typically for several weeks) before it enters the bile ducts and matures into an adult fluke. Egg production begins about a month and a half after infection. Eggs (fertilized ovum and a cluster of vitelline cells enclosed in an operculated capsule) are carried with the bile into the intestinal lumen and then exit the body in the feces. If eggs fall into water it will develop a ciliated larva inside it called a miracidium. The miracidium has a cone-shaped papilla at its anterior end for boring into the intermediate host, the snail, and is covered in cilia for mobility. The miracidium also has a pair of eye spots, a brain, a rudimentary excretory system, and a cluster of germinal cells (Bowman, 2009). After 2–4 weeks at summer temperatures the miracidium is ready to hatch and leaves the egg capsule to swim in search of a lymnaeid snail, its intermediate host. The miracidium needs to find a host within 24 hours of hatching, otherwise it will exhaust its energy supply and die (Bowman, 2009). Once a miracidium finds a suitable host, it bores into the snail body and migrates to the gonad or digestive gland (often called the liver) and forms a sporocyst (Bowman, 2009). The germinal cells grow and divide into germinal balls which develop into redia. The redia grow until they rupture the sporocyst wall and enter the tissues of the snail where they use their mouth and digestive organs to eat their way through the tissues. The redia contain germinal balls also which grow and divide into a third type of larva, the cercaria (Bowman, 2009). The cercaria, a tadpole-like larva with a disc-shaped body and a long tail, develops in 1–2 months at summer temperatures and leaves the redia through a birth pore. The cercaria travels through the tissue of the snail into the surrounding water. The cercaria contains some

adult organs along with secretory cells near the pharynx that are used to secrete a cyst wall around the final larval stage (Bowman, 2009). After leaving the snail, the cercaria swim through the water until reaching plant material. The cercaria travels up the plant material to a level above the surface of the water where it encysts, loses its tail, and becomes a metacercaria and waits to be ingested.

CLINICAL MANIFESTATIONS

Some sources report asymptomatic infection of rabbits with *Fasciola hepatica* (Schoeb et al., 2007). Other sources describe acute and chronic forms most typically seen in large ruminant animals but with the potential to occur in any host (Bowman, 2009). The acute clinical syndrome is attributed to the invasion of the liver by the metacercariae and their subsequent migration through the liver. Damage caused by the migration results in inflammation with clinical signs of abdominal pain and reluctance to move. Other animals with fluke migration and concurrent bacterial infection with clostridial organisms often present as acute death with no outward clinical signs (Bowman, 2009). The chronic clinical syndrome is attributed to the presence of adult flukes in the bile ducts. Clinical signs include progressive weight loss, weakness, anemia, and hypoproteinemia with development of edema (Bowman, 2009).

PATHOLOGY

Gross necropsy findings in the acute clinical syndrome may include blood-stained exudate in the abdominal cavity and an enlarged, friable liver covered with fibrin tags (Bowman, 2009). Microscopic findings include fibrous tracts in the liver due to parasite migration and granulomatous reactions surrounding eggs in the liver parenchyma (Hofing and Kraus, 1994). Gross necropsy findings in the chronic clinical syndrome may include distended, thickened bile ducts with adult organisms present (Bowman, 2009). Microscopic findings include ulcers in the gallbladder, chronic cholangitis, and hyperplasia of the bile ducts (Hofing and Kraus, 1994). Some sources attribute the bile duct hyperplasia to the excretion by *F. hepatica* of large amounts of the amino acid proline (Isseroff et al., 1977).

PATHOGENESIS

Clinical signs are due to the presence of the organism and body response due to fluke migration, foreign body presence, and functional obstruction of the biliary tract.

DIAGNOSIS

Ante-mortem diagnosis is typically by demonstration of eggs in the feces. Post-mortem diagnosis is by observation of flukes in the liver and/or bile ducts.

PREVENTION AND THERAPY

Prevention of infection can be achieved by preventing ingestion of infective metacercariae via careful selection of food sources for laboratory animals, including vegetation used for enrichment. Albendazole and clorsulon can be administered for removal of liver flukes (Bowman, 2009).

INTRODUCTION

Preliminary Considerations

Several earlier reviews have summarized the literature dealing with spontaneous neoplasia in the domestic rabbit, *Oryctolagus cuniculus* (Blount, 1957; Cohrs et al., 1958; Courteau, 1935; Dobberstein and Tamaschke, 1958; Dumas, 1953; Fardeau, 1931; Lesbouyries, 1963; Lombard, 1962b; Polson, 1927; Seifried, 1937; Stedham, 1976). This chapter presents new data that have accumulated on the subject from case reports, descriptions of biological aspects of a variety of naturally occurring tumors, and reports of experimentally induced tumor models. This chapter gathers the data and presents an overview of the neoplastic process in the various rabbit species. It should be pointed out that where it appears that information is lacking on particular organs or systems (e.g., in Table 16.3) that is only because it was not encountered in our review.

Sufficient information is available to enable the description of an oncological profile as a function of age and sex for *Oryctolagus*. Although much of the early data originated from rabbit colonies associated with major research institutions, the growing popularity of domestic rabbits as pets allows an increased ability to accumulate data on the spontaneous incidence of tumors in rabbits that are allowed to live a natural life span. Whereas, naturally occurring neoplasms in the rabbit were previously thought to be sporadic, there is evidence for a regular pattern in the incidence of the various tumor types known to be naturally associated with *Oryctolagus*. It should be noted that many pet animals are neutered and this condition may skew the information on the incidence of urogenitary tumors, especially those tumors that are known to be hormone-responsive, such as uterine and mammary adenocarcinomas. More information is available with regard to the neoplastic process in *Oryctolagus* than is the case with species of *Lepus* (hares) or *Sylvilagus* (cottontail rabbits), but this perhaps is fortunate since *Oryctolagus* is the major research, domesticated, food, and companion animal species of the lagomorphs.

Influence of Genetic Predisposition

The influence of genetic background on cancer incidence has been well established in many species. This is clearly evidenced when linebreeding and inbreeding are practiced for the purpose of promoting the occurrence of tumors. This has been the pattern in domestic poultry (Hutt, 1958) and in the mouse, not only with reference to spontaneous tumors but also with neoplasia induced by oncogenic viruses (Gross, 1970), ionizing radiation (Upton and Futh, 1958), and more recently,

in genetically engineered mice. Several lines of evidence lead to the conclusion that this is also the case in domestic rabbits.

In the large rabbit colony maintained by Greene between 1933 and 1955 for the purpose of studying the influence of genetics on a number of disease processes, particularly cancer, records were kept on many stocks (14 "pure" breeds), stock crosses, and familial lines. Conclusive evidence was drawn on the inheritance of susceptibility to adenocarcinoma of the uterus (Greene, 1959); the familial distribution of mammary carcinoma of two distinct (papillary versus adenoid) types (Greene, 1939a, 1939b, 1939c); and on the inheritance of embryonal nephroma (Greene, 1943) in *Oryctolagus*. Similarly, in the Phipps colony maintained for some 30 years by Lurie in which inbred lines were established for studying the inheritance of resistance to tuberculosis (Lurie, 1964) the occurrence of adenocarcinoma of the uterus, as a function of age and familial relationship, was studied as well, with observations similar to those reported by Greene (Adams, 1962; Ingalls, 1964).

The Brown-Pearce carcinoma is also heritably influenced both in terms of transplantability and with regard to tumor antigens that are recognized by host rabbits. As examples, Casey (1939) found that Blue Cross and Lilac Cross breeds of *Oryctolagus* possess natural resistance to growth of Brown-Pearce carcinoma, whereas Chocolate Dutch rabbits were more susceptible and remain the favored breed for transplantation of this tumor. Kidd et al. demonstrated that the carcinoma contained both normal tissue antigens and tumor-specific antigens (Friedewald and Kidd, 1945; Kalfayan and Kidd, 1953; Kidd, 1946a) and showed further that certain host breeds recognized only the tumor antigen(s) as foreign (e.g., Blue Cross and Chocolate Dutch) whereas others recognized, in terms of antibodies produced in response, both types or neither.

From the rabbit colony maintained for the study of genetics at the Jackson Laboratory, a series of reports has indicated that susceptibility to certain malignancies of the lymphoreticular system are inherited (within strains) according to a pattern consistent with that of an autosomal recessive gene (or, alternatively that of a vertically transmitted C-type RNA virus). This pattern was shown to be true for lymphoma in the WH strains (Fox et al., 1970) and for a disease with features of autoimmune hemolytic anemia and thymoma in the X strain (Fox et al., 1971b) similar to that described in the New Zealand Black mouse.

Incidence of Neoplastic Disease

It is difficult to determine the actual incidence of spontaneous neoplasms in the domestic rabbit, *Oryctolagus cuniculus*, as well as wild rabbits of the

Genus *Sylvilagus* and *Lepus*. The normal lifespan of the domestic rabbit *Oryctolagus* is 7–8 years, but they are used at younger ages in most research studies and breeding colonies and are seldom maintained through their natural lifespan. Rabbits are similar to most species in that neoplasia is infrequent in juveniles and young adults. Fragmented data reported from various research laboratories from 1950–1970 reported an overall tumor incidence of 0.5–2.7% in rabbits that were primarily 2 years of age or younger (Weisbroth, 1994). Some authors have suggested that most of the rabbits in these necropsy series were too young to be in an cancer-prone age group, which tended to give an artificially low and misleading picture of the true incidence of neoplasms in this species (Dobberstein and Tamaschke, 1958; Hoffman, 1954; Loliger, 1968). Greene (1959) reported that 16.7% of 849 female rabbits (dying of various causes) were found to have uterine adenocarcinoma. Importantly, the rabbits in the colony were permitted to live until death from natural causes, and the average age was substantially greater (>4 years) than those in the surveys mentioned previously. The importance of the age factor in these data is underscored by the observation that the tumor incidence was 4.2% in female rabbits 2–3 years of age and 79.1% in rabbits aged 5–6 years. Others, notably Ingalls (Ingalls, 1964), have observed the age-associated increase in frequency of uterine adenocarcinoma.

The factors of age and sex are further analyzed in Table 16.1 using data from the tumor series collected in Weisbroth's laboratory over a 5-year period, drawn from a necropsy series of approximately 600 rabbit accessions from a colony of laboratory rabbits. Table 16.2 summarizes the frequency of tumor types, ranked in terms of decreasing frequency, as a function of age and sex. A dramatic increase (seven times) in the incidence of neoplastic disease occurs after the second year of life. The incidence was approximately the same (about 8%) for both males and females over 2 years of age, but the incidence was determined by different types of tumors in the two sexes (see Table 16.2). In the younger age groups, however, the tumor incidence was approximately six times greater in females than males (1.00% compared to 0.16%) and was almost entirely due to adenocarcinoma of the uterus. In fact, if the latter entity were eliminated from the series for females less than 2 years of age, the tumor incidence would be similar to that for young males.

Much of the data presented in the earlier edition of this text originated from colonies of laboratory rabbits kept for use in biomedical research. The tumors with the greatest incidences noted in these animals were uterine adenocarcinoma, lymphoma, embryonal nephroma, and bile duct adenoma. Table 16.3 summarizes reports of 855 naturally occurring tumors which

includes these earlier reports as well as a large number of more recently reported cases of neoplasms in both laboratory and pet rabbits. Adenocarcinoma of the uterus continues to be the most frequent and important spontaneous neoplasm of *Oryctolagus*, both in the laboratory and in pet animals. It has been the subject of intensive investigation and is well understood biologically. The three next most common tumors occurring in laboratory rabbits in those earlier reports were lymphoma, embryonal nephroma, and bile duct adenoma. This incidence has now changed due to the increased number of reports submitted from pet

rabbits seen in veterinary practices. Lymphoma/lymphoid leukemia continues to be the second most commonly reported tumor in rabbits, with the third and fourth most common tumors now being mammary gland tumors (papilloma and adenocarcinoma) and skin tumors (trichoblastomas and collagenous hamartomas). Uterine leiomyosarcoma, embryonal nephroma, and pituitary adenoma were the next most commonly reported tumors, in rank of decreasing frequency. The changes in tumor incidence from the previous text may be attributed to the differences between laboratory and pet rabbits in average age of tumor occurrence, exposure to pathogens (in the case of Shope papilloma virus-related skin tumors), and the relatively larger number of necropsies performed on laboratory rabbits without antemortem clinical signs, which may result in a higher number of tumors reported as incidental findings.

Tumor Models

In addition to reviewing the naturally occurring neoplasms, this chapter summarizes a number of transplantable and experimentally induced tumor models that have been developed in the laboratory rabbit since the previous edition. Surveying the literature in the last 10 years, VX2 carcinoma has become an extremely popular transplantable tumor model (more than 350 publications in the last 10 years), used for studies on interventional radiology, targeted therapy, as well as molecular biology of cancer. However, Brown-Pearce carcinoma and Greene melanoma, which were once popular experimental tumor models, were sparsely used in the last 10 years (<10 Pubmed citations). On the other hand, use of transplantable human melanoma cell lines in the rabbit eye for studies on primary

and metastatic tumors seems to be on the rise (da Silva Correa et al., 2009; Di Cesare et al., 2009; Maloney et al., 2009; Marshall et al., 2007). The animals used were either immunocompetent (studies with tumors in the eye only) or animals with an induced specific state of immunosuppression (e.g., for metastases studies). This could be due to the fact that use of human cell lines has more translational potential.

Another active area of research has been the development of animal models of viral oncogenesis. Naturally occurring pox, papova, and papilloma virus infections in rabbits have been used to answer basic biological questions about viral oncogenesis, and the rabbit has been used as a model for the study of the human papilloma virus (HPV) (Brandsma, 2005; Breitburd et al., 1997; Govan et al., 2008; Wilgenburg et al., 2005). Experimental inoculation of various breeds of domestic rabbits with primate herpesviruses induced generalized lymphoproliferative diseases and lymphoma. These models are used to investigate the pathogenesis of Epstein-Barr virus (EBV) in man as well as for the development of antiviral drugs and vaccines against EBV (Hayashi and Akagi, 2000; Medveczky et al., 1989; Timanovskaia et al., 1988; Wutzler et al., 1995; Yakovleva et al., 1987).

Induction of skin tumors in rabbit through chemical carcinogenesis has allowed investigation into the role of the *ras* family of genes in the multistep process of cancer development. These models allow easy monitoring of tumor development and accessibility to the tumor site (Corominas et al., 1991; Leon et al., 1988).

Finally, transgenic rabbits have been created to study the interaction of the genome with oncogenes and viral DNA inserts (Knight et al., 1988; Sethupathi et al., 1994).

NEOPLASMS OF *ORYCTOLAGUS CUNICULUS*

Table 16.3 summarizes the reported naturally occurring neoplasms in *Oryctolagus*. This section includes descriptions and illustration of the gross and microscopic morphology of the tumors, an assessment of biological behavior, and an estimate of the value they might have as model systems for cancer research.

Tumors of the Female Reproductive Tract

Tumors of the Uterus

UTERINE ADENOCARCINOMA

Adenocarcinoma of the uterus (ACU) continues to be recognized as the most commonly encountered neoplasm of the *Oryctolagus* rabbit. It has received the greatest attention in the literature and has been

the subject of several well-organized and intensively investigated longitudinal studies of individual rabbits so designed as to follow the progression of individual lesion development (Adams, 1962; Baba and von Haam, 1967b; Greene, 1959; Ingalls, 1964). The tumor has been the subject of review articles over the years that deal with both laboratory (Elsinghorst et al., 1984; Greene, 1959, 1965; Weisbroth, 1974, 1994) and pet rabbits (Asakawa et al., 2008; Cutler, 1998; Heatley and Smith, 2004; Saito et al., 2002).

Most investigators have emphasized that metastatic ACU is the final stage of an evolutionary process in tumor development and that the identifying biological and morphological attributes develop slowly over a period of time. Two main lines of evidence lead to this conclusion. The first is that female breeder rabbits with ACU invariably have a preceding case history that includes reproductive disturbance prior to detection of the tumor (Greene, 1959, 1965; Greene and Saxton, 1938). Fertility is diminished, litter size is reduced, there are more stillborn births and desertion by the mother is more common. Dystocia, litter retention in utero, abdominal pregnancy, and fetal resorption are also more likely. The period of altered reproductive performance precedes clinical detection (palpation) by some 6–10 months. Early tumors may be palpated as persistent uterine nodules about the size of a 10-day fetus. They are usually multiple and present in both uterine fundi. In 25% of Greene's cases, cystic changes were also detectable in the mammary glands (Greene, 1959; Greene and Newton, 1948; Greene and Saxton, 1938). The growth rate varies, but the tumor usually progresses from approximately 1 cm initially to 5–6 cm or larger in 6 months. In some cases, the tumors do not enlarge prior to metastasis. In Greene's work, the duration in time between clinical detection and death from metastasis averaged about 12–24 months (Greene and Newton, 1948). Of the rabbit females studied by Ingalls et al. (1964), although 11 of the 12 developed ACU, metastasis did not occur with eight of the 11 during the 3-year period between detection and death (from other causes). This evidence, taken with the recognized age-related factors in tumor incidence, suggests that ACU develops slowly in most cases. Incidence of the tumor does not seem to bear any relationship to degree of parity. Adams (1962) reported no differences in the incidence of the tumor in breeder rabbits as opposed to aged virgin females. Weisbroth's cases all occurred in nulliparous female rabbits (1994).

The other line of evidence is more direct and has been acquired by the technique of periodic laparotomy and uterine biopsy (pioneered by Greene) over the lifespan of individual rabbits (Adams, 1962; Baba and von Haam, 1967a; Greene, 1959; Ingalls, 1964). This work has not only supported the clinical observations

outlined above, but has permitted sequential developmental study of ACU. The normal endometrium of the rabbit should be reviewed for comparison (Baba, 1970; Baba and von Haam, 1967b). Against this normal background, a number of endometrial abnormalities have been characterized, including endometriosis, papillary, cystic and adenomatous hyperplasia, endometritis, pyometra, and senile atrophy (Baba and von Haam, 1967b; Meissner, 1957; Merrian, 1960). Each of these lesions, of course, is characterized by a typical histological appearance. There is general agreement that ACU develops from the glandular epithelium and preserves an identifiable adenomatous appearance of irregular glandular elements embedded in a richly vascular myxoid stroma. The tumors are usually initially situated in the mucosal folds adjacent to the mesometrial insertion and they arise most frequently as multicentric foci irregularly spaced in the fundus of both uteri.

One key question is whether any of the aforementioned endometrial abnormalities are precancerous lesions. There is no uniformity of opinion on this. In studies by Greene (Greene, 1939a, 1942a, 1959, 1965; Greene and Newton, 1948; Greene and Saxton, 1938), based on 140 cases of ACU in which the onset of cancer could be monitored by changes detected by sequential biopsy, every case was preceded by cystic endometrial hyperplasia. In another technically similar study (Baba and von Haam, 1967b), antecedent endometrial lesions (dysplasia and carcinoma in situ) were also described, but the findings could not support cystic hyperplasia as a precancerous lesion in spontaneous ACU. In the case of the Phipps rabbit colony (similarly studied by sequential biopsy) preneoplastic changes were described as including hyperplasia and cystic degeneration, which progressed to focal anaplasia and then ACU (Adams, 1962; Ingalls, 1964).

Greene concluded that mammary carcinoma and ACU were both reflective of pre-existing endocrinologic disturbances in the rabbit (Greene, 1965). The evidence included an incidence of ACU of 48% and 34% in genetic transmitters of pituitary dwarfism and cretinism, respectively, compared to an incidence of 14% in the remainder of his sample group. ACU was not found in the Belgian or Rex breeds, but occurred in other breeds in the following (decreasing) order: Tan, French Silver, Havana, Dutch, Marten, English, Chinchilla, Beveran, Sable, Himalayan, and Polish. Evidence of endocrine disturbance included small adenoma-like thyroids, pronounced accumulations of lipoid substance in the zona fasciculate adrenal, hyperplasia of the pars intermedia of the pituitary in ACU-bearing rabbits, and the statistically significant association of mammary carcinoma in greatest frequency with ACU (when multiple primary tumors were present). Finally, we may cite the observation that breast changes other

than neoplasia (e.g., epithelial hyperplasia, adenosis, and cyst formation) almost invariably accompany ACU (Greene and Strauss, 1949).

These observations have prompted experimentation relating to the carcinogenicity of estrogen in the rabbit, and the issue has been reviewed along with other carcinogens in the rabbit uterus (Baba and von Haam, 1967b). There is little experimental evidence to support the role of estrogen as a factor in spontaneous ACU in the rabbit. Moreover, the model of estrogen-induced glandular hyperplasia that develops in the uterus is known to not involve a precancerous lesion (Baba et al., 1970; Baba and von Haam, 1967b) and to show histochemical changes not characteristic of adenocarcinoma (Baba and von Haam, 1967). The evidence is conflicting, however, because others have reported induction of uterine carcinoma in the rabbit with estrogenic hormones (Meissner, 1957). The data are extremely difficult to interpret because of the naturally occurring high incidence of ACU in untreated rabbits. Estrogen enhances the carcinogenic effect of certain chemicals (Baba and von Haam, 1967b) but in those cases (as in carcinogen alone) the sequence of squamous metaplasia leading to squamous carcinoma is morphologically dissimilar to naturally occurring ACU. Moreover, inasmuch as ACU appears correlated with senescence of the endometrium (Baba and von Haam, 1972) treatment with estrogen appeared to actually reduce the incidence of ACU. More recently, it has been shown that while uterine tissue of most cases of cystic endometrial hyperplasia were ER- α (estrogen receptor- α) and progesterone receptor (PR)-positive, suggestive of stimulation by estrogen, ER- α , and PR positivity correlated with tubular/solid ACUs, but not with papillary ACU (Asakawa et al., 2008). The latter group could find no direct correlation between cystic endometrial hyperplasia and progression to ACU in their series of 88 rabbits studied by biopsy or necropsy. While decidosarcoma is a rarely occurring spontaneous uterine tumor in the rabbit (Cooper et al., 2006), Zook and his coworkers have developed an interesting and reproducible model for induction of decidosarcoma in the rabbit by continuous instillation of contraceptive steroids (Janne et al., 2001; Zook et al., 1987, 2001). Treatment with exogenous estrogen in utero first induces decidualization of uterine epithelium, which then progresses to malignant decidosarcoma. The process was enhanced by cotreatment with progesterone and was reversible by withdrawal of the hormones. The spontaneous tumor tissues of Cooper et al. (2006) were positive for estrogen and progesterone receptors.

The course of ACU is relatively slow, but inexorable. Histologically, the tumor progresses by increasing degrees of dedifferentiation and anaplasia with increase of the vascular, myxoid stroma often at the expense of

FIGURES 16.1 Uterine adenocarcinoma. Note multiple neoplastic foci in uterine horns.

glandular elements. Carcinomatous endometrium loses such cellular elements as cilia and secretory vesicles, and histochemically demonstrates absence of alkaline and acid phosphatases that normally occur in both normal and hyperplastic uterus. Areas of necrosis are common in mature tumors and correlate with capacity to metastasize (Greene and Newton, 1948). The tumor is illustrated in Figures 16.1–16.3. Excellent photographs may be studied in the papers by Greene (Greene and Newton, 1948; Greene and Strauss, 1949). Further histologic classification of ACU into carcinomas with either papillary or tubular/solid cytoarchitecture are illustrated in the paper by Asakawa et al. (2008).

Notwithstanding heredity as a factor, the incidence of ACU has been noted to exceed 50% in certain colonies of Dutch and New Zealand White random bred rabbits kept past the age of 3–4 years. This is a useful feature for investigators seeking model systems for ACU because it means that naturally occurring material to work with experimentally can be obtained with certainty and almost at a predictable rate (Baba and von Haam, 1972). Tumor cell lines for serial rabbit passage and for autologous transplantation have been established (Bieseke, 1945; Greene, 1939a, 1940, 1942b; Ingalls, 1972; Lombard, 1962b). The ability to metastasize appears to be a requisite stage of development before successful passage to homologous or heterologous hosts (Greene, 1942b, 1959). Greene pioneered the technique of using the anterior chamber of the eye for tumor growth (e.g., the Brown-Pearce carcinoma, Greene melanoma, etc.) with the use of the ACU tumor (Greene, 1958; Greene and Saxton, 1938).

At least two other rarely occurring tumors have been described as naturally occurring in the decidualized endometrium of the rabbit. The first of these is the mixed Müllerian tumor (syn.: carcinosarcoma or mixed mesodermal tumor) encountered by Goto et al. (2006)

FIGURES 16.2 Uterine adenocarcinoma. Note metastatic foci in the lung.

as a well-demarcated mass in one of the uterine horns. The contralateral horn was normal. It is distinguished from deciduosarcoma by also having well-differentiated carcinomatous elements of glandular epithelium. The second is the choriocarcinoma described and illustrated by Kaufmann-Bart and Fischer (2008) in a presumptively virgin 3-year-old pet rabbit (Kaufmann-Bart and Fischer, 2008). Choriocarcinomas are highly malignant neoplasms arising from trophoblastic cells of the uterus, ovary, or testis, but may also arise from sequestered loci of totipotent cells of the mediastinum or abdomen. This tumor occurred in the uterus and was

FIGURE 16.3 Uterine adenocarcinoma. Photomicrographs illustrating a premetastatic tumor, with well-differentiated acinar components (A); and a poorly differentiated tumor with loss of tubular differentiation and increased stromal elements associated with increased metastatic potential (B).

metastatic to the lungs and mediastinum, but its origin was not definitively determined. Choriocarcinomas have been induced experimentally in pregnant rabbits (Kushima et al., 1967).

LEIOMYOMA AND LEIOMYOSARCOMA

Both leiomyomas and leiomyosarcomas have been reported from rabbits as sporadic and usually incidental findings at necropsy. Although the benign form is most common, there have been reports of metastasizing leiomyosarcomas (Polson, 1927). These smooth muscle tumors are most frequently associated with the digestive and female reproductive tracts (see Table 16.3). The histology is typical for the same tumor in other species, i.e., whorls and bundles of fusiform cells arranged in a crisscrossing pattern. Malignant forms usually appear less regular, with more abundant nuclei and more mitotic figures. They are generally reported from older rabbits. The collision in the same uterine horn between a malignant ACU that invaded a benign leiomyoma was reported as occurring in a 7-year-old pet rabbit (Kurotaki et al., 2007).

SQUAMOUS CELL CARCINOMA

Squamous cell carcinoma of the vaginal squamocolumnar junction is a comparatively rare tumor. It has been described only by Greene (Greene, 1947) who reported three cases from a necropsy series of 1100 females over the age of 2 years. It is an important tumor, however, because in the rabbit the columnar epithelium of the uterus is continued out over the cervix into the vagina. The transition to squamous epithelium occurs at the level of the urethral meatus. This location would, in the rabbit, appear to be the homolog of the external cervical os in the human female, as that is where the epithelial transition occurs in humans. The difference between

the two species in the location of the transitional zone emphasizes the importance of the junction as a predisposing factor in carcinogenesis. Moreover, perhaps for this reason, cervical cancer has neither been observed nor reported in the *Oryctolagus* rabbit. Greene's rabbits were not related genetically, and all were over 4 years of age. Interestingly, all three had fundic ACU and two also had mammary neoplasia. In all cases the fundic tumor was in a non-metastatic stage of development, but the vaginal squamous carcinomas had metastasized via lymph nodes and/or peritoneal implants to other organs. Two of the tumors were used for transplantation studies and at least 14 anterior chamber-passaged generations were obtained from them.

Tumors of the Mammary Gland

MAMMARY ADENOCARCINOMA

Mammary adenocarcinoma (MAC) has been reported with some frequency in laboratory rabbits (see Table 16.3). The tumor appears to most commonly arise in multiparous females in the third and fourth years of life but occurs often in nulliparous does as well. The clinical appearance of swollen, lumpy, nodular mammae, perhaps with palpable grapeshot structures, often with discoloration of the glands and/or teats and with discharges that may be obvious or expressed requires differential diagnosis because of a number of conditions with similar presentation (Blevins et al., 2009; Harcourt-Brown, 1998). These conditions include pseudopregnancy, prolactin-driven cystic hyperplasia, bacterial mastitis, cyclosporin A-induced hyperplasia (Petraitiene et al., 2001), testicular interstitial cell tumor-induced gynecomastia (Maratea et al., 2007) and, of course, MAC. Greene (1939b, 1939c, 1939d, 1940) described 23 cases of MAC that occurred exclusively in two families of the Belgian and English breeds

from his colony. Of them, 19 were associated with antecedent abnormalities of mammary tissue, including cystic hyperplasia, while four appeared to arise *de novo*, without preceding lesions. Greene further studied the progressive changes leading to invasive MAC over the lifespan of individual rabbits (Greene, 1939c, 1939d, 1940). In one family of the Belgian breed, 19 rabbits were observed to have mammary tissues that progressed from cystic hyperplasia, benign neoplasia (adenosis), to invasive MAC as succeeding events. Considerable individual variation was observed in the time required to pass through the successive stages, varying from 10 to 29 months. Cystic mastitis occurred only in multiparous does and was most common in females 2–3 years of age. Numerous animals of unrelated lines were foster-reared by tumor-bearing rabbits and observed for long periods of time without subsequent development of mammary tumors. This observation, together with the low incidence of tumors in daughters of tumor-bearing dams was interpreted by Greene as evidence against passage in the milk of a virus (analogous to the Bittner virus of mice) influencing MAC development.

Cystic disease in Greene's series was preceded by a variable period of intense mammary congestion that waxed and waned, seemingly according to events in the estrous cycle. Cysts were observed to arise simultaneously from dilated acini and ducts in many areas (which were palpable *in situ* as shot-like structures). Microscopically the cyst epithelium was flattened and as the disease progressed, cystic enlargement occurred by coalescence of acini. Later, fibrous connective tissue accumulated around dilated acini and enlarged cysts. After the variable period of cystic disease, early preneoplastic changes within cysts included sessile growths of either cystic epithelium or uniradicular papillomas. The purely epithelial growths were not seen in later stages, however the papillomata were found in all breasts and all stages of development were found in different sections of the same mammae. The papillomatous structures rapidly became multiradicular and formed epithelium-lined spaces, resembling acini. The walls of the structures gave rise to papillary forms comparable to those seen in humans and referred to as intracystic adenomata (Greene, 1939c). Eventually, malignant changes including disorder in the papillary epithelium, irregularity in the shape and size of neoplastic cells, nuclear hyperchromaticity and more common mitotic figures occurred in widely separated areas of breast tissue. These characteristics of papillomata, in some cases, persisted for more than 6 months before the invasive stages began. In at least four rabbits, in contrast to the picture of progression initiating with cystic hyperplasia, mammary adenomas appeared to begin as atypical proliferations of previously normal acini.

Invasive MAC was the inexorable outcome of the papillomatous stage. Metastatic foci would form neoplastic structures initially identical to those of the primary tumor. In some instances, further dedifferentiation occurred and the cells proliferated in solid, medullary sheets. Characteristically, in different areas, all stages from cystic disease to metastatic carcinoma could be observed. This has been a consistent observation of others describing MAC, as well (Blevins et al., 2009; Burrows, 1940; Heiman, 1937; Pearce and Greene, 1938; Polson, 1927; Sikoski et al., 2008). Invasion to muscle and connective tissue surrounding the mammary gland occurred commonly and was not accompanied by inflammatory response. Metastasis occurred in some cases to the lung and regional lymph nodes, as well as to other organs in different animals.

Although the dominating lesion in affected rabbits was the MAC, pathological changes in other organs reflected profound physiological disturbances that were also observed clinically. The adrenals, pituitary, and uterus appeared to be consistently involved in rabbits with MAC preceded by cystic hyperplasia. The adrenals had numerous foci of large, pale-staining vacuolated cells with pyknotic nuclei. The adenohipophysis was enlarged 3–5-fold owing to chromophobe cell hyperplasia and the uterine epithelium was hyperplastic and cystic. Greene believed that these changes were consistent with a syndrome of hyperestrinism (Greene, 1939d, 1965). He pointed out the frequent involvement of mammary tissues (50%) in the case of ACU, and the unusual frequency of concomitant tumors of these two organs in the rabbit. Of 23 cases of MAC, six also had ACU. Furthermore, he argued, the similar endocrine gland changes (particularly in the adrenal and pituitary) supported a common etiologic basis.

These findings, and the conclusions, as well, were shared by Burrows (1940) who followed 25 female rabbits up through about 3 years of age. Of them, 15 developed ACU, and three developed MAC as well. The females were frequently observed to be pseudo-pregnant owing to the continuous presence of males in the room. The MACs were of the type described by Greene (and others cited above) as being preceded by cystic mastopathy. In different areas of the same breast, all stages described by Greene, including intracystic papillomata and adenocarcinoma were observed. More importantly, however, observation by Greene of (a) cystic mastopathy, (b) cystic hyperplasia of the endometrium, (c) ovarian changes in which the bulk of the organ was changed to luteal tissue, (d) lipid degeneration of the adrenal (similar to that seen in mice by treatment with estrogen), and (e) the unusually frequent association of uterine and mammary tumors as multiple primary neoplasia were all confirmed by Burrows (1940). The fact remains, however, that neither uterine

nor mammary adenocarcinomas of the type that occur spontaneously have been experimentally induced by hyperestrinism, and the role of estrogen, if any, in ACU and MAC in the rabbit remains moot. A more likely endocrine basis has been demonstrated for the role of prolactin. More recently, it has become clear that cystic hyperplasia (mastopathy) of the mammary gland and uterus in rabbits is driven by prolactinemia and may be triggered by progesterone derived from retained corpora lutea (pseudopregnancy), or from hyperplasia of the anterior pituitary or pituitary adenomas with active, prolactin-secreting cells demonstrated by special stains (Blevins et al., 2009; Lipman et al., 1994; Sikoski et al., 2008) and by elevated serum prolactin levels. In addition, Sikoski et al. (2008) were able to diagnostically image pituitary enlargement by tomography in a rabbit with MAC. The hyperprolactinemia observed by Petraiteine et al. (2001) as induced by treatment with cyclosporin A (and methylprednisolone) especially underscores the role of prolactin because of the chemical induction of cystic mastopathy during treatment, and its regression following withdrawal of the drug(s) (Petraitiene et al., 2001). In like manner, the proliferating cells of the gynecomastia (mammary hyperplasia) accompanying the interstitial cell tumor (of the testis) in the male rabbit reported by Maratea et al. (2007) exhibited intense staining for progesterone (PR) receptor.

MAMMARY FIBROADENOMA

Mammary fibroadenoma, although quite common in the laboratory rat (Percy and Barthold, 2007) appears not to have been previously reported as occurring in *Oryctolagus* rabbits. A single case is reported here (Weisbroth, 2010). As in the rat, the tumor was benign, sharply encapsulated from adjacent tissue, well tolerated by the host and, because left untreated, grew to an enormous size (see Figure 16.4). On gross section, the tumor was a pale yellowish color and distinctly lobulated. Microscopically, the architecture of the tumor illustrated above closely resembled that of the counterpart rat lesion, i.e., acinar epithelial elements in a collagenous, fibrous tissue matrix.

Tumors of the Male Reproductive Tract

Tumors of the Testes

Tumors of the testicle are infrequent in the rabbit, most probably owing to the limited population of males over the age of 2–3 years, since most reports have occurred in rabbits even older. Reports of tumors of the male reproductive tract in the rabbit, at present, are limited to testicular neoplasms. Differential diagnosis of the clinical presentation in the rabbit of unilateral (or less commonly) bilateral enlargement of the

FIGURE 16.4 Mammary fibroadenoma in a Dutch Belted rabbit illustrating the very large size that can be attained by this benign tumor.

testicle includes bacterial orchitis, of course, but must also include an increasing array of tumor types, some of which have had interesting physiologic concomitants. It should be noted that enlargement of the testicle does not always accompany neoplasms of this gland (Veeramachaneni and Vandewoude, 1999). Teratoma has also been observed as arising in rabbit testicle, but will be separately described in that section.

INTERSTITIAL CELL TUMOR

Interstitial cell (syn.: Leydig cell) tumors are, arguably, the most common type of testicular neoplasm in domestic rabbits, certainly they are the most commonly reported. Interstitial cell tumors (ICT) can occur as unilateral or bilateral neoplasms (DeFaria, 1961; Devaux, 1951–1952; Flatt and Weisbroth, 1974; Zwicker and Killinger, 1985) and may accompany other primary tumors (Roccabianca et al., 1999; Veeramachaneni and Vandewoude, 1999). Grossly, the tumors occur as enlargements of the testicle and are encapsulated, lobulated, firm, blotchy, and tan or pale in color. Areas of hemorrhage or coagulation necrosis are not uncommon. The tumor initiates as a proliferation of interstitial cells between the seminiferous tubules, which appear to represent a continuum from hyperplasia in early stages to solid sheets and masses of polygonal cells with eosinophilic cytoplasm, separated into lobules by cords of connective tissue as the ICT develops. Examples of these neoplasms are shown in Figures 16.5 and 16.6. The tumor cells stain for Melan A in the cytochrome (Maratea et al., 2007) and may demonstrate Reinke's crystals and vimentin (Marino et al., 2003). The ICT in the rabbit expands radially, but is not locally invasive nor is it known to metastasize. The tumors are hormonally active and, in at least one case, gynecomastia was described as an accompaniment to the primary ICT

FIGURE 16.5 Interstitial cell testicular tumor. Bilateral tumors in a New Zealand White rabbit. Note enlargement of the testicle and multiple encapsulated tumor nodules (arrows).

FIGURE 16.6 Interstitial cell tumor. Photomicrograph showing sheets of tumor cells with abundant cytoplasm.

(Maratea et al., 2007). Although neoplastic interstitial cell tumors are known to secrete increased amounts of estrogen, and that estrogen inhibits the cytochrome P450 enzymes necessary for testosterone formation leading to feminization in other species, the relationship of the tumor to gynecomastia in this rabbit was not determined (Maratea et al., 2007). Other reports of ICT in the rabbit have not described status of the breast tissue at necropsy.

SEMINOMA

The seminoma (syn.: germ cell tumor) is a much less frequently reported testicular neoplasm of the rabbit. Although the first case was reported in 1918 (Paine and

FIGURE 16.7 Seminoma. Low-power photomicrograph showing lobulation and dense cell sheets.

FIGURE 16.8 Seminoma. Higher magnification showing detail of monolithic sheets of polygonal cells with hyperchromatic, basophilic cell nuclei with scanty cytoplasm.

Peyron, 1918), 71 years would elapse before the next report (Brown and Stafford, 1989). These tumors present clinically as usually unilateral enlargements of the testicle in older male rabbits. Grossly, the tumors are firm, nodular, and pale in color, but often are with areas of hemorrhage (Anderson et al., 1990). Microscopically, the tumor is composed of densely cellular packed sheets of large, round or polygonal tumor cells with densely basophilically staining nuclei and scanty basophilic cytoplasm (Figures 16.7 and 16.8). The tumors may invade the capsule of the testis and blood vessels within the organ, but are not known to be malignant. The case described by Veeramachaneni and Vandewoude (1999) additionally had areas of seminiferous tubules with atypically large cells with clear cytoplasm containing PAS-positive material that the authors termed carcinoma in situ. Seminomas, interstitial cell tumors, and carcinoma in situ are well illustrated in the latter article.

GRANULAR CELL TUMOR

Irrizarry-Rovira et al. (2008) have reported the first occurrence of a granular cell tumor (GCT) in the rabbit as a unilateral testicular neoplasm. Clinically, the tumor was seen as an enlargement of the testicle in an 8-year-old male, was encapsulated, tan in color, and there was no evidence of gynecomastia. In other species, including the human, the neoplasm tends to arise in other structures of the female and male reproductive tracts, but this was the first rabbit case observed to occur in the postnatal testicle. The tumor is thought to arise from pluripotential cells of neuroectodermal origin. The authors stress the importance of impression smear exfoliative cytologic demonstration of granular cells in distinguishing between ICT and GCT, which are quite similar in histologic sections. In addition, the tumors may be differentiated by their appearance in transmission electron microscopy. Microscopically, the tumor was seen to consist of sheets of a monotonous population of polygonal cells and dense cellular aggregates in an abundant pink to magenta granular background. Neoplastic cells contained the Melan A and vimentin markers, and there were aggregates of neuron-specific enolase-positive cells.

PAPILLOMATOSIS

Non-viral papillomas in the rabbit have an interest out of proportion to their incidence. The prominence of the Shope papilloma (of *Sylvilagus*) as a research model, on the one hand, and the oral papilloma (of *Oryctolagus*), on the other, has tended to produce in the popular mind an assumption that all papillomas in the rabbit are associated with papova group viruses. Detailed review of virally induced tumors is given in a separate section in this chapter.

Dobberstein and Tamaschke (1958) briefly described papillomatosis of the skin in *Oryctolagus*. They were not able to passage the papilloma in transplantation experiments, and details of the histology were not given. Recently, four cases of non-viral squamous papilloma were reported (von Bomhard et al., 2007). Non-viral origin was concluded based on lack of any features of viral cytopathic effect in the tumor tissues. Tumors occurred on the third eyelid, the pinna, and on the scrotum. These locations seem to match those that also occur with canine papillomatosis. The histologic changes consisted of exophytic papillated projections of mildly pleomorphic squamous epithelium.

Non-viral papillomas of the digestive tract also have been infrequently observed in the rabbit. The single reported case of polyps occurred in the sacculus rotundus (Polson, 1927). In a series of necropsies performed by Weisbroth, one fungating cauliflower-like papilloma was observed at the rectoanal junction of a 5-year-old

male rabbit, and an additional case at the same location was provided by Dr. Barbara Geistfeld (Geistfeld, 1992). Both papillomas were well-differentiated and benign, and inclusion bodies could not be demonstrated.

Tumors of the Gastrointestinal Tract

Reports of primary tumors originating in the GI tract in the rabbit are rare. Shibuya et al. (1999) reported a spontaneous lymphoma with extensive involvement of stomach, liver, and spleen. The majority of the reports of primary GI tumors in laboratory rabbit (*Oryctolagus*) involve the liver.

Tumors of the Liver

Starost (2007) reported a single case of hepatic hamartoma arising from the medial liver lobe of a transgenic New Zealand White rabbit that was diagnosed concurrently with cholelithiasis. Even though the tumor mass showed microscopic similarities to human cases of biliary hemartoma, this tumor was extrahepatic, had no involvement of hepatic parenchyma and was composed of cystic structures.

There is a single report of primary hepatic hemangiosarcoma with pulmonary metastasis in a 5-year-old New Zealand White rabbit (Guzman et al., 2000). Neoplastic nodules of varying size were observed to be distributed on the visceral surface as well as throughout the liver parenchyma. Histologically, blood-filled cavernous spaces of various sizes were separated from the hepatic parenchyma by streams of tightly packed spindle cells that in many cases extended to the central aspects of the cavity to form irregular blood-filled vascular channels. Cells had poorly defined cytoplasmic boundaries with scant eosinophilic cytoplasm and a large, oval, often-cleaved nucleus with finely stippled chromatin and inconspicuous nucleoli. Mitotic figures were rare.

Tumors of the Biliary System

Bile duct adenoma (or cyst adenoma) and its malignant counterpart, the bile duct adenocarcinoma (or cholangiocarcinoma), are relatively common as spontaneous tumors of *Oryctolagus* (see Table 16.3 for reported cases). Bile duct adenomas present as massive solitary growths or as multiple tumors of variable size. The lesions are unencapsulated but sharply circumscribed from normal liver. The tumor is frequently described as a cystadenoma because the gross appearance of multiple intercalating cysts filled with honey-like fluid is matched by the microscopic pattern of variably differentiated ductal forms within a myxoid to fibrotic stroma (see Figures 16.9 and 16.10). The tumor is of some interest because it may be reflective of the hyperirritability associated

FIGURE 16.9 Bile duct adenocarcinoma. Gross photograph showing adenocarcinoma (A) sharply circumscribed from liver (B). Note metastatic nodules in the mesentery (C).

FIGURE 16.10 Bile duct adenocarcinoma. Photomicrograph showing aberrant and incomplete ductal epithelial formations.

with rabbit bile duct epithelium. Since [Schweizer's \(1888\)](#) observation (of coccidia in a liver tumor), it has been known that any of a variety of noxious stimuli may induce the proliferation of bile duct epithelium in the rabbit. For example, bile duct hyperplasia has been associated with *Eimeria steidae* infection. One is tempted to speculate that the genesis of bile duct carcinoma may originate from initially hyperplastic epithelium. This view is consistent with Weisbroth's observation that early developing and small bile duct adenomas are well-differentiated compared to those that are large, presumably more developed, and of longer duration. The histological pattern of the tumor may vary from that of a hamartoma in the most differentiated forms to that of a cystic honeycombed carcinoma with less

FIGURE 16.11 Embryonal nephroma. Gross photograph showing kidney in cut section. Note the sharp demarcation of the tumor nodules from the adjacent renal tissue.

obviously differentiated tubular forms. Metastases in the form of peritoneal, diaphragmatic, and mesenteric implants are common.

All known cases of bile duct tumors have been studied retrospectively from postmortem tissues and have been encountered only sporadically as incidental findings at necropsy. The tumor appears to have little potential as a research model, primarily because of the difficulty of case finding.

Tumors of the Urinary Tract

Tumors of the Kidney

EMBRYONAL NEPHROMA

Embryonal nephromas (syn.: nephroblastomas, Wilms' tumors) are comparatively common tumors in *Oryctolagus* rabbits and have been reported on many occasions (see [Table 16.3](#)). In the review by Dobberstein and Tamsachke (1958), the incidence of this tumor was second only to uterine malignancies. Embryonal nephromas (EMN) are most often encountered as incidental findings at necropsy, indeed, all reported cases in the rabbit have been benign and not obviously a cause of impaired renal function. Cases have been described from both young (18–24 months) and old (60–72 months) rabbits. The EMN tend to enlarge quite slowly, as can be inferred from the observation that tumors from aged rabbits (2cm diameter) are larger than those from younger rabbits (1cm or less). Grossly they are whitish, sharply demarcated nodules of tissue projecting above the cortical surface ([Figure 16.11](#)). The tumors

FIGURE 16.12 Embryonal nephroma. Note fibrosis of pseudocapsule (A) by nephroma (B) and compression of adjacent renal tissue (C).

may be single or multiple and appear to occur uni- or bilaterally with equal frequency in either kidney.

Histologically, the EMN of *Oryctolagus* is remarkably similar to that of man (Greene, 1943) and swine (Moulton, 1990). The basic histologic pattern is that of cylindrical cells arranged in tubular formations with spindle-shaped or round stromal elements in indifferent arrangement. The tubular formations are disuniform and many appear cystic. One distinctive feature is the pseudoglomerulus structures seen within tubular formations in the more differentiated areas. Muscle, cartilage, and other tissues common to human Wilm's tumors have not been seen in the rabbit analog. The tumors arise from the cortex and compress the surrounding renal tissue and project above the capsule as they expand radially (Figure 16.12).

Secondary polycythemia has been reported as associated with EMNs in rabbits (Lipman et al., 1985; Wardrop et al., 1982). Interestingly, in the report by Wardrop et al. surgical removal of the neoplasm resulted in correction of the polycythemia. In neither report, however, could a reactive rise in erythropoietin levels be demonstrated, as is commonly the case with human Wilm's tumors. EMN in the human is limited almost entirely to childhood and has an often fatal clinical course. In spite of the remarkably similar microscopic appearance, polycythemia, and youthful incidence, the rabbit EMN, on the other hand is routinely benign and metastases have not been reported. Because the tumor occurs in other species with biologic properties more similar to those of the human EMN (Moulton, 1990), the EMN of the rabbit would seem to offer little of interest as an EMN model. In the four cases encountered by Greene (1943), successful transplants were established in about 20% of rabbit hosts heterografted either in the testicle or anterior chamber of the eye. The very slow rate of growth noted with spontaneous EMNs was characteristic of transplanted tumors as well, even into the fourth transplant generation.

RENAL CARCINOMA

Renal carcinoma (syn.: clear cell carcinoma, hypernephroma) is rare in most animal species and has been reported in the rabbit only once (Kaufmann and Quist, 1970). Grossly, the tumor presented as a large, smooth-surfaced cortical mass on the lateral-posterior aspect of the right kidney. There was a large cyst (10 cm) on one side, but the remainder of the tumor was solid, albeit with necrotic foci. No metastases were observed on necropsy dissection. Microscopically, the low cuboidal to spindle-shaped tumor cells were arranged in irregular tubular formations, or in solid sheets and nests. The cells had eosinophilic cytoplasm, but were extensively vacuolated to form clear cells.

Tumors of the Skin

Based on the literature, there is a significant difference between the type of tumors most commonly seen in pet and laboratory rabbits, which could be attributed to the longer life span of pet rabbits (12 years or more) compared to laboratory rabbits (from a few months to 2 years on average). It is also possible that occurrences of previously reported tumors have been underreported due to lack of novelty. In addition, most of the skin tumors in laboratory rabbits are created by oncogenic viruses or transplanted squamous cell carcinomas. These tumors will be discussed separately later in this chapter.

There are very few reports of primary skin tumors of laboratory rabbits which are non-viral in origin. The majority of the primary cutaneous neoplasm found in laboratory rabbits are squamous cell carcinomas, six cases of which were reported previously (Carini, 1941; Greene and Brown, 1943). Recently, five cases of squamous cell carcinomas were reported in pet rabbits with a mean age of 7.5 years (von Bomhard et al., 2007). There appeared to be no common denominator of significance in the origin of the tumors. All known cases have arisen in different locations, literally from the head (Greene and Brown, 1943) to the tail (Pearce, cited by Greene, 1943). The sites involved haired as well as glabrous skin. The metastatic potential of these tumors was found to be low.

Most reports on skin tumors in the last two decades come from a recent retrospective study in pet rabbits by von Bomhard et al. (von Bomhard et al., 2007). According to the study, the most common cutaneous neoplasm in pet rabbits was trichoblastoma, observed in 58 of 179 reported cases. The incidence was equally distributed in both sexes, with a mean age of 5 years, starting at the age of 1 year. The majority of the cases appeared as solitary neoplasms. In most cases, the epidermis was elevated and frequently ulcerated.

FIGURE 16.13 Basal cell adenoma. Gross photograph showing adenoma projecting above skin of the right dorsal abdomen.

Incidences of cutaneous lymphoma were reported in four pet rabbits recently (Gomez et al., 2002; White et al., 2000). Three of these rabbits were less than 2.5 years old (one New Zealand White, one Netherlands dwarf, and one Dutch dwarf), placing them in the age group of laboratory rabbits. Most of the lesions reported in the young animals (White et al., 2000) occurred in the head and neck region. Histologic studies showed epitheliotropism in two rabbits, suggesting T-cell lymphoma.

Other major cutaneous tumors reported in rabbits include basal cell adenoma (Weisbroth, 1974), trichoepithelioma (Altman et al., 1978; von Bomhard et al., 2007), myxosarcoma, liposarcoma, fibrosarcoma, malignant peripheral nerve sheath tumors, lipoma, and leiomyosarcoma, apocrine carcinomas, and Meibomian adenomas (von Bomhard et al., 2007). Basal cell adenomas (carcinomas) are rare and seen in relatively old rabbits (>4 years). The case reviewed by Weisbroth consisted of two small (2 × 1 cm) pedunculated adenomas of multicentric origin, both on the right abdominal dorsum, projecting above the skin (Figures 16.13 and 16.14) of a doe that also had adenocarcinoma of the uterus (Weisbroth, 1974). Histologically the tumors were similar to those described from other species, especially canine (Moulton, 1990).

Tumors of Bone and Cartilage

Osteosarcoma

Primary bone and cartilage tumors in domestic animals can vary widely, based on the anatomic location,

FIGURE 16.14 Basal cell adenoma. Photomicrograph showing clumps of neoplastic basilar cells (white arrows) surrounded by sparsely cellular collagenous stroma (black arrows).

tumor cell characteristics, as well as the tumor matrix as given in Meuten (2002). Even though spontaneous osteosarcomas are rare in rabbits, the reported cases show similar heterogeneity. Osteosarcomas can be experimentally induced in rabbits by various techniques, which will be discussed later in this chapter (Barnes et al., 1950; Coventry et al., 1959; Hulse, 1969; Janes et al., 1954; Sabin et al., 1932; Schurch and Uehlinger, 1931; Tapp, 1966, 1969a, 1969b; Ubertaini, 1972).

The “round cell tumors” of bone reported by Katase (1912) are difficult to evaluate in terms of present-day descriptive terminology for osteosarcomas because of the insufficient description provided by that author. Orr (1936) described a multicystic tumor of the mandible that he classified as an adamantinoma. The cysts were within a loose fibrous tissue matrix, were lined with stratified squamous epithelium, and had numerous desquamated cells in the cyst cavities. Other areas of the tumor consisted of solid alveolar masses of cells of squamous (non-keratinized) type. The description and illustrations provided by Orr were not typical of adamantinomas in other species (Moulton, 1990) and indeed, when critically reviewed by Gillett and Gunther (1990), Orr’s description was held to closely resemble the tumor more properly described as a mucoepidermoid carcinoma.

Even though a number of cases of osteosarcoma in rabbits have been reported (Kondo et al., 2007; Mazzullo et al., 2004; Renfrew et al., 2001) there are still only very few reports of primary neoplasia of bone and cartilage in rabbit. Kondo et al. (2007) described a primary osteosarcoma in rabbit that was anatomically and histologically similar to osteosarcoma in dogs. The tumor lesions extended from the distal scapula to the diaphysis of the humerus. However, it was different from most osteosarcomas in that the proliferative and destructive lesions extended into the glenohumeral

FIGURE 16.15 Osteosarcoma. Radiographs of mandibular osteosarcoma (A) in lateral and ventrodorsal orientation.

joint space. Histologic description of these lesions varied from giant-cell-type osteosarcoma (Kondo et al., 2007) that is similar to canine osteosarcoma of the same category (with similar locations as canine) to primary extraskeletal osteosarcomas (Renfrew et al., 2001) with neoplastic foci occurring in multiple soft tissue sites including the subcutaneous tissue and organs. Examples of osteosarcoma are shown in Figures 16.15–16.17.

Radiographic descriptions of osteosarcoma, which are important from a clinical stand point, are rare in reports on rabbits. Alkaline phosphatase (ALP) was found to be elevated in some reports (Ishikawa et al., 2007; Weisbroth and Hurvitz, 1969). Kondo et al. (2007) suggested that ALP might be useful as a diagnostic and prognostic factor in rabbits with primary osteosarcoma.

Tumors of the Hemolymphatic System

Lymphoid Tumors

LYMPHOMA AND LYMPHOID LEUKEMIA

Lymphoma is the second most common spontaneously occurring tumor in domestic rabbits (*Oryctolagus cuniculus*) and the most common tumor in young and juvenile rabbits. Most early cases were studied retrospectively from postmortem material which impeded progress in the characterization of lymphoma in the rabbit because the early cases occurred sporadically and with unknown histories. There has been an increase in the numbers of pet rabbits of diverse genetic background that are allowed to achieve a natural lifespan and cases have been reported in different breeds and ages of rabbits. Lymphoma has been reported in a variety of domestic breeds including New Zealand White,

FIGURE 16.16 Osteosarcoma. Gross photograph of mandibular osteosarcoma lesions (A) shown in Fig. 16.15.

multicolor English type, Japanese White, Dutch dwarf, and domestic cross-bred rabbits as well as in *Sylvilagus* and *Lepus* spp. in North America and Europe (Finnie et al., 1980; Gomez et al., 2002; Ishikawa et al., 2007; Reed et al., 2009; Shibuya et al., 1999; White et al., 2000). The most common age of occurrence of naturally occurring tumors is young, from 6–18 months of age, although increased cases of lymphoma have been

FIGURE 16.17 Osteosarcoma. Radiograph of thorax showing extensive “cotton ball” metastases (A) and gross photo showing pleural metastases (B, arrows).

reported in rabbits as old as 9.5 years of age (Ishikawa et al., 2007; Reed et al., 2009; White et al., 2000). Most early cases of lymphoma were identified in laboratory rabbits which generally do not achieve a natural lifespan since they are consumed for research purposes before reaching 2 years of age. The larger number of pet rabbits now seen in clinical practice may be resulting in an increased volume of case reports of lymphoma in older animals. The disease incidence does not appear to have a sex predilection. Cases of lymphoma characterized in early literature (Fox et al., 1976; Weisbroth, 1976) were uniformly aleukemic but more recent cases reported leukemia associated with multi-organ involvement (Cloyd and Johnson, 1978; Finnie et al., 1980; Toth et al., 1990). In these cases, clinical pathology findings included anemia, leukocytosis due to lymphocytosis, and sporadic hypercalcemia, which might have been attributable to diet. Other laboratory findings may occur with or without the presence of overt leukemia and include depressed hematocrit, low hemoglobin attributable to infiltrative obliteration of the marrow by tumor cells and, late in the course, elevated blood urea nitrogen attributable to infiltrative destruction of the renal cortex (Fox et al., 1976; Kolappaswamy et al., 2006; Toth et al., 1990). Clinical signs depend somewhat on organ involvement and include anorexia, weight loss, depression, alopecia, cutaneous nodules, with and without ulceration, blepharitis, swollen palpebrae, sudden onset of paralysis, or lymphadenopathy (Ishikawa et al., 2007; Kolappaswamy et al., 2006; Reed et al., 2009; Shibuya et al., 1999; Volopich et al., 2005; von Bomhard et al., 2007; White et al., 2000). Necropsy findings commonly

FIGURE 16.18 Lymphoma. Gross lesions illustrating hepatomegaly, splenomegaly and enlarged, pale renal kidneys.

include hepatosplenomegaly, enlarged, pale kidneys, enlarged thoracic and mesenteric lymph nodes, pulmonary nodules, pale bone marrow, and skin nodules. The presence of four gross lesions occurs consistently in cases reported in the literature and can be considered pathognomonic for lymphoma in *Oryctolagus*. This common tetrad of signs is enlarged, light tan kidneys with an irregular lumpy surface and thickened whitish cortex but normal medulla on cut surface, hepatomegaly with diffuse small (0.5mm) pale foci, splenomegaly, and lymphadenopathy (Weisbroth, 1994) (Figure 16.18).

Although practically any organ of the body may be susceptible to lymphomatous infiltrates, the most

FIGURE 16.19 Lymphoma. Infiltration of the cornea, orbital and periorbital structures.

FIGURE 16.20 Lymphoma. Iliac lymphadenopathy. Note enlarged iliac lymph nodes (arrow).

commonly involved organs are the spleen, liver, kidneys, lymphoid tissues of the GI tract, and lungs, and the structures of the eye, particularly the choroid, ciliary body, iris, and anterior chamber (Figures 16.19 and 16.20). Histopathologic findings generally include diffuse infiltration of neoplastic lymphocytes into multiple organs. Neoplastic lymphocytes may infiltrate the skin, occasionally occupying the entire dermis, epidermis, and periadnexal regions. Eyelids and the Harder's gland may be affected (Volopich et al., 2005; White et al., 2000). The lymphoid tissues of the alimentary tract, including the pharyngeal tonsils, stomach, Peyer's

patches, and mesenteric lymph nodes, appear to be routinely involved in the sarcomatous process. Pulmonary lymphoma often appears as exaggerated peribronchial lymphoblastic infiltrates that may obliterate the normal aggregates of lymphoid tissue. The interalveolar septa may be infiltrated as well. Liver infiltration typically starts with periportal aggregates which progressively extend into hepatic sinusoids. Over 50% of hepatic tissues may be obliterated by solid lymphoma. The spleen has been involved in most cases but was essentially normal in the case reviewed by Van Kampen (Van Kampen, 1968). The splenic white pulp becomes uniformly obliterated by neoplastic cells which move by radial extension of the white pulp through the spleen. Hematopoietic activity in the red pulp is an apparent reflection of decreased functional ability of infiltrated bone marrow. Virtually all of the lymph nodes in the body may be involved in the neoplastic process, often bringing to prominence lymph nodes difficult to discern in normal rabbits. The normal architecture of the node usually is entirely obliterated by masses of neoplastic lymphoblasts (Weisbroth, 1994). The architecture of the mesenteric and peripheral lymph nodes is often effaced due to the extensive invasion of neoplastic cells. Lymphoid tissue involvement in the lungs appears as robust peribronchial lymphocytic expansion that exceeds and replaces the normal lymphatic tissue. The pattern of renal lesions is distinctive with the cortex usually extensively involved but the medulla relatively spared. Neoplastic cells invade the renal cortical interstitium and widely separate the normal glomeruli, causing the normal-appearing glomeruli and cortical tubules to stand out in relief as widely separated structures (Figure 16.21). The ovary and adrenals are usually involved in the sarcomatous process, frequently to the point where only scattered remnants of organ-distinctive tissue may persist.

The neoplastic lymphocytes are typically larger than normal lymphocytes, ranging in size from 5 to 35 μm in diameter, with large basophilic nuclei, two or more nucleoli, and scanty cytoplasm (Figure 16.22). Regardless of the organ, mitotic figures are common and indicative of the rapidity with which lymphomas progress in *Oryctolagus*. Lymphomas of B cell, T cell, and mixed cell origin have been described that present with these same gross lesions. T and B cell lymphomas appear to be reported in approximately equal numbers, with only one report of a mixed cell type (Gomez et al., 2002; Ishikawa et al., 2007; Reed et al., 2009; Toth et al., 1990; Volopich et al., 2005; White et al., 2000). B cell lymphoma cells were routinely positive for the cell surface marker CD79 α . and T cell lymphomas were routinely positive for the CD3 cell surface marker. The single case of a mixed cell lymphoma was a naturally occurring case in a 2.5-year-old pet Dutch dwarf rabbit that

was classified as a T-cell-rich, B cell lymphoma (Gomez et al., 2002).

Medlar and Sasano (1937) described a single case of retroperitoneal sarcoma involving the appendix, adrenals, mesentery, pancreas, and left ureter in a solitary large neoplastic mass. Microscopically, the tumor mass itself and focal infiltrates in several organs were not typical of lymphoma in the rabbit. It is possible that the “abdominal sarcomas” of Wallner (1922) and of Baumgarten (1906) were of this type.

The cause of lymphoma in rabbit has not been established. Although most reports of lymphoma describe sporadic occurrences, a genetic susceptibility has been described in colonies of Wirehaired and laboratory

rabbits (Fox et al., 1970). Fox et al. reported well over 100 lymphomas in the series at the Jackson Laboratory (Fox and Meier, 1976; Fox et al., 1970, 1971a, 1971b; Meier and Fox, 1973). Loliger (1966, 1968) reported ten cases from a necropsy series of 602 from a single rabbitry, too great an incidence for a random distribution. The data revealed a pattern of incidence that led to the conclusion that an autosomal gene (designated *ls*) confers, in homozygosity, susceptibility to vertically transmitted lymphoma.

The occurrence of hemolytic anemia in the same strains was also reported by Fox and group (1971b). This condition segregated similarly to the autosomal recessive pattern of *ls*, and it was interpreted as

an allelic alternative and given the designation *ha*. Evidence was submitted to show that the gene designated *ls* in strain WH rabbits (associated with lymphoma) and the gene designated *ha* in the strain X rabbits (associated with hemolytic anemia and thymoma) might in fact be the same gene (at the same locus) expressing itself differently in the two substrate strains (Fox et al., 1971b; Meier and Fox, 1973). Supporting evidence included not only common ancestry for the two strains, but also the fact that blood cells from *ls* individuals were Coomb's test positive and 21% of all individuals in both strains were Coomb's test positive. The data presented were compatible with a concept of genetic susceptibility to vertically transmitted oncogenic virus analogous to the pattern now known for the C-type RNA genome. The authors hypothesized that the conditions might result from the interactions of *ls* and *ha* genes with the remainder of the host genotype and with a (posited) vertically transmitted C-type RNA virus, with the presence of the viral genome in the WH strain being expressed as lymphoma, whereas in the X strain it is manifested as an immunopathy similar to that described in the New Zealand Black mouse and culminating in thymoma when sublethal and chronic. This was an extremely important finding because the variables of age, sex, and genetic background can be purposefully manipulated in order to gain insight into the mechanism of the disease.

Support for interaction with a retrovirus was provided by the observation of Gupta that rabbit lymphoma tissues had virus-like particles on electron microscopic examination (Gupta, 1976). Shortly afterward, marker enzyme for the presence of type C retrovirus (RNA-directed DNA polymerase, or RDDP) was demonstrated in rabbit lymphoma tissues (Bedigian et al., 1976) and, finally, type C retrovirus was isolated in culture from rabbit lymphoma cells (Bedigian et al., 1978). A causative type C retrovirus has not been identified and no further significant work has been done since then to further study the role of C-type retroviruses in rabbit lymphoma or to identify the genes involved in rabbit leukemia.

Lymphoma has been encountered as an unanticipated complication of drug treatment. In the search for nitroarene trypanocides in the treatment of Chagas disease, Teixeira 1990 produced malignant, mixed cell, non-Hodgkins type lymphomas in 25–42% of rabbits treated with nitroimidazole compounds (Teixeira et al., 1990). A developing area of study is the role of retroviruses and Herpesviruses in rabbit lymphoma.

PLASMA CELL MYELOMA

A single case of plasma cell myeloma has been described from the rabbit (Pascal, 1961). It occurred as a large solitary mass lying on the left ventral side of the

brain, extending from the medullopontine groove to the pyramidal decussation and projecting laterally to the edge of the cerebellum. It is not known if the tumor had the functional characteristics (gammopathy) of plasma cell myelomas in other species because the diagnosis was established retrospectively on the solely histopathological criteria. The microscopic description of this tumor was not typical for plasma cell myelomas of other species (Moulton, 1990).

Tumors of the Spleen

No primary tumors of splenic tissue have been reported in rabbits. The small (5mm) tumor within the spleen described by Ball (1926) was composed of normal-appearing intestinal epithelium, including goblet cells. This finding, and a lack of any other lesions, suggests the tumor was a fetal nest or hamartoma of intestinal tissue lodging in the spleen.

Tumors of the Thymus

Tumors of the thymus have been reported infrequently in the rabbit (Blanchard, 1939; Clippinger et al., 1998; Dirven et al., 2009; Drieux, 1938; Florizoone, 2005; Orr, 1939; Greene and Strauss, 1949; Vernau et al., 1995). Thymic tumors typically occur in mature rabbits between 1 and 9 years of age. Complicating the diagnosis of thymic sarcoma in rabbits is the observation that hyperplasia of the thymus in adult rabbit is not uncommon; and enlargement of the organ up to 3–4 times normal size without acquisition of neoplastic characteristics can lead to a gross diagnosis of tumor that may not be supported by careful microscopic observation. Three cases of thymic hyperplasia were observed in Weisbroth's necropsy series of approximately 600 rabbits (Weisbroth, 1974).

THYMIC CARCINOMA

A thymic reticulum cell tumor described by Orr (1939) was metastatic to thoracic organs and abdominal lymph nodes. Another case of a thymic carcinoma was reported in 2005 that occurred in a 5-year-old castrated male chinchilla rabbit. The rabbit presented for bilateral exophthalmos and a mediastinal mass was identified on thoracic radiographs. Necropsy findings revealed a large cystic mass in the cranial thorax with nodules present in both kidneys. The masses were diagnosed as metastasizing thymic carcinoma. It should be noted that the diagnosis of malignancy was based on evidence of epithelial metastases to the kidneys rather than the histologic appearance of the tumor, which was difficult to distinguish from a thymoma (Wagner et al., 2005).

THYMOMA

Thymomas in rabbits and other species have been associated with the occurrence of a paraneoplastic

syndrome with immune dysregulation. Three cases of thymoma were reported in association with systemic immunopathy (Fox et al., 1971b; Meier and Fox, 1973). The disease occurred in the X strain and was characterized in homozygotes (for a newly designated gene, *ha*) by hemolytic anemia. Disturbances in the peripheral blood included regenerative anemia characterized by polychromatophilia, anisocytosis, decreased numbers of erythrocytes, and numerous nucleated erythrocytes and lymphocytes. The erythrocytes of *haha* rabbits were Coomb's test positive. Lesions and signs included petechiation of most tissues, darkened feces, icterus, hemoglobinemia, pale liver, hemorrhagic spleen and kidney, hemoglobinuria, and edema of most tissues. The age at death in homozygous ranged from 1.5–12 months, with an average of 4–5 months. Thymoma occurred only in protracted cases. Although key kidney lesions were lacking in *haha* rabbits, the authors believed the condition to be an excellent model for systemic lupus erythematosus and to have most of the pathological features of the canine and murine models. More recent sporadic cases of thymoma have been reported in pet rabbits with diverse genetic backgrounds (Clippinger et al., 1998; Florizoone, 2005; Vernau et al., 1995). The cases reported by Clippinger and Vernau were diagnosed by identification of a mediastinal mass on thoracic radiographs and were not associated with immunopathy. Florizoone (2005) reported a case in a 5-year-old pet rabbit that presented for exfoliative dermatitis; thymoma was diagnosed at necropsy. Exfoliative dermatitis has been reported in conjunction with thymomas in cats, and may be part of the paraneoplastic syndrome that accompanies this disease.

Myeloid Tumors

Granulocytic sarcomas are rare neoplasms of domestic animals and are the result of solid extramedullary growth of myelogenous stem cells. These tumors occur most in dogs and are typically located in the lungs, gastrointestinal tract, and skin. Most cases are non-leukemic initially, but may progress to acute myelogenous leukemia. A single case of an eosinophil granulocytic sarcoma was reported in an 18-month-old, female New Zealand White laboratory rabbit that was used for polyclonal antibody production. The animal developed a rapidly growing perianal mass and was euthanized. The perianal mass was composed of neoplastic myeloid cells that contained large eosinophilic granules in varying stages of maturation. Special stains and electron microscopy confirmed the presence of eosinophil granules. Bone marrow aspirates featured a prominent population of eosinophils. Although no hematological analysis was performed to document the presence of myelogenous leukemia, numerous neoplastic cells were present in the bone marrow, cardiac chambers, and lung

which suggested that rabbit was leukemic (Perkins et al., 1996).

Vascular Tumors

Tumors of vascular origin are very rare in domestic or wild rabbits. One case of malignant peritoneal endothelioma was reported in 1927 and Green described a single case of benign ovarian hemangioma in a rabbit in 1949 (Greene and Strauss, 1949; Polson, 1927). Pletcher and Murphy (1984) reported on two cases of naturally occurring metastatic hemangioendotheliomas in rabbits submitted to the Armed Forces Institute of Pathology. One case occurred in a wild rabbit (presumed to be *Sylvilagus* sp.) of unknown age and sex that was found dead. Multiple tumorous masses were present in subcutis, adjacent skeletal muscle, and visceral organs. The other animal was an adult female New Zealand White rabbit from a research laboratory. The animal did not exhibit antemortem clinical signs and multiple nodules were seen grossly in the liver and lung during a standard necropsy. Guzman et al. (2000) reported diagnosis of a primary hepatic hemangiosarcoma that occurred in a 5-year-old New Zealand White male laboratory rabbit. The animal was found dead in the cage without antemortem clinical signs. Postmortem exam revealed good body condition, a fluctuant abdomen, and pale mucous membranes. At necropsy the abdomen contained partially clotted blood and the liver (primary site) and lung contained multiple dark red nodules. The liver and lung contained multiple blood-filled cavernous spaces that were formed by disorganized, tightly packed spindle cells. Immunohistochemistry of the neoplastic cells for von Wildebrand's (factor VIII-related antigen) was inconclusive due to intense background staining but the neoplastic cells were positive for CD31 (platelet endothelial cell adhesion molecule) which is a useful marker for endothelial cells in human and canine tissue.

Tumors of Endocrine Glands

Tumors of the Pituitary Gland

PITUITARY GLAND ADENOMA

Tumors of the endocrine glands have been rarely reported in *Oryctolagus*. Several cases of teratoma arising in the pituitary are described ahead in the section on teratomas. Polson (1927) reported an adenoma of the anterior pituitary. The tumor was small (2mm), clearly demarcated from the normal tissue, and not associated with clinical signs. Histologically it was classified as an eosinophil adenoma.

Lipman (1994) described the first report of prolactin-secreting acidophil adenomas in a group of rabbits that were also associated with mammary dysplasia. Female New Zealand White rabbits from a specific

pathogen-free colony were used for antibody production. The animal's ages ranged from 2–4.75 years, with an average age of 3.2 years. Clinical signs included enlarged mammary glands, that were cystic on palpation. Some of the rabbits had discolored teats that expressed red or yellow fluid. All of the rabbits had significant serum prolactin elevations, ranging from 22.4 ng/ml–2.21 µg/ml, which was 10–1000-fold higher than normal (1.7–2.1 ng/ml). All rabbits had enlarged pituitaries at necropsy and acidophil adenomas were subsequently diagnosed in all rabbits. The tumor tissue stained positive for prolactin. Anterior pituitary tumors are relatively frequent occurrences in man, dogs, rats, and have also been reported in cats, sheep, mice, and non-human primates, but are rarely reported in rabbits. Prolactin-secreting anterior pituitary adenomas (prolactinomas) are the most common pituitary tumors in humans, where their occurrence is associated with irregular menses and galactorrhea. Rats frequently have prolactin-secreting tumors, but mammary changes are not usual in other species with prolactinomas. Mammary changes may occur more frequently in rabbits with prolactin-secreting tumors because rabbit mammary tissue is more sensitive to the lactogenic properties of prolactin and rabbits are more dependent on prolactin for mammary functions than other species. (See also the section on mammary tumors.)

Tumors of the Adrenal Gland

ADRENAL CORTICAL CARCINOMA

Carcinoma of the adrenal cortex has been reported twice in the literature. The case described by [Boycott and Pembrey \(1912\)](#) occurred in a feral *Oryctolagus* rabbit, was bilateral, and appeared to involve the anterior pole of each kidney and the corresponding adrenal cortex. The normal tissue within each adrenal was separated from the tumor by a well-developed capsule. The cell type of the tumor (described as “round cell”) was not characteristic of adrenal cortical tumors described later from the rabbit or from other species ([Moulton, 1990](#)). Asymptomatic carcinoma of the adrenal cortex (also occurring bilaterally) was described as an incidental finding in a male rabbit of unknown age by Hueper and Ichniowski ([Hueper and Ichniowski, 1944](#)). The tumors were located primarily in the adrenal glands, which had been largely replaced by tumor tissue consisting of sheets of very large foamy cells with small, oval nuclei. The tumors had metastasized radially to the subserosa of the duodenum and periadrenal fat and connective tissue. Cholesterol crystal clefts were scattered throughout the tumor tissue. The carcinoma was typical of adrenal cortical tumors reported in other species ([Moulton, 1990](#)). The authors emphasized that the tumor tissue was not separated from the normal

adrenal cortex by a capsule. This observation is perhaps worth emphasizing because non-neoplastic nodular hyperplasia of the adrenal cortex is a very common lesion in *Oryctolagus*, but in all cases the nodules appear to be well demarcated from the remainder of the organ by a capsule.

Melanomas

At least 12 cases of malignant melanomas in rabbits are reported in the literature, including the Brown-Pearce carcinoma, which was later used for creating transplantable tumor models. The case described by Brown and Pearce arose in the eye of a 10-month-old male rabbit that had been infected with *Treponema pallidum* 2 months previously ([Brown and Pearce, 1926](#)). The authors believed the treponemal infection to have been of significance in predetermining the neoplasm. The cases described by [Sustmann \(1922\)](#) and [Holz and Heutgens \(1955\)](#) were more typical of malignant melanomas in other species. More recently, in a retrospective study based on tumor specimens submitted, [von Bomhard et al. \(2007\)](#) reported eight cases of melanoma in pet rabbits, predominately in male (six males, two females). The lesions (11 sites) were distributed in ear pinna (three), eyelid (three), head (one), perivulvar haired skin (one), scrotum (one), thigh (one), and stifle (one). Out of eleven tumors, all except three neoplasms contained abundant melanin. Histologically, all tumors had a high mitotic index, marked anisocytosis, and anisokaryosis. Lymphatic invasion was present in four tumors. Malignant melanoma on the upper eyelid of an 8-year-old Himalayan dwarf rabbit was reported by [Stanley et al. \(2003\)](#). The tumor regressed after the use of radiation through brachytherapy.

Interestingly, there was only one report of melanomas in laboratory rabbits for the 55 years prior to this review ([Hotchkiss et al., 1994](#)). One reason could be that melanoma seems to occur in older rabbits and most of the laboratory rabbits are used at a younger age. Except the case described by [Brown and Pearce \(1926\)](#) and Holz and Heutgens (1955), all reported cases of melanoma have been in rabbits 2 years of age or older. The mean age of rabbits with melanoma, based on all 12 melanoma cases reported so far, is around 4 years. It is possible that, as in the case of other rabbit tumors, underreporting also played a role in the scarcity of melanoma reports in laboratory rabbits. Increased exposure of pet rabbits to sunlight compared to laboratory rabbits which are usually kept indoors could be another compounding factor. It is worth pointing out here that literature references to the Greene melanoma in rabbits are actually to a tumor of hamster origin adapted for propagation in rabbits (see the section on Experimental Tumor Models).

Miscellaneous Neoplasia

Teratomas

Teratomas are seen infrequently in animal species, including the rabbit. They arise as generally benign, slow-growing tumors containing often mature derivative tissues, e.g., bone, muscle, hair, teeth, neuronal aggregates simulating ganglia, glandular formations, etc. arising from totipotential cells of at least two of the three embryonic layers (ectoderm, mesoderm, and endoderm). Teratomas develop from germ cells in the gonad (and that is the most common location of teratomas), or from aberrant ectopic nests of germ cells in the abdominal midline or central nervous system. Mutinelli et al. (2008) reviewed the presumptive differences in histogenic origin of gonadal versus extragonadal teratomas. The clinical signs associated with the cases were related to their location, but they were often asymptomatic and detected as incidental findings at necropsy. A pituitary gland teratoma, described by Margulies (1901), was not associated with clinical signs. The tumor was approximately 1 cm in diameter, located at the pituitary infundibulum, and had infiltrated the brain. Histologically the tumor was cystic and composed of mucus-secreting columnar epithelium, hairs, smooth muscle cells, connective tissue, and glands resembling gastric epithelium and cartilage. The teratoma described by Bishop (1978) was also intracranial (but was the cause of CNS signs), as were a number of the older, particularly German references he cited. The teratomas reported by Meier et al. (1970) and by Mutinelli et al. (2008) were gonadal, and in a retroperitoneal location, respectively.

Experimental Tumor Models

Transplantable Tumors

VX2 CARCINOMA

The rabbit VX2 tumor originated from a papilloma induced by Shope's papilloma virus. The Shope papilloma virus was originally limited to cottontail *Sylvilagus* rabbits indigenous to the American Midwest and Mississippi basin region. The disease occurs occasionally in laboratory rabbits of genus *Oryctolagus*. The natural disease causes cutaneous, pigmented warts on the head and body, which regress spontaneously in approximately 33% of animals. The papillomas progress to squamous cell carcinomas in approximately 25% of affected animals. The original tumor occurred in a Dutch Belted male rabbit in the 1940s that carried a Shope papilloma for 9–11 months (Kidd and Rous, 1940). The tumor progressed from an aural papilloma to a squamous cell carcinoma. The axillary lymph node of the rabbit contained metastatic carcinoma that

was minced to provide transplantation fragments. The tumor was then serially passaged through donor rabbits. The success of transplantation averaged only about 5%, even in genetically related Dutch Belted rabbits, until after the fifth transplant generation. The tumor, described originally as a squamous cell carcinoma, became increasingly anaplastic in the course of serial transfer, but, at least through the twenty-second transplant generation (Kidd and Rous, 1940), it unfailingly induced neutralizing antibodies against Shope papilloma virus (SPV) in homografted rabbits. Serological testing in the rabbits was suspended during World War II, and, when resumed after the war (subsequent to the forty-sixth transplant generation) it was found that antibody to SPV was no longer present in the sera of rabbits bearing the carcinoma (Rous et al., 1952). Although phenolic nucleic acid extracts of papillomas and other papilloma-derived carcinomas (e.g., VX7) retain the ability to induce papillomas in susceptible hosts, such extracts of VX2 carcinomas do not (Chambers and Ito, 1964; Hodes et al., 1963; Ito, 1960, 1970; Ito and Evans, 1965a, 1965b). The tumor take rate has increased in accordance with the increased anaplastic appearance.

In its present form, the tumor is reliably transplantable in laboratory rabbits of genus *Oryctolagus*, with a take rate of over 90% without immunosuppression (Tinkey and Uthamanthil, 2009). Following implantation, the tumor aggressively invades the host organ parenchyma, surrounding muscle, and connective tissue. The tumor does not become encapsulated, but does cause inflammation in the surrounding tissue, with variable desmoplastic reaction. The tumor frequently develops central areas of necrosis but there is little associated hemorrhage. The tumor grows rapidly, progressing from the volume of inoculum (0.5 cc) to a solid tumor nodule measuring ~1.5 cm × 1.5 cm by 14 days post-implantation (Chen et al., 2004; Tinkey and Uthamanthil, 2009). The tumor's invasiveness has been linked to the expression of high levels of tumor-associated hyaluronan (Knudson et al., 1989). The tumor reliably metastasizes to regional lymph nodes and lungs within 21 days post-implantation, but only occasionally to other organs despite the tumor's aggressive nature (Figure 16.23). The apparent barrier to unrestricted metastasis has been the subject of several investigations (Engzell et al., 1968; Fisher and Fisher, 1966; Wood et al., 1967). Greene (1953) found the host range of transplantability to include the brain of guinea pig, mouse, rat, and hamster, anterior chamber of guinea pig eye, and subcutaneous tissues and testis of hamster and mouse.

On histopathologic examination, the cells are organized into uniform sheets separated by thin cords of stroma and blood vessels with a moderate population of inflammatory cells. Nuclei are hyperchromatic and uniform in size and shape, and giant cells are

FIGURE 16.23 VX2 carcinoma. Primary inoculation site in the kidney (A) with extensive metastases to the lung (B) about 4 weeks after inoculation.

infrequent. The tumor is known to secrete a hormone-like substance that depresses the renal tubular reabsorption of phosphorus and causes hypophosphatemia, hypercalcemia, and dystrophic calcification of the tumor and soft tissues (Gertner et al., 1964; Shtacher, 1969; Vogel et al., 1967; Wilson et al., 1964, 1965). Typical features of the tumor are illustrated in Figures 16.24 and 16.25, and the excellent photomicrographs in the monograph by Stewart et al. (1959) can be used as a reference. Other carcinomas (e.g., VX7) have been developed in like manner from Shope papillomas by the same and other laboratories. Some have used newborn rabbits to develop tumor strains of greater malignancy (Fischer and Syverton, 1951; Smith et al., 1952).

The rabbit VX2 carcinoma has remained a widely used model of transplantable malignancy and has been used extensively in rabbits for a variety of research purposes (Kreider and Bartlett, 1985; Strauli and Haemmerli, 1984). Utilization has shifted from that of intrinsic exploration of the papilloma-to-carcinoma transition to employment as a reproducible, easily carried model system in random-bred hosts for exploration of treatment modalities. The tumor has been implanted in diverse anatomic locations, including liver, kidneys, intestines, brain, tongue and larynx, and extremities (subcutaneous and intramuscular locations) (Boehm et al., 2002; Carson et al., 1982; Davidson and Wallace, 1986; Davidson et al., 1986; Kim et al., 2004; Nakase et al., 1977). One common research use is to create a solid tumor for imaging studies. Imaging modalities used include radiography, CT, US, MR, and PET imaging. The tumor has been used to study various approaches to therapies, including chemotherapy, interventional radiology, and immunotherapy (Rosales et al., 2000). This model has also been used to investigate

tumor angiogenesis and paraneoplastic syndromes, such as tumor-associated hypercalcemia, granulocytosis, and cachexia (Doppelt et al., 1982; Hough et al., 1983; Ishiko et al., 1999; Tamargo et al., 1990). At The University of Texas M.D. Anderson Cancer Center, this tumor model has been implanted into skeletal muscle in the rear leg, liver, and kidney, and used extensively to study the efficacy of treatment using embolic compounds delivered via intravascular catheters, development of devices for non-surgical ablative techniques, such as radiofrequency and MR-guided focused ultrasound, and as a model to allow correlation of images with histopathology. Although an exhaustive cataloging of references to the VX2 carcinoma is beyond the scope of this chapter, a review of recent uses of this important tumor model is presented in Table 16.4.

The tumor cell line has never been reliably established in cell culture and is generally maintained by serial passage in rabbits. There have been two reports of establishment of cell lines from the VX2 tumor, but no additional references have been published and the cell lines are no longer available from either source (Easty and Easty, 1982; Georges et al., 1985). The most reliable implantation site is intramuscular and it is typically implanted in one or both caudal thigh muscles of the donor animal. The tumor is generally harvested 14 days postimplantation, when the tumor nodule has reached ~2.0 cm × 2.0 cm. Delaying harvest past 14 days results in morbidity due to pulmonary metastasis and poor quality of tumor due to increased amounts of necrosis. The tumor can be minced, placed in media, and frozen at -80°C to preserve inocula for propagation of the tumor. Implantation of frozen tumor inocula results in reliable but slightly lower tumor take rates and slightly slower growth rates (Tinkey and Uthamanthil, 2009).

BROWN-PEARCE CARCINOMA

The Brown-Pearce carcinoma, one of the most useful of the transplantable rabbit tumors, has great historic importance and was used extensively to study tumor immunogenicity. The Brown-Pearce carcinoma is an anaplastic carcinoma that was originally derived from a syphilitic chancre of an experimental rabbit used to study *Treponema pallidum*. Despite the exhaustive description provided by Brown and Pearce (Brown and Pearce, 1923a, 1923b, 1923c, 1923d, 1923e, 1923f, 1923g, 1924) an understanding of the antecedent tissue from which the carcinoma originated is destined to remain somewhat ambiguous. For that reason it is worth describing the circumstances of the rabbit in which the tumor arose. Wade Brown and Louise Pearce of the Rockefeller Institute were intensively engaged in the study of syphilis. In June, 1916, a rabbit, injected

As a model for imaging studies	(Parker et al., 1990; Phillips et al., 1991; Pillai et al., 1991; Suga et al., 1991; Choi et al., 1993; Shmulewitz et al., 1993; Taupitz et al., 1993; Forsberg et al., 1995; Ra et al., 1995; Robinson et al., 1995; Leander 1996; Oya et al., 1996; Runge et al., 1996; Kono et al., 1997; Runge et al., 1997a; Runge et al., 1997b; Tajiri et al., 1997; Brown et al., 1998; Runge and Williams, 1998; Brown et al., 1999; Moon et al., 2000; Purdie et al., 2001; Sayegh et al., 2001; Herborn et al., 2002; Herborn et al., 2003; Maehara and Maehara, 2003; Malich et al., 2003; Purdie et al., 2003; Winter et al., 2003; Wyman et al., 2003; Kondo et al., 2004; McDannold et al., 2004; Kim et al., 2005; Yuan et al., 2005; Yuan et al., 2005; Choi et al., 2006; Hu et al., 2007; Choi et al., 2008; Jiang et al., 2008; Youn et al., 2008; Yuan et al., 2008; Ohira et al., 2009)
As a model for tumor behavior and physiology	(Wunderlich et al., 1992; Yoshikawa et al., 1993; Gadeholt-Gothlin and Gothlin, 1994; Kubota et al., 1994; Thorstensen et al., 1994; de Baere et al., 1996; Fujimiya et al., 1997; Hatton et al., 1999; Kaneko et al., 1999; Prudhomme et al., 1999; Ishida et al., 2000a, 2000b, 2000c; Kuszyk et al., 2000; Murata et al., 2000; Ishiko et al., 2001; Wilkinson et al., 2001; Chikui et al., 2002; Obata et al., 2003; Seki and Fujimura, 2003; Wissniowski et al., 2003; Zhao et al., 2004; Li et al., 2006; Quan et al., 2006; Saad-Hossne et al., 2007; Weinberg et al., 2007; Qi et al., 2008; Lee et al., 2009)

with testicular tissues from another rabbit infected with *Treponema pallidum*, developed typical syphilis chancres at each of the intra-scrotal sites. In the intervening period between 1916 and 1919, the testicles of the rabbit became fibrotic and atrophic. In April 1919, the rabbit developed generalized cutaneous lesions and, by 1920, an eczematoid dermatitis of the left scrotum. This process became chronic but was marked by exacerbations and remission. In October of 1920, a nodule was noted at the site of the primary chancre in the left scrotum. The nodule, which rapidly increased in size, proved to be a malignant tumor. Treponemes, although demonstrable in a popliteal lymph node as late as 1 month prior to the appearance of the nodule, could not be demonstrated in dark-field preparations from nodule biopsies. The nodule was removed twice by surgical excision but recurred.

The rabbit was euthanized in March 1921. Necropsy findings were those of metastatic cancer and chronic syphilis. Tumor metastases were present in liver, bone, bone marrow, lung, spleen, kidneys, left testicle, inguinal adipose tissue, and the iliac, inguinal, and

retroperitoneal lymph nodes. The eczematoid dermatitis of the scrotum extended cranially to the skin of the abdominal ventrum. Chronic degenerative and inflammatory changes were evident in the epithelium of the tongue, oral cavity, esophagus, respiratory tract, and testes. Elsewhere, the skin was fibrotic with atypical pilofollicular proliferations, and the endocrine glands were abnormal.

Neoplastic tissue from the left inguinal lymph node was minced and injected into the testes of other rabbits. Brown and Pearce described the biological behavior of the transplanted tumor (Brown and Pearce, 1923b, 1923c, 1923d, 1923e, 1923f, 1923g, 1924) and noted the characteristic variable results. Tumor take rates varied from 100% in the testicle, anterior chamber, and brain, to 80% intramuscularly to 20% by the subcutaneous or intravenous route. Spontaneous regression of the tumor was common, even after the onset of metastasis, and varied with the genetic background of the recipient. The course might be fulminating with death 6–7 weeks after inoculation or prolonged to more than 6 months. Most commonly death occurred 8–12 weeks after

transplantation. The tumor was remarkably stable, and after some 15 years of continuous transplantation Casey (Casey, 1939; Casey and Pearson, 1939) wrote that the tumor had undergone no change with regard to metastatic distribution. It was noted that rabbits in which the tumor had regressed were resistant to subsequent transplants.

Neither desiccated tumor nor cell-free extracts were successful in establishing tumors (Pearce, 1927). Greene and colleagues (1949), who pioneered the technique of anterior chamber preparations for tumor transplantation, reported 100% success with the Brown-Pearce carcinoma (Ellerbrook et al., 1952; Saphir, 1941). Growth in the anterior chamber was rapid, often filling the chamber within 7–10 days and producing metastases within 4–6 weeks. Greene (1949) was unable to transplant the tumor to guinea pigs, and, although initial growth occurred in testicle, eye, and subcutaneous sites in rats, mice, and hamsters, regression was the invariable rule in these hosts. Growth of the tumor is supported on embryonating chicken chorionic allantoic membrane (Schechtman, 1950). Rabbits transplanted with the tumor may die as early as 10 days after inoculation or may survive for over 100 days (Stewart et al., 1959).

The tumor itself is soft and friable, has areas with hemorrhage, and may be necrotic, particularly toward the center. Microscopically the tumor is an anaplastic carcinoma with a monotonous medullary pattern of cords of carcinoma cells supported in a scanty stroma of connective tissue with a few reticular fibers and blood vessels. The tumor cells are typically round or oval with hyperchromatic centrally located nuclei in a slightly basophilic but pale cytoplasm. The prominent nuclear membrane encloses two or four acidophilic nucleoli, dense chromatin bars, and a lace-like meshwork. Mitotic figures are common. Necrosis is more common centrally than at the periphery. The tumor provokes little inflammation unless regression supervenes. The tumor is illustrated in Figures 16.26 and 16.27. Excellent illustrations of the tumor are to be found in the original reports by Brown and Pearce, the reviews by Snell (1953) and Stewart et al. (1959), and the investigation by Appel et al. (1941).

The Brown-Pearce carcinoma elicits tumor-specific antibody response in some rabbits (with donor-specific responses in some rabbits depending on genetic background), thus the carcinoma has been used extensively as a model of tumor immunity (Snell, 1953). Casey observed in 1932 that rabbits injected with killed Brown-Pearce carcinoma tissues were rendered more susceptible to malignant consequences when later inoculated with the tumor (Casey, 1932, 1933). He believed there were “enhancing materials” or an “XYZ factor” in the preserved tumors which was responsible for the specificity of the effect (Casey, 1941). The effects could

FIGURE 16.26 Brown-Pearce carcinoma. Carcinoma explant in anterior chamber of the eye, approximately 30 days after inoculation. Note corneal perforation by the tumor.

FIGURE 16.27 Brown-Pearce carcinoma. Photomicrograph of tumor. Note abundant mitotic figures (arrows).

last as long as 7 months after injection (Casey, 1934a, 1934b) and provided important support for the general theory of immunologic enhancement of tumor growth developed by Nathan Kaliss. Kaliss, in a review of this evidence, emphasized the conditions required for maximal expression of immunologic enhancement and the dependency of the phenomenon on late-appearing immunoglobulin G (IgG) antibody (Kaliss, 1969).

Even before it was realized that the XYZ factor(s) was an immunogen of the tumor, it was generally recognized that there were other immunologic consequences of transplantation. Saline extracts of the tumor contain antigens that fixed complement when mixed with sera from rabbits bearing the tumor (Appel and Strauss, 1942; Cheever, 1940; Ellerbrook et al., 1952; Friedewald

and Kidd, 1945; Jacobs and Houghton, 1941; Kidd, 1938). Rabbits implanted with the tumor developed antibodies that were either tumor-specific or donor-specific, or both, depending on the genetic background of the recipient. Blue Cross and Chocolate Dutch rabbits formed antibodies only against the tumor-specific antigens, and other breeds, if they produced antibody at all, produced both types (MacKenzie, 1945). It has been generally concluded that the Brown-Pearce carcinoma contains antigens different from those of normal tissues. The antigen is probably a ribonucleoprotein (MacKenzie, 1945) and located on tumor cell microsomes (Kidd, 1946b). Certain methods of antigen extraction (e.g., methanol precipitation) preferentially favor release of tumor-specific antigens (Zilber, 1958). Tumor-specific antibodies inhibit culture of the tumor in vitro (Kidd, 1944, 1946a). Despite this extensive early work performed with this model, research use has decreased substantially and from 1990 to 2009 there have only been less than five publications describing the use of the Brown-Pearce carcinoma.

GREENE MELANOMA

In an initial report, Greene (1958) described a spontaneous melanoma from the pigmented flank organ of a 2.5-year-old Syrian golden hamster (*Mesocricetus auratus*). The tumor was transplantable to homologous hosts and heterologously to DBA mice and guinea pigs, but not to rabbits. In certain recipients melanomas developed with amelanotic foci, whereas other developed foci that appeared sarcomatous. This feature led Greene to consider the tumor to be a carcinosarcoma in which the sarcomatous elements were thought to arise from neoplastic transformation of the stroma of the primary melanocarcinoma.

Further study of the tumor revealed that metastatic foci from primary subcutaneous melanomas (or from intravenous injection of tumor suspensions) arose in the lung and were invariably melanotic (Greene and Harvey, 1966). On the other hand, tumor suspensions injected into the left heart, or aorta, produced tumor foci that were partially or completely amelanotic. Subsequent transplants of an amelanotic tumor line were transplantable as xenografts to additional hosts, including the rabbit.

The tumor has been a useful model in the rabbit for studying the physiology and treatment of ophthalmic tumors, including human ophthalmic melanomas. Literature references to animal "uveal melanoma" or "choroidal melanoma" refer, in fact, to the Greene melanoma (Panagopoulos et al., 1989; Swift et al., 1990). More recently, a refined model for ocular tumors using Greene melanoma was described using immunosuppressive agent, cyclosporine (de Waard-Siebinga et al., 1994).

The only experimental melanoma successfully implanted in the rabbit eye without immunosuppression

is the Greene melanoma (Hu et al., 1994), which makes it a good model for immunotherapy studies. The limitations of this model in ophthalmic tumor research include its lack of melanin pigments as well as the clinical course, which is different from human uveal melanomas (Romer et al., 1992). To fill this gap, highly melanotic tumor cells of mouse (B16F10 cells) (Hu et al., 1994; Pineda et al., 1998) and human (Lopez-Velasco et al., 2005; Maloney et al., 2009; Marshall et al., 2007) origin are used more often.

OTHER TRANSPLANTABLE TUMORS

A transplantable squamous cell carcinoma cell line, named "RSCC-1" was recently reported by Wulong et al. (2008). The cell line was established from tongue tumors of epithelial origin, which had been induced in New Zealand White rabbits by topical application of dimethyl benzanthracene (DMBA) and repeated mechanical stimulation of the site. The resulting tumors were harvested and serially passaged into additional NZW rabbits. The tumor take rate reached 100% in rabbits after 70 passages, and was also 100% successful when implanted in immunodeficient mice. The cells transplanted to the lateral margin of tongue of ten rabbits grew to solid nodules adhered tightly to lingual mucosa within 1 week. Later stages demonstrated cervical lymph node metastasis in 50% of animals as well as lung metastasis in 20% of animals. No spontaneous regression was noted in any animals bearing this tumor.

Oncogenic Studies

Virally Induced Tumors

NATURALLY OCCURRING

Certain Pox and Papova group of viruses, especially cottontail rabbit papillomavirus (CRPV) (Breitburd et al., 1997; Govan et al., 2008), rabbit oral papilloma virus (ROPV) (Wilgenburg et al., 2005) and Shope fibroma have played an important role in furthering the understanding of viral oncogenesis as a basic biological process. The rabbit has been used as a model for study of human papilloma viruses (HPV). Recombinant mutants of cottontail rabbit papilloma virus (CRPV) harboring the E6 or E7 genes from IIPV induced papillomas in rabbit hosts. By this means, Brandsma (2005) demonstrated that the E7 gene of HPV is required for induction of papillomas. It has been observed that among commonly known oncogenic papilloma model systems including canine and bovine papillomas, only ROPV had a tissue tropism and a life cycle organization that resembled those of the human mucosal papilloma types (Peh et al., 2002). ROPV and CRPV and the lesions they induce have been among the most intensively investigated in the entire field of viral oncogenesis. Early concepts of viral oncogenesis in mammalian species

were formed on the basis of experimentation with these tumors and they still remain as important models of viral tumorigenesis, and the concept of coevolution between host and virus was generated largely from investigations employing these viruses. The natural history, host range, epizootiology, virology, pathology, and immunology of the viruses are reviewed in Chapter 9. Additional reviews with important bibliographical resources include the monographs by Fenner (1965), Gross (1970), and Moulton (1990) and the texts edited by Dalton and Haguénau (1962) and Stewart et al. (1959). All of the viruses (with the exceptions of hare fibroma and oral papilloma viruses), namely, myxomatosis, Shope fibroma viruses, Shope papilloma virus, the herpesvirus lymphoma of Hinze, and the Dos Santos hepatoma, have been discovered in and limited in natural distribution to the American continents.

Malignant rabbit fibroma virus (MV) is a poxvirus related to the Shope fibroma virus and the Moses strain of rabbit myxoma virus. Rabbits receiving intradermal inoculation with MV developed a primary tumor at the site of inoculation, with subsequent rapid development of secondary tumors in the extremities including the ears, nose, and feet. The tumors were malignant and resembled myosarcomas. The rabbit developed a profound virus-associated immunosuppression and succumbed to secondary opportunistic infections by commensal Gram-negative organisms within 12–14 days after inoculation. The immunosuppression affected both B and T lymphocytes. This has been touted as a model for AIDS in man (Strayer, 1985).

EXPERIMENTALLY INDUCED MODELS

Models of rabbit lymphoma have been induced by inoculation with oncogenic viruses from various species of animals. A rabbit model for adult human T-cell leukemia was developed in 1990 by Isono. The model was produced by inoculation of B/J X Chbb:HM rabbit F1 hybrids with a transformed T-cell line maintained in culture. The cell line was established from peripheral blood lymphocytes of an F1 hybrid infected with human T-cell leukemia virus 1 (HTLV-1). This HTLV-1 transformed cell line, 647a, is leukemogenic in newborn F1 rabbits, with a median lethal dose of 10^7 cells. The animal model closely resembles the human disease in the development of leukocytosis associated with leukemic infiltration of the major organs. The cell line was used to reproducibly supply leukemia rabbits for exploration of treatment modalities, for example, zidovudine (AZT) (Isono et al., 1990). In the early 1990s Hayashi and Simpson reported the induction of lymphomas in rabbits after the inoculation of HTLV-1 producing leukocyte cell lines. A confounding factor was that DNA analysis of the resulting rabbit lymphomas did not show any integration of the HTLV genome. Although it has been shown that the

HTLV-1 virus consistently infects rabbits, the majority of animals are asymptomatic for clinical disease and do not develop neoplasia. However, these models are useful for the study of viral transmission and vaccination (Akagi et al., 1985; Lairmore et al., 2005). There have been some reports of production of an “ATL-like” disease in rabbits following intraperitoneal or intravenous inoculation of HTLV-1 transformed cells, but the studies did not conclusively demonstrate whether the leukemia cells were from the inoculums or generated de novo (Ogawa et al., 1989; Seto et al., 1988; Zhao et al., 1993). There have been sporadic reports of neoplasia occurring in HTLV-1-infected rabbits. Zhao et al. (2002) reported the occurrence of a thymoma 5.5 years after inoculation with an HTLV type 1 molecular clone. In this case, an HTLV-1 provirus was demonstrated in thymocytes and thymic epithelium. A second rabbit in the study developed an endometrial carcinoma 2.5 years after inoculation.

Further study by Hayashi and Akagi (2000) demonstrated that the HTLV-1 producing cell line was also producing an EBV-like gamma herpesvirus which was later shown to be the causative agent of the lymphomas. A significant amount of work has now been done to establish rabbits as a model of Epstein-Barr-virus-associated diseases in man. Epstein-Barr virus (EBV) is one of several human herpesviruses and is a member of gamma herpesvirus family (lymphocryptovirus). EBV is closely linked with the development of human neoplasms including Burkitt's lymphoma, nasopharyngeal carcinoma, oral hairy leukoplakia in AIDS patients, and a number of other cancers, but no firm causal relationship has been established to date. Work by several laboratories showed the macaque herpesviruses caused lymphoma or lymphoproliferative diseases in domestic rabbits. In a study by Yakovleva et al. (1987), six of six young gray rabbits developed generalized lymphoma following inoculation with *Macaca arctoides* peripheral lymphocyte cell cultures producing B-lymphotropic herpesvirus and C-type retroviruses. Yakovleva concluded that the lymphoma development was related to co-inoculation of the EBV-like herpesvirus (HVMA) and the C-type retrovirus similar to HTLV1. Subsequent studies by Timanovskaia et al. (1988) and Wutzler et al. (1995) were conducted in which rabbits of various breeds were inoculated with Herpesvirus of *Macaca arctoides* (HVMA) from either HVMA-producing cell lines or cell-free virus. Around the same time, a study was performed by Medveczky et al. (1989) in which New Zealand White rabbits were inoculated with Herpesvirus saimiri. In these three studies, inoculation of various breeds of rabbits with these different primate herpesviruses induced generalized lymphoma with multiple organ infiltration. Wutzler (1995) showed definitely that the development of malignant lymphoma in New Zealand White, black, and gray rabbits was caused

by the HVMA virus by demonstrating that the disease occurred in animals that were directly inoculated with the virus rather than the virus-producing cell line. In that study, 17 of 32 rabbits infected with HVMA derived from the simian cell line MAL-1 developed lymphoproliferative disease; 13 developed malignant lymphoma and four developed lymphoid hyperplasia. Wutzler demonstrated the expression of EBER-like transcripts and HVMA-DNA in the lymphoma cells. This model was reported to be a suitable animal model for studying antiviral drugs and vaccines against EBV.

Hayashi and Akagi (2000) reported a rabbit model of EBV-associated lymphomagenesis in the rabbit created by inoculation of EBV-like viruses from macaques. Malignant T cell lymphomas developed in 80–90% of the rabbits 2–5 months following either intravenous infection or peroral spray of EBVs from cynomolgus monkeys (Si-IIA-EBV or Cyno-EBV). This rabbit model of Herpesvirus-induced lymphoma and lymphoproliferative disease has been used to study the oncogenesis of herpesviruses and the efficacy of drug therapy. These models are good models for fatal lymphoproliferative disease seen in fatal infectious mononucleosis/X-linked lymphoproliferative disease and EBV-pos T cell lymphoma. This rabbit model offers a good substitute for monkeys for studying the biology and pathogenesis of EBV, and can be used to study the mechanism of the oropharyngeal route of infection.

A rabbit model of T-cell lymphoma was produced by inoculating New Zealand White rabbits intravenously with primate T cells that were infected with a naturally occurring herpesvirus (HV-MNE) or by direct IV inoculation of cell-free virus. HV-MNE is novel Epstein-Barr-like virus that was isolated from a pig tailed macaque (*Macaca nemestrina*) that was diagnosed with a T cell mycosis fungoides-T cell lymphoma. Eight of 14 rabbits developed T cell lymphoma with lymphocytic infiltrates in spleen, liver, lungs, kidney, heart, lymph nodes, thymus, skin, and subcutaneous tissues. Viral sequences from lymphomatous tissue were detected by PCR; therefore this is a valuable model for studying the genetic determinants of T-cell transformation by this EBV-like primate virus (Ferrari et al., 2001).

Hemophagocytic syndrome (HPS) is a syndrome seen in human Epstein-Barr-virus-associated disease in man. HPS is a systemic lymphohistiocytic proliferative disorder characterized by systemic activation of macrophages to undergo phagocytosis and is characterized by fever, liver dysfunction, coagulopathies, and pancytopenia. Hayashi et al. (2001) described a new model of this disease in rabbits. Rabbits were inoculated with Herpesvirus papio either by intravenous inoculation of virus-producing cells or by peroral spray of cell-free HPV. Rabbits inoculated by either of these routes developed lymphoproliferative disease with hemophagocytic

syndrome. For a further description of these models, the reader should read the two-part review written by Hayashi in 2005 which reviewed the existing models of EBV-associated diseases and their applications (Hayashi, 2005a, 2005b).

The rabbit has also been used as a model for study of human papilloma viruses (HPV). Recombinant mutants of cottontail rabbit papilloma virus (CRPV) harboring the E6 or E7 genes from IIPV induced papillomas in rabbit hosts. By this means, Brandsma (2005) demonstrated that the E7 gene of HPV is required for induction of papillomas.

Malignant rabbit fibroma virus (MV) is a poxvirus related to the Shope fibroma virus and the Moses strain of rabbit myxoma virus. A rabbit receiving intradermal inoculation with MV developed a primary tumor at the site of inoculation, with subsequent rapid development of secondary tumors in the extremities including the ears, nose, and feet. The tumors were malignant and resembled myosarcomas. The rabbit developed a profound virus-associated immunosuppression and succumbed to secondary opportunistic infections by commensal Gram-negative organisms within 12–14 days after inoculation. The immunosuppression affected both B and T lymphocytes. This has been touted as a model for AIDS in man (Strayer et al., 1985).

Chemically Induced

Chemical induction of tumor is a commonly used technique to study various aspects of oncogenesis in rodents. Chemical carcinogenesis is known to activate various oncogenes that are important in the initiation, promotion, and progression of cancer. The laboratory rabbit has received limited attention as a model for exploration of oncogene activation in neoplasia. The chemical compounds that have been used for induction of tumors in rabbits include dimethylbenzanthracene (DMBA) (Corominas et al., 1991; Ghadially, 1958; Wulong et al., 2008), dimethyl nitroso-amine (DNA) (Reznik and Padberg, 1991), and beryllium salts (Barnes et al. 1950; Janes et al., 1954; Tapp, 1969b).

Members of the ras gene family (H-ras, K-ras, and N-ras) are one of the most commonly active oncogenes in human tumors, and are activated in about 26% of human tumors (Corominas et al., 1991). Cellular oncogenes are highly conserved in vertebrate species, and the K-ras-2 locus, which has been characterized in both humans and mice, has been located to the centromere area of the rabbit chromosome 16 by use of the labeled human cDNA probe (Martin-DeLeon and Picciano, 1988). In like manner, Xu and Hardison (1989), have localized the H-ras-1 proto-oncogene onto rabbit chromosome 1 and demonstrated synteny of the Harvey-ras-1 (H-ras-1) gene with those for parathyroid hormone and beta-like globins in a number of mammalian orders,

underscoring the strong conservation of the gene groups in the evolution of chromosomes. There is a marked correlation between the type of ras gene activated and the tissue type affected, with the H-ras gene activated in epithelial tumors and either K-ras or N-ras genes activated in mesenchymal tumors.

Dimethylbenzanthracene-induced keratoacanthomas (KA) and squamous cell carcinomas (SCC) of rabbit ear skin have been employed to investigate activated oncogenes (H-ras) in both developing and regressing KA and metastasizing SCC (Corominas et al., 1991; Leon et al., 1988). Application of DMBA on the inner ear skin of the rabbit causes development of keratoacanthomas, which are benign tumors. Keratoacanthomas induced with DMBA on the ear spontaneously regress after some time, thus the rabbit model is considered useful for investigation of the ras genes because it results in an array of both developing and regressing tumors and thus offers a unique model in which to identify and study oncogenes that are not sufficient to maintain tumor growth. The rabbit tumors were regarded as morphologically and histologically identical to human keratoacanthomas (Ghadially, 1958; Prutkin, 1967; Prutkin and Gerstner, 1966). Corominas et al. (1991) showed that these keratoacanthomas has high genetic similarity to human keratoacanthoma. The DMBA-induced keratoacanthomas show a high frequency of H-ras-activated genes carrying a mutation in codon 61. The same is observed in human keratoacanthomas, although in humans mutations they are in both the 12th and the 61st codons of the H-ras gene. Other benefits of this model include the accessibility of the tissue to chemical carcinogenesis, and the ease of monitoring tumor development.

More recently, DMBA was used to induce tumors on the tongue of New Zealand White rabbits (Wulong et al., 2008). Out of 100 rabbits used for the study, two rabbits developed an aggressive, poorly differentiated, squamous cell carcinoma that was transplantable to other rabbits. The authors also report a transplantable tumor cell line developed from this model, which is discussed elsewhere in this chapter.

The chemical carcinogen diethylnitrosamine (DENA) is a potent carcinogen, and has been used to induce tumors in many species of animals, including rodents, swine, and non-human primates. In a report from a single laboratory (Reznik and Padberg, 1991), rabbits were administered oral DENA three times weekly over 14 months. Eleven rabbits (100%) developed liver tumors by the end of the study; hepatocellular carcinomas were the most common tumor found in ten rabbits, with one rabbit developing hepatocellular adenoma. The hepatocellular carcinomas metastasized to the lungs in 70% of the affected animals. Five of the animals also developed additional primary tumors, including adenomas and carcinomas of the nasal cavity, kidney, and uterus. This

study was done to create a model which allowed study of the clinicopathological changes that occurred during the development of hepatocellular carcinoma. The study was not repeated and no cell line was established from these tumors.

Beryllium salts were found to be highly carcinogenic to rabbits, inducing osteosarcomas (Fodor, 1977; Groth, 1980; Hiruma, 1991; Komitovski, 1971; Mazabraud, 1975). The tumors typically originate from medullary area of the bone. Various refinements of the technique was reported including a single injection to the epiphysis (Mazabraud, 1975) and deposition of hydroxypropylcellulose mixed beryllium oxide pellet into the fracture callus (Hiruma, 1991).

Radiation-Induced Models

There is one report of radiation-induced tumorigenesis in rabbits (Buchholz et al., 1999). One hundred and two female New Zealand White rabbits underwent mandibular radiation treatments with a total dose of 64Gy in 20 treatment fractions. Nineteen percent of the surviving animals developed osteosarcoma. The report suggested that TP53 mutations may have played a major role in development of these tumors.

Genetically Engineered Models

Genetically engineered rabbits were created by Sethupathi et al. (1994) by conjugating c-myc to the Ig k-chain enhancer gene Ek. Eight of 19 progeny from the resulting transgenic line developed a variety of tumors, including four rabbits with lymphoma, one with embryonic nephroma, one with hepatoma, one with ovarian carcinoma, and one with basal cell carcinoma. The lymphomas were of B-lymphoid lineage. Becker et al. (1990) created Emu-myc transgenic rabbits which developed Polyclonal B cell leukemias at 17–20 days of age. Rabbits have also been used as recipients of oncogenes fused with DNA segments that enhance or regulate gene transcription in a tissue-specific manner (Knight et al., 1988). This approach was used to produce transgenic rabbits with the c-myc oncogene fused with DNA for the rabbit immunoglobulin heavy-chain enhancer region (E_H). Single-cell zygotes microinjected with the above construct and implanted into pseudopregnant does developed (in three of 21 cases) malignant lymphocytic (B-cell) leukemia as juveniles. Finally, Peng et al. (1993) developed transgenic rabbits carrying multiple copies of CRPV genomic DNA. The tumor development was restricted only to the skin in these rabbits. CRPV DNA was detectable in all tissues of the transgenic rabbits, however, the transcripts of CRPV genes only were found in skin and skin tumors. It was suggested that extensive methylation of CRPV genome, especially in the URR, might be a factor in controlling its tissue-specific expression (Peng, et al., 1995). Table 16.5 summarizes the experimentally induced tumor models.

TABLE 16.5 Induced Rabbit Tumor Models

Type of Tumor	Reference	Biology	Induction Method
Tongue squamous carcinoma cell line	(Wulong et al., 2008)	Transplantable	Initially developed by local DMBA application
Hepatocellular carcinoma	(Reznik and Padberg, 1991)	Primary and metastasizing	Oral DENA
Bone and cartilage sarcomas	(Sisson, 1950; Kelly et al., 1961; Higgins et al., 1964; Mazabraud, 1975; Hiruma, 1991)	Primary tumor development	Beryllium salts
Keratoacanthoma	(Matesanz et al., 1995)	Benign – self regressing	DMBA – skin application
Keratoacanthomas and squamous carcinoma	(Corominas et al., 1991)	Primary	Diethybenzanthracine on pinna
Splenic and ovarian decidosarcomas	(Janne et al., 2001)	Primary	Estrogen/progestrone
Radiation induced			
Osteosarcoma	(Buchholz et al., 1999)	Primary	Radiation (60Gy total, 19% incidence)
Viral			
Malignant lymphoma	(Koirala et al., 1997; Hayashi, et al., 1994)	Primary and metastasizing	IV or oral spray of cells producing Epstein-Barr-related herpes virus or direct virus
Transplantable neoplasia			
VX2 carcinoma	(Kidd and Rous, 1940; Rous et al., 1952; Chen et al., 2004)	Transplantable	
VX7 carcinomas	(Ito and Evans, 1965; George et al., 1992; Hamaguchi et al., 2003)	Transplantable	
Brown-Pearce carcinoma	(Greene, 1949; Shivas and Gillespie, 1969; Harzmann et al., 1979)	Transplantable tumor of rabbit origin – allograft	Used as tumor model for multiple sites – bladder, liver, and other organs
Choroidal melanoma	(Lopez-Velasco et al., 2005; Hu et al., 1994)	Xenografts – human melanoma cells	Rabbit's immunosuppressed (cyclosporin). Metastasis in two tumor cell types
Transplantable rabbit hepatoma	(Tanaka et al., 1950)		May be transplantable, however, no further reference found
Uveal melanoma	(Blanco et al., 2005)	Xenografts – human uveal melanoma cells	
Extrascleral extension of ocular melanoma	(Pineda et al., 1998)	Surgical technique of extension	B16F10 melanoma cell line
Hamster green melanoma	(Hahn and Spitznas, 1981; Liu and Ni, 1983; Shikishima, 2004)	Xenograft	
Transgenic rabbits with tumor susceptibility			
Lymphoma and other tumors	(Sethupathi et al., 1994)	E kappa-myc transgenic rabbits	Other tumors also seen – hepatoma, ovarian carcinoma, etc.
B-cell leukemia (polyclonal)	(Becker et al., 1990)	Emu-myc transgenic rabbits	
Papillomas and carcinomas	(Peng et al., 1993)	EJ-ras transgenic rabbits with papilloma virus DNA	Mostly skin tumors
Hemangiomas of liver	(Kitajima et al., 2005)	Transgenic – increased VEGF in liver	

Other Tumors of Historical Interest

Rabbit Tumor Necrosis Factor

The serum of rabbits (and a range of laboratory rodents) injected with the BCG strain of *Mycobacterium bovis* (or with other forms, including *Corynebacterium* or *Propionibacterium* species) and then challenged with bacterial lipopolysaccharide (endotoxin) develop a transiently circulating oncolytic factor termed tumor necrosis factor or TNF (Ostrove and Gifford, 1979). The factor has been so designated because TNF will cause hemorrhagic necrosis of certain transplanted solid tumors and is cytotoxic for transformed or tumor cell lines in culture, but not for normal cells. TNF is also inhibitory to a range of viruses and parasites (Gifford and Flick, 1988). A macrophage-derived product, TNF may be classed as a low-molecular-weight protein or cytokine (Ruff and Gifford, 1980). Recombinant murine interferon will serve to prime macrophages, in vivo, for TNF production (Lorence et al., 1990). The inflammatory cytokines include the interleukins (e.g., IL-1, IL2), cachectin, and TNF as a group of closely related factors with profound and diverse biological effects on both host and invading foreign forms (Langstein and Norton, 1991).

The amino acid sequence of rabbit TNF is known (estimated molecular weight 39000), and it is immunologically distinct from mouse TNF (Haranaka et al., 1985). Although the mechanism for oncolysis by TNF is non-immunologic, the actual means is still somewhat uncertain but may relate to the wide spacing between neoplastic cells, compared to more closely packed normal cells (Matthews and Neale, 1989).

Dos Santos Hepatoma

Dos Santos reported 35 fatal cases of hepatoma in a necropsy series of 120 rabbits (*Oryctolagus*) from a breeding colony in Brazil (Dos Santos, 1961). The hepatoma was limited to the liver in ten cases, but metastases were observed in 25 cases, most commonly to the lung. The tumors were more common in the females by a ratio of 1:6. Thirty-two tumors were hepatomas, two were mixtures of hepatic cell and bile duct elements, and one appeared to be a bile duct carcinoma. In ten of the tumors, intranuclear inclusion bodies were observed in hepatoma cells. The latter finding led the author to conclude that the tumors were induced by a virus.

Kato Sarcoma

The older literature contains occasional references to a transmissible tumor discovered as a naturally occurring sarcoma by T. Kato (1925). The tumor, which bears his name, was described as a spindle cell sarcoma with pronounced metastatic properties. The tumor was used in experiments to study the nature of metastasis (Nakano,

1929; Tomozowa, 1931), interaction of the sarcoma with certain endocrine glands (Hayashi, 1930; Maeda, 1930; Murohara, 1930), and several biochemical properties (Mori, 1939a, 1939b). It does not appear in the literature after the reports by Mori, and it is doubtful if the sarcoma has been maintained and is still available.

Andrewes Rabbit Sarcoma

In studies on the generalization of fibromatosis in tar-treated rabbits, Andrewes and Ahlstrom (1938) happened on an unusual occurrence. In one rabbit given two intramuscular injections of tar 4.5 months apart and 15 topical treatments of tar during the intervening period, a tumor developed at the intramuscular tar injection site 7 days following the intravenous injection of OA strain Shope fibroma virus. The tumor was described initially as a transplantable fibroma (Andrewes et al., 1937); however, subsequent changes led to its reclassification as a sarcoma (Andrewes and Ahlstrom, 1938), and the tumor has since come to be known as Andrewes rabbit sarcoma I (RSI). The tumor was passed for 12 transplantation generations in rabbits during the "fibroma phase." During this phase the tumor had the histological characteristics of a typical fibroma: elongated, spindle-shaped cells arranged in bundles and whorls with abundant fibrils. As a rule the tumor grew to an average size of only 20 × 10 × 10 mm, with central necrosis beginning by the fourteenth day.

The tumor, which had begun to fail by the twelfth transplant generation, was "restored" by injection of OA fibroma virus into rabbits with regressing fibromas during the thirteenth passage. During the next five transplant generations (the "sarcoma phase"), the tumor became less differentiated and more cellular, fibrils were less frequent, and mitoses more numerous. The transplanted sarcoma underwent growth in only about one-third of inoculated rabbits, but in them metastasis was not infrequent, occurring most commonly to the inguinal and iliac lymph nodes.

All attempts to demonstrate either fibroma virus (in RSI) or antifibroma antibodies in rabbits bearing RSI fibrosarcomas met with failure. Inclusion bodies typical for fibroma virus were never observed in RSI. Interestingly, several years later (Andrewes, 1940), the sarcoma became infected with Herpesvirus cuniculi (virus III of Rivers and Tillett (1923)). Virus III does not influence the course of RSI transplant growth, although it does abort or ameliorate the course of OA fibroma virus infection, apparently by the process of the interference phenomenon. This finding further strengthened the concept that fibroma virus was no longer detectable in RSI fibrosarcomas. After the 1940 report by Andrewes the tumor does not appear in the literature, and it is assumed that it is now extinct.

Kondrateva Osteogenic Sarcoma

In the earlier section on naturally occurring osteogenic sarcoma, it was mentioned that transplantable bone sarcomas have been reported from the Russian literature. The first of these was described by A.F. Kondrateva in the course of several experiments (Kondrateva, 1958; Kondrateva and Melnikov, 1965). The tumor arose 890 days after a paraffin pellet containing 9,10-dimethyl-1,2-benzanthracene had been inserted into a bone. The tumor was found to be transplantable. By 1958 it was in the fortieth transplantation generation and had an overall transplant success rate of at least 75%.

The tumor typically caused death 30–95 days after transplantation by both extensive local invasion and metastasis. The incidence of pulmonary metastasis was 100% in early transplant generations but became less frequent later. Transplantation of the tumor to bony tissues (virtually 100%) was more successful than that to soft tissues. Similarly, the rate of tumor growth was faster in bony tissues although tumors generally obtained a larger size in soft tissues. Tumor growth (and success of transplantation) was higher in muscle than in liver, and transplantation to testicle or subcutaneous sites was not generally successful. The morphology of the tumor (osteolytic osteosarcoma) was similar irrespective of the host tissue to which it was transplanted (Kondrateva, 1958).

The Kondrateva osteosarcoma has been used to some degree in experimental oncology. It has been exploited as a model for the study of tumor vascularization by making use of the technique of intraosseous phlebography (Kleinman and Chernomordikova, 1964). The intra-arterial

injection of a contrast medium (Diodon) has been reported to exert a marked inhibitory effect on the tumor, culminating in regression and cure (Ivanov and Pavlov, 1963). Several similar tumors including the LOI osteoblastic osteosarcoma and the UzIKEM osteolytic osteosarcoma have been reported in Russian journals and used for a variety of purposes (Karminov and Subkhankulova, 1963). The relation of the LOI and UzIKEM tumors to the Kondrateva osteosarcoma is not certain.

NEOPLASMS OF SYLVILAGUS

Although neoplasms induced by oncogenic DNA viruses have been frequently reported as spontaneous findings in *Sylvilagus* rabbits, reports describing other tumors in cottontail rabbits are rare. Tumors of the former type (Shope fibromas and Shope papillomas and malignant derivatives) are described in further detail in Chapter 1. It is generally believed that neoplasms of all types have a very low incidence in wildlife. Numerous factors contribute to such an observation, but some we may cite include the facts that the rigors of life in the wild are such that rabbits rarely survive into old age; that most animals which die naturally are not available for prosections; that ill and tumor-bearing rabbits are rarely encountered by hunters; and also the *Sylvilagus* rabbits have not been successfully domesticated so as to enable the longitudinal lifetime observation of colonized cottontails. Accordingly, the infrequent reports of neoplasms (of non-viral origin) in *Sylvilagus* rabbits have been summarized in Table 16.6. Additional

TABLE 16.6 Naturally Occurring Tumors of *Sylvilagus*

Organ System	Organ	Tumor Type and Site	No. of Cases	Reference
Urinary tract	Kidney	Embryonal nephroma	1	(Lopushinsky and Fay, 1967)
		Hamartoma	1	(Carlton and Dietz, 1977)
		Renal adenocarcinoma	1	(Carlton and Dietz, 1977)
Lymphoreticular system	Lymph tissue	Generalized lymphoma	6	(Lopushinsky and Fay, 1967)
		Hodgkins'-like lymphoma	1	(Bell and Chalgren, 1943)
Connective tissue	Subcutaneous tissue	Lipoma	1	(Lopushinsky and Fay, 1967)
Other	Cardiovascular	Hemangioendothelioma	1	(Pletcher and Murphy, 1984)

TABLE 16.7 Naturally Occurring Tumors of *Lepus*

Organ System	Organ	Tumor Type and Site	No. of Cases	Reference
REPRODUCTIVE SYSTEM				
Female				
	Uterus	Fibroma	12	(Flux, 1965)
			1	(Jardine et al., 2004)

GI tract				
	Liver	Hemangioma	4	Haberman (cited by Cheatum)
	Liver and mesentery	Mesenchymal tumor (metastatic – primary site not identified)	1	(Jardine et al., 2004)
Respiratory tract				
	Lung	Leiomyosarcoma (metastatic – primary site not identified)	1	(Jardine et al., 2004)

reports may be found in the compilation by [Stedham \(1976\)](#) as well. The bulk of the reported tumors of *Sylvilagus* are lymphomas and renal tumors, neoplasms associated with adolescence in *Oryctolagus* rabbits.

The published description of the embryonal nephroma by [Lopushinsky and Fay \(1967\)](#) was not typical of the same tumor type in *Oryctolagus* rabbits. Although it had not metastasized, the tumor was

extremely large (55g) and had almost completely replaced all normal renal structures in the affected kidney. The descriptions of lymphomas by Lopushinsky and Fay, however, appeared to be similar to those observed in *Oryctolagus*, involving diffuse infiltrative destruction of the liver, spleen, and stomach. The extent of renal involvement was not reported. The lymphoma reported by Bell and Chalgren (1943) was more of a Hodgkin's type with sarcomatous infiltration of cervical, mesenteric, axillary, and cervical lymph nodes, but with sparing of the liver, spleen, and kidney. Histological descriptions and illustration were not provided.

NEOPLASMS OF *LEPUS*

The comments above with reference to the difficulty of case finding and assessment of the true incidence of neoplasms in *Sylvilagus* apply equally to *Lepus* (hares); most observations are obtained in a casual random way from wild populations. Although an insufficient number of cases have been described and reported to enable a confidence profile of the tumors affecting the genus to be outlined, preliminary evidence (Table 16.7) indicates the tumors' distribution in *Lepus* spp. to be similar to that of *Oryctolagus*. This is supported by the retrospective study submitted by Elvestad and Henriques (1985) which categorized cases of leukemic neoplasia submitted as diagnostic necropsy samples to the State Veterinary Diagnostic Laboratory in Denmark from 1934–1984. The samples were submitted from 15 brown hares presumed to be *Lepus europaeus*. The majority of the animals were diagnosed with lymphoma, with lesser numbers exhibiting an accompanying lymphoid leukemia. One important exception is the finding of myeloid leukemia in six separate accessions of *Lepus* rabbits reported from France and Switzerland (see Table 16.5) (Burgisser, 1957; Guillon et al., 1963). The gross pattern of splenomegaly, hepatomegaly, and generalized lymphadenopathy was typical for all six cases. Although no individual was observed prior to death, the infiltration of most major organs and tissues with neoplastic cells typical of the myeloid series suggested a leukemic state.

Another exception includes the ovarian teratomas found in Europe (Goyon, 1959) and Australia (Flux, 1965) by investigators surveying wild *Lepus* populations. This tumor has not been observed in *Oryctolagus* (or *Sylvilagus*). Flux (1965) has suggested that the high incidence of ovarian cysts and teratomas in wild hares may be attributed to the proximity of the animals to agricultural insecticides (e.g., DDT).

INTRODUCTION

This chapter discusses those disorders and diseases of the rabbit that are not readily classified into the other chapters. Much of the initial information for this chapter was obtained from chapters in earlier volumes in the American College of Laboratory Animal Medicine series (Bergdall and Dysko, 1994; Lindsey and Fox, 1994). With regard to the genetic diseases of rabbits discussed throughout this chapter (and also in previous texts), some may have “disappeared” through loss of breeding stock or discontinuation of the inbred strain in which the mutation was seen. The authors endeavored to include only those inherited diseases of significance that might be seen in existing outbred colonies or in inbred strains that were still maintained at one or more global locations. We acknowledge that some disorders noted in previous editions may have been omitted accidentally, and that some mutation/strain combinations may have been included that are no longer in existence.

MYCOTIC DISEASES

Superficial Mycoses

Dermatophytoses (ringworm, favus) are uncommonly encountered in the domestic rabbit. The disorders are comparatively rare under laboratory conditions or in commercial rabbitries with satisfactory hygienic standards. Under these conditions, dermatophytoses are most often encountered as individual infections of a sporadic nature, although epizootics have been reported (Banks and Clarkson, 1967; Cohrs et al., 1958; Hagen, 1969). Most reports indicate that younger or immunosuppressed rabbits are most susceptible.

Ringworm is caused by infection of the epidermis and adnexal structures such as hair follicles and hair shafts with pathogenic dermatophytic fungi. *Trichophyton mentagrophytes* is the dermatophyte most commonly encountered in ringworm infections of both *Oryctolagus* (Banks and Clarkson, 1967; Hagen and Gorham, 1972; Saito et al., 2001; Van Rooij et al., 2006), and wild lagomorphs (Adams et al., 1959; Gallo et al., 2005). Infections with other species of dermatophytes, such as *Microsporum canis*, *M. gypseum*, *M. cookei*, *T. terrestre*, and *T. ajelloi* have also been documented (Gallo et al., 2005). The latter four fungal species are geophilic and not as commonly isolated. In a sampling of *Sylvilagus* sp., seasonal variation in the prevalence of geophilic fungi was identified and assumed to be due to environmental effects on fungal survival. Environmental contamination is a significant risk factor for spread of clinical dermatophytosis within a population, as well as to other species occupying the area. With regard to pet rabbits, lesions have been

detected on both the rabbit and the owner (Van Rooij et al., 2006).

Dermatophytic infections usually arise on or about the head in rabbits. The lesions are pruritic and may secondarily spread to the feet, especially the toenail beds, and to other areas of the body. The lesions usually appear as areas of patchy alopecia, erythema, and crustiness with an underlying inflammatory reaction. Hyperkeratosis, acanthosis, and diffuse infiltration of the dermis with polymorphonuclear leukocytes are observed histologically. Lymphocytes and plasma cells are also present in the dermis and adnexal structures. Abscessation of hair follicles by secondarily invading bacteria is common. Mycotic elements can be identified with Gridley fungus stain, the periodic acid-Schiff (PAS) reaction, or Gomori methanamine silver stain.

Diagnosis of dermatophytosis involves differentiation from other causes of crusty alopecia of the head and ears. Incidental lesions such as genetic hairlessness, trauma, hair clipping or depilatory hair loss, and fur pulling should be ruled out by obtaining a thorough history. Routine dermatophyte tests such as hair/skin scrapings mounted in 10% potassium hydroxide, Wood's light (ultraviolet) illumination, and culture on a suitable dermatophyte media should be performed. Reliance cannot be placed on culture alone to substantiate a diagnosis of dermatophytosis because rabbits have been shown to be asymptomatic carriers of dermatophytic fungi (Balsari et al., 1981; Franklin et al., 1991). Substantiation of the diagnosis must include histological evidence of epithelial invasion by the fungus. The use of polymerase chain reaction – restriction fragment length polymorphism (PCR-RFLP) for diagnosis has been successfully used for the rapid identification of *T. mentagrophytes* from clinical specimens (Arabatzis et al., 2006). In this report, one of the sexual forms of *T. mentagrophytes*, *Arthroderma vanbreuseghemii*, was identified as the cause of dermatophytosis in several commercial rabbitries. It was proposed that PCR-RFLP might be useful in epidemiological investigations of outbreaks since there is some evidence to support species-specificity associated with different teleomorph forms of *T. mentagrophytes* (Summerbell et al., 2002).

Treatment of dermatophytosis involves isolation of infected animals owing to the zoonotic hazard. Untreated cases should be euthanized and the immediate environment disinfected. Enilconazole is reported to be effective for environmental decontamination when used in a spray or fogger application (Rochette et al., 2003). Experimentally induced rabbit dermatophytosis (*T. mentagrophytes*, *M. gypseum*, and *M. canis*) responded well to orally administered griseofulvin (25 mg/kg in aqueous suspension by gastric intubation) once daily for 14 days (Hagen 1969). Colonies may be mass treated by providing a ration containing 0.375 g of powdered

griseofulvin per pound of feed for 14 days (Hagen, 1969). Other treatments suggested for colony outbreaks included topical azole antifungals such as enilconazole (Rochette et al., 2003), or a 1:10 dilution of a MECA spray (metastabilized chlorous acid/chlorine dioxide), twice weekly for 3–4 weeks using about 8 ounces per rabbit at each application (Franklin et al., 1991). In most cases, euthanasia of infected laboratory rabbits is the most prudent approach due to the potential for spread and the research side effects associated with treatment. The development of vaccines shows promise as another potential treatment option for dermatophytosis (Chermette et al., 2008).

Deep Mycoses

Rabbit species of all genera appear to be remarkably resistant to deep or systemic mycotic infections (Schwartz, 1954). Only two naturally occurring mycoses seem to be significant: aspergillosis of the domestic rabbit and adiaspiromycosis of several wild lagomorph species. Isolated case reports of other deep mycotic infections have been published (Barrington, 1921; Soerensen and Saliba, 1961; Turn and Eveleth, 1954).

Clinical aspergillosis is primarily of historical significance as a disease of *Oryctolagus* rabbits (Blount, 1957; Cohrs et al., 1958; Dumas, 1953; Lesbouyries, 1963; Seifried, 1937), particularly as the standards of husbandry have advanced. *Aspergillus fumigatus* had been the primary species isolated, but *A. niger* and *A. flavus* were also associated with clinical cases. The course of the disease is commonly chronic in nature with gradual onset of cachexia and dyspnea as the chief clinical findings. The disease has also been observed as a subclinical problem in young rabbits (less than 5 weeks of age) obtained from a commercial rabbitry (Matsui et al., 1985).

Lesions of aspergillosis are typically confined to the lungs. Focal caseous necrosis is the primary lesion; cases must be differentiated from tuberculosis and necrobacillosis (Schmorl's disease). Diagnosis is established by histopathological demonstration of the organism and is confirmed by cultural isolation of *Aspergillus*. The disease in rabbits is similar in most pertinent details to avian infections (Chute, 1972).

Adiaspiromycosis (haplomycosis) is caused by fungi of the genus *Emmonsia* (*Haplosporangium*). Two species, *E. parva* and *E. crescens*, are distributed worldwide and recognized as important agents of feral animal infections. Adiaspiromycosis has been described as a natural infection in a domestic rabbit (Dvorak et al., 1966). *Emmonsia* spp. have been encountered principally in the western United States as pathogens of wild rodents, carnivores, and lagomorphs of the genera *Sylvilagus* and *Ochotona*. Naturally occurring infections appear to be benign and generally confined to the lungs (Jellison, 1970).

Cultures of *Emmonsia* on artificial media grow as typical fungi with profuse spore production. *Emmonsia parva* isolates produce spores of 10–40 µm in diameter, whereas *E. crescens* spores are unusually large at 250–500 µm. The large spores (adiaspores) correspond to the form found in infected tissues. Jellison (1970) provides a more thorough discussion of the disease.

Pneumocystosis

Pneumocystis species are well-recognized opportunistic pathogens infecting the lungs of many animals. This genus of fungi has been investigated using molecular genotyping techniques and strong host specificity has been identified among *Pneumocystis* isolates. The isolate which infects rabbits is *Pneumocystis oryctolagi* sp. nov., and it does not appear to cross to other species (Dei-Cas et al., 2006).

Clinical signs occur in weanling rabbits and consist of respiratory distress with complete recovery in 3–4 weeks. *P. oryctolagi* sp. nov. has been isolated from diverse geographical areas and rabbit breeds, indicating that this agent has been well adapted to the rabbit for a relatively long time.

Diagnosis of the agent can be made using nasal lavage with sterile saline followed by PCR, or via histopathology at necropsy. Special stains such as toluidine blue O can be used to identify the organisms lining the alveolar epithelium. One unique feature of this disease in rabbits is the lack of foamy eosinophilic honeycomb material in the alveoli on histopathologic analysis, a common finding of *Pneumocystis* infection in other species. Because rabbits are infected and develop clinical signs without the use of corticosterone for immunosuppression, they represent an important natural animal model for investigations of pneumocystosis (Dei-Cas et al., 2006).

NON-INFECTIOUS DISEASES

Ocular

Buphthalmia

Buphthalmia (synonyms: hydrophthalmia, congenital or infantile glaucoma) is recognized as one of the most common inherited diseases of contemporary domestic rabbits. Although information on frequency of occurrence in various breeds is generally lacking, the condition is regularly seen in some New Zealand White stocks bred for laboratory purposes (Hanna et al., 1962). The term buphthalmia is of Greek origin and literally means "ox eye." Originally used as a descriptive term for enlargement of the eye, buphthalmia has become the accepted term for this particular disease of rabbits.

Buphthalmia has been observed in rabbits of many stocks around the world (Aurichio and Wistrand, 1959; Greaves and Perkins, 1951; Hanna et al., 1962; Pichler, 1910; Rochon-Duvigneaud, 1921; Schloesser, 1886; Smith, 1944; Vogt, 1919). Grossly visible abnormalities of the eye may appear as early as 2 or 3 weeks of age, but most appear much later. Initially, one may see an increased anterior chamber size with either a clear cornea or a slight cloudiness and very delicate bluish tint to the cornea. Subsequent changes include progressive opacity and flattening of the cornea, increased prominence of the ocular globe, and conjunctivitis. Corneal ulceration may develop, and ultimately result in traumatic rupture of the cornea with scarring and vascularization. General health, appetite, and libido are reported to be reduced (Geri, 1954; Nachtsheim, 1973).

The development of buphthalmia in rabbits seems to be related to abnormalities in production and removal of aqueous humor from the anterior chamber, as in congenital glaucoma of humans. Evidence suggests that affected rabbits have an abnormal trabecular meshwork and may develop chronically increased intraocular pressures as early as 3 months of age (Burrows et al., 1995; Gelatt et al., 1998; Ueno et al., 1999). Because of the similarities in development of the disorder, buphthalmic rabbits serve as a useful experimental model of human congenital glaucoma. A major difference, however, is that the scleral coat of the rabbit is less mature (more elastic) at the onset of increasing pressures, thus permitting the globe of the eye to enlarge (i.e., buphthalmia).

Buphthalmia is inherited as an autosomal recessive trait (*bu/bu*). It has been suggested that this mutation and resulting loss of appropriate gene function perturbs differentiation of the trabecular meshwork, resulting in the buphthalmic phenotype (Knepper et al., 1997). Unfortunately, attempts to completely characterize the effects of the *bu* gene have met with variable results. There appears to be incomplete penetrance of this gene, as clinical disease appears in some but not all homozygotes. The eye lesions may be unilateral or bilateral. Age of onset of recognizable disease is extremely variable, as is true of several physiological parameters associated with production and removal of fluid from the anterior chamber of the eye. The variable age of onset may account for some of the incomplete penetrance. In general, however, there is demonstrable decrease in outflow of aqueous humor from the anterior chamber of the eye by 3 months of age and an increase in intraocular pressure by 5 months of age (Fox et al., 1969; Kolker et al., 1963; McMaster, 1960; McMaster and Macri 1967). Even at birth there is reported to be an underdevelopment or absence of outflow channels in the ciliary body and sclera (Hanna et al., 1962). As the disease progresses, there is widening and even complete loss of the drainage angle, thickening of Descemet's membrane, increased

corneal diameter, increased vascularity and opacity of the cornea, atrophy of the ciliary processes, glaucomatous excavation of the optic disk, and possible atrophy of the optic nerve (as a secondary effect). Striking differences in cytological features and turnover rate of corneal epithelial cells have been observed in buphthalmic rabbits as compared to unaffected ones (Babino and Fox, 1967; Fox and Babino, 1965; Sheppard and Shanklin, 1968; Sheppard et al., 1971).

Fox et al. (1969) obtained suggestive evidence that buphthalmic males have reduced spermatogenesis. Administration of ascorbic acid has been reported to have no effect on buphthalmic rabbits although it apparently facilitates outflow of anterior chamber fluid in normal rabbits (Noah and Geeraets, 1971). Lam et al. (1989) suggested that the deposition of fibrin in the trabecular tissue contributes to the obstruction of aqueous humor drainage in hereditary buphthalmic rabbits. Glucose metabolism in buphthalmic animals is probably normal; however, buphthalmic rabbits have been shown to be significantly more resistant to insulin shock than normal controls (Fox et al., 1971b).

As already mentioned, incomplete penetrance is an important factor in the inconsistent clinical presentation of buphthalmia. Another possible reason that fewer than the expected number of buphthalmics are produced may involve losses in utero. Hanna et al. (1962) found that larger litters (≥ 6) yielded fewer than predicted buphthalmic littermates when compared to smaller litters (≤ 5), which had affected offspring at the calculated rate of incidence.

Specific treatment for buphthalmia has not been described for rabbits; however affected animals should not be used for breeding purposes (Suckow et al., 2002).

Aberrant Conjunctival Stricture (*Pseudopterygium*)

Pterygium, a condition that occurs in humans, is a limbal-based, triangular fold of conjunctival membrane that protrudes onto the cornea. Generally, it is a progressive lesion that advances to the pupillary area. True pterygium adheres closely to the cornea resulting in invasion of the corneal stroma and destruction of Bowman's membrane. Its growth is due primarily to the proliferation of connective tissue fibroblasts.

A similar condition in rabbits has been reported repeatedly throughout the literature. It has been referred to by numerous terms including pseudopterygium, epicorneal conjunctival membrane occlusion, conjunctival centripetalization, membranous occlusion of the cornea, and aberrant conjunctival stricture (Allgoewer et al., 2008; Arnbjer, 1979; Dupont et al., 1995; Roze et al., 2001). Consistently the lesion is described as a membrane that originates from the bulbar and limbal conjunctiva. Though similar, it is a different entity to pterygium in humans. It does not have the triangular shape as seen in

humans, but progresses centripetally and symmetrically across the cornea towards the pupil. Most significantly, it does not alter, nor is it adhered to the underlying cornea (Allgoewer et al., 2008; Roze et al., 2001). Clinically, visual impairment occurs as the membrane moves towards the central aperture.

The pathogenesis and etiology of this condition have not yet been elucidated. There is an increased incidence in young, male dwarf and pygmy rabbits. Though originally thought to be a congenital condition, it has presented in both adult and juvenile animals (Allgoewer et al., 2008). Causative factors in humans have included infection, ultraviolet (UV) radiation, and microtrauma. Histologically, the lesion in the rabbit is described as a focal excess and dysplasia of conjunctival collagen. This is consistent with a type of collagen nevus that has been described as a cutaneous lesion in both humans and dogs. These nevi are thought to be secondary to decreased collagenase production and increased fibroblast proliferation, but the mechanism and inciting factor is unknown (Roze et al., 2001). Treatment in the rabbit consists of removing and preventing the obstruction. Arnbrjer (1979) discussed two cases of pseudopterygium in the pygmy rabbit (*Brachylagus idahoensis*). One case was successfully treated by detachment of the conjunctival tissue with a blunt instrument, subconjunctival injection of methylprednisolone acetate, and a 3-week course of a topical steroid/antibiotic ophthalmic solution. The other case received only topical antibiotics after pseudopterygium detachment and the condition recurred within a few weeks.

Roze et al. (2001) described four cases in dwarf rabbits where the abnormal conjunctival fold was excised at the limbus. Follow-up treatment with 0.1% topical dexamethasone was provided for two of the four animals and recurrence was noted 3 and 4 weeks post-operatively. The remaining two rabbits received topical dexamethasone and topical 0.2% cyclosporine ointment. At 3 months post-operatively there was no recurrence. Based on this study, it was concluded that there may be local immunity factors involved in the pathogenesis as suggested by the efficacy of the cyclosporine.

Most recently, Allgoewer et al. (2008) reported a centrifugal surgical technique that provided efficacious long-term resolution. This technique included six radial incisions of the conjunctival fold with fixation via sutures to the eyelids. There were no incidences of recurrence following six cases (ten eyes) where this technique was utilized.

Corneal Dystrophy

True corneal dystrophies differ from other corneal disorders in that they are non-inflammatory, typically bilateral, and involve the central cornea. They are also unassociated with any systemic disease, such

as hyperlipidemia, and primarily involve a single corneal layer with other layers only secondarily involved (Moore et al., 1987). Two reports of variants of corneal dystrophy in domestic rabbits have appeared in the literature.

Port and Dodd (1983) described a unilateral epithelial dystrophy in two New Zealand White rabbits. The lesion appeared as an opaque membranous ring originating at the limbus and extending towards the center of the cornea. Histologically, the membrane was an irregular accumulation of corneal epithelial cells, interspersed with a pathologically thin epithelium. No inflammation was present, and the center of the cornea was normal, as were the other component structures of the eye. The authors refuted the possibility of trauma or chemical injury as a cause of the lesion.

Moore et al. (1987) described primary anterior corneal dystrophy in members of a colony of American Dutch belted rabbits. In these cases, the corneal opacities were irregularly shaped lesions in the superficial layers of one or both corneas. The lesions were found to be caused by thickened and irregular sections of the corneal basement membrane, with occasional disorganization and detachment of the basal epithelium. Genetic involvement was suspected, based on the breeding records of the colony. The authors postulated about the usefulness of the animals as a model of anterior corneal dystrophies in humans.

Band Keratopathy

Band keratopathy, a degenerative disease of the human cornea, is characterized by the deposition of calcium salts in the subepithelial corneal stroma. The first description of the disease in rabbits was in a colony which had received an intraocular injection of albumin to produce experimental uveitis (Economon et al., 1963). In addition to the uveitis, which was produced intentionally, the rabbits also had calcium deposits in several visceral organs. The metastatic calcification was presumed to have been caused by an accidental hypervitaminosis D as the result of an error in feed formulation. Band keratopathy was observed only in rabbits that had both uveitis and hypervitaminosis D. Rabbits with either condition alone did not develop band keratopathy. The development of the corneal disease, therefore, appeared to depend on the concomitant hypercalcemia.

Doughman et al. (1969) described two models for the production of band keratopathy. The first model reproduced conditions similar to those that occurred in the case report by Economon et al. (1963): creation of immunologic uveitis following vitamin D intoxication. Band keratopathy developed 100% of the time under these conditions. The authors found, however, that this model did not feature hypercalcemia (as proposed by Economon et al., 1963) and that the deposition of

calcium in the cornea was best explained by the theory of calciphylaxis. Calciphylaxis was defined as “a condition of induced systemic hypersensitivity (vitamin D intoxication) in which tissues respond to appropriate challenging agent (uveitis) with local calcification.” It was proposed that the uveitis might alkalinize the cornea, altering metabolism to promote calcium deposition. The second model involved the development of band keratopathy in 35% of the eyes injected with polyethylene sulfonate.

Lipid Keratopathy

Lipid keratopathy is characterized by intracellular or extracellular lipid deposition within the cornea, iris, and ciliary body. This disease has been reported in both humans and animals as a sequela of hyperlipidemia and hypercholesterolemia. Rabbits do not have an effective mechanism for processing excess cholesterol and thus have been utilized as an animal model for hypercholesterolemia (Kruth, 1987; Terpstra et al., 1981). Due to the ease and severity with which rabbits can be rendered hypercholesterolemic, this species has been also been targeted as a model for studying the pathogenesis of lipid keratopathy.

Diet-induced corneal lipidosis has been reported in New Zealand White (NZW) rabbits. In one publication (Sebesteny et al., 1985) this ocular lesion was noted in rabbits that were accidentally fed a fishmeal diet; affected rabbits also had elevations in their serum cholesterol and atheromatosis. Once the fishmeal diet was replaced with a standard vegetarian diet, the presence of these lesions in the colony resolved. In other reports (Reddy et al., 1987; Roth et al., 1988; Stock et al., 1985), the lesions were created intentionally utilizing a high-cholesterol diet in conjunction with corneal suture placement. In these studies, rabbits that were fed a high-cholesterol diet, but did not have corneal suture placement, developed the lipid keratopathy more slowly, and the lipid deposition only occurred circumferentially at the corneal limbus. This indicated that for the NZW rabbit model for lipid keratopathy, combination with a corneal neovascularization stimulant (suture) promoted more significant lipid deposition than did diet alone.

The pathogenesis of experimentally induced lipid keratopathy involves an increased intracellular uptake of LDL and cholesterol esters within the stromal keratocytes, pericytes, and endothelial cells. Cell death occurs when the intracellular lipid metabolic mechanisms of these cells are overwhelmed. The lipid and protein debris then enters the corneal stroma. This debris is phagocytosed by macrophages, thus creating the characteristic “foamy” cells that are seen histologically (Roth et al., 1988).

The Watanabe heritable hyperlipidemic (WHHL) rabbit is commonly utilized as a model of human

FIGURE 17.1 Eye of a WHHL rabbit with circumferential lipid keratopathy at the margin of the cornea and sclera. This rabbit also has a detached retina. Courtesy of The Ohio State University.

familial hypercholesterolemia. Homozygous WHHL rabbits have a genetic deficiency of low-density lipoprotein (LDL) receptors and as a result develop high serum cholesterol levels and atherosclerotic plaques. Additionally, these animals have been reported to develop a lipid keratopathy without either surgical or dietary intervention (Figures 17.1 and 17.2). Garibaldi and Pecquet Goad (1988) describe a lipid keratopathy in these animals as a pearly corneal opacity comprised histologically of lipid laden, or “foamy,” macrophages. Kouchi et al. (2006) described the corneal opacities as yellowish-white lesions predominantly found along the corneoscleral junction. No ophthalmoscopic lesions of the fundus or retina have been reported; however, histopathologically clusters of “foamy” cells and crystalline clefts were present in the choroid and sclera in association with blood vessels (Figures 17.3 and 17.4). In WHHL rabbits with severe and prolonged hyperlipidemia, retinal involvement, including complete bullous retinal detachment, has been observed (Figures 17.1 and 17.3) (L. Gallagher, personal observation, 2007).

Cataracts

Historically, at least two types of inherited cataracts have been reported in rabbits. Nachtsheim and Gürich (1939) described one type (gene symbol *Cat-1*) that was transmitted as a simple recessive allele. Slight bilateral dullness was present in the posterior wall of the lens at birth and subsequently progressed to complete opacity of the lens by 5–9 weeks of age. The rate of progression was slower if animals were fed dry diets as opposed to foods with high water content. A second type of hereditary cataract (gene symbol *Cat-2*) was described by Ehling (1957); it was considered an incomplete dominant trait with 40–60% penetrance. In contrast to the *Cat-1* version of cataract, the *Cat-2* form was often unilateral in occurrence.

In addition to the reports above, [Munger et al. \(2002\)](#) and [Jeong et al. \(2005\)](#) described spontaneous cataract formation in New Zealand White (NZW) and New Zealand White–New Zealand Red (NZW × NZR) hybrid rabbits that was consistent with an autosomal recessive inheritance. In their study, [Munger et al. \(2002\)](#) demonstrated a higher incidence of cataracts in NZW than in the NZW × NZR rabbits, further supporting this mode of inheritance. Additional studies are needed to fully characterize this condition and its potential similarity to the condition previously described by [Nachtsheim and Gürich \(1939\)](#).

Skeletal Diseases

Hydrocephalus

Hydrocephalus is generally considered a hereditary disease in most species; although it has been

well-documented that hydrocephalus is also caused in rabbits by both vitamin A deficiency and toxicity (see below). [Nachtsheim \(1939\)](#) studied a family of rabbits in which hydrocephalus segregated as an autosomal recessive trait (*hy*), and was frequently associated with dwarfing (*nan*) and brachygnathia. A second, probably different, inherited hydrocephalus was observed by [Rosa \(1946\)](#) to behave as an autosomal trait with incomplete dominance. In those rabbits, hydrocephalus was commonly associated with several anomalies including anophthalmia, microphthalmia, ectopia of the eyeball, coloboma of the iris and choroid, and cataracts. Unfortunately, the studies of [Nachtsheim \(1939\)](#) and [Rosa \(1946\)](#) were based mainly on detection of cases of hydrocephalus by gross examinations. As such, their analyses would have been unable to detect mild cases that survived and appeared clinically normal. Cases of hydrocephalus without a clear pattern of inheritance are known to occur sporadically in many contemporary stocks ([Sawin, 1955](#)).

Whether abnormal vitamin A metabolism was a factor in any of the above examples remains unknown, although [Greene \(1965\)](#) described a form of hydrocephalus in rabbits apparently based on an inherited defect in vitamin A metabolism. However, it has been well established that both vitamin A deficiency ([Harrington and Newberne, 1970](#); [Lamming et al., 1954](#)) and toxicity ([Cheeke et al., 1984](#)) in pregnant does regularly produces hydrocephalic young. Vitamin A is required for maintenance of pregnancy in rabbits, and deficiency results in abortion, fetal resorption, neonatal death, and small, weak litters ([Cheeke, 1987, 1994](#)). Interestingly, the same reproductive effects, including the development of hydrocephalus, are seen with vitamin A toxicity.

Rabbits appear to be especially sensitive to high levels of this vitamin. Cheeke et al. (1984) observed the reported reproductive complications and hydrocephalic young with a diet containing 191 180 IU per kg feed; Scott et al. (1982) reported the toxicity of vitamin A (as retinol and its esters) in "animals" to be greater than 1 million IU per kg feed. Hydrocephalus is rarely seen in laboratory colonies now due to the production of high-quality commercially available feed, but as with all nutritionally based diseases, it could recur due to accidental errors in diet formulation.

Mandibular Prognathism

Mandibular prognathism (synonyms: malocclusion, underbite, walrus teeth, buck teeth) is probably the most common of the known inherited diseases in the rabbit. Few laboratory or commercial breeding stocks are free of the problem. The term mandibular prognathism refers to an abnormally long mandible relative to the length of the maxilla. However, in rabbits the primary defect is actually a short maxilla in relation to a mandible of normal length, so the common name is actually a misnomer. Both conditions are known to occur in humans (Rubbrecht, 1939), dogs, and sheep (Nordby et al., 1945).

Mandibular prognathism in rabbits is somewhat unique because of peculiarities of the dentition in this species. Rabbits have open-rooted adult teeth which continuously grow, and are one of only five species classified as full elodonts (Legendre, 2002). The dental formula for the normal rabbit is I 2/1, C 0/0, PM 3/2, M 3/3 (Craigie, 1960). There is a single pair of large chisel-shaped lower incisors. The upper incisors consist of a similar pair of large primary incisors and a pair of smaller secondary incisors, also called *peg teeth*, positioned directly behind the primary incisors. Normally, the lower incisors occlude behind the primary upper incisors and against secondary incisors, which protrude only slightly beyond the gingiva. The lower incisors wear at approximately right angles to the secondary incisors, and the primary upper incisors wear along the arc followed by the lower incisors. This is due in part to the fact that the enamel layer in the rabbit incisor tooth is not distributed evenly around the tooth. The anterior edge has the heaviest layer of enamel, progressing to little, if any, enamel on the posterior surface (Weisbroth, 1973). Thus, a sharp cutting edge is present at the labial surface of the lower and primary upper incisors. The primary upper incisors curve posteriorly and laterally, whereas the lower incisors grow in an anteromedial direction. Between the incisors and first premolars (where canine teeth would normally be located) is a toothless space known as the diastema. The premolars and molars meet evenly to form a flat occlusal surface (Fox and Crary, 1971; Weisbroth and Ehrman, 1967).

The large incisors of the rabbit grow throughout life at average rates of about 2.0 and 2.4 mm per week for upper and lower incisors, respectively. On an annual basis this is approximately four inches for each upper incisor and five inches for each lower incisor (Shadle, 1936). Optimal occlusion of incisors is critical for counterbalancing the rapid extrusive growth with normal attrition. Absence of good occlusion from any cause quickly leads to overgrowth of incisors and/or cheek teeth in the rabbit. Clinically significant malocclusions may result from a variety of hereditary and environmental causes.

In the rabbit with hereditary mandibular prognathism (*mp/mp*), malocclusion of incisors is usually first observed after the third week of life. Initially there is an edge-to-edge bite of the incisors with resultant blunting of the cutting edges; this eventually progresses to positioning of the lower incisors anterior to the upper ones. In accordance with the usual planes of growth, the primary incisors tend to curl within the mouth, whereas the lower incisors grow anteriorly to protrude from the mouth. The upper incisors may pierce the gingival or buccal mucosa, leading to ulceration and/or abscess formation. Impaired closure of the mouth also interferes with normal attrition of molars and premolars. If the incisors are not trimmed, an affected animal will have difficulty eating and may die of inanition.

Fox and Crary (1971) reported evidence of autosomal recessive inheritance of mandibular prognathism with incomplete (81%) penetrance. Affected animals were also found to have reduced length measurements for the skull and maxillary diastema, without significant deviation from normal length of mandibles. Thus a postulated genetic mechanism involves a gene (*mp*) causing differential growth of dorsal and basal skull bones, with resultant anterior displacement of the mandible. The condition in rabbits has been compared to class III malocclusion, a similar abnormality in humans (Nepola, 1969).

Mandibular prognathism with attendant malocclusion of incisors should be distinguished from the condition involving malocclusion of premolars and molars, which has been reported in a few older rabbits (Ireson, 1968; Pollock, 1951; Zeman and Fielder, 1969). It has been speculated however that the latter condition may also have a genetic basis.

Absence of Second Upper Incisors

The absence of the second upper incisors (peg teeth) has been reported (Crossley, 2003; Nachtsheim, 1938, 1958) in domestic rabbits and occasionally in wild specimens. There are no known ill effects associated with this phenotype. Affected animals develop small rudimentary structures that resemble teeth, but in most instances disappear very shortly thereafter. The absence of the second

upper incisors described by Nachtsheim was considered to be a dominant trait, however other cases indicate that there may be multiple modes of inheritance (Crossley, 2003).

Scoliosis and Torticollis

Scoliosis is a term meaning lateral curvature of the spine. Serious investigations of scoliosis are very few. In the limited rabbit studies to date it is considered familial and perhaps polygenic in inheritance. Anatomically, the findings in affected rabbits have included missing, reduced, or extra half-vertebral units and bifurcations or fusions of ribs. Depending on the breed of rabbit in which the anomaly occurs, vertebrae in either the cervicothoracic, thoracic, or lumbar regions of the spine may be deformed (Sawin and Crary, 1955, 1964).

Torticollis, also called wryneck, is a term that refers to twisting of the neck with associated abnormal positioning or carriage of the head. It generally implies an etiology involving muscular, neurological, or inner ear disease. Although the term has been applied frequently to diseased rabbits in the past, little is known about the underlying etiology. However, torticollis has been associated with *Pasteurella multocida* infection of the middle ear (Fox et al., 1971e), and *Encephalitozoon cuniculi* infections (Valencakova et al., 2008). Thus, there is a distinction between the clinical sign of torticollis, which occurs secondary to disease processes, and the anatomic condition of scoliosis caused by vertebral defects as described above.

Traumatic Vertebral Fracture

Posterior paralysis as a consequence of mechanical damage to the spinal cord following vertebral fracture or dislocation occurs commonly in the domestic rabbit (Roe and Stiff, 1962; Templeton, 1946). This seems to be a result of the attachment of powerful hindlimb muscles to a relatively light and fragile skeleton (Harkness and Wagner, 1989); the skeleton of the rabbit is approximately 7–8% of the body weight, as compared to 12–13% for cats (GeoChemBio, 2011). The injury may be referred to as broken back, paralysis of the hindquarters, spinal fracture, or traumatic vertebral dislocation. Onset is generally acute and coincides with struggling or inadequate hindquarter support when animals are handled. The heavy hindquarters can twist about the lumbosacral junction when improperly supported; this acts as a fulcrum, applying leverage to the vertebral column. Often the incident is not immediately observed (or recognized), and the rabbit is later found paralyzed in the cage. The L7 vertebral body or its caudal articular processes are considered to be the most frequent sites of such fractures, with fractures of these vertebrae more common than dislocation (Flatt et al., 1974). Of ten paralyzed rabbits with survey radiographs taken

at the University of Michigan between 1986 and 1990, only two had fractures of L7, specifically one compression fracture and one transverse fracture of the vertebral body. Three rabbits had compression fractures of L6, one had a transverse fracture of L6, and four rabbits had no detectable skeletal lesions. A transverse fracture of L6, resulting in posterior paralysis, was previously reported by Jones et al. (1982).

Diagnosis may be established on clinical criteria and confirmed by radiography. Clinical criteria include complete or partial rear limb paralysis and loss of sensory innervations. If the cord is completely severed (paraplegia), motor control of the anal sphincter and urinary bladder is lost as well. This condition results in urine retention and bladder distention, followed by clinical signs of uremia if the bladder is not expressed frequently. It is important, therefore, to distinguish overflow urination from normal micturition. Other common findings include staining of the perineum with liquid feces, owing to the loss of anal sphincter function, and decubitus ulcers. Serious cases that affect urination and defecation should be considered for euthanasia if no improvement in condition is observed after several days.

Frequently, however, the signs of spinal cord injury are related to transient edema at the site of trauma if the fractured bone ends do not become displaced. Corticosteroid and diuretic therapy may be initiated for the treatment of spinal edema, if warranted (De Lahunta, 1985). Over the course of 1–2 weeks, resolution of spinal shock may result in return of locomotor function such that the rabbit can independently move about the cage. Euthanasia need not be considered in cases where control over the urinary bladder and anal sphincter remains unimpaired and where partial to complete motor recovery follow an observation period of 2 weeks. Frequently an episode of spinal fracture with substantial recovery may be recognized months or years later as hyperflexion of the sacrum.

Splay Leg

The term “splay leg” is the descriptive name commonly applied to rabbits that lack the ability to adduct one or more legs and come to a standing position. Affected animals assume the typical splay leg appearance when ventrally recumbent and, at best, are able to move horizontally for only short distances by making weak, clumsy leg movements. In more severe cases all legs may be completely non-functional. Affected animals usually appear mentally alert. Although use of the term suggests a specific disease, “splay leg” is actually the leading clinical manifestation of several independent disease entities of rabbits, including the mutants syringamelia (*sy/sy*), hypoplasia pelvis (*hyp/hyp*), femoral luxation (*lu/lu*), and hereditary distal foreleg curvature (*fc/fc*).

Innes and O'Steen (1957), who studied ten cases in rabbits of the New Zealand White and Dutch breeds, advanced the idea that splay leg is a recessively inherited achondroplasia with pathological effects restricted to the hip and shoulder joints. Partial and complete dislocations were regarded as late sequelae. In contrast, Arendar and Milch (1966) studied 30 cases from a strain of inbred lop rabbits and found that the primary pathological defect was anteversion (forward tipping) of the femoral neck. This was sometimes secondarily associated with subtrochanteric torsion of the femoral shaft. As a consequence of both processes, the femoral heads projected from the anterior rather than medial surfaces of the femoral shafts. Rabbits with these femoral malformations consistently had subluxation of the hip joint; complete dislocation was observed only once. Arendar and Milch also considered the disease in their rabbits to be a recessive trait. Pedigree analysis and genetic mating tests by Joosten et al. (1981) showed that, in contrast to previous reports, splay leg is not determined by a single recessive gene with complete expressivity. They state that the underlying genetic mechanism is composed either of one recessive gene with reduced expressivity or of multiple genes with the probable involvement of environmental factors.

A possible environmental component to the clinical condition of splay leg was suggested by Owiny et al. (2001). The authors noted the development of hip dysplasia (coxofemoral luxation) in 2–4-week-old Dutch-belted rabbits born as part of a reproductive toxicology study. The incidence of the problem was significantly influenced by the type of flooring on which the rabbits were raised; non-slippery flooring during the post-natal period was associated with reduced hip dysplasia and splay leg-associated pathology in the young rabbits.

Splay leg remains a descriptive clinical term without clearly established pathological meaning(s). Further systematic investigation of the problem is needed.

Hereditary Distal Foreleg Curvature

Pearce (1960a) described a deformity of the forelegs in rabbits of the Beveren, Belgian, French silver, and Dutch breeds. Beginning at 2–3 weeks of age, the forelegs were observed to bow inwardly while the paws deviated laterally in a seal-like manner. The condition usually reached full expression by 2–3 months of age. There was marked widening of the distal epiphysis in each ulna. Histologically, this epiphysis showed retarded calcification and an abundance of osteoid tissue. The abnormally wide plate of cartilage usually diminished in thickness by about 2.5 months of age and became histologically normal by about 4 months of age. The forelegs remained permanently deformed by the inward bowing of radii and ulnae and the lateral deviation of the paws. Bones of the carpal joints and paws were considered normal.

Pearce (1960b) described the effects of a single autosomal recessive gene, which at least strongly predisposed the rabbits to the foreleg deformity. However, a similar condition is recognized among rabbit breeders when young rabbits are raised on smooth surfaces, such as when a doe persistently removes bedding from the hutch. Some of these affected rabbits have been observed to “return to normal” when transferred to cages with wire floors (Lindsey and Fox, 1994). The relationship of such cases to the mutation described by Pearce is not clear, and the overall contributions of environment versus genetic predisposition have not been discerned.

Dwarfism

Pituitary dwarfism, the earliest reported form of dwarfism in the rabbit, has been noted in both the United States (Greene, 1940; Greene et al., 1934) and Europe (Kröning, 1939; Nachtsheim, 1973; Schnecke, 1941). The American (gene symbol *Dw*) and European (gene symbol *nan*) mutations appear to be similar, and may well be the same mutation occurring in different stocks.

Both were originally reported as autosomal recessive mutations symbolized by *dw* and *nan*, respectively. The homozygous animals are typically unable to nurse and die within a few days of birth, although some have survived for longer. Because the mutation came to be considered an incomplete dominant lethal or semi-lethal, the mutant symbol was changed from *dw* to *Dw* (Latimer and Sawin, 1955; Sawin, 1955). The birth weight and adult body size of heterozygous animals are approximately one-third that of unaffected littermates (Castle and Sawin, 1941; Latimer and Sawin, 1955).

The affected animals are perfectly proportioned miniatures, with the exception of shortened ears and a disproportionately large central nervous system (CNS) (Castle and Sawin, 1941; Latimer and Sawin, 1955). Thus, the animals have bulging foreheads and protuberant eyes, and the skulls of those surviving more than 2 or 3 days have numerous large foramina (Sawin and Crary, 1964). Cause of death is attributable to either the CNS lesions or to hydronephrosis, which also develops in many of these animals.

Another dwarf mutation was observed in 1957 at the Institute of Human Genetics at the University of Münster (Germany). It was described by Degenhardt (1960) as a single autosomal recessive gene and designated *zw*. Hydrocephaly was observed as a common occurrence with the *zw* gene. The animals had features similar to the *Dw* and *nan* mutations and may well be another variant of the same gene.

Osteopetrosis

The autosomal recessive mutation osteopetrosis was discovered in a Dutch stock of rabbits and extensively studied by Pearce and Brown (1948) and Pearce (1948,

1950). This same line, later designated as the OS strain, was maintained at the Jackson Laboratory.

At birth affected animals are normal in appearance except for slightly reduced body size and abnormalities of the teeth. The incisors, particularly the uppers, are retarded in development, abnormally shaped, and usually rudimentary in appearance. One or all incisors may be completely absent. At necropsy changes similar to those in incisors are observed in molars. At birth, radiographs reveal a marked increase in density of the skeleton with practically no internal detail in bones throughout the body. For the first 2–3 weeks of life affected rabbits grow at a rate only slightly less than normal. Thereafter, growth ceases, and animals become cachectic, have diarrheal stools, and usually die at about 4 or 5 weeks of age.

The outstanding anatomic findings are persistence of spongy bone and failure to form normal marrow cavities. Marrow cavities that do form are filled with undifferentiated mesenchymal tissue (Walker and Fox, 1973). The spongy bone is composed of bony trabeculae having an irregular arrangement and variable staining. Although little compact bone is present, the bones are harder and more brittle than normal. Only sparse hematopoietic tissue ever appears in the bones, and despite the persistence of centers of extramedullary hematopoiesis in other tissues, such as liver and spleen, there is progressive macrocytic anemia with thrombocytopenia.

Pearce (1948, 1950) also observed that osteopetrotic rabbits had enlarged parathyroids and suggested that this finding was in some way related to the cause of the disease. Affected animals initially had normal serum calcium levels, which declined with age. Serum phosphorus levels were low initially but slightly exceeded normal values by the fourth week of age. These and other findings in osteopetrotic rabbits bear a close similarity to osteopetrosis seen in humans (synonyms include marble bone disease and Albers-Schönberg disease) and the gray lethal mutation of mice (Bateman, 1954). Familial osteopetrosis also has been reported in calves (Leipold et al., 1970). Although definitive evidence is not available except for the mouse (Marks and Walker, 1969), it seems extremely probable that all these diseases eventually will be explained by a defect(s) in parathormone and/or thyrocalcitonin regulation of bone metabolism.

Popoff et al. (1989) used osteopetrotic mutant rabbits to study the effects of calcitriol on elevated serum values of 1,25-(OH)₂ vitamin D (which are detected in some osteopetrotic children and animal models) and osteoclast-mediated bone resorption. Calcitriol was able to increase the osteoclast populations in both normal and osteopetrotic rabbits, but increased bone resorption and improvement of skeletal sclerosis were not observed.

Integumentary

Moist Dermatitis

Moist dermatitis is a chronic progressive disease of the skin that occurs with sporadic distribution (Casady et al., 1971; Pollock, 1951; Templeton, 1962; Vail and McKenny, 1943). The disease is also known as slobbers, ptyalism, and wet dewlap. It is thought that the dermatosis resulting from chronic wetness of the chin, intermandibular space, and cervical ventrum predisposes these sites to secondary bacterial tissue invasion. The condition can also present on other areas of the body if chronic wetness occurs (Garibaldi et al., 1990). Predisposing factors include drooling as a result of chronic dental diseases (especially malocclusion), drinking from crocks or water pans which cause continual wetting of the skin, presence of cold, damp contact bedding, and general unsanitary environmental conditions. Caging with ledges that retain water or sipper tubes that leak may also contribute to the problem.

A variety of bacterial species can invade chronically wet skin, and as the dermatitis progresses, gross pathological features consist of inflammation, partial alopecia, ulceration, and necrosis of the affected dermis. Microscopic examination demonstrates irregular patches of ulceration, coagulative necrosis, abscessation, and colonization of the dermal layers with bacteria. Cellular elements of both acute and chronic inflammation are found in the tissues surrounding the ulceration. Lymphatic and hematogenous extension may occur, especially to the ventral cervical and pulmonary lymph nodes. It has been suggested that Schmorl's disease (necrobacillosis) represents a special variant of moist dermatitis with more extensive invasion and tissue destruction.

Unless the bacterial invasion has become systemic, the prognosis for individual cases of moist dermatitis is good if treated. Treatment consists of eliminating the cause of chronic wetting, clipping the affected area, and scrubbing with a surgical scrub. A topical broad-spectrum antibiotic should be applied daily for a 10–14-day course. If the infection appears extensive, a course of systemic antibiotics should be administered as well.

Ulcerative Pododermatitis

Traumatic ulcerative dermatitis of the plantar surface of the metatarsal region, and less commonly the volar surface of the metacarpal-phalangeal region, is commonly referred to as sore hocks. The name "sore hocks" is actually a misnomer since the affected area is most commonly the metatarsus, not the hock (tibio-tarsal area). The condition is caused by pressure necrosis of the skin, usually resulting from the bearing of heavy body weight on wire-bottom cages (Ostler, 1961). Immature rabbits and rabbits of smaller breeds are seldom affected (Templeton, 1962; Vail and McKenny, 1943). Wet cage

floors, especially from urine-soaked feces, may predispose to development of pododermatitis (Ostler, 1961; Schwartz and Shook, 1928; Templeton, 1962; Vaida, 1959; Vail and McKenny, 1943), but it can also occur despite excellent sanitation practices. Other predisposing factors include excessive thumping, thin plantar fur pads (Harkness, 1987), and certain forms of wire crimp in the floor.

The lesions consist of circumscribed ulcerated areas in the skin covered by a dry, crusty scab. Secondary bacterial dermatitis adjacent to the ulcers and abscessation under the crusty debris sometimes occurs. *Staphylococcus aureus* is a common cause of such bacterial abscesses. Affected rabbits may appear healthy in every regard except for the lesions described; however, anorexia, weight loss, humping of the back, stilted movements, and death (Vaida, 1959) have been described in association with this condition. Frequent shifting of body weight from limb to limb has also been observed (Templeton, 1962; Vail and McKenny, 1943). Lesions of the front feet are thought to be a result of the shifting of weight from sore hind feet to the front feet.

Use of solid-bottom cages with frequently changed soft bedding or placement of resting boards in wire-bottom cages have been used to treat ulcerative pododermatitis. These approaches minimize trauma to the affected limbs and allow healing to proceed. Resting boards tend to prevent feces from falling through the cage floor, however, and thus can increase the problem of ensuring adequate sanitation. Topical use of zinc and iodine ointments and 0.1% solution of aluminum acetate have been described, and topical antibiotics are occasionally used. If abscesses are present they should be drained and systemic antibiotics administered.

Pulmonary and Cardiovascular

Pulmonary Emphysema

Naturally occurring pulmonary emphysema in rabbits was first reported by Strawbridge (1960a). The disease was initially observed in rabbits which were control animals for a study on the experimental induction of emphysema by the intravenous injection of a particulate dye. More than 50% of rabbits over 2½ years old were found to have spontaneous generalized pulmonary emphysema. The histological lesions were characterized by fenestrations of the alveolar wall which progressed to alveolar wall atrophy or destruction. Young rabbits given the particulate dye had similar lesions, and the author suspected that ischemic atrophy of the alveolar walls was the cause of the emphysema (Strawbridge, 1960b). An electron microscopy study of the alveolar walls in naturally affected rabbits supported the contention of an ischemic pathogenesis, as affected tissue

had a loss of papillary endothelium, partial or complete filling of capillaries with collagen, and recanalization of some damaged capillaries (Boatman and Martin, 1965). Strawbridge (1960a) proposed that spontaneous pulmonary emphysema in the rabbit could serve as a model for the human disease. This has apparently not been the case however, as an extensive literature search identified only chemically induced rabbit models of pulmonary emphysema. Further study of the spontaneous condition in rabbits has not been reported, and so it appears either that the cases were a unique circumstance, or that the practical significance of pulmonary emphysema in rabbits is minimal.

Hypertension

Inherited strain differences in blood pressure have been observed in rabbits (Fox et al., 1969). A population of hypertensive rabbits has been developed by selection (Alexander et al., 1954), with a high percentage of the progeny in subsequent generations also having hypertension (Alexander et al., 1956). Direct arterial pressure measurements in the selected population of hypertensive rabbits showed the mean systolic blood pressure to be 30 mmHg higher than normotensive stock rabbits. The hypertensive rabbits also had larger Traube-Hering waves than did normotensive rabbits (Alexander et al., 1956). A review of the literature (Schlager, 1972) suggests that the heritability of this condition in various laboratory animal species is in the order of 20%.

Aortic Arteriosclerosis

Spontaneous arteriosclerosis of the aorta in rabbits was first described by Israel in 1881, and many additional reports have been subsequently published (Bragdon, 1952; Kesten, 1935; Levin and Larkin, 1910; Maegraith and Carleton, 1939; Miles, 1907). Although the exact cause of the arterial lesion remains obscure, there is ample evidence that genetic factors play an important role in its expression. Lesions have been observed in practically all domestic breeds and even in wild rabbits. However, among the breeds there are distinct differences in incidence. The Dutch breed in the United States (Gaman et al., 1967) and the "Danish Country" strain of albino rabbit in Europe (Garbarsch et al., 1970) have low (10%) incidences of aortic arteriosclerosis, but incidences of 40% or greater are common in many contemporary breeds including laboratory stocks of the New Zealand White breed (Gaman et al., 1967). Diseased aortas have been observed as early as 6 weeks of age. It has been suggested that the early lesions also may have a non-genetic basis, as induction has been attributed to one or more factors in milk from some does rather than to the genotype of the young (Feigenbaum and Gaman, 1967).

In the typical case, lesions can occur in all major arteries but predominate in the ascending aorta and

aortic arch (Schenk et al., 1966). Grossly, the appearance of the intimal surface is quite variable, with longitudinal striations and furrows, raised plaques with or without central depressions, intimal nodules, or an admixture of the above. Schenk et al. (1966) characterized the lesions into two categories: type A lesions were nodular, located in the inner one-third to one-half of the media, and primarily consisted of fragmentation and disruption of the elastic lamina with the intercellular accumulation of acid mucopolysaccharide. Type B lesions affected the outer one-half of the media, and featured massive calcification and focal areas of cartilaginous metaplasia. The type B lesion was usually seen throughout the length of the aorta and in advanced cases gave the aortic wall an egg shell consistency. This extensive mineralization results in what appears to be an equivalent of Mönckeberg's medial sclerosis in humans. These lesions in the rabbit are free of lipid substances such as those occurring in human atherosclerosis (Feigenbaum and Gaman, 1967; Haust and Geer, 1970; Haust and More, 1965; Schenk et al., 1966) and the hyperlipidemic rabbit mentioned later in this chapter (Watanabe et al., 1985).

Many questions remain unanswered about the specificity of the anatomic lesions seen in so-called aortic arteriosclerosis of rabbits. For example, the lesions in this disease and vitamin D toxicity are remarkably similar, raising the question of dietary factors in aortic arteriosclerosis. The need for clear delineation of etiologies and types of vascular lesions in the rabbit is further supported by the sizable number of instances in which naturally occurring arteriosclerotic lesions of rabbits reportedly have been erroneously interpreted to be the result of experimental procedures (Gaman et al., 1967).

Blood and Vascular Mutants

ATROPINE ESTERASES ($Est-2^F/Est-2^F$; $Est-2^F/Est-2^{f1}$; $Est-2^{f1}/Est-2^{f1}$)

Some rabbits have a circulating atropine esterase that is capable of hydrolyzing atropine and other tropine esters (Glick, 1940; Glick and Glaubach, 1941; Lévy and Michel, 1938), thus explaining the astonishing reports going back to the mid-19th century that rabbits can thrive on belladonna leaves (Kalow, 1968). The presence of serum atropine esterase is controlled by a semidominant gene, $Est-2^F$, which was originally designated as *As* (Sawin and Glick, 1943; Zutphen, 1974b). Three genotypes are recognizable: $Est-2^F/Est-2^F$ with a high level of enzyme; $Est-2^F/Est-2^{f1}$ with a reduced level of enzyme; and $Est-2^{f1}/Est-2^{f1}$ in which the enzyme is absent (Lévy, 1946; Sawin and Glick, 1943). The actual absence of the enzyme in homozygous recessive animals, rather than the presence of an inactive enzyme, has been supported by failure to demonstrate an immunologically related

protein in sera of such rabbits (Margolis and Feigelson, 1964). In animals homozygous or heterozygous for the $Est-2^F$ gene, the enzyme first appears in the serum at about 1 month of age, and it occurs at higher levels in females than males. Atropine esterase is linked with the gene *E* for extension of black pigment in the coat (Fox and Zutphen, 1979; Sawin and Glick, 1943).

There are no known harmful effects of an absence of serum atropine esterase on the health of rabbits. However, the presence or absence of the enzyme makes a significant difference in the response to the administration of atropine for pharmacotherapeutic purposes, regardless of whether it is given by injection or applied topically to the eye (Werner, 1965). The rabbit has been studied extensively to provide information on the classification of esterase enzyme systems and on the genetic and phenotypic variations associated with atropine esterase and cocaine esterase (van Zutphen, 1972, 1974a, 1974b; van Zutphen and den Bieman, 1975; van Zutphen et al., 1977).

PELGER (Pg/Pg) AND SUPER-PELGER (Pg/Pg)

In 1928, Dutch physician Karel Pelger noted two patients who had leukocytes with much reduced nuclear segmentation. Later, G.J. Huët disproved Pelger's mistaken idea that this was associated with tuberculosis and showed that the abnormality was inherited in humans as an autosomal dominant trait. Subsequently, the condition has been referred to as either the Pelger or Pelger-Huët anomaly and has been recognized as an inherited trait in many animals including rabbits, dogs, and mice (Nachtsheim, 1958). In humans the disorder is caused by a mutation in the lamin B receptor (LBR) on the nuclear membrane (Hoffmann et al., 2002).

In rabbits (Robinson, 1958) and humans (Hoffmann et al., 2002) the condition is now recognized to be a partial dominant, i.e., heterozygotes have an intermediate phenotype between those seen with homozygous dominant or recessive genotypes. The Pelger anomaly is fairly well known in rabbits because of studies by the Swiss hematologist Undritz on a single stock of animals established in 1939 (Nachtsheim, 1950). The heterozygotes (Pg/pg), designated as "Pelgers," are normal except that the nuclei of their neutrophils have a reduced number of lobes (usually one or two, possibly three). In the homozygotes (Pg/Pg), referred to as "super-Pelgers," all leukocytes have round, hyperchromatic nuclei which actually appear pyknotic with usual stains. Because of fetal death, only about 18% of theoretically expected super-Pelgers are born, and most of these die during or shortly after birth. Super-Pelgers are smaller than normal at birth due to a marked reduction in the length of long bones. When placed in an upright position, these rabbits rest on their sternums with the forelimbs extending laterally; the deformed limbs

can only make paddling movements. Very rarely do super-Pelgers live to maturity. One super-Pelger buck survived to be used successfully in breeding trials, which helped to confirm the pattern of partial dominant inheritance in the rabbit.

The skeletal abnormality of the super-Pelger is considered a chondrodystrophy. This is particularly noticeable in the ribs, which are reported to be thickened at the costochondral junction. The rib deformity is considered to be responsible for death from asphyxiation in most live-born super-Pelgers. In older animals the epiphyses remain thickened, and often there is fusion of the radius and ulna.

LYMPHOSARCOMA (*LS/LS*)

In general lymphosarcoma has been considered rare in rabbits (Van Kampen, 1969), however it was found to be a common occurrence in strain WH rabbits (Fox et al., 1970a, 1970b, 1971c) with a reported pattern of transmission as an autosomal recessive gene (*ls*), compatible with concepts of both genetic susceptibility to the neoplasm and vertical transmission of a virus.

The disease manifests at an average age of 8 months (range: 2–27.5 months) with the appearance of anorexia, lethargy, and weight loss. Most affected animals die between 5–13 months of age. Terminally, there is severe anemia, with total erythrocytes (RBCs) as low as 2×10^6 and hematocrit as low as 10%. Hematological examination of rabbits with lymphosarcoma reveals an essentially aleukemic picture. Even though the total white blood cells (WBCs) are only 2000–10000/mm³, a shift in cell types is observed, with 80% or more being lymphoblasts. The lymph nodes are increased in size and have a preponderance of lymphoblasts. Advanced cases often have elevated blood urea nitrogen levels coinciding with occurrence of massive infiltration of malignant lymphoid cells into the kidneys. Other anatomic findings include lymphomatous infiltrates in Peyer's patches, liver, and spleen, and sometimes in adrenal glands, gonads, and thymus. The bone marrow from such animals is similar to that in the Hodgkins-type sarcoma observed in humans (Meier and Fox, 1973). Rabbit lymphoma is described in further detail in the chapter on neoplastic diseases of the rabbit.

HEMOLYTIC ANEMIA (*HA/HA*)

Fox et al. (1970a, 1971d) and Meier and Fox (1973) have reported a hereditary hemolytic anemia occurring in the X strain of rabbits at the Jackson Laboratory. Approximately 60 cases were observed in the stock over a period of years. Pedigree analysis suggested autosomal recessive inheritance, and the gene symbol *ha* was assigned.

Clinically, the disease was characterized by anemia with Coomb's-positive red blood cells (RBCs),

hemoglobinemia, petechial hemorrhages on mucous membranes, and weakness, with death generally occurring between 4 and 5 months of age. Severe icterus was seen in some rabbits. The peripheral blood was characterized by reduced hematocrit, polychromatophilia, anisocytosis, increased nucleated RBCs, and lymphocytosis. Necropsy findings included icterus, visceral hemorrhages, hemoglobinuria, swelling of kidneys, and subcutaneous edema. Histologically there was widespread erythrophagocytosis, edema, and accumulated iron pigment in visceral organs. Some animals also had visceral lymphadenopathy and thymoma. No lesions suggestive of glomerulonephritis or arteritis were observed.

It is particularly interesting that the X strain of rabbits with hemolytic anemia shares a common ancestry with the WH strain known to develop lymphosarcoma (*ls*). Indeed, *ha* and *ls* might be a single gene, with the ascribed lesions merely representing different phenotypic expressions (Fox et al., 1971c). Both lesions are of interest because of analogies to such diseases as systemic lupus erythematosus of humans and dogs, various lesions occurring in NZB mice, and hemolytic anemias of other species.

C3 HYPOCOMPLEMENTEMIA (*C3^L/C3^L*)

Serum levels of complement component 3 in a colony of New Zealand White rabbits were separable into three distinct groups: C3 hypocomplementemia (*C3^L/C3^L*), C3 intermediate (*C3^H/C3^L*), and C3 normal (*C3^H/C3^H*) (Komatsu et al., 1988). The hypocomplementemic rabbits (*C3^L/C3^L*) had reduced serum C3 concentrations (6–12% of normal), hemolytic C3 activities (8–13% of normal), and total complement hemolytic activities (27–37% of normal). The C3 hypocomplementemia was transmitted as an autosomal dominant trait with a gene dosage effect. Hypocomplementemic rabbits had reduced survival, with sera showing reduced bactericidal activity.

C6 DEFICIENCY (*C6^D/C6^D*; *C6^N/C6^D*)

Deficiency of the sixth complement component has been recognized in three stocks of rabbits from Freiburg, Germany (Rother et al., 1966), Mexico (Biro and Garcia, 1965), and the United Kingdom (Lachmann, 1970). Thus, they presumably represent three different mutations that may be closely related genetically. The Freiburg and Mexico strains and crosses between the two have been studied most. Homozygous C6-deficient (*C6^D/C6^D*) animals lack detectable C6 antigen in the serum, and heterozygotes (*C6^N/C6^D*) have serum levels approximately half that of normal (*C6^N/C6^N*) animals (Tedesco and Lachmann, 1971). Serum from homozygous C6-deficient rabbits lack hemolytic, bacterial, and leukocyte chemotactic activities. Inheritance is autosomal dominant with a gene dosage effect (Biro and

Garcia, 1965; Lachmann, 1970; Nelson and Biro, 1968; Rother et al., 1966; Tedesco and Lachmann, 1971).

C8 α - γ ^P DEFICIENCY (C8 α - γ ^P/C8 α - γ ^P)

The eighth component of complement (C8) consists of three polypeptide chains, α , β , and γ . The α and γ chains are linked to one another to form the α - γ subunit, which is covalently associated with the β subunit. Genetic deficiency of the α - γ subunit of C8 has been reported in humans and rabbits, including the New Zealand White breed (Komatsu et al., 1985, 1990). Sera lacked both the immunochemical and functional α - γ subunit of C8, and the deficiency was transmitted as an autosomal dominant trait with a gene dosage effect. Double-homozygous rabbits had consistently lower thymus weights but no histological abnormalities. Affected rabbits also had reduced body weight, reduced litter size, and survival up to 3 months of age.

HYPERLIPIDEMIA (Hc/Hc; Hc/+)

Familial hypercholesterolemia (FH) is one of the most common and important inherited diseases affecting humans. It is a "receptor disease" in which a mutation in the gene encoding the receptor for low-density lipoprotein (LDL) causes reduced transport and metabolism of cholesterol. Humans homozygous for this gene mutation have 5–6-fold elevations in plasma cholesterol and develop skin xanthomas as well as coronary, cerebral, and peripheral vascular atherosclerosis early in life. Heterozygotes have 2–3-fold increases in plasma cholesterol and experience premature atherosclerosis in adult life (Cotran et al., 1989). The discovery by Watanabe and colleagues of the Watanabe heritable hyperlipidemic (WHHL) rabbit (Kondo and Watanabe, 1975) provided an important animal model for the study of FH (Aliev et al., 2004; Goldstein and Brown, 1989; Shiomi and Ito, 2009; Tanzawa et al., 1980) as the disease in these rabbits is quite similar to FH in genetic (Watanabe, 1980; Watanabe et al., 1985), clinical, metabolic (Bilheimer et al., 1982; Kita et al., 1981) and biochemical features.

Hyperlipidemia in the WHHL rabbit is due to a nucleotide deletion (the provisional symbol of *Hc* for hypercholesterolemic is used here) in the LDL binding domain of LDL receptor cDNA (Shiomi and Ito, 2009), and is inherited as an autosomal dominant gene with a gene dosage effect. As in FH, homozygotes (*Hc/Hc*) have plasma cholesterol levels of 500–950 mg/dl (90% of which is contained in LDL), marked reduction in the removal of LDL from plasma, virtually no LDL receptors on cell membranes, cholesterol deposits (xanthomas) in tissues, and develop severe atherosclerosis. Heterozygotes (*Hc/+*) have one-half the normal number of LDL receptors and have less severe clinical disease (Atkinson et al., 1989; Bilheimer et al., 1982; Goldstein and Brown, 1989; Havel et al., 1989; Kita et al., 1981;

Tanzawa et al., 1980; Watanabe, 1980; Watanabe et al., 1985). The WHHL rabbit has proved particularly useful in experimental trials to investigate therapeutic modalities prior to use in human patients with FH, including serum cholesterol-lowering drugs (Shiomi et al., 1990), anti-inflammatory drugs (Makheja et al., 1989), antioxidant drugs (Carew, 1989; Carew et al., 1987; Mao et al., 1991) and gene therapy (Chowdhury et al., 1991).

Gastrointestinal

Gastric Trichobezoars

A trichobezoar, or hairball, is a gastric mass composed of hair, fur, or wool. The hair accumulates in the stomach and may mix with ingesta to form round-to-oval masses. A lack of sufficient roughage in the diet and/or boredom has been suggested as reasons for hair ingestion behavior; however, the precise cause for this pica is unknown. The clinical condition associated with these masses was historically termed "wool block." More recently it is referred to as gastrointestinal stasis syndrome (Pilny and Hess, 2004). It is thought that rabbits are predisposed to the gastric accumulation of hair because of both their inability to vomit and the small lumen of the rabbit pylorus (Harkness and Wagner, 1989). Generally the hairballs do not cause an obstruction, and they are often found incidentally during postmortem examination. Leary et al. (1984) found that 48 of 208 (23.1%) clinically healthy New Zealand White rabbits had gastric trichobezoars at necropsy.

Although gastric trichobezoars are typically asymptomatic, they occasionally cause partial or complete obstruction of the digestive tract. Gastric motility can be decreased in rabbits for a number of reasons including a high-carbohydrate, low-fiber diet, dehydration, anorexia, stress, and pain. Decreased gastric motility can cause dehydration and impaction of the normal stomach contents leading to the formation of trichobezoars (Meredith, 2007).

Clinically affected animals may present with anorexia, decreased fecal output, lethargy, and weight loss. The diagnosis of a trichobezoar is typically made with palpation and radiography, though a positive finding on either of these is not always conclusive. A mass in the stomach may be palpable; however, the rabbit stomach remains full even after periods of anorexia (Gillett et al., 1983) and palpable trichobezoars can be an incidental finding, not contributing to the clinical illness. Additionally, Leary et al. (1984) found that the size of the mass does not correlate with the incidence of clinical illness, as small, non-palpable trichobezoars at the pylorus can be clinically significant. Contrast radiography of the stomach has been attempted, but is often non-diagnostic unless the pyloric obstruction completely prevents passage of the liquid barium (Gillett et al., 1983; Wagner et al., 1974).

Radiographic evidence of a large stomach containing gas and ingesta in conjunction with a clinical history of anorexia in a rabbit can support a diagnosis of gastric stasis (Pilny and Hess, 2004); however, in most cases the diagnosis is ultimately made by either response to empiric treatment or exploratory gastrotomy.

Treatment should be aimed primarily at hydration and nutritional support. Quality hay should be made available at all times. Analgesia may be utilized to reduce the pain associated with gaseous distention. The use of enzymatic products, such as papain, is controversial as these do not actually digest the hair, but may help break down the matrix holding the material together (Meredith, 2007). Pro-motility agents such as metoclopramide may be administered, but only if it is certain that there is not a complete obstruction. Rabbits should also be encouraged to exercise to stimulate gastrointestinal motility. Surgery is not recommended as the initial treatment; however if the rabbit does not respond to aggressive medical treatment, surgery is a viable option (Pilny and Hess, 2004). Appropriate peri-operative care and management, including fluid administration, broad-spectrum antibiotics, and use of live *Lactobacillus* culture is critical to the success of surgical management of trichobezoars (Gillett et al., 1983).

Reported complications from trichobezoars include hepatic lipidosis, gastric rupture, and peritonitis (Leary et al., 1984; Lee et al., 1978). For rabbits exhibiting prolonged anorexia, placement of a percutaneous endoscopic gastrostomy (PEG) tube is a feasible and safe option for providing enteral nutrition (Smith et al., 1997).

Pyloric Stenosis

Congenital pyloric stenosis with muscular hypertrophy was first reported in a rabbit by Cardy in 1973. A pre-weanling Flemish Giant male died suddenly, and gastric dilatation with complete closure of the pylorus was observed at postmortem examination. Histologically, the external muscularis layer of the pylorus was extremely thickened. Weisbroth and Scher (1975) reported three cases of hypertrophic pyloric stenosis in rabbits, all of which were older than 12 weeks of age. The rabbits had similar clinical histories of anorexia, listlessness, weight loss, and constipation. Hypertrophy of the muscularis was noted in all three cases, and postmortem measurements indicated that the pylorus was thickened at the expense of the lumen. It could not be determined if the three cases were exacerbations of congenital pyloric stenosis, whether they arose de novo in adulthood, or whether they were secondary to pylorospasm. There have been no further reports of this condition.

Liver Lobe Torsion

Liver lobe torsion has been reported infrequently in *Oryctolagus*. Though it cannot definitively be stated

that French lop and Dwarf lop rabbits are predisposed to this condition, the current literature does present a bias towards these breeds. The clinical presentation of liver lobe torsion in rabbits can vary from an incidental necropsy finding to sudden death. Weisbroth (1975) reported an incidence of three out of 984 rabbits with torsion of the caudate lobe of the liver seen at necropsy in a large research colony. In these cases, no clinical signs were reported, nor were there secondary lesions or sequelae to the torsion.

In rabbits that have been reported with clinical signs, the initial presentation included a sudden onset of lethargy, anorexia, and abdominal pain. Wenger et al. (2009) found heart rate and respiratory rate to be increased and mucous membranes to be pale and slightly jaundiced upon physical examination. Moderate to severe anemia was found consistently on hematologic examination. Clinical chemistry abnormalities included elevations in alanine aminotransferase (ALT), alkaline phosphatase (ALP), and gamma-glutamyl transferase (GGT). Other clinical findings included dehydration, as evidenced by an increase in blood urea nitrogen (BUN) and creatinine, and bilirubinuria (Taylor and Staff, 2007; Wenger et al., 2009).

Diagnostic modalities, such as radiography and ultrasound, have been of limited benefit in diagnosing this condition (Saunders et al., 2009). This is due to extensive gastric stasis and gas accumulation secondary to the liver lobe torsion, which results in reduced abdominal contrast. Additionally, when ultrasound examination has revealed potential hepatic abnormalities, such as enlargement and heterogeneity, fine needle aspiration with cytologic examination has been unremarkable. In all cases histological examination revealed a loss of normal hepatic architecture and extensive hemorrhage of the affected lobe consistent with ischemic necrosis (Wenger et al., 2009). Though the caudate lobe has been reported to be predisposed to torsion in this species, there are reports of torsion involving both the quadrate and the right liver lobes as well (Weisbroth, 1975, Wenger et al., 2009).

Anecdotal reports exist describing diagnosed cases of rabbits with liver lobe torsion that have recovered uneventfully with only supportive care. In these animals the liver enzymes decreased and the hepatic lobe atrophied over time (Wenger et al., 2009). Current literature, however, suggests that rabbits presenting with clinical signs and hematological alterations indicative of liver lobe torsion can be systemically compromised and may die without surgical intervention. Additionally, there are two successful reports of curative surgical hepatic lobectomies in rabbits with this condition (Saunders et al., 2009; Taylor and Staff, 2007).

There may be cases of liver lobe torsion in rabbits that are undiagnosed either because the rabbit exhibited no

clinical signs or because the rabbit died spontaneously without diagnostic evaluation (Wilson et al., 1987). Liver lobe torsion should be considered as a differential diagnosis for rabbits that present clinically with anorexia, lethargy, and abdominal pain. Although radiology and ultrasound may be unremarkable, the presence of anemia and elevations in liver enzymes appear to be the best markers for this condition (Saunders et al., 2009). Despite anecdotal reports of spontaneous resolution with only supportive care, surgical intervention early in the onset of the clinical course is reported to be a promising treatment option for complete recovery.

Urogenital

Renal Cysts

Fox et al. (1971a) have reported the occurrence of multiple small cysts in kidneys of strain III_{VO} rabbits. Cysts were detectable only at necropsy, as there were no adverse effects on health or preliminary renal function tests. Significant numbers of cysts were never found in animals less than 1 month of age, but were found in increasing numbers up to approximately 6 months of age. Pedigree analysis provided evidence consistent with autosomal recessive inheritance with incomplete (76%) penetrance.

Affected kidneys have from one to hundreds of cysts, up to 1 mm diameter and limited in location to the subcapsular region of the cortex. Microdissection studies showed the cysts to be of tubular origin, as was also demonstrated in selected histological sections. A single layer of flat to low cuboidal epithelium surrounded by little or no fibrous tissue usually lined the larger cysts. Elsewhere cysts had the appearance of primitive ductules and tubules in abundant cellular mesenchymatous stroma. The latter areas resembled closely the histological findings of renal cortical dysplasia in humans (Bernstein, 1968; Kissane, 1966). The histologic appearance, the subcapsular location of lesions, and the age at which cysts first appear all tend to point toward an interruption of development in the late stages of renal organogenesis. It is of at least passing interest that similar subcapsular renal cysts have been produced experimentally in the rabbit by a single injection of long-acting adrenal corticosteroids given at birth (Perey et al., 1972). As of 2008, inbred III_{VO}/JU rabbits were maintained by the University of Utrecht (Belgium) from the original Jackson Laboratory stock.

Urolithiasis

Urolithiasis historically has occurred as a sporadic condition in rabbits with no definitive causative etiology. Most reports cite the unique calcium metabolism of rabbits as a potential factor in the development of urolithiasis. Rabbits passively absorb dietary calcium

and serum calcium levels typically are higher than most other species (Buss and Bourdeau, 1984). Calcium regulation occurs primarily via renal excretion or conservation depending upon metabolic needs. High dietary levels of calcium therefore result in high levels of calcium in the urine. Normal rabbit urine is slightly alkaline, with an average pH of 8.2 (Williams, 1976), and has a cloudy appearance owing to the presence of calcium carbonate and triple phosphate crystals (Flatt and Carpenter, 1971). At higher pH (8.5–9.5) the crystals precipitate out of the urine (Leck, 1988). Factors that enhance the development of urolithiasis may include genetic predisposition, metabolic disturbance, nutritional imbalance, infection, and inadequate water intake (Garibaldi et al., 1987).

In the cases reported in the literature, clinical signs if present are usually non-specific and may include weight loss, anorexia, and/or irritability. Radiography is a valuable diagnostic tool in these cases and will detect calculi as well as hypercalcification of soft tissues, which is present in about 26% of affected rabbits in a report by Harcourt-Brown (2007). In most cases, the urolith is composed of calcium carbonate and ammonium magnesium phosphate (triple phosphate) (Garibaldi et al., 1987; Whary and Peper, 1994; White, 2001). Fleming and Carpenter (2000) reported a case of severe bladder distention characterized by about 500 ml of calculi “sand” rather than larger discrete uroliths. Calculi may be located in the kidney, ureters, or bladder with secondary effects such as hydronephrosis present. While pathologic findings include expected trauma to the urinary epithelium, Harcourt-Brown also found a very high incidence of lesions suggestive of *Encephalitozoon cuniculi* infection in the kidneys. The author proposed that inflammatory foci in the kidney in response to *E. cuniculi* may cause obstruction of urine flow as well as provide a nidus for subsequent stone formation. Itatani et al. (1981) proposed that sulfated glycosaminoglycans, which are increased in the urine of rabbits with urolithiasis, may bind calcium crystals together to form a massive aggregate resulting in urolith formation.

Treatment of urolithiasis is surgical removal of the calculus or flushing of the urinary bladder for removal of sand-type calculi. Diazepam for relaxation of the urethralis muscle is useful for catheterization approaches (Keeble, 2007). Prevention is aimed at ensuring adequate water intake and treating any predisposing factors such as excessive dietary calcium intake. Exercise has also been suggested as a preventive measure via encouraging normal urination patterns (Keeble, 2007).

Hydrometra

Hydrometra has historically been reported in rabbits (Bray et al., 1991; Hobbs and Parker, 1990; Morrell, 1989). Coincidentally, all reported cases were rabbits being used experimentally for the production of serum

antibodies. In the report by [Morrell \(1989\)](#), four cases were seen over a 2-year period. Clinical signs consisted of abdominal distention and tachypnea. On gross post-mortem examination, the uterine horns were distended with a transudative fluid. No etiology was determined, although it was proposed that increased progesterone levels could stimulate endometrial gland secretion and a functional cervical closure. [Bray et al. \(1991\)](#) reported on a case in which the abdominal distention resolved with diuretic therapy, but recurred more severely 2 months later. Hydrometra was assumed to be the cause of initial abdominal enlargement as the transudate aspirated during the clinical episode was similar to the intrauterine fluid collected at necropsy. Persistent corpora lutea or follicular cysts were not observed. In the cases reported by [Hobbs and Parker \(1990\)](#), hydrometra was associated with uterine torsion.

Vaginal Prolapse

When compared to other species, rabbits rarely experience maternal injury during vaginal birth, and as a result, spontaneous vaginal prolapse secondary to gestation and parturition is uncommon. This is in part due to differences in the mechanical and anatomical properties of the *Oryctolagus* vagina ([Abramowitch et al., 2009](#)). Pelvic organ collapse in rabbits can occur secondary to reproductive abnormalities such as extrauterine pregnancy, uterine adenocarcinoma, or endometrial venous aneurysms (L. Gallagher, personal observation, 2009).

An increased incidence of prolapsed vagina does occur in the III_{VO}/JU inbred strain of rabbits ([Van Herck et al., 1989](#)). Eight cases were reported over a 5-year period in closely related females. In these cases the prolapse was not associated with gestation, but rather occurred at a time of increased sexual activity when blood supply to the vulva/vestibulum was increased. The authors proposed that an underlying genetic factor may contribute to the incidence in the III_{VO}/JU strain.

Affected rabbits present with a prolapse of engorged vaginal tissue that is bloody ([Figure 17.5](#)) and possibly ulcerated secondary to self-mutilation. Often, the first sign of this condition may be the detection of blood in the cage. Clinically, animals may be lethargic, tachypneic, pale, and have cold extremities consistent with hypovolemic shock. Hematocrit measurements may be as low as 9% ([Van Herck et al., 1989](#)). Treatment including fluid administration and reduction of the prolapsed tissue can be attempted, though there are no reports of successful recovery.

Toxemia of Pregnancy

Pregnancy toxemia is a disease that is seldom recognized in domestic rabbits. Pregnant as well as postparturient and pseudopregnant females may be affected ([Greene, 1937, 1938, 1965](#)). In a large outbreak of

FIGURE 17.5 Vaginal prolapse in a New Zealand White rabbit. Courtesy of The Ohio State University.

pregnancy toxemia involving 72 cases ([Greene, 1937](#)), 60% occurred in pregnant does, 21% in postparturient does, and 19% in resting or pseudopregnant females. The incidence in multiparous does was approximately four times that observed in primiparous does. Affected females were most often obese. [Greene \(1937, 1938\)](#) also found that Dutch, Polish, and English breeds had the highest incidence of pregnancy toxemia. There was also an increased incidence of pregnancy toxemia in carriers of dwarfism in the Polish breed and cretinism in the Dutch breed.

The clinical appearance of pregnancy toxemia varied greatly, with a mild, nearly asymptomatic condition at one end of the spectrum and a severe, rapidly fatal disease at the other end. In the pregnant females, the clinical disease was first detected while nest building was occurring. The most commonly observed clinical signs were depression, dyspnea with acetone odor on the breath in severe cases, and decreased urine production. Abortion, incoordination, convulsions, and coma sometimes preceded death ([Greene, 1937](#)). Recovery occurred in the mild to moderate cases.

Severe cases were accompanied by marked elevation in serum non-protein nitrogen and phosphate and a decrease in serum calcium. Tests for serum acetone were positive. Affected animals that died or were euthanized were characterized by obesity, actively secreting mammary glands (even in the pseudopregnant does), large corpora lutea in the ovaries, and areas of necrosis in the mesenteric fat. The liver was enlarged and pale due to fat deposition ([Figure 17.6](#)); the kidneys and heart were also pale. The thyroid and adrenal glands were small and pale. Enlargement of the pituitary gland was also common. Severe fatty infiltration of the liver and focal hepatic necrosis were seen on histopathological examination of some cases. Fatty infiltration was also observed in

FIGURE 17.6 Hepatic pallor in a rabbit with hepatic lipidosis secondary to pregnancy toxemia. Courtesy of The Ohio State University.

the kidney tubules, heart, and adrenal cortex, especially within the thickened zona fasciculata. Cortical adenomas were often present in the adrenal glands. The thyroid follicles were filled with pale colloid and lined by low cuboidal epithelium. The pars distalis of the pituitary gland contained many acidophils and multiple adenomas, and the pars intermedia was thickened.

Like pregnancy toxemia in other domestic animals, the cause of disease in rabbits is complex. Many factors may have an influence on the development of the syndrome including breed, age, obesity, and the number of previous pregnancies. Harkness (1987) indicated that pregnancy toxemia may be the result of insufficient arterial flow to the uterus, leading to a metabolic derangement. The decreased blood flow could be due to obesity, poor development of the uterine vasculature, or a large fetal mass. On the other hand, Greene (1938) proposed that the disease may be related to abnormal hypophyseal function. The outbreak of pregnancy toxemia in his rabbits was associated with other reproductive problems, including abortions and stillbirths, and an increased incidence of uterine tumors. He postulated that environmental changes might lead to an endocrine imbalance resulting in pregnancy toxemia and other reproductive disturbances. In a more recent case report, it was proposed that there was a possible relationship between pancreatitis and pregnancy toxemia (Leland et al., 1995). No definitive etiology for pregnancy toxemia in rabbits has been determined, however. Successful attempts to treat the disease in rabbits have not been reported.

Extra-Uterine Pregnancy

Extra-uterine pregnancy is a pregnancy that occurs elsewhere than within the uterine lumen. Primary abdominal pregnancy is when an oocyte is fertilized in the abdominal cavity or a fertilized ovum enters the peritoneal cavity and placentation occurs on either

the peritoneal or omental surface. Secondary abdominal pregnancy is when a fetus which has already been implanted enters the abdominal cavity secondary to oviduct or uterine rupture, usually as a result of external trauma or increased internal pressure (Corpa, 2006). Primary abdominal pregnancies are rare, whereas secondary abdominal pregnancies have been reported in several animal species, including rabbits (Corpa, 2006; Eales, 1932; Harper and Ensley, 1982; Segura et al., 2004). Segura et al. (2004) reported 28 abdominal pregnancies out of 550 adult fertile female New Zealand White rabbits from two rabbit farms in Valencia, Spain. Seven of the 28 showed no evidence of uterine rupture, though evidence of intra-abdominal placentation was found in only two of the animals.

Discovery of an ectopic fetus is often an incidental finding as the condition is not generally of great clinical significance to the affected rabbit. There are reports of rabbits exhibiting clinical signs including lethargy and anorexia, though these presenting signs may not have been secondary to the extra-uterine pregnancy (Harper and Ensley, 1982; Segura et al., 2004). Other clinical signs that may be present include vaginal discharge, vaginal prolapse, and mammoplasia, although these are uncommon and not reported in the current literature (L. Gallagher, personal observation, 2009). Additionally, there is no known association between the development of clinical signs and the length of time for which an ectopic fetus has been present (Corpa, 2006).

If a previously normal reproductive doe does not undergo parturition and a firm, non-fluctuant mass (or masses) is palpable in the abdominal cavity, extrauterine pregnancy should be suspected. Diagnosis can be confirmed utilizing radiography and abdominal ultrasonography. The fetuses may appear as dystrophic mineralized abdominal masses upon radiography. Confirmation of fetal tissue versus foreign body can be made via ultrasound which can determine the consistency and texture of the abdominal mass (Eshar and Mayer, 2008).

If the fetuses are expelled from the uterus prior to 21 days of gestation, and there is no implantation within the abdominal cavity, fetal death will occur. After 21 days, incomplete resorption occurs, resulting in mummification of fetuses. However, rabbits have a similar placentation as human beings that permits them to produce a viable extrauterine pregnancy (Segura et al., 2004). Fetuses can implant to the peritoneal or omental surface and establish an extensive blood supply; as such, fetal development can continue until placental perfusion becomes inadequate (Owensby et al., 2001; Segura et al., 2004). It is not uncommon to see multiple fetuses within the abdominal cavity at varying stages of development including term-sized fetuses (Segura et al., 2004; L. Gallagher, personal observation, 2009). Ectopic fetuses typically appear well preserved (Figure 17.7),

FIGURE 17.7 Mummified ectopic fetus in a New Zealand White rabbit (same rabbit as with vaginal prolapse seen in Figure 17.5). Courtesy of The Ohio State University.

though dehydrated, and most commonly they are found encapsulated within a thin, tough connective tissue (Jacobson et al., 1975). Histologically, the fetuses show moderate autolysis, but no active inflammatory response (Segura et al., 2004).

Other Systems

Abnormal Ear Carriage

Rabbits normally carry the ears erect pointing dorsolaterally, or in a relaxed position against the dorsum of the trunk and pointing posterolaterally. Chai and Clark (1967), while studying a number of inbred lines of rabbits, observed a condition designated as “droopy ear” in which the ears drooped downward and antero-ventrally from the base. The condition is thought to be due to more than one gene. Droopy ear is distinguished from the lop ear or flop ear characteristic of certain breeds in which the ears, perhaps due to excessive weight, simply hang downward from their attachments on the head. This trait too is thought to be controlled by multiple factors (Castle and Reed, 1936).

Plant Toxicosis

The poisoning of rabbits by toxic plants has been reported infrequently and generally occurred before commercial feed was widely used (Bergdall and Dysko, 1994). Some of the plants implicated as being toxic to rabbits include the wooly-pod or broad-leafed milkweed, *Asclepias eriocarpa*; ladino clover; comfrey; and a mixture of cock, buttercup, and wild parsnip.

Drug Acetylators – Rapid and Slow

An important metabolic step in the biotransformation of carcinogens called arylamines, and toxins called

hydrazines, is N-acetylation via the cytosolic enzyme N-acetyltransferase (EC 2.3.1.5) located predominantly in the liver and small intestine (Weber, 1973). Differences in N-acetylation rates among humans have been found to be due to a single autosomal locus with two alleles, *R* and *r*. Hein et al. (1982) surveyed a large group of inbred rabbit strains and found, using a variety of substrates, three clear-cut groups: a group of rapid acetylators strains, designated *RR*; an intermediate obligate heterozygous group, *Rr*; and a group of homozygous slow acetylators strains, labeled *rr*. Outbred rabbits studied (NZW) were in the slow acetylators category.

Resistance/Susceptibility to Infection

The hereditary resistance and susceptibility of rabbits to experimental infections was studied in depth by Lurie and colleagues using *Mycobacterium* species as the infectious agent (Lurie, 1964; Lurie and Dannenberg, 1965; Lurie et al., 1952). In general, the studies compared the relative abilities of several families of rabbits to eliminate or suppress standard doses of human or bovine tubercle bacilli. These rabbits were derived from brother-sister matings for approximately ten generations and subsequent line breeding for many generations thereafter. The different families of rabbits varied greatly in response and were classified as resistant, susceptible, or intermediate. Resistance was found to be most directly dependent on the ability of host macrophages to engulf and inhibit the growth of bacilli in their cytoplasm. The family differences in macrophage efficiency were attributable to differences in endocrine balances, involving particularly thyroid and adrenal hormones. The determinants of resistance were considered to be polygenic (Lurie et al., 1952).

Genetic factors also are known to influence the susceptibility of rabbits to certain viral infections. Greene (1935) observed striking breed differences in mortality during an epizootic of rabbit pox. The natural selection of resistance to myxomatosis has been observed in the wild rabbit population since release of the myxoma virus in Australia in 1950 (Fenner, 1953; Marshall and Douglas, 1961; Marshall and Fenner, 1958), and this has been largely duplicated by selective breeding of domestic rabbits (Sobey, 1969). The inheritance of resistance to viral infection is clearly controlled by multiple genes, but the mechanisms by which resistance is conferred remain obscure.

Heat Prostration

Rabbits have limited capability for thermoregulation under elevated ambient temperatures as they cannot sweat, and panting and salivation are inefficient; their primary means of temperature control is the countercurrent heat exchange system provided by the vasculature of the ear (Brewer and Cruise, 1994).

As such, rabbits have been found to be unusually sensitive to elevated ambient temperatures (greater than 28°C or 85°F). In the summer months, losses due to heat prostration may exceed losses due to other diseases in facilities that lack proper environmental control. The *Guide for the Care and Use of Laboratory Animals* recommends that rabbits be housed at temperatures between 16 and 22°C (61–72°F), a range which is noticeably below that listed for other laboratory animal species (ILAR, 2011).

Clinical signs of heat prostration may include hyperthermia, tachypnea, cyanosis, prostration, and blood-tinged fluid from the nose and mouth. Does near kindling are reported to be most susceptible to this condition (Hagen and Lund, 1962). During bouts of especially hot weather, quarters without environmental control may be cooled by such means as water sprays, foggers, and fans. Affected animals may be cooled by placing wet burlap over them (Hagen and Lund, 1962), or by immersion in a cold water bath until the rectal temperature approaches the normal range (March, 1938).

High ambient temperatures can also affect the fertility of male rabbits in breeding colonies. Experimentally, Rathore has shown that New Zealand White bucks exposed to environmental temperature of 36.1°C (96.8°F) at 45% humidity for 1 or 2 days were not as fertile as control (unheated) bucks (Rathore, 1970a) and that abnormal spermatozoa were present in the ejaculate of the heated animals (Rathore, 1970b).

Miscellaneous Abnormalities

Many congenital malformations have been observed in instances where inbreeding of rabbits has been practiced (Chai, 1970; Chai and Degenhardt, 1962; Sawin and Crary, 1964). The abnormalities include conjoined twinning in Y strain rabbits (Chai and Crary, 1971), thoracogastroschisis in Lurie's C line (Crary, 1951; Sawin, 1955), hypospadias in the AX strain (Lindsey and Fox, 1994), and many other conditions that almost certainly have a genetic basis.

INTRODUCTION

The total number of rabbits used for research and testing in the United States has declined from a peak value of approximately 550 000 per year in the late 1980s to the current level of approximately 230 000 (Figure 18.1). Of the several factors contributing to this decline, the most important was the rapid expansion of genetically engineered rodent models which largely replaced rabbits for investigation of many diseases such as candidiasis (de Repentigny, 2004) and variola (Smee, 2008). Even for conditions such as herpes simplex keratitis in which rabbits are still a classic and frequently used model, murine models are being developed to replace rabbits (Neumann et al., 2007). During the same period, refined testing methods for the Draize eye and skin irritation tests diminished the number of rabbits needed for toxicity evaluations. These tests were developed in the 1960s and adopted by the Environmental Protection Agency (EPA) to meet the testing requirements of the Federal Insecticide, Fungicide, and Rodenticide Act and the Toxic Substances Control Act. The albino rabbit remains the preferred species for both of these tests (EPA, 1998). While investigators are actively working to develop and validate in vitro substitutes to evaluate product safety, few alternatives have been accepted for regulatory purposes, requiring the continued use of rabbits (Vinardell and Mitjans, 2008).

The relatively large size, gentle disposition, and ease of maintenance in the laboratory are characteristics that ensure the continued use of rabbits as a valuable and essential animal model for many diseases. A Pubmed search of biomedical publications covering the period

from January 2005 to July 2009 returned over 23 500 references using rabbit as a key phrase. While the rabbit may not have been the only species used in these manuscripts, this simple statistic demonstrates the continued high use of rabbits particularly in the areas of atherosclerosis, ophthalmic disease, infectious disease, orthopedic research, and experimental neoplastic research. This chapter will provide an overview of these conditions, by system. Of necessity we will not attempt to describe every disorder for which rabbits have been evaluated as a model, or to summarize the 23 500 articles that have used rabbits. The utilization of the rabbit for cancer research is described in a separate chapter in this book.

CARDIOVASCULAR DISEASES

Heart disease is the leading cause of human mortality in developed countries. A wide variety of animal models of cardiovascular disease have been used to better understand the mechanisms and potential gene regulation underlying cardiac dysfunction and to develop therapeutic strategies. These models include dogs, pigs, pigeons, non-human primates, and small rodents, especially rats and mice. With the advances in genetic engineering, many novel murine models of cardiovascular disease have been developed in recent years. It should be noted, however, that there are major differences between rodent and human cardiovascular systems and this should be appreciated before extrapolating results from mouse to man. In contrast to other model species, including the mouse and rat, rabbits and humans are similar with respect to chemical composition and

FIGURE 18.1 Total number of rabbits reported to the USDA for use in research and testing in the United States from 1973 to 2007.

content of lipoproteins (including apoB), production of lipoproteins in the liver (including apoB-100), and the presence of cholesteryl ester transfer protein (CETP), a key regulator of lipoprotein metabolism and development of atherosclerosis (Brousseau, 1999; Son and Zilversmit, 1986). The rabbit's cardiac physiology is also more analogous to human cardiac physiology than that of the mouse or rat. One such similarity is related to cellular electrophysiology and Ca^{2+} transport, which is critical when using animal models to study heart failure and arrhythmias due to alterations in ion channel and Ca^{2+} transporter function (Bers, 2001, 2006; Pogwizd 2004).

Although the laboratory rabbit has been used extensively for nearly one hundred years to study the pathophysiology of atherosclerosis, it has also been used to model many other manifestations of cardiac disease. Table 18.1 provides an overview of a number of rabbit models used in cardiovascular research (Pogwizd and Bers, 2008). The conditions for which rabbits have been used most extensively and have provided the greatest advances are discussed below.

Atherosclerosis

Etiology and Disease in Humans

Elevated blood cholesterol levels ($>249\text{mg/dl}$) and vascular plaque formation (atherosclerosis) is now recognized as a major risk factor for cardiovascular disease (CVD) which has accounted for more deaths in the United States than any other major cause of death

every year since 1900, except 1918 (Lloyd-Jones et al., 2009; Rosamond et al., 2008). The specific events contributing to these deaths include coronary heart disease (CHD, 52%), stroke (17%), and high blood pressure (6%) among others (Lloyd-Jones et al., 2009; Rosamond et al., 2008). Atherosclerosis is a complex, chronic progressive disease that develops in a distinct pattern classified into five distinct types. Briefly, these atheroma lesions are inflammatory sites that progress from proliferation and remodeling of smooth muscles cells with lipid infiltration and endothelial cell-monocyte interactions, to a lesion characterized by a deep intimal lipid-rich necrotic core. During the final stage of development the plaques have deep-intimal necrosis and a lipid-rich necrotic core composed of cholesterol clefts, calcium depositions, and neovascularization (Bocan, 1998). While the number of deaths from CVD has decreased from peak levels in the 1970s, largely due to an increased understanding of the risk factors and improved therapies, ongoing research to minimize atherosclerosis continues to be a major public health focus.

Rabbit Model

CHOLESTEROL-FED RABBIT MODEL

While there is no animal model that completely replicates all of the complexities of human atherosclerosis, rabbits are used extensively to study the pathogenesis of atherosclerosis and to evaluate therapeutic interventions. The cholesterol-fed rabbit in particular is the most common model used to evaluate pharmacologic treatments for atherosclerosis (Bocan, 1998). The

demonstration, by the young Russian pathologist Antischokow in 1913, that rabbits fed a diet supplemented with purified cholesterol dissolved in sunflower oil developed vascular lesions resembling human atherosclerosis marked the beginning of the modern era of atherosclerosis research (Anitschkow, 1913; Steinberg, 2004). Regrettably, Antischokow's discovery was largely dismissed as a peculiarity of the rabbit for about 40 years because similar studies using rats and dogs, species now known to be very efficient in converting cholesterol to bile acids, were unable to reproduce similar lesions. The cholesterol-fed rabbit model is created by feeding a diet supplemented with 1–3% cholesterol and 4–8% fat for 4–6 weeks (Bocan, 1998). The developing atherosclerotic lesions start as fatty streaks on the aorta and progress into advanced lipid-laden intimal plaques that approximate early human atheromas, which is the stage targeted by therapeutic intervention. In the rabbit, the atheromas localize to the aortic arch and thoracic aorta primarily, including the origins of the intercostal arteries (Yanni, 2004). Wilson et al. (1982) created a rabbit model with atherosclerotic lesions typical of advanced human atherosclerosis including a necrotic core and cholesterol clefts by feeding rabbits a diet containing 19% butter and 1% corn oil for up to 5 years. LeVeen et al. (1982) induced similar lesions in a shorter time using a balloon catheter to mechanically denude the aortas of Flemish

Giant rabbits which were then fed a 2% cholesterol, 6% peanut oil diet for about a month. Hypercholesterolemic rabbits, either with or without mechanical endothelial trauma, are the most widely used model for evaluating anti-atherosclerotic interventions including the 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors, the “statins”, which can reduce serum cholesterol by as much as 47% in rabbits (Bocan, 1998; Wei et al., 2003), anti-inflammatory compounds such as terutroban (Worth et al., 2005), antioxidants including dietary flavanoids (Terao, 2009; Terao et al., 2008), and drug-eluting stents (Nakamine et al., 1998) among others. The hypercholesterolemic rabbit also serves as a model of valvular heart disease (Rajamannan, 2006), Alzheimer disease (Woodruff-Pak, 2008), and is being evaluated as a model of non-alcoholic, non-obese, non-insulin-resistant fatty liver disease (Kainuma et al., 2006).

Recognition that atherosclerosis is a chronic inflammatory disease (Ross, 1999) prompted interest into the role of infectious agents in disease progression. Several studies have demonstrated the presence of *Chlamydia pneumoniae* organisms in atherosclerotic lesions of humans (Belland et al., 2004). *C. pneumoniae* is an obligate intracellular prokaryotic pathogen that is extremely common in people, with approximately 80% of the population having serologic evidence of infection by 65 years of age (Belland et al., 2004). Rabbits fed

0.25% cholesterol in their diet and intranasally inoculated with *C. pneumoniae* developed significantly accelerated aortic atherosclerosis compared to uninfected rabbits or rabbits treated with an antibiotic, azithromycin (Muhlestein, 2000). However, rabbits infected with *Mycoplasma pneumoniae* (Fong, 2000), which causes similar lung pathology, failed to develop inflammatory changes or atherosclerotic lesions. While human clinical trials found no evidence that antibiotic treatment of *C. pneumoniae* reduced vascular risk (O'Connor et al., 2003), the rabbit studies helped fulfill Koch's postulate that chronic infectious burdens, perhaps by exacerbating inflammation, are an additional risk factor for development of atherosclerosis and its associated complications (Elkind et al., 2010).

SPONTANEOUS HYPERCHOLESTEROLEMIC RABBITS

In 1973, Japanese veterinarian Yoshio Watanabe discovered a male Japanese White rabbit with elevated serum lipid levels despite being fed a standard rabbit chow (Watanabe, 1977). The hyperlipidemia was characterized by grossly elevated levels of serum cholesterol, phospholipids, and triglycerides (Watanabe, 1980). He confirmed that the hyperlipidemia was an inherited recessive trait and used selective inbreeding strategies to develop what is now known as the Watanabe heritable hyperlipidemic (WHHL) rabbit strain, which is the first animal model with natural endogenous hypercholesterolemia (Watanabe, 1980). WHHL rabbits develop spontaneous atherosclerosis by 3–5 months of age, progressing to moderate to severe aortic atherosclerosis by 16 months of age (Figure 18.2). The atherosclerotic lesions are most extensive in the thoracic aorta, coronary arteries (Figure 18.3), abdominal

FIGURE 18.2 Gross photographs comparing the aortas in age-matched NZW and WHHL rabbits (>1 year). Note the lack of atherosclerotic plaques in the endothelial areas within the abdominal aorta and at the aortic bifurcation in the NZW (top); and the large amount of raised atherosclerotic plaques present in both the aorta (long arrow) and at the aortic bifurcation (short arrow) of an age-matched WHHL (bottom).

FIGURE 18.3 (A, B) Atherosclerotic plaque in thoracic aorta (A) and in left anterior coronary artery (B) from a 1.5-year-old WHHL rabbit.

FIGURE 18.4 (A–C) Intravascular ultrasound (IVUS) is often used to assess atherosclerosis within the wall of major blood vessels of rabbits. (A) demonstrates placing the IVUS catheter into the carotid artery of a rabbit. (B) IVUS of a normal NZW rabbit aorta (left) with an aorta of a WHHL rabbit (right) with atherosclerosis. EEM, the external elastic membrane; Media, media adventitia (composed of smooth muscle cells). (C) demonstrates a carotid artery of a WHHL rabbit with severe atherosclerosis.

FIGURE 18.5 Dermal xanthomas in WHHL rabbits. Cholesterol deposits (dermal xanthomas) in the subcutaneous tissue skin of WHHL rabbits are a common finding in animals >1 year of age. These lesions are composed of typical histiocytic foam cells which contain oil-red-O-positive, strongly birefringent lipid deposits.

aorta, and adjacent to branching vessels (Figure 18.4). Approximately 60% of WHHL rabbits also develop cholesterol deposits in the skin (xanthomas) (Figure 18.5), and other tissues, including the cornea (Figure 18.6), and digital joints, by 22 months of age. Homozygous animals have serum cholesterol concentrations 8–14-fold higher than normal control Japanese White rabbits. This phenotype is due to a defective low-density lipoprotein (LDL) receptor, a spontaneous in-frame deletion of 12 nucleotides that eliminates four amino acids from the cysteine-rich,

ligand-binding domain of receptor 7 in exon-4 of the LDL receptor gene (Gross, 2009; Yamamoto et al., 1986). The clinical and subsequent pathologic progression of the hypercholesterolemic trait in WHHL rabbits closely resemble those found in humans afflicted with familial hypercholesterolemia (FH) (Kita et al., 1981).

Like homozygous human hypercholesteroleemics, WHHL rabbits have a severe lack of LDL receptors in the liver, adrenal glands, lymph nodes, and spleen, elevated plasma LDL cholesterol concentrations, reduced plasma high-density lipoprotein (HDL) concentrations, and increased plasma apolipoprotein E concentrations (Buja et al., 1983; Kita et al., 1981). Son and Zilversmit (1986) demonstrated that the activity levels of CTEP are high in homozygous WHHL rabbits. Increased lipid deposition in liver is a common occurrence (Figure 18.7). In contrast to the cholesterol-fed NZW rabbit, the WHHL rabbit does not develop either hepatic cholesterol toxicity or other organ damage (Donnelly et al., 1991).

Several noteworthy differences exist between FH patients and the WHHL rabbit models. Unlike human patients with homozygous FH, WHHL rabbits are also hypertriglyceridemic (300–600 mg/dl) (Havel, 1982; Watanabe, 1980). In addition, the LDL, as well as intermediate-density lipoproteins and very-low-density lipoproteins, contain a substantial amount of triglycerides (Havel et al., 1982). Unlike the WHHL rabbit, the St. Thomas Hospital strain, now referred to as the St. Thomas mixed hyperlipidemic (SMHL) rabbit, develops hypercholesterolemia with normal LDL receptor function and has only mildly elevated levels of triglycerides (La Ville et al., 1987). The SMHL rabbit exhibits an

FIGURE 18.6 Comparison of eyes from aged (>1 year old) NZW rabbit (left) and WHHL rabbit (right). Note the cholesterol deposits in the cornea of the WHHL rabbit: arcus cornea.

FIGURE 18.7 Gross comparison of livers from NZW rabbit (left) and WHHL rabbit (right). Note the paleness and rounded edges, consistent with a high lipid deposition, in the WHHL rabbit livers.

inherited hyperlipidemia similar to that seen in human familial combined hyperlipidemia and offers a potential valuable animal model system in which to study the relationship between hypertriglyceridemia and insulin resistance (de Roos et al., 2001, 2005).

Many advances in our understanding of the pathogenesis and treatment of atherosclerosis have been made using WHHL rabbits (Shiomi and Ito, 2009). Of particular note, Goldstein and Brown (1983) proved the relationship between LDL receptor activity and atherosclerosis using WHHL rabbits, for which they were awarded the Nobel Prize in 1985. WHHL rabbits have also been used extensively in the development of the anti-atherosclerotic statin drugs (Shiomi and Ito, 2009).

TRANSGENIC RABBITS

The rabbit is an excellent model system for evaluating the metabolic pathways in the pathogenesis of

atherosclerosis. New Zealand White (NZW) rabbits have low plasma total cholesterol concentrations, CTEP activity, hepatic lipase (HL) activity, and lack an analog to human apolipoprotein (hApoA-II). These traits make the NZW an attractive animal model for studying the effects of human transgenes on plasma lipoproteins and atherosclerosis susceptibility (Brousseau and Hoeg, 1999). Details on the generation of transgenic rabbits can be found in Chapter 7.

Utilizing the over-expression of genes relevant to lipoprotein metabolism, researchers have generated a series of transgenic animals, using both the NZW and WHHL rabbits, designed to assess the polygenic nature of the atherosclerotic process. These genes include human transgenes for different apolipoproteins (hapo), the apolipoprotein A-I/C-III/A-IV gene cluster (hapoA-I/C-III/A-IV gene cluster), hepatic lipase (hHL), lecithin:cholesterol acyltransferase (hLCAT), lipoprotein

lipase (hLPL), and scavenger receptor class B type I (hSRB-I) (Table 18.2).

In 1990, Badimon and coworkers first reported that the weekly intravenous administration of HDL protein to cholesterol-fed NZW rabbit models caused regression of previous existing atherosclerotic lesions (Badimon et al., 1990). Duverger and coworkers subsequently generated transgenic New Zealand White (NZW) rabbits that expressed hApoA-1 in the liver and studied its impact on the animal's susceptibility to atherosclerosis (Duverger et al., 1996a). Their results demonstrated that the hApoA-1 transgenic animals developed significantly less atherosclerotic lesions when compared to the control group (Duverger et al., 1996b). The administration of hApoA-1 Milano (a variant of apolipoprotein A-1) was later shown in a clinical trial to significantly regress atherosclerotic lesions in human patients with acute coronary artery syndrome (Nissen, 2003).

Another significant discovery was found in WHHL rabbits over-expressing hLCAT (Hoeg et al., 1996). When fed a high-cholesterol diet these animals showed

a marked reduction in the development of atherosclerosis compared to control rabbits (Hoeg et al., 1996). These results established the importance of LCAT in the metabolism of both HDL and apolipoprotein B-containing lipoprotein particles. The therapeutic impact of over-expressing LCAT was quite surprising. It not only resulted in increased plasma levels of HDL, but was also instrumental in reducing the levels of apolipoprotein B-containing lipoproteins in their transgenic animals (Yanni, 2004). WHHL animals over-expressing hApo(a) on the other hand experienced a more rapid progression in the development of atherosclerotic lesions (Sun et al., 2002).

The generation of genetically engineered rabbit models in recent years has allowed for a better understanding of the functions of genes involved in the pathogenesis of atherosclerosis (Brousseau and Hoeg, 1999; Duverger et al., 1996a, 1996b; Fan et al., 1994, 1995, 2001; Hoeg et al., 1996; Taylor, 1997; Taylor and Fan, 1997). This understanding has led to a number of preclinical discoveries resulting in clinical applications.

Myocardial Infarction and Reperfusion

Etiology and Disease in Humans

Myocardial infarction and reperfusion occurs when plaques rupture and block the arteries of the heart leading to a condition known as acute coronary syndrome (ACS). ACS is the leading cause of morbidity and mortality and according to the World Health Organization will be the major cause of death by the year 2020 (Ostadal et al., 2009).

Rabbit Model

Until recently there were no spontaneous animal models of ACS. To evaluate the cardioprotective potential of different pharmaceuticals and treatments, an induced model of ACS was developed. The advantages of the induced model include predictability in onset of the ischemic event, as well as consistent size and location of the infarcted myocardium. In rabbits, the model is created in anesthetized, mechanically ventilated rabbits via a left thoracotomy. Suture is passed beneath a major branch of the left coronary artery and the ends of the ligature are passed through a short polypropylene tube to form a snare. Myocardial ischemia occurs when the ends of the sutures are pulled through the tubing. The length of the ischemic period varies but is typically maintained for 30–90 min. Reperfusion occurs when the snare is released. In recent years the induced rabbit model has been used to demonstrate the cardioprotective effects of several regimens following infarction which include: rapid cooling of the heart with total liquid ventilation (Chenoune et al., 2010), oral acarbose

(Minatoguchi et al., 2009), high dose of insulin during the infarction period (Wong et al., 2011) and the antidiabetic drug pioglitazone (Yasuda et al., 2009). Acarbose, insulin, and pioglitazone most likely are cardioprotective due to the prevention of hyperglycemia which occurs in response to stress.

Through selective breeding of WHHL rabbits with high plasma cholesterol and severe coronary lesions a colony of myocardial infarct-prone WHHL (WHHLM) rabbits have been developed (Shiomi et al., 2003). In the original WHHL rabbits, atherosclerotic lesions mainly developed in the aorta and the incidence of severe coronary artery disease, including the animals that developed spontaneous myocardial infarctions, was low; approximately 23% cumulative incidence at 30 months of age (Gross, 2009; Nakamura et al., 1997; Rekher, 2002; Shiomi et al., 2003). The cumulative incidence of coronary artery disease WHHLM rabbits approaches 97% by 30 months of age. The tendency of WHHLM rabbits to develop myocardial infarcts is likely due to a change in composition of their coronary plaques from the fibrous lesions described in WHHL rabbits to fibroatheromas, more closely mimicking human disease pathogenesis (Shiomi and Ito, 2009; Shiomi et al., 2003). WHHLM rabbits expressing C-reactive protein and matrix metalloproteinases, both increased in patients with ACS are showing promise in investigating genetic factors that may serve as triggers promoting plaque rupture (Shiomi and Fan, 2008).

Bacterial Endocarditis

Etiology and Disease in Humans

Bacterial endocarditis is characterized by inflammation or infection on the inner surface of the heart. The heart valves and any devices implanted in the heart, such as artificial valves, pacemakers, and implantable defibrillators can be affected, and as a result patients with these devices are at an increased risk of infection (Corey and Lalani, 2008). Patients with vascular access catheters, such as those receiving hemodialysis are also at a higher risk for developing endocarditis (Lafrance et al., 2008). Overall, the disease affects approximately 10 000–20 000 people a year in the United States (Cabell and Fowler, 2003). Histologically, endocarditis lesions are composed of bacteria embedded in a meshwork of fibrin, which protects the bacteria from the body's white blood cells, and leads to poor penetration of antibiotics. Several microorganisms, predominately Gram-positive bacteria, can cause endocarditis in humans (Ge et al., 2008).

Rabbit Model

Infectious endocarditis can be experimentally induced through means such as ventricular catheterization and

intravenous inoculation of bacteria directly onto the valves (Asseray et al., 2002) or surgical exposure of the carotid artery to introduce an indwelling catheter with a subsequent intravenous inoculation (Chambers, 2006). The induced rabbit model is advantageous because it closely simulates the characteristics of the infection in humans, and it allows greater statistical comparisons since the number of bacteria inoculated can be controlled (Carbon, 1994). This model is used to evaluate the kinetics of antimicrobial penetration into vegetations, host–organism interactions, and to evaluate potential therapies (Carbon, 1994). A recent advancement in therapy using the rabbit model includes demonstration of the efficacy of ceftibiprole, a broad-spectrum cephalosporin, for treatment of methicillin-resistant *S. aureus* MRSA (strain 76) and a vancomycin intermediately resistant *S. aureus* induced valvular (aortic) endocarditis (Chambers, 2006).

OPHTHALMIC DISEASES

Laboratory rabbits continue to be one of the most widely used species in experimental ophthalmology research. The large size of the rabbit eye compared to its body size makes rabbits an attractive and economical model for surgical and drug delivery experiments. Rabbits also have few spontaneous ocular diseases. However, the eyes of rabbits share few anatomic characteristics with human eyes. The cornea of rabbits is thinner than humans, and the rabbit's lens is larger (Figure 18.8) causing the iris to bulge forward creating a more curved anterior chamber (Figure 18.9) (Werner et al., 2006). Rabbits also have rod-rich retinas that are very

FIGURE 18.8 Gross photographs of a rabbit (left) and a human (right) natural crystalline lens. Note that the rabbit lens is thicker than the human lens. While both rabbit and human lens are normally clear, the human lens pictured exhibits a yellow discoloration due to cataractogenesis. (courtesy of L. Werner, used with permission of the publisher)

FIGURE 18.9 (A–D) Ultrasound scans obtained from rabbit and human eyes (phakic, containing the natural lens and pseudophakic, containing synthetic intraocular lens (IOL)). The scan from the rabbit phakic eye (A) shows the anterior surface of the natural crystalline lens pushing the iris forward. The anterior chamber of the normal rabbit eye is more curved and shallower than in the human phakic eye (C). The geometry of the anterior chamber of the pseudophakic rabbit eye (B) is much more similar to that of the pseudophakic human eye (D). (*courtesy of L. Werner, used with permission of the publisher*)

poorly vascularized compared to humans (Perlman, 2009). As a result, the effects of drugs on the retina of a rabbit are not easily translated to humans (Perlman, 2009) and rabbits are infrequently used to study the pathogenesis of ocular diseases. Non-human primate eyes share the closest anatomy to the human eye, and of the non-primate species, the eyes of the pig most closely approximate those of humans (Albrecht May, 2008).

Cataract

Etiology and Disease in Humans

Chief among the risk factors for developing cataracts, a clouding of the lens, are chronic ultraviolet light exposure, diabetes, oxidative stress, smoking, and genetic predisposition (West, 2007). Cataracts affect more than 20 million people worldwide, and are a leading cause of blindness, particularly in developing countries (Wong and Hyman, 2008).

Rabbit Model

Rabbits have been used as a model of radiation-induced cataracts since the 1950s when investigators performing radiation studies observed that rabbits developed cataracts similar in structure to human radiation-induced cataracts (Cogan and Donaldson, 1951). The rabbit model is still being used to examine the effects of ultraviolet radiation on the development of cataracts (Hightower and McCready, 1992). While variations in method vary, in general the model is created by exposing the corneas of anesthetized rabbits to ultraviolet light from a distance of 0.05 m for various

frequencies and durations to create different doses of radiation exposure (Fris et al., 2008). The rabbit model is being used to develop treatments for or protection against radiation-induced lens damage (Bigsby et al., 2009; Sasaki et al., 1998).

Despite the overall smaller size of the rabbit eye compared to the human eye (Figure 18.10), the anterior chambers of the two eyes are similar and rabbits can easily accommodate intraocular lenses (IOL) designed for humans (Werner et al., 2006). As a result, the rabbit is a valuable model for training surgeons in the removal of cataracts and replacement with IOL, evaluation of novel IOL designs (Werner et al., 2006), and in the evaluation of new surgical approaches (Gwon, 2008). Rabbits are also used to study the pathogenesis and immune responses to staphylococcal endophthalmitis, one of the most feared complications of cataract surgery (Giese and Mondino, 2001). This model is created by direct inoculation of organisms into the anterior chamber. Two unique characteristics of rabbits warrant modification of standard human protocols when performing surgery on rabbit eyes. Compared to humans, rabbits mount a more pronounced inflammatory reaction following surgery to the eye, which necessitates the use of anti-inflammatories during the post-operative period (Werner et al., 2006). Finally, rabbits, and in particular Dutch belted rabbits, experience a massive protein release into the anterior chamber of the eye in response to disruption of the blood–aqueous barrier. To prevent complications from this protein release, heparin should be injected into the anterior chamber as soon as an incision is made, and heparin should be used in the irrigation solutions (Werner et al., 2006).

FIGURE 18.10 (A, B) Gross photographs of a rabbit (left) and a human (right) eye from anterior (A) and superior (B) views. The differences in the dimensions of the corneal diameter (white-to-white), equatorial diameter, and anterior-posterior length can be appreciated. (courtesy of L. Werner, used with permission of the publisher)

Herpes Simplex Virus Keratitis

Etiology and Disease in Humans

Herpes simplex virus type 1 (HSV-1) remains a leading cause of unilateral infectious corneal blindness worldwide, with an estimated 59000 new and recurrent cases of disease annually in the USA (Wilson et al., 2009). The virus is acquired by close human contact and spreads to the local sensory ganglia where it either replicates or establishes latency. HSV-1 is ubiquitous, with approximately 90% of the population seropositive by the age of 40 (Pepose et al., 2006). Herpetic stromal keratitis (HSK) occurs when reactivated virus travels down the sensory axon to the cornea leading to tissue destruction, edema, opacification, corneal scarring, and neovascularization (Pepose et al., 2006). Interactions between the recurrent virus and the host's immune response are implicated as the main cause of the corneal scarring (Naito et al., 2005). The aims of current research into HSK include developing improved therapies to target both the virus and the immune system, understanding the complex immune mechanisms responsible for viral reactivation, and using this knowledge to develop a vaccine to prevent primary infection or to minimize recurrent reactivation of the virus (Wilson et al., 2009).

Rabbit Model

Rabbits reliably develop HSK following ocular inoculation with HSV-1 with or without corneal scarification. The disease in rabbits follows a similar course to the human disease including viral reactivation (Nesburn et al., 2007), a characteristic that differs from the murine models (Naito et al., 2005). This characteristic, the large size of the rabbit cornea, and the similarities rabbits and humans share in the conjunctiva-associated lymphoid

tissue has allowed investigators to use rabbits to study the immune mechanisms involved in viral reactivation. Rabbits and humans also have a similar corneal follicular ultrastructure with an abundance of conjunctival lymphoid follicles, unlike rats and mice, which do not have corneal lymphoid follicles. Using rabbits, investigators are characterizing the cellular response to HSV-1 at the mucosal level with the aim of using this information to optimize topical treatments and/or mucosal vaccines (Nesburn et al., 2007). For example, Lambiase et al. (2008) evaluated the role of nerve growth factor (NGF) in modulating the immune response during infection with HSV-1. They discovered that topical NGF was as effective as acyclovir in diminishing the deleterious response to HSV-1. In contrast, 20% of rabbits treated with topical anti-NGF experienced worsening of the clinical outcome and a spreading of HSV to the brain.

Rabbits are also being used to characterize the stromal HSV-1 proteins or antigens in the HSK cornea that incite the inflammatory response. Until recently, investigators had been unable to identify any HSV-1-specific viral proteins in either naturally infected human, or experimentally infected animal, corneas (Naito et al., 2005). However, since some water-soluble corneal proteins diffuse out of the cornea, Naito et al. (2005) evaluated tears from rabbits infected with HSV-1, as well as the buffer soaking solution for corneal sections from these rabbits, for the presence of viral proteins. From both, the authors were able to identify the HSV-1 immediate-early protein ICP0 (Naito et al., 2005). Further studies have confirmed that ICP0 is localized to the anterior stromal layer of infected corneas throughout the course of viral infection. The anterior stromal layer is most affected by corneal scarring caused by epithelial keratitis, suggesting that ICP0 is a likely target of the immune response (Morishige et al., 2006).

Glaucoma

Etiology and Disease in Humans

Open-angle glaucoma is a chronic disease characterized by increased intraocular pressure that results in pathologic changes to the optic nerve, and clinically by loss of vision (Albrecht May, 2008). The disease generally occurs in older humans, and is the second leading cause of visual impairment worldwide, the first among persons of African descent (Wong and Hyman, 2008).

Rabbit Model

While glaucoma occurs as an inherited condition in rabbits, the mode of inheritance differs from that of humans, and rabbits with this condition are not used for glaucoma research. Glaucoma is induced in rabbits using corticosteroids or intraocular injection of alpha-chymotrypsin (Albrecht May, 2008). Recent comparative anatomy studies demonstrate that unlike humans, rabbits have an incompletely vascularized retina restricted to the myelinated portion of the nerve fiber layer (Albrecht May, 2008). As a result of this optic nerve area difference, rabbits are not a useful model of the pathogenic process of glaucoma, and rodent models are increasingly being developed and used (Pang and Clark, 2007). Rabbits continue to be used to evaluate refinements of surgical and medical treatment for glaucoma. Using the established rabbit model of the glaucoma filtration surgery, investigators demonstrated that the combined use of subconjunctival injections of bevacizumab and 5-fluorouracil decreases the aberrant healing and fibrosis that is a major complication of this procedure (How et al., 2009). Rabbits are also used to evaluate novel methods of drug delivery to the eye such as nanoemulsion eye drops containing the drug dorzolamide (Ammar et al., 2009). This formulation had a faster onset of drug action, and prolonged effect compared to the market product allowing a decrease in the number of applications per day and a better patient compliance.

Uveitis

Etiology and Disease in Humans

Uveitis is an inflammation of the highly vascular uveal tract (the portion of the eye including the anterior chamber, iris, and ciliary body). The condition most often occurs in young or middle-aged adults (Smith et al., 1998) and may account for up to 10% of legal blindness (vision that is 20/200 or worse) in Western countries (Suhler et al., 2008). The cause of most cases of uveitis is unknown, however, the disease may occur as a secondary complication of herpes virus infection among others (Suhler et al., 2008).

Rabbit Model

Numerous inflammatory mechanisms have been used to induce uveitis in the rabbit. The classic rabbit model of uveitis, called experimental autoimmune uveitis (EAU), is induced by immunizing rabbits with a soluble bovine retinal extract (Wacher and Lipton, 1968). Acute, bilateral uveitis occurs approximately 2 weeks after immunization in this model. The research utility of the EAU model has largely been replaced by the endotoxin-induced uveitis (EIU) model which is created by intravitreal injection of 10ng *Escherichia coli* endotoxin (Allen et al., 1998). EIU is clinically and histopathologically similar to acute anterior uveitis in humans. The rabbit model is often used in pre-clinical trials for novel therapeutic strategies such as piroxicam nanoparticles for drug delivery to the eye (Adibkia et al., 2007), the successful use of infliximab as a prophylaxis for recurring uveitis (Diaz-Llopis et al., 2007), and the anti-inflammatory properties of topical application of the herbs *Curcuma longa* and *Berberis aristata* (Gupta et al., 2008). The rabbit EIU model is also used to study the role of nitric oxide and peroxynitrite in the pathogenesis of uveitis (Allen et al., 1998). An alternative model is created using two subcutaneous injections, 1 week apart with *Mycobacterium tuberculosis* H37Ra antigen, which creates a severe, non-specific uveitis (Shin et al., 2009). This model is being used to develop a biodegradable intrascleral implant of triamcinolone that is proving effective in suppressing the inflammation of uveitis for at least 4 weeks (Shin et al., 2009).

Proliferative Vitreoretinopathy

Etiology and Disease in Humans

Proliferative vitreoretinopathy (PVR) occurs after retinal detachment and is a major complication of surgical reattachment of the retina, occurring in 3.9–13.7% of human patients (Lei et al., 2009). Disease progression is thought to involve retinal pigment epithelium (RPE), retinal glial cells, fibroblasts, and inflammatory macrophages migrating over the inner and outer surfaces of the retina (Lei et al., 2007). These cells form contractile membranes that can distort the retina or lead to retinal detachment. Retinal detachment leads to blindness if not treated immediately.

Rabbit Model

Rabbits are extensively used as an induced model of PVR using a number of intraocular manipulations to produce contractile membranes. One method of inducing PVR in rabbits, called gas vitrectomy, involves injecting an expanding gas, such as perfluoropropane (C₃F₈), into the eye, thereby compressing the vitreous and creating a void in the posterior segment (Thresher et al. 1984).

FIGURE 18.11 Unstained rabbit RPE cells in primary culture following adherence to the culture plate. Note the lack of confluency and the spread of their cytoplasm.

FIGURE 18.12 Rabbit RPE cells in primary culture that have undergone mitogenesis to form myofibroblastic cells.

Thresher et al. (1984) first described this technique as an alternative to mechanized vitrectomy, which cuts and aspirates the vitreous. Fibroblasts or cultured RPE cells are then injected into the voided space and allowed to proliferate to form contractile membranes that model the human condition (Mukherjee and Guidry, 2007). Early in the culture process, RPE cells appear phenotypically normal (Figure 18.11). However, if confluency and cell-to-cell contact is not obtained, these cells will proliferate and undergo mitogenesis to form myofibroblastic RPE cells (Figure 18.12). An analogous process occurs in vivo when retinal tears lead to migration of RPE and other cells into the vitreous. The rabbit PVR model is used both to investigate the pathogenesis of the disorder (Lei et al., 2008) and to evaluate novel treatments for the condition

such as an intravitreal sustained release naproxen and 5-fluorouracil system (Cardillo et al., 2004) and a partial thickness autologous RPE–choroid graft placement (Hu et al., 2008) both of which are showing promise as improved therapies over the current standard of care.

Diabetic Retinopathy, Age-Related Macular Degeneration (AMD), and Other Neovascularization Disorders

Etiology and Disease in Humans

Diabetic retinopathy (DR) and age-related macular degeneration (AMD) differ in their inciting causes. However, both are complicated by choroidal neovascularization (CNV) and edema and, because the two diseases occur in the posterior segment of the eye where drug delivery is difficult, the diseases share many of the same treatment approaches (Doukas et al., 2008; Majumdar and Srirangam, 2009). Hyperglycemia and prolonged duration of diabetes are risk factors in the development of DR, which is characterized by microvascular abnormalities, proliferation of retinal vessels, and increased vascular permeability (Arar et al., 2008). Vision loss with DR can occur due to macular edema or the new blood vessels can distort the retina leading to retinal detachment (Arar et al., 2008). DR is the leading cause of blindness among adults in the United States, affecting approximately 4.1 million people (Arar et al., 2008). Advanced age and cigarette smoking are risk factors for AMD which is characterized by the accumulation of drusen, a whitish yellow deposit under the retinal epithelium (Coleman et al., 2008). More than 8 million Americans are affected by early-stage AMD, making AMD the most common cause of vision impairment in individuals over 55 years of age. The disease will progress to blindness in approximately 1 million of these individuals (Coleman et al., 2008).

Rabbit Model

Because of the size of the rabbit eye, rabbits are one of the most widely used species to investigate novel methods of drug delivery to the posterior segment of the eye for treatment of vitreoretinal diseases (Myles et al., 2005). The outer and inner blood–retinal barriers limit influx of drugs into the retina, therefore simple topical and systemic drug delivery approaches to treat these diseases have limited efficacy. Novel approaches such as iontophoresis, in which a constant electrical field is applied across the conjunctiva, resulting in constant drug flow to the retina, are being studied in rabbits to treat these conditions (Myles et al., 2005).

Yasukawa et al. (2007) developed an AMD rabbit model by introducing glycoxidized microspheres with albumin into the subretinal space via a sclerotomy. In

contrast to previous models which are induced via a non-specific local inflammatory reaction, rabbits in this model developed drusen within 4 weeks. Four out of seven rabbits developed CNV within 12 weeks. Follow-up studies demonstrated that these rabbits have an abnormal fundus autofluorescence similar to the pattern seen in aging human eyes, making this a useful model to elucidate drusen biogenesis and pathogenesis of AMD (Hirata et al., 2009).

CENTRAL NERVOUS SYSTEM DISEASES

Coccidioidomycosis

Etiology and Disease in Humans

Coccidioides is a genus of fungi that causes coccidioidomycosis, an endemic condition in the deserts of the United States (Johnson and Einstein, 2006). *Coccidioides immitis* and *Coccidioides posadasii* are two pathogenic species in this genus, which might become established when a person inhales *Coccidioides* species spores from the environment (Clemons et al., 2007). Typically, the infection is limited, but some cases can lead to fatal meningitis (CM) (Johnson and Einstein, 2006; Williams, 2001; Williams et al., 1992). Treatment can be required for an extended duration, even for the lifespan of the individual, and relapses are a potential complication (Dewsnup et al., 1996; Stevens and Clemons, 2007). Despite prolonged treatment with antifungal oral azole compounds, a cure is not always realized (Dewsnup et al., 1996).

Rabbit Model

Rabbits are particularly valuable to study CM because the induced disease closely mimics the CNS involvement in patients with acute infection. The model is created by inoculating anesthetized rabbits with a viable anthroconidial suspension of *C. immitis*. Rabbits inoculated with 3×10^5 arthroconidia develop a progressive illness of 2–7 weeks' duration before requiring euthanasia (Clemons et al., 2007). Pathological lesions in experimentally infected rabbits are consistent with those found in people and include: hyperproteinemia, progressive pleocytosis, arteritis, granulomatous cerebrospinal meningitis, and infarction (Clemons et al., 2007). Clinical monitoring during infection in experimentally inoculated rabbits includes well-established parameters such as body temperature, hydration, mobility, posture, presence or absence of neurologic signs, and weight to assess the course of the disease (Clemons et al., 2000, 2002; Sorensen et al., 2000a, 2000b; Williams et al., 2002).

The large size of the rabbit brain, compared to the widely used murine models of CM, allows isolation and dissection of large vessels that can be used to

detect the gene expression of inflammatory mediators. Using this technique, metalloproteinase-9 was found to be over-expressed during acute CM. This enzyme is involved in vascular regeneration and may play a role in the vasculitis which is a major complication of CM (Williams, 2001). Recently, the rabbit model was used to show the efficacy of intravenous lipid-complexed amphotericin B and liposomal amphotericin B for treatments of CM (Clemons et al., 2009). The two drugs were similar in their ability to reduce clinical signs and number of fungi, and both provided a 100% survival rate in this model (Clemons et al., 2009).

Listeriosis

Etiology and Disease in Humans

Listeriosis is a rare but potentially fatal food-borne illness caused by *Listeria monocytogenes*, a Gram-positive bacterium found throughout the environment in soil, vegetation, and water supplies. *Listeria* can survive in acidic and salty foods, and continue to multiply at low temperatures, allowing for growth in poorly refrigerated foods (Jacobson, 2008). Raw milk and products made from raw milk are often the source of infection. The bacteria gain access to the body through ingestion and disseminate hematogenously. Pregnant women, neonates, the elderly, and immunocompromised patients are at highest risk for listeriosis due to impaired T-cell function. The most common clinical manifestations of listeriosis are sepsis and meningoencephalitis (Hof et al., 1997; Levidiotou et al., 2004).

Rabbit Model

Listeriosis is induced in rabbits via direct inoculation of into the cistern magna. The use of this model is diminishing, but was recently used to demonstrate that moxifloxacin treatment is similar to ampicillin plus gentamicin for *Listeria monocytogenes* infections when the following parameters (minimum thresholds) for meningitis were assessed: body temperature $>40^{\circ}\text{C}$, cerebrospinal fluid (CSF) bacterial count $>10^3$ CFU/ml, and CSF pleocytosis of >1000 cells, with $>96\%$ polymorphonuclear cells (Sipahi et al., 2008).

RESPIRATORY DISEASES

Bacterial sinusitis

Etiology and Disease in Humans

Sinusitis is inflammation or infection of the nasal passages and is one of the most common conditions treated by family physicians in the United States accounting for 25 million office visits annually (Scheid and Hamm, 2004). Although usually caused by viruses,

rhinosinusitis can be complicated by a bacterial infection, a condition called acute bacterial rhinosinusitis (ABRS). Approximately one in eight patients presenting with upper respiratory symptoms has ABRS (Scheid and Hamm, 2004). Obstruction of the ostia is the most important risk factor predisposing to ABRS, generally caused by inflammation and edema. Patients with septal deviation, nasal polyps, and anatomic variations of the nasal passages or tumors are also at an increased risk (Kara, 2004). *Haemophilus influenzae*, *Moraxella catarrhalis*, *Staphylococcus* spp., and *Streptococcus pneumoniae* are the most common isolates in cases of ABRS (Kara, 2004).

Rabbit Model

Rabbits are a valuable model of ABRS because humans and rabbits share important anatomical and immunologic similarities in their nasal passages (Liang et al., 2008). In both species, the nasal fossa is divided by the septum in the sagittal plane, and the lateral wall of the rabbit has structures similar to the turbinates in humans (Figure 18.13) (Kara, 2004). An ostium on the lateral side of the endoturbinates serves as the connection between the sinuses and the nasal cavity, an anatomical arrangement similar to the middle meatus in humans (Kara, 2004). In the past, ABRS was induced in rabbits via surgical preparations in which the ostium was closed and bacteria were inoculated into the sinuses of rabbits (Kara, 2004). This model reliably produced maxillary sinusitis, but was non-rhinogenic and was criticized for excess surgical manipulation (Liang et al., 2008). More recently, the rabbit model was refined by placing of a polyvinyl acetate absorbent

sponge (impregnated with the bacterium of interest) in the nasal cavity via the nares of the rabbit. This model produces marked mucosal inflammation with purulent exudation by 2 weeks in 83% of rabbits, but the inflammation decreases over time and is generally absent by 10 weeks (Kara, 2004). Surgical preparations are still needed for some studies related to the characterization of topical antimicrobial therapy for sinusitis (Chiu et al., 2007). For example, a technique using surgical placement of an irrigating catheter for delivery of bacteria or saline resulted in a model that could be used for future studies to develop topical therapy guidelines after functional endoscopic sinus surgery (FESS) (Chiu et al., 2007). Rabbits prepared in this fashion and given *Pseudomonas aeruginosa* were successfully treated with topical tobramycin, a commonly used therapy in cystic fibrosis patients because of its anti-pseudomonal effects (Antunes et al., 2007). Rabbits have also been critical in the study of biofilm-forming strains of *Pseudomonas aeruginosa* that can contaminate stents used in frontal sinus surgeries (Palmer, 2006).

Anthrax

Etiology and Disease in Humans

Anthrax is caused by *Bacillus anthracis*, a Gram-positive, facultative anaerobic, spore-forming bacterial pathogen (Skoble et al., 2009). Humoral immunity is the primary defense against anthrax, especially antibodies that neutralize LeTx (Skoble et al., 2009). Depending on the mode of infection, *Bacillus anthracis* can cause lesions in the gastrointestinal tract, skin, or respiratory system (Pile et al., 1998). Edema toxin (EdTx), lethal toxin (LeTx), and the poly- γ -D glutamic (PGA) capsule are the major components responsible for disease in anthrax cases (Skoble et al., 2009). Protective antigen (PA) is a common subunit of EdTx and LeTx, which are classic A-B toxins (Skoble et al., 2009). Edema factor (EF) and lethal factor (LF) are the active moieties that enter the cytoplasm through the action of PA (Skoble et al., 2009). As only PA was used as an antigen in the original vaccine, its modification could thwart vaccine protection in a bioterrorism attack (Skoble et al., 2009). The currently licensed anthrax vaccine uses EF, LF, and PA from *B. anthracis* adsorbed to an adjuvant (aluminum hydroxide gel) (Skoble et al., 2009). The anthrax vaccine-adsorbed (AVA) inoculum is often associated with inflammation at the injection site and sometimes more serious adverse reactions such as neuropathy (Sever et al., 2004). A vaccine composed of purified recombinant PA (rPA) has been developed for humans (Little et al., 2006). Recently, a novel vaccine was developed for protection against anthrax: the psoralen-killed but metabolically active (KBMA) vaccine, which offers the

FIGURE 18.13 Lateral wall of the right nasal cavity of the rabbit. Arrow in inset shows the ostium of the right sinuses, which is evident just lateral to the endoturbinates. E, endoturbinates; M, maxilloturbinate. (courtesy of Kara, 2004, used with permission of the publisher)

immunogenicity of attenuated vaccines with the safety of inactivated vaccines (Brockstedt et al., 2005).

Rabbit Model

Rabbits have played an important role in the development and refinement of anthrax vaccines. To address the concern about the conventional PA-based vaccine that relied on one antigen, an experiment using a multiple antigenic peptide with a heptameric structure of PA for immunizations resulted in the *in vitro* neutralization of LeTx (Oscherwitz et al., 2009). Additional promising vaccine research with rabbits includes evidence that the novel KBMA vaccine provides a wider base of humoral immunity than current subunit vaccines (Skoble et al., 2009). Recombinant virus type 1 (rAAV1) vectors that contain genes synthesized from LF or PA produce significant neutralizing antibodies after one administration, indicating a potential use as a vaccine (Liu et al., 2009). Anthrax vaccine safety related to the use of the current vaccine, AVA, in pregnant women has been tested in rabbits, and was found to have no untoward effects on the pregnant does or their kits (Franco et al., 2009). An intranasal rPA vaccine was effective in protecting rabbits against an aerosol inoculum with anthrax spores 9 weeks following a single injection, demonstrating a potentially more practical form of vaccine delivery (Klas et al., 2008). The repertoire of rabbit models for the study of anthrax has been expanded with recent work in the Dutch belted rabbit (Lawrence et al., 2009), which has physiologic parameters comparable to those in humans exposed to anthrax (Lawrence et al., 2009).

Tuberculosis

Etiology and Disease in Humans

Pulmonary tuberculosis (TB) is caused by *Mycobacterium tuberculosis*. *M. tuberculosis* is a facultative intracellular, non-sporeforming, aerobic, acid-fast, Gram-positive organism that can infect and multiply in macrophages and other cells. There are more than two million fatal cases of TB each year (North and Jung, 2004). Most of the fatalities are in Southeast Asia and Africa (North and Jung, 2004). In 2000, there were over eight million new cases of TB globally, and 11% of deaths among adults with AIDS were attributed to TB during the same year (Corbett et al., 2003). Susceptibility to infection with *M. tuberculosis* appears to be related to genetic polymorphism involving genes for mannose-binding protein, natural resistance-associated macrophage protein (NRAMP1), and the receptor for vitamin D (North and Jung, 2004). Infection with *M. tuberculosis* typically presents as a delayed-type hypersensitivity, a result of a Th1 immune response, and most infections are

FIGURE 18.14 Aerosolization chamber for infecting rabbits with TB.

confined to the lungs (North and Jung, 2004). However, immunocompromised patients can suffer from systemic disease and infections in many organs (North and Jung, 2004). If infected, pulmonary granulomas can evolve to include caseous necrosis centrally that can cavitate (North and Jung, 2004). Individuals with cavitations can easily spread *M. tuberculosis* (Helke et al., 2006). The cavities are the most highly oxygenated among the lesions related to infection, allowing enhanced multiplication of the *M. tuberculosis* bacteria (Helke et al., 2006; Via, 2008). A hypoxic environment and/or exposure to nitric oxide (NO) from activated macrophages might account for persistent *M. tuberculosis* infections (Converse et al., 2009). Fibrosis within the granuloma and parenchyma results in the characteristic nodules or tubercles. *M. tuberculosis* can also cause serious cases of tuberculous meningitis, especially in children; this form of TB has a 50% mortality rate (Tsenova et al., 2005).

Rabbit Model

While both mice and guinea pigs are used as animal models of TB, the rabbit model is advantageous because rabbits are more resistant, develop a spectrum of disease, and eventually clear the organism, which mimics the clinical course of disease in humans (Manabe et al., 2002). TB is induced in rabbits via aerosolization in a nose-only system in a class II biosafety glove box cabinet under negative pressure (Figure 18.14) (Manabe et al., 2002). The severity of disease produced in rabbits varies with the virulence of the TB strain used, but in general rabbits have visible pulmonary tubercles 5 weeks after infection (Manabe et al., 2002). This clinical feature has made the rabbit a valuable model to examine the relative pathogenesis of different strains of TB. The strain of rabbit used in the experiment also impacts disease expression. When challenged with the Erdman or

FIGURE 18.15 (A–D) Series of images (10×) showing the comparison of H&E-stained and anti-PIMO adduct-labeled pulmonary sections from rabbits experimentally infected with *M. tuberculosis*. (A) shows granulomas devoid of necrosis. The corresponding image (B) shows weak PIMO staining. (C) is the H&E section for (D) (anti-PIMO adduct-labeled). In (D) the caseous necrotic granuloma has low oxygen tension foci indicated by the brown coloration.

H37Rv strain of TB, inbred NZW rabbits had larger and more tubercles with more colony-forming units in each tubercle than the outbred NZWs (Dorman et al., 2004). The inbred NZWs also had a greater level of caseous necrosis in pulmonary granulomas, a lower number of mature epithelioid cells, lower delayed-type hypersensitivity reaction, more visible *M. tuberculosis* organisms, and a lower amount of tumor necrosis factor alpha from LPS-stimulated peritoneal macrophages than outbred NZWs, indicating a higher susceptibility in inbred NZWs (Dorman et al., 2004). In pulmonary TB cases, lesions that are common to humans and rabbits include granulomas with liquefaction and caseous necrosis, and possibly most significantly, cavitations (Dorman et al., 2004), which is illustrated using pimonidazole hydrochloride (PIMO), a compound that is bioreductive only in hypoxic mammalian tissues (Figure 18.15) (Via et al., 2008). Rabbits have been used for models of central nervous system infections in humans via direct inoculation into the cisterna magna. A similar spectrum of disease based on the virulence of the injected TB strain is observed in this model (Tsenova et al., 2005).

UROGENITAL DISEASES

Papillomatosis

Etiology and Disease in Humans

Human papillomaviruses (HPVs) are double-stranded DNA, non-enveloped, viruses that include more than one hundred different viral “types” (de Villiers et al., 2004). Papillomatosis can include genital warts/cancers, and respiratory lesions (de Villiers et al., 2004; Govan et al., 2008). Depending on their predisposition to

manifest as malignancies, HPVs are classified as “high-risk” or “low-risk” viruses (de Villiers et al., 2004; Munoz et al., 2003). HPV 6 and 11 are the most common “low-risk” HPVs and cause 90% of genital warts (Govan et al., 2008). HPV 16 and 18 are the most prevalent “high-risk” types and the etiologies of 70% of cervical cancers (Govan et al., 2008). Spontaneous resolution of proliferative epithelial lesions can occur over an extended period of time (up to years) in HPV infections (Brandsma et al., 2007). Persistence of the “high-risk” types can last decades, and changes can lead to carcinoma formation in the absence of therapy (Govan et al., 2008). In less developed nations, cervical neoplasia is the most prevalent type of cancer in females, and represents the second most prevalent cancer in this gender globally (Govan et al., 2008). The current L1 virus like particle (VLP) vaccine confers immunity in humans (Hu et al., 2007). Nonetheless, a vaccine that could produce a wider array of protective antibodies would be more beneficial given the diversity of HPV genotypes (Hu et al., 2007). Another shortcoming of the L1 VLP vaccine is that it protects against new HPV infections, but it fails to protect or fully protect the individual if there is an existing infection (Hu et al., 2007).

Rabbit Model

Papillomaviruses are very species-specific (Hu et al., 2007). Thus, the cottontail rabbit papillomavirus (CRPV) has been used to investigate papillomatosis in rabbits (Fausch et al., 2003). Genetically modified rabbits have also been useful in the exploration of HPV biology and pathogenesis (Hu et al., 2007). Researchers developed a transgenic rabbit line that expresses the extensively studied human major histocompatibility complex class I (MHC-I) gene, HLA-A2.1 (Hu et al.,

2007). Germline transfer of this transgene has been confirmed with breeding schemes using outbred NZW rabbits and the EIII/JC inbred strain (Hu et al., 2007). The genome of the CRPV can withstand significant genetic modifications, meaning that it could possibly serve as a mechanism to test HLA-A2.1-specific epitopes (Hu et al., 2007). Promising vaccine study results also include the use of an “ubiquitin-fused” CRPV recombinant DNA vaccine (Brandsma et al., 2007). This “UbE1267” vaccine removed papillomas in rabbits with covert infections and significantly lessened the volume of papillomas in overt cases of papillomatosis (Brandsma et al., 2007). CRPV VLP vaccines reduced the size of papillomas in vaccinated NZW rabbits, which suggests a similar therapy with VLPs vaccines might be possible in humans with low-risk HPVs (Govan et al., 2008).

GASTROINTESTINAL DISEASES

Colibacillosis

Etiology and Disease in Humans

Escherichia coli (*E. coli*) is an important foodborne illness that causes diarrhea particularly in infants and in travelers from developed to underdeveloped countries, affecting approximately 60% of visitors to tropical and subtropical countries (Okoh and Osode, 2008). Traveler’s diarrhea is generally caused by the enterotoxigenic *E. coli* (ETEC) and causes a watery or bloody diarrhea that resolves within a few days. Several serovars of *E. coli* cause more serious clinical conditions: enteroaggregative *E. coli* (EAEC) causes persistent watery diarrhea that has been implicated as a possible cause of irritable bowel syndrome (Kaur et al., 2010), enterohemorrhagic *E. coli* (EHEC) can result in serious hemolytic-uremic syndrome (Kulasekara et al., 2009), enteroinvasive *E. coli* (EIEC), and enteropathogenic *E. coli* (EPEC) (Edelman and Levine, 1983; Levine, 1987; Vial et al., 1988) cause severe diarrhea in infants by attaching and effacing the intestinal epithelia surfaces (Abe et al., 1998). *E. coli* are often involved in foodborne illness outbreaks in the United States affecting adults as well as children (Kulasekara et al., 2009). As a result, *E. coli* remains a significant public health concern.

Rabbit Model

A surgical model designated the RITARD model which stands for removable intestinal tie-adult rabbit diarrhea for producing colibacillosis in rabbits was first described in 1981 (Spira et al., 1981). The model is created via a laparotomy in an anesthetized rabbit. The cecum is ligated and a temporary reversible obstruction (a slipknot tie) of the small bowel is created at the time of challenge and removed 2 hours later. Rabbits reliably develop diarrhea using this technique and this model

continues to be used to understand the pathogenesis of *E. coli* (Fagundes-Neto et al., 1995; Moon et al., 1983; Nobe et al., 2009). The nomenclature of *E. coli* strains in animals often includes a letter in the acronym to identify the natural host: REPEC is the EPEC found in rabbits and used as a model of disease associated with EPEC in humans (Wales et al., 2005). Rabbits, particularly young rabbits are increasingly being inoculated with different strains to *E. coli* via orogastric intubation to more closely mimic the natural course of disease. For example, when 28–56-day-old rabbits were inoculated with *E. coli* serogroup O103 (REPEC O103) 65% developed diarrhea and bacterial shedding, and 23% of the rabbits died between 2 and 10 days after infection (Heczko et al., 2000). This study used scanning electron microscopy to characterize the pathogenesis of these bacteria in vivo, which showed that the organism first adhered to the villi of Peyer’s patches in the ileum forming “fimbriae-like” organelles within the first 24 hours, resulting in attaching-effacing lesions in the ileum, ileal Peyer’s patches, and proximal colon 72h later (Figure 18.16) (Heczko et al., 2000). Various adherence factors cause an initial non-intimate attachment of REPEC organisms in rabbits (Wales et al., 2005). REPEC adhesion-mediated binding was limited to Peyer’s patches of the ileum, which is similar to the condition involving EHEC O157:H7 in humans (Phillips and Frankel, 2000). AAEC bacteria in rabbits are usually associated with a pattern consistent with EPEC bacteria (Wales et al., 2005). However, REPEC strains vary according to serotype, virulence, how they colonize the intestines, and the age of the host (Wales et al., 2005). Attaching-effacing lesions can be diagnosed using a number of methods including microscopy (Wales et al., 2005), murine monoclonal anti-alpha-actinin antibodies (Ismaili et al., 1995), epifluorescent microscopy (Vallance et al., 2002), and laser scanning confocal microscopy (Abe et al., 1998). A naturally occurring rabbit model of EHEC in Dutch belted rabbits was recently described (Garcia et al., 2002). In addition to developing diarrhea, these rabbits develop the clinical and pathological evidence of human hemolytic-renal syndrome and are being further characterized with the goal of establishing an experimental model of this syndrome (Garcia et al., 2002).

Campylobacteriosis

Etiology and Disease in Humans

Campylobacter jejuni is the leading cause of bacterial diarrhea in the world (Stintzi et al., 2005). This agent has been associated with 14.2% of the annual food borne illnesses in the U.S. presenting as mild diarrhea to significant intestinal discomfort (Mead et al., 1999; Stintzi et al., 2005). Guillain-Barré syndrome (GBS), a condition of acute paralysis, can be an uncommon

FIGURE 18.16 Scanning (A, C–F) and transmission (B) electron micrographs of rabbit intestinal segments 24 hours after infection with REPEC O103. (A) ileal villi with normal appearance. (B) during early stages of infection bacteria express fimbriae-like structures at their surface (→) resulting in initial non-intimate adherence to epithelial host cells. Bar = 1 μm. (C, D) in response to infection, microvilli on Peyer's patch enterocytes show irregular arrangements resulting in a bowl-like (→) surface appearance. but significant sequella to the infection (van Vliet and Ketley, 2001).

Rabbit Model

The Rabbit Ileal Loop (RIL) model is an established preparation performed prior to inoculating the intestine with an agent of interest. This procedure involves exposure of a section of ileum with a viable mesenteric blood supply and its ligation to inhibit peristalsis, which promotes colonization by the infectious agent (Caldwell et al., 1983; Everest et al., 1993; Stintzi et al., 2005). Using this method to experimentally infect rabbits with *C. jejuni*, it has been shown that the *C. jejuni* transcriptomes were different among infected rabbits, indicating a likely attempt by *C. jejuni* to survive in diverse intestinal conditions (Stintzi et al., 2005).

An up-regulation of the stringent response (microbial stress response to a nutrient-depleted environment) by *C. jejuni* potentially contributes to intestinal colonization (Stintzi et al., 2005).

The neurologic effects of a *C. jejuni* infection are attributed to a "carbohydrate mimicry" involving the lipo-oligosaccharide of *C. jejuni* and GM1 ganglioside in humans, resulting in an autoimmune condition consistent with Guillain-Barré syndrome (Yuki et al., 2004). To illustrate the potential neurologic effects of a *C. jejuni* infection, lipopolysaccharide obtained from *C. jejuni* found in a human with Guillain-Barré syndrome, combined with Freund's adjuvant and keyhole limpet hemocyanin, served as an inoculation for rabbits that subsequently presented with sciatic nerve axonal degeneration and weakness (Caporale et al., 2006).

Endotoxemia

Etiology and Disease in Humans

Sepsis and the systemic inflammatory response resulting from systemic infections are the most common cause of death in adult intensive care units, with the number of deaths increasing over the past two decades (Parker and Watkins, 2001). Despite active research into treatments for septicemia and endotoxemia, management of patients remains largely supportive. Multiple Gram-negative bacteria can produce endotoxins that disrupt the physiology of the gastrointestinal tract including nutrient, water, and electrolyte absorption in humans and animals (Gardiner et al., 1995; Hecht and Koutsouris, 1999). Lipopolysaccharide (LPS), found in the outer bacterial wall, is an example of an endotoxin that induces cellular signaling involving several types of protein kinases (Chow et al., 1995) that result in cytotoxic effects (Amador et al., 2007).

Rabbit Model

Many animal models from mice to non-human primates have been used to study different aspects of endotoxemia (Parker and Watkins, 2001). Large mammals, such as rabbits, are often used in physiological studies requiring invasive monitoring. The rabbit, along with sheep and chimpanzees are more sensitive to the effects of endotoxin and show an enhanced response to lower doses of LPS than other species (Parker and Watkins, 2001). The rabbit endotoxemia model is created by injecting either *E. coli* organisms or LPS into the marginal ear vein (Elmas et al., 2008). This model has been used to demonstrate the poor enteric uptake of D-fructose and L-leucine associated with facilitation of LPS activity by protein kinase C and calmodulin (Amador et al., 2007), and the efficacy of simultaneous treatment with a fluorinated quinolone antibiotic and a non-steroidal anti-inflammatory for the treatment of septicemia (Elmas et al., 2008).

MUSCULOSKELETAL DISEASES

Osteomyelitis and Implant-Related Infection

Etiology and Disease in Humans

Osteomyelitis is an inflammatory process accompanied by bone destruction due to an infectious organism. Infections can result as a complication of bone fracture therapy and joint surgeries or spread hematogenously, particularly in juvenile and elderly patients and in those with diabetes (Lew and Waldvogel, 2004). Approximately 15% of diabetics will develop osteomyelitis as a result of a foot infection during their lifetimes. Some of these patients will eventually require

limb amputation due to non-healing lesions (Lew and Waldvogel, 2004). *Staphylococcus aureus* represents the most common etiology of osteomyelitis (Lew and Waldvogel, 2004). A troubling recent development is the increase in the number of osteomyelitis cases involving gentamicin-resistant or methicillin-resistant *S. aureus* (MRSA) (Giavaresi et al., 2008). Another reason for concern is an increase in the number of *S. aureus* clinical isolates that produce Panton-Valentine leukocidin (PVL), a hetero-oligomeric toxin (with subunits, LukFPV and LukS-PV), that is unrelated to methicillin resistance but often associated with *S. aureus* infectious osteomyelitis or arthritis (Cremieux et al., 2009). An increase in PVL-producing *S. aureus* is attributed to the rising prevalence of community-acquired methicillin-resistant *S. aureus* (CA-MRSA) strains (especially USA300) (King et al., 2006; Tristan et al., 2007). Infections surrounding foreign bodies and internal fixation devices often involve a biofilm on the indwelling object from which *Staphylococcus epidermidis* is most often recovered (Donlan, 2001; Vuong and Otto, 2002). In cases of indwelling medical devices, antimicrobial agents, removal of the device, debridement of necrotic tissue, and potential stabilization with an external device are frequently necessary for a positive outcome (Giavaresi et al., 2008). Local application of antimicrobials to infected osteomyelitis sites has typically involved polymethylmethacrylate for delivery (Jia et al., 2009). Other materials such as bioceramic compounds (silicate-based bioactive glass, synthetic hydroxyapatite, and tricalcium phosphate) have been similarly utilized (Jia et al., 2009). Polymers and composites have also been employed to promote tissue healing and repair (Shi et al., 2009).

Rabbit Model

Anatomically, the tibia of the rabbit lends itself to bone and joint experiments because of the relatively small mass of associated soft tissue, facilitating access and manipulation (An et al., 2006). The femur is more substantial than the tibia, with a greater medullary space which makes it a commonly used site for implantation and internal fixation research (An et al., 2006).

Rabbits are suitable immunologically for studies with microorganisms that infect bones and joints in humans (Cremieux et al., 2009). The significant pathophysiology of a PVL-positive CA-MRSA strain (USA300) has been demonstrated in a rabbit model (Cremieux et al., 2009). Experimental osteomyelitis using *S. aureus* in rabbits was successfully treated when ethyl cellulose microspheres were impregnated with gentamicin for local antimicrobial application (Shi et al., 2009). Additional promising results were seen when a different local therapy regimen with borate glass plus chitosan pellets were filled with the antibiotic, teicoplanin, which is known to have good activity against

most Gram-positive (including MRSA) aerobic and anaerobic bacteria (Jia et al., 2009). Rabbits were also used to evaluate the efficacy of ciprofloxacin-releasing SR-PLGA 80/20 miniscrews to minimize infection in bone fixation devices (Ashammakhi et al., 2006).

Electrical current has been used as part of a novel treatment of fracture non-unions that have been stabilized with indwelling devices (Del Pozo et al., 2009). Rabbit experiments suggested that an electrical current plus doxycycline was more beneficial in treating infections involving foreign bodies (implants) and *S. epidermidis* biofilms, than doxycycline alone (Del Pozo et al., 2009). Extracorporeal shockwave therapy (ESWT), another novel therapy that promotes remodeling in bones and increased vascularity, is becoming more widely used in therapy for fractures and non-unions, and soft tissue conditions such as fasciitis, chronic ulcers, and wound healing (Gollwitzer et al., 2009). ESWT has been withheld for infectious conditions because of an assumed dissemination of bacteria with a potential septicemia (Gollwitzer et al., 2009) secondary to shock-wave-induced neovascularization. However, when applied to rabbits with experimentally induced cases of *S. aureus* osteomyelitis, ESWT did not cause the organisms to spread or an intensification of the infection (Gollwitzer et al., 2009). Instead, ESWT was proven to be beneficial when histologic samples from treated and control groups were compared (Gollwitzer et al., 2009).

Osteoarthritis and Non-Infectious Orthopedic Disease

Etiology and Disease in Humans

Osteoarthritis (OA) is a chronic degenerative disorder characterized pathologically by cartilage loss and clinically by severe pain, joint deformity, and loss of joint motion (Swieszkowski et al., 2007). More than 20 million people in the United States are affected by the disease, making OA one of the major causes of disability among the adult population. Recent studies have demonstrated that OA is a risk factor for early mortality from other systemic diseases, possibly due to poor musculoskeletal function and limited exercise (Hochberg, 2008). Joint trauma, age, obesity, genetic factors, and race are among the many risk factors for acquiring OA (Das and Farooqi, 2008). Articular cartilage and subchondral bone form a load-bearing system that provides joint stability, cushioning, and lubrication to the joint (Swieszkowski et al., 2007). Cartilage is an avascular tissue that has a very limited ability for regeneration. As a result, therapies for early OA including analgesics, intra-articular injections, and acupuncture (Das and Farooqi, 2008) have been largely palliative; with surgery, including partial or total joint replacement, reserved for patients with unrelieved pain.

Rabbit Model

The rabbit is frequently used in orthopedic research to understand the natural history of disease, to evaluate the effects of novel clinical treatments, and to develop new and refined surgical techniques (Pelttari et al., 2008). Gupta and Lee (2007) recently developed a rabbit model to investigate the pathophysiology of rotator cuff injury by creating a tenotomy on the subscapularis tendon complex. Traditional rat models of rotator cuff injuries are made by creating a tenotomy on the supraspinatus tendon (Soslowsky et al., 2002). The supraspinatus tendon is chosen because it is the most common source of injury in human rotator cuff disease. However, the anatomical and biomechanical forces on the shoulder of a quadrupedal animal differ from those in a human, and the supraspinatus tendon is a fairly rudimentary tendon in rats. The subscapularis rabbit model more closely mimics the disease condition in humans and will allow investigation into the natural history of tears and the healing response to surgical correction (Gupta and Lee, 2007).

The rabbit is one of the models used to evaluate the effects of damage to the knee following anterior cruciate ligament (ACL) injuries, one of the most commonly damaged ligaments in the human knee (Zhou et al., 2009). The ACL cannot be naturally repaired due to poor vascularization, rendering the knee unstable and causing damage to the cartilage and meniscus that subsequently results in OA. The classic rabbit model of ACL injury is created by surgically ligating the ACL in an anesthetized rabbit (Kimura et al., 2008). This model is being extensively used to investigate novel therapeutic approaches, such as tissue engineering of the ACL which will allow regeneration of the ACL via integration of cells, a scaffold for cell proliferation and differentiation and growth of trophic factors (Kimura et al., 2008; Petrigliano et al., 2006).

A new rabbit model of traumatic ACL injury was recently described that mimics the high-energy jump landing insult to the knee without bone fracture that often results in ACL rupture (Killian et al., 2009). This model was created in anesthetized Flemish Giant rabbits restrained in a supine position with the femur fixed with Velcro straps, the knee flexed 90° and the foot fixed in a custom-designed boot fixed with Velcro straps. A 1.75-kg mass was dropped from a height of 75 cm to strike the distal femur of the left leg. The tibia was not constrained and subluxated on impact, resulting in rupture of the ACL. In addition to ACL rupture, the left lateral menisci of these animals was also torn, which is a common feature of natural ACL injuries and absent from the surgical model. This is the first ACL injury model to replicate both the acute and chronic meniscal damage following ACL trauma and promises to be an important animal model to investigate the pathogenesis of OA in the knee.

The limited potential for regeneration of cartilage has prompted research into methods to achieve osteochondral regeneration, such as tissue engineering. The rabbit has been one of the primary animal models for these studies (Pelttari et al., 2008). Several investigators demonstrated cartilage growth in the medial condyle of rabbits after transplanting bone marrow progenitor cells that had been seeded on a hyaluronan or collagen matrix (Grigolo et al., 2001; Pelttari et al., 2008). The rabbit, along with mice, goats, pigs, and calves are used to investigate bi-phasic tissue engineering scaffolds for the junction between cartilage and the underlying bone (Keeney and Pandit, 2009). Rabbits are also being used to evaluate the therapeutic potential of bone morphogenetic protein (BMP), particularly osteogenic protein-1 (OP-1), for cartilage repair (Chubinskaya et al., 2007). BMPs are expressed in a variety of tissues and have wide-ranging biological effects including regulation of cell proliferation, apoptosis, and maintenance of tissue homeostasis during adult life (Chubinskaya et al., 2007). OP-1 was the first BMP to receive regulatory approval for bone repair treatment. The encouraging results from multiple rabbit studies may serve as a foundation for approval of the compound for cartilage repair as well (Chubinskaya et al., 2007).

MULTISYSTEMIC DISEASES

Candidiasis

Etiology and Disease in Humans

Most cases of candidiasis in humans are caused by *Candida albicans* (Kao et al., 1999). Typically, this dimorphic fungus is a commensal organism found in the mucosa and gastrointestinal tract. Local infections are common, and it is reported that 75% of all women have had at least one episode of vaginal candidiasis (de Repentigny, 2004). However, *C. albicans* can cause invasive infections as an opportunist. This is particularly true of immunocompromised patients, in whom *C. albicans* is the most frequently isolated fungal pathogen associated with infection in a hospital setting (Bujdakova et al., 2008). Disseminated candidiasis can occur if the organism enters the cardiovascular system from another site, such as the oral mucosa or the gastrointestinal tract, especially in patients with neutropenia or leukemia (Abi-Said et al., 1997; Walsh and Merz, 1986). Infection of the oropharynx can often be a complication of HIV-AIDS (de Repentigny, 2004). Hematogenous infections with fungi, including *Candida*, often involve contaminated indwelling catheters or medical devices that are difficult to treat (Mukherjee et al., 2009).

Rabbit Model

Many animal species have been used as models to evaluate the spectrum of disease caused by *C. albicans*. Transgenic and knockout mice with targeted immune defects have largely replaced rabbits for pathogenesis studies of *C. albicans*, but rabbits are still used to evaluate treatments for systemic, particularly hematogenous *Candida* meningoencephalitis (HCME) (Hope, 2008; Mukherjee et al., 2009) and ocular candidiasis (Suzuki et al., 2008). HCME is induced in rabbits via intravenous inoculation generally through a centrally placed indwelling catheter. Rabbits reliably develop *Candida* positive blood cultures 24h after inoculation, although few have positive cerebral spinal fluid (CSF) cultures despite positive *Candida* cultures from the brain tissue when the rabbits were euthanized (Petraitiene et al., 2008). Patients with HCME likewise rarely have positive CSF fungal cultures which often delays therapy. The rabbit model was used to demonstrate the potential utility of β -glucan, a component of the fungal cell wall in the CSF as a biomarker of *Candida* infection (Petraitiene et al., 2008). Rabbits with HCME has significantly elevated CSF β -glucan levels that reliably fell in response to treatment with the antifungal micafungin (Petraitiene et al., 2008). The rabbit HCME model is also used to evaluate the efficacy of antifungals for systemic disease (Egermann, 2009; Hope et al., 2008; Mukherjee, 2009) as well and *C. albicans* endophthalmitis (Kusbeci et al., 2007; Louie, 1999; Suzuki, 2008).

Variola (Smallpox)

Etiology and Disease in Humans

The potential use of orthopoxviruses, including variola virus (smallpox) and monkey pox, as biological weapons has renewed interest in the development of anti-orthopoxvirus agents (Smee, 2008). The characteristics that make these viruses ideal biological weapons include a high mortality rate (50% or more) (Panchanathan et al., 2008) with low levels of virus, generalized dissemination with secondary lesions, and ease of communicability (Adams et al., 2007). Lesions can range from multiple pustules over much of the body to pneumonia, fatal hypotension, and immune complex disease (Panchanathan et al., 2008).

Rabbit Model

Rabbits inoculated intradermally with either rabbit pox virus (RPV) or the Western Reserve strain of vaccinia virus (VV-WR) develop disease beginning 1 or 2 days post intradermal inoculation with injection site swelling and progressing to systemic disease including a fever and severe respiratory disease requiring euthanasia by 6–9 days post infection (Adams et al., 2007).

RPV and VV-WR infected rabbits are 100% efficient in transmitting lethal disease to co-housed rabbits, and slightly less than 50% efficient in transmitting disease to animals housed 15cm away, suggesting an aerosol route of transmission (Adams et al., 2007). The rabbit is the only small animal model for human smallpox in which natural aerosol transmission has been reported (Adams et al., 2007). This model is being used to evaluate the efficacy of anti-orthopox treatments such as cidofovir and ST-246 which inhibit assembly of the viral envelope and escape of the virus from RPV-infected cells (Smee, 2008) and novel vaccines (Garza et al., 2009).

Syphilis

Etiology and Disease in Humans

Treponema pallidum subspecies *pallidum*, is the causative agent of syphilis. The spiral-shaped bacterium or spirochete belongs to the order, Spirochaetales. In the absence of therapy, this sexually transmitted disease can cause cardiovascular and central nervous system lesions. Antimicrobials, including penicillin, are effective in the treatment of syphilis. However, this disease is a major health issue, especially in less developed countries, in which there are approximately twelve million new cases each year (Brinkman et al., 2008). The disease follows a pattern of three stages over the course of several years. In the initial stage, one or more chancre develop in the genitals approximately 21 days post-infection which may be associated with regional lymphadenopathy (Peeling and Hook, 2006). During this stage, *Treponema* organisms likely penetrate the endothelial intercellular junctions and gain access through the bloodstream to different parts of the body such as the central nervous system (Thomas et al., 1988). The secondary stage generally begins 6–8 weeks later. Depending on the dissemination of the organism, the clinical signs of stage two syphilis can vary widely but often include a generalized maculopapular rash and lymphadenopathy, headache, and malaise (Peeling and Hook, 2006). Individuals with primary or secondary lesions spread the disease through sexual contact. Transplacental infection from an infected mother to the fetus represents the most serious transmission of the organism, and often results in fetal death, or mental retardation and abnormal growth for those who survive to parturition (Peeling and Hook, 2006). Left untreated, about a third of adults infected with *Treponema* will progress to the tertiary stage disease involving neurological and cardiovascular impairment (Peeling and Hook, 2006).

Rabbit Model

While humans are the only natural hosts of *T. pallidum*, rabbits have susceptibility and humoral immune responses similar to those seen during the early stages

of illness in man (Peeling, 2006; Pierce et al., 1983). These characteristics have made rabbits one of the most widely used animal models of syphilis for many years, and the rabbit infectivity test (RIT) in which rabbits are inoculated intradermally with serial dilutions of *T. pallidum* is the “gold standard” laboratory test to determine treponemal viability (Cox et al., 2003). In the RIT test, inoculation with as few as one organism can produce a chancre within 30 days, which is considered a positive test (Cox et al., 2003). Since *T. pallidum* cannot be sustained for prolonged periods using artificial media, the organism is propagated in vivo by inoculating it into the testes of rabbits, which yields substantial numbers of organisms (Peeling and Hook, 2006). Unlike the disease in humans, rabbits inoculated intradermally do not develop stage three neurological manifestations (Peeling and Hook, 2006). To create a model of the late-stage neurosyphilis, rabbits are inoculated either intracisternally (Marra et al., 1991) or intravenously (Tantalo et al., 2005). While the clinical progression varies with the strain inoculated, rabbits develop generalized skin lesions and have *T. pallidum* detectable in the CSF within 2–4 weeks of inoculation. The rabbit has also been used to create a model of experimental congenital syphilis by inoculating pregnant does intravenously with *T. pallidum* (Fitzgerald, 1985). Infected does have a 7–10-fold increase in fetal mortality, and a 49% reduction in birth weight for live births. Extracts of fetal tissue were able to produce syphilis when inoculated into adult rabbits, demonstrating that transuterine infection occurred. The rabbit syphilis model is continuing to be used to understand the pathogenesis (Tantalo et al., 2005) of syphilis and to develop a vaccine to prevent syphilis (Brinkman et al., 2008).

Streptococcal Pneumonia and Meningitis

Etiology and Disease in Humans

The rise in penicillin-resistant *Streptococcus pneumoniae* (pneumococci) is a significant threat to world health. Internationally, these strains rose from 6% in 1997 to 22% in 1999 (Egermann et al., 2009). Pneumococci are the most prevalent infectious agents in cases of adult meningitis involving negative clinical outcomes (Aronin et al., 1998; McMillan et al., 2001). A high dose of vancomycin with or without a third-generation cephalosporin (such as ceftriaxone) is usually prescribed for strains that are significantly resistant to penicillin (Quagliarello and Scheld, 1997). An accepted adjunct for therapy in adults is to include a glucocorticoid in pneumococcal meningitis cases (Egermann et al., 2009). However, vancomycin penetration into the CSF is substantially lower with this regimen (Martinez-Lacasa et al., 2002; Paris et al., 1994). Group

B. streptococcus (GBS) can be found in the genitourinary or gastrointestinal systems of up to 30% of clinically normal females (Hensler et al., 2005). GBS can be vertically transmitted from the mother to an infant when the infant is exposed to microbes from the mother's genitourinary or gastrointestinal tract (Hensler et al., 2005). Newborns infected in such a manner can suffer from pulmonary symptoms within a few hours after birth, and in most cases the organisms escape from the lungs to cause septicemia and meningitis (Hensler et al., 2005; Vollman et al., 1976). In children, *Streptococcus pneumoniae* colonizes the nasopharyngeal cavity, typically reaching a maximum concentration when the child reaches 3 years of age (Bogaert et al., 2004). This colonization provides a means for more invasive dissemination of the bacteria into the lower respiratory tract (Chiavolini et al., 2008). Approximately one million children under the age of five succumb to streptococcal pneumonia in less developed nations annually (Obaro and Adegbola, 2002). Multi-valent vaccines provide effective protection against most serotypes of pneumococci in humans 2 years of age or older and non-geriatric individuals (Chiavolini et al., 2008). Development of protein subunit vaccines could enhance the protection provided by the current polysaccharide vaccines (Barocchi et al., 2007).

Rabbit Model

Induced models of pneumococcal pneumonia in the rabbit include experimental surgeries for intrabronchial, intratracheal, or intrapulmonary inoculation exposures (Chiavolini et al., 2008). The intranasal route is not effective in rabbits (Chiavolini et al., 2008). A widely held tenet is that pneumonia occurs when the dose of the bacteria exceeds the limits of the defenses in the respiratory system (Yershov et al., 2005). Surprisingly, this hypothesis was only recently borne out when an experiment using an inoculum of $>4.60 \log^{10}$ CFU in NZW rabbits demonstrated that lower doses were less likely to cause disease versus a 90% infection rate when the higher dose was used (Yershov et al., 2005). Neonatal rabbits intratracheally inoculated with GBS developed much greater rates of bacteremia, reduced pulmonary compliance under mechanical ventilation, and a 40% mortality rate (vs. 0%) compared to those inoculated with the GBS mutant $\Delta 3h/c$ mutant NCTC:cy/IE Δcat (Hensler et al., 2005). This study was the first to show the importance of the GBS β -hemolysin/cytolysin ($3h/c$) toxin in the damage to pulmonary epithelial barriers that can lead to a hematogenous spread of the organism (Hensler et al., 2005). The rabbit model has also been used to demonstrate that the cyclic lipopeptide, daptomycin, is very effective in treating penicillin-resistant pneumococcal meningitis (Egermann et al., 2009). In related studies, daptomycin alone or in combination with

dexamethasone was much more effective than vancomycin combined with ceftriaxone, or dexamethasone followed by vancomycin and ceftriaxone (Egermann et al., 2009).

Acknowledgments

The authors of this chapter kindly thank Kristina Adams at the Animal Welfare Information Center for providing the information on the number of rabbits used in research presented in Table 18.1, and to Dr. Ginger Tansey for providing editorial assistance with the ophthalmic diseases section. We would also like to thank Dr. Kathy Perdue and Dr. Jeanne Wallace for their careful reading and thoughtful comments on the first draft of this chapter. This review was supported by the Intramural Research Program of the Office of Research Services, National Institutes of Health, and the National Heart, Lung and Blood Institute.

INTRODUCTION

Guinea pigs (*Cavia porcellus*) occupy a special place in research. This rodent species, with its unique physiology and anatomy, has come to symbolize all experimental subjects (Smithcors, 1963; Wagner, 1976). Since 1913, when a human or animal participates in research or tries something new, they have been called “guinea pigs” to represent that newness of what will be taking place (Oxford English Dictionary, 2007).

This special place in research implies that guinea pigs are one of the most commonly used laboratory animals in research. However, after a peak of usage in the 1960s at an estimated 2.5 million guinea pigs per year, with most animals being used for tuberculosis research, the number of guinea pigs used per year in biomedical research has steadily declined (Kydd, 2010; OTA, 1986; USDA, 1996, 2007) (Figure 19.1). Much of the decline in guinea pig usage in research stems from the growing use of genetically engineered mice and rats for specific disease models plus the acceptance of a replacement animal model, the mouse local

lymph node assay or LLNA, as recommended by the Interagency Coordination Committee on the Validation of Alternative Methods (ICCVAM) for the major allergenic contact dermatitis test for chemicals, i.e., the Klignman guinea pig maximization test (Dean et al., 2001; ICCVAM, 1999; Stokes, 2003).

Even with a decrease in their use in research, guinea pigs have continued to increase in popularity as pets. Their “small size, cleanliness, docileness, and relatively easy maintenance” appeals to pet owners who live in smaller living spaces more common in urbanized societies (Little, 1978; Pritt, 1998). Well over 600 000 guinea pig-owning households exist in the United States (AVMA, 2007). Veterinary medical literature focused on individualized pet guinea pig medicine and surgery can now be found outside of laboratory animal medicine, allowing laboratory animal practitioners to be experts in individual animal treatments as well as herd health medicine (Hillyer, 1997; Pritt, 1998; Richardson, 1992). Veterinary information for pet guinea pigs may be lumped into so-called “pocket pet medicine” or “exotic animal” themed texts and journals (Johnson-Delaney, 1996;

FIGURE 19.1 Guinea pig use in research (US). Data compiled from the U.S. Office of Technology Assessment (OTA, 1986), years 1965, 1967 and 1970; and USDA (2007), years 1973–2006.

Pritt, 1998). This marks a shift from just a few decades ago when most medical information for guinea pig breeders and fanciers came from books intended for children and not from veterinarians (Pritt, 1998).

Some major areas of current research involving guinea pigs include infectious diseases, allergenic assays that cannot be performed via the LLNA method, mechanisms of hearing, reproductive toxicology, and the provision of blood meal sources for blood-feeding insects such as mosquitoes.

TAXONOMY AND GEOGRAPHICAL DISTRIBUTION

Taxonomy

Cavia porcellus, the scientific name for the domesticated guinea pig, was conferred upon the species by the naturalist Erxleben in the late 18th century. The taxonomic outline for domesticated guinea pigs is as follows (Wagner, 1976):

- Kingdom Animalia
- Phylum Chordata
- Class Mammalia
- Order Rodentia
- Suborder Hystricomorpha
- Family Caviidae
- Subfamily Caviinae
- Genus *Cavia*

Guinea pigs are rodents within the hystricomorpha (porcupine-like rodents) suborder while the suborders sciuromorpha (squirrel-like rodents) and myomorpha (rat-like rodents) contain the other rodent species. Within the hystricomorpha suborder are chinchillas, porcupines, capybaras, and other rodents with a zygomatic arch where the “jugal bone forms the center block” (Wagner, 1976). An enlarged infraorbital canal is also present in many hystricomorph rodents, as with the capybara.

Members of the Caviidae family all have four digits on their forefeet and three on their hindfeet, with the soles of the feet being hairless (Harkness et al., 2002). Guinea pigs and others from the *Cavia* genus have one pair of mammae and a vestigial tail (Harkness et al., 2002).

While the tendency to gnaw and the presence of two front incisors (one set of hypsodontic incisors with the enamel being restricted to the buccal surface) were the primary reasons behind the guinea pig being classified as a rodent, several researchers have recently tried to re-classify the species outside the order Rodentia based on molecular studies of evolutionary changes to key proteins (Frye and Hedges, 1995). Accelerated evolutionary rates of change in insulin, as demonstrated by deviating amino acid sequences, led the guinea pig to have an insulin protein that deviates strongly from other mammals starting a controversy (Beintema and Campagne, 1987; Pritt, 1998). It was later noted that the apparent rapid rate of amino acid substitution and other descriptors of unique evolutionary mechanisms for guinea pigs as discussed in the literature stemmed from the species' phylogenetic position (Graur et al., 1991). From there, it was postulated that if the guinea pig was moved to another position, a “separate mammalian order distinct from the Rodentia”, known as rodent polyphyly, that the molecular phylogenetics data would make more sense (Graur et al., 1991, 1992; Ma et al., 1993). Quick refutation of the proposed reclassification of the guinea pig came with the findings that several nucleotide sequences unique and specific to rodents are also found in guinea pigs, but the controversy remained alive for several years with published research supporting both sides (Cao et al., 1994, 1997; D'Erchia et al., 1996; Frye and Hedges, 1995; Harkness et al., 2002; Kuma and Miyata, 1994; Martignetti and Brosius, 1993; Pritt, 1998). Konno and co-authors suggested that depending on which sequences were studied, amino acid versus nucleotide, different phylogenetic position (non-rodent versus rodent, respectively) could be argued (Konno et al., 1999). The controversy was essentially put to rest just a few years ago based on an eventual

FIGURE 19.2 Current distribution of domestic guinea pigs in South America. From *The Guinea Pig: Healing, Food, and Ritual in the Andes* by Edmundo Morales Copyright © 1995 The Arizona Board of Regents. Reprinted by permission of the University of Arizona Press.

preponderance of data supporting the existing classification scheme. The guinea pig now remains in its historical classification position (Carleton and Musser, 2005).

Geographical Distribution

Peruvian archeologist Luis Lumbreras has proposed that the earliest domestication of guinea pigs occurred around 5000BC in the Altiplano area of the Andes Mountain areas in South America (Morales, 1995). Almost 4500 years later there is archeological evidence that guinea pigs were also being raised in South American coastal areas (Morales, 1995). Modern-day Peru contains the largest populations of both domestic and wild guinea pigs. Population estimates of cuy,

as guinea pigs are known in South America, in Peru put the number at approximately 30 million animals (Morales 1995). Ecuador follows next with over 10 million, then Bolivia with over 3 million, and Colombia with over 700000 (Morales, 1995). Range distribution estimates for wild guinea pigs include Venezuela, from Guiana to Argentina, and from Peru to the state of Pernambuco in Brazil (Caras, 1996; Cooper and Schiller, 1975). In South America, guinea pigs may live very closely with families, roaming in and out of village houses at will (Caras, 1996; Morales, 1995). Morales documented the current distribution of domestic guinea pigs in South America (Figure 19.2).

Movement of guinea pigs throughout the globe did not begin until thousands of years after domestication,

when the colonization of South America by Europeans resulted in an era of active global trade between the 16th and 18th centuries. Guinea pigs were transported on primarily Dutch and Spanish ships traveling from South America to Europe. Their first arrival in Europe occurred in the late 16th century by following established slave trade routes (Caras 1996; Cumberland, 1886; Wagner 1976; Weir, 1974). They might have appeared in West Africa at this time as well (Caras, 1996). Europeans first began documenting the presence of guinea pigs in South America in the literature at this time, noting that they were a common food source for the Incan empire (Caras, 1996). From Europe, guinea pigs traveled to North America with initial arrival probably occurring in the 17th century (Wagner, 1976).

Neither the Europeans nor North Americans utilized guinea pigs as agricultural animals like the South Americans, even though the climates in these diverse geographical areas are able to support efficient guinea pig growth and reproduction (Pritt, 1998; Ragland, 1979; Wagner, 1976). Instead, they became popular as pets and “fancy animals” on these continents and were kept for show, and then eventually used as research animals. By the 19th century, a strong industry for pet and show guinea pigs had emerged in Europe, particularly in England (ARBA, 1991; Cumberland, 1886; Hillyer, 1997).

Therefore, after hundreds of years of traveling throughout the world and thousands of years of domestication, the main population hubs for guinea pigs today remain South America, North America, and Europe. Guinea pigs can be found in other areas of the world typically as research animals and perhaps pets.

ORIGIN AND DOMESTICATION

Historical Considerations

Curiosity surrounds how the name “guinea pig” originated. The name itself is considered a misnomer (Cooper and Schiller, 1975; Cumberland, 1886; Morales, 1995). While the term “cavy” is perhaps more appropriate since it reflects the scientific name and South American origin of the species, the name guinea pig is more widely used in the research, veterinary literature, and popular media (Pritt, 1998; Wagner, 1976). Interestingly, fanciers and show breeders continue to use the term cavy (Wagner, 1976). Theories helping to explain the foundation of the name include (Cumberland, 1886; Morales, 1995; Wagner 1976; Weir, 1974):

- European explorers felt that they looked like suckling pigs
- They were sold for the monetary unit “guinea” in England

- People thought that they came from the country Guinea in Africa due to their travel in ships traveling along slave trade routes
- People mistook the country name Guiana in South America for Guinea, the African country.

Keeping guinea pigs as pets by Europeans and North Americans is documented as early as the very late 16th century when it was observed that Queen Elizabeth I from England owned a pet guinea pig (Morales, 1995). Such notoriety helped to contribute to the species’ popularity (Morales, 1995). Later, guinea pigs were brought to life in popular Beatrix Potter stories and inhabited the White House as pets for presidents Theodore Roosevelt and John F. Kennedy (Anderson, 1996; Comfort, 1994; Pritt, 1998). With recent depictions of guinea pigs in books and movies, they are considered a trendy pet.

Domestication

The domestication of guinea pigs occurred thousands of years ago in the Andes mountain regions of South America, most likely Peru, and since that time the guinea pig continues to be an important part of native culture life (Caras, 1996; Morales, 1995). Domestication efforts resulted in a new species, *Cavia porcellus*, which is closely related to several wild species (Caras, 1996).

Guinea pigs are used as food (called “cuy” in native languages, which also refers to the living animal) as well as in some healing and other rituals in the Andes by indigenous peoples (Morales, 1995). Their manure can be successfully used as fertilizer (Pritt, 1998). Some non-profit groups even provide small herds of guinea pigs to small villages to enable them to build sustainable agricultural programs to bring a good source of a high-protein, low-fat meat to the villagers’ diets.

Cavia porcellus is closely related to several other caviomorph species such as *C. aperea* (the smallest cavy like rodent), *C. cutleri*, *C. fulgida*, and *C. tschudii* (Clutton-Brock and Wilson, 2002; Morales, 1995; Wagner, 1976). Cavies from these related species, but not *C. porcellus*, still exist in the wild in areas of Argentina, Uruguay, Bolivia, Peru, and Brazil (Clutton-Brock and Wilson, 2002; Morales, 1995; Wagner, 1976; Weir, 1970). Wild guinea pigs live in open grasslands or marshy areas in small groups feeding on fresh fruits and resident vegetation (Clutton-Brock and Wilson, 2002; Cooper and Schiller, 1975; Wagner, 1976; Weir, 1970). These guinea pig groups are typically formed around harems, similar to breeding schemes utilized in modern-day breeding operations for research, and seek out burrows created by other animals (Cooper and Schiller, 1975). All guinea pigs are unable to climb and are “strictly terrestrial”, as well as crepuscular, thus they avoid bright sunlight and darkness (Cooper and Schiller, 1975).

Through domestication, guinea pigs became a staple agricultural animal in South America and were used as food along with llamas, shellfish, and fish (Diamond, 2005; Morales, 1995). Besides llamas and alpacas, guinea pigs were the only other animal species domesticated in South America, and the sole animal species domesticated in North, Central, and South America for food (Caras, 1996; Diamond, 2005; Dunlop, 1996). Representation of guinea pigs in ancient art is seen as early as 1400AD, signifying the importance of the species to native peoples (Morales, 1995).

Use in Research

Use of guinea pigs in science is thought to have started with Lavoisier in 1780 who used them in the measurement of heat production, although earlier records exist of the species being dissected for 17th century anatomical studies (Cumberland, 1886; Guerrini 2003). Louis Pasteur, Edward Koch, and others used them in their studies to ascertain various aspects of infectious disease pathogenesis (Guerrini, 2003). Currently, guinea pigs have the distinction of being the only New World rodent commonly used in research (Harkness et al., 2002). Less than two hundred years after Lavoisier, guinea pigs became a major research animal used in the United States with, as previously mentioned, their use peaking in the 1960s (Pritt, 1998).

Space exploration even included guinea pigs as several countries, including the Soviet Union and China, launched them into orbit starting in the 1960s (CNN, 2004; Gray, 1998). Several Nobel prizes have been awarded for research employing guinea pigs. A sampling of such research includes the development of diphtheria antiserum in 1901, the discovery of the antibiotic streptomycin in 1952, the discovery of the mechanism involved in the stimulation of the cochlea in 1961, and the identification of the structure of antibodies in 1971 (AALAS, 2002). Similar to the reasons that their popularity as a pet has grown, their docile nature, availability, ease of maintenance, and historical research database of physiological parameters have contributed to their widespread use in research (Harkness et al., 2002).

It was in North America “that use in scientific research became a defining part of the species” (Pritt, 1998). Dunkin and Hartley established the widely utilized out-bred, albino strain (Figures 19.3 and 19.4) that has been the mainstay of biomedical research for nearly 100 years (Wagner, 1976). Since then, several other strains for research have been developed. Historically, guinea pigs have been used in allergy (including delayed hypersensitivity, anaphylaxis, and asthma), genetic, immunology, infectious disease, nutritional, auditory, and other areas of research (Harkness et al., 2002).

Breed Formation

As with other rodents used in animal-based research, the breeds used in laboratory animal facilities were developed to meet a burgeoning need for science starting over 100 years ago (Dunlop and Williams, 1996). Breed formation for guinea pigs traditionally focused on hair coat structure and/or texture, color, and length along with albino versus non-albino features (Castle, 1905). All breeds can intermix (Harkness et al., 2002). Individual animal size generally does not differ between the common breeds. Given the prevalent use of guinea pigs as fancy animals, meaning they are used for show, it was natural that Europeans, and particularly the English, were the first to develop acknowledged breeds in the 19th and very early 20th centuries. Commonly recognized breeds like Abyssinians (Figure 19.5) with their unique cowlicks called “swirls” and “rosettes” in their fur were first identified in England while Peruvians (Figure 19.6) with their long fur brushing the ground were first identified in Paris.

FIGURE 19.5 Rough-haired Abyssinian Guinea Pig (adult). Reprinted from Cooper and Schiller (1975) by permission of Harvard University Press.

FIGURE 19.6 Long-haired Peruvian Guinea Pig (adult). Reprinted from Cooper and Schiller (1975) by permission of Harvard University Press.

The Zoological Society of London had the responsibility of naming these emerging breeds (Wagner, 1976). For the pet and fancy industries, several breeding groups including the American Cavy Breeders Association (ACBA) and the British Cavy Council as well as other clubs in British commonwealth countries establish contemporary breed standards, of which dozens exist.

American (smooth-coated, short-haired guinea pigs also called English), Abyssinian, and Peruvians are the three most frequently encountered pet guinea pig breeds today. Fancy animal breeders pay special attention to coat color and these breeds can display a wide variety of color combinations with white, dark brown, and gray being the most common and black being the rarest (Morales, 1995).

Laboratory guinea pigs throughout the world are largely derived from the strain begun by Dunkin and Hartley in 1926 (Wagner, 1976). These strains are out-bred, albino, smooth-coated, and usually referred to as “Dunkin-Hartleys” or “Hartleys.” Research animal vendors will sell

FIGURE 19.7 Tri-color outbred guinea pig for research. (Photograph courtesy of Elm Hill Breeding Labs.).

them as specific pathogen-free (SPF) and/or virus antibody free (VAF). At least one albino, hairless strain that is euthymic and immunocompetent is commercially available for dermatology research (CRL, 2009).

On occasion, multi- or tri-colored Americans (also called “American short-hair” or “English short-hair”) or Abyssinians may be used in the research environment (Figure 19.7). Their pigmented coloration allows for studying certain hearing structures and functions that cannot be studied in the albino breeds available from research-only guinea pig vendors. These breeds may or may not be SPF and/or VAF. Laboratories using these breeds are encouraged to work with the vendor to perform pre-shipment disease testing and/or implement an appropriate health-monitoring program to ensure an acceptable health status to support research.

GENETICS

Genetic Features

Festing (1976) describes two eras of guinea pig genetics, the first era starting in 1900 and extending into the 1960s and the second beginning in the 1960s. The first era was distinguished by studies on phenotypical differences such as coat color and fur characteristics while the second era focused on biochemical, physiological, immunological, and other traits and which could be argued continues today. Festing also noted that mutants described in the literature had not been adequately conserved for future study, a trend that continues today.

Early genetic work in guinea pigs focused on the inheritance of coat color which is complex. Comprehensive reviews of coat color, including post-natal changes in coat color appearance, began in the early 20th century and provide information that is still

FIGURE 19.8 Dr. Sewall Wright with guinea pig, 1950s (approximate). (Image K9637-1 from the United States Department of Agriculture (USDA) Agricultural Research Service Image Gallery).

used by fancy guinea pig breeders today (Castle, 1905; Chase, 1939; Ginsburg, 1943; Gurney, 2000; Heidenthal, 1939; Wolff, 1954; Wright, 1959, 1960a, 1960b). Several of these articles were authored by Dr. Sewall Wright who is credited with the development of the two most widely used inbred guinea pig strains, strains 2 and 13 (Figure 19.8). A compilation of the genetics involved with coat pigmentation and length can be found in the 1976 publication, *The Biology of the Guinea Pig*. The mode of inheritance for these traits is believed to be controlled by single gene loci although mixed phenotypes resulting from gene interaction do occur, e.g., different pigments or intermediate hair lengths (Festing, 1976).

Later studies focused on genes controlling histocompatibility, delayed hypersensitivity, anaphylaxis, and complement. Several strains of guinea pigs are based on these genetic differences, as described later in this chapter. Various congenital anomalies have been reported by Wright and others with extremely low occurrence rates (Festing, 1976). Overall, there has been a lack of interest in commercializing many of the strains described here.

Outbred Strains

Dunkin-Hartley outbred, smooth-coated, albino guinea pigs as described previously are utilized as the standard strain for biomedical research. Two sublines of the Dunkin-Hartley strain, Hartley A and B, with unique characteristics, were defined and characterized by a research group from the New York State Department of Health laboratories in Albany, New York, and are referenced in several research articles. Rarely, other Hartley strains have been described.

The Hartley A or Albany strain was discovered to have a natural resistance to *Treponema pallidum*, the causative agent of syphilis. Only 10–17% of the Hartley A strain succumb to infection while 80–100% of other strains display susceptibility to infection by the pathogen (Wicher K et al., 1985, 1992; Wicher V et al., 1990; Zhao et al., 1992). This strain arose as a closed colony with a period of inbreeding that was preceded and followed by random breeding, and is reported to be genetically related to inbred strain 2 (Wicher K et al., 1985; Zhao et al., 1992). The Hartley B strain, also described by the Wicher group, arose from the Buckbery Animal Farm in New York (Wicher K et al., 1985). Descriptions of the Hartley A and B strains are scant outside of the syphilis research performed at the Albany laboratory, and their impetus for establishing the strains came from the need for an inbred species as an alternative to the rabbit to study adoptive transfer of cellular immunity in syphilis (Wicher K et al., 1985; Wicher V et al., 1987).

Occasional reports of a multi-colored, outbred, BFA strain (Figure 19.9) from a Charles River Laboratories facility in Germany exist. This strain is no longer available from Charles River Laboratories but can be found in other locations such as a medical center in Leipzig (Charles River Deutschland, n.d.; Giroux, 2010; Medizinisch-Experimentelles Zentrum, 2007). Originating in 1963 from a federal labor office in Tübingen, Germany, it was transferred to the University of Zurich a few years later and then eventually to Charles River. Its name stems from the initials for Germany's federal labor office. A defining characteristic of this strain is its ability to produce large amounts of complement rapidly (Charles River Deutschland, n.d.). Research uses for this strain include parasitology, teratology, pharmacology, and dermatology (Charles River Deutschland, n.d.; Yamashita et al., 2004).

Inbred Strains

Evolutionary theorist and geneticist Sewall Wright began his work with guinea pigs in the early 1900s at the United States Bureau of Animal Industry, the agency that would eventually become the United States Department of Agriculture (USDA) (Banks,

1989; Lescoufflair, n.d.). Wright obtained his Ph.D. from Harvard and his thesis was on the coat colors of guinea pigs (Lescoufflair, n.d.). His prolific scientific research career gave rise to several inbred strains of guinea pigs, two of which are still used, Strains 2 and 13. However, some published reports state that that work on the strain 13 guinea pig began as early as 1906 for histocompatibility (Stone and Amsbaugh, 1984; Wagner, 1976). In addition to noting that inbred strains of guinea pigs had smaller litter sizes, adding to the concept of hybrid vigor, Dr. Wright also founded the concept of genetic drift, which was initially called the Sewall Wright effect (Fisher and Ford, 1950; Joshi, 1999).

Strains 2 and 13 may also appear in the literature as strain 2N or 13N (Trahan, 1987). Although not available from commercial research animal vendors in the United

States at this time, scattered colonies of these strains exist at some university, government, and military facilities. Guinea pigs from non-commercial sources may not be SPF and/or VAF, so health testing and monitoring programs as described elsewhere in this text should be considered. Both inbred strains are multicolored as well as having lower growth rates and less robust physiological parameters compared to outbred Dunkin-Hartley guinea pigs (Liu, 1988).

Several studies document behavioral and physiological differences between strains 2 and 13 guinea pigs. Major differences are provided in Table 19.1.

Strains 2 and 13 are now used in studies pertaining to infectious agents (*Bordetella bronchiseptica*, *Mycobacterium* spp., *Treponema* spp., vaccinia virus, Junin virus, and Pichinde virus) and serve as animal models for experimental allergic encephalomyelitis, leukemia, experimental retinal autoimmunity and hepatic toxicity (Barna et al., 1984; Cohen, 1987; Connolly et al., 1993; Devalle, 2005; Evans and Miller, 1982; Fujiwara et al., 1981; Guo and Liu, 1991; Holt et al., 2002; Huang et al., 1996, 1998; Karlick et al., 1989; Lind et al., 1989; Liu, 1988; Liu and Guo, 1991, 1992; Meyers-Elliott et al., 1983; Preece et al., 1993; Qian et al., 1992, 1993, 1994; Raskin and Arnon, 1981; Sobel and Colvin, 1985; Trahan et al., 1987; Traugott, 1983; Schaeffer and Bitrick, 1993; Stephenson et al., 1989; Wicher et al., 1992; Yun et al., 2008).

Several inbred strains of guinea pigs were created in Japan in the late 1970s based on coat color (Figure 19.10). These strains were designated JY 1, JY 2, JY 3, JY 6, JY 9, and JY 10 (Chiba et al., 1978). Additional strains designated JY 4, JY 5, JY 7, JY 8, and JY G have subsequently been described but only JY 1 and 2 are currently available (NIBIO, 2006). Only scattered reports, mostly regarding histocompatibility complexes and immune responses, about these strains appeared in the literature 30 years ago. The two strains still in use are currently

FIGURE 19.9 BFA guinea pig. (Photograph courtesy of Charles River Laboratories).

TABLE 19.1 Behavioral and Physiological Differences Between Strains 2 and 13 Guinea Pigs

Areas of Difference	Strain 2	Strain 13	References
Lordosis	More ready elicitation of lordosis		Thornton et al., 1987
Dietary insufficiencies		Increased sensitivity	Cohen et al., 1987
Body weight	Higher daily body weight gains		Liu, 1988
Immune Response	Varied differences		Asano et al., 1981; Clark and Shevack, 1982; Clement et al., 1980; Dos Reis and Shevach, 1983; Hasløv et al., 1990
Research models – experimentally induced allergic encephalomyelitis	Resistant	Susceptible	Raskin and Arnon, 1981; Traugott, 1983
Research models – cataracts		Congenital nuclear cataracts due to autosomal dominant trait	Bettelheim et al., 1997; Stone and Amsbaugh, 1984

utilized in superovulation, embryo transfer, and embryo culture research (Chiba and Egashira, 1978; Suzuki et al., 1993, 2000, 2003).

Another inbred strain, Weiser-Maples, was developed in the United States at the Buckshire Corporation (Perkasie, PA, USA) in 1977 but subsequently moved to Japan (Inaba and Wakisaka, 1992; Kitagaki et al., 2005). A “uniform response to experimental tuberculosis”, “radical and vertical growth patterns” of skin melanocytes similar to malignant melanomas in people, strong responses to exposure to UV radiation, and congenital skeletal malformations are features of this strain (Inaba et al., 1992; Kitagaki et al., 2005; Maeda and Naganuma, 1998). Weiser-Maples apparently have a similar appearance to the JY 2 strain pictured here (Suzuki, 2010).

Published Mutations

The complement 4-deficient, also known as C4D or C4D/N, strain was discovered and established at the National Institutes of Health (NIH) from a spontaneous mutation in 1970 (Banks, 1989; Ellman et al., 1970; Wicher K et al., 1985). Described as either outbred or partially inbred, the strain contains a haplotype identical to inbred strain 13 (Wicher K et al., 1985; Zhao et al., 1992). The complete lack of the fourth component of complement is transmitted as an autosomal recessive trait (Ellman et al., 1970). Of the strains studied for susceptibility to syphilis, it is described as the most susceptible strain with up to 100% of the test populations developing disease after exposure to *Treponema pallidum* (Wicher K et al., 1985; Wicher V et al., 1987; Zhao et al., 1992). Many other immunologic reactions in this strain are considered to be normal (Banks, 1989).

Waltzing (Wz) guinea pigs have a mutation resulting in atrophy of the organ of Corti beginning shortly after birth, which results in deafness and “waltzing” or

circling behaviors (Banks, 1989; Festing, 1976). Initially the hair cells begin to atrophy and disappear and then subsequently the other components of the organ of Corti meet the same fate (Festing, 1976). The mutation occurred spontaneously in a guinea pig colony at the NIH in 1953 (Banks, 1989; Festing, 1976). As an autosomal dominant condition, homozygosity leads to high levels of perinatal mortality despite the lack of observable anomalies (Banks, 1989; Festing, 1976).

German waltzing guinea pigs are from a spontaneous mutation found in a guinea pig breeding facility in Bayreuth, Germany in 1996 and were first described in the literature in 1998 (Ernstson and Ulfendahl, 1999; Kawaguchi et al., 2007; Skjõnsberg, 2006). Affected animals display deafness, balance disorders, and the characteristic “waltzing”, from birth (Skjõnsberg, 2006). After identification, the strain was transferred to the Karolinska Institute in Solna, Sweden, where it was subsequently bred (Skjõnsberg, 2006). Unlike the earlier described waltzing guinea pigs, the German origin mutation is a recessive inner ear defect arising from a collapse of the Resinner’s membrane and an absence of the scala media (Kawaguchi et al., 2007). Homozygotes are affected whereas heterozygotes have normal behaviors with an increased resistance to noise-induced trauma and an “augmented” response to the ototoxic drug cisplatin (Skjõnsberg, 2006; Skjõnsberg et al., 2008). Both homozygotes and heterozygotes have albuminuria and sometimes hematuria (Ernstson and Ulfendahl, 1999). German waltzing guinea pigs serve as an animal model of human vestibular atelectasis since the morphology of the mutation and human disease are identical (Kawaguchi et al., 2007).

A hairless and immunodeficient, mutant guinea pig strain was noted from a spontaneous mutation in a closed breeding colony of Dunkin-Hartley guinea pigs at the Eastman Kodak Company in 1979 (Banks, 1989; Reed and O’Donoghue, 1979). Affected animals were described as being smaller at birth, having wrinkled skin, and stunted vibrissae (Banks, 1989; Reed and O’Donoghue, 1979). Hair shaft production was abnormal, resulting in the hairlessness. Animals were either athymic or hypothyroid resulting in immunodeficiencies including agammaglobulinemia). Due to the immunodeficiencies, these mutants experience a shortened lifespan and die from infections common in immunodeficient animals including cytomegalovirus, balanitis, *Pneumocystis carinii* (Banks, 1989; Reed and O’Donoghue, 1979).

Another albino, immunocompetent, hairless mutant strain (Figure 19.11) is commercially available (CRL, 2009). This strain was initially identified in 1978 at the Institute Armand Frappier in Montreal, thus giving the strain the designation of IAF (CRL, 2009). Hairlessness comes from defective hair shafts (Banks, 1989). Charles

FIGURE 19.10 JY strain guinea pig. (Photograph courtesy of Osamu Suzuki, Laboratory of Experimental Animal Models, National Institute of Biomedical Innovation, Osaka, Japan).

FIGURE 19.11 IAF hairless guinea pig. (Photograph courtesy of Charles River Laboratories).

River Laboratories acquired the strain in 1982. Use of this strain is limited mostly to dermatology research (CRL, 2009).

Polydactyly exists as a heterozygous condition (Festing, 1976). The homozygous condition results in a “polydactylous monster” that typically dies in utero (Wright, 1934, 1935). Festing reported that lines “breeding true” for this condition have been developed (1976). However, there are no reports of such lines in the current veterinary and scientific literature.

INTRODUCTION

The domestic guinea pig is a descendant of the wild cavy (*Cavia aperea*) which is a common rodent in South America (Kunzl and Sachser, 1999). It is a non-burrowing, herbivorous, crepuscular, hystricomorph (porcupine-like) rodent with a stocky body, short neck and limbs, and with either no tail or a vestigial one. This rodent is considered to be more closely related to chinchillas and porcupines than to mice and rats (North, 1999). The adult male weighs between 900–1200 grams and the smaller female weighs between 700–900 grams, except during pregnancy (Quesenberry et al., 2004). Their lifespan ranges from 2–8 years with the breeding female having the shorter lifespan (North, 1999).

EXTERNAL ANATOMY

Hair

The hair consists of large guard hair and a finer hair undercoat (Quesenberry et al., 2004). Depending on the breed of guinea pig, it can be a variety of colors (mono, bi-, or tricolored): fine or rough; arranged in whorls or rosettes; and long, medium, or short in length (Harkness et al., 2002). Between the sexes, there are no differences in coat patterns or colors (Manning et al., 1984). Color is influenced by the genotype at several minor and six main coat-color loci with some having multiple alleles (North, 1999; Terril and Clemons, 1998). Guinea pigs are typed according to the length, direction, and texture of their hair. Examples of the short smooth-haired variety include the English (Duncan-Hartley and Hartley strains) and American. The Peruvian has long hair, the Abyssinian has short hair that grows in either rosettes or whorls resulting in the rough pattern, and the Silky has medium-length soft hair (Harkness et al., 2002; Quesenberry, 1994).

Each hair follicle has an androgen-dependent sebaceous gland that is most abundant along the dorsum and around the anus (Breazile and Brown, 1976; Quesenberry et al., 2004). Externally, the glandular area is slightly elevated with pigmented skin and greasy fur (Lipkow, 1953). The glands are more developed in the male and are used to secrete a sexual attractant and for marking of territory. In older, overweight animals, overproduction of the glands results in a greasy, matted dorsum.

The hairless areas of the body include the external orifices to the respiratory, digestive, urogenital systems, around the inguinal mammary glands, and caudal to the ear pinna. The hairless area behind the ear is larger in albino guinea pigs. In addition, this area lacks sebaceous and sweat glands (Zackheim and Langs, 1962).

Vibrissae are located around the eyes dorsal to the medial canthus and caudal to the lateral canthus, lateral to the nose, above the upper lip in 5–6 rows, and under the chin (Figure 20.1). These long tactile hairs are known as supraorbital, infraorbital, nasal, buccal or mystacial, and mental vibrissae, respectively (Cooper and Schiller, 1975). Not observed in guinea pigs are interramal and suborbital vibrissae which are present in other rodents (Cooper and Schiller, 1975).

Ear

The ear has cartilaginous and osseous sections. The large external ear (pinna) consists of prominent cartilaginous ridges and folds and an external meatus that leads to the long ear canal. The dorsorostral pinna forms the concha and the caudodorsal border is known as the helix (Cooper and Schiller, 1975). The cartilaginous portion of the guinea pig ear is approximately two to three times the length of the osseous portion of the external auditory meatus. Due to the length and tortuosity of the cartilaginous canal, it is extremely difficult to visualize the tympanic membrane. An important, unique anatomical feature of the external ear canal and bony portion of the guinea pig ear is that the extratemporal portion of the facial nerve lies in close proximity to the caudal and ventral aspects of the cartilaginous ear canal at its junction with the osseous canal (Cooper and Schiller, 1975). This is due to the unusual location of the stylomastoid foramen in the temporal bone which is positioned caudal and dorsal to the external osseous auditory canal.

Nose

This hair-covered, triangular-shaped structure consists of two nares with hairless perimeters. The nares are S-shaped, longitudinal slits and oblique dorsoventrally (Cooper and Schiller, 1975). The shape of each nostril results from the imperfect cartilaginous ring that supports the overlying skin and inner lining of respiratory epithelium (Cooper and Schiller, 1975). The nares come together at the midline dividing the upper lip into two halves. This cleft upper lip, known as a philtrum, is also observed in hamsters and rabbits.

External Reproductive Anatomy

Both the male and female guinea pig have a single pair of mammary nipples located in the inguinal area, however, the sow's nipples are more prominent and longer. Only in the female are mammary glands present.

The female genital region is a Y-shaped depression in the perineal tissues (Figure 20.2). The top branches of the Y point cranially and surround the urethral opening. A paired lateral labia with the vulvar opening lies

FIGURE 20.1 Lateral aspect of the head showing vibrissae. Reprinted by permission of the publisher from *Anatomy of the Guinea Pig* by Gale Cooper, M.D. and Alan L. Schiller, M.D., Cambridge, Mass.: Harvard University Press, Copyright © 1975 by the President and Fellows of Harvard College.

centrally at the intersection of the branches, and the anus is located at the base of the Y (Quesenberry et al., 2004). The perineal sac is a bilateral diverticula from the anal mucocutaneous junction and separates the vagina from the anus. The sac is well developed and surrounded by large sebaceous glands which secrete into the sac. It can be filled with oily fluid, skin debris, and trapped hair (Cooper and Schiller, 1975).

A male guinea pig can be easily identified due to obvious scrotal pouches which are visible as a pair of swellings on either side of the perineum (Figure 20.3). Each pouch contains the testis, epididymis, caudal end of the spermatic cord, and fat bodies (Cooper and Schiller, 1975). The ridge between the pouches is the glans of the penis. Unique to hystricomorphs, the intro-mittent sac is located within the ventral surface of the glans penis (Cooper and Schiller, 1975). This long cylindrical sac opens as a transverse slit caudal to the urethral orifice. During erection, the sac everts and two keratinaceous horny styles (3–5 mm long) which are attached to the caudal end, protrude externally (Cooper and Schiller, 1975). The function of the styles is unknown.

The most cranial orifice is the urethral opening covered by the skin of the prepuce and the most caudal orifice is the anus (Terril and Clemons, 1998). The penis

can be everted from the prepuce by placing gentle pressure at its base (Quesenberry et al., 2004).

MUSCULOSKELETAL SYSTEM

The skeletal system consists of the axial portion (head, hyoid apparatus, ribs and sternum, vertebrae); the appendicular portion, consisting of the pectoral and pelvic girdles and limbs; and the heterotopic portion which includes the os penis and sesmoids. The number of bones (256–261) varies in the guinea pig (Cooper and Schiller, 1975).

Axial Skeleton

Head

The major regions of the skull are the cranium, mandible, facial, and palatal (Cooper and Schiller, 1975). The skull has complete, prominent zygomatic arches which are a hystricomorph characteristic with large orbits and deep pterygopalatine fossae (Landry, 1957).

The triangular mouth consists of maxillary bones and the largest bone in the skull, the mandible, leading to a small oral cavity. The mandible is flared caudally (Gannon et al., 1994). The total dental formula is 20 which is I 1/1, C 0/0, P 1/1, M 3/3 (Breazile and Brown, 1976). All 20 teeth are open rooted and erupt continuously (hypsodontic) (Harkness et al., 2002). Only one set of teeth (monophyodont) is present with no primary teeth. In comparison, developing two successive sets of teeth, one deciduous and one permanent is known as diphyodont. The incisors are white and not yellow as observed in other rodents. The lower incisors are longer than the upper incisors (Harkness et al., 2002). The molars lack cusps and possess a groove or deep indentation (Cooper and Schiller, 1975). The toothless space between the incisors and molar teeth is known as the diastema. The upper premolar and molar occlusive surfaces are positioned

towards the buccal mucosa and overgrowth of these maxillary teeth will occur laterally resulting in buccal mucosal ulcerations (Quesenberry, 1994; Quesenberry et al., 2004). The mandibular cheek teeth occlusive surfaces are positioned towards the center of the mouth and overgrowth of these teeth occurs medially, which can cause tongue entrapment (Quesenberry, 1994; Quesenberry et al., 2004). The premolars and molars are the most common to overgrow (Harkness et al., 2002). Incisor overgrowth often occurs secondary to the cheek teeth malocclusion (Quesenberry, 1994). Malocclusion can be due to genetics, trauma, infection, or nutrition.

The muscles of mastication include the masseter (superficial, medial, and lateral layers), temporalis, and pterygoideus (lateral and medial) (Cooper and Schiller, 1975; Myers et al., 2006). The four rodent suborders Myomorpha (mice and rats), Sciuromorpha (squirrels), Hystricomorpha (South American caviomorph rodents and porcupines), and Protogomorpha (mountain beaver) are based on differences in the muscles of mastication and other characteristics of the masticatory apparatus (Druzinsky, 2010; Wood, 1955). The origin of the masseter muscle and the point of insertion on the mandible differ within the rodent suborder. Myers et al. (2006) gives a description and illustrations on the differences. A hystricomorph characteristic is the well-developed masseter muscle (Cooper and Schiller, 1975). Herbivores, including the guinea pig, use the muscles of mastication (Figure 20.4) for gnawing and grinding rather than chewing.

Thorax

Vestigial clavicles are present which attach laterally to the small coracoid processes of the scapula with some references stating the attachment is medially to the sternal manubrium (Breazile and Brown, 1976) or without sternal attachment (Cooper and Schiller, 1975). The sternum consists of the presternum, manubrium, three sternebrae and xyphoid processes. There are 14 pairs of ribs and the first six pairs of true ribs articulate with the sternum. Ribs 7–9 (false ribs) do not directly attach to the sternum, however, they articulate with the sixth rib cartilage. The floating ribs (10–14) do not articulate with the sternum. The vertebral column is composed of 32–36 vertebrae, of which are seven cervical, 13–14 thoracic, six lumbar, 2–3 sacral, and 4–6 caudal (Breazile and Brown, 1976).

Appendicular Skeleton

The suborder, Hystricomorpha, is distinguished by a separate fibula and tibia (Cooper and Schiller, 1975). There are four digits on each front foot (manus; Figure 20.5) and three digits on each hind foot (pes; Figure 20.6). Each digit consists of three phalanges (proximal, middle, and distal) with the distal one arched

having a curved nail (Cooper and Schiller, 1975). The nails are longer on the hind digits. The footpads are well developed on the hairless sole of the foot (Teril and Clemons, 1998). Ambulation occurs by alternating all four feet and the animal's weight is distributed on all legs with only the foot pads touching the surface (Bays, 2006). When running, the legs also alternate and when excited or playing, the rear legs occasionally kick out from behind (Bays, 2006).

Pelvis

The pelvic girdle consists of the ilium, ischium, and pubis bone which is known as the os coxae. As the animal matures, the acetabular bone fuses with the three bones to form the acetabulum. Each os coxae is joined at the midline at the pelvic symphysis which consists of symphysis pubis and symphysis ischii and in most

animals, the connection remains cartilaginous (Breazile and Brown, 1976). Ossification of the symphysis may occur in older males. As relaxin production increases in the pregnant guinea pig, the symphysis will soften and the two halves will separate (7–8 mm) in preparation for the delivery of the large fetuses (Hisaw, 1926; Hisaw et al., 1944). The female should be bred before 6 months of age to prevent dystocia that can occur due to pelvic symphysis (Figure 20.7) fusing as the suture line mineralizes (Bays, 2006).

Heterotrophic Skeleton

On the dorsal surface of the glans of the penis is a thin, small bone known as the os penis. This bone is found the entire length of the glans and is approximately 10 mm long.

FIGURE 20.7 Pelvic girdle showing the pubic symphysis. Reprinted by permission of the publisher from *Anatomy of the Guinea Pig* by Gale Cooper, M.D. and Alan L. Schiller, M.D., Cambridge, Mass.: Harvard University Press, Copyright © 1975 by the President and Fellows of Harvard College.

DIGESTIVE SYSTEM

The digestive system begins with the oral cavity and ends at the anus. In addition, it contains accessory organs that aid in digestion which include the teeth, salivary glands, pancreas, liver, and gall bladder (Cooper and Schiller, 1975). There are four pairs of salivary glands including the parotid, mandibular, sublingual, and molar (Quesenberry et al., 2004). The glands' ducts empty near the molars (Quesenberry et al., 2004).

Oral Cavity

The lateral walls of the mouth (cheeks) include the buccal pads and bristle areas. The buccal pads are the folded-inward edges of the lips that separate the incisors from the molar teeth. The bristle areas are present in the middle of the diastema and are described as small circular hair-covered flaps (Cooper and Schiller, 1975). Guinea pigs do not have cheek pouches. A large

tongue is present, covering most of the oral cavity and oral pharynx, however, a distinct lingual frenulum is not always present (Breazile and Brown, 1976).

The soft palate is continuous with the base of the tongue covering most of the back of the throat (Figure 20.8). On the median surface there is a small opening, the palatal ostium, from the oropharynx to pharynx (Timm et al., 1987). It has been referenced as the intrapharyngeal ostium and is observed in chinchillas, capybaras, and other hystricomorph rodents. Due to the unique anatomical structure of the pharynx, oral gavage and endotracheal intubation can be challenging.

Abdomen

The adult alimentary tract is 2.3 meters in length from pharynx to anus (Jilge, 1980). The monogastric stomach is located in the left cranial abdomen and is in contact with the left liver lobe and small intestine (Breazile and Brown, 1976). The four regions of the

FIGURE 20.8 Pharynx showing the palatal or intrapharyngeal ostium. Reprinted by permission of the publisher from *Anatomy of the Guinea Pig* by Gale Cooper, M.D. and Alan L. Schiller, M.D., Cambridge, Mass.: Harvard University Press, Copyright © 1975 by the President and Fellows of Harvard College.

stomach include the cardia, fundus, body, and pylorus. The esophagus obliquely enters the cardiac region at the lesser curvature of the stomach (Breazile and Brown, 1976). Formation of an angle of the small, lesser curvature of the stomach with the esophagus is termed the angular notch (Cooper and Schiller, 1975). The fundus is a large pouch located cranial and to the left of the cardia. The body of the stomach is located to the right of fundus and leads into the thick-walled pylorus which connects to the small intestine (Cooper and Schiller, 1975). The stomach's inner surface is smooth and the pylorus consists of longitudinal folds or rugae (Breazile and Brown, 1976). Guinea pigs are monogastric with completely glandular stomachs unlike other rodents, there is no non-glandular portion (Harkness et al., 2002).

Grossly there are no features that distinguish the three sections of the small intestine (duodenum, jejunum, and ileum) which is approximately 125cm in length and the longest part of the alimentary tract (Breazile and Brown, 1976). Of the three sections, the duodenum is the shortest (10–12cm long), the jejunum the longest at 95cm and the ileum is about 10cm (Cooper and Schiller, 1975). The ileum exits to the ileocecal papilla to the cecum. In the small intestine, lymph nodes and Peyer's patches increase in number moving distally.

The large intestine does not contain any epiploic appendices, sigmoid colon, or vermiform appendix and it is approximately 70–75cm in length (Cooper and Schiller, 1975). The first section of the large intestine, the cecum, is the largest dilatation of the alimentary tract occupying most of the ventral abdominal cavity and is known for its most unique characteristics. It is 15–20cm in length and contains approximately 65% of the gastrointestinal contents (Manning et al., 1984). It makes up 15% of the body weight and is responsible for the production of large quantities of vitamins. Located on the left side of the abdominal cavity, this large, semicircular thin-walled organ has numerous lateral pouches (haustra) and contains a large source of smooth muscle in three white longitudinal bands: dorsal, ventral, medial taenia coli. The taenia coli run the length of the large intestine. For physiology experiments, the linear smooth muscle fibers are harvested from the taenia coli because they can be obtained without damaging the cecum and large intestine.

The colon can be identified as three sections based on the location in the abdominal cavity; ascending, transverse, and descending. The descending colon terminates at the rectum which appears similar to the colon, located on the midline for approximately 10cm before entering the anal canal (Cooper and Schiller, 1975).

The gastric emptying time is 2 hours and the gastrointestinal transit time is approximately 20 hours (range 8–30) (Jilge, 1980). Due to guinea pigs' high metabolic

rate, cecotrophy or coprophagy is observed several times per day within laboratory settings and animals can be observed eating cecotropes (soft cecal feces) directly from the anus (Ebino, 1993). Obese or pregnant animals may eat feces from the floor and unweaned guinea pigs may eat dam's feces. Coprophagy is a source of vitamin B and protein utilization, however its contribution to guinea pig nutrition has not been fully investigated. There is an increase in the gastrointestinal transit time to 66 hours when coprophagy is included (Jilge, 1980). Prevention of coprophagy results in decreased digestion of fiber, increased excretion of minerals, and weight loss (Cheeke, 1987; Ebino, 1993).

The gastrointestinal flora consists of Gram-positive organisms which are similar to the rabbit's flora (Navia and Hunt, 1976). In the large intestine, anaerobic lactobacilli are the most common organism (Cheeke, 1987). Coliforms, yeasts, and clostridia may be present in small numbers (Harkness and Wagner, 1995). Guinea pigs are sensitive to antibiotics which can disrupt the microbial balance in the gastrointestinal tract. Antibiotic administration leads to a decrease of Gram-positive bacteria and an overgrowth of *Clostridium difficile* which can lead to enterotoxemia and death (Manning, 1984). Antibiotics including erythromycin, clindamycin, lincomycin, penicillins, ampicillin, chlortetracycline, and oxtetracycline should be avoided (Morris, 1995).

Liver, Gall Bladder, Pancreas, Spleen

The firm, smooth, dark red liver is located in the cranial abdomen and consists of six lobes (right lateral, right medial, left lateral, left medial, caudate, and quadrate) that are not well demarcated by connective tissue, instead blend with each other. The guinea pig, humans, non-human primates, and specific bats are unable to produce the hepatic enzyme L-gulonolactone oxidase (Nishikimi et al., 1992). This enzyme catalyzes the terminal step for ascorbic acid biosynthesis and therefore endogenous vitamin C cannot be produced (Hasan et al., 2004). The non-functional L-gulonolactone oxidase gene has been mapped to specific chromosomal regions in pigs and humans (Hasan et al., 1999; Nishikimi et al., 1994).

The gallbladder is a well-developed, thin-walled oval sac attached to a fossa in the quadrate liver lobe and is drained by the cystic duct. The cystic duct and several hepatic ducts join to form the common bile duct. At the end of the common bile duct, there is a unique ampullary swelling from which a small duct drains into the duodenum (Higgins, 1927). When the gall bladder contracts, the bile flows through the ducts into the ampullary swelling. After filling, a sphincter located proximal to the ampullary swelling contracts and bile flows into the duodenum. The sphincter prevents regurgitation of the bile back into the ducts (Higgins, 1927).

The triangular pancreas consists of three lobes extending to the spleen and in contact with the descending duodenum (Breazile and Brown, 1976). The lobes are separated into lobules and lobular ducts drain into a single pancreatic duct which joins the common bile duct before its opening into the duodenum (Breazile and Brown, 1976). Other references do not describe the pancreatic duct joining the common bile duct; in contrast, the pancreatic duct drains separately into the duodenum at approximately 7 cm distal to the common bile duct (Cooper and Schiller, 1975; Mann et al., 1920). The guinea pig lacks an accessory pancreatic duct (Cooper and Schiller, 1975). Similar to other species, the islets of Langerhans are located throughout the pancreas (Breazile and Brown, 1976).

The red-brown spleen is soft to firm and covered by a thin transparent capsule, the tunica serosa. The shape of the spleen is broader than observed in other rodents and rabbits. It is approximately 26 mm in length and at the widest portion, it is 13 mm (Breazile and Brown, 1976). It is located in the left, cranial abdomen along the dorsolateral portion of the stomach and is attached to the stomach's greater curvature by the gastrosplenic (gastrosplenic) ligament. The phrenicosplenic ligament attaches the cranial spleen to the diaphragm.

CARDIOVASCULAR SYSTEM

Circulatory System

Unique features of the circulatory system include the caudal cerebral artery arising between the basilar and internal carotid arteries. In some species, this artery may arise as two separate arteries very close to each other. The internal carotid arteries do not supply a significant amount of blood to the cerebral arterial circle; however, paired internal ophthalmic arteries do provide major collateral input (Shively and Stump, 1974).

The guinea pig has a lower basal coronary blood flow and lower peak coronary blood flow in comparison to the rat (Harkness et al., 2002). With its well-developed collateralization of the coronary arteries, it is very difficult to produce a myocardial infarction by acute coronary artery occlusion compared to humans, cat, dog, pig, and rat (Brewer and Cruise, 1994).

Guinea pig's myocardiocytes are not as "stiff" as the rat's myocardiocytes which makes the rat's heart develop a stronger force at comparable myoplasmic calcium concentrations (Kapelko and Navikova, 1993).

Another unique feature that deviates from the normal mammalian vascular pattern is the bronchoesophageal artery which originates from the right costocervical, the right internal thoracic, or the brachiocephalic trunk instead of from the aorta (Shively and Stump, 1974).

In the guinea pig, the pulmonary trunk differs from the aorta in that it is made up of short irregular branching elastic fibers interspersed with smooth muscle and collagen. The pulmonary artery and its branches are heavily muscled (Kay, 1983). The lumen size of the pulmonary arteries changes abruptly at areas of branching. Arteriovenous anastomoses of the tracheobronchial vasculature in guinea pigs are present (Widdicombe, 1996). The pulmonary capillaries are smaller in the center than in the periphery and pulmonary capillaries are fenestrated (Sekhon et al., 1995). The pulmonary veins also possess muscle swellings in this species (Kay, 1983).

A common incidental finding on histology of guinea pig pulmonary vasculature is a visible aggregation of lymphocytes in the adventitia of the pulmonary vessels. These perivascular nodules are normally seen only in the lung (Percy and Barthold, 2001).

In some guinea pigs and other animals, there may be 2–3 pairs of renal arteries located cranially and caudally to each kidney arising as separate arteries. The testicular artery arises from the aorta supplying the testis and epididymis. When two renal arteries are present bilaterally, the testicular artery may originate from the renal arteries; arise between them from the aorta; or arise caudally to the caudal renal artery (Favre, 1967). In the female, the ovarian artery has a similar origin to the testicular artery. It divides into several branches supplying the oviduct, ovary, and uterus. When two renal arteries are present bilaterally, the ovarian artery may originate from the aorta between the two renal arteries; directly from the caudal renal artery; or caudal to the renal arteries at the aorta with the left ovarian artery originating from a left caudal renal branch (Mattei, 1966).

Thymus

The thymus is located in the cervical region (neck) extending from the mandible to almost the thoracic inlet. It consists of two pink-tan elongated lobes with fat and fascia connecting the lobes (Cooper and Schiller, 1975) and no afferent lymphatic vessels (Ernstrom and Larsson, 1967). Accessory thymic nodules can be located in most animals (Cooper and Schiller, 1975). At birth, the thymus weight is at its maximum. In the immature guinea pig, the functional thymus is located in the ventral cervical area and cranial mediastinum (Breazile and Brown, 1976). As the animal matures and by 12 months of age, the thymus involutes and is replaced by fatty tissue (Ernstrom and Larsson, 1970). The accessible location of the thymus for removal, measurements, and manipulations makes the guinea pig a useful model for immunology studies.

Hematology and Clinical Chemistry Parameters

Guinea pigs lack easily accessible peripheral veins. There is a wide range of blood reference ranges noted

TABLE 20.1 Reference Ranges for Guinea Pig Hematological Values

Parameter	Reference Range
Erythrocytes	$5.4 \times 10^6/\text{mm}^3 \pm 12\%^a$
Hematocrit	$43 \pm 12\%$
Hemoglobin	$13.4\text{ g/dl} \pm 12\%$
MCV	$81\text{ }\mu\text{m}^3$
MCH	25 pg
MCHC	30%
Leukocytes	$9.9 \times 10^3/\text{mm}^3 \pm 30\%$
Neutrophils	28–44%
Lymphocytes	39–72%
Kurloff cells	3–4%
Eosinophils	1–5%
Monocytes	3–12%
Basophils	0–3%
Platelets	$250\text{--}850 \times 10^3/\text{mm}^3$

Laird, C.W. (1974). Clinical pathology: Blood chemistry. In "Handbook of Laboratory Animal Science" (E.C. Melby, Jr., and N.H. Altman, Eds), Vol 2, pp. 345–436. CRC Press, Cleveland.

^aCoefficient of variation.

in the literature. The variables that contribute to these ranges include breed, age, gender, diet, housing conditions, method of collection, anesthesia administered, venipuncture location, and laboratory performing sampling. Refer to [Tables 20.1 and 20.2](#) for a list of reference ranges for hematological and clinical chemistry values.

White Blood Cells

Neutrophils are known as heterophils or pseudoeosinophils due to the eosinophilic cytoplasmic granules (Harkness et al., 2002). These cells are similar to the rabbits' heterophils. Both small and large lymphocytes are the predominant leukocyte in the peripheral blood with the thymus producing many of these circulating cells. Lymphocytes are slightly higher and neutrophils are slightly lower than average human counts (Lewis, 1992). Steroids do not affect the thymic physiology or peripheral lymphocytes of guinea pigs, non-human primates, humans, and ferrets, therefore, these species are considered to be corticosteroid-resistant (Sisk, 1976). Other species such as mice, rats, hamsters, and rabbits respond to steroids with decreased thymus weights and lymphocyte counts (Calman, 1972).

Kurloff cells (Foa-Kurloff) are unique mononuclear leukocytes with natural killer activity that are found in guinea pigs. The cells are found in the circulating blood, splenic sinusoids, bone marrow, and thymus

TABLE 20.2 Reference Ranges for Guinea Pig Clinical Chemistry Values (Serum)

Parameter	Reference Range
Total protein	4.5–5.9 g/dl
Albumin	2.3–3.0 g/dl
Globulin	1.7–2.6 g/dl
Glucose	80–110 mg/dl
Blood urea nitrogen	15.7–31.5 mg/dl
Creatinine	1.0–1.8 mg/dl
Total bilirubin	0.2–0.4 mg/dl
Lipids	95–240 mg/dl
Phospholipids	25–75 mg/dl
Total triglyceride	28–76 mg/dl
Cholesterol	20–43 mg/dl
Calcium	9.0–11.3 mEq/dl
Phosphorus	4.2–6.5 mEq/dl
Magnesium	2.1–2.7 mg/dl
Sodium	121–126 mEq/liter
Potassium	4–6 mEq/liter
Chloride	96–98 mEq/liter
Alanine aminotransferase	31–51 IU/liter
Alanine transaminase	32–51 IU/liter
Alkaline phosphatase	68–71 IU/liter
Aspartate aminotransferase	38–57 IU/liter
Aspartate serum transaminase	38–58 IU/liter
Creatine phosphokinase	80–130 IU/liter
Lactate dehydrogenase	37–63 IU/liter

stromal tissue (Percy and Barthhold, 2001). This cell is most prominent during pregnancy, as the estrogen level increases, the Kurloff cells increase in number with many migrating to the placental labyrinth (Revell et al., 1971). The cells act as barrier-separating fetal antigens from immunologically competent maternal cells to protect the embryo from IgM and sensitized lymphocytes therefore preventing the maternal rejection of the fetal placenta during pregnancy (Marshall et al., 1971). These cells are usually not observed in newborn guinea pigs and in the fetus (Smith, 1947).

The cells contain a granular structure (Kurloff body) that ranges in size from 1–8 μm within a cytoplasmic

FIGURE 20.9 Photomicrograph of a blood smear showing a Kurloff body (100× objective oil; Wright-Giemsa stain).

vacuole that may exceed the size of the nucleus of the cell in which it is found. Staining of the intracytoplasmic material is positive for periodic acid Schiff and the Lendrum stain which is interpreted as proteoglycans and mucopolysaccharide material (Percy and Barthold, 2001). Figure 20.9 is a photomicrograph of a Kurloff cell.

L2C leukemia (an acute lymphoblastoid B cell leukemia) occurs in the Strain 2 guinea pig and has been used as the animal model for human acute leukemia (Khar et al., 1997). With this disease, the Kurloff cells increase in number and in lysosomal enzyme activity which cause cytolysis of the L2C cells (Debout et al., 1999). Studies have indicated that natural killer cells cause tumor cell death by apoptosis and necrosis, however the process by which natural killer cells bind to the tumor cells is not completely understood but it does include target recognition (Debout et al., 1999; Herbermann et al., 1986).

Erythrocytes

The red blood cell size is 7.1–8.27 μm and its life span is 60–80 days (Terril and Clemons, 1998). Peripheral blood values vary depending on the age of the guinea pig; reticulocytes and hemoglobin decrease with age (Sisk, 1976). Guinea pig erythrocytes, hemoglobin, and packed cell volume are low compared to other laboratory rodents (Manning et al., 1984). The erythrocyte parameters fall within human ranges (Lewis, 1992). Hemoglobin is similar to dog, rat, horse, rabbit, and humans for its high affinity for oxygen yet differs from dog, rabbit, and human hemoglobin by resistance to oxidation by nitrates to methemoglobin (Sisk, 1976). Excess dietary cholesterol causes guinea pigs to develop an acute hemolytic anemia in comparison to other animals which develop cardiovascular lesions. The difference in the species has been attributed to the

TABLE 20.3 Reference Ranges for Guinea Pig Clotting Values

Parameter	Reference Range	Reference
Prothrombin time (PT)	50–100 seconds	a
	20–32 seconds	b
Partial prothrombin time (PTT)	13.0–22.9 seconds	a
	40–49 seconds	c
Thrombin time	27.5–48.0 seconds	a
Factor II	85–150 units/100 ml	a
Factor V	68–140 units/100 ml	a
	55–105 units/100 ml	c
Factor VIII	63–142 units/100 ml	c
Factor IX	67–141 units/100 ml	c
Fibrinogen	263–572 mg/100 ml	c

differences in the composition of the red blood cell lipids which can affect the stability of the cell membrane (Ostwald et al., 1970).

Blood Coagulation

The guinea pig's platelet function resembles humans when compared to other species, in particular aggregation. It has the longest prothrombin conversion time of up to 4 minutes when compared to rabbits, rats, dogs, hamsters, cats, and human (Hwang and Wosilait, 1970). The activated partial prothrombin time is short compared to the human (Lewis, 1992). In addition, when compared to other species, it has the least amount of Factor VII and low levels of Factor V (Sisk, 1976). Factors V, VIII, and XII are higher than human levels and Factors II, IX, XI, and fibrinogen are within or close to the human range (Lewis, 1992). Refer to Table 20.3 for a list of reference ranges for clotting values.

Heart

Occupying most of the small thoracic cavity, the four-chambered heart is surrounded by a two-layer pericardium within the mediastinum. The heart is located mostly on the midline and approximately 1 cm cranial to the xiphoid process. Externally, the thin-walled atria are separated from the ventricles by the coronary sulcus that contains the coronary veins and arteries (Breazile and Brown, 1976). The ventricles are separated dorsally and ventrally by two shallow

interventricular sulci (Cooper and Schiller, 1975). Internally, the atria are separated by the intra-atrial septum and externally by the aorta and pulmonary trunk. A thick intraventricular septum separates the ventricles. Usually, the right ventricular lumen contains a single septomarginal trabeculum (moderator band) that is sometimes lacking in the left ventricle (Breazile and Brown, 1976). The larger left ventricle with thicker walls forms the apex of the heart.

The guinea pig electrocardiogram wave forms are similar to humans unlike the mouse, rat, and hamster (Petelenz, 1971). Positive in deflection, the P wave is most distinct in lead II (Lombard, 1952; Peletnz, 1971; Pratt, 1938). The QRS complex is usually diphasic and with most leads, the first deflection is of higher voltage (Mikiskova and Mikiska, 1968). The S-T segment duration does not correlate with the weight of the Cavioidea species (guinea pig, agouti) as it does with animals from the same order (Brewer and Cruise, 1994). For example, many rodents including large species have either shorter or no S-T segment, whereas the guinea pig has a distinct S-T segment (Brewer and Cruise, 1994). Depending on the lead, the T wave can be either positive or negative or diphasic (Pratt, 1938). The time duration of the guinea pig electrocardiogram has been described elsewhere (Lombard, 1952; Petelenz, 1971; Pratt, 1938; Zeman and Wilber, 1965). Reliable measurements of the QT interval makes the guinea pig an excellent model for torsade de pointes predictive studies and for identifying the arrhythmia resulting from the lengthening of the QTc (Eckardt et al., 1998; Hamlin, 2006).

The guinea pig heart is used as an ex vivo model for the Langendorff preparation. Established in 1897 by Oscar Langendorff, this preparation of isolating a mammalian heart for perfusion has been used in research that includes pharmacology, biology, cardiac physiology, pathology, and toxicology (Skrzypiec-Spring et al., 2007). An intact heart contains ion channels, enzymes, receptors, hemodynamic functions, electrophysiology, and action potentials that can be analyzed. The intact guinea pig heart contains receptors, channels, Purkinje M fibers, endocardium, and epicardium which are useful for the testing of a new chemical entity that may impact ventricular repolarization which cannot be evaluated when using the cloned hERG channel, the papillary muscle, or isolated Purkinje fiber (Hamlin et al., 2004). This is especially useful for evaluating new chemical entities and identifying cardiovascular risks early in the drug development program. The guinea pig heart would not be used as the Langendorff model for ischemia studies due to their extensive collaterals in the coronary circulation (Hearse and Sutherland, 2000).

Over the past decade, there has been a withdrawal of marketed efficacious drugs or the revision of drug labels that can be attributed to unexpected, sudden

cardiac death. The events can be associated with QT prolongation due to the inhibition of the rapid potassium current (I_{kr}), which in the human myocardium is the major repolarizing current, and can lead to a rare, but life-threatening ventricular arrhythmia known as torsade de pointes (TdP) (Fermini and Fossa, 2003; Guo et al., 2009). As a consequence, there has been further development of in vivo and in vitro models to evaluate the electrophysiological events and cardiovascular risk assessment of new drug entities to predict TdP in humans. The guinea pig ventricle has potassium channels similar to humans which are delayed, rectifier potassium currents, I_{kr} (r – rapid), I_{ks} (s – slow), and inward rectifier potassium currents (I_{ki}) which make them an interesting animal model to examine cardiac repolarization (Brouillette et al., 2007).

Guinea pig Purkinje fibers are used as an in vitro assay to measure the drug effects on the action potentials and other cardiac channels (Fermini and Fossa, 2003).

PULMONARY SYSTEM

General Anatomy

The guinea pig is an obligate nasal breather (Nixon, 1974). The nasal cavity extends caudal from the nostrils to the choanae and is bounded dorsally by the nasal bones and laterally and ventrally by the incisive and maxillary bones (Cooper and Schiller, 1975). The nasal cavity is rectangular when viewed laterally but T-shaped on cross-section due to its broadness dorsally and extreme narrowness ventrally (Cooper and Schiller, 1975). The stratified squamous epithelium of the skin continues into the external nasal orifices and covers the nasal vestibules (Breazile and Brown, 1976). Nasal hairs measure approximately 1.8×10^{-3} cm in diameter and 35.4×10^{-3} cm in length (Kliment et al., 1972). The lining changes abruptly to ciliated pseudostratified columnar epithelium with goblet cells within the nasal cavity (Breazile and Brown, 1976). There are two recesses in the nasal cavity, the rostral recess and maxillary recess. Multiple sources state that the guinea pig lacks a maxillary, frontal, and sphenoid sinus, although others may refer to the maxillary recess as the maxillary sinus (Cooper and Schiller, 1975). Variations in the number and position of the ethmoturbinates have been documented, with four being the most common (Cooper and Schiller, 1975). The guinea pig has a large nasolacrimal duct which is found in the lateral wall of the nasal cavity (Cooper and Schiller, 1975). The medial or septal wall has a large defect where the two nasal fossa are joined. Just rostral to the defect in the septum is a slight bulge which is the area of the vomeronasal organ (Cooper and Schiller, 1975) associated

FIGURE 20.10 Septum after removal of the right side of the nasal cavity. Reprinted by permission of the publisher from *Anatomy of the Guinea Pig* by Gale Cooper, M.D. and Alan L. Schiller, M.D., Cambridge, Mass.: Harvard University Press, Copyright © 1975 by the President and Fellows of Harvard College.

with pheromone detection. The lining of the caudodorsal portion of the nasal cavity is olfactory epithelium (Breazile and Brown, 1976). The choanae are the caudal terminations of each nasal fossa and communicate with the nasopharynx (Cooper and Schiller, 1975). Figures 20.10–20.13 show the nasal cavity and positions of the turbinates.

The nasopharynx is relatively short (Breazile and Brown, 1976). The soft palate forms the floor of the nasopharynx (Cooper and Schiller, 1975) and is continuous with the base of the tongue (Brewer and Cruise, 1997). The openings of the Eustachian tube appear as two prominent slit-like openings dorsal to the soft palate on the dorsolateral walls of the nasopharynx.

The larynx is square in shape and is comprised of five cartilages similar to other mammals: epiglottis, thyroid, cricoid, and paired arytenoids (Cooper and Schiller, 1975). The laryngeal cavity is divided into three portions: the vestibule, the glottis, and the infraglottis (Cooper and Schiller, 1975). The laryngeal opening is caudal to the pharynx and is bound laterally by the right and left aryepiglottic folds, ventrally by the epiglottis, and dorsally by the arytenoid cartilages. The aryepiglottic fold extends from the arytenoid cartilage to the dorsolateral border of the epiglottis. The piriform recess is the external depression lateral to each fold (Cooper and Schiller, 1975). The guinea pig has no laryngeal ventricle and the vocal cords are small and poorly developed (Brewer and Cruise, 1997). However, the guinea pig has the ability to vocalize and can produce numerous sounds.

The trachea consists of 35–40 cartilaginous rings joined dorsally by annular ligaments (Cooper and Schiller, 1975). The trachea is lined with ciliated pseudostratified columnar epithelium (Breazile and Brown, 1976). The proportion of ciliated cells decreases distally with only approximately 15% of terminal bronchi cells being ciliated (Rhodi, 1959). The primary bronchi stem from the trachea at the level of the third rib (Breazile and Brown, 1976). The right primary bronchus

is shorter and wider than the left (Cooper and Schiller, 1975). Similar to other rodents, the intralobular airways branch from the primary bronchi laterally and all intrapulmonary airways are therefore bronchioles (Brewer and Cruise, 1997). The bronchioles give rise to respiratory bronchioles which possess alveoli. Compared to other mammals, the guinea pig has the most prominent smooth muscle in the distal bronchi and the muscle is

spirally arranged (Brewer and Cruise, 1997). A detailed morphological description of the guinea pig airways is described by Schneider and Hutchens (1980).

The larger right lung consists of four lobes: cranial, middle, caudal, and accessory each separated by deep fissures. The right cranial lobe is the smallest. The right middle lobe is caudal to the cranial lobe and its medial surface has a concave cardiac impression. The right caudal lung lobe is the largest and has a concave diaphragmatic surface and extends to the eighth rib. The accessory lobe has an irregular shape with a deep notch on its ventral border for the caudal vena cava and a concave diaphragmatic surface (Cooper and Schiller, 1975).

The left lung consists of three lobes: cranial, middle, and caudal. The left cranial lobe has an intralobar fissure that divides it into a smaller cranial segment and larger caudal segment. The medial border is deeply concave to accommodate the heart. The small left middle lobe has a shallow medial notch for the esophagus and a concave diaphragmatic surface. The large left caudal lobe has a concave medial border in contact with the middle lobe (Cooper and Schiller, 1975). There are no intralobular septa in the lung or secondary individual lobulations. Due to the lack of septation between lobules, there exists extensive collateral ventilation. Respiratory bronchioles give rise to terminal sacs with outpockets of alveoli. Alveolar development is almost complete at birth in the guinea pig (Brewer and Cruise, 1997).

Cells of the Respiratory System

There are approximately 40 different cell types in the guinea pig lung (Brewer and Cruise, 1997). Fibroblasts are the most numerous and release cytokines such as interferon β -1, interleukin 6, interleukin 8, monocyte chemotactic factor, colony stimulating factors, and tumor necrosis factor (Brewer and Cruise, 1997; Gauldie et al., 1992). The second most numerous cell type is the pulmonary endothelial cell which makes up part of the pulmonary capillary bed (Brewer and Cruise, 1997). Guinea pigs possess more goblet cells in the airway compared to other rodents but serous cells have not been identified in the guinea pig respiratory system. Clara cells, non-ciliated epithelial cells with a high metabolic rate, make up approximately 73% of the cells lining the bronchioles (Crapo et al., 1983), but have not been identified in the trachea or bronchi in the guinea pig (Brewer and Cruise, 1997). Brush cells are found in the guinea pig, but submucous glands have not been identified, which differs from the murine rodents (Brewer and Cruise, 1997).

The alveoli consist of five major cell types: type I, type II, endothelial cells, interstitial cells, and lung macrophages (Brewer and Cruise, 1997). The type I cells do not divide. The type II cells are the stem cells of the

alveolar epithelium and replace type I cells. The type II cells secrete surfactant and may be involved in defense against oxidative damage. The lung macrophages consist of alveolar, tissue, and intravascular macrophages, but intravascular macrophages are not prominent in the guinea pig or other rodents. In the guinea pig, the neutrophil, not macrophage, captures intravascular foreign bodies up to the size of an erythrocyte (Brewer and Cruise, 1997). The neutrophils also adhere to the endothelial cells, a characteristic of the guinea pig (Terada, 1993).

Mast cells are also present in the lung. In the guinea pig, smooth muscle fibers are prominent in the pleura and mast cells are found in most abundance within the lung along these smooth muscle fibers (Wintrobe and Soter, 1981). Guinea pig mast cells contain no tryptase and only approximately 10% of lung mast cells contain chymase (Brewer and Cruise, 1997).

Eosinophils are also found within the lung. In the guinea pig, there are approximately 300 times more eosinophils in the loose connective tissue under the epithelial surface of the respiratory tract than there are in the circulating blood (Hudson, 1968).

Respiratory Physiology

The guinea pig is a common animal model for studying lung function impairment, asthma, and airway hyperresponsiveness. Some aspects of the normal respiratory physiology of the guinea pig are covered here. A detailed review can be found in Brewer and Cruise (1997) with an emphasis on species differences. Refer to Tables 20.4 and 20.5 for relevant respiratory physiology values in anesthetized and unanesthetized guinea pigs and blood gas values, respectively.

In the guinea pig, sympathetic nerve stimulation of the trachealis muscle causes the muscle to relax. This is in contrast to other species, such as the rat and rabbit (Doidge and Satchell, 1982). Mechanoreceptors are present in the upper airways that respond to touch (e.g. endotracheal tube) with strong laryngeal spasm. The trachea is well innervated but the small airways have little to no innervation (O'Donnel et al., 1978).

Hyperpnea is associated with airway constriction (Nagase et al., 1994). Peptides released from C-fibers, unmyelinated afferent fibers in the vagus nerve, are responsible for bronchoconstriction. On post-mortem, massive bronchoconstriction may be observed in guinea pigs after exsanguination or excision of the lungs (Lai et al., 1984). Contraction of the peribronchial muscle may cause distortion or other artifact of respiratory epithelium on histology (Percy and Barthold, 2001).

In contrast to mice and rats, guinea pig airways are sensitive to histamine and demonstrate early and late allergic reactions. In the late reaction, both eosinophils and neutrophils are present. IgG1 as opposed to IgE

appears to play a critical role in allergic responses in guinea pigs. Guinea pigs are rather insensitive to cromolyn (Ricciardolo et al., 2008).

Guinea pig bronchi are more sensitive to constriction by acetylcholine compared to other species. In the guinea pig, three of the five muscarinic receptors predominate, M-1, M-2, and M-3 (Brewer and Cruise, 1997). M-1 receptors are located in the sympathetic ganglia in the guinea pig (MacLagen et al., 1989) and enhance acetylcholine reflexes. Pre-synaptic M2 muscarinic receptors modulate M3-induced contraction (Gies et al., 1989). Release of the acetylcholine from the vagus causes airway constriction through M-3 receptor stimulation on the smooth muscle. Activation of the M-2 receptor hinders constriction. Loss of function of M-2 receptors which can occur due to viral infection, ozone exposure, or antigen stimulation may facilitate bronchoconstriction (Gies et al., 1989).

Guinea pig lungs possess β -inhibitory adrenoreceptors, but lack α -excitatory adrenoreceptors. The β -2 subtype predominates in the guinea pig (Zaagsma et al., 1983). β -2 adrenergic agonists inhibit release of mediators from mast cells and basophils, increase movement of chloride ions and water into the bronchial lumen, and increase cilia movement frequency (Brewer and Cruise, 1997).

Adenosine does not cause bronchoconstriction in normal conscious or anesthetized guinea pigs, but in conscious guinea pigs sensitized to ovalbumin, a bronchoconstrictor response to inhaled adenosine is observed (Thorne and Broadley, 1994) and is biphasic (Fozard and Hannon, 2000).

Bradykinin causes intense bronchoconstriction in the guinea pig and the route of administration is important in the response. Intravenous bradykinin causes bronchoconstriction through the release of COX products mediated mainly by thromboxane A₂, whereas aerosolized bradykinin causes bronchoconstriction through cholinergic neuronal activation and the release of neuropeptides (Ellis and Fozard, 2002).

GENITOURINARY SYSTEM

Urinary System

The kidneys in the adult guinea pig are approximately 18–21mm long and 12–14mm in diameter. The cranial border of the right kidney is at the level of the twelfth intercostal space and the caudal border at the third lumbar vertebra. The cranial border of the left kidney is at the thirteenth rib and its caudal border at the fourth lumbar vertebra (Cooper and Schiller, 1975). Both kidneys lie retroperitoneal and lack mesentery (Breazile and Brown, 1976). The renal pelvis is relatively large with a single longitudinal renal papilla (Quesenberry et al., 2004). Ultrasonographic measurements of normal renal parameters in guinea pigs have been published (Beregi et al., 2001), including estimation of renal volume by renal length and area. There is no significant difference in the ratio of short- and long-loop nephrons in guinea pig kidneys, whereas mice and rats have significantly greater short-loop nephrons and hamsters and gerbils, significantly greater long-loop nephrons (Ichii et al., 2006a). Sex differences in the histological and morphometric details of the kidney have been studied and reveal a significantly higher ratio of total kidney weights to body weight in the male guinea pig, no sex differences in the diameter of the renal corpuscle, and significantly higher PAS-positive granules in the proximal tubules of female guinea pigs (Ichii et al., 2006b). The paired ureters are approximately 80mm in length and 2mm in diameter. The urinary bladder is pyriform. When empty, it lies entirely within the pelvis and when distended may extend high above the margin of the pubis. The urinary bladder of the guinea pig lacks a trigone. Urine is alkaline and normally thick and cloudy white or yellow containing many crystals. See Table 20.6 for reference values for guinea pig urine.

Atypical “pacemaker” cells are smooth muscle cells of the upper urinary tract concentrated within sling-like muscle attachments of the pelvic-calyceal junction to the kidney parenchyma. These cells generate pacemaker potentials in the proximal renal pelvis. Cells similar to interstitial cells of Cajal (ICC), termed ICC-like cells, have been found within the lamina propria of the renal pelvis and pelvic-calyceal junction and play

a role in conducting pacemaker cell signals to smooth muscle cells of the renal pelvis and ureter (Klemm et al., 1999). The guinea pig has intramural ganglia closely associated with the ureters and bladder which are most likely associated with local coordination of the muscular activity involved in continence and micturition. Approximately 2000–2500 neurons are present in the guinea pig bladder (Gabella, 1990). Neurons are either individual or more commonly within ganglia of up to 40 neurons. The ganglia are more numerous on the dorsal wall compared to the ventral wall and are abundant in a radius of 800µm from the entrance of the ureters and urinary arteries into the bladder (Gabella, 1990).

Male Reproduction

The paired testes each measuring approximately 25mm long and 15mm wide lie in obvious scrotal

FIGURE 20.14 Photograph of the horny styles of an adult male guinea pig.

pouches (Cooper and Schiller, 1975). The epididymis lies along the dorsolateral surface of the testis and is composed of head, neck, and tail portions. The tail gives rise to the ductus deferens (Breazile and Brown, 1976). Inguinal canals remain open for life. The penis consists of a body and glans with an associated intromittent sac (Cooper and Schiller, 1975). The S-shaped penis is approximately 45–55 mm in length and 4–6 mm in diameter (Cooper and Schiller, 1975). The glans has the same diameter as the body of the penis and has minute, saw-toothed white scales or spurs along its cranial, lateral, and ventral surface. The spurs are a unique feature of hystricomorphs and are arranged dorsolaterally in two parallel lines extending from the urethral orifice to the glans. The dorsal line is discontinuous, whereas the ventral is continuous. The tip of the glans has ventral and lateral scales. An os penis is present in the guinea pig and is found within the dorsal surface of the entire length of the glans (Cooper and Schiller, 1975).

The intromittent sac is unique to the hystricomorphs and is within the ventral aspect of the glans. The dorsal inner lining has two longitudinal folds continuous with the corpus spongiosus and is covered with tiny scales similar to those of the external glans. There are two retractor tendons attached to the base of the intromittent sac attached to the crura and penile skin. The tendons are mostly elastic with a central artery and vein and during erection, longitudinal folds become engorged. The sac then everts with two horny styles each 3–5 mm in length protruding externally. The function of this anatomical variation remains unknown (Cooper and Schiller, 1975). Figure 20.14 is a photograph of the horny styles of an adult male guinea pig.

The male urethra consists of a pelvic and spongy portion. The pelvic portion extends from the urinary bladder neck through the pelvic canal to the penis.

The pelvic portion is 15–25 mm in length and 4 mm in diameter and has a predominantly straight cranio-caudal course (Man, 2007). The urethral sphincter is incomplete dorsally except in the area of the prostate in which it is complete. The spongy portion is approximately 33–50 mm in length and 3 mm in diameter, and opens externally at the urethral orifice (Cooper and Schiller, 1975). There is no fossa navicularis at the external termination. Studies demonstrate three-dimensional anatomy of the male urogenital system including the urethra, accessory sex glands and corresponding musculature (Neuhaus et al., 2001). Specifically, it is shown that the male guinea pig has a well-developed musculus sphincter vesicae forming the bladder outlet, a tender musculus sphincter urethrae glaber which surrounds the urethra caudally, a strong musculus sphincter urethrae transversostriatus which partially surrounds the urethra with a horse-shoe shape leaving the dorsal surface open, a strong ventral longitudinal urethral muscle, the musculus dilatator urethrae, and a faint musculus ejaculatorius running from the colliculus seminalis. In contrast to humans, there exists a dorsal longitudinal urethral muscle which extends from the bladder outlet to the colliculus seminalis (Neuhaus et al., 2001).

The accessory sex glands of the boar include: seminal vesicles (vesicular glands), prostate gland, coagulating glands, and bulbourethral glands (Quesenberry et al., 2004). The paired seminal vesicles are the largest accessory gland and measure 100 mm in length and 6–9 mm in diameter. They are long, coiled blind sacs that lie ventral to the ureters and enter the urethra by a pair of ducts immediately caudodorsal to the ductus deferens (Cooper and Schiller, 1975). The prostate gland consists of two pairs of lobes, a smaller ventral lobe and larger dorsal lobe connected by a transverse isthmus which lies caudomedial to the coagulating glands and lateral to the base of the seminal vesicles. The paired coagulating glands are pyramidal and lobulated and lie near the seminal vesicles and caudal to the urinary bladder (Cooper and Schiller, 1975). The prostate and coagulation glands are closely related and form an elongate gland which is not encapsulated (Neuhaus et al., 2001). The paired bulbourethral glands are small, lobulated oval masses each connected to the urethra by a single duct. A rudimentary preputial gland may be present (Cooper and Schiller, 1975). Figures 20.15 and 20.16 show the male urogenital system.

Testosterone levels increase in males at 30 days of age (Resko, 1970). The average age of sexual maturity of a male guinea pig is approximately 70 days (Sisk, 1976). Guinea pig spermatozoa cohere in rouleau formation in the epididymis prior to ejaculation. In other species, rouleau formation and dissociation occurs entirely within the male reproductive tract, whereas

FIGURE 20.15 Male urogenital system in situ. Reprinted by permission of the publisher from *Anatomy of the Guinea Pig* by Gale Cooper, M.D. and Alan L. Schiller, M.D., Cambridge, Mass.: Harvard University Press, Copyright © 1975 by the President and Fellows of Harvard College.

in the guinea pig, it is not until the spermatozoa reach the female's tract after copulation when the complete dissociation of rouleaux occurs (Martan and Sheperd, 1973; Sisk, 1976). Guinea pig sperm have a curvilinear movement with irregular forward progression and the rouleau formation may cause difficulties in rating sperm motility in this species (Sisk, 1976). Ejaculate volume is approximately 0.5 ml (0.1–1.2 ml) with an average of 13.376×10^6 sperm per ejaculate and a transit time from copulation until reaching the oviduct is approximately 15 minutes (Freund, 1969; Martan and Shepherd, 1973).

Female Reproduction

The paired intraperitoneal ovaries measure approximately 3–6 mm by 2–4 mm by 2–3 mm. The right ovary lies caudolateral to the right kidney. The left is cranio-lateral to the left kidney. The oviducts are 50–60 mm long and 1 mm in diameter. The guinea pig uterus is bicornate and consists of paired uterine horns each 30–50 mm long and 3 mm in diameter, a short uterine body approximately 12–20 mm long and 6 mm in diameter, and a single os cervix. The vagina is 30–40 mm long and consists of prominent longitudinal ridges.

FIGURE 20.16 Male reproductive tract. Reprinted by permission of the publisher from *Anatomy of the Guinea Pig* by Gale Cooper, M.D. and Alan L. Schiller, M.D., Cambridge, Mass.: Harvard University Press, Copyright © 1975 by the President and Fellows of Harvard College.

There is no vestibule between the vagina and the external vaginal orifice (Cooper and Schiller, 1976). The vaginal orifice is U-shaped and is closed by a vaginal closure membrane that opens at estrus, at parturition, and between the 20th and 35th days of gestation, most usually at days 26 or 27 (Weir, 1974). Figures 20.17 and 20.18 show the female reproductive tract.

The estrous cycle is approximately 16 days in length but can range from 13–21 days. Proestrus lasts 1–1.5 days and is characterized by vulvar swelling and rupture of vaginal closure membrane. The vaginal smear

reveals nucleated and cornified epithelial cells. Females show an increase in activity and may be observed chasing their cagemates, swaying their hindquarters and making guttural sounds (Quesenberry et al., 2004). Estrus lasts between 8 and 11 hours and frequently occurs overnight. Estrus is characterized by vaginal swelling, congestion, a mucus secretion, and a perforate vaginal membrane. Females may display lordosis. The vaginal smear contains cornified epithelial cells. Ovulation is spontaneous and usually occurs late in the estrous period, at approximately 10 hours. The number

FIGURE 20.17 Female urogenital system *in situ*. Reprinted by permission of the publisher from *Anatomy of the Guinea Pig* by Gale Cooper, M.D. and Alan L. Schiller, M.D., Cambridge, Mass.: Harvard University Press, Copyright © 1975 by the President and Fellows of Harvard College.

of follicles reaching maturity and ovulating is reported as 3.34 and is evenly divided between the two ovaries (Hermreck and Greenwald, 1964). Metestrus lasts approximately 3 days and has three distinct phases: an initial phase in which vaginal secretions become thick and vaginal and uterine vessels are congested, a subsequent phase in which vaginal fluid is serous and vessel congestion markedly increased, and lastly a phase in which the vaginal and uterine epithelium sloughs producing a slight blood secretion. Diestrus lasts for 11–12 days and is characterized by lack of vessel congestion and lack of vaginal secretion.

The hormonal changes during follicular maturation, ovulation, and luteinization have been studied (Reed and Hounslow, 1971). Approximately 13 days after ovulation, the level of progesterone decreases in the corpus luteum and the follicles reach maturity. At this time, follicle stimulating hormone (FSH) increases and stimulates the theca interna which promotes estrogen synthesis by the developing follicle. The estrogen production and basal levels of luteinizing hormone (LH) facilitate an increase in follicle size. An LH surge from the anterior pituitary occurs and ovulation occurs. Plasma progesterone increases rapidly after ovulation (Challis et al., 1971).

FIGURE 20.18 Female reproductive tract. Reprinted by permission of the publisher from *Anatomy of the Guinea Pig* by Gale Cooper, M.D. and Alan L. Schiller, M.D., Cambridge, Mass.: Harvard University Press, Copyright © 1975 by the President and Fellows of Harvard College.

Approximately 3.5 days post-fertilization, the eight-cell stage embryo reaches the uterus, loses the zona pellucida, and implants at 6 days (Chavatte-Palmer and Guillomot, 2007). The guinea pig has an implantation that differs from the murid rodents. While the blastocyst is in the uterine lumen, it develops an implantation cone at the opposite pole from the inner cell mass. The implantation cone is composed of the syncytial trophoblast and sends processes through the zona pellucida to adhere to the uterine luminal epithelium (Enders and Schlafke, 1969). The entire blastocyst intrudes into

the endometrial stroma beneath the luminal epithelium before a decidual response similar to the murid rodents occurs (Carson et al., 2000).

The guinea pig has a postpartum estrus approximately 2–10 hours after parturition. Guinea pigs are polyestrous breeders in captivity. Gestation is 66–72 days in length. Prominent morphological changes occur during pregnancy at the pubic symphysis. The cartilage joining the two pubic bones begins to dissolve by the thirteenth day of pregnancy. By day 40, only a small cartilaginous bridge extends across the symphysis and by

birth, no cartilage is present. The symphysis widens by 50 times during parturition. Guinea pigs are born precocial. The mammary glands lie just lateral to either side of the midline and become larger during pregnancy. Milk production peaks at 7 days post-partum and regresses at 4 weeks post-partum (Cooper and Schiller, 1976).

NERVOUS SYSTEM

Central Nervous System

The adult guinea pig brain weighs approximately 4g and the cerebral hemispheres are approximately 2.1 cm × 2.25 cm (Cooper and Schiller, 1975). The brain is considered lissencephalic, although a few shallow sulci are evident (Cooper and Schiller, 1975). Most gross anatomical features of the central nervous system including the cerebrum, ventricles, brain stem, cerebellum, and spinal cord are similar to other rodents and mammals. Larsell (1952) described the topographical anatomy of the cerebellum and standardized the nomenclature of the lobules. Larouche et al. (2003) used zebrin II, a widely studied marker of cerebellar homogeneity, to study the topographical anatomy of the guinea pig cerebellum in immunohistochemistry studies. The parasagittal bands of Purkinje cells expressing zebrin II in the guinea pig cerebellum were found to be similar to other animals studied. One characteristic in the guinea pig appears to be at least three levels of expression of zebrin II in the Purkinje cells, whereas other rodents studied either express or do not express zebrin II (Larouche et al., 2003).

As the guinea pig is a common animal model for respiratory studies, it is important to note that respiration control involves the dorsal respiratory group (DRG) and ventral respiratory group (VRG) within the medulla. The guinea pig DRG is located immediately ventral to the tractus solitarius which differs from the rat and cat (Richerson and Getting, 1992).

Peripheral Nervous System

Species differences in the anatomy of the cranial cervical ganglion (CCG) which contain neurons from which post-ganglionic nerve fibers arise providing sympathetic innervation to the smooth muscle, glands, and mucosa of the head have been described (Kabak, 2007). The three major branches of the CCG are the internal and external carotid and jugular nerves. The jugular nerve was found to be a single branch originating from the CCG later splitting into two branches to the vagus and glossopharyngeal nerves near the jugular foramen. No sex differences were noted in studies of the guinea pig CCG (Kabak, 2007). The vascularization of the CCG has also been described (Kabak and Gültiken, 2006).

The guinea pig is a common model of respiratory diseases and literature is published regarding the peripheral nervous system as it relates to the cough reflex in the guinea pig. In the guinea pig, the trachea is well innervated but the small airways have little to no innervation which is similar to humans (O'Donnel et al., 1978; Richardson, 1983). Rapidly adapting and slowly adapting stretch receptors (RARs and SARs, respectively) innervate intrapulmonary airways and lungs which may enhance and facilitate coughing and extrapulmonary C-fibers and RARs can initiate coughing upon activation. However, in the guinea pig, RARs described in some other species like the dog have not been described in the extrapulmonary airways of guinea pigs. Instead, RAR-like receptors in addition to C-fibers, unmyelinated slow-conducting fibers, are present in the extrapulmonary airways of the guinea pig (Canning et al., 2006). Specifically, a distinct class of afferent nerve endings has been identified which stems from the vagus nerve via the recurrent laryngeal nerve to the tracheal muscles that may correspond to slow-adapting stretch receptors (Baluk and Gabella, 1991; Canning et al., 2006). Others describe RAR-like fibers in the guinea pig extrathoracic airways as being derived from nodose and jugular ganglia (Carr, 2004; Undem et al., 2002). Recent interest surrounds the prominent role of transient receptor potential (TRP) ion channels as sensors of airway irritation and initiators of the cough reflex. TRPV1 stimulation results in a robust tissue response in guinea pigs and the TRPA1 channel is being evaluated for its role in the cough reflex in the guinea pig (Geppetti et al., 2010).

SPECIAL SENSES

Hearing

Characteristics of the guinea pig ear such as a large bullae and easy access to the middle and inner ear have caused the guinea pig to be a common animal model for auditory research. Consequently, the anatomy of the guinea pig ear has been detailed in many references (Asarch et al., 1975; Cooper and Schiller, 1975; Goksu et al., 1992; Sanli et al., 2009; Wysocki, 2005). The terminology can differ considerably among references and details of morphology may vary by reference.

The osseous portion of the ear is described as three segments of the temporal bone: the tympanic, bullar, and petrous segments (Cooper and Schiller, 1975) or by others as four elements of the temporal bone: squamous, petrous, tympanic, and mastoid (Wysocki, 2005).

The tympanic portion can be described as three parts: the tympanic ring, tympanic bulla, and dorsal bulla. The tympanic ring forms the walls of the external auditory canal. The tympanic bulla includes the air

spaces of the middle ear and has a trapezoid shape with rounded edges and thin walls. The petrous segment of the temporal bone is the bony capsule of the labyrinth, is pyramid-shaped, and contains three openings for branches of the seventh and eighth cranial nerves. The squamous part adjoins the parietal, frontal, palatine, and ethmoid bones in the area of the acetabulum of the temporo-mandibular joint and is underdeveloped in the guinea pig. The mastoid part forms the mastoid process joined with the occipital bone. The external orifice of the facial nerve canal is in the border of the mastoid and tympanic portions of the temporal bone (Wysocki, 2005). Figures 20.19 and 20.20 show the orientation and internal aspects of the temporal bone.

The inner ear is made of two air spaces termed the tympanic bulla and dorsal bulla, and a bony labyrinth consisting of the cochlea, vestibule, and three semi-circular canals (Wysocki, 2005). Two windows are associated with the cochlea, the oval window placed vertically and the round window placed horizontally (Sanli et al., 2009). In contrast to most mammals, the round window of the guinea pig is directed caudally and dorsally as opposed to ventrally (Cooper and Schiller, 1975). Since this window lacks an overhanging lip of bone, the round window is more prone to injury but also easily accessible to surgical exposure. The round window membrane faces almost directly toward the stapes bone in the oval window. A unique feature of the guinea pig oval window region is the delicate bridge of bone that extends from the fallopian canal through the intercrural space of the stapes bone to the promontory (the basal turn of the cochlea). This may be the remnant of the stepedial artery (Cooper and Schiller, 1975). The guinea pig cochlea lacks a thick bony sheath and consists of 3.5–3.75 turns (Sanli et al., 2009; Wysocki, 2005). The long axis of the cochlea runs almost in a sagittal plane in guinea pigs which differs from humans (Wysocki, 2005).

To analyze solute movements for drug delivery in cochlear fluids, studies have been published detailing the guinea pig round window and its relationship to the scala tympani (Ghiz et al., 2001). The cochlear aqueduct enters the scala tympani at the medial limit of the round window membrane which is approximately 1 mm from the end of the scala when measured along its mid-point (Ghiz et al., 2001). To determine the volume of the aqueduct, the area–distance relationship should be considered (Ghiz et al., 2001) but has been found to average 0.113 mm^3 (Shinomori et al., 2001). The round window in adult guinea pigs has a total surface area of approximately 1.18 mm^2 (Ghiz et al., 2001). The tympanic membrane measures approximately 9–10 mm in diameter and the auditory canal approximately 1 cm in length (Cooper and Schiller, 1975).

Some literature refers to the stylomastoid foramen as the location where the facial nerve exits the medial wall

FIGURES 20.19 and 20.20 Details of the temporal bone. Reprinted by permission of the publisher from *Anatomy of the Guinea Pig* by Gale Cooper, M.D. and Alan L. Schiller, M.D., Cambridge, Mass.: Harvard University Press, Copyright © 1975 by the President and Fellows of Harvard College.

of the temporal bone and courses without protection in a caudal direction towards the cartilaginous external auditory canal (Cooper and Schiller, 1975). Wysocki (2005) gives a detailed description of the course of the facial nerve as it relates to the topographical anatomy of the temporal bone and in his description notes that the guinea pig lacks an internal auditory meatus.

The crista traversa of the internal auditory canal separates the facial and superior vestibular nerves from the other branches of the eighth cranial nerve. The cochlear nerve in the guinea pig consists of approximately 24000 neurons and the vestibular nerve approximately 8000 neurons (Cooper and Schiller, 1975). The cellular anatomy of the guinea pig nuclear complex has been detailed (Hackney et al., 1990).

Rodents can emit and detect acoustical signals between 22 and 85 kHz (Morton, 2002). Data exist

on the arrangement and properties of hair cells in the guinea pig (Pickles, 1985). In addition, comparative studies regarding the number of hair cells, synapses at the hair cell base, and innervation patterns are also published (Nadol, 1988).

Published material is available of intracellular recordings from cochlear hair cells during auditory stimulation. For inner hair cells situated in the high-frequency end of the guinea pig cochlea, resting potentials are in the order of -40 to -45 mV with the response to sound consisting of an alternating potential (Pickles, 1985; Russell and Sellick, 1978, 1983). Others have recorded resting potentials in the low-frequency apical turn of the guinea pig cochlea to be more negative than the inner hair cells at -70 mV (Dallos et al., 1982; Pickles, 1985).

The use of newborn guinea pigs to evaluate hearing began over 100 years ago when Professor Preyer studied sensory function development in neonate humans and animals. The Preyer reflex is a hearing test in which the pinna moves backwards in response to sounds. A normal Preyer reflex may not mean that hearing is normal, however, if the threshold is increased that indicates hearing impairment. This reflex is a value method to evaluate animals used in otologic research and for cochlear function (Bohmer, 1988).

Taste

Interspecies differences in taste preference are most likely due to demonstrated variations in the regional expression of taste receptors among taste regions of the oral cavity and between species (Roper, 2006).

The guinea pig tongue has numerous filiform papillae over the entire surface. Prominent fungiform papillae, four groups of foliate papillae, and two circumvallate papillae are also present (Cooper and Schiller, 1975).

The fine structure of guinea pig taste buds has been characterized and consists of basal, type I, type II, and type III cells. Basal cells are the precursors of the other cell types. The type I cells intervene between other cells to act as structural support. The type II cells are the largest and possess stacks of smooth endoplasmic reticulum above the nucleus. They have a close association with the nervous system and are believed to receive efferent innervation. The type III cells make synaptic contacts with nerves and provide gustatory function (Yoshie et al., 1990).

Vision

The microscopic structure of the cornea is similar to other mammals and has a diameter of approximately 7–7.5 mm (Cooper and Schiller, 1975). The lens is 5.5 mm at its equatorial diameter and 4.0 mm

in its anteroposterior diameter (Cooper and Schiller, 1975). At birth, guinea pigs can visually distinguish between different objects (Gaston et al., 1969). The retina has few vessels clustered around the optic disk (De Schaepdrijver, 1989). The retina is layered similar to other mammals and rods dominate (Peichl and Gonzalez-Soriano, 1994). The guinea pig has dichromatic vision (Howlett and McFadden, 2006; Jacobs and Deegan, 1994) with rods having a peak sensitivity of 494 nm and two classes of cones with peak sensitivities of 429 and 529 nm (Jacobs and Deegan, 1994). The nictitating membrane is a rudimentary structure in this species (Cooper and Schiller, 1975).

Olfaction

On serial coronal sections of the guinea pig nasal cavity, olfactory mucosa is observed lining the posterior roof, the upper nasal septum, and all ethmoturbinates. The olfactory epithelium is avascular. The vomeronasal organ is observed as a paired tubular structure in the lower bony part of the anterior one-third of the nasal septum. It enters into the vestibule of the nasal cavity through a duct lined with stratified squamous epithelium. Its medial wall and upper and lower margins are lined by olfactory neuroepithelium which is pseudostratified columnar and contains intra-epithelial capillaries. The lateral wall of the vomeronasal gland is lined by respiratory epithelium which is avascular. The presence of capillaries in close association with olfactory neurons may be evidence of its neurosecretory activity (Sangari et al., 2002).

Olfaction plays a crucial role in guinea pig behavior, especially regarding reproductive behavior. Additional histological descriptions of the olfactory mucosa of the guinea pig have been published (Sangari et al., 1987).

Tactile

Rodents have a strong tactile sense of touch achieved by well-developed vibrissae which may have a sensitivity of less than 90 μ m (Morton, 2002).

BEHAVIOR

Wild cavies of the genus *Cavia* are social animals that live in small groups of 5–10 in burrows or crevice shelters (Nowak, 1999). In wild cavies neither sex is known to maintain an exclusive territory, but scent marking by secretions of the anal and supracaudal glands and urine to delineate territory has been documented elsewhere in domesticated guinea pigs (Harkness et al., 2002). Males may be seen rubbing their hind quarters along surfaces and may display vocalization, agonistic behavior,

and fighting to define territory. In wild cavies, each sex has its own linear dominance hierarchy. Subordinate animals either retreat or are attacked (Nowak, 1999). Domesticated guinea pigs show less severe aggression but may display aggressive actions such as hair pulling and ear nibbling (Quesenberry et al., 2004). Specifically, the animal may be observed using teeth to pull hair from cagemates and ingesting the hair. This may be used as a means to displace animals from water licks or feed hoppers (Reinhardt, 2005). Mating privileges, space, and food are considered primary stimuli for aggressive interactions (Terril and Clemons, 1998). Attend postures, stand-threats, head-thrusts, and leaping attack lunges are behaviors displayed when guinea pigs respond to a potential threat. In general, though, guinea pigs will seek contact with other guinea pigs when housed together and stand together at rest or at feeding. They do not, however, display social grooming behavior (Quesenberry et al., 2004).

For male guinea pigs, social rearing conditions are crucial for social interactions and endocrine stress responses later in life, as colony-reared animals are found to adjust easily to new social situations as opposed to males raised in pairs which show increased agonistic behavior and shorter latency to escalated aggression with conspecifics (Kaiser et al., 2007). This has not been found to be true in female guinea pigs (Kaiser et al., 2003).

Guinea pigs do not build nests. Approaching parturition, male wild cavies will gather around a pregnant female. The most dominant male will guard the female and will mate her first after parturition (Nowak, 1999). In laboratory settings, within mixed age and sex colonies, male guinea pigs form small harems of females with attachment-like social bonds. These familiar partner males can buffer the cortisol responses of females when exposed to a novel environment (Hennessy et al., 2008).

Under unstable social conditions, the sex ratio of guinea pig pups is significantly more biased towards females than in stable social situations (Kemmer et al., 2009). Preference tests have shown that guinea pig young remain near their mother well beyond weaning, increased time is spent with unrelated females but not males after weaning and littermates spend considerable more time together as opposed to associating with novel animals or potential breeding partners (Hennessy et al., 2003). If guinea pig pups are isolated in a novel environment, they show an initial active phase characterized by vocalizations and locomotor activity followed shortly by a passive stage of crouched stance, eye-closing, and extensive piloerection. This behavior can be alleviated if pups remain with their mother during the introduction to the novel environment (Hennessy et al., 2004). The passive behaviors of pups

during isolation are mediated by proinflammatory cytokines (Perkeybile et al., 2009). Similar behaviors have not been documented if guinea pig pups are left in the home cage when the mother is removed as a familiar socio-spatial environment buffers the endocrine stress response that normally occurs due to maternal separation (Wewers et al., 2003).

Vocal communication is important in precocial species where offspring are actively mobile (Kober et al., 2006) and pups make distinct calls when separated from their mother. Playback studies reveal that mothers respond significantly stronger to calls from their own pups compared to unfamiliar pups, suggesting that mothers are able to use vocal cues in pups recognition (Kober et al., 2006). Mothers of large litters are more responsive to their offspring for a longer period of time than females with smaller litters (Kober et al., 2008).

Vocalizations of guinea pigs have been categorized into 11 call types within five functional categories, specifically – chutt, chatter, whine, tweet, whistle (single or in long bouts), purr, dr, scream, squeal, chirp, and grunt which are used to communicate an increased proximity, greeting and maintaining proximity, regaining proximity, distress, or alarm (Berryman, 1976).

As noted among other rodents, guinea pigs are thigmotactic and will avoid open spaces including middle of cage floors (White et al., 1989). Providing guinea pigs with adequate shelter is an important aspect of their environmental enhancement (Baumans, 2005).

INTRODUCTION

Facility design, environment, and basic husbandry recommendations for the guinea pig are set forth in the *Guide for the Care and Use of Laboratory Animals (Guide)* (NRC, 2011). Since the inception of basic guidelines, standards have become increasingly performance- and “best practices”-based. Although general laboratory animal facility design and principles for rats, mice, and

hamsters have applicability to the guinea pig, characteristics and behavior unique to this species have fostered implementation of new and/or adjunct husbandry practices to improve the care and use of this laboratory animal.

In addition to the natural behavior and physiology of the species, the nature of the research activity to be performed must be considered in planning, design, or modifications of guinea pig holding rooms. Quarantine

facilities, breeding colonies, conventional and infectious disease research have different requirements for housing.

HANDLING

Guinea pigs are generally docile and seldom bite, however they are easily frightened and will try to avoid capture or being held. Guinea pigs not already conditioned to handling will generally run if approached from behind (Bradley, 2001). For instance, guinea pig startling/stampeding may cause abortion or result in orthopedic injuries, particularly in young cavy. It is best to place your hand in the cage in front of the animal to let it become used to it then approach the head, stroke the head and/or top of the nose. Ear scratching and stroking under the chin generally provide positive reinforcement (Bradley, 2001). When picking up a guinea pig, gently place one hand over the dorsum of the thorax and upper abdomen and use the opposite hand to support the hindquarters; or place one hand over the ventrum of the thorax and upper abdomen using the opposite hand to support the hindquarters (Figure 21.1). Care should be taken not to apply too much pressure over the thorax which could result

FIGURE 21.1 Proper method of restraining a guinea pig. (Photo courtesy of the Comparative Medicine Program, Texas A&M University.)

in damage to the viscera or compromise respiration. Pregnant females require additional care in supporting the hindquarters due to significant weight gain in late pregnancy. Never restrain a guinea pig by solely grasping or “scruffing” the skin. The lack of loose skin in the cavy may result in hair depilation using this technique. Due to their precocious development, neonates may be handled from day of birth (University of Miami, 2010). Traditional rodent restraint devices used for mice and rats do not easily adapt for use in the guinea pig due to their compact body structure (Harkness et al., 2002). Wrapping guinea pigs in a towel and holding them close to your body helps to deter struggling.

Allergies to guinea pigs are not uncommon and when handling, it is advisable to wear latex gloves. Surgical or N95 masks (note: an N95 respirator must be fit tested) may provide additional protection for more sensitive individuals. Cage changing stations and dirty bedding dumping stations also help to prevent aerosolization of allergens from dander or urine in the bedding. Small animal cage changing stations that provide laminar air-flow-no recirculation are commercially available. These stations provide high-efficiency particulate air (HEPA) filtered intake and exhaust air for protection of both the research animal and the animal research professional. Similarly, commercially available bedding disposal cabinet systems are available. Protection from allergens is provided through an air barrier across the access opening (100 FPM 0.5 m/s) and HEPA filtration (NuAire, Inc.). Bedding disposal unit options may include vacuum or conveyor belt connections to external dumpsters.

In the wild, guinea pigs live in herds of five to ten with a defined social hierarchy having a dominant male/female pair. Due to their social nature, guinea pigs generally do best in bonded pairs or trios (Bradley, 2001; Walker, 1975). Guinea pigs do vocalize and these vocalizations have been divided into 11 call types based on physical structure of the sonograms. Five functional categories have been defined: calls used to increase proximity; greeting; proximity-maintaining calls; proximity-regaining calls; and distress and alarm calls. These vocalizations include sounds such as whistling (excitement), purring (pleasure), chattering (pursuit), chirping (young wanted to be fed), chattering (agitated), squealing (discontent, danger), rumbling (mating purr), and cooing (mothering sounds) (Berryman, 1976).

HOUSING

Environmental Conditions

Ventilation

Ventilation for laboratory animals should balance air quality, animal comfort, and energy efficiency to

provide cage environments that will optimize animal welfare and research results (Memarzadeh, 1998).

Ten to 15 fresh-air changes per hour have been used as the guideline for secondary enclosures in laboratory animal indoor housing. Drafts should be avoided. Use of performance-based standards as guidance will accommodate a range of mitigating factors including individual species, body size, the number of animals, the type of bedding, type of caging and the frequency of cage changing (primary enclosure factors) and number of cages, room dimension, and air distribution efficiency between these enclosures (secondary enclosure factors). Over-ventilation of the secondary enclosure is not energy-efficient and may create a problematic draft, but under ventilation may inadequately dissipate heat, and allow excessive odor and pollutant accumulation (NRC, 2011).

Historically, air change requirements have been calculated by determining the ventilation requirements (NRC, 1996). The minimal ventilation rate (generally reported in cubic feet per minute) to accommodate the heat loads generated by animals can be calculated with the average-total-heat-gain formula as published by the American Society of Heating, Refrigeration, and Air-Conditioning Engineers (ASHRAE, 1993). This formula is species-independent and is applicable to any heat-generating animal. The minimal required ventilation is determined by calculating the amount of cooling required (total cooling load) to control the heat load expected to be generated by the largest number of animals to be housed in the enclosure in question, plus any heat expected to be produced by non-animal sources and heat transfer through room surfaces. The total-cooling-load calculation methods can also be used to determine the maximal number of animals (based on total animal mass) that can be housed in a fixed ventilation rate space. Odor control, allergen control, and particle generation must also be considered when using minimal required ventilation rates (often calculated below ten air changes per hour) and may necessitate ventilation beyond the determined rate. Conversely, calculated minimal required ventilation may exceed 15 air changes per hour, in which case, increased frequency of cage changes or reduction in animal numbers may be warranted (ASHRAE, 2007a; NRC 1996). Modern heating, ventilation, and air conditioning (HVAC) systems (e.g., variable air volume, or VAV, systems) allow ventilation rates to be set in accordance with heat load and other variables (NRC, 2011).

Individually ventilated cages that utilize an active air supply of filtered room air, or an active independent air supply, reduce the ventilation capacity required of the macroenvironment when compared to passive ventilated caging systems. Passive ventilated systems may need more frequent cage changes than active systems. Non-recycled air is preferred, but not mandatory, in

animal use and holding rooms. The use of recycled air in animal facilities entails risks, particularly for cross-contamination between rooms with animal pathogens that can be airborne or travel on fomites. It is imperative that recycled air should be filtered with 85–95% (at a minimum) ASHRAE-efficient filters to remove airborne particles (NAFA, 1996). More extensive discussion in regards to use of recycled air in animal facilities may be found in the *Guide* (NRC, 2011).

Illumination

Guidelines for illumination take into consideration the physiology, morphology, and behavior of an animal species (Brainard et al., 1989; Erkert and Grober, 1986; Tucker et al., 1984). Factors include; light intensity, duration of exposure, wavelength of light, light history of the animal, pigmentation of the animal, time of light exposure during the circadian cycle, body temperature, hormonal status, age, species, sex, and stock or strain of animal (Brainard et al., 1986). Light in animal holding areas should provide sufficient illumination to allow good housekeeping practices, adequate inspection of animals including cages housed on the bottom of racks, safe working conditions, and general well-being of the animals (NRC, 2011).

The light/dark activity of guinea pigs was first reviewed by Nicholls (1922). Nicholls noted that guinea pigs did not have a true diurnal cycle of activity like traditional laboratory rodents; rather they were active throughout the day and less at night and did not have periods of prolonged sleep. Wild guinea pigs are crepuscular, feeding at dawn and dusk. In the laboratory setting (12 hour: 12 hour light/dark cycle) they feed during the day and night with rest periods between meals (White et al., 1989). One commercial producer of laboratory guinea pigs reports using a 12 hour: 12 hour (light/dark) light cycle for their production colony and 14 hour: 10 hour (light/dark) cycle for their stock colony (Harlan Laboratories, 2010).

Albino animals (including albino guinea pigs) are generally thought to be susceptible to phototoxic retinopathy, although the albino rat is considered the most sensitive to these effects (Beaumont, 2002; Bellhorn, 1980). Recommended light levels are based on levels considered safe for albino rats; 325lux (30 ft-candles) at approximately 1.0m (3.3ft) above the floor with levels between 130–325lux at the cage level (Bellhorn, 1980). This intensity appears to be sufficient for animal care and still safe for albino animals. Very low light intensity has been shown to have a deleterious effect on reproductive physiology, fecundity, and estrus cycles in some rodents (Weihe et al., 1969). For example, light intensity has been reported to affect vaginal opening time, ovarian and uterine weights, estrous cycle length, and preweaning mortality (Donnelly and Saibaba, 1993;

Hautzinger and Piacsek., 1973; Porter et al., 1963; Weihe et al., 1969; Williams, 1971).

Temperature and Humidity

An ambient temperature of 20–26°C (68–79°F), with a relative humidity of 30–70% is recommended for guinea pig housing (NRC, 2011). Ambient temperature recommendations take into consideration the animal's thermoneutral zone (TNZ). The TNZ is the temperature range of a homeothermic animal in which minimal energy exertion is needed to maintain core body temperature. The TNZ is bound by the upper (UCT) and lower critical temperature (LCT) (Gordon, 1993). Ambient temperature outside of an animal's TNZ requires behavioral and physiologic adjustments to ensure homeostasis. These adjustments include postural adjustments, huddling, piloerection, peripheral vascular dilatation or constriction, alterations in respiratory rate, and food consumption. Continued alterations in the ambient temperature for a species combined with inadequate adaptive adjustments result in changes in basal metabolic rate (Clough, 1982; Newton, 1978). Small mammals (i.e. rodents) are generally impacted to a greater degree by alterations in ambient temperature due their large surface area: body weight ratios (Lipman et al., 2002). Even subtle changes in ambient temperature have resulted in changes in the biological effects of insulin, drug effects in toxicity studies, hormonal changes resulting in deleterious effects in breeding, lactation, and offspring survivability (Jans et al., 1987; Yagil et al., 1976). Ideally, a temperature control system should be capable of adjustment in dry-bulb temperature of $\pm 1^\circ\text{C}$ ($\pm 2^\circ\text{F}$) (NRC, 1996). LCT for the guinea pig has been reported as 20–21°C or 29–30°C. and the UCT ranges between 29–34°C; in comparison to the rat with most references in the range of 28–30°C and 30–34°C, respectively (Gordon, 1993). It is recommended that the dry-bulb temperature in animal rooms be set below the animals' LCT to avoid heat stress (NRC, 2011).

Relative humidity (RH) values that trend low or high may also impact research. Elevations in RH affect thermoregulation ability, impact on food consumption (higher RH has shown decreases in consumption) and may potentiate the transmission of infectious organisms (Weihe et al., 1961).

The RH of animal rooms can affect the survival of airborne pathogens and the settling rate of aerosols. Settling rates are a function of air movement and aerosol diameters (for aerosols with a diameter less than 100 μm) (Arundel et al., 1986). High settling rates decrease the amount of aerosols and therefore, reduce the probability of contact with aerosols contaminated with pathogenic substances. High humidity (80–90%) generally leads to higher settling rates by increasing the absorption and therefore size of the aerosol (Hanel, 1977). Conversely, low RH may increase the amount

of infective aerosols produced by exhalation or sneezing by limiting the size of the aerosol (Smith, 1983). Infectious organisms vary on survivability rates in relation to RH. Fungi and mites have increased survivability at RH greater than 70% (Arundel et al., 1986). Viruses composed entirely of nucleic acids and proteins have improved survival in high RH versus lipid-containing viruses which prefer low RH (Knight, 1980). Some bacterial organisms have increased survivability at both low and high RH (<40%, >60%) but decreased survivability at mid-range humidity (Fitzgerald, 1975). The optimum RH range for minimizing adverse health effects appears to be 40–60% (Arundel et al., 1986).

Ammonia production in rodent cages is directly related to the RH of the room (Hasenau et al., 1993; Memarzadeh, 1998). A RH range of 30–50% may be more desirable when static microisolator caging is in use (Hessler and Leary, 2002). Low humidity may slow sexual maturity in rodents (Drickamer, 1990).

Noise

Noise control is a major consideration in the design and operation of animal facilities. Changes in patterns of sound exposure have varied effects on different animals (Armario et al., 1985; Muchnik et al., 1992). Therefore, personnel should try to minimize the production of unnecessary noise, and radios, alarms, and other devices producing sound should not be used in animals' rooms unless they are included as part of a research or enrichment protocol (Lipman and Perkins, 2002). Like other rodents, guinea pigs are susceptible to noise stress (Anthony and Harclerode, 1959). Animals exposed to sounds louder than 85 dB (decibels) can have both auditory and non-auditory effects including eosinopenia, increased adrenal weight, reduced fertility, audiogenic seizures, and reduced locomotor activity (Fletcher, 1976; Geber, 1966; Nayfield and Besch, 1981; Peterson, 1968, 1980; Zondek and Tamari, 1964).

The normal human hearing range is generally noted to be 0.02–20 kHz at 60 dB (Jackson et al., 1999). Wever (1959) reported the hearing range of guinea pigs to be 0.1–40 kHz, with the most sensitive range being between 0.2–2 kHz at 97 dB. More recently, the guinea pig hearing range has been reported as 0.32–50 kHz at 60 dB and 4–28 kHz at 10 dB (Heffner and Heffner, 2007). Rodents (including guinea pigs) and other animals can detect ultrasounds (>20 kHz) that are outside the human hearing range and this ultrasound range may be very important in rodent intraspecies communication, particularly between dam and pup, dominance hierarchies, and mating (Hofer and Shair, 1978; Sales and Pye, 1974; Sales and Smith, 1980; White and Barfield, 1987). Low frequencies (<20 kHz) have also been shown to affect behavior and physiology of laboratory animals. Altered water consumption,

reproductive performance, body weight, learning ability, eosinophil counts, immune responsiveness, corticosteroid blood levels, glucose and insulin concentrations have been impacted in rodents exposed to these low-frequency noises (Anthony, 1959, 1962; Armario et al., 1985; Buckley and Smookler, 1970; Fay, 1988; Lockett, 1970; Wolstenholme and O'Conner, 1967; Zondek and Tamari, 1967).

Due to concern for deleterious effects of noise produced by fire alarm systems, the "silent fire alarm" was developed. The "silent fire alarm" produces a noise intensely irritating to humans but does not awaken rats and mice, or appear to induce a startle response or ear twitching in awake rats and mice. Rabbits and guinea pigs show only "mild disturbance". This alarm produces pure tones alternating between 430 and 470 Hz, below the optimal hearing range for mice and rats (Clough and Fashsam, 1975). Some exotic species of rodents have been reported to still display adverse effects from these "silent alarms". As another alternative, voice alarms have also been used to replace traditional siren alarms.

Vibration has also been associated with biochemical and reproductive changes in laboratory animals (Briese et al., 1984; Carman et al., 2007). Internal sources of vibration include housing systems with moving components (ventilated caging), mechanical equipment, and human activities. Groundborne vibration is related to traffic (subways, trains, trucks). Vibration suppression systems are available (ASHRAE, 2007b).

Sanitation

The *Guide* defines sanitation as "the maintenance of environmental conditions conducive to health and well-being – involves bedding change (as appropriate, cleaning, and disinfection". It further defines cleaning as the removal of excessive amounts of dirt and debris, and disinfection as the reducing or elimination of unacceptable concentrations of microorganisms (NRC, 2011). The Animal Welfare Act (9 CFR Ch. 1 Subchapter A, 1993) requires that "primary enclosures for guinea pigs shall be cleaned and sanitized often enough to prevent an accumulation of excreta or debris, and such enclosures shall be sanitized at least once every 2 weeks by washing them with hot water (180°F) and soap or detergent in a cage washer, or washing followed by a safe, effective disinfectant or live steam". Sanitation schedules and methodology will vary with the type and size of the primary enclosures, the bedding materials utilized, as well as the number and size/age of guinea pigs housed. Protocol-specific requirements related to husbandry may also impact the sanitation schedule. Removal of soiled bedding should be performed as often as necessary to keep guinea pigs clean and dry and frequency is based on professional judgment.

Typical changing schedules vary from daily to weekly. Consideration must be given to the guinea pigs' propensity to "play" with water sippers which may lead to frequent wetting of the cage bedding and fouling of water if water bottles are used. Guinea pigs on water bottles may need daily change outs. Frequent bedding changes may be contraindicated pre- or post-partum and interfere with successful reproduction (NRC, 2011).

Guinea pigs, like hamsters and rabbits, produce urine with high concentrations of proteins and minerals which often adhere to the cage surface and may necessitate acid solution treatment prior to washing. Cages may be disinfected with chemical, hot water, or both. If hot water is used alone, it is the "cumulative heat factor" applied to the surface which provides disinfection; i.e., length of time at a given temperature (Wardrip, et al., 1994); 82.2°C (180°F) is the standard temperature requirement for rinse water. Effective disinfection can be achieved with wash and rinse water at 143–180°F based on time and temperature (1s at 82.2°C/180°F, 15s at 71.6°C/161°F, 30min at 61.7°C/143°F) however, many washers do not allow the machine to complete a cycle that does not reach 82.2°C (180°F) (Hessler and Leary, 2002). When detergents and chemical disinfectants are used, caging, water bottles, sipper tubes, etc., must be thoroughly rinsed prior to reuse. The selected washing time and conditions should be sufficient to kill vegetative forms of common bacteria and other organisms presumed to be controllable by a sanitation program (NRC, 2011).

Automatic watering systems require some mechanism to prevent build up of microorganisms and/or debris. Periodic flushing with large volumes of water or appropriate chemical agent(s) followed by thorough rinsing with water are methods that may be used.

Animal holding rooms, hallways, and support areas should have regular cleaning and disinfection schedules appropriate for the facility.

Sanitation practices should be routinely monitored for compliance and effectiveness. Monitoring may include visual inspection, cage cleaning water temperature monitoring, and/or microbiologic monitoring with swabs and culture, direct agar contact plates, or ATP (adenosine triphosphate) detection systems.

Enrichment

Enrichment of laboratory animals has typically been categorized as social or physical. Social enrichment includes contact and non-contact methods (Baumans, 2005). Guinea pigs are social animals and housing conspecifics may provide the primary valued enrichment, although detailed investigation into their social structure has not been performed. Physical enrichment includes enclosure complexity, nesting material, sensory enrichment, and nutritional enrichment (Baumans,

FIGURE 21.2 Example of enrichment ball and extruded wire flooring with wood shaving bedding. (Photo courtesy of Comparative Medicine Program Texas A&M University.)

2005). Although multiple sources (Bradley, 2001; White et al., 1989) indicate that guinea pigs do not utilize the whole cage space; preferring the periphery, Scharmann noted that when hay or straw was added to the cage, guinea pigs burrowed and hid in it (Scharmann, 1991). Gray et al. (1988) found guinea pigs seek out intracaging shelter when it is available particularly when startled or in breeding situations. Toys such as commercially available ferret roll-about balls stuffed with foraging material, balls with bells inside, bedding bags, hide boxes, PVC piping, foraging materials such as hay and corn husks, and varied food treats have been used (Figure 21.2). Scharmann (1991) noted chewing on bars and hoppers by guinea pigs ceased if wood was added to the cage. Others have noted that hay reduces chewing episodes (Reinhardt, 2007; Sutherland and Festing, 1989). Toys should be made of easily sanitizable materials and be changed out/sanitized, in conjunction with the cage changing schedule. When natural materials such as hay are incorporated into the enrichment program, they should be autoclaved prior to use to prevent microbial contamination (Banjanin et al., 2004).

The potential impact of the cage environment on experimental outcomes must be considered when adding or changing enrichment methodology. “The most significant unexpected impact occurs when an item intended to enhance the animal’s welfare results in harming the animal in some way” (Bayne, 2005).

Caging and Space Requirements

Cage space requirements for the guinea pig are set forth in the *Guide* (see Table 21.1) and are identical

TABLE 21.1 Space Recommendations for the Guinea Pig^a

Weight (g)	Floor Area	
	Per Animal (c ²)	Height (cm)
≤350	387 (60 in ²)	17.8
>50 ^b	≥651.5 (>101 in ²)	17.8

^aFrom the *Guide for the Care and Use of Laboratory Animals* (NRC, 2011).

^bLarger animals may require more space to assure performance standards are met.

to the requirements set forth by the Animal Welfare Regulations (NRC, 2011; 9 CFR, 2002). Cage floor space recommendations generally reflect several times the resting area of the animal. Space requirements for communal species such as guinea pigs have been adjusted to accommodate their communal structure (White et al., 1989). Whenever possible, social animals such as guinea pigs should be housed in pairs or groups as long as group housing is not contraindicated by the protocol in question or causes undue risk to other animals (Brain and Bention, 1979). The cage space should also consider enrichment, individual animal behavior, group housing, and the goals of the housing situation and research protocol (NRC, 2011).

Actual floor space usage was evaluated in groups of breeding guinea pigs. That study found that breeding guinea pigs utilize the periphery of the cage almost to the total exclusion of the center of the cage; approximately 75–85% of day and night time occupancy occurred in 47% of the cage floor periphery (White et al., 1989). In communal groups with pups, the adults align along the perimeter of the cage, end to end, with the pups near the end of the line (Harkness et al., 2002; White et al., 1989).

Additional considerations for housing guinea pigs include their heavy body build. Adults may weigh 1 kg and are prone to developing pressure sores and pododermatitis on wire mesh floors (Fullerton and Gilliatt, 1967). Wire-mesh flooring may also potentiate injuries to feet and legs of smaller, younger guinea pigs which may catch their smaller limbs in spaces between wires. Reduced production in breeding animals, and weight and hair loss in the young, have been reported in guinea pigs housed on these floors (Eidger, 1976).

In the research setting, guinea pigs are commonly held in solid-sided, wire-mesh or solid-floored cages on multi-level racks; individual shoebox style microisolator caging, solid-bottom plastic caging, or solid-bottom plastic caging on ventilated rack systems. Solid-bottom caging is usually bedded with commercially available bedding materials (Harkness et al., 2002). Some institutions place wire bottoms within plastic caging but also use bedding materials. Traditional drawer style rack caging for guinea pigs is available with solid or perforated extruded plastic flooring which allows feces to

FIGURE 21.3 (A, B) Examples of plastic shoebox style microislator caging, dual water bottle system, and J-feeder for guinea pig housing from the side (A) and end (B). (Photos courtesy of the Comparative Medicine Program, Texas A&M University.)

fall through to a catch pan, and provides a comfortable walking surface without the need for bedding. Others have used mouse cages filled with hay or bedding to house guinea pigs, although use of this method requires attention to assure that internal cage height is sufficient for the needs of the animal(s) and to meet regulatory requirements (Banjanin et al., 2004).

In addition to the safety and comfort of the animal, caging durability and resistance to rust and chemicals should be considered. Stainless steel is the most common metal used and is very durable. Polycarbonate caging (molded plastic) has been used since the 1960s. This caging has high-impact strength and holds up well in 82.2°C wash water. Although polycarbonate withstands autoclaving at 120°C, repeated autoclaving does shorten the life of the cage (opaque changes, cracking). For this reason, various thermoplastics (polyphthalate, polyetherimide, polysulfone, polypenylsulfone) resistant to the detrimental effects of autoclaving were introduced in the 1980s and 1990s (Hessler and Leary, 2002).

When water bottles are used, guinea pigs may have a propensity to push or pile up bedding material which results in wicking of water from the sipper tube, subsequently flooding the cage. The combination of wire flooring (preferably extruded wire) and bedding helps to prevent this problem. Shoebox-style caging often incorporates the use of wire-bar or mesh tops, or plastic mesh tops with filters. Modification of traditional shoebox cages including HEPA filtration of air (passive or active) has been made to accommodate infectious disease work. In non-breeding situations, guinea pig housing typically accommodates one or two animals. Racks with drawer-style caging have been used for breeding colonies (Figures 21.3–21.5).

The Animal Welfare Regulations (9 CFR, Subpart B, section 3.36 parts a–h, 2002) detail the requirements for transport caging of guinea pigs. Briefly summarized,

FIGURE 21.4 Example of microislator filter lids with plastic mesh. (Photos courtesy of Comparative Medicine Program Texas A&M University.)

key requirements include: primary enclosures shall have solid bottoms to prevent leakage, clean litter of a suitable absorbent material which is safe and non-toxic in a sufficient quantity to absorb and cover excreta (unless non-solid floor is also used within the primary enclosure), labeling on the top and one or more sides with “Live Animals” (unless the primary enclosure is permanently affixed to the cargo space of the primary conveyance), and appropriate shipping documents attached (9 CFR, 2002). Guinea pigs from commercial production colonies are usually shipped in standard heavy-duty cardboard shipping boxes with filter-lined air openings, commercial bedding, food and water source (such as gel packs). Air transport must also comply with IATA (International Air Transport Association) rules and regulations.

Transport of guinea pigs within research facilities is generally accomplished using standard solid-bottom, solid-sided microislator caging with filter tops. During

FIGURE 21.5 (A, B) Examples of a microisolator caging system using room supply air as one way flow through. (Photos courtesy of University of Texas Health Science Center, San Antonio, Department of Laboratory Animal Resources.)

transport, particularly through common corridors in academic or public settings, cages or racks are generally covered with solid drapes or similar material. This helps to prevent additional stress to the animal as well as limit public view of the animals.

Bedding

Bedding materials traditionally consist of corncob, hardwood chips, shavings, and paper products (Figure 21.6). Some bedding materials may interfere with vitamin C depletion studies due to the presence of low levels of vitamin C in the bedding (Dunhan et al., 1994). Bedding is commonly placed directly onto the cage floor allowing the absorption of urine and providing

material for the animal to burrow into. Sawdust is not recommended as it may lodge in the perineum or prepuce (Plank and Irwin, 1966; Harkness and Wagner, 1995). The preference of guinea pigs for bedding material was reviewed by Kawakami et al. (2003). They concluded that guinea pigs preferred wood shavings to paper cutting sheets (OMEGA-Dri®, Omni Bio Resources, Inc., New Jersey; 6.5–8.0 mm² in size) during light hours and paper bedding during the dark period. It was postulated that the wood shavings provided better nest-building material and shelter from overexposure to light (Lynch et al., 1972). More eating and drinking, and evacuation behavior was noted in the dark period when the paper bedding was preferred (Kawakami et al., 2003).

FIGURE 21.6 Guinea pig housed on wood chip bedding. (Photo courtesy of University of Texas Health Science Center Department of Laboratory Animal Resources.)

Several authors and sources have indicated that high-quality hay should be included as part of the diet and to serve as bedding material. Although guinea pigs were not originally thought to be burrowers, recent references have indicated they do use hay or straw for burrowing, and these products also decrease gnawing on cage components. Hay has also been shown to increase reproductive rates in guinea pig breeding colonies (Reinhart, 2002; Sutherland, 1989).

Room Configuration

Room configurations within a facility incorporate many factors, including security; species to be housed; biological, chemical, and radiation safety; animal health; occupational health; and access to support areas and animal procedure laboratories to name a few. The animal housing area for guinea pigs, as for other rodent species, may include conventional housing, quarantine, biocontainment, and barrier housing (Hessler and Leary, 2002).

The animal room (secondary holding) size should allow easy access to and manipulation of racks for change outs, daily observations, and should include space for support equipment such as changing stations, feed bins, and PPE (personal protective equipment) carts or holders. PPE for conventionally held guinea pigs (gloves, masks, coveralls or lab coats, and booties) can be placed in anteroom areas just outside or just inside the primary animal holding room. PPE and standard operating procedures (SOPs) for barrier facilities (production colonies, biocontainment rooms) will

vary in accordance with the requirements and design of the production facility, or biosafety policies. In general, larger individual animal rooms decrease construction costs but several smaller rooms may make it easier to control infectious disease. Additional safety equipment and specialized housing for containment may require larger room sizes (Ediger, 1976; Hessler and Leary, 2002).

Animal rooms should be close or contiguous with research support areas such as procedure rooms and necropsy (NRC, 2011).

REPRODUCTION AND BREEDING

Guinea pigs are precocious in nature. Male guinea pigs will begin mounting behavior as early as 4 weeks of age, with intromissions occurring around 6 weeks, but are usually not fertile until 8–10 weeks of age. Generally, boars are first used for breeding at 3–4 months, or when they reach 600–700 grams in body weight. Sows may be bred as early as 2–3 months of age, or 350–450 grams body weight and the first breeding should take place prior to 6–7 months of age. After this age, the fibrocartilaginous joint of the pubic symphysis may not separate, resulting in dystocia.

The estrus cycle in the sow is approximately 16 days (13–21-day range) with proestrus lasting 1–1.5 days. Proestrus is characterized by vaginal swelling, rupture of the vaginal membrane, nucleated and cornified epithelial cells on vaginal smear and increased activity (Harkness, 1986; Stockard and Papanicolaou, 1917; Young et al., 1935). Vaginal swelling and congestion, lordosis, perforate vaginal membrane, and cornified epithelial cells signal the onset of estrus which lasts 8–11 hours. The estrus period is followed by metestrus and diestrus lasting 3 and 11–12 days, respectively. In the guinea pig, a fertile postpartum estrus occurs 2–10 hours after parturition (Harper, 1968; Phoenix, 1970; Sisk, 1976). During estrus, the boar will circle the sow, sniff, lick, nibble, and mount the sow. One to two intromissions usually precede ejaculation. Post coitus, the boar may scoot (perianal marking) and groom (Manning et al., 1984). A copulatory or vaginal plug is formed post mating and may be found in the bedding. Mating of guinea pigs typically occurs in the dark (Young, 1969). Generally, 60–85% of all matings are fertile (Harkness, 1986).

Pregnancy can be detected through gentle abdominal palpation. Firm, oval swellings approximately 5 mm in diameter can be felt at day 15 of gestation. By day 25, these swellings measure approximately 7–15 mm in diameter and by day 35 approximately 25 mm in diameter. Individual body parts may be palpated after 35 days of gestation. Obvious abdominal distention

is noted in late pregnancy. In response to relaxin produced by the placenta, the fibrocartilaginous pubic symphysis begins to loosen around day 30 of gestation and this separation grows to approximately 3cm during the last week of gestation (Zarrow, 1947). Pregnancy toxemia or pre-eclampsia in guinea pigs may occur, especially in obese, stressed, multiparous sows with large fetal load (Ganaway and Allen, 1971; Golden et al., 1980). Placentation is hemochorial and strikingly similar to the human (Carter, 2007; Oliveria et al., 2008). Gestation lasts 59–72 days with the gestation length being inversely proportional to the size of the litter. Sows do not build nests. Litters generally consist of 2–5 pups, delivered every 3–7 minutes. The guinea pig is a precocious species, whose pups are born fully haired, with teeth and open eyes and ears. They are fully mobile at birth, with weights ranging from 45–115g and wean at 180g or 14–28 days. Pups begin eating solid food and drinking water a few days after birth, although without milk from the sow during the first 3–4 days of life, pup mortality may reach 50%. Voluntary micturition occurs between 1–2 weeks of age and weaning at 21 days of age (Harkness et al., 2002).

Guinea pig breeding systems incorporate both monogamous (one male, one female) and polygamous (one male, several females) pairings. Males may be left with the sow(s) throughout the gestation and parturition process to take advantage of the sow's fertile postpartum estrus. Continuous cohabitation can result in five litters per year per sow. Heavily bred sows may cease hair growth, resulting in partial alopecia. If the boar is removed prior to parturition, the average number of litters per year is reduced to 3.5 (Harkness et al., 2002). Evidence of estrus cycle synchronization among group-housed sows has not been noted (Donovan and Kopriva, 1965; Harned and Casida 1972). An extended estrus (2–3 days) has been induced in the sow by administration of 1000µg of estradiol for 6 days. The estrus was induced for non-breeding experiments and details on how or if it differs from natural estrus have yet to be determined (Lilley et al., 1997).

Naguib et al. (2009) has shown that concurrent pregnancy reduces lactating guinea pigs' responsiveness to pup calls. Non-pregnant lactating females responded to pup calls whereas most pregnant lactating females did not respond at all.

Hennessy et al. (2003) demonstrated that continuous housing of the pups with the mother suppresses maternal and female sibling-directed sexual behavior in periadolescent (approximately 35 days of age) guinea pig males. If males were housed apart from the mother for as little as 24 hours prior to re-cohabitation, significantly more sexual behavior was observed. This interest (anogenital investigation and other courtship behaviors) was proportional to the time away from

the mother. Interest in strange/new females was not affected. This phenomenon may be the result of pheromones in the home cage or an avoidance of breeding with familiar females as a potential vehicle to reduce inbreeding is not known. In a related study, female novelty in the courtship behavior of male guinea pigs was assessed. This study investigated the sexual behavior of sexually satiated males when placed in contact with a novel mate. The results indicated the existence in male guinea pigs of a process of habituation/recovery of courtship responses under the control of female novelty; i.e., less interest with increased contact of same female(s) and increased interest in new females (Cohn et al., 2004).

Of interest, is a recently identified monogamous wild guinea pig, the "Monogamous Cavy", *Galea monasteriensis*. Mated pairs of this species live harmoniously with each other but are aggressive with other conspecifics, both male and female (Adrian et al., 2007; Hohoff et al., 2002; Solmsdorff et al., 2004). The males of this species exhibit increased levels of paternal care and suppressed reproductive capacity. The testes weight of the males of this species is lower than other wild guinea pigs (Adrian et al., 2005).

NUTRITION

Guinea pigs, like rabbits, are strict herbivores and hind-gut (cecal) fermenters. Unlike rabbits, they do possess lactobacilli and produce propionic acid as the primary fatty acid (Smith, 1965). Guinea pigs require vitamin C in their diet and should be fed chow specifically prepared for this species and supplemented with vitamin C (ascorbic acid). Guinea pigs are coprophagic, usually ingesting fecal pellets directly from the anus (King, 1956; Navia and Hunt, 1976). Pregnant or obese guinea pigs may ingest feces from the cage floor and young animals inoculate their intestines with normal flora by ingesting maternal feces (Harper, 1976; Hintz, 1969).

Feed

Commercial laboratory guinea pig chow is pelleted and contains approximately 18–20% crude protein and 9–18% fiber. Due to the vitamin C supplementation in guinea pig chows, the chow should not be used beyond the manufacturer's recommended shelf life. The use of encapsulated or stabilized vitamin C in the chow has extended the shelf-life of most feeds from 90 to 180 days post milling date, although many institutions still choose the 90-day limitation. Feed should be stored in a cool, dry, dark area that is enclosed to prevent entry of pests. Feed should be stored off the floor on pallets, racks, or carts to allow easy sanitation of the room.

Opened bags of food should be stored in vermin-proof containers to minimize contamination and to avoid potential spread of pathogens (NRC, 2011). Containers of opened feed should be labeled with the milling date and type of feed. Pelleted feed is generally fed in J-type feeders which hang inside the cage suspended from the lid or side; or attached to the cage doors.

Nutritional Requirements

Comprehensive reviews of guinea pig nutrition are available (Mannering, 1949; Navia and Hunt, 1976; Reid and Bieri, 1972). Guinea pigs consume approximately 6 grams of food per 100 grams body weight per day, and require approximately 35% fiber in their diet (Harkness, et al., 2002; Smith 1990). The estimated nutritional requirements for the guinea pig have been summarized elsewhere (Harkness et al., 2002). Guinea pigs will alternate periods of eating with resting through the day and night. As previously noted, several references believe the inclusion of hay for dietary supplementation and enrichment is prudent if not necessary. Timothy hay is preferred (Reinhardt, 2002; Sutherland, 1989). Hay may be autoclaved or irradiated to kill microorganisms. In vitro studies have indicated that autoclaving hay may inhibit fiber degradation (Lancaster and Patterson, 1988). Prepackaged “hay bricks” suitable for autoclaving or irradiated (25 kGy) are commercially available (Lillico Biotechnology, 2009).

Supplementation with vegetables may be incorporated into the diet and enrichment program if not contraindicated by the research, however, vegetable matter may provide a source of bacterial contamination. Supplementation with vegetables and fruit is not commonly done in the research setting for this reason, but if it is included in the diet, vegetables and fruit should be thoroughly cleaned prior to feeding, fed in a separate container from pelleted feed, and leftover supplements removed on a daily basis. Guinea pigs are fastidious eaters and may not readily adapt to novel food items.

Water

Guinea pigs will consume approximately 10 ml of water per 100 grams of body weight per day. Importantly, guinea pigs have a tendency to play with their water bottles which leads to drainage of water into the cage and spitting, reflux, or fouling of the water bottles with saliva and feed particles; thus, water bottles may need to be changed more frequently than with other rodents. If automatic watering systems are used in solid-bottom caging, the valves should be located outside of the cage to lessen the chance of flooding (Harkness et al., 2002). If the water source is changed from water bottles to automatic watering or

from automatic watering to bottles, guinea pigs should be observed for water and food consumption. Abrupt changes in the water delivery system may result in decreased water consumption, and in turn food consumption. One author reported problems with moving guinea pigs from standard caging with water bottle with a 1.4-mm (inner diameter) spout to individual metabolic cages with water bottles with a 0.7-mm spout. This change resulted in decreased fluid intake and subsequent weight loss during a 2-day experimental period. Once the sipper tubes were replaced with the larger size, the animals quickly returned to normal water and feed intake, and regained body weight (Fenske, 1989).

The type of water for guinea pigs ranges from chlorinated tap water, to RO (reverse osmosis) and acidified water sources already in place for rat and mouse housing areas. Consideration must be given to potential effects of the processing and delivery of water. For example, Hall et al. (1980) found that depending on the pH of the water and the acid (hydrochloric vs. sulfuric) used for acidification, there may be a decrease in weight gain, water consumption, and intestinal bacteria isolated from the gut of both immunosuppressed and immunocompetent mice.

Nutritional Diseases

Nutritional diseases are rarely seen in modern research colonies but may be seen as clinical conditions in pet guinea pigs. The following is a brief overview of these conditions.

Hypovitaminosis C (Scurvy)

The primary nutritional disease of concern in the guinea pig is hypovitaminosis C. Like primates and some species of birds, fish, and bats, scurvy in the guinea pig is the result of the inability to produce the hepatic enzyme L-gulonolactone oxidase which converts L-gulonolactone into the isomers L-ascorbate (AH) and 1-dehydroascorbic acid (DHA), thus preventing the conversion of glucose to ascorbic acid (Marcus and Coulston, 1990). Deficiency is often subclinical, and may present as mild conjunctivitis, or non-specific respiratory or intestinal signs. More advanced cases present with weight loss, reluctance to move, and swollen joints (Clarke et al., 1980). The vitamin C deficiency leads to an impaired synthesis of collagen secondary to defective hydroxylase reactions in the formation of hydroxylysine and hydroxyproline amino acids. Treatment consists of supplementation of vitamin C up to 230 mg/kg daily. Recovery is short, often only taking 1–2 weeks (Harkness et al., 2002). Vitamin C deficiency in early postnatal life may result in impaired neuronal development and a functional decrease in spatial

memory in the guinea pig (Tveden-Nyborg, 2009). Because current laboratory guinea pig diets are supplemented with vitamin C, scurvy has essentially been eliminated from the research setting.

Deficiencies of other vitamins

B vitamin deficiencies may occur with symptomology similar to other rodent species. For example, thiamin (B1) deficiency leads to central nervous system problems such as tremors and imbalance. Riboflavin (B2) deficiency leads to corneal vascularization and niacin (nicotinic acid) deficiency in the young may lead to anemia and diarrhea. Pyridoxine (B6) results in folic acid deficiency in young guinea pigs and may progress to terminal convulsions. Pantothenic acid deficiency presents with anorexia, weight loss, and intestinal hemorrhage. In the pregnant sow, it may lead to abortion and possibly death of the sow. Vitamin E and selenium deficiencies may lead to limb weakness (muscular dystrophy), reproductive decline, and even death (Percy and Barthold, 1993).

Pregnancy Toxemia/Pregnancy Ketosis/Pre-eclampsia

Pregnancy toxemia in the guinea pig is recognized to consist of two distinct patterns of disease; a fasting or metabolic (nutritional) form and a circulatory or toxic form. Both forms normally occur in late pregnancy and present with similar clinical signs; depression, acidosis, ketosis, proteinuria, ketonuria, and a lowered urinary pH (5–6).

The metabolic form of pregnancy toxemia occurs in obese sows during the last 2–3 weeks of a sow's first or second pregnancy. The weight of the uterine contents of affected guinea pigs may represent as much as 50% of the total non-pregnant weight of the sow. The disease may be induced by the stress of shipping or changes in feeding routine. Hypoglycemia, glucose, ketosis, and hyperlipidemia are typical findings, with coma and death following 5–6 days after the onset of disease. Necropsy generally reveals abundant fat reserves, fatty infiltration of the liver with microscopic fatty changes in the liver kidneys and adrenals (Percy and Bartold, 2008; Seidl et al., 1979).

The circulatory form of pregnancy toxemia (pre-eclampsia) occurs secondary to vascular changes that lead to ischemia of the uterus and placenta via compression of the aorta (caudal to the renal vessels) by the gravid uterus. The resulting ischemia of the uterus and placenta leads to hemorrhage, necrosis, thrombocytopenia, ketosis, and death. Histological changes include uterine and placental hemorrhage, necrosis and leukocytic infiltration, liver necrosis, nephrosis, and adrenocortical hemorrhage (Percy and Bartold, 2008; Seidl et al., 1979).

Deficiencies of Amino Acids

Restricted diets may result in protein and fatty acid deficiencies. Reproductive complications are a common result. The limiting amino acid for guinea pigs is arginine, followed by methionine and tryptophan (Reid et al., 1960).

Metastatic Calcification

Metastatic calcification may present as muscle stiffness and unthriftiness in the guinea pig. Mineralization may be focal (elbow and rib soft tissue) or diffuse (lung, trachea, heart, aorta, liver, kidney, stomach, uterus, and sclera) and is most often seen in guinea pigs over 1 year of age. It appears this condition is due to dietary imbalances such as low magnesium and high phosphorus, but the exact etiology has not yet been defined (Percy et al., 1993).

Malocclusion

Malocclusion, although not a nutritional disease, may result in nutritional problems in the guinea pig. The hypsodont molars of the guinea pig are prone to overgrowth if the dental surfaces become malaligned. This may result in lingual entrapment, buccal and lingual lacerations, inability to masticate food with resulting weight loss and malnutrition. Drooling or “slobbers” is a classic sign of this condition (Wagner, 1976).

COLONY HEALTH

Preventive Medical Strategies

Preventive medicine strategies should incorporate a multi-faceted program which includes biosecurity, health surveillance, quarantine programs, pest control, well-defined SOPs for cleaning and disinfection, monitoring for compliance of these SOPs, and sound technical and investigative staff training. Detailed descriptions of incorporation of such programs can be found elsewhere (Fox et al., 2002). Biosecurity focuses on preventing transference of infection between animals, from biological and mechanical vectors, and fomites that may contaminate bedding, water, or food (Brachman, 1996; Cohen, 1998; Prince et al., 1991; Waggle et al., 1994).

Today, most laboratory guinea pigs are specific pathogen-free (SPF) animals bred and raised by commercial vendors under barrier conditions. Generally, acclimatization periods for SPF rodents varies from 3–7 days post-shipment. During this time, the animals should be observed by husbandry staff to assure normal activity, ambulation, appetite, and fecal production; and any abnormalities in these parameters or other signs of disease, such as abnormal swellings or masses,

presence of discharges or exudates, or wounds should be reported to the veterinary staff. Quarantine periods for animals transferred from other institutions vary from weeks to months and are based on the animal health histories from the source institution, the receiving institution, housing availability, and research goals.

Once it has been established that an infectious disease is present in the colony, a determination must be made on how to best contain and eradicate the problem. If SPF animals can be obtained for replacement, then depopulation and disinfection is standard practice. Contamination with a zoonotic disease usually warrants euthanasia and disposal of carcasses as biohazardous waste, and decontamination of the premises and support equipment.

Separation of species and animals of different health status can be a very important aspect of preventive medicine. For example, guinea pigs are very susceptible to *Bordetella* infection. Laboratory rabbits, even SPF rabbits, often harbor *Bordetella* without showing any signs of disease. Thus, it is important to separate guinea pigs from rabbits and other species (e. g., dogs, cats, and swine) that could potentially carry *Bordetella*, and husbandry tasks should be assigned and performed in a manner that minimizes the potential for transmission of pathogens such as *Bordetella*. Although vaccination of guinea pigs for *Bordetella bronchiseptica* has been reported, it is not a common practice for the preventive medical care of guinea pigs (Ganaway et al., 1965; Nikkels et al., 1999).

Colony Health Monitoring

SPF guinea pigs are available through established commercial laboratory animal vendors. Current breeding and housing conditions of commercial vendors have provided generally healthy stock which are not typically quarantined, but may need to undergo a period of acclimatization (Harkness et al., 2002; Hessler et al., 2002). Microbiological surveillance programs for guinea pig colonies should be tailored to meet the needs and reflect the concerns of individual programs. Research programs which use limited numbers of SPF guinea pigs for acute or short-duration studies do not necessarily require quarantine or extensive monitoring. Institutions which receive or ship non-SPF, i.e., “conventional” guinea pigs between facilities should incorporate quarantine health-screening procedures (microbiological serologic, and parasite testing). The length of quarantine would reflect the primary infectious disease concerns of the individual institution. Sentinel programs that incorporate euthanasia and harvesting of animals exposed to dirty bedding similar to those used for rats and mice may be cost-prohibitive in guinea pig colonies. Alternatively, surveillance

programs may incorporate the use of retired breeders or necropsy and culture of animals found dead. Screening for ecto- and endoparasites may be performed without sacrifice of the animal.

Barrier facilities are not typically required for most research with guinea pigs, but if the need should arise, the principles and procedures would be based on traditional rodent barrier practices. More commonly, it may be necessary to house guinea pigs in biocontainment areas for hazardous infectious disease work. Practices for laboratory safety, techniques, safety equipment, and facility design are described in detail elsewhere (CDC-NIH 2009; Hessler et al., 2002).

RECORD KEEPING

Identification of Animals

Typically, cage cards are used for identification of guinea pigs. Cards should include the strain of guinea pig, sex, number, principal investigator, and research protocol identification. Breeding group cards may also contain mating and birth records. Individual animal identification may be accomplished by several methods. Temporary identification can be accomplished by dyeing, marking, or clipping of the fur. Dyes such as trypan blue, picric acid, fuschin, or methyl violet as well as permanent marking pens have also been used. These methods generally last only a few weeks. Traditional metal ear tags provide more permanent identification, but may be pulled out by trauma, particularly in group housing situations. Colored guinea pigs have also been identified by coloration patterns (University of Miami, 2010). Microchips provide reliable means of identification. Toe clipping is not a recommended form of identification.

Breeding Records

For many small- to moderate-sized projects involving breeding, notations on breeding, copulatory plug confirmation, pregnancy confirmation, and parturition have been included on the cage card for easy reference. At institutions where cage cards are used as part of colony census and billing, there is a potential for loss of information as cards are turned in. A back-up log, hard copy or computerized format should also be maintained. Room husbandry logs may incorporate breeding records into their database. For institutions using microchip technology, some breeding data may be linked to the ID chip. Automated information systems to aid in the record keeping of rodent breeding colonies have been in use since the 1970s. These systems often have keyboard terminals in each breeding colony room linked to a local

computer for data collection, editing, and short-term storage; with a larger computer network for permanent storage and report generation. Technicians record and enter all breeding activities (births, weaning, disposition of animals, and health observations). Additional information such as pedigrees may be incorporated into these programs (Kalback et al., 1977).

Husbandry and Health Records

Husbandry logs may be kept as hard copy in notebooks, or as data entries for institutions with computer network support within their animal facilities. For individual health checks, many institutions have incorporated “sick call” cards with multiple carbon copies that husbandry staff can place in cage card holders to identify animals requiring veterinary examination or animals that are currently under treatment. With multiple copies, one copy is placed in the cage card holder, one copy is sent to the principal investigator, and another copy is sent to the veterinary staff. These sick call cards include room, cage, animal identification, nature of the problem, space for diagnosis and treatment, dates for reporting, and examination and resolution. Veterinary copies may be filed in the appropriate animal or colony record.

For computerized systems, it is imperative that backup data recovery systems are in place. For institutions that must comply with Good Laboratory Practices (GLP) regulations, additional record-keeping requirements and computer/data security systems may need to be in place as part of software validation requirements (CFR 21, 2003).

The type of colony management software chosen will be based on the needs of the individual institution; the types and numbers of species, type of research involved, regulatory requirements such as GLP, etc. For small organizations with limited numbers of animals, spreadsheets may prove adequate. The upfront costs are low and little training is required to implement a spreadsheet system. However, incorporation of accounting, reports, and statistics into this system requires significant setup time. Data backup requires manual intervention, and accessibility to the information may be slow due to the need for multiple spreadsheets to accommodate broad-based colony information (Duperon, 2010).

Relational databases are more effective methods of storing animal colony data. Whereas spreadsheets are excellent for time-series data (i.e. each row contains a date and then one or more values) and experimental results (treatment data versus outcome), it is difficult to link these different types of information into an easily accessible, interrelated knowledge base. Relational databases are the most effective solution for storing animal colony data, although their use is still inconsistent

through the industry. The key to relational databases is the ability to link together multiple tables or spreadsheets with each other (Tyeus, 2006).

Colony management software systems may be (1) developed in-house, (2) professional client/server database systems, or (3) professional web-based database systems. Solutions developed in-house provide for better backup and data acquisition for reporting, statistics and accounting, and multiple people can usually access those data at one time. However, such systems often have mushrooming expenses, as the systems are often modified to meet additional needs or resolve problems. Other limitations of these systems include the length of time to learn to use these systems, they may not be ACID (Atomicity, Consistency, Isolation, Durability)-compliant with other commonly used databases (Oracle, MySQL, MSSQL, PostgreSQL), and frequently are under-designed leading to system crashes and data corruption and/or loss.

Professional client/server database systems and web-based database systems involve the installation of software on one machine which acts as a server for satellite stations throughout the facility. Advantages of this system include centralization of data; automated backups; capability for simultaneous access by multiple users; and, if using an ACID-compliant database, corruption of the database caused by crash of multi-user accessing is avoided. The company providing the database service typically maintains the software and thus can “fix bugs”, provide support, and install new features. Disadvantages include expense and requiring multiple installations of software throughout the facility, significant training time, and the difficulty to change to a new system if a “transient vendor” goes out of business (Duperon, 2010).

Professional web-based database systems involve the installation of a server which is then accessed via the web on any machine with a browser. The advantages of these systems include: features similar to client/server database systems (i.e., centralization with data matching that in the facility); automated backups; multi-user access; data security with ACID-compliant, reporting ability; and readily available professional support and maintenance. Additionally, there is no client software to install. Crashes generally do not involve the entire application. Disadvantages include expense, training time, and difficulty in transferring to another system.

Benefits of database systems includes real-time census capability, easier budgeting calculations, work tracking, breeding management, and automatic reporting. Pitfalls include the potential for poor implementation and hidden costs. For GLP studies due consideration must be given for how “original data” (handwritten anesthesia sheets, radiographs, and/or lab work that is not digitized) are captured into the computerized data system.

INTRODUCTION

Extensive use of the guinea pig in a variety of experimental procedures ranging from inhalation studies to hearing research has given rise to common biotechnology and the introduction of specialized experimental techniques. All surgical techniques described in this chapter should be performed using aseptic technique, and with the administration of appropriate anesthesia and analgesia.

HANDLING AND RESTRAINT

The handling and restraint of guinea pigs has been previously discussed (Donnelly and Brown, 2004; Terril

and Clemons, 1998). Guinea pigs are easily handled and are docile animals; and they should be approached slowly as they are easily startled and will stampede when being caught. Guinea pigs can squeal and struggle if not handled gently. Most simple procedures can be performed on guinea pigs under manual restraint and chemical restraint is rarely required. When holding the guinea pig, use both hands to grasp it around the chest with one hand placed beneath the thorax and abdomen to provide support while holding (Figure 22.1). Use care not to squeeze too firmly or for too long. For a large guinea pig or pregnant sow, the rear quarters should be supported with one hand while being held to prevent injury. The animal can be held firmly against the body or with the head held in the crook of the elbow for minor procedures. Another restraint

FIGURE 22.1 Manual restraint of the guinea pig with one hand grasping the chest and the other hand supporting the rear legs.

technique involves holding up the anterior portion of the animal while its rear legs remain on the surface supporting the animal, or by holding the chest and forelegs in one hand and the pelvis and hind legs in the other hand. With repeated handling, guinea pigs become accustomed to being held and struggle less.

SAMPLING TECHNIQUES

Blood Sampling

Obtaining blood samples from guinea pigs is difficult. The site for percutaneous blood sampling should be chosen based on the size of the guinea pig, the volume of blood needed, and the expertise of the person performing the phlebotomy. The volume of blood collected depends upon the size of the guinea pig and the time interval between collections. As a general rule, 10% of the circulating blood volume can be collected every 3–4 weeks. For daily sampling, no more than 1% of blood volume should be collected without adverse effects to

FIGURE 22.2 Blood collection from the ear vein. The needle is used to nick the vessel for collection of small amounts of blood.

the animal. The average blood volume of the guinea pig is 75 ml/kg, therefore 7.5 ml/kg body weight could be removed every 3–4 weeks (Terril and Clemons, 1998).

Methods employed to obtain small-volume samples of blood include cutting the nail bed (Hochman and Blanchard, 1983), puncture of the lateral saphenous vein (Hem et al., 1998), the digital veins (Keino et al., 2002), ear vein (Bullock, 1983) (Figure 22.2), the lateral metatarsal vein (Dolence and Jones, 1975), and puncture of the orbital sinus (Sorg and Buckner, 1964). The size of the needle tip or lancet used for nicking the blood vessel should be the smallest possible to enable rapid blood flow. Pressure should be applied after collection to stop the bleeding. For collection of larger volumes of blood, cardiac puncture has been used; however, this technique is always traumatic, must be performed under anesthesia, and is potentially fatal. Indwelling cannula placement in the femoral vein or external jugular vein requires surgical cutdown (Shrader and Everson, 1968), while cannulation of the lateral saphenous vein can be performed percutaneously (Nau and Schunck, 1993). Venipuncture of the cranial vena cava (Reuter, 1987), femoral vein or artery (Palumbo et al., 1975), and medial saphenous vein (Figure 22.3) (Carraway and Gray, 1989) has yielded up to 3 ml per sample. The gauge of needle used for venipuncture should be slightly smaller than the size of the vessel. Stone et al. (1961) reported that carbon dioxide anesthesia increased the yields of blood and serum particularly when exanguinating the animal.

Cerebrospinal Fluid Collection

Up to 300 µl of cerebrospinal fluid (CSF) may be collected by tapping the cisterna magna through the atlanto-occipital space in anesthetized guinea pigs

FIGURE 22.3 Venipuncture of the saphenous vein. This location can also be used for intravenous injections.

using 23-gauge hypodermic needles (Reiber and Schunck, 1983; Suckling and Reiber, 1984). CSF samples (100 μ l) were obtained two times per week from anesthetized guinea pigs by inserting a cannula attached to a 1 ml syringe between the spinous process of the first and second cervical vertebrae (Fassbender et al., 2001). By restraining the head of anesthetized animals using a stereotaxic instrument with ear bars, the tip of the puncture needle can be maintained stably within the cisterna magna for 6–12 hours. This method allows for repeated collections with a total volume as large as 1 ml of CSF (Liu and Guo, 1991). Chronic CSF collection techniques involve surgically fixing a guide cannula secured to a silicone rubber disc to the atlanto-occipital membrane, allowing for daily CSF samples to be collected from conscious, unrestrained guinea pigs (Jones and Robinson, 1981).

Milk Collection

Milk can be collected from guinea pigs by hand milking or by a mechanical milking apparatus. A miniature milking machine using a mechanical vacuum pump has been described for collecting between 1.0–9.0 ml from a lactating sow in one milking (Gupta et al., 1970; Nelson et al., 1951). To eliminate the need for a mechanical pump system, decreasing noise and allowing for collection in animal holding rooms, the operator can serve as the vacuum source using a mouth piece (Anderson, 1990; McKenzie and Anderson, 1979), however the practice of mouth pipetting is discouraged. For satisfactory milking, the level of vacuum should be about 10 inches of mercury and the vacuum pulsations at about 25 per minute (Nelson et al., 1951). It is also possible to

aspirate mammary gland ducts with a 30-gauge needle, if required for experimental procedures (Nonnecke and Targowski, 1984).

Semen Collection

Semen can be collected by singly housing adult male guinea pigs in open-bottom cages and observing service pans for spontaneous ejaculate. One study showed the average number of spontaneous ejaculates ranged from 1–5 over a 14-day period (Shepherd and Martan, 1983). Guinea pig semen can be collected by electroejaculation using an electrode in the lumbar area and an anal electrode. The mean ejaculate volume using this technique was 0.5 ml (Freund, 1958). This technique was detailed further in a report of the characteristics of guinea pig semen (Freund, 1969).

Urine

Urine collection can be performed using a number of techniques (Terril and Clemons, 1998). The urinary bladder is palpated in the caudal abdominal area and when gentle pressure is applied, a stream of urine should be produced. Care should be taken to not apply too much pressure and rupture the bladder. Cystocentesis may be used to collect uncontaminated urine using a needle inserted into the urinary bladder through the abdominal wall. Cystocentesis should be performed following a surgical preparation of the caudal abdomen. If bacterial contamination of the urine is acceptable, urine may be collected from the cage floor or in the pan beneath a suspended cage or using a metabolism cage which can separate urine from feces. A surgical method of complete and continuous urine collection from conscious unrestrained animals via an exteriorized catheter and tether has been described (Mandavilli et al., 1991).

Bile, Gastric Juice, and Feces

The portal vein can be cannulated for blood collection or compound administration by advancing a catheter from a mesenteric tributary vein. Bile can be collected from a catheter inserted in the gall bladder to avoid the difficulty of cannulating the friable bile duct. Both cannulae can be exteriorized via stab incisions in the flank for intermittent sampling (Talbot and Hynd, 1985).

Gastric juice can be collected from conscious restrained guinea pigs. The animals are fasted and housed on wire-bottom cages to prevent consumption of bedding and feces. The guinea pigs are restrained in a vertical position with a gauze loop around the upper incisors maintaining its head in extreme dorsoflexion. A 5- or 6-F infant feeding tube is inserted down the throat, being careful not to

deviate to either side of the buccal cavity. The tube is slid directly down the esophagus, and gastric juice is withdrawn, using a 5-ml syringe attached to the feeding tube. Once the desired volume of juice is collected, the tube is pinched off as it is withdrawn from the esophagus, to prevent backflow of gastric juice (Shomer et al., 1999).

Feces can be easily collected from the floor of the guinea pig's cage. Bauer et al. (2008) measured fecal steroids using enzyme immunoassays to eliminate the profound effect of restraint and the blood sampling procedure on serum cortisol levels. This non-invasive method was validated for the assessment of fecal cortisol, progesterone, and estrogen metabolites, however, fecal and plasma testosterone levels did not correlate significantly.

COMPOUND ADMINISTRATION

Liquids or solids, particularly materials which create problems of contamination such as radioisotopes or microorganisms, may be administered in a gelatin capsule with a small version of a large animal balling gun (Nelson and Hoar, 1969) or through an administration tube inserted into the stomach via the oropharynx (De Brant and Remon, 1991). A simple mouth gag may be used to enable intragastric intubation of the guinea pig by one person without the use of sedation or anesthesia (Smith et al., 1993). Administering compounds by adding them to the drinking water does not provide precise dosing, and due to the guinea pig's aversion to novel tastes, is usually not effective. Solutions or suspensions may be introduced into the bronchopulmonary circulation by occluding the esophagus with a special probe and allowing normal respiratory movements to aspirate liquids placed in the animal's oral pharynx (Vlad et al., 1970). The most common procedure for the introduction of materials in various forms is by injection, either subcutaneous (Figure 22.4), intramuscular (Figure 22.5), intraperitoneal, intrathoracic, intracardiac, or intravenous. Intravenous injections have been administered to guinea pigs by way of the dorsal metatarsal vein (Nobunaga et al., 1966), lateral metatarsal vein (Dolence and Jones, 1975; Grice, 1964), dorsolateral vein of the penis (Grice, 1964; Karlson, 1959), superficial veins of the ventral abdominal wall (Johnson, 1950), the marginal ear veins (Grice, 1964; Karlson and Feldman, 1953; Markham and Kent, 1951), sublingual vein (Waynforth and Parkin, 1969), medial saphenous vein (Hochman and Blanchard, 1983), or the cranial vena cava (Reuter, 1987). Choice of injection site will depend on the size of the guinea pig, amount of compound administered, and the experience and preference of the handler. An indwelling cannula was used in guinea pigs for both repeated injections and blood sampling (Nau and Schunck, 1993; Shrader and

FIGURE 22.4 Technique for subcutaneous injection in the guinea pig. Creating a skin fold aids insertion of the needle under the skin.

FIGURE 22.5 Technique for intramuscular injection into the gluteal muscles of the guinea pig. The volume of injection should be limited to 0.3ml in adults and care should be taken to avoid the sciatic nerve.

Everson, 1968). Implantable osmotic pumps can be used for continuous administration of compounds into the subcutaneous, peritoneal, or vascular spaces.

SPECIALIZED RESEARCH TECHNIQUES

Endotracheal Intubation

Endotracheal intubation of the guinea pig is difficult due to the narrow oral cavity and the anatomy of the larynx and upper airway. A modified commercially available laryngoscope blade (Kujime and Natelson, 1981; Turner et al., 1992) or pediatric blade using a catheter can be used for direct laryngeal intubation

(Blouin and Cormier, 1987; Tremblay et al., 1990). Kramer et al. (1998) utilized a specially constructed restraint device which assisted in the positioning of the guinea pig for intubation using an endotracheal tube with an outside diameter of 2 mm.

Blouin and Cormier (1987) described a technique for endotracheal intubation without the assistance of another person. The anesthetized guinea pig was placed in a supine position on a surgery board with the upper jaw attached to the surface of the board by an elastic band over the incisor teeth. By proper positioning, the operator could look directly into the opening of the trachea. A small laryngoscope with a modified Wisconsin pediatric blade #0 was used. The blade was narrowed laterally by filing both sides near its extremity, permitting the blade to advance deeper into the laryngeal region without causing trauma while still retaining the tongue and soft palate up and out of the visual path. A cotton tip applicator was used to clean secretions as required. A tracheal cannula was made from an intravenous catheter (14 gauge, 60 mm). The catheter stylet was filed down to remove the sharpened point. Under direct vision, the sterile catheter, with the modified stylet, was advanced into the epiglottis which was lifted with the tip of the catheter. The catheter was then lifted slightly and pushed gently forward into the curved trachea. The laryngoscope and stylet were withdrawn. Formation of water vapor on a clean mirror, with each breath of the animal, confirmed that the endotracheal tube was in place.

Electrophysiology

The guinea pig is preferred by many investigators for study of pre- and neonatal cardiac or cortical activities under various maternal conditions. The technique of Flexner et al. (1950) for determining fetal EEG involved delivery by cesarian section into a bath of warm Ringer's solution while maintaining an intact umbilical circulation. Following craniotomy, electrodes were placed on the cerebral cortex. This procedure was modified by pushing hook electrodes directly through the fetal skull where they would rest on or perhaps 1–2 mm into the fetal cortex (Bergstrom et al., 1961). The technique was further modified in order to prevent loss of amniotic fluid and avoid the trauma of hysterotomy by compressing the fetal vertex against the uterine wall and then pushing the needle electrodes through the myometrium, scalp, and skull to reach the cerebral cortex. A third electrode was sutured to the myometrium over the fetal thorax to record the fetal ECG (Rosen and McLaughlin, 1966a, 1966b; Singer et al., 1973). A chronic model was developed to measure long-term uterine activity for up to 4 weeks in pregnant guinea pigs using a uterine EMG array, intrauterine and intra-abdominal

balloon catheters and vascular catheters (Schellenberg et al., 1995).

Electrical activity has been recorded from the brain in adult guinea pigs by implanting electrodes on the surface of the skull, the epidural tissue, or by stereotactically implanting bipolar electrodes into specific regions of the brain. These techniques have been used for repeated EEG recording for studying central control of heart rate (Pedemonte et al., 2003), sleep–wake cycles (Kato et al., 2007), treatments for epilepsy (Dorandeu et al., 2005), and auditory and visual evoked potentials in response to noise and light (Goksoy et al., 2005) in the guinea pig.

EMG activity was measured to determine musculophysiologic activity. The cutaneous trunci muscle reflex, initiated by brief tactile or electrical stimulation of the skin was shown to be useful as a measure of spinal tract function following spinal cord injury (Blight et al., 1990). Apomorphine-induced jaw movement in ketamine-anesthetized guinea pigs was shown to be similar to lapping jaw movements observed during drinking in awake animals by recording electrical activity of the left anterior digastric and the genioglossus muscles (Gerstner and Goldberg, 1991). To study how work load on a treadmill affects the overall muscle activity and assists in training induced muscle biochemical alterations, EMG fine wire electrodes were chronically implanted in fast-twitch and slow-twitch hind limb muscles (Gardiner et al., 1982). The bladder cooling reflex in response to infusions of cold saline and its effect on external urethral sphincter activity in both the anesthetized and awake guinea pig was studied using electromyographic recordings (Jiang et al., 2008). Avan et al. (1992) studied the protective role of the middle ear muscle in response to loud sounds and active self-vocalization using implanted EMG electrodes.

Cardiovascular Studies

The early drug development process has put great emphasis on the potential of the effect of the compound on QT interval prolongation and other cardiac abnormalities. QT and RR intervals were measured in 6-week and 23-month female conscious guinea pigs to study age-related characteristics on cardiac repolarization (Shiotani et al., 2008). The electrical activity of the hearts of newborn guinea pigs was validated using two different lead systems (Schwartz and Thoss, 1981). Cardiovascular parameters were measured in guinea pigs anesthetized with urethane (1.5 g/kg, i.p.). A polyethylene catheter was inserted into the carotid artery and attached to a pressure transducer. A Millar microtip catheter pressure transducer was inserted into the contralateral carotid artery and advanced to the left ventricle, allowing contractile properties to be measured,

and ECG was recorded by inserting needle electrodes according to standard limb leads. These animals were found to be good models for the hemodynamic effects of repeated intravenous administrations of compounds for safety pharmacology studies, allowing for the measurement of heart rate, blood pressure, left ventricular pressure and ECG (Hauser et al., 2005).

Telemetry has been used to collect cardiovascular measurements from conscious freely moving guinea pigs. Using sterile technique, an abdominal incision was made and a blood pressure sensor was placed in the descending aorta below the renal arteries, pointing upstream. Bipolar electrodes were implanted in the right thoracic ventral serratus muscle and external oblique abdominal muscle to measure ECG. The telemetry transmitter was implanted in the peritoneal cavity and sutured to the abdominal wall. ECG intervals and arterial blood pressure were monitored in these animals for up to 8 months (Hess et al., 2007; Stemkens-Sevens et al., 2009). Implantation of the telemetry system was also accomplished without opening the abdominal cavity. Telemetry transducers were implanted subcutaneously into the back of the neck with the leads for detecting the lead II ECG fixed on the right shoulder and left lower thorax, and a blood pressure catheter introduced into the carotid artery. This subcutaneous approach allowed for longitudinal measurement of cardiac parameters for over 28 days (Provan et al., 2005). It has been difficult to instrument small rodents for multi-lead ECG recording to fully assess cardiac risks of new pharmaceutical agents. By comparing cardiac electrical activity to the magnetic field generated by cardiac activation currents measured by contactless magnetocardiography, Brisinda et al. (2007), showed that multisite recordings could be used for surface cardiac mapping and replace the need for surgical implantation of telemetric devices for long-term longitudinal studies.

A method for inducing prolonged (30s or more) cardiac tachyarrhythmias was developed after rapidly pacing the heart prior to a single 200-V transthoracic stimulus, establishing a small animal model for evaluating short-term pharmacologic effects of electrical therapies (Malkin et al., 1998). Ventricular arrhythmias were also induced in halothane-anesthetized guinea pigs receiving a continuous infusion of adrenaline (epinephrine) (12.5 µg/kg/min). Arrhythmogenicity was significantly increased with vagotomy and higher concentrations of halothane (Noda and Hashimoto, 2004).

A reproducible technique for creating congestive heart failure by aortic banding was detailed by Ling and Bold (1976). Briefly, guinea pigs were anesthetized and ventilated with a small animal respirator. An incision was made in the skin and a thoracotomy was performed in the left third intracostal space. The lung was pushed dorsally to expose the left ventricle and atrium

and the pericardium was opened. Blunt dissection separated the tissue connecting the ascending aorta and the pulmonary trunk. An aortic constrictor (clip bored with a 1.99-mm diameter drill bit) was placed around the ascending aorta, the muscles and skin were closed, and the animal was allowed to recover. This technique resulted in a 74% survival rate, and animals euthanized at 10 days post-surgery showed marked passive congestion of liver, spleen, kidney, and lung, as well as severe centrilobular fatty change of the liver. This technique was used by Kingsbury et al. (1999) to study chronic left ventricular outflow obstruction. After an average of 149 days of banding, there was marked evidence of cardiac hypertrophy (72% increase in heart to body weight ratio compared to sham operated controls) and heart failure.

Aortic outflow was measured using a 2.5-mm electromagnetic flow probe placed on the ascending aorta following a midline thoracotomy. Aortic flow was also measured using thermodilution cardiac output determined by bolus injection of 0.4 ml of physiologic saline solution (25°C) into the right atrium. The temperature change was registered by a thermistor probe in the superficial saphenous artery and cardiac output was calculated with a dedicated thermodilution cardiac output computer. After comparing the thermodilution method to the instantaneous aortic flow, it was determined to be a useful, reliable, and less invasive means of determining cardiac output in the guinea pig (Hart et al., 1987).

Watanabe et al. (2008) showed that the lower lip of the guinea pig contains parasympathetic fibers originating from the otic parasympathetic ganglion which evoke decreases in lower lip blood flow and systemic arterial blood pressure when electrically stimulated by a bipolar silver electrode.

Reproductive Studies

Guinea pigs have not typically been used for reproductive toxicology studies. Compared to other rodents, the estrous cycle is approximately 18 days long, the vagina is closed by a membrane making evaluation of vaginal cytology difficult to impossible during much of the cycle, and the 64-day gestation period is relatively long. Other disadvantages compared to the traditional rodent species are the variability in pregnancy rates, small and variable litter size, relative maturity at birth, and difficulty in repeat dosing of pregnant females (Rocca and Wehner, 2009).

To determine the time of conception for fertility studies and for obtaining cohorts of pregnant females for developmental studies, guinea pigs were mated on the females' post-partum estrus. Pregnant females were co-housed with males starting approximately 4 weeks prior to expected parturition to decrease female

mortality rates associated with pairing during later gestation (Rocca and Wehner, 2009).

Several techniques have been used to determine the timing of the estrous cycle for timed pregnancy and for early determination of pregnancy. Vaginal smears were taken when the vagina was perforate to time the estrous cycle, with the first day of the cycle taken as the day preceding the post-ovulatory influx of leukocytes when cornification was at a maximum (Poyser, 1987). Electrical impedance of the vaginal mucous membrane was measured in the guinea pig using a probe constructed from two silver ring electrodes set 3 mm apart and firmly attached to a plastic rod, diameter 4–5 mm. The probe was introduced into the vagina and electrical impedance was measured by a transistor indicator with a 1-kHz oscillator (Bartos, 1977). A cyclic increase was found during the proestrus phase, more than at other times of the cycle. The disappearance of this cyclic affect indicated early pregnancy (Bartos and Sedlacek, 1977). For early pregnancy studies, the presence or absence of implantation sites in the uterus could be observed at 8 days of pregnancy (Wisel et al., 1994).

Prenatal growth has been studied in guinea pigs. Several methods have been used to influence fetal growth (Jones et al., 1990). Guinea pigs at gestational days 41–42 were injected four times daily over 4 days with 10 ml of 50% glucose intraperitoneally resulting in increased fetal weight. The withholding of food from guinea pigs at days 43–44 of pregnancy for 48 hours led to a sharp fall in maternal and fetal plasma insulin and thyroid hormone concentration, and elevations in plasma glucagon and cortisol, and also depressed fetal weight by about 10%. A unilateral ligation of the uterine artery at day 30 of gestation caused growth restriction of >50% in fetuses adjacent to the arterial tie when measured 10–15 days after the ligation. This effect of growth was particularly apparent in the visceral tissues and liver, whereas the brain was relatively spared. A modification of the uterine artery ligation technique performed between days 30–35 of gestation, resulted in a similar reduction in fetal growth, but a higher fetal survival rate. Instead of ligating the main uterine artery which supplies the blood to one horn of the uterus, approximately half (typically two of four) of the branches leading from the uterine artery directly to one placenta were ablated using a diathermy unit. The treated fetuses showed a 70% reduction in mean body weight at term and had a 245% increase from normal mean values for the brain/liver weight ratios showing the “brain sparing effect” from the redistribution of blood flow to maintain development of the brain (Turner and Trudinger, 2009). The uterine artery ligation method was used to study uterine and placental blood flow by injecting 15- μ m microspheres labeled with ^{46}Sc and counting radioactivity in dissected tissues

(Jones and Parer, 1983). Jansson (1991) showed that three consecutive radiolabeled-microsphere injections at 10-minute intervals in guinea pigs at 47–52 days gestation had minimal effect on regional blood flows and central hemodynamics in anesthetized and awake animals, and allowed for multiple measurements of placental blood flows.

The signs of estrus, including lordosis, in response to manual touch of the back of the guinea pig, and the opening of the vaginal orifice have been described (Young et al., 1937). The effects on spontaneous ovulation associated with the unilateral or bilateral sectioning of the superior ovarian nerves (SON) were analyzed in guinea pigs at different time intervals of the estrous cycle with day 1 defined as the day when the animal presents complete loss of the vaginal membrane. Sectioning of the right, left or both SONs on day 5 (early luteal phase) resulted in a significant increase in the number of fresh corpora lutea, however, ovulation rates were not affected when unilateral or bilateral sectioning was performed during the late luteal phase (day 12) suggesting that the SON modulates ovulation and the degree of modulation varies along the estrous cycle (Luna et al., 2003). Lordosis has been used to study the noradrenergic system and its effects on this behavior (Thornton et al., 1988) and to investigate a non-luteal source of progesterone secretion in guinea pigs (Feder and Goy, 1985).

Surgical sterilization of guinea pigs has been described by Jenkins (2000). Ovariohysterectomy of guinea pigs is performed aseptically through a midline abdominal incision using care when entering the abdomen to avoid the large thin-walled cecum and bladder. The uterus is located and followed to the oviduct and infundibulum. The blood vessels to the ovary are identified and ligated, taking care not to leave a portion of the oviduct. The uterus and uterine vessels are ligated just cranial to the cervix. The mesometrium of hystricomorph rodents can contain an abundance of fat, so care must be taken when locating and ligating the ovarian and uterine vessels. Abdominal closure is routine. To perform an ovariectomy, the ovaries are accessed through individual incisions in the skin caudal to the kidney continued into the retroperitoneal space. Light pressure placed on the abdomen causes the ovary and oviduct to enter the incision. The ovary is exteriorized, ligated with suture at its base, and resected. The ligated vascular pedicle is returned to the abdomen and the dorsal abdominal wall and skin are closed.

Orchiectomy of the male guinea pig is done aseptically by making a 1-cm incision through the skin and vaginal tunic ventrally on both sides of the scrotum. The testis is removed from the tunic and retracted caudally to expose a section of the vas deferens and the vascular structures of the spermatic cord, which are ligated. The duct and vessels are transected distally to the

ligature and the stump is returned to the inguinal canal. Because of the large inguinal opening, the inguinal canal is closed by suturing the tunic and the skin is closed (Jenkins, 2000).

Hearing Studies

Preyer described for the first time in 1881 a pinna reflex in guinea pigs in response to sound, reporting the reflex movements to tones from 1000–41000 cycles per second (Horton, 1933; Preyer, 1890). Using tone-shock conditioning to specific tones, it was shown that guinea pigs could respond to specific tones rather than just noise (Upton, 1929) and that the auditory sensitivity ranged between 64 and 8192 cycles per second, similar to the perception of sound by humans (Horton, 1933). Early studies using recording electrodes in the cochlea showed that tonal interference has its locus in the hair cells of the organ of Corti (Wever and Lawrence, 1941), described the threshold of auditory action potentials for low tones in the guinea pig (Davis et al., 1950), and developed techniques for recording single-fiber responses from the cochlear nerve of guinea pigs from acoustical stimulation (Tasaki, 1954).

Asarch et al. (1975) presented an excellent description of the anatomy of the guinea pig ear and detailed two surgical approaches to the guinea pig temporal bone and to the inner ear. The superior approach, made by an incision at the superior anterior attachment of the auricle and removing the lateral wall of the epitympanic space, exposed the round window, epitympanum, lateral canal, and external auditory canal, leaving the tympanic membrane intact. The inferior approach through the neck exposes the cochlea, Eustachian canal, horizontal and posterior semicircular canals, tympanic membrane, and ossicles. A description of the surgical approach to the endolymphatic sac and the cochlear aqueduct surgical closure of the endolymphatic sac and duct is described for creation of a model of endolymphatic hydrops in the guinea pig (Andrews and Bohmer, 1989). Efferent cochlear innervation, through the olivo-cochlear bundle, has been postulated to exert a protective mechanism on the inner ear. A technique for vestibular neurectomy of both ipsi- and contralateral cochlear efferent fibers in the guinea pig involving a suboccipital route to the posteromedial aspect of the temporal bone allowed for minimal removal and retraction of cerebellar tissue (Barbara et al., 1999).

The guinea pig has been used to study the progression and treatment of deafness by employing aminoglycoside antibiotics to eliminate hair-cell function in the organ of Corti. Bilateral destruction of the organ of Corti was produced by administering 14 subcutaneous injections of 450mg/kg of amikacin with one daily injection 5 days a week (Cazals et al., 1983). A single

subcutaneous dose of kanamycin (400mg/kg) followed in 2 hours by an intravenous injection of the potent diuretic, ethacrynic acid (40mg/kg), caused the permanent loss of hearing and death of cochlear hair cells in guinea pigs for both acute and chronic studies (Nourski et al., 2004; West et al., 1973). Deafness was also induced by administering the loop diuretic, furosemide (100mg/kg) intravenously, followed by kanamycin (400 or 500mg/kg) subcutaneously. Loop diuretics increase the concentration of the aminoglycoside in the scala media causing the loss of the mitochondrial membrane which results in apoptosis of the hair cells (Hildebrand et al., 2005). Conlon and Smith (1998) showed that the co-administration of gentamycin (100mg/kg/day for 30 days) and iron (2mg/kg/day or 6mg/kg/day for 30 days) resulted in a more rapid and profound elevation in compound action potential thresholds compared with animals receiving gentamycin alone. When neomycin is administered systemically at levels high enough to induce ototoxicity, nephrotoxicity also results. To avoid the systemic results and to allow for a contralateral control ear, neomycin was applied by surgical intracochlear infusion. Using a post-auricular approach and exposing the temporal bone in anesthetized guinea pigs, two holes were drilled into the bullae. A 26-gauge needle was used to dispense approximately 0.1ml of 100mg neomycin/ml normal saline solution into one of the holes while the second served as a vent, then the incision was closed. This technique produced significant loss of spiral ganglion cells along the cochlear spiral (Zappia and Altschuler, 1989). Dodson et al. (1994) used this method of cochlear perfusion of neomycin in guinea pigs at ages 1 week and 6 weeks to study the effects of postnatally acquired sensorineural deafness on the maturation of the auditory pathway. The mechanisms for noise-, chemical-, and drug-induced ototoxicity in developing guinea pigs and other mammals are reviewed by Henley and Rybak (1995).

Once deafness is established, therapeutic treatment success can be studied by recording action potentials in the auditory nerve. These potentials can be simulated by both bipolar and monopolar electrical stimulation (Miller et al., 1998) or 4-millisecond tone pips at varying frequencies (Conlon and Smith, 1998). Anatomical changes to the hair cells can be assessed by histological examination of the tissue following fixation with paraformaldehyde (Zappia and Altschuler, 1989). The use of intravital confocal laser scanning microscopy allows the visualization of individual cells inside intact tissue with preserved blood and nerve supply and for the investigation of structural changes caused by toxicity or trauma. A ventral surgical approach to expose the middle ear cavity allowed optical access to the cochlea. Fluorescent vital dyes (calcein AM and RH 795) were administered directly to the cochlea and stained the

cytoplasm and cell membranes of sensory inner and outer hair cells. After exposing the tympanic membrane to 130 dB of sound pressure for 10 minutes, there was a distinct reorganization of the cytoarchitecture and a change in the shape of the visible outer hair cells (Tomo et al., 2007).

The low regenerative capacity of the hair cells of the mammalian inner ear is a major obstacle for functional recovery following sensorineural hearing loss. Mouse embryonic stem cells labeled with green fluorescent protein were transplanted to the aminoglycoside-damaged organ of Corti of guinea pigs. These cells were injected into the scala media cavity of the inner ear. Nine weeks after the xenotransplant, the cells were shown to localize close to the damaged organ of Corti structure in the scala media, however, there was no evidence of integration (Hildebrand et al., 2005). An adenoviral vector expressing the bacterial *lacZ* reporter gene was injected in the endolymphatic sac of guinea pigs. A large number of transduced cells were found in the endolymphatic sac and duct, the vestibular end organ, the cochlea, and the stapes 4 days after the injection. Gene transfer could be used to substitute specific defective genes for treating hereditary deafness or allow for long-term overexpression of protective tropic factors to protect inner ear cells from death due to ototoxicity (Yamasoba et al., 1999). In order to determine the best technique for delivery of cells or gene therapy to the inner ear cells, Backhouse et al. (2008) assessed three surgical procedures for cell delivery into the cochlea; a cochleostomy into the scala tympani; direct access to Rosenthal's canal via localized fracture of the osseous spiral lamina; and direct access to the auditory nerve via a translabyrinthine surgical approach. Using microspheres to simulate placement, delivery, and dispersion of cells, they found that the technique giving direct access to Rosenthal's canal to offer the most promising approach.

Another approach to improve hearing in patients with residual acoustical hearing is the use of cochlear implants. The guinea pig ear can be utilized to test new implant devices or develop techniques for surgical implantation. To install the implant, a dorsolateral, posterior auricular approach is used to gain access to the bulla and the cochlea. A cochleostomy is made with a 0.7-mm diameter drill over the basal turn at a low speed. The implant electrode is inserted with atraumatic technique to the first point of resistance and the cochleostomy is plugged with fascia to prevent perilymph leakage. The extra-cochlear portion of the electrode is secured to muscle with sutures to prevent extrusion (Chang et al., 2009). Preservation of hearing in the implanted ear is a goal of cochlear implant surgery. Utilizing an application of dexamethasone to the round window at the time of the implant protected the residual hearing of guinea pigs with cochlear implants (Chang et al., 2009).

Respiratory Studies

Guinea pigs are one of the oldest models of allergic airway response in asthma, with studies conducted for over 100 years (Auer and Lewis, 1910; Gay et al., 1909; Zosky and Sly, 2007). Smith and Broadley (2007) determined an optimal sensitization protocol for creating a guinea pig with an early asthmatic response followed by a late-phase bronchoconstrictor response, airway hyperresponsiveness to inhaled histamine and methacholine and inflammatory cell infiltration in the airways, hallmarks of human asthma. The guinea pigs were sensitized by intraperitoneal injection of ovalbumin (OA, 100 µg per animal) and aluminum hydroxide (100 mg) in 1 ml of normal saline, in divided doses bilaterally, with a booster injection of the same solution on day 5. After 14–21 days from the first injection, the animals were placed in a stainless steel chamber and exposed to a nebulized solution of OA (10 µg in saline) for 1 hour with animals showing bronchoconstriction at the time of exposure. For collection of pulmonary inflammatory cell infiltrates, bronchoalveolar lavage can be performed after euthanasia by inserting an intravenous catheter into the trachea, instilling saline into the lung, and collecting the fluid (Mukaiyama et al., 2004; Smith and Broadley, 2007).

Normal average values for tidal volume (1.68 ml), respiratory rate (84/minute), minute volume (139 ml), resistance (0.73 cmH₂O/ml/second), and compliance (0.20 ml/cmH₂O) were reported by Amdur and Mead (1958) following their development of techniques for measurement of intrapleural pressure and ventilatory activity. Intrapleural pressures were measured by a fluid-filled tube inserted into the chest cavity and connected to pressure recorders, while ventilatory measurements were determined by a body plethysmography. The technique of plethysmography improved with the use of computer systems to extract the data and by recording from animals without surgical preparation (Alarie et al., 1970; Douglas et al., 1972).

Various plethysmograph chambers and exposure chambers have been designed by research laboratories to measure airway conductance in guinea pigs for studying asthma and other respiratory diseases. Several plethysmography units were designed with two chambers, one encasing the head/neck cavity and the other containing the thoracic/abdominal cavity with a rubber neck divider ensuring a tight seal around each chamber. These systems are useful in exposing the guinea pig to the aerosol, while measuring respiratory-related changes in pressure within the chamber containing the body (Ball et al., 1991; Danko and Chapman, 1988). A single-chamber plethysmograph chamber was designed which allowed for repeated and long-term evaluation of pulmonary performance since the animal

was not restrained by a neck divider used as a seal between the two-chamber units (Wong and Alarie, 1982). Chong et al. (1998) compared the measurement of histamine-induced bronchoconstriction using a double-chamber plethysmograph to that using a single-chamber body box plethysmograph with a central inlet for aerosol administration. They found that the single-chambered plethysmograph correlated well with the double-chambered unit in measuring pulmonary resistance, and the single chamber eliminated stress from restraint, the potential for non-physiological airway resistance due to the neck collar, and allowed for long-term studies since the animal was unrestrained and able to eat and drink during the study.

To test the pulmonary or toxic effect of various compounds on the lungs, several systems have been designed for aerosol exposure of substances to guinea pigs, both while restrained by a neck collar (Snyder et al., 1988), unrestrained (Lewis et al., 2007), or while unrestrained in permanent housing units allowing for exposure of up to 60 guinea pigs at one time (Brown and Moss, 1981).

Chambers have been developed for hyperbaric exposure (Ederstrom et al., 1971; Giblin et al., 1995; Rose et al., 1970; Shoshani et al., 1998). In one long-term study, adult guinea pigs were exposed to 2.5 atmospheres absolute (22.3 psig) for 2–2.5 hours three times per week on alternate days for up to 50 weeks with no apparent ill effects and a steady gain in body weight (Giblin et al., 1995). To study the effects of hypoxia, guinea pigs have been exposed to inspired gas containing 100% down to 8% O₂ balanced with N₂. Yilmaz et al. (2005) exposed 4-month-old, awake, spontaneously breathing guinea pigs raised at sea level, intermediate altitude (1250 meters), and high altitude (3800 meters), to 100%, 21%, and 12% inspired O₂.

The effect of hypoxia was studied in the developing fetal guinea pig brain by inducing maternal hypoxia in dams at 50 and 60 days gestation. Dams were placed in a chamber with a probe to monitor oxygen tension and exposed to 7% O₂ for 40 minutes. There was a 50% reduction in Na⁺, K⁺, and ATPase activity in brains of the 60-day (near-term) fetuses compared to the 50-day preterm fetuses, indicating a high degree of susceptibility of the near-term brain cell membrane functions to maternal hypoxia (Mishra and Delivoria-Papadopoulos, 1988).

Musculoskeletal Studies

Spontaneous joint degeneration and osteoarthritis occur in the knee of the Dunkin-Hartley guinea pig and appear to provide an excellent model for the human disease. Changes in the cartilage and responses to therapy can be studied histologically and by scanning-electron

microscopy, but is limited to observing the cartilage at single time points. A cohort of 30 animals between 2 and 9 months were imaged using a 2.35-T Oxford Instrument 31-cm bore magnet. High-quality 2-D MR images of the knee of anesthetized guinea pigs were generated in about 30 min showing the articular cartilage, subchondral bone, trabecular bone, triangular menisci, and other facets of joint anatomy in fine detail and allowed for serial studies demonstrating the progression of arthritis (Watson et al., 1997). The imaging technique was improved using three-dimensional Varian 4.7-T MRI system, and anesthetized animals were imaged for less than 2 hours. High-resolution, high signal-to-noise 3-D images of the animals serially generated at 3, 6, 9 and 12 months of age, showed changes in cartilage integrity, and bone and meniscus changes which correlated to macroscopic and histological changes in the animals at 12 months (Tessier et al., 2003). Using the change in medial tibial plateau cartilage volume as a MRI biomarker of osteoarthritis, 3-D MR images of 9-month-old guinea pigs treated with doxycycline (0.6 or 3.0 mg/kg/day) or vehicle for 66 days were acquired 7 days pre- and 66 days post dosing. The medial tibial plateau cartilage loss for vehicle treated was 20.5%, while animals treated with 0.6 mg/kg/day doxycycline lost 8.6%, and those treated with 3.0 mg/kg/day lost 10%, demonstrating the value of data collected by serial MRI (Bowyer et al., 2009).

Endocrine Studies

A technique for bilateral adrenalectomy of guinea pigs in two stages was presented by Hoar (1966). The presentation includes a review of the literature, photographs of the operation, a list of equipment, and comments on anesthetic techniques and post-operative care. Hopcroft (1966) used a transverse abdominal incision to remove both adrenals in a single-stage operation. This approach allowed better exposure of both adrenals and, with the intestines limited within a plastic bag containing normal saline, it also allowed more space in which to maneuver within the abdominal cavity.

Surgical thyroidectomy in guinea pigs is a relatively simple procedure but care must be taken to avoid injury to the recurrent laryngeal nerves. Young et al. (1952) and Peterson et al. (1952) were among the first to describe a thyroidectomy technique while Fabre and Marescaux (1966, 1969) and Fabre et al. (1970) noted and measured the rapid recovery of thyroid activity due to the development of small areas of remaining thyroid tissue. Kromka and Hoar (1975) drew from these published reports and added some procedural refinements in their presentations of an improved technique.

Skin Studies

Historically, the most commonly used safety tests to detect either skin or systemic immune-based hypersensitivity reactions are those using guinea pigs (Landsteiner and Chase, 1939; Ramsdell, 1928; Weaver et al., 2003). Protocols of predictive contact allergy tests can generally be divided into three main phases: the induction phase, which stimulates the first contact with the chemical and during which antigen is presented to lymphocytes in the skin, the rest period without treatment during which sensitized cells are proliferating in the lymph nodes, and the challenge or provocation phase during which skin reactions are elicited after new exposure to the chemical (Maurer et al., 1994). A number of protocols have been described identifying chemicals that possess the ability to cause significant skin sensitization, but ultimately only the guinea pig maximization test of Magnusson and Kligman (1969) and the closed patch test of Buehler (1965) continue to be accepted by regulatory authorities in Europe and the USA (Basketter and Kimber, 2007; Consumer Product Safety Commission, 2009; Organisation for Economic Co-operation and Development, 1981, 1992). The maximization test is the most frequently used test in Europe while the Buehler test is most common in the USA (Maurer et al., 1994). Several reviews have questioned the ability of these tests to predict human systemic hypersensitivity (Weaver et al., 2003) and to identify skin sensitization hazards (Basketter and Kimber, 2007; Kimber et al., 2001). More recently, the local lymph node assay (LLNA) using mice has been described to evaluate skin sensitization potential to chemicals and has been accepted by validation authorities in the United States and Europe (Gerberick et al., 2007). While the maximization test and the Buehler test continue to be used, the LLNA is now the recommended method for new assessments of relative potency, and/or for the investigation of the influence of vehicle or formulation on skin sensitization potency (Basketter et al., 2008; Kimber et al., 2001). The methods for the Magnusson and Buehler tests are described below.

For the Magnusson maximization test (Magnusson and Kligman, 1969), albino outbred guinea pigs weighing 300–500 grams are used, avoiding older animals since they are less sensitive. Groups of 10–25 animals are used per test compound. The fur from the dorsal neck is shaved and three intradermal injections of 0.1 ml each are made with the chemical, the chemical incorporated in Freund's complete adjuvant, and adjuvant alone. These injections are repeated on the other side of the neck. One week after the injections, the same area is clipped. The test agent in petrolatum is spread over a 2 cm by 4 cm patch of filter paper and placed on the guinea pig's neck area and secured with overlapping

adhesive tape and then secured by an elastic adhesive bandage wound around the torso of the animal. The dressing is left in place for 48 hours. The animals are challenged 2 weeks after the topical application with another patch test, this time the patch is secured and remains in place for 24 hours. The challenge is read 24 hours after removing the patch to allow for any irritation from the securing tape to subside, and again at 48 hours to detect any weak, slowly developing reactions. Uncertain tests can be repeated within 3–4 days. The reactions are scored on a 4-point scale, 0 = no reaction, 1 = scattered mild redness, 2 = moderate and diffuse redness, 3 = intense redness and swelling. The important parameter in maximization testing however is the frequency of sensitization not intensity.

The Buehler closed-patch sensitization test (Buehler, 1965; Buehler et al., 1985) used young 250-gram albino outbred either-sex guinea pigs. Prior to testing, the primary irritation threshold of the test agent is determined in a pilot study, and the concentration producing minimal amounts of erythema is used to sensitize. An absorbent pad (patch) approximately 4–6 cm² is wetted with 0.5 ml of the test solution and is applied to the shaved back or flank of a guinea pig and secured with a coverlet. The animal is then placed in a restrainer with adjustments made to ensure the animal is restrained but not immobilized. Patches are left on the restrained animal for 6 hours. The compound is applied in the same area weekly for 3 weeks. Two weeks after the last compound application, the animals are challenged with the highest non-irritating concentration of the same test material applied by the patch for 6 hours on a shaved naïve site. At 24 and 48 hours after application of the challenge patch, the sites are graded for degree of erythema and are assigned numbers of 0 through 3, similar to the scoring described for the Magnusson maximization test. Animals with inconclusive results can be retested within a couple of weeks of the primary challenge.

Guinea pigs have also been used to study skin wound healing and for testing a variety of agents to treat or promote wound repair (Carrel and Hartmann, 1916; Spain and Loeb, 1916). Typically partial- or full-thickness wounds are created by excising approximately 2 × 2 cm skin segments from the dorsum of the anesthetized animal. Biopsy punches can also be used to create the skin lesions (Bernstein et al., 1994). Wounds can be closed by primary intention with simple interrupted sutures (Silverstein and Landsman, 1999) or covered and allowed to heal by contraction (Davidson et al., 1992; Lindenbaum et al., 1995). Burns to the skin have also been studied in the guinea pig. Partial-thickness skin burns can be inflicted by immersing the ventral part of the anesthetized animal in 100°C water for 3 seconds (Nanney, 1982; Sakurai et al., 1997) or bathing small

areas of the guinea pig's shaved back in 75°C water for 10 seconds (Tan et al., 2002). A reproducible method to create deep partial-thickness burns utilizes a cylindrical aluminum template (3.76 cm diameter) heated in a water bath for 2 hours prior to the injury at a constant temperature of 75°C. The heated templates are applied to the skin surface in the mid back area on either side for 5 seconds using minimal pressure creating burn wounds (Kaufman et al., 1990).

A wound model for studying ischemic skin ulcers utilized guinea pigs. A 5-cm trans-scapular incision was made in the anesthetized guinea pigs. Using blunt dissection, a subcutaneous path is opened wide enough to accommodate the rubber tip of the plunger of a 10-ml syringe. The stopper is inserted through the tunnel to a site over the vertebral column and 2 cm posterior to the scapula. The insert and skin overlying it are tightly encircled with a rubber band tourniquet, preventing blood flow to a 5-cm² circle of skin over the insert. After 24 hours, the rubber band tourniquet is released and the insert is removed. These ulcers resemble human ischemic ulcers in their progression from edema and blister development through black eschar formation (Constantine and Bolton, 1986).

INTRODUCTION

Although guinea pigs are sensitive and susceptible to the development of lesions from a wide range of viruses, bacteria, protozoa, and parasites, only a small number of organisms cause natural infection and only a portion of that group cause clinical disease. The intent of this chapter is to discuss naturally occurring diseases of guinea pigs, although some data from experimental infections may be covered as they relate to the pathogenesis of the disease.

The material is presented under the following headings: background, etiology, epizootiology/pathogenesis, clinical manifestations, pathology, diagnosis, prevention, and therapy. The diseases are discussed in an alphabetical order based on the taxonomic groups to which the organisms belong and are independent of the order of perceived importance of the various diseases.

In laboratory colonies, routine surveillance of guinea pigs is conducted monthly, quarterly, or yearly as required. The Federation of European Laboratory Animal Science Associations (FELASA) recommendations include monitoring for guinea pig adenovirus, guinea pig cytomegalovirus, *Sendai virus*, ectoparasites, endoparasites, *E. cuniculi*, and a variety of bacteria including *Bordetella bronchiseptica*, *Chlamydia psittaci*, *Corynebacterium kutscheri*, dermatophytes, *Pasteurellaceae*, *Salmonella* spp., *Streptobacillus moniliformis*, *Streptococcus* spp., *Yersinia pseudotuberculosis*, and *Clostridium piliforme*. Most laboratories also monitor for these additional viruses, simian virus-5 (SV5), pneumonia virus of mice (PVM), reovirus, lymphocytic choriomeningitis virus (LCMV), and parainfluenza virus-3 (PIV-3). These viruses are routinely monitored both to minimize the risk of transference to mouse and rat colonies (PVM, Reovirus, *Sendai virus*, LCMV) and to identify infections that are zoonotic (LCMV, PIV-3).

VIRAL INFECTIONS

The viral taxonomy used follows the recommendations of the VIIIth International Committee on Taxonomy of Viruses (Fauquet, 2005), but well-established common names for viruses are used when appropriate. Historically, PVM, parainfluenza viruses, cytomegalovirus, and reovirus have been commonly found in guinea pig colonies. From 1984 to 1988 serologic investigations of laboratory animal colonies originating from ten different European countries found seropositivity for four viral infections in guinea pig stocks; reovirus, PVM, *Sendai virus*, and SV5 (see *Paramyxoviridae* section for discussion of serological specificity of *Sendai virus* and SV5) (Kraft and Meyer, 1990). In a 2004 study guinea pigs reared conventionally were positive serologically for *Sendai virus*, PVM, and reovirus (Park et al., 2006).

DNA Viruses

Adenoviridae: guinea pig adenovirus (GPAdV)

BACKGROUND Virus-associated necrotizing bronchopneumonia in guinea pigs is a spontaneous multifactorial disease that has low morbidity, high mortality, and a worldwide distribution (Percy and Barthold, 2007). After the first description in Germany and experimental reproduction of the disease (Kunstyr et al., 1984; Naumann et al., 1981), sporadic spontaneous cases were reported from the United States, Australia, and Switzerland (Brennecke et al., 1983). A 10-year endemic "in-house" occurrence of adenovirus-associated disease was reported in a British pharmaceutical research facility. In all described spontaneous cases, some additional stress factors were involved (Pring-Akerblom et al., 1997).

ETIOLOGY GPAdV is a member of the *Adenoviridae*, genus *Mastadenovirus* that contains canine and bovine adenoviruses as well (Fauquet, 2005). A portion of the hexon gene was cloned and sequenced and found to be

FIGURE 23.1 Section of lung with airway occlusion by necrotic epithelial cell debris and prominent intranuclear inclusions in bronchial epithelium due to adenoviral infection. Photo provided by Cynthia Besch-Williford.

similar to human adenovirus types 2 and 5 in structurally conserved areas, but different in areas associated with type-specific antigenicity (Feldman et al., 2001).

EPIZOOTIOLOGY AND PATHOGENESIS Adenoviral infections in guinea pigs may be more prevalent than are currently recognized as serological tests used to monitor guinea pig colonies use mouse antigens that may not robustly detect serologic responses in guinea pigs (Hankenson et al., 2010; Percy and Barthold, 2007). The virus and disease are reproducible in intranasally inoculated newborn guinea pigs, however, older animals are less susceptible to experimental disease (Kunstyr et al., 1984). The incubation period from experimental infection is 5–10 days.

CLINICAL MANIFESTATIONS GPAdV may cause inapparent infections (Crippa et al., 1997; Hankenson et al., 2010) or severe acute outbreaks with high mortality and low morbidity (Finnie et al., 1999; Naumann et al., 1981; Percy and Barthold, 2007). Dyspnea and tachypnea have been report as well as sudden death. Clinical disease occurs primarily in young animals.

PATHOLOGY Necropsy reveals well-demarcated areas of pulmonary consolidation in the cranial and ventral areas of the lungs (Eckhoff et al., 1998; Finnie et al., 1999; Percy and Barthold, 2007). Histologically, necrotizing bronchitis/bronchiolitis is evident with pronounced desquamation of the epithelium and predominantly mononuclear cell infiltration. Airway occlusion by necrotic epithelial cell debris, leukocytes, and fibrin is seen (see Figure 23.1). In infected epithelial cells of the bronchi, nuclei contain distinctive round to oval basophilic inclusions that are 7–15µm in diameter. Electron microscopy of pneumonic lesions reveals classic intranuclear

adenoviral arrays in epithelial cells. Typical lesions have been observed in the airways of non-symptomatic animals (Crippa et al., 1997; Hankenson et al., 2010).

DIAGNOSIS GPAdV infection can be detected by serology (ELISA, MFIA, or IFA) using antigen from mouse adenovirus (MAV) (Hankenson et al., 2010). Diagnostic labs use both MAV-1 (FL) and MAV-2 (K-87) strains, but unfortunately this method is not specific for GPAdV and infected animals may be only weakly positive using these reagents (Hankenson et al., 2010). Clinically ill animals can be diagnosed by PCR, immunohistochemistry, or characteristic lesions including intranuclear, basophilic inclusion bodies on electron microscopy (Finnie et al., 1999; Hankenson et al., 2010; Percy and Barthold, 2007; Pring-Akerblom et al., 1997).

PREVENTION AND THERAPY Animals with GPAdV are not appropriate for guinea pig pulmonary research projects. Rederivation of infected colonies with aseptic hysterectomy or embryo transfer should eliminate the virus. In addition, there could be a concern that natural infection with GPAdV would interfere with the use of adenovirus gene vectors. This was examined in a study of GPAdV naturally infected guinea pigs that were used as recipients of a human adenoviral vector carrying the gene for green fluorescent protein (Hankenson et al., 2010). In this model system, no difference in transfection-efficiency was seen in guinea pigs naturally infected with GPAdV or GPAdV-free.

Herpesviridae

Three members of the family *Herpesviridae* that specifically infect guinea pigs are catalogued in the Eighth Report of the International Committee on the Taxonomy of Viruses (Fauquet, 2005); *Caviid herpes virus 2* (commonly known as guinea pig cytomegalovirus and in some publications as caviid herpesvirus 1 (Staczek, 1990)), *Caviid herpes virus 1* (also known as guinea pig herpes-like virus or Hsiung-Kaplow herpesvirus, or in some publications as caviid herpesvirus 2 (Staczek, 1990)), and *Caviid herpes virus 3* (also known as guinea pig X virus) (Fauquet, 2005). In addition, *Equid herpes virus 1*, a virus of horses, has been shown to cause severe disease in guinea pigs in one outbreak in a zoo (Wohlsein et al., 2010). Of these viruses, guinea pig cytomegalovirus is the most commonly isolated herpes virus from guinea pigs and serological reactivity to this virus in colonies is not unusual. Guinea pig cytomegalovirus is used extensively in research as an animal model for human cytomegalovirus.

CAVIID HERPES VIRUS 2 (COMMONLY REFERRED TO AS GUINEA PIG CYTOMEGALOVIRUS (GPCMV))

BACKGROUND GPCMV was the first herpes virus identified in guinea pigs and was originally detected by observing intranuclear inclusion bodies in the salivary

glands (Jackson, 1920). Subsequently, virus isolation resulted in the identification of this important animal model of human cytomegalovirus infection (Cole and Kuttner, 1926).

ETIOLOGY GPCMV (species name *Caviid herpes virus 2*) is an unassigned species of the family of *Herpesviridae*, subfamily *Betaherpesvirinae* (Fauquet, 2005). Cytomegaloviruses are species-specific, large, enveloped, double-stranded, DNA viruses that cause diseases in animals and humans (Fox, 2002). The GPCMV genome has been sequenced, is 233kb in length, and consists of highly conserved areas as well as unique open reading frames (ORFs) (Schleiss et al., 2008). When the sequenced glycoproteins of GPCMV were compared to other cytomegaloviruses, most were found to be more closely related to primate cytomegaloviruses (human, chimpanzee, and rhesus) than rodent cytomegaloviruses (rat and mouse).

EPIZOOTIOLOGY AND PATHOGENESIS GPCMV was once relatively common with 70–80% of guinea pigs of 6 months of age or older having typical salivary gland inclusion (Van Hoosier and Robinette, 1976). Current prevalence of GPCMV in laboratory animal colonies is lower with only six out of 15 institutions in Europe from 2000–2003 reporting positive antibody responses to GPCMV (Schoondermark-van de Ven et al., 2006). The incidence of natural infection in guinea pigs appears to be dependent on breeding conditions and husbandry (Staczek, 1990).

Transmission is transplacental and by contact with infected urine or saliva (Choi and Hsiung, 1978; Percy and Barthold, 2007). Transplacental infection occurs primarily during acute infection as once maternal neutralizing antibodies are present, transplacental infection of fetus declines significantly (Choi and Hsiung, 1978). Transmission to neighboring guinea pigs in the same cage is less efficient than transmission via sexual contact with only six out of nine of the same sex pairs seroconverting in one study, while 100% of male/female pairs seroconverted (Choi and Hsiung, 1978).

The pathogenesis of GPCMV has been studied via experimental infection. The severity of the infection is dependent on the virus type, the strain of guinea pig, and the route of infection (Schleiss, 2002). Generally tissue culture-adapted strains produce milder infections than salivary gland-adapted strains. Outbred strains of guinea pigs, such as Hartley, are less susceptible to severe infection and excrete less virus in the urine than inbred strains such as strain 2 and JY-9 (Bia et al., 1979; Hsiung et al., 1980). Infection by mucosal routes usually results in less severe disease than intravenous, subcutaneous, or intraperitoneal inoculation.

Following experimental infection, two distinct phases of infection, acute and chronic, have been observed (Hsiung et al., 1980). In the acute phase, virus

is consistently recovered from the blood and many other tissues including lung, spleen, and kidney during a 10-day period beginning at day 2 post-inoculation (Hsiung et al., 1978, 1980). Viral clearance from the blood and most tissues occurs by 10 days post-infection, but virus remains consistently detectable in the urine and salivary gland during the chronic phase of infection (Bia et al., 1979; Hsiung et al., 1980). Less consistently, virus is found in splenic macrophages, B lymphocytes, kidneys, spleen, pancreas, and cervix of infected animals during this chronic phase.

Pregnancy can lead to more severe disease and changes in viral load following experimental GPCMV infection (Choi and Hsiung, 1978; Griffith and Hsiung, 1980; Griffith et al., 1983). Pregnant guinea pigs may develop interstitial pneumonia, splenomegaly, and necrosis of the liver, kidney, thymus, pancreas, and bone marrow (Griffith et al., 1983). The mortality rate for pregnant animals during an acute viremic episode following experimental infection is significantly greater than for non-pregnant females.

Although the fetus is susceptible to GPCMV infection at any time throughout gestation, transplacental transmission occurs most readily during the acute phase of maternal infection. The frequency of stillbirths and viral infection in neonates is highest in animals infected late in gestation. In neonates, brain lesions are observed and virus can be recovered from the salivary glands and, to a lesser extent, from the brain, lungs, pancreas, and liver of the neonates. In some cases, lesions are detected in the salivary glands of offspring up to 14 weeks postpartum. Placental infection may be detected after maternal clearance of viremia and maintained despite the presence of significant levels of GPCMV neutralizing antibody. The site of infection is localized at the transitional zone between the capillarized labyrinth and the non-capillarized interlobrium of the placenta. Whenever infection of the fetus is demonstrated, the placenta is invariably infected; however, infected placentas may be associated with uninfected fetuses. The status of maternal immunity before pregnancy can favorably affect the outcome of maternal or fetal infections with virulent GPCMV strains (Staczek, 1990).

CLINICAL MANIFESTATIONS Natural infection with GPCMV causes a latent, persistent infection in the salivary gland generally without serious disease in animals in the vivarium (Staczek, 1990; Van Hoosier and Robinette, 1976). However, the death of a sow and fetuses (Motzel and Wagner, 1989) and disseminated infection, including pneumonia, in guinea pigs that were not being manipulated experimentally have been reported (Van Hoosier et al., 1985). Illness is more likely when associated with pre-existent immune suppression or pregnancy (Percy and Barthold, 2007).

PATHOLOGY Natural infection of guinea pigs is characterized by lesions in the salivary glands, kidneys, and liver (Percy and Barthold, 2007; Van Hoosier and Robinette, 1976; Van Hoosier et al., 1985). Infected salivary glands may be enlarged at necropsy. Large, eosinophilic, intranuclear inclusions with karyomegaly and margination of the nuclear chromatin are most commonly seen in the epithelial cells of the salivary duct. Occasional, intracytoplasmic inclusions are seen in ductal epithelial cells as well as mononuclear cell infiltrate around infected ducts. Similar lesions have been described in the epithelium of the proximal and distal convoluted tubules of the kidney. In acute systemic infections, usually associated with experimental infection, interstitial pneumonia with necrosis may be seen with necrosis and inclusions in the liver, kidney, lung, spleen, and lymph node.

DIAGNOSIS Diagnosis has historically been determined by characteristic histopathologic lesions, MFIA, ELISA, or in situ hybridization. A quantitative-competitive PCR (qPCR) assay has been developed, based on the GPCMV homolog of the HCMV UL83 gene, GP83 (Schleiss et al., 2003). The most consistent isolation and highest quantities of viral DNA were observed in liver and spleen, although viral genome could be readily identified in brain, lung, and salivary gland (McGregor et al., 2004; Schleiss et al., 2003).

PREVENTION AND THERAPY Natural infection with GPCMV in laboratory animals likely confounds a variety of research models (Fox, 2002; Percy and Barthold, 2007; Van Hoosier and Robinette, 1976). There is no effective treatment and persistence has been seen. Appropriate screening for the agent prior to studies is suggested. Pet guinea pigs will likely show no clinical signs and treatment will likely not be required.

CAVIID HERPESVIRUS 1 (GUINEA PIG HERPES-LIKE VIRUS, HSIUNG AND KAPOW VIRUS)

BACKGROUND AND ETIOLOGY Guinea pig herpes-like virus (GPHLV) is an unassigned species in the family *Herpesviridae* (Fauquet, 2005). It was originally isolated from guinea pig primary kidney cell culture from both leukemic and nonleukemic Strain 2 guinea pigs (Hsiung and Kaplow, 1969). It does not produce disease in the natural host.

EPIZOOTIOLOGY GPHLV was found primarily in inbred guinea pigs such as strain 2 or strain 13. In one study, GPHLV was isolated from 80% of the guinea pigs of two inbred strains (Hsiung et al., 1980).

CLINICAL MANIFESTATIONS, PATHOLOGY, AND DIAGNOSIS GPHLV does not cause clinical disease in natural infection. Following experimental infection, a

transient increase in mononuclear cells is seen as well as histopathological evidence of lymphoid hyperplasia of the spleen in both the T cell and B cell zones, although no changes were noted in the cervical and mesenteric lymph nodes (Dowler et al., 1984). Intranuclear inclusions in tissues have not been noted in vivo, although they are evident in tissue culture cells (Dowler et al., 1984; Hsiung et al., 1971a, 1971b; Van Hoosier and Robinette, 1976). Virus can be recovered from the lymph nodes and spleen of infected animals well after clinicopathological signs of infection end. Serologically, this virus is distinct from GPCMV and GPXV and can be differentiated from these viruses both morphologically and serologically (Hsiung et al., 1980).

PREVENTION AND THERAPY GPHLV is not a clinically important disease of guinea pigs, but could be a complicating factor in research either through interaction with other viruses or cytopathological effects on cultured cells.

CAVIID HERPESVIRUS 3 (GUINEA PIG X-VIRUS)

BACKGROUND AND ETIOLOGY Guinea Pig X-Virus (GPXV) is an unassigned species in the family *Herpesviridae* (Fauquet, 2005). It was originally isolated from leukocytes of strain 2 guinea pigs that were free of GPHLV and GPCMV (Bia et al., 1980). In one study of 112 Hartley and strain 2 guinea pigs tested serologically for GPXV, 38% were found to be positive.

CLINICAL MANIFESTATIONS AND PATHOLOGY Inoculation of GPXV into Hartley guinea pigs caused viremia which persisted for at least 3 weeks (Bia et al., 1980). Virus could be recovered 5–6 months after inoculation suggesting a persistent infection. In this study, 50% of the animals died between 6 and 11 weeks post-inoculation. Hepatic necrosis was the only consistent lesion seen. GPXV is both morphologically and serologically distinct from GPCMV and GPHLV.

PREVENTION AND THERAPY Natural disease from GPXV is unknown, but similar to GPHLV, this virus may be a complicating factor in research.

EQUID HERPESVIRUS 1 (EHV1) (ALSO KNOWN AS EQUINE HERPES VIRUS 1 AND EQUINE ABORTION VIRUS)

BACKGROUND AND ETIOLOGY EHV1 is an equine pathogen that causes a persistent infection in horses with a variety of clinical presentations including respiratory disease, abortion, neonatal death, and neurologic disease (Reed and Toribio, 2004). EHV1 is a species in the genus *Varicellovirus* of the *Alphaherpesvirinae* subfamily (Fauquet, 2005). Other members of this genus include

the type species *Human herpesvirus 3* (varicella-zoster virus or chickenpox) and *Bovine herpesvirus 1* (infectious bovine rhinotracheitis virus).

PATHOGENESIS AND CLINICAL MANIFESTATIONS

One recent report describes infection with EHV1 resulting in hindlimb paralysis, ataxia, abortion, or stillbirth in 18 of 80 guinea pigs at a European zoo (Wohlsein et al., 2010). In this outbreak, Thomson gazelles (*Equus thomsoni*) kept in the same building as the guinea pigs were first affected and suffered a short course of fatal neurologic disease. The source of the virus was unclear, although a similar strain of virus was isolated 6 months earlier from affected black bears (*Ursus americanus*) and clinically unaffected onagers (*Equus hemionus kulan*). In the second outbreak, a similar strain of virus was also recovered from clinically unaffected zebra (*Equus quagga boehmi*) housed in the same building as the guinea pigs and gazelles.

PATHOLOGY Lympho-histiocytic meningoencephalitis was seen predominantly in the olfactory bulb and the frontal cortical regions of the brain with neuronal and glial necrosis, gliosis, and intranuclear inclusion bodies (Wohlsein et al., 2010). EHV1 antigen was demonstrated in the neurons, neuronal processes and glial cells by immunohistochemistry and encapsulated herpes viral particles of 120–150 nm were detected by electron microscopy.

DIAGNOSIS Differentiation from other members of the *Herpesviridae* is important for diagnosis. Immunohistochemistry, virus isolation, PCR, and DNA sequencing were used in this report to identify the virus involved (Wohlsein et al., 2010).

PREVENTION AND THERAPY EHV1 infection of guinea pigs is an example of the severe disease seen when members of the *Alphaherpesvirinae* infect unusual hosts similar to *Human herpes virus 1* (herpes simplex virus) which has been shown to infect guinea pigs experimentally (Wohlsein et al., 2010) and has also been reported to cause naturally acquired clinical disease in rabbits (Weissenböck et al., 1997) and chinchillas (Wohlsein et al., 2002). Separation of species, control of fomites, and use of appropriate personal protective equipment can be used to prevent transmission of members of the *Alphaherpesvirinae* subfamily of viruses to aberrant hosts such as guinea pigs.

Pox-Like Viruses

There has been one report of pox-like virus particles obtained from tissue culture samples of fibrovascular proliferations involving the rear limb of half of a colony of guinea pigs (Hampton et al., 1968). Particles resembling pox viruses were observed by electron microscopy.

RNA Viruses

Arenaviridae: Lymphocytic Choriomeningitis Virus (LCMV)

BACKGROUND The first identified arenavirus, LCMV, was isolated in 1933 and shown to cause aseptic meningitis in humans and was named for its ability to cause lymphocytic choriomeningitis in mice and monkeys upon intracerebral injection (Amman et al., 2007; Charrel and de Lamballerie, 2010; Percy and Barthold, 2007; Van Hoosier and Robinette, 1976). LCMV is a rodent-borne zoonotic arenavirus endemic in housemice (*Mus musculus*) worldwide. Infection by LCMV in people is known to cause acute central nervous system disease and congenital malformations.

ETIOLOGY The viral genus *Arenavirus* includes 22 viral species, the type species is LCMV (Fauquet, 2005). Like other *Arenaviruses*, LCMV is a non-cytopathic, enveloped, single-stranded RNA virus.

EPIZOOTIOLOGY AND PATHOGENESIS LCMV is uncommon to rare in guinea pigs (Fox, 2002; Percy and Barthold, 2007). In May 2005, the Centers for Disease Control and Prevention reported a cluster of LCMV infections among four solid organ recipients in Rhode Island and Massachusetts who received organs from a single apparently asymptomatic donor (Centers for Disease Control and Prevention [CDC], 2005a). Recipients became gravely ill shortly after transplantation; three subsequently died. LCMV was identified as the etiologic agent. Viral sequences from the organ recipients were identical to those from a pet hamster acquired by the donor's household 17 days before organ donation. Sequence and phylogenetic data provided strong support for the presence of the same LCMV lineage in hamsters and guinea pigs in the Rhode Island pet store and the Ohio distribution center (Amman et al., 2007; CDC, 2005b).

CLINICAL MANIFESTATIONS Clinical signs of LCMV are uncommon in the guinea pig, however meningitis with hind limb paralysis has been reported (Van Hoosier and Robinette, 1976).

PATHOLOGY LCMV in guinea pigs results in lesions involving the brain including lymphocytic infiltrates in meninges, choroid plexus, and ependyma (Percy and Barthold, 2007). Lymphocytic infiltrates are also seen in the liver, adrenal, and lungs. Experimentally, neutrophilic destruction of the splenic red pulp, focal bone marrow necrosis, lymphopenia, and death occur following infection with the more virulent (WE) strain (Djavani et al., 1998).

DIAGNOSIS Diagnosis is typically by PCR, IFA, ELISA, or MFIA (Charrel and de Lamballerie, 2010; Fox,

2002; Percy and Barthold, 2007). Detection of viral antigen in tissue or section via immunohistochemistry is also feasible. Immunity to LCMV is primarily cellular, but virus-specific antibody is produced.

PREVENTION AND THERAPY Lymphocytic choriomeningitis is a zoonotic disease of concern with rodents kept as pets (Pickering et al., 2008). Human infection occurs most commonly through exposure to secretions or excretions of infected animals. In addition, LCMV can contaminate transplantable tumor or cultured cell lines from mouse, hamster, and guinea pig, and viral stocks (ILAR, 1991; Percy and Barthold, 2007). In mice, LCMV has been shown to limit tumor induction by polyomavirus, mouse mammary tumor virus, and transplantable guinea pig leukemia, delay tumor rejection, and alter sensitivity to endotoxins (ILAR, 1991). Natural infections would be expected to interfere with research studies involving enterohepatic, lymphoid, musculoskeletal, nervous, respiratory, and urinary systems.

Coronavirus-Like Infection

Coronavirus-like particles were found in the feces of young guinea pigs that developed wasting, anorexia, and diarrhea with low morbidity and mortality (Jaax et al., 1990). At necropsy, there were large amounts of mucoid material throughout the small intestine. Histologically, the primary lesion was acute to subacute necrotizing enteritis involving the distal ileum with blunting and fusion of the affected villi, necrosis and loss of enterocytes, and mucosal syncytial cells were evident. By electron microscopy, viral particles consistent with coronavirus were demonstrated in fecal matter from affected animals. Coronavirus shedding was also noted in the feces of clinically normal guinea pigs (Marshall and Doultree, 1996). The virus has not been isolated.

Paramyxoviridae

Paramyxoviridae is composed of pleomorphic, enveloped, linear, negative-sense single-stranded RNA viruses occurring worldwide in animals and humans, often associated with subclinical infections of the respiratory tract (Fauquet, 2005; Simmons et al., 2002). The family is split into two subfamilies, *Paramyxovirinae* and *Pneumovirinae* (Fauquet, 2005). In guinea pigs, three distinct members of the *Paramyxovirinae* have been described; *Human parainfluenza virus 3* (including *Human parainfluenza virus 3*, *Cavian parainfluenza virus 3*, and *Guinea pig parainfluenza virus 3*), *Sendai virus*, and *Simian virus 5* (SV5). In addition, murine pneumonia virus, a member of the *Pneumovirinae*, has been described in guinea pigs.

HUMAN PARAINFLUENZA VIRUS 3, CAVIAN PARAINFLUENZA VIRUS 3, GUINEA PIG PARAINFLUENZA VIRUS 3

ETIOLOGY *Human parainfluenza virus 3* is a member of the genus *Respirovirus*, whose type species is *Sendai virus* (Fauquet, 2005). Sequence analysis of a Guinea-pig parainfluenza virus 3 isolated in 1998 from a colony of guinea pigs in Japan indicates that it has 95.6–97.9% nucleotide identity to *Human parainfluenza 3 virus* and 71.0–79.6% to *Bovine parainfluenza virus 3* suggesting this virus was introduced into guinea pigs from a human with human parainfluenza virus 3 (Ohsawa et al., 1998). A novel paramyxovirus (cavian parainfluenza virus 3) was isolated in 2002 from a colony of guinea pigs (Simmons et al., 2002). This virus has 94% nucleotide identity to guinea-pig parainfluenza virus 3 and *Human parainfluenza virus 3* and 80% nucleotide identity to *Bovine parainfluenza virus 3*.

EPIZOOTIOLOGY AND PATHOGENESIS Seroconversion in endemic parainfluenza-3-positive breeding colony was studied in 2002 (Blomqvist et al., 2002) and indicated that pups become infected from 2 weeks to 8 weeks of age. The virus did not persist as sentinels exposed to 4–5-month-old seropositive animals did not seroconvert. Experimental infections indicate that seroconversion in naïve animals occurs approximately 10 days following infection (Graziano et al., 1989). In an infection study guinea pigs inoculated with cavian parainfluenza virus 3, *Sendai virus*, simian virus 5 (SV-5), murine pneumonia virus, or bovine parainfluenza virus developed no clinical signs of disease or lesions during the eight-week course of the study although they developed robust homologous or heterologous serologic responses to the majority of the antigens (Simmons et al., 2002). The serologic response, using an ELISA, of those inoculated with SV-5 was modest or equivocal. In addition, SV-5 ELISA resulted in the highest degree of non-specific reactivity among all of the paramyxovirus assays.

CLINICAL MANIFESTATIONS AND PATHOLOGY In one study, no clinical signs or lesions were seen when guinea pigs were infected with Cavian parainfluenza virus 3 (Simmons et al., 2002). In a separate study, guinea pigs were shown to be susceptible to human parainfluenza virus 3, developing peribronchiolar and interstitial lesions (Clyde, 1980).

DIAGNOSIS Identification of the virus via PCR and sequencing is ideal as cross-reactive serological results make interpretation of serology difficult (Simmons et al., 2002).

PREVENTION AND THERAPY It is apparent that Human parainfluenza virus 3 can be transmitted to

guinea pigs and infection-control measures such as the use of face masks, gloves, and laminar flow hoods to prevent transmission in laboratory settings is prudent. It isn't known whether human or cavian parainfluenza virus 3 can be transmitted to humans from guinea pigs.

SENDAI VIRUS

ETIOLOGY *Sendai virus*, also known as Murine parainfluenza virus, is the type species in the genus *Respirovirus*, which also contains the species *Human parainfluenza virus 3*, *Bovine parainfluenza virus 3*, and *Human parainfluenza virus 1* (Fauquet, 2005).

EPIZOOTIOLOGY AND PATHOGENESIS Numerous studies have reported seropositivity to *Sendai virus*, including a publication in 1978 which describes seropositive reactions by HI or CF in seven out of 16 colonies tested over a 13-year period in the United States (Parker et al., 1978). In addition, there is one report of isolation of *Sendai virus* from guinea pigs associated with mice (Van Hoosier and Robinette, 1976), although no clinical signs were reported. More recently, five of 15 European guinea pig colonies were seropositive to either *Sendai virus*, *Human parainfluenza virus 3*, or both (Schoondermark-van de Ven et al., 2006). Inoculation of guinea pigs with *Sendai virus* in one report resulted in no clinical signs of disease or lesions (Simmons et al., 2002).

DIAGNOSIS As with the other *Paramyxoviridae*, lack of specificity can result in false-positive results with routine serological testing (Simmons et al., 2002). In one study, Sendai ELISA-positive samples were seen in guinea pigs infected with Pneumonia virus of mice and Bovine parainfluenzavirus 3. Guinea pigs were also positive by IFAT in the case of Bovine parainfluenza virus 3 infection.

PREVENTION AND THERAPY The importance of *Sendai virus* infections in guinea pigs is unclear. However since it is a significant disease of mice housed in laboratory animal colonies, guinea pigs should be maintained free of *Sendai virus*. In addition, *Sendai virus* is used as a vector in research and natural infection or sero-reactivity may interfere with such uses (Baker, 1998).

SIMIAN VIRUS 5 (SV5)

SV5 is a species of the genus *Rubulavirus* which also contains mumps virus and human parainfluenza virus 4 (Fauquet, 2005). SV5 was initially isolated from simian kidney cell cultures and has also been shown to infect guinea pig cells in vitro (Zakstelskaya et al., 1976). Serological reactivity to SV5 has been reported in guinea pig colonies (Kraft and Meyer, 1990). Seropositive guinea pigs show no clinical signs or lesions and inoculation with SV5 results in seroconversion, but not clinical signs

of disease (Simmons et al., 2002). Infection of guinea pigs with *Sendai virus*, pneumonia virus of mice, or *human parainfluenza virus 3* can result in positive SV5 ELISA results which were negative by indirect fluorescent antibody test, indicating low specificity of the SV5 ELISA (Simmons et al., 2002).

MURINE PNEUMONIA VIRUS

(FORMERLY PNEUMONIA VIRUS OF MICE (PVM))

ETIOLOGY PVM is a member of the genus *Pneumovirus*, species *Murine pneumonia virus* (Fauquet, 2005). Other members of the genus *Pneumovirus* include the human and bovine respiratory syncytial viruses. The complete genomes of two strains of this virus were sequenced in 2005 (Thorpe and Easton, 2005). PVM is most often subclinical in immunocompetent mice although in immunodeficient mice, it can cause chronic wasting with cyanosis and dyspnea (Percy and Barthold, 2007).

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Seropositive reactions to PVM have been seen historically in guinea pig colonies in animals without apparent disease (Van Hoosier and Robinette, 1976). Inoculation of guinea pigs with a strain of PVM that caused mortality in immunocompetent and immunodeficient mice resulted in no clinical signs, although the guinea pigs seroconverted within 11 days after inoculation (Griffith et al., 1997).

PREVENTION AND THERAPY Transmission of PVM from guinea pigs to mice, or vice versa, appears to be possible and similar in this regard to *Sendai virus*. In laboratory colonies, it is important to keep guinea pigs free of PVM in order to minimize potential transmission to mice.

Picornaviridae (Poliovirus, Theiler's Murine Encephalomyelitis Virus)

It is unclear whether laboratory guinea pigs may harbor a poliovirus which, in 1911, was described as the cause of a disease called guinea pig lameness (Hansen et al., 1997; Van Hoosier and Robinette, 1976). A similar disease was described by Rohrer in 1958 (Van Hoosier and Robinette, 1976). In these investigations, sera from affected guinea pigs reacted positively to Theiler's murine encephalomyelitis virus (TMEV) antigens. Clinical signs involved a flaccid paralysis and weight loss with an incubation period of 9–23 days, and a duration of 1–2 weeks. Affected animals had meningoencephalitis. More recently, two pet shop guinea pigs were reported to suffer from rear limb paresis and generalized debilitation. The guinea pigs had extremely high titers against "poliovirus", while healthy guinea pigs from the same pet shop were negative (Hansen et al., 1997). The diseased guinea pigs recovered

fully after treatment with vitamin C in the drinking water. Further testing of other guinea pig colonies by the same authors demonstrated antibody responses to TMEV in 35 out of 152 laboratory guinea pig sera. Positive results were found in two out of six breeding centers, and in three out of three experimental units, all of which purchased guinea pigs from one of the seropositive breeding colonies. Guinea pig sera from some of the breeding units were also positive serologically for other infections; adenovirus, PVM, reovirus type 3, *Sendai virus*, SV5 and *Encephalitozoon cuniculi*. In experimental studies of susceptibility of laboratory animals to six strains of human poliovirus, newborn guinea pigs were the only species of laboratory animals in which multiplication of any of the viruses could not be detected (Koroleva et al., 1975).

Reoviridae: Reovirus

Naturally occurring antibodies to reovirus have been detected in laboratory guinea pig colonies by IFA, ELISA, and MFIA (Percy and Barthold, 2007; Van Hoosier and Robinette, 1976). No clinical signs or lesions have been described. Experimentally guinea pigs have been exposed to a reovirus associated with the SARS coronavirus (Liang et al., 2005).

Retroviridae: Cavian Leukemia

BACKGROUND Cavian leukemia was first described in 1954 by Congdon and Lorenz as being caused by a retrovirus, however herpes viral inclusions have also been seen in leukemic guinea pigs (Jungeblut and Opler, 1967; Opler, 1969; Percy and Barthold, 2007; Van Hoosier and Robinette, 1976).

ETIOLOGY Type C retrovirus particles have been seen in cases of cavian leukemia (Hsiung et al., 1980; Van Hoosier and Robinette, 1976). An endogenous guinea pig retrovirus was induced by bromodeoxyuridine (Michalides et al., 1975; Nayak, 1974). Molecular hybridization techniques were used to show that guinea pig virus nucleotide sequences are endogenous to both domestic (*Cavia porcellus*) and indigenous (*Cavia aperea*) guinea pigs, but cannot be detected in the DNA of other mammals tested (Dahlberg et al., 1980).

In 1982, a transplantable leukemia (KSL) of unknown etiology, that had the characteristics of a B cell tumor, was found in a female Sewall-Wright strain 2 guinea pig. KSL leukemia was also shown to be distinct from another guinea pig lymphatic leukemia (L2C) with respect to cell morphology, antigenicity, and in vivo growth rate (Key, et al., 1983). A C-type virus was reported in the urine of diabetic guinea pigs (Lee et al., 1978).

CLINICAL MANIFESTATIONS Clinical signs of cavian leukemia include lethargy, pale mucous membranes, secondary infections, peripheral lymph node enlargement,

and death (Van Hoosier and Robinette, 1976). Leukocyte counts may vary from 25000–250000, with the preponderance of cells being lymphoblastic. Peripheral lymphadenopathy is generally evident.

PATHOLOGY Enlarged lymph nodes in the cervical, axillary, mediastinal, retroperitoneal, and inguinal areas are seen in cavian leukemia with splenomegaly and hepatomegaly (Van Hoosier and Robinette, 1976). There is a moderate infiltration of leukemic cells in all organs including the spleen, liver, bone marrow, lung, thymus, gastrointestinal associated lymphoid tissue (GALT), heart, eyes, and adrenals (Opler, 1969).

TREATMENT AND CONTROL There is no described treatment.

Rhabdoviridae: Rabies

Rabies has been reported in a pet guinea pig associated with a bite from a raccoon (Eidson et al., 2005).

BACTERIAL INFECTIONS

Gram-Positive Organisms

Clostridia

Most clostridia are large, spore-forming, Gram-positive, anaerobic rods. The one exception is *C. piliforme* which is Gram negative and is discussed in the section covering Gram-negative organisms below. Two species of clostridia are discussed here, *C. difficile* and *C. perfringens*.

CLOSTRIDIUM DIFFICILE (ANTIBIOTIC-ASSOCIATED TYPHILITIS)

BACKGROUND Severe profuse diarrhea, associated with *Clostridium difficile* in guinea pigs treated with antibiotics, is an important and preventable disease process.

ETIOLOGY *Clostridium difficile* is most commonly associated with antibiotic-induced typhilitis in guinea pigs, although other organisms including *Escherichia coli*, *Clostridium perfringens*, *C. sordelli*, *C. histolyticum*, and *Bacillus pumilis* have been implicated in different studies (Boot et al., 1989; Brophy and Knoop, 1982; Knoop, 1979; Lowe et al., 1980; Rehg and Pakes, 1981, 1982; Rehg et al., 1980; 1982). *C. difficile* is a common anaerobic, spore-forming, fecal-borne, Gram-positive, rod-shaped organism that generally produces both an enterotoxin (toxin A) and a cytotoxin (toxin B) that are crucial in the pathogenesis of disease (Greenwood, 2007).

EPIZOOTIOLOGY AND PATHOGENESIS Normal guinea pigs may carry low resident populations of *C. difficile* in the intestines and toxins can be identified

in normal cecal contents (Boot et al., 1989). In one study, *C. difficile* was recovered by culture in one out of eight normal guinea pigs and 18 out of 34 guinea pigs with typhilitis. Oral or parenteral antibiotic administration, including penicillin, ampicillin, streptomycin, clindamycin, lincomycin, spiramycin, aureomycin, erythromycin, and bacitracin, have all been implicated in causing antibiotic-associated typhilitis by permitting an overgrowth of primarily Gram-negative organisms including toxin-producing *Clostridium* such as *C. difficile* (Young et al., 1987). The enteric flora of guinea pigs is primarily Gram-positive and those antibiotics that target Gram-positive organisms preferentially are of greatest risk to cause this disease (Farrar and Kent, 1965). One study demonstrated that in the 24–48 hours post-administration of penicillin, there was a significant increase in Gram-negative anaerobic and aerobic (coliforms predominantly) bacteria bringing the levels of coliform bacteria from less than 100 organisms per gram to 10^8 – 10^9 organisms per gram. This shift in the normal gut flora allows bacteria such as *C. difficile*, which is generally nearly undetectable, to predominate (Farrar and Kent, 1965; Fox, 2002; Percy and Barthold, 2007). Other Gram-negative organisms, *E. coli* in particular, and other *Clostridium* spp. also can contribute to disease.

Clostridium difficile (toxin)-associated typhilitis has also been diagnosed in guinea pigs not treated with antibiotics that had been rederived by caesarian section and were exposed to mice as a source of anaerobic flora (Boot et al., 1989). Two years after rederivation, an outbreak of typhilitis was investigated. Young guinea pigs 2–4 weeks old and a few adults were affected. *Clostridium difficile* was isolated from half of the animals tested and the cytotoxin was identified in cecal contents from 95% of the affected animals. Co-infection with *C. perfringens* and *Encephalitozoon cuniculi* was present. The authors speculate that the anaerobic flora that the animals were exposed to was not sufficient to protect guinea pigs from *C. difficile* infection. This same flora has been shown to be unsuitable for rats and rabbits.

CLINICAL MANIFESTATIONS Generally, affected guinea pigs have weight loss, rough hair coats, anorexia, dehydration, decreased activity, and hypothermia beginning 24–48 hours after antibiotic administration (Farrar and Kent, 1965; Fox, 2002; Knoop, 1979; Wasson et al., 2000). Some animals have no stool, while others have diarrhea and acute death has been reported.

PATHOLOGY At necropsy, the cecum is often gas-filled and dilated with hemorrhage evident in the cecal mucosa. Histopathologically, there is usually hyperplasia of the ileal mucosa as well as ulceration, edema, and degeneration of the cecal epithelium with leukocytic infiltration.

DIAGNOSIS *C. difficile* can be isolated from cecal contents via anaerobic culture (Boot et al., 1989; Greenwood, 2007). Detection of toxin in cecal contents, tissue, or feces via an enzyme immunoassay, cytotoxin activity in cell culture, serum neutralization assay, or PCR are considered the gold standard, however, false positives and false negatives are not uncommon (Greenwood, 2007; Houser et al., 2010; Songer, 1996).

PREVENTION AND THERAPY Antibiotic-associated diarrhea is usually treated symptomatically. In humans, administration of metronidazole or vancomycin is standard (Greenwood, 2007; Rupnik et al., 2009; Songer, 1996). Anecdotal information suggests that administration of yogurt or other *Lactobacillus*-containing products in conjunction with antimicrobial agents will prevent or minimize the effects of antibiotic-associated enteritis. A recent study attempted to induce antibiotic-associated enteritis by a single subcutaneous injection of clindamycin (Wasson et al., 2000). *C. difficile* and other enteric pathogens were not isolated, however, several guinea pigs that received clindamycin developed enteritis. In affected animals, administration of antibiotics with the oral *Lactobacillus* preparation did not result in any clinical improvement over those animals receiving antibiotics alone.

Certain PCR ribotypes of *C. difficile* are found in both human and animal populations, suggesting that this can be a zoonotic disease, although most of these studies are concerned with *C. difficile* found in food animals rather than guinea pigs (Rupnik et al., 2009).

CLOSTRIDIUM PERFRINGENS (ENTEROTOXEMIA)

Clostridium perfringens is a ubiquitous Gram-positive anaerobic spore-forming bacterium that is the primary cause of enterotoxemia in domestic animals. *C. perfringens* strains produce a variety of toxins, as many as 17 exotoxins, although four major toxins are associated with typing of the bacteria; alpha, beta, epsilon, and iota. Infections typically occur via contaminated food, water, bedding, or soil and primarily affect sheep, pigs, and cattle.

Confirmed *C. perfringens* infections have been reported in germ-free guinea pigs in 1970 and, more recently, in a conventionally housed guinea pig (Feldman et al., 1997; Madden et al., 1970; Songer, 1996). Clinical signs seen in the conventionally housed guinea pig were lethargy and anorexia. At necropsy, there were fibrinous adhesions involving the small intestine and liver (Feldman et al., 1997). The ileum and cecum had ecchymotic hemorrhages. Histopathology revealed acute, multifocal, severe, necrotizing, ulcerative typhilitis and ileitis as well as focal, severe, necrotizing, centrilobular vascular thrombosis of the liver with infarction and coagulative necrosis of the adjacent hepatocytes. PCR was used

to identify the toxins of *C. perfringens* both in the intestine and the liver.

Corynebacterium

ETIOLOGY *Corynebacterium* spp., members of the family *Corynebacteriaceae*, are Gram-positive, non-spore-forming, non-motile, aerobic, pleomorphic rods with coccoid or club-shaped appearance that are catalase-positive and non-acid-fast (Boone et al., 2001; Greenwood, 2007).

PATHOGENESIS, CLINICAL MANIFESTATIONS, AND PATHOLOGY *Corynebacterium* spp. can cause disease in guinea pigs, but are also part of the normal flora. Specifically, they are commonly isolated from guinea pig conjunctiva. In one study, 27 out of 30 clinically normal pet guinea pigs grew *Corynebacterium* spp. from conjunctival cultures (Coster et al., 2008).

Spontaneous disease of guinea pigs associated with corynebacterial infections has rarely been reported, but have involved numerous different species of *Corynebacterium*. In one report, *Corynebacterium pyogenes* was isolated from a guinea pig with septicemia (Ganaway, 1976). Further research with that agent demonstrated it was pathogenic when administered IP to other guinea pigs, but not if it was given orally or intranasally. In another report, *C. kutscheri* was isolated from the lung of a guinea pig during an epizootic of group C, beta-hemolytic streptococcal disease. Further research with this isolate was similar to *C. pyogenes*, in that intraperitoneal administration resulted in disease while intranasal administration did not. The organism was also given intravenously in this case and was rapidly fatal. In a retrospective study of urinary bladder calculi in guinea pigs, it was reported that *Corynebacterium renale* was the most common isolate from urine and bladder samples (Hawkins et al., 2009). Of the 44 cases submitted for bacterial culture, 77% were negative. The most common pure culture isolate was *C. renale*, which was also commonly found in mixed infections with *Staphylococcus* and *Streptococcus* spp.

DIAGNOSIS Diagnosis is made by recovering the organism using aerobic culture conditions, generally on blood agar plates with standard biochemical tests to differentiate corynebacterium from other species (Greenwood, 2007). PCR and sequencing has been used for further identification (Greenwood, 2007; Hawkins et al., 2009).

PREVENTION AND THERAPY Many *Corynebacterium* spp. have significant resistance to a number of antibiotics and this may be true of some organisms in guinea pigs as well (Greenwood, 2007). In the study isolating *C. renale* from the urine and bladder wall, many of those animals were already on antibiotics when those isolates were obtained (Hawkins et al., 2009). In addition, the

Corynebacterium spp. recovered from the normal conjunctiva of guinea pigs, demonstrated some bacterial resistance with six out of nine isolates resistant to oxy-tetracycline, four out of nine resistant to polymyxin B, two out of nine resistant to bacitracin, and one out of nine resistant to erythromycin, gentamicin, amikacin, and ciprofloxacin (Coster et al., 2008).

Mycobacterium tuberculosis

Guinea pigs are highly susceptible to *M. tuberculosis*. Natural infection has rarely been reported in the literature, but in those cases, the sources of the infections were believed to be from contact with human cases (Van Hoosier and Robinette, 1976).

Staphylococcus aureus

BACKGROUND Markham and Markham (1966) studied the prevalence of staphylococcal organisms in various animal species. A 42% incidence of coagulase-positive *Staphylococcus* was noted in the nasal passages of guinea pigs. This was the greatest incidence of staphylococcal infection of any species tested, including humans. All of the guinea pigs cultured appeared clinically normal.

ETIOLOGY The *Staphylococcus* genus, members of the *Staphylococcaceae* family, are common inhabitants of the skin, oral cavity, respiratory system, and intestine, and cause suppurative lesions and septicemia in all species (Songer and Post, 2005). These Gram-positive cocci are coagulase-positive, catalase-positive, oxidase-negative, non-spore-forming and facultative anaerobic organisms (Harkness and Wagner, 1995; Songer and Post, 2005). In guinea pigs, *Staphylococcus aureus* has been isolated from cases of ulcerative pododermatitis and exfoliative dermatitis (Percy and Barthold, 2007).

PATHOGENESIS Despite the existence of species-specific serotypes and biotypes, human *Staphylococcus aureus* phage types have been recovered from animals, and human-animal contact is one means of transmission of *S. aureus* (Harkness and Wagner, 1995). Additionally, direct contact with an infected animal or contaminated surface, as well as spread via aerosol can result in the dissemination of infection.

Ulcerative pododermatitis, or dermatitis of the footpad, is also known as "bumblefoot". Trauma to the footpad from fighting, a sharp cage edge, or abrasive flooring creates a site of entry for bacteria (Harkness and Wagner, 1995). Obese guinea pigs, as well as any other natural or experimental cause that results in a sedentary lifestyle, can predispose an animal to bumblefoot, since perfusion is decreased and the pressure on the feet is increased (Brown and Donnelly, 2008; Harkness and Wagner, 1995).

Exfoliative, or acute staphylococcal, dermatitis has also been associated with *S. aureus* in guinea pigs. Strain 13 guinea pigs are reported with this condition more frequently than other strains, and mortality rates due to this condition are higher in young animals, especially if born to an affected dam that is too painful to nurse (Ishihara, 1980; Percy and Barthold, 2007).

CLINICAL MANIFESTATIONS Swollen, erythemic paws and lameness are noted with bumblefoot (Brown and Donnelly, 2008). Paws will often have erosions or ulcerations on the palmar or plantar surfaces. Osteoarthritis or osteomyelitis may result, and animals that develop such sequela have a poorer prognosis. Alopecia and erythema of the ventral abdomen, leading to cracking and scabbing of the epidermis, are often observed with exfoliative dermatitis (Fox, 2002; Ishihara, 1980; Percy and Barthold, 2007). In addition to its association with ulcerative pododermatitis and exfoliative dermatitis, pneumonia, mastitis, conjunctivitis, cheilitis, and osteoarthritis have been attributed to *S. aureus* infection in guinea pigs (Fox, 2002). Systemic amyloidosis can develop secondary to chronic *S. aureus* infection (Brown and Donnelly, 2008; Fox, 2002; Percy and Barthold, 2007).

PATHOLOGY Hypertrophy of the stratum corneum with a minimal inflammatory response is noted histologically in cases of dermatitis associated with *S. aureus* (Percy and Barthold, 2007). Diffuse cellulitis is the primary lesion associated with ulcerative pododermatitis (Brown and Donnelly, 2008). In cases that progress to amyloidosis, amyloid may be noted in the liver, spleen, adrenal glands, and pancreatic islets (Ganaway, 1976).

DIAGNOSIS Stained impression smears of lesions can demonstrate clumps of Gram-positive cocci (Harkness and Wagner, 1995). *S. aureus* can often be cultured directly from affected tissues and from the upper respiratory tract and pharynx of affected animals (Percy and Barthold, 2007). Blood agar or selective mediums, such as mannitol salt or Staph 110 agar, can be used for primary culture (Songer and Post, 2005). *S. aureus* colonies often present with a golden pigmentation.

PREVENTION AND THERAPY Prevention of ulcerative pododermatitis and exfoliative dermatitis is easier than treatment. Preventing cutaneous wounds by providing sturdy, smooth flooring to guinea pigs, offering non-abrasive feedstuff, and preventing obesity are highly effective in minimizing infection with *S. aureus*. Pododermatitis and exfoliative dermatitis are not usually conditions conducive to lesion drainage and surgical removal (Brown and Donnelly, 2008). Lesions can be cleaned, but the possibility of causing greater trauma to the affected area must be considered. Also,

disinfectants that dry out the skin or agents that are cytotoxic to fibroblasts and reduce white blood cell viability and phagocytic efficiency, such as povidone-iodine or chlorhexidine, should be avoided. Long-term antibiotic treatment is necessary, and enrofloxacin or ciprofloxacin administered twice a day for 2–6 months has been reported in the treatment of ulcerative pododermatitis. Use of an analgesic agent, especially a non-steroidal anti-inflammatory drug such as meloxicam, is also recommended. Low-level laser therapy, or phototherapy, has been reported as successful in treating bumblefoot by accelerating angiogenesis and stimulating vasodilatation, although such therapy can only be used after the infection is first controlled.

Streptococcus

Two strains of *Streptococcus* cause disease in guinea pigs. *Streptococcus pneumoniae* can lead to severe pneumonia and *Streptococcus equi* subsp. *zooepidemicus* is associated with the development of chronic lymphadenitis (Wagner et al., 1976). Infections due to *S. equi* subsp. *zooepidemicus* are more prevalent in guinea pigs than are pneumococcal infections. Members of the *Streptococcus* genus are part of the *Streptococcaceae* family and consist of Gram-positive, catalase-negative, facultative anaerobic bacteria that are non-spore-forming and non-motile (Songer and Post, 2005).

STREPTOCOCCUS PNEUMONIAE

BACKGROUND *Streptococcus pneumoniae* was first recognized in guinea pigs in Europe in the late 1800s (Wagner et al., 1976). Homberger et al. (1945) are credited with the first report of this organism in guinea pigs in the United States; the animals were from a colony in Massachusetts and presented with signs of respiratory infection.

ETIOLOGY *Streptococcus pneumoniae* is an oval- to lancet-shaped, encapsulated coccus that presents in pairs (diplococcus) or short chains (Fox, 2002; Percy and Barthold, 2007). *S. pneumoniae* is an α -hemolytic streptococcus that ferments trehalose and is optochin-sensitive (Harkness and Wagner, 1995; Keyhani and Naghshineh, 1974; Songer and Post, 2005). Additionally, it is not categorized according to one of the Lancefield groupings (Songer and Post, 2005). Serovars of pneumococci are differentiated according to their capsular polysaccharide content, and serovars 4 and 19 are the two most often recovered from guinea pigs (Fox, 2002; Percy and Barthold, 2007).

EPIZOOTIOLOGY AND PATHOGENESIS Asymptomatic guinea pigs can carry pneumococci in the upper respiratory passages; the carrier rate for laboratory colonies can be as high as 50–55% (Fox, 2002; Percy and Barthold, 2007). While

pneumonia epidemics due to *S. pneumoniae* seldom occur in well-managed facilities, stressors which may predispose to infection include poor husbandry, pregnancy, sudden or prolonged changes in temperature, poor ventilation, shipping, inadequate nutrition, concurrent infections, and experimental procedures (Nakagawa et al., 1986; Percy and Barthold, 2007). Transmission of *S. pneumoniae* is by aerosol or via direct contact with abraded skin or oral mucosa (Fox, 2002; Percy and Barthold, 2007; Wagner et al., 1976). Infection can also be passed at the time of parturition by an infected dam. Abortions and stillbirths can accompany a high mortality rate during an epizootic outbreak in a guinea pig colony (Percy and Barthold, 2007).

CLINICAL MANIFESTATIONS In 1974, a spontaneous epizootic of respiratory infection involving 2400 guinea pigs was caused by *S. pneumoniae* type 19 (Keyhani and Naghshineh, 1974). During this outbreak, 450 guinea pigs died within 33 days of infection, and a short course of listlessness and failure to thrive were the only noted clinical signs prior to death. In less acute cases of *S. pneumoniae*, guinea pigs display depression and lethargy, anorexia, and have ruffled fur. They may have a wet nose, nasal or ocular discharge (rhinitis, conjunctivitis), sneezing, coughing, dyspnea, or torticollis (head tilt due to otitis media) (Fox, 2002; Wagner et al., 1976). Wagner, Owens, Kusewitt, and Corley reported that otitis media occurred in 177 of 1373 guinea pigs necropsied during a 6-year period in the 1970s (Wagner et al., 1976). *Streptococcus pneumoniae* was noted in 20% of these cases, and was the most common bacteria isolated. Gupta et al. (1970), reported mastitis caused by *S. pneumoniae* in two guinea pigs.

PATHOLOGY Acute bronchopneumonia is most often associated with *S. pneumoniae* infections. Fibrinous exudate, a polymorphonuclear cell infiltrate and thrombosis of the pulmonary vessels may be observed in the lung (Fox, 2002; Keyhani and Naghshineh, 1974; Percy and Barthold, 2007). Other pyogenic processes noted in infected animals include pericarditis, peritonitis, otitis media, arthritis, endometritis, and suppurative meningitis (Fox, 2002; Percy and Barthold, 2007). Additionally, splenitis, fibrinopurulent meningitis, metritis, and lymphadenitis with focal hepatic and ovarian abscessation have been reported (Percy and Barthold, 2007). Pneumococci are readily demonstrated on impression smears and in stained tissue sections (Wagner et al., 1976).

DIAGNOSIS Culture of nasal washings is an ante-mortem means of diagnosing *S. pneumoniae* (Homburger et al., 1945), as is culture of the nasal passages (Harkness and Wagner, 1995). Post-mortem, direct smears and culture of inflammatory exudates can be performed.

S. pneumoniae is a fastidious bacterium that grows best when incubated under 5–10% CO₂ on blood agar or enrichment media (Fox, 2002; Percy and Barthold, 2007). Serological diagnosis via ELISA has been reported (Matsubara et al., 1988).

PREVENTION AND THERAPY Antibiotic treatment of a clinical animal usually results in reversion to a sub-clinical carrier state, so elimination of clinical animals is recommended whenever possible (Fox, 2002). Chloramphenicol, trimethoprim-sulfa combinations, and tetracycline have been used during epizootic outbreaks (Harkness and Wagner, 1995; Homburger et al., 1945; Keyhani and Naghshineh, 1974). Prevention should focus on good husbandry, adequate diet, early isolation of streptococcal carrier animals, and reduction of environmental stressors.

The same *S. pneumoniae* serovars commonly detected in guinea pigs have been isolated from humans (Songer and Post, 2005). *S. pneumoniae* can lead to respiratory and neurological disease in humans, especially in older and immune-compromised individuals. To date, interspecies transmission of *S. pneumoniae* has not been reported (Harkness and Wagner, 1995; Percy and Barthold, 2007).

STREPTOCOCCUS EQUI SUBSP. ZOOEPIDEMICUS

BACKGROUND Charles Boxmeyer (1907) described his findings of epizootic lymphadenitis in over 3000 guinea pigs in 1907. Cunningham (1929) reported on 20 guinea pigs from a colony of 150 that had “lumps,” and from which “the same unusual type of mucoid hemolytic streptococcus was isolated”. Cunningham noted a 3:1 female to male ratio among the animals with chronic lymphadenitis.

ETIOLOGY *Streptococcus equi* subsp. *zooepidemicus* is a Lancefield group C streptococcus that is beta-hemolytic, encapsulated, and ferments sorbitol (Percy and Barthold, 2007; Songer and Post, 2005). *S. equi* subsp. *zooepidemicus* has a high degree of DNA homology with *S. equi* subsp. *equi*. *S. equi* subsp. *zooepidemicus* has been recovered from human infections, while *S. equi* subsp. *equi* has not (Songer and Post, 2005).

EPIZOOTIOLOGY AND PATHOGENESIS Guinea pigs can carry *S. equi* subsp. *zooepidemicus* asymptotically in the nasopharynx and conjunctiva (Percy and Barthold, 2007), but compared to *S. pneumoniae*, clinical disease is more often noted in guinea pigs infected with *S. equi* subsp. *zooepidemicus*. As noted by Cunningham, females are indeed more susceptible to disease than males (Cunningham, 1929; Fox, 2002; Percy and Barthold, 2007). Strain 2 guinea pigs also appear to be more sensitive than other strains (Fox, 2002; Percy and Barthold, 2007;

Wagner et al., 1976). Transmission is via aerosol, as well as direct contact with abraded skin or oral mucosa (Harkness and Wagner 1995; Fox, 2002; Percy and Barthold, 2007). The organism can be transmitted via bite wounds and secondary to abrasion by rough foodstuff (Ganaway, 1976). While this is likely the route of entry for most natural infections, Murphy et al. (1991) showed that the oral mucosa does not need to be abraded in order for entry of the bacterium. The female genital tract can be infected during farrowing (Percy and Barthold, 2007). After initial entrance, the organism travels to the draining lymph node and replicates (Harkness and Wagner, 1995). Cervical lymphadenitis is commonly noted in guinea pigs when the point of entry for infection is via the conjunctiva or nasal mucosa (Harkness and Wagner, 1995).

CLINICAL MANIFESTATIONS Clinical disease associated with *S. equi* subsp. *zooeidemicus* is colloquially referred to as “lumps,” due to the pyogenic nature of the bacteria and its propensity to travel to and replicate in the lymph nodes (Fox, 2002; Percy and Barthold, 2007). While the cervical lymph nodes are the most common site of *S. equi* subsp. *zooeidemicus* replication and abscessation, any lymph node, and practically any organ, can be affected (Harkness and Wagner, 1995). A common presentation for infection with this organism is an animal that appears in good condition except for a swelling in the neck at the position of the cervical lymph node (Fox, 2002). The swelling is often soft to firm, pus-filled, non-fluctuant and freely moveable (Percy and Barthold, 2007). Cunningham’s (1929) observations were that “in some cases, one or two nodes were greatly enlarged; in others, as in one animal with cervical node involvement, several plum-sized encapsulated abscesses formed a collar across the front and side of the neck”. Depending on what additional organs are affected, torticollis (if middle ear involvement), dyspnea and cyanosis or nasal and ocular discharge (if respiratory involvement), or hematuria and hemoglobinuria (if septic) may be noted (Fox, 2002; Harkness and Wagner, 1995). Abortions, stillbirths and unexpected deaths are possible (Fox, 2002). During epizootic outbreaks, septicemia, acute pneumonia, and high mortality can occur (Harkness and Wagner, 1995).

PATHOLOGY The most common finding at necropsy is that of an abscessed, encapsulated cervical lymph node (Fox, 2002). The node architecture is often destroyed by central necrosis and peripheral fibrosis, and a thick pustular exudate is present (Cunningham, 1929; Fox, 2002; Percy and Barthold, 2007). Smears of the exudate reveal numerous Gram-positive cocci in short chains (Cunningham, 1929). A generalized lymphadenitis may be noted, as may retroorbital abscessation, otitis media, pneumonia, pleuritis, pericarditis, or hepatitis (Cunningham, 1929; Fox, 2002; Percy and Barthold, 2007).

DIAGNOSIS *S. equi* subsp. *zooeidemicus* can be cultured from affected tissues or heart blood (Harkness and Wagner, 1995; Percy and Barthold, 2007; Quesenberry and Carpenter, 2004; Wagner et al., 1976). Culture requires blood agar, on which after 24 hours, a clear zone of hemolysis is observed (Harkness and Wagner, 1995).

PREVENTION AND THERAPY Trimming of teeth, elimination of sharp edges to feeders, and feeding non-abrasive feed may assist in prevention of *S. equi* subsp. *zooeidemicus* infection (Fox, 2002). Infected animals should be isolated from the colony. Surgical removal of abscess contents and capsule can be done with creation of drainage and lavage. Antibiotic therapy is required. In epizootic cases, depopulation of affected animals and disinfection of the environment is advised. Enzootic disease represents significant potential for research complications. Disease-free replacement stock should be obtained and is available from commercial vendors. Vaccines are typically type-specific and do not provide reliable protection (Fox, 2002; Mayora et al., 1978).

Gram-Negative Organisms

Actinobacillus

Actinobacillus lignieresii and *Actinobacillus equuli* have been noted in laboratory guinea pigs (Songer and Post, 2005). The genus *Actinobacillus* is a member of the *Pasteurellaceae* family (Boone et al., 2001). These organisms are pleomorphic Gram-negative rods that on Gram stain, can have a “Morse code” appearance (Songer and Post, 2005).

Actinobacillus lignieresii and *Actinobacillus equuli* were cultured from 36 guinea pigs, rats and mice during a 6-month period at the University of Missouri Research Animal Diagnostic and Investigative Laboratory (Lentsch and Wagner, 1980). Organisms grew on blood agar inoculated with swabs from the posterior nasopharynx, conjunctiva, and middle ear. Conjunctivitis was noted in one animal and otitis media was noted in six.

Bordetella

BACKGROUND Tartakowsky is credited with one of the first accounts of *Bordetella* infection in guinea pigs in the late 1880s (McCartney and Olitsky, 1923; Smith, 1913). Woolfrey and Moody (1991) in their review of this organism stated “Ferry, using the name *Bacillus bronchisepticus*; McGowan, using the term *Bacillus bronchicanis*; and Torrey and Rahe, using Ferry’s epithet, independently observed the association of a small gram-negative coccobacillus with outbreaks of “canine distemper” and respiratory tract illness in laboratory animals such as the cat, rabbit, and guinea pig”. In the early 1970s, *B. bronchiseptica* was still considered to be the primary cause of acute pneumonia in guinea pigs and while it is not often

noted in modern laboratory facilities, it continues to be a major cause of respiratory disease in pet guinea pigs and this species is thought to be quite susceptible to infection (Percy and Barthold, 2007; Rigby, 1976).

ETIOLOGY *Bordetella bronchiseptica* is a short, Gram-negative rod or coccobacillus, that is aerobic, motile, and non-spore-forming (Fox, 2002; Percy and Barthold, 2007). *B. bronchiseptica* is oxidase, catalase, and urease positive, as well as positive for citrate utilization and nitrate reduction (Songer and Post, 2005; Woolfrey and Moody, 1991). *B. bronchiseptica* is considered a commensal organism in the guinea pig, as well as many other mammalian species, including humans (Fox, 2002; Percy and Barthold, 2007; Woolfrey and Moody, 1991). The *Bordetella* genus is a member of the *Alcaligenaceae* family (Songer and Post, 2005).

EPIZOOTIOLOGY AND PATHOGENESIS *B. bronchiseptica* is carried by guinea pigs in the nasal cavity and trachea, and up to 20% of non-clinical animals in a colony can be carriers (Ganaway, 1976). Stressful events, such as transport or pregnancy, may trigger an acute fatal pneumonia in carriers or animals with previously inapparent infections. Transmission of *B. bronchiseptica* is via aerosol spread, direct contact, direct contact with respiratory secretions of infected animals, or fomites (Fox, 2002; Ganaway, 1976). *B. bronchiseptica* adheres to ciliated respiratory epithelium and causes ciliary paralysis (Fox, 2002). Pathogenic *B. bronchiseptica* produce adhesion and cytolytic toxins that lead to an inflammatory response, antiphagocytic activity, and dermonecrosis. While not explicitly described in the guinea pig, the impairment in mucociliary clearance caused by the binding of *Bordetella* is known to reduce the clearance of additional respiratory pathogens in other animal species. The incubation period is 5–7 days (Ganaway, 1976). The highest levels of morbidity and mortality due to *B. bronchiseptica* have been noted in young guinea pigs, as well as strain 2 animals (Fox, 2002; Ganaway, 1976). It is possible for infected animals to develop immunity and clear the organism. Yoda et al. (1972), noted that within 6–54 weeks of initial infection, 69 of 79 naturally infected guinea pigs completely recovered from infection.

CLINICAL MANIFESTATIONS Infection with *B. bronchiseptica* is often subclinical in nature (Fox, 2002). It has been suggested that the clinical signs associated with *Bordetella* in the past have actually been due to infections with a secondary invader, such as guinea pig adenovirus, which has not been recognized as an infectious agent of the guinea pig for as long as *B. bronchiseptica*. During an epizootic outbreak, death may follow respiratory disease and septicemia within a 24–72-hour period (Fox, 2002). Abortion and stillbirths can occur in pregnant

dams (Percy and Barthold, 2007). In an enzootically infected colony, sporadic deaths may occur throughout the year, with highest levels during the winter months. Inappetance, depression, nasal discharge, dyspnea, and cyanosis may also be observed (Fox, 2002).

PATHOLOGY At necropsy, cranioventral pulmonary consolidation is seen, and whole lobes or individual lobules will present as dark red to red-gray in color (Ganaway, 1976; Percy and Barthold, 2007). A blood-tinged froth is noted in the trachea. Mucopurulent exudates may be noted in affected airways. Pleuritis and otitis media may be observed. Suppurative bronchopneumonia is noted histologically, with an influx of heterophils and mononuclear cells. Uterine infections may result in dead fetuses or pyosalpinx.

DIAGNOSIS *B. bronchiseptica* can be cultured on blood or MacConkey's agar from nasal or other respiratory secretions (Songer and Post, 2005). In cases of otitis media, *B. bronchiseptica* can be isolated from the middle ear, and in cases of metritis, from the uterus (Fox, 2002; Yoda et al., 1972) at 35–37°C (Songer and Post, 2005). Smith and Baskerville medium selects for *B. bronchiseptica*, and is another option for culture (Songer and Post, 2005). ELISA and IFA tests have been developed for the detection of guinea pig *Bordetella*, and have been noted as equally successful in identifying infected animals as cultures of the respiratory tract (Boot et al., 1993a; Wullenweber and Boot, 1994).

PREVENTION AND THERAPY Purchasing *Bordetella*-free animals is the best means of control in laboratory colonies of guinea pigs. It is recommended that rabbits and guinea pigs not be co-housed since guinea pigs are highly susceptible to disease and rabbits are frequently sub-clinical carriers of *B. bronchiseptica* (Charles River Laboratories, 2011). Rats and other rodents can be additional sources of infection (Rigby, 1976). Antibiotic treatment with fluoroquinolones or trimethoprim-sulfonamides may successfully resolve clinical signs, but elimination of infection is rare, with animals often reverting to the sub-clinical state. If infection is suspected in a colony, restocking, test and cull, or rederivation may be more beneficial than treatment (Fox, 2002). The efficacy of canine, porcine, human, and autogenous *Bordetella* vaccines and bacterins has been evaluated by several individuals; reports suggest that these vaccines do not completely protect guinea pigs from infection, but a decrease in the incidence and severity of clinical disease has been noted in experimentally challenged animals (Matherne et al., 1987; Stephenson et al., 1989).

B. bronchiseptica apparently does not cause epidemic disease in man, but it can cause a whooping cough-like syndrome in immune-competent children or respiratory

tract infections in immune-suppressed individuals (Songer and Post, 2005). Endocarditis, meningitis, and peritonitis have also been associated with *B. bronchiseptica* infections in humans. The ease of transmission between guinea pigs and humans is unknown.

Brachyspira

BACKGROUND AND ETIOLOGY Spirochetes of the genus *Brachyspira* (formerly *Serpulina*) have been associated with diarrhea and colitis in a variety of animals including birds and mammals. *Brachyspira* contains seven distinct species. Of these, two species have been implicated in guinea pigs, either in natural infections or as an animal model; *B. hyodysenteriae*, the primary cause of swine dysentery, and *B. pilosicoli*, a zoonotic agent associated with disease in chickens, pigs, and humans. Spirochetes have been associated with disease in guinea pigs in several publications, although purposeful infection to demonstrate causality has not been done and in many cases, identification of the species involved has also not been accomplished (Duhamel, 2001). Guinea pigs have been used as an animal model for *B. hyodysenteriae* infection.

CLINICAL MANIFESTATIONS AND PATHOLOGY Two reports in the 1970s describing Tyzzer's disease in guinea pigs also report observing spirochetes on histopathology (McLeod et al., 1977; Zwicker et al., 1978). The significance of the spirochete infections in the progression of the disease seen is unclear. A subsequent report describes a series of cases submitted for necropsy between 1992 and 1996 in Belgium (Vanrobaeys et al., 1998). In 29 of 33 cases when spirochetes were identified, the presenting complaints were either sudden death or a short course of diarrhea followed by sudden death. Flagellated parasites were seen in 12 animals and lesions consistent with vitamin C deficiency in six cases. Gross necropsy of affected animals most commonly demonstrated liquid, occasionally mucoid or hemorrhagic large intestinal contents, and dilation of the cecum and colon. Histologically, the cecum was characterized by hyperemia, mucosal infiltration of neutrophils, a mixed inflammatory infiltrate in the lamina propria, and occasionally, necrosis of crypt epithelium. Lesions involving other organs were present in 30 of the 37 animals identified, suggesting multifactorial disease processes. In a report of a single pet guinea pig, clinical signs of tenesmus, tachycardia, pale mucous membranes, and dehydration were associated with acute rectal prolapse (Helie et al., 2000). Histopathology identified superficial mucosal necrosis and ulceration and congestion with hemorrhage in the intussuscepted segment. Although spirochetes and organisms consistent with *Eimeria* spp. were seen in the rest of the intestinal tract, no other lesions were noted. *B. pilosicoli* was identified by PCR.

DIAGNOSIS Diagnosis can be made by identifying typical organisms on histopathology. PCR of intestinal contents is diagnostic (Helie et al., 2000).

PREVENTION AND THERAPY Treatment with ranidazole stopped the spread of the disease in some cases as described by Vanrobaeys et al. (1998), although cessation of treatment resulted in resumption of disease. As the majority of reports describe co-pathogens, controlling co-pathogens may be the most effective prevention.

Brucella

Brucella spp. are zoonotic, Gram-negative, strictly aerobic, intracellular, non-motile coccobacilli, which infect a variety of species, including guinea pigs (Martirosyan et al., 2011; Pappas, 2010; Van Hoosier and Robinette, 1976). Natural infections in guinea pigs have been described likely associated with contaminated food, bedding, or other biological materials (Van Hoosier and Robinette, 1976). In these outbreaks, guinea pigs developed disease similar to that seen in other species including testicular and joint swelling as well as abscesses in the liver and pancreas. Modern husbandry practices should limit transmission of *Brucella* spp. to guinea pigs.

Campylobacter jejuni

Campylobacter jejuni is a species of curved, rod-shaped, non-spore-forming, Gram-negative, microaerophilic, bacteria that naturally colonize the digestive track of birds and numerous other species, including domestic farm animals, dogs, cats, various wildlife, and rodents (Horrocks et al., 2009). It is a common cause of human gastroenteritis worldwide primarily from contamination of food. It was isolated from laboratory animal guinea pigs in one report where the prevalence of *C. jejuni* in a multispecies laboratory animal facility was investigated (Meanger and Marshall, 1989). In this report, no clinical signs were seen in any of the animals involved and pathological analysis was not done. Guinea pigs have been used as an animal model of *C. jejuni* infection (Burrough et al., 2009; Coid et al., 1987).

Chlamydia caviae

BACKGROUND AND ETIOLOGY Guinea pig inclusion conjunctivitis was first described in 1964 associated with an experiment to examine the correlation between vitamin deficiency and the development of trachoma virus (Murray, 1964). The organism was identified as a type of *Chlamydia psittaci*, a member of the psittacosis-lymphogranuloma-trachoma group, first thought to be protozoa, then viruses because they could pass through a 450-nm filter, and finally in 1966 recognized as bacteria (Longbottom and Coulter, 2003; Moulder, 1966; Songer and Post, 2005). As members of the family *Chlamydiaceae*, they are

Gram-negative, obligate intracellular pathogens that infect a variety of animals, including amoeba, birds, sheep, humans, and guinea pigs (Greenwood, 2007). Recently they have been divided into two genera: *Chlamydia* and *Chlamydophila*. *Chlamydophila* species include *C. caviae* as well as *C. pneumoniae* (humans, horses, koalas) and *C. psittaci* (birds) (Everett et al., 1999; Murray, 1964).

Unlike most bacteria, the cell walls of *Chlamydiaceae* do not have a peptidoglycan layer, but they do have a major outer-membrane protein, which is the determinant for serologic classification (Greenwood, 2007; Songer and Post, 2005). They also have a unique life cycle which consists of two forms; a small infectious elementary body which is more similar to a spore in that it is environmentally resistant and not metabolically active and a larger metabolically active, non-infectious reticulate body that is responsible for division within the host cell.

EPIZOOTIOLOGY AND PATHOGENESIS Generally, *C. caviae* infection is thought to be endemic in guinea pig colonies (Percy and Barthold, 2007), although its detection in colonies has been variable. In a survey done in 1964 of five herds of guinea pigs, conjunctival staining revealed the organism in four out of five herds, although not in any guinea pigs less than 4 weeks of age (Murray, 1964). In 2006, two breeding facilities of conventional guinea pigs in Korea were examined by conjunctival staining and no positive organisms were seen (Park et al., 2006). A survey of pet guinea pigs with normal conjunctiva, also revealed no positive staining (Coster et al., 2008), which may reflect the sensitivity of the test used or the actual prevalence of *C. caviae*. In a study using real-time PCR for diagnosis, *C. caviae* was detected in 12 out of 12 guinea pigs tested, four out of four rabbits, and one dog from samples obtained from a diagnostic laboratory (Pantchev et al., 2010). *C. caviae* in a second report was identified via PCR from conjunctival swabs from a rabbit, cat, and human that lived in the same household as infected guinea pigs (Lutz-Wohlgroth et al., 2006). Also utilizing PCR and DNA sequencing, *C. caviae* was detected in foals with conjunctivitis, rhinitis, and coughing, indicating the host range of the species of *Chlamydiaceae* may continue to be refined as new diagnostic tests are utilized (Gaede et al., 2010).

One study identified *Acanthamoebae* spp. via PCR from two guinea pigs with conjunctivitis that were also PCR positive for *C. caviae* (Lutz-Wohlgroth et al., 2006). Their role in the disease process is unclear.

Urogenital disease has been reported in natural infections with *C. caviae* and has been reproduced in experimental models (Lutz-Wohlgroth et al., 2006; Mount et al., 1973). In experimental infections, inoculation with *C. caviae* in the lower genital tract of female guinea pigs causes a self-limiting infection lasting 3–4 weeks. Typically, the infection involves the epithelium of the

cervix with very little inflammation. However, in 80% of the animals, the infection progresses to involve the oviducts, with half of the animals developing pathologic changes in the oviducts including inflammation and fibrosis (Barron et al., 1979; Rank and Sanders, 1992). Infection can be transferred from infected male animals to females during sexual intercourse and vertically from dam to pups (Padilla-Carlin et al., 2008; Miyairi et al., 2010).

In experimental infections, both cell-mediated and humoral immunity are important in recovery and resistance to re-infection (Miyairi et al., 2010). Early infection is characterized by influx of polymorphonuclear cells while later in infection, lymphocytes predominate. T-cell depletion results in chronic infection and delayed clearance of the organisms. Decreased antibody response also correlates with delayed clearance of the organisms (Miyairi et al., 2010; Rank et al., 1979).

CLINICAL MANIFESTATIONS *C. caviae* has been primarily associated with conjunctivitis. Guinea pigs have reddened, swollen conjunctiva with serous to purulent discharge, follicular hypertrophy, and pannus (Deeb et al., 1989; Lutz-Wohlgroth et al., 2006; Murray, 1964; Padilla-Carlin et al., 2008; Strik et al., 2005). Generally the conjunctivitis resolves in 3–4 weeks. Occasionally, conjunctivitis is accompanied by rhinitis. In one study, nasal discharge was present in 31 of 39 of the animals with ocular discharge (Lutz-Wohlgroth et al., 2006). Vaginal discharge was seen in 25% (ten of 39) of the animals although the organism could not be recovered by PCR from either the nose or the vagina. Abortion was recorded in two animals. An early study also reported rhinitis, bronchopneumonia and abortions, although this study was complicated by infection with *Streptococcus pneumoniae* and *Bordetella bronchiseptica* (Schmeer et al., 1985).

PATHOLOGY Histological evaluation of the eyes and surrounding tissue reveals a mixed inflammatory response and congestion beneath the conjunctival epithelium (Deeb et al., 1989; Lutz-Wohlgroth et al., 2006). Histological examination of the urogenital tract has primarily been described following experimental infection and consists of inflammation of the endometrium, mesosalpinx, and oviduct with a mixed inflammatory infiltrate and fibrosis (Barron et al., 1979; Rank and Sanders, 1992).

DIAGNOSIS Diagnosis is by cytology, PCR, culture, tissue assays, and serology (Songer and Post, 2005). Giemsa, Gimenez, or Macchiavello stains on cytologic preparations reveal inclusions in the cytoplasm. Inclusions are a dark purple with Giemsa and red with Gimenez or Macchiavello stains. Cytology can be insensitive hence PCR can be used in addition (Pantchev et al., 2010; Strik et al., 2005). In one study, 31 samples

were tested via cytology and PCR (Lutz-Wohlgroth et al., 2006). Twenty-one were positive by PCR for *C. caviae*, however, no samples were positive by cytology. As *C. caviae* is an obligate intracellular pathogen, it cannot be cultured in cell-free media, but only on specific cell lines (Songer and Post, 2005). This is an insensitive and difficult process that is not typically used for diagnosis. Direct fluorescent antibody test and enzyme immunoassays can be used to detect antigens in cytology samples or tissues (Percy and Barthold, 2007; Songer and Post, 2005).

PREVENTION AND THERAPY Generally, the disease is self-limiting and treatment is not required (Percy and Barthold, 2007; Quesenberry and Carpenter 2004). No current vaccine prevents chlamydial infection, although vaccination studies have demonstrated a decrease in the intensity of the disease following vaccination (Padilla-Carlin et al., 2008). Recognition that zoonotic transmission is a possibility should guide appropriate personal protective equipment choices (Lutz-Wohlgroth et al., 2006).

Citrobacter

BACKGROUND AND ETIOLOGY *Citrobacter* is a genus of Gram-negative coliform bacteria of the family *Enterobacteriaceae* (Boone et al., 2001). In the 1960s and 1970s, a disease eventually named transmissible murine colonic hyperplasia caused by coliform bacteria of the genus *Citrobacter* was recognized (Mundy et al., 2005; Percy and Barthold, 2007; Petty et al., 2010). Originally described as unusual biotypes of *Citrobacter freundii*, these organisms were eventually separated into their own species, *Citrobacter rodentium*, on the basis of DNA sequencing studies (Luperchio et al., 2000; Petty et al., 2010). Whether the organisms that caused severe septicemia and death in guinea pigs in 1988 (Ocholi et al., 1988) and other disease syndromes in hysterectomy-rederived guinea pigs (Boot and Walvoort, 1986) are *C. freundii* as originally indicated or *C. rodentium* is unclear.

PATHOGENESIS, CLINICAL MANIFESTATIONS, AND PATHOLOGY There are two reports of disease associated with *Citrobacter* spp. in guinea pigs (Boot and Walvoort, 1986; Ocholi et al., 1988). First, *Citrobacter* spp. were isolated from germ-free guinea pigs that were exposed to defined flora from gnotobiotic mice (Boot and Walvoort, 1986). *Citrobacter* spp. were isolated from the middle ear, spleen, mammary gland, and kidney of some animals as well as the intestinal tract, suggesting an ability to cause varied disease in guinea pigs that are not populated with normal flora. Second, an epizootic of *Citrobacter* spp. septicemia in a large colony of conventional guinea pigs was reported (Ocholi et al., 1988). Animals presented with diarrhea, dyspnea, and

decreased appetite. Mortality in weanlings and breeders was 115 of 1300 animals. Gross necropsy revealed lung consolidation with pleural adhesions as well as enteritis and thickening of the intestinal wall. Fibrinous pneumonia and septic thrombi in the capillaries of the lung, liver, and spleen were seen histopathologically. *Citrobacter* spp. were consistently isolated in pure culture from the lung, liver, spleen, and intestine.

DIAGNOSIS Culture is the traditional method of detecting *Citrobacter* spp. which grow well on normal media, are aerobic or facultative anaerobic, ferment glucose, produce catalase, but not oxidase, and are generally lactose-negative or later lactose-fermenting (Greenwood, 2007). However, PCR is more sensitive than bacterial culture for detection of *C. rodentium* in feces from mice (McKeel et al., 2002).

PREVENTION AND THERAPY *C. freundii* strains utilize a number of methods to encode resistance to ampicillin and cephalosporins (Pfeifer et al., 2010). Enrofloxacin has been successful in treating mice infected with *C. rodentium* (Maggio-Price et al., 1998). Prevention would include eliminating contact with *C. rodentium*-infected mice and other rodents.

Clostridium piliforme (Tyzzer's Disease)

BACKGROUND *Clostridium piliforme*, first described in 1917 (Tyzzer, 1917), causes severe disease in many laboratory animals as well as other mammals (Percy and Barthold, 2007). Although rare in modern colonies, outbreaks in mice, rats, rabbits, and guinea pigs have been reported and *C. piliforme* is found in both wild (Wobeser et al., 2009) and domestic mammals (Borchers et al., 2006; Ikegami et al., 1999). While Tyzzer's disease is not generally considered zoonotic, infection of an HIV-positive patient has been reported (Smith et al., 1996).

ETIOLOGY *Clostridium piliforme* (formerly *Bacillus piliformis*) is a Gram-negative, spore-forming, anaerobic rod that can survive for as long as five years in the environment (Percy and Barthold, 2007; Songer and Post, 2005).

PATHOGENESIS *C. piliforme* is thought to be transmitted via fecal-oral transmission. In experimental models, oral inoculation was successful when other routes of inoculation did not result in disease (Waggie et al., 1987). Vertical transmission has been reported in one case of hysterectomy-rederived guinea pigs (Boot and Walvoort, 1984). In outbreaks of Tyzzer's disease in other species, usually predisposing factors such as stress, overcrowding, poor sanitation, or immune-modulating treatments contribute to the development of disease (Percy and Barthold, 2007).

CLINICAL MANIFESTATIONS Clinical signs generally consist of diarrhea, unthriftiness, dehydration, cachexia, or acute death (Boot and Walvoort, 1984; McLeod et al., 1977; Zwicker et al., 1978) typically seen in weanlings. Subclinical infections have been noted (Boot and Walvoort, 1984).

PATHOLOGY Lesions are usually found only in the gastrointestinal tract in young guinea pigs, although liver lesions have been reported in some animals (Sparrow, 1978; Waggle et al., 1987). Grossly, pinpoint gray foci occur on the ileum, cecum, and colon as well as enlarged, reddened mesenteric and colonic lymph nodes (McLeod et al., 1977; Sparrow, 1978; Waggle et al., 1987; Zwicker et al., 1978). White to tan pinpoint foci are also observed on the liver. Microscopically, foci of necrosis occur in the mucosa of the ileum, cecum, and colon as well as foci of periportal coagulative hepatocellular necrosis when the liver is involved. Clusters of intracellular organisms can be observed via silver stain or Giemsa stain in affected enterocytes and hepatocytes. In two reports, affected animals have also had large numbers of spirochetes evident at necropsy (McLeod et al., 1977; Zwicker et al., 1978).

DIAGNOSIS *C. piliforme* cannot be cultured using standard media, although it can be isolated by inoculation of cell lines, embryonated hen's eggs, and primary mouse or chick embryo cell cultures (Niepceon and Licoism, 2010; Percy and Barthold, 2007). Therefore, diagnosis typically relies on characteristic lesions and organisms observed on histopathology using a Warthin-Starry silver stain or Giemsa stain (Percy and Barthold, 2007). PCR has been used to detect *C. piliforme* in feces from rats (Furukawa et al., 2002). Nested PCR was developed to increase the specificity of detection in tissues, better separating *C. piliforme* from other closely related organisms used conserved regions of 16S ribosomal RNA (Niepceon and Licois, 2010). Serology to detect antibodies has been used to monitor colonies for this organism (Boot and Walvoort, 1984; Kraft and Meyer, 1990).

TREATMENT AND CONTROL Treatment of individual animals has not been reported. Tyzzer's disease affects a wide variety of animals and immune-compromised people. Prevention entails modern husbandry and sanitation practices, preventing contamination of food and bedding, and separation of species.

Escherichia coli

Escherichia coli are aerobic, straight Gram-negative rods and are part of the normal intestinal flora of most vertebrates, including guinea pigs (Crecelius and Rettger, 1943; Songer and Post, 2005). Several pathotypes have been reported (e.g. EPEC-enteropathogenic strains),

some which produce cytotoxins. Diarrhea, rough hair coats, wasting and death have been reported to be associated with *E. coli* infection in conjunction with other environmental stressors (Ganaway, 1976). In addition, there is one report of a compilation of cases of mastitis in guinea pigs from a diagnostic lab over a four year period (Kinkler et al., 1976). Of the 26 cases where cultures were taken, *E. coli* was found in 17 cases with the next most common isolate being *Klebsiella pneumoniae* in six cases. Diagnosis may be obtained by culture of affected organs on MacConkey agar and differentiation from other enteric Gram-negative bacteria by a number of biochemical reactions such as indole production and utilization of certain sugars (Greenwood, 2007).

Klebsiella pneumoniae

BACKGROUND Perkins (1901) described an epizootic outbreak in 25 laboratory guinea pigs that resulted in the death of all but two animals 18–24 hours after the onset of disease. A short bacillus, often paired, was isolated in the blood, spleen, liver, and peritoneal exudates. Disease was reproduced in naïve guinea pigs subsequently administered the bacterium by the intraperitoneal route. Perkins' findings were similar to those of Howard (1899), who inoculated dogs, rabbits, mice, pigeons, and guinea pigs with a bacillus organism isolated from human patients.

ETIOLOGY *Klebsiella pneumoniae* is a Gram-negative, rod-shaped bacillus from the genus *Klebsiella* and family *Enterobacteriaceae* (Boone et al., 2001). *K. pneumoniae* is facultatively anaerobic, oxidase-negative, and produces acid and gas from lactose. It is an enteric bacterium, noted in the intestinal tract of 5% of healthy humans (Ganaway, 1976). It can also reside in the skin and mouth. *K. pneumoniae* causes pneumonia in guinea pigs of both sexes and all ages, although there are few reports of natural infections of this animal species with this organism.

CLINICAL MANIFESTATIONS In the epizootic outbreak described by Perkins, animals presented as anorexic and ungroomed, and their illness escalated in severity until, in some animals, a comatose condition ensued (Perkins, 1901). Animals usually died 18–24 hours after the onset of clinical signs. In other epizootic outbreaks, dyspnea has been reported prior to reaching the comatose state (Ganaway, 1976). Less severely infected animals may be able to recover from disease and develop immunity to re-infection (Perkins, 1901). Otitis media and other signs consistent with a state of septicemia have been associated with clinical disease (Fox, 2002; Ganaway, 1976; Kohn, 1974).

PATHOLOGY Seropurulent or serofibrinous peritonitis is noted at necropsy (Fox, 2002; Ganaway, 1976;

Perkins, 1901). Additionally, such exudates may be observed in the pleural cavity and pericardial sac. Congestion of the liver, spleen, and kidney has been noted, as has hepatic coagulative necrosis and degeneration of the renal tubule cells. An acute, necrotizing bronchopneumonia may be observed.

DIAGNOSIS Diagnosis of *K. pneumonia* is usually via culture of the upper respiratory tract. The bacterium has been isolated from blood, spleen, liver, peritoneal exudate, and cerebrospinal fluid (Fox, 2002; Ganaway, 1976; Perkins, 1901). *K. pneumoniae* can be differentiated from *K. oxytoca*, another *Klebsiella* spp. frequently recovered in animals, by the fact that it is indole-negative and does not grow at 10°C, while *K. oxytoca* is indole-positive and does grow at 10°C.

PREVENTION AND THERAPY Antibiotic treatment for *Klebsiella* infection should be based on sensitivity of culture isolates. Ceftriaxone and cefodizime were found effective at clearing *K. pneumoniae* in experimentally infected guinea pigs (Drago et al., 1999), although generally, chloramphenicol, enrofloxacin, trimethoprim-sulfa, and aminoglycoside drugs are considered the safest antibiotic choices for use in guinea pigs.

Lawsonia intracellularis

BACKGROUND AND ETIOLOGY Proliferative enteritis associated with *Campylobacter*-like organisms has been reported in many species including pigs, hamsters, rats, rabbits, foals, NHPs, ferrets, and deer (Lawson and Gebhart, 2000). In the early 1990s, molecular techniques resulted in the identification of *Lawsonia intracellularis* as the causative agent of many of these syndromes. Since that time, diagnostics, including PCR, have enabled the diagnosis of *L. intracellularis* infection (Collins et al., 2011).

PATHOGENESIS, CLINICAL MANIFESTATIONS, AND PATHOLOGY There have been two reports of disease in guinea pigs associated with *Campylobacter*-like organisms, both prior to the identification of *L. intracellularis*. In 1981, one 3.5-month-old guinea pig, treated with steroids for 90 days as part of a study, displayed no clinical signs of disease but on necropsy had marked duodenal mucosal hyperplasia with intracellular Warthin-Starry stained argyrophilic bacteria in affected epithelial cells (Elwell et al., 1981). Two cagemates of this guinea pig, that had the same steroid treatment, died at days 13 and 30. One had diarrhea for two days prior to death. Histopathology revealed acute enteritis with mucosal erosions without mucosal hyperplasia in both animals. Bacteria similar to that seen in the first case were found in the epithelial cells. The authors noted this organism was very similar to the organism associated with

transmissible mucosal hyperplasia of hamsters (subsequently identified as *L. intracellularis*).

In 1983, two dams and five young guinea pigs in a laboratory in Japan developed diarrhea, anorexia, weight loss, and dehydration. Two young animals died 5–7 days post-onset of clinical signs. Grossly, there was thickened jejunum and ileum. Histopathologically, there was hyperplasia and proliferation of the epithelial cells and dilation of the glands primarily in the ileum and the distal part of the jejunum. Immature epithelial cells contained various numbers of intracytoplasmic, non-membrane-bound, curved organisms resembling *Campylobacter* spp. bacteria.

DIAGNOSIS Characteristic histopathological lesions, immunohistochemistry, and PCR are diagnostic (Collins et al., 2011; Lawson and Gebhart, 2000).

PREVENTION AND THERAPY Antibiotics have been used to treat a similar proliferative enteritis in swine with success (Lawson and Gebhart, 2000). Care should be taken to avoid penicillins and other antibiotics implicated in antibiotic-associated dysbacteriosis (Percy and Barthold, 2007).

Leptospira

BACKGROUND AND ETIOLOGY *Leptospira* are tightly coiled, aerobic, Gram-negative, flagellated spirochetes belonging to the genera *Leptospira*, family *Leptospiraceae*, phylum, Spirochaetes (Boone et al., 2001). Before 1989, the genus, *Leptospira*, was divided into two species, *L. interrogans* (pathogenic) and *L. biflexa* (non-pathogenic) which each contained strains separated into numerous serovars (Levett, 2001). More recently, DNA analysis has identified 20 species of *Leptospira* and revisions of these taxonomic groups are ongoing (Galloway and Levett, 2010; Levett, 2001).

EPIZOOTIOLOGY AND PATHOGENESIS *Leptospira* are zoonotic organisms with a world-wide distribution that infect a variety of mammals, including mice, rats, carnivores, and ruminants (Ko et al., 2009; Levett, 2001; Percy and Barthold, 2007). Wild guinea pigs in South America (*Cavia porcellus apera*), infected with *Leptospira* spp., have been implicated as the natural reservoir responsible for transmitting the disease to domestic cattle (Blood et al., 1963). In domestic guinea pigs, there have been only a few reports of natural infection, although the guinea pig infection models have been used extensively in *Leptospira* research (Ko et al., 2009; Van Hoosier and Robinette, 1976). Data from research models and infections in other species indicate that transmission occurs from direct contact with infected urine, soil, or water as *Leptospira* are excreted in the urine (Ko et al., 2009; Lourdault et al., 2009).

CLINICAL MANIFESTATIONS AND PATHOLOGY A report from 1937 describes a natural infection where one out of 12 guinea pigs died from leptospirosis (Ganaway, 1976). Pathological findings include jaundice, petechial hemorrhages in the skin, fascia, and muscles, and ecchymosis in the lung. A more recent report of a case of leptospirosis in a 21-year-old man, described 20 out of 50 guinea pigs that died on his farm in Germany. Three of the remaining guinea pigs were tested and were serologically positive for *Leptospira* serovar *bratislava* similar to the man. No necropsies of affected animals were described.

DIAGNOSIS Direct examination of infected tissue, urine, or blood with dark-field microscopy, immunofluorescence, or light microscopy with special stains is useful for diagnosis (Greenwood, 2007; Levett, 2001). Culture and PCR are additional diagnostic tools. Growth in culture can be slow. Generally, antibody detection is used to demonstrate previous infection.

PREVENTION AND THERAPY Antimicrobial treatment of individual animals is generally successful in other species (Pischke et al., 2010; van de Maele et al., 2008), although in guinea pigs, care must be taken to avoid antibiotic-associated dysbacteriosis (Percy and Barthold, 2007). Prevention includes preventing exposure to wild rodents and *Leptospira*-infected food, bedding, soil, or water.

Listeria monocytogenes

BACKGROUND *Listeria monocytogenes* was first discovered in 1926 by Murray et al. (1926), who isolated it from laboratory rabbits and guinea pigs. Since that time, few cases have been reported in guinea pigs, although guinea pigs are very susceptible and have been used extensively to model the pathogenesis of listeriosis (Cossart, 2007; Disson et al., 2009; Fox, 2002).

ETIOLOGY *Listeria monocytogenes* is a facultative intracellular, non-spore-forming, zoonotic, food, soil-, and silage-borne bacterium which causes disease in birds and many mammals.

PATHOGENESIS, CLINICAL MANIFESTATIONS, AND PATHOLOGY In spontaneous infections of guinea pig colonies, *L. monocytogenes* infection has been correlated with acute death, reproductive disorders such as abortions and still births, as well as conjunctivitis (Chukwu et al., 2006; Colgin et al., 1995; Fox, 2002). In an outbreak associated with feeding infected greens to a colony of 80 guinea pigs, the mortality rate was reported to be 80–100% with lung and liver lesions predominating (Chukwu et al., 2006).

Conjunctivitis was reported in one outbreak affecting 11 out of 49 newly arrived guinea pigs (Colgin et al.,

1995). *L. monocytogenes* was cultured from 10 of 12 specimens submitted. The animals presented with unilateral or bilateral serous to purulent discharge with hyperemic conjunctiva. Histologically, there was corneal ulceration, stromal edema, and vascular proliferation. The conjunctiva contained an inflammatory infiltrate and the lacrimal gland had multifocal areas of inflammation and necrosis. Intracytoplasmic Gram-positive rods were seen in the conjunctival epithelium and no chlamydial organisms were identified on conjunctival scrapings or by histopathology. Experimentally, guinea pigs have been shown to be susceptible to *Listeria*-induced conjunctivitis.

PREVENTION AND THERAPY Prevention of contamination of food or bedding is essential to prevent this infection.

Pasteurella multocida

BACKGROUND Pasteurellosis is rare in present-day guinea pig laboratory colonies. Reports of epizootic outbreaks due to Gram-negative coccobacilli were reported in Europe in the late 1800s (Wright, 1936).

ETIOLOGY *Pasteurella multocida*, a Gram-negative, non-spore-forming and non-motile rod is a member of the *Pasteurella* genus and the *Pasteurellaceae* family (Songer and Post, 2005).

EPIZOOTIOLOGY AND PATHOGENESIS *Pasteurella* spp. are mucosal commensal organisms of the oropharynx and gastrointestinal tract of many species, including man (Songer and Post, 2005). When stressed, the animal's immune system can be overwhelmed and, in guinea pigs, pneumonia may result. *P. multocida* can be transmitted to man via contact with infected saliva, which is likely to occur as a result of a bite wound or scratch.

CLINICAL MANIFESTATIONS Wright detailed an outbreak of pasteurellosis that killed 600 guinea pigs over a 1-year period (Wright, 1936). Clinical signs were not noted prior to death. *P. multocida* has been isolated from cases of conjunctivitis (Percy and Barthold, 2007).

PATHOLOGY Fibrinopurulent serositis is present in cases of guinea pig pasteurellosis (Fox, 2002; Ganaway, 1976; Wright, 1936). Such serositis has been noted in the pericardium, pleura, and peritoneum. Lung consolidation may also be observed (Fox, 2002).

DIAGNOSIS *Pasteurella* infection is diagnosed via culture. The bacteria do not reliably grow well on MacConkey agar, therefore blood agar is routinely used for isolation (Ganaway, 1976; Songer and Post, 2005). Plates should be incubated at 3–5% CO₂ at 37°C for

24–48 hours (Songer and Post, 2005). In animal tissue or fluids, *P. multocida* appears as a bipolar rod after aniline dye staining, but in a smear taken from culture, it stains evenly (Ganaway, 1976). Unlike *P. pneumotropica*, *P. multocida* is o-nitrophenyl- β -D-galactoside (ONPG) and urease-negative (Songer and Post, 2005). *P. pneumotropica* is also positive for the fermentation of mannose, while *P. multocida* is negative. An ELISA-based assay has been developed to monitor antibodies to the SP group of *Pasteurellaceae*, which is one of five serologically distinct groups of *Pasteurellaceae* in guinea pigs (Boot et al., 1995).

PREVENTION AND THERAPY Antibiotic treatment of *P. multocida* should be based on culture sensitivities. Antimicrobial therapy will eliminate clinical signs, but will not eliminate the organism from the colony (Songer and Post, 2005).

Pseudomonas* and *Aeromonas

BACKGROUND Scherago (1937) reported on a fatal epizootic septicemia in a colony of young guinea pigs received from a local breeder. Animals died within 5–6 hours after showing clinical signs and “Gram-negative, non-spore-forming encapsulated rods with rounded ends and straight sides appearing singly and occasionally in pairs end to end” were found on smears from the peritoneal cavities of all examined animals. The route of infection was not determined in this colony, but Scherago did complete the required steps to fulfill Koch’s postulates and demonstrated that the infection was due to *Pseudomonas caviae*. *P. caviae* has since been reclassified as *Aeromonas caviae*, of the *Aeromonadaceae* family.

Pseudomonas aeruginosa was noted as the cause of pulmonary botryomycosis in two guinea pigs (Bostrom et al., 1969).

ETIOLOGY *P. aeruginosa*, a member of the genus *Pseudomonas*, is part of the *Pseudomonadaceae* family (Songer and Post, 2005). *Pseudomonas* spp. are Gram-negative rods that are aerobic, non-spore-forming, oxidase-positive, and non-fermentative.

EPIZOOTIOLOGY AND PATHOGENESIS *Pseudomonas* organisms thrive in aqueous environments (Songer and Post, 2005). Additionally, they are ubiquitous in soil, decaying organic matter, and vegetation. *Pseudomonas* spp. are opportunistic pathogens of both humans and animals, yet, there are few reports of infections caused by these agents in guinea pigs (Fox, 2002).

CLINICAL MANIFESTATIONS Bostrum et al. (1969), did not describe the clinical signs associated with the epizootic outbreak of pulmonary botryomycosis. Otitis

media, conjunctivitis, and an inflamed prostate gland are signs that have been associated with *Pseudomonas* in other reports of guinea pig infection (Fox, 2002).

PATHOLOGY A focal, necrotizing bronchopneumonia, along with pulmonary consolidation has been described in cases of guinea pig *Pseudomonas* infection (Bostrom et al., 1969; Fox, 2002; Ganaway, 1976; Percy and Barthold, 2007). Bostrum noted atypical “sulfur granules”, resembling the spherules of *Coccidioides immitis*, in the lungs of affected animals (Bostrom et al., 1969).

DIAGNOSIS *P. aeruginosa* can be cultured from infected tissues (Songer and Post, 2005). *P. aeruginosa* grows well on MacConkey agar and trypticase soy agar. Additionally, Cetrimide agar, a commercial formulation, selectively isolates *P. aeruginosa*.

PREVENTION AND THERAPY The best means of controlling *Pseudomonas* is to reduce possible sources of infection, such as damp bedding or stagnant water. Animal drinking water should be monitored for *P. aeruginosa*, and in some situations, water may be chlorinated to eliminate contamination (Songer and Post, 2005). Reducing stressors, such as overcrowding and concurrent infection, also aids in control. *Pseudomonas* spp. have an inherent resistance to many antimicrobials.

Salmonella

BACKGROUND Some of the earliest reports of salmonellosis in guinea pigs date back to the 1800s (Nelson and Smith, 1927). Multiple outbreaks of natural infections in guinea pig colonies in the United States were documented throughout the early 1900s (Holman, 1916; Nelson and Smith, 1927). Since this period of time, as laboratory standards have grown more stringent and general hygiene and sanitation have improved, the occurrence of salmonellosis in laboratory guinea pigs has declined greatly (Fox, 2002; Harkness and Wagner, 1995; Percy and Barthold, 2007).

ETIOLOGY Members of the genus *Salmonella* are Gram-negative, non-spore-forming bacilli that are facultative anaerobes. *Salmonella* other than *S. typhi* or *S. paratyphi* produce hydrogen sulfide, as well as acid and gas from glucose, but not lactose (Ganaway, 1976; Songer and Post, 2005). *Salmonella* is a member of the *Enterobacteriaceae* family. While multiple serovars have been recovered from guinea pigs, the most frequently isolated are *S. typhimurium* and *S. enteritidis* (Fox, 2002; Ganaway, 1976; Harkness and Wagner, 1995; Quesenberry and Carpenter, 2004; Percy and Barthold, 2007). Humans are susceptible to disease from the same serovars and phage types as guinea pigs (Fish et al., 1968; Percy and Barthold, 2007; Rigby, 1976).

EPIZOOTIOLOGY AND PATHOGENESIS Guinea pigs are extremely susceptible to *Salmonella* (Fox, 2002). Transmission of *Salmonella* is primarily fecal–oral or via ingestion of contaminated feed (contaminated with feces of infected guinea pig or a wild rodent) (Fox, 2002; Harkness and Wagner, 1995; Percy and Barthold, 2007; Quesenberry and Carpenter, 2004). Entry via the conjunctiva has also been reported in guinea pig epizootics (Iijima et al., 1987; Moore, 1957). Additionally, ingestion of contaminated blood or tissue can transmit *Salmonella* (Fox, 2002). Stressed animals, due to conditions such as weaning, parturition, old age or poor nutrition, are more susceptible to infection (Quesenberry and Carpenter, 2004). Recovered animals can develop an asymptomatic carrier state with intermittent shedding in the feces, making elimination of this bacterium from a colony difficult (Fox, 2002; Harkness and Wagner, 1995; Percy and Barthold, 2007). The incubation time for *Salmonella* is 5–7 days and epizootic or enzootic patterns of infection are possible (Fox, 2002; Ganaway 1976).

CLINICAL MANIFESTATIONS Disease due to *Salmonella* occurs as peracute septicemia or acute, subacute, or chronic enteritis (Songer and Post, 2005). Acute disease is characterized by high morbidity and low to moderate mortality. Clinical signs include depression, weakness, and fever. Dehydration and electrolyte imbalance may be severe. Infection spreads rapidly within a colony. Conjunctivitis and abortions have also been noted (Percy and Barthold, 2007). Although weight loss is present, diarrhea may or may not occur in guinea pigs. In an epizootic outbreak, young guinea pigs may die suddenly without prior signs of illness.

PATHOLOGY In acute and peracute cases, there may be no lesions seen at necropsy (Harkness and Wagner, 1995; Percy and Barthold, 2007). Splenomegaly may be observed in subacute and chronic infections. Minute white foci and/or yellowish-white nodules, up to several millimeters in diameter, may occur in the spleen, liver, or other lymph nodes. Similar foci or nodules may also occur in the lung, pleura, peritoneum, and in the wall of the uterus. Rupture of the nodules may result in a suppurative pleuritis, peritonitis, and/or pericarditis. Gas may be observed in the small and large intestine, along with catarrhal enteritis (Fish et al., 1968).

On histopathology, lesions support bacterial invasion, with subsequent necrosis and abscess formation (Ganaway, 1976). Nodules are noted to be “typhoid-like” granulomas, with areas of central necrosis, surrounded by histiocytes. Polymorphonuclear leukocytes and histiocytes are present in the Peyer’s patches of the ileum and jejunum.

DIAGNOSIS *Salmonella* can be isolated from blood, feces, and affected organs (most commonly from the

spleen) (Fox, 2002). Recovery requires special conditions: enrichment in a broth such as selenite-F or tetracycline and culture at 37°C on MacConkey’s or brilliant green agar (Fox, 2002; Songer and Post, 2005).

PREVENTION AND THERAPY Prevention is the best approach (Harkness and Wagner, 1995; Rigby, 1976). All fresh fruit and vegetables should be thoroughly washed and stored in airtight containers. Since so many species of mammals are potential carriers, the exclusion of wild rodents, birds, and other vermin is essential. When increased colony mortality is apparent and a chronic case is recognized at necropsy, *Salmonella* infection is likely widespread and well established in the colony. In situations such as this, it is reasonable to depopulate the colony, sanitize the premises, and restock with *Salmonella*-free guinea pigs.

Treatment on an individual basis will include the appropriate antibiotics with fluid therapy. Animals that become asymptomatic after treatment may become carriers, a problem with zoonotic potential. Antimicrobial resistance is expanding; 90% of *Salmonella* isolates from domestic animals demonstrate multi-drug resistance (Songer and Post, 2005).

Streptobacillus moniliformis

BACKGROUND *Streptobacillus moniliformis* is one of the causative agents of rat bite fever, a significant worldwide, zoonotic, systemic infection of humans associated with contact with rats (Gaastra et al., 2009; Khatchadourian et al., 2010). It was described in early recorded history in India and was recognized in the US as early as 1839 as a syndrome that developed following contact with rats (Gaastra et al., 2009). *S. moniliformis* also causes Haverhill fever, a systemic infection of those who eat food contaminated with rat urine or feces (Abdulaziz et al., 2006; McEvoy et al., 1987; Shanson et al., 1983).

ETIOLOGY *Streptobacillus moniliformis*, a facultative anaerobic, non-motile, non-capsulate, pleomorphic, Gram-negative rod, is the type species of the genera, *Streptobacillus*, family *Leptotrichiaceae* within the phylum *Fusobacteria* (Greenwood, 2007; Nolan et al., 2009). Its genome has been completely sequenced (Nolan et al., 2009).

EPIZOOTIOLOGY AND PATHOGENESIS *S. moniliformis* is commonly found in the nasopharynx of wild and pet rats (Gaastra et al., 2009; Wullenweber, 1995), although typically excluded from modern SPF laboratory animal facilities (Nicklas et al., 2002; Pritchett-Corning et al., 2009). The organism has also been found in carnivores, calves, pigs, turkeys, and a variety of rodents including guinea pigs presumably following contact with infected rats (Gaastra et al., 2009; Wullenweber, 1995).

CLINICAL MANIFESTATIONS AND PATHOLOGY Most commonly, *S. moniliformis* in guinea pigs has been associated with cervical lymphadenitis and other localized abscesses (Aldred et al., 1974; Fleming, 1976; Percy and Barthold, 2007; Van Hoosier and Robinette, 1976; Wullenweber, 1995). Severe necrotizing bronchopneumonia with pyogranuloma formation was reported in one guinea pig by Kirchner et al. (1992). No clinical signs of disease were noted in their report.

DIAGNOSIS Gram stain of smears can be suggestive of infection by demonstrating short bacilli in chains or long filaments followed by bacterial culture and isolation (Greenwood, 2007; Kirchner et al., 1992; Wullenweber, 1995) although because of the fastidious nature of *S. moniliformis*, PCR is more commonly used for detection (Boot et al., 2002). If culture is attempted, samples must be cultured on a media containing serum, blood or ascitic fluid, such as Loeffler's serum medium (Greenwood, 2007). Cross-reactive sequences between *Leptotrichia* spp. and *S. moniliformis* have been demonstrated and can result in false positives when PCR is used for diagnosis (Boot et al., 2008; Wouters et al., 2008). Sequence of the amplicon can differentiate these outcomes. As the entire sequence of *S. moniliformis* has recently been completed (Nolan et al., 2009), new primers for diagnosis may be forthcoming. Antibodies to *S. moniliformis* can be demonstrated by ELISA (Boot et al., 1993b, 2006).

PREVENTION AND THERAPY Because the organism is not spread easily, outbreaks can be controlled by culling affected guinea pigs (Van Hoosier and Robinette, 1976). Treatment of individual animals with antibiotics is effective in other species (Gaastra et al., 2009; Wullenweber, 1995), although treatment should be approached with caution because of the zoonotic potential of this organism. Prevention of contact with infected rats, other animals that contact wild or infected rats, or infected food and/or bedding should eliminate introduction of this organism (Van Hoosier and Robinette, 1976).

Yersinia pseudotuberculosis

BACKGROUND Ganaway states that "one of the earliest recognized bacterial disease of the guinea pig was caused by *Yersinia pseudotuberculosis*" (Ganaway, 1976). In present day colonies of laboratory guinea pigs, natural outbreaks of pseudotuberculosis are rare (Fox, 2002; Percy and Barthold, 2007).

ETIOLOGY *Yersinia pseudotuberculosis*, an ubiquitous enteropathogen, is a Gram-negative, non-spore-forming, facultative anaerobic rod that is oxidase-negative and catalase-positive (Ganaway, 1976). It is non-hemolytic and produces both exotoxin and enzyme (Fox, 2002). Growth is

optimal at 20–30°C (Fox, 2002; Ganaway, 1976). The genus *Yersinia* is part of the family *Enterobacteriaceae* and, in addition to guinea pigs, it causes pseudotuberculosis in other rodents, cats, and turkeys (Songer and Post, 2005).

EPIZOOTIOLOGY AND PATHOGENESIS *Y. pseudotuberculosis* can result in clinical disease or a sub-clinical carrier state. Guinea pigs are very susceptible to infection with this bacterium (Fox, 2002; Ganaway, 1976). *Y. pseudotuberculosis* is shed in feces, therefore ingestion of food contaminated with feces from a carrier guinea pig, wild rodent, or bird can transmit the organism, as can aerosol spread, or entry via a bite wound or skin laceration (Fox, 2002; Ganaway, 1976; Rigby, 1976). Dams can pass infection to their pups (Fox, 2002). Orally absorbed organisms disseminate from the intestinal tract to the mesenteric lymph nodes.

Acute and chronic forms of disease have been described (Ganaway, 1976; Rigby, 1976). An acute septicemic form of infection can lead to mortality in 24–48 hours. A chronic infection that often lasts several weeks to months and ultimately results in death is the more classic pseudotuberculosis presentation.

CLINICAL MANIFESTATIONS The classic clinical presentation associated with *Y. pseudotuberculosis* is that of wasting and lymphadenitis, sometimes with accompanying diarrhea, and frequently resulting in death about a month after initial infection (Obwolo, 1977; Sebesteny, 1976). The acute form of the disease can present with no clinical signs or consist of one to two days of coughing and respiratory distress prior to death (Rigby, 1976).

PATHOLOGY Necropsy of animals chronically or sub-acutely infected with *Yersinia pseudotuberculosis* reveals nodules throughout the body, including the regional lymph nodes, spleen, liver, lung, and bone marrow (Fox, 2002; Percy and Barthold, 2007). The grayish-white spherical nodules vary from miliary pinpoint to 2–3 cm in diameter and may contain creamy to caseous exudate. In acute cases, nodules are noted in the intestinal wall, especially at the location of the terminal ileum and cecum, and often with accompanying mucosal ulceration and acute enteritis (Percy and Barthold, 2007). Lung congestion may be seen in acute cases (Rigby, 1976).

Yersinia nodules often have a central area of necrosis with neutrophilic infiltration; foamy macrophages are often noted in the periphery (Fox, 2002; Ganaway, 1976). Blood vessels within the nodule may contain bacterial emboli. In chronic lesions, fibroblasts and epithelial cells proliferate and nodules may become granulomatous, but do not calcify.

DIAGNOSIS *Y. pseudotuberculosis* can be cultured from abscesses (Rigby, 1976). Direct smears may also

be beneficial. In acute septicemic cases, *Yersinia* may be cultured from the blood (Ganaway, 1976). *Yersinia* spp. can be cultured on standard media and *Y. pseudotuberculosis* can be differentiated from *Y. pestis*, the causative agent of plague, by the fact that it is urease, and rhamnose-positive, while *Y. pestis* is negative for both of these growth conditions (Songer and Post, 2005).

TREATMENT AND CONTROL Euthanasia of infected animals is advised due to the fact that antibiotic treatment can result in a carrier state, which, due to its zoonotic potential, puts human handlers and staff at risk. A killed vaccine has been unsuccessful at protecting guinea pigs from infection, but a more recent live vaccine has produced promising results (Quintard et al., 2010).

FUNGAL INFECTIONS

Dermatophytosis – *Trichophyton mentagrophytes*, *Microsporum canis*, *Microsporum gypseum*

BACKGROUND Dermatophytosis, also known as ringworm or tinea, indicates infection with pathogenic fungi in the phylum Ascomycota that cause the bulk of superficial fungal infections in humans and animals (Ameen, 2010; Howard et al., 2003). The fungi are keratinolytic and keratinophilic and infection is usually limited to cornified layers of the skin, hair, or nails (Howard et al., 2003; Weitzman and Summerbell, 1995). Their importance as pathogens is clear in that the majority of dermatophytes infecting animals are zoonotic (Chermette et al., 2008). Originally, the dermatophytes were organized into three anamorphic, or asexual, genera, *Microsporum*, *Trichophyton*, and *Epidermophyton*. The primary structure associated with asexual reproduction is the conidium and classification into these genera was based on the morphology of the macroconidia in culture. Subsequent studies revealed sexual reproduction in certain *Microsporum* and *Trichophyton* spp. that occurs by means of an ascospore found within an ascus. The dermatophyte sexual states (teleomorphs) are classified in the genus, *Arthroderma* (Weitzman and Summerbell, 1995). Recent efforts at phylogenetic analysis and identification of dermatophytes have been achieved by sequencing 28S ribosomal DNA (rDNA) and internal transcribed spacer (ITS) regions flanking 5.8S rDNA (Drouot et al., 2009; Frealle et al., 2007; Symoens et al., 2011). Dermatophyte species can also be divided into three groups determined by their adaptation to a certain habitat. Human-associated dermatophytes are anthropophilic (e.g. *Trichophyton rubrum*), those primarily found on animals and occasionally infecting humans are zoophilic (e.g.

Trichophyton mentagrophytes), and species persisting in the soil are termed geophilic (e.g. *Microsporum gypseum*) (Weitzman and Summerbell, 1995), however some overlap does occur. Zoophilic and geophilic dermatophytes infecting humans cause a more intense inflammatory reaction than anthropophilic species (Weitzman and Summerbell, 1995).

ETIOLOGY Dermatophytosis in animals is most often caused by the anamorph species *Microsporum* and *Trichophyton*, however the infecting species can vary with the geographic region (Bond, 2010). Of these genera, *Trichophyton mentagrophytes* is the most common cause (Aho, 1980; Balsari et al., 1981; Drouot et al., 2009; Feuerman et al., 1975; Lopez-Martinez et al., 1984; McAleer, 1980a, 1980b; Papini et al., 1997; Pombier and Kim, 1975; Stenwig, 1985; Vangeel et al., 2000). *T. mentagrophytes* is a species complex with several variants including both anthropophilic and zoophilic pathogens. Pollock (2003) considered *T. mentagrophytes* var *mentagrophytes* as the most common variant infecting rodents, however the specific variant is not always reported in the literature. The teleomorphs are known for the *T. mentagrophytes* complex and there are two, *Arthroderma benhamiae* and *A. vanbreuseghemii*. The *A. benhamiae* genome has been sequenced (Burmester et al., 2011). The different variants and sexual states of the *T. mentagrophytes* complex coupled with more recent phylogenetic analyses presents confusion about proper nomenclature and species assignment (Drouot et al., 2009; Fumeaux et al., 2004). Infection with either *M. canis* or *M. gypseum* has also been reported in the guinea pig but less frequently (Feuerman et al., 1975; Papini et al., 1997).

EPIZOOTIOLOGY AND PATHOGENESIS Guinea pigs, and other animals, are infected by direct exposure to an infected animal, contaminated environments, or fomites. Arthroconidium produced by septation of hyphae are infectious and persist in the environment for months to years (Bond, 2010; Weitzman and Summerbell, 1995). Hyphae invade the stratum corneum eventually colonizing the hair follicles. The sequenced genome of *A. benhamiae* revealed numerous predicted protease-encoding genes and their secretion was confirmed experimentally in a keratin digestion assay indicating an important role in invasion and pathogenesis (Burmester et al., 2011). Young guinea pigs appear to be more susceptible to disease and other predisposing and susceptibility factors include pregnancy, high temperature and humidity, health status, and genetics (Pollock, 2003; Pombier and Kim, 1975). Surveys of dermatophytosis in guinea pigs have been reported from around the world, with prevalence ranging from 1.3–56% (Balsari et al., 1981; Drouot et al., 2009; Feuerman et al., 1975; Lopez-Martinez et al., 1984; Papini et al., 1997; Vangeel et al., 2000).

FIGURE 23.2 A well-circumscribed, hairless, scaling lesion on a guinea pig with dermatophytosis. Photo provided by Dr. Martha Hanes.

CLINICAL MANIFESTATIONS Infected guinea pigs are most often asymptomatic but can exhibit lesions typical of dermatophytosis. When present, lesions are most common on the head and appear to begin on the nose or muzzle and then can spread over the body to the trunk and limbs (Figure 23.2). Circumscribed or irregular lesions with combinations of alopecia, scale, crust, erythema, and ulceration develop, with or without pruritis, and spontaneous remission is possible (Drouot et al., 2009; McAleer, 1980a; Pollock, 2003; Pombier and Kim, 1975). Pustules may be associated with the lesions due to secondary bacterial infections. Furthermore, in one outbreak of *T. mentagrophytes*, affected animals were in poor body condition and there was approximately 50% mortality in young guinea pigs (Pombier and Kim, 1975). Onychomycosis is rare in the guinea pig (Drouot et al., 2009).

PATHOLOGY Microscopic analysis of affected epidermis and adnexa can include acanthosis, vascular congestion, dermal lymphocytic infiltration, folliculitis, perivascular, and interstitial dermatitis, and intra-epidermal pustules (Chermette et al., 2008; Pombier and Kim, 1975).

DIAGNOSIS Microscopy and culture are the primary means of diagnosing dermatophytosis. Wood's lamp can be used as a screening tool for *M. canis* and infected hairs will fluoresce with an apple-green color. However, false negatives can occur (Chermette et al., 2008). Hairs are plucked or the skin scraped from the periphery of an active lesion or from the whole lesion

FIGURE 23.3 Skin section stained with periodic acid-Schiff demonstrating dermatophyte arthroconidia and hyphae. Photo provided by Dr. Martha Hanes.

if there is no evidence of inflammation and samples placed in 10% potassium hydroxide to remove keratin. The samples are then examined for hair or skin invasion with hyphae and/or arthroconidia. To increase sensitivity, fluorescent microscopy with Calcofluor white and Congo red can be used (Bond, 2010; Robert and Pihet, 2008). Geimsa staining will also identify arthroconidia. All the dermatophytes infecting guinea pigs will have ectothrix hair shaft involvement. Prior to obtaining a skin or hair sample for culture, the area should be wiped with alcohol to reduce contamination. Saprophytic fungi contamination of the fur may hinder isolation of dermatophytes (Aho, 1983). Hair, skin, or crusts are collected using a sterile toothbrush, swab, forceps, scalpel blade, or surgical scrub brush and placed onto culture medium. Sabouraud's dextrose agar supplemented with cyclohexamide and chloramphenicol is commonly used. Dermatophyte Test Medium is available, however contamination can cause both false-positive and false-negative results (Robert and Pihet, 2008). If the animal is simply a mechanical carrier, results of repeated testing will vary (Chermette et al., 2008). Biopsy samples can be stained with periodic acid-Schiff or silver stains to detect arthroconidia and hyphae (Figure 23.3) (Chermette et al., 2008). As mentioned earlier, polymerase chain reaction (PCR) amplification and sequencing of ITS and 28S ribosomal DNA (Drouot et al., 2009; Fumeaux et al., 2004; Symoens et al., 2011) will identify isolates, and mating experiments can be performed (Hironaga et al., 1981).

PREVENTION AND THERAPY Reducing exposure to infected animals and contaminated environments is critical in preventing dermatophytosis. Assuring a well-managed facility with no overcrowding, parasite control, and proper temperature and humidity regulation are important preventive components (Pollock, 2003;

Pombier and Kim, 1975). Infected animals should be removed, the environment thoroughly decontaminated and any items that cannot be disinfected should be discarded. Animal care staff should wear proper personal protective equipment when handling potentially contaminated items or bedding since zoonosis is a concern (McAleer, 1980a). Dilute bleach, benzalkonium chloride, and glutaraldehyde are effective surface disinfectants (Pollock, 2003). In a laboratory setting, it is doubtful that animals will be treated for ringworm. Readers are referred to other summaries of available topical and systemic treatments (Pollock, 2003).

Encephalitozoonosis/Microsporidiosis

BACKGROUND The Microsporidia (members of the phylum Microspora) are a group of single-celled intracellular spore-forming eukaryotic parasites that infect a wide range of animals, from insects to mammals. The defining and unique feature of the phylum is the presence of a polar filament (tube) in the mature spore (Wasson and Peper, 2000). The microsporidia also have one of the smallest genomes of any eukaryote and lack several key features, such as typical mitochondria. Long thought to be protozoa, certain characteristics indicated that these organisms were fungi-like such as presence of a chitinous spore wall, genes for trehalose metabolism, and intranuclear division (Brosson et al., 2006; Dunn and Smith, 2001). Recently, Lee et al. (2008) concluded that microsporidia are true fungi related to zygomycetes. Of the microsporidial species infecting humans, *Enterocytozoon bieneusi* is the most common with lesser, but still significant, numbers of cases due to the *Encephalitozoon* spp. The majority of patients are immunocompromised as a result of HIV infection, AIDS, or are organ transplant recipients. However, healthy immune-competent persons are also susceptible to disease (Didier and Weiss, 2006; Mathis et al., 2005). Animals are hosts for those common species strongly supporting their zoonotic potential.

ETIOLOGY The primary agent of microsporidiosis in guinea pigs is *Encephalitozoon cuniculi* (syn. *Nosema*). *E. cuniculi* was first reported in the rabbit as the cause of "Infectious Motor Paralysis" (Percy and Barthold, 2007) and subsequently has been identified in a wide range of animal species (Wasson and Peper, 2000). Katinka et al. (2001) have sequenced the 11 chromosomes of the approximately 2.9-Mb genome, highlighting the genome compaction and shortened protein sequences that reflect its intracellular location and host dependence.

EPIZOOTIOLOGY AND PATHOGENESIS Wasson and Peper (2000) provide an informative summary of the mammalian microsporidian life cycle. Environmentally

resistant spores are shed in feces, urine, and mucus and then ingested or inhaled. Transplacental transmission has been documented in the rabbit (Baneux and Pognan, 2003) and has been claimed in the guinea pig (Boot et al., 1988). Predictably, primary sites of infection commonly include the small intestine, respiratory tract, and placenta. An unknown signal triggers the polar filament (tube) to be extruded from the spore and infectious sporoplasm is injected into the host cell cytoplasm. The sporoplasm then divides into meronts (merogony) that differentiate through intermediary forms before becoming mature spores (sporogony). For *E. cuniculi* and other *Encephalitozoon* spp., developing spores are packaged in a parasitophorous vacuole. The host cell ruptures releasing spores that commonly disseminate to the kidney, liver, and brain. Host protection from infection is primarily achieved by cell-mediated immunity with lesser contributions from the humoral immune system (Khan et al., 2001).

From serologic surveys, prevalence of encephalitozoonosis in guinea pig colonies has ranged from 13%–63%. This variability may be due to differences in housing and husbandry for the particular colony and diagnostic methodology (Boot et al., 1988; Gannon, 1980).

CLINICAL MANIFESTATIONS Encephalitozoonosis is subclinical in the guinea pig (Boot et al., 1988; Gannon, 1980; Illanes et al., 1993; Moffatt and Schiefer, 1973; Wan et al., 1996).

PATHOLOGY Gross lesions of encephalitozoonosis in the guinea pig are not consistently found and when present have only been described in the kidney. Infected animals may have pale kidneys and/or pitting of the renal cortex (Gannon, 1980; Moffatt and Schiefer, 1973). Histologic lesions are found primarily in the brain and kidney. Focal to multifocal granulomatous encephalitis may be evident in different regions of the brain, with or without associated necrosis, and perivascular and meningeal mononuclear cell infiltrate (Moffatt and Schiefer, 1973; Wan et al., 1996). Organisms approximately 1–1.5 µm in width × 1.5–2.5 µm in diameter (Illanes et al., 1993; Wasson and Peper, 2000) can be found within or adjacent to lesions or free in the tissue with no associated inflammation. In the kidney, interstitial nephritis and necrosis, fibrosis, perivascular cuffing and tubular ectasia have all been described (Boot et al., 1988; Gannon, 1980; Moffatt and Schiefer, 1973). Here, organisms may occasionally be visualized in renal epithelial cells and collecting tubule lumens. Absence of typical lesions in the brain or kidney in a seropositive animal may be due to the multifocal nature of the lesions and insufficient sections being analyzed (Gannon, 1980; Wan et al., 1996). Other lesions reported include necrotic liver foci and interstitial pneumonia

FIGURE 23.4 *Encephalitozoon* spores in a brain section. Note absence of inflammation in the surrounding tissue. Photo provided by Dr. Kim Waggle.

with perivascular and peribronchial lymphoid accumulation.

DIAGNOSIS Serology tests including carbon immunoassay, IFA, ELISA, multiplex fluorescent immunoassay, and Western blot have all been or currently are being used for colony monitoring (Percy and Barthold, 2007; Wasson and Peper, 2000). Presence of typical histopathologic lesions and special stains confirm the infection. While indistinct with hematoxylin and eosin staining, spores are periodic acid-Schiff, Gram, and modified trichrome positive (Figure 23.4). Chemofluorescent agents such as Calcofluor white can also be used (Garcia, 2002) and spores are birefringent (Tiner, 1988). PCR primers are available (Baneux and Pognan, 2003; Ghosh and Weiss, 2009) providing a fast and easily interpretable means of diagnosis and the genome for *E. cuniculi* has recently been sequenced providing further opportunities for novel molecular diagnostic strategies (Katinka et al., 2001). Urine, brain, and kidney are optimal specimens for testing by PCR. Electron microscopy is the gold standard for diagnostic confirmation and offers species identification which is particularly important for human infections (Garcia, 2002).

PREVENTION AND THERAPY *E. cuniculi*-free guinea pigs are commercially available and therefore, protection from contaminated animals or environments is the primary means of prevention (Gannon, 1980). Faced with contamination, eradication may be successful through serological analysis and euthanasia of seropositive animals (Baker, 2007) coupled with environmental decontamination. *E. cuniculi* spores are environmentally stable for days to weeks depending on the temperature and humidity, but are susceptible to common disinfectants (Jordan et al., 2006; Waller, 1979). Vertical transmission is

thought to occur in guinea pigs (Boot et al., 1988), so hysterectomy rederivation should be used with caution and offspring extensively tested. It is unlikely that laboratory guinea pigs would be treated for encephalitozoonosis.

Miscellaneous Diseases

Candida pintolopesii (Formerly Known as *Torulopsis pintolopesii*)

Two of four laboratory-bred guinea pigs were found dead several days to two weeks after adoption (Kunstyr et al., 1980). Diarrhea was noted in one animal prior to death and each had gross evidence of enteritis at necropsy which was confirmed histologically. The yeast *Candida pintolopesii*, a normal inhabitant of the gut, was isolated from the small intestine, lung, and ascitic fluid of one animal. The authors hypothesized that a change in social structure, diet, and environment precipitated disease.

Cryptococcus neoformans

Cryptococcus neoformans is a basidiomycetous yeast causing serious infections of the lungs and central nervous system in immunocompromised persons (Boekhout and Guého, 2003). Betty (1977) reported chronic, subclinical cryptococcal meningitis in laboratory-reared Dunkin Hartley guinea pigs with no evidence of generalized infection. The source of infection was not identified. Van Herck et al. (1988) described dermal cryptococcosis of an adult male pet guinea pig. Histopathologic analysis of a large ulcerative lesion on the dorsal aspect of the nose showed extensive focal ulcerative dermatitis with infiltrating neutrophils, plasma cells, lymphocytes, and macrophages with edema and ovoid organisms. Dermal and subcutaneous tissue also contained large numbers of these thick-walled organisms that were positive by periodic acid-Schiff staining.

Enterocytozoon bieneusi

Enterocytozoon bieneusi is a significant cause of intestinal microsporidiosis in immunocompromised persons and has been identified in many mammalian and non-mammalian hosts (Mathis et al., 2005). Microsporidian spores were found in the feces of a two-year-old male entered into a prospective study of pediatric enteric parasites in Peru. To investigate the source of infection, stool was analyzed from animals in the household, including guinea pigs, chickens, dogs, and cats. Seven of eight asymptomatic guinea pigs were positive for spores, whereas all the other animals were negative. Polymerase chain reaction and sequence analysis confirmed that both the child and guinea pigs were infected with *E. bieneusi* and with the same genotype. Furthermore, this specific genotype was found in guinea pigs from other unrelated

households suggesting that guinea pigs are the natural host and there is zoonotic potential for this organism.

Histoplasma capsulatum

There is a single report from Brazil of a naturally occurring histoplasmosis outbreak in laboratory guinea pigs (Correa and Pacheco, 1967). Clinical signs of disease in adults included progressive emaciation and hindlimb dysfunction before death. Young animals exhibited a hunched back, ruffled fur, and conjunctivitis with discharge before dying at two months of age. Gross and histologic lesions were numerous; however, for these authors a characteristic lesion of colitis with the wall expanded by numerous lymphocytes, macrophages, epithelioid and giant cells with basophilic organisms free or inside macrophages and culture results established the diagnosis. There may have been a link between this outbreak and histoplasmosis diagnosed in a cow on a farm from which the grass used to feed the guinea pigs was sourced.

Hortaea werneckii

Hortaea werneckii, the causative agent of tinea nigra in people, was diagnosed in a household guinea pig in Japan (Sharmin et al., 2002). Lesions included a focal area of ulceration and alopecia on the back and black pigmentation on the palmar aspect of the right forepaw. *H. werneckii* was detected by mycologic culture of the back lesion and DNA sequencing of an amplified region of large subunit ribosomal DNA. The authors hypothesized that the animal contracted the infection from the environment, but could not definitively rule out contamination with the fungus rather than a real infection.

Paecilomyces

Paecilomyces spp. are occasional opportunists in humans and animals (Summerbell, 2003). This fungus was identified during routine monitoring from a single conventionally housed laboratory guinea pig with no apparent clinical signs (Kunstyr et al., 1997). *Paecilomyces* spp. were most commonly identified in specific pathogen-free rats from one particular animal facility with the trachea and lungs being the most common site of infection in all animals analyzed. Mild dermatitis was noted in a group of hairless mice; however, the vast majority of animals had no clinical or histologic evidence of disease.

Pneumocystis carinii

A hairless mutant arose in a closed colony of Hartley guinea pigs. In addition to abnormal haircoat development, affected guinea pigs were smaller than their haired siblings and died early due to infections otherwise associated with an abnormal immune system such as systemic cytomegalovirus and balantidiasis, and *Pneumocystis* pneumonia (Reed and O'Donoghue, 1979). Abnormal

thymic and lymphoid follicle morphology and agammaglobulinemia confirmed the immunodeficiency.

PROTOZOA INFECTIONS

Protozoa rarely cause disease in guinea pigs and intestinal protozoa are often considered part of the normal flora. In this review, the more frequently reported protozoa of domestic guinea pigs will be discussed. The reader is referred to *Parasites of Laboratory Animals* (Baker, 2007) and *Morphology and Taxonomy of the Intestinal Protozoa of the Guinea Pig* (Nie, 1950) for a more detailed description of the protozoa of this species. The nomenclature used in this section is in accordance with the 2007 reference.

Amoebiasis

ETIOLOGY *Endolimax caviae* and *Entamoeba caviae* (syn. *Entamoeba cobayae*) are the causative agents of amoebiasis in guinea pigs (Levine, 1985). Nie (1950) reported the incidence of *Endolimax caviae* to be 18% and the incidence of *Entamoeba caviae* to be 14% in a colony of guinea pigs studied at the University of Pennsylvania.

PATHOGENESIS *Endolimax caviae* and *Entamoeba caviae* are observed in the cecum of the guinea pig (Nie, 1950). Both of these organisms are thought to feed upon the fecal material and microflora of the host intestine, without invasion of tissue or consumption of blood. Transmission is via ingestion of cysts passed in the feces.

CLINICAL MANIFESTATIONS Infection with either organism does not generally result in clinical signs (Levine, 1985).

PATHOLOGY *Entamoeba* and *Endolimax* are usually non-pathogenic (Baker, 2007; Levine, 1985).

DIAGNOSIS Trophozoites can be observed in a smear of intestinal contents (Baker, 2007; Levine, 1985). Cysts are detected by zinc sulfate float. *Endolimax caviae* trophozoites are smaller than those of *Entamoeba caviae*, with an average diameter of 1.6 µm and 14.4 µm, respectively (Nie, 1950). The cyst forms of either organism have rarely been observed, and little detail has been recorded on their appearances.

PREVENTION AND THERAPY Generally, treatment is not necessary for guinea pig amoebiasis.

Balantidia caviae

BACKGROUND Upon initial description, controversy developed over whether *B. caviae* was the same organism as *B. coli* in swine (Vetterling, 1976). Morphological

descriptions and infection studies have since proved that the two species are distinct.

ETIOLOGY *Balantidium caviae* is the causative organism.

PATHOGENESIS *B. caviae* transmission is via ingestion of cysts in the feces (Baker, 2007).

CLINICAL MANIFESTATIONS If the mucosal barrier of the intestine is compromised, *B. caviae* can become invasive and result in enteritis; otherwise infection is non-pathogenic (Baker, 2007).

PATHOLOGY *B. caviae* may be observed in the walls of the cecum and colon, but penetration can occur post-mortem, a consideration that should be made when diagnosing infection at the time of necropsy (Baker, 2007; Nie, 1950). If invasion is ante-mortem, intestinal inflammation should be present; more often, though, *B. caviae* is considered a commensal protozoan.

DIAGNOSIS In addition to diagnosing *B. caviae* in histologic sections of the cecum or colon, ciliated organisms with micro- and macro-nuclei can be observed in fresh fecal smears (Baker, 2007; Fox, 2002).

PREVENTION AND THERAPY Proper hygiene is most important in controlling *B. caviae* infection in guinea pigs (Baker, 2007). Tetracyclines have been used to treat balantidiasis in other species.

Cryptosporidiosis

BACKGROUND *C. wrairi* is named after the Walter Reed Army Institute of Research where the organism was first identified in a colony of laboratory guinea pigs (Vetterling et al., 1971).

ETIOLOGY *Cryptosporidium wrairi* is the causative organism.

PATHOGENESIS The route of infection for *C. wrairi* is likely fecal–oral, with ingestion of oocysts in feces (Baker, 2007; Fox, 2002). Experimental infection has shown that the duration of infection for animals older than 16 weeks is usually short, lasting as little as 1–2 weeks, after which the organism is cleared (Chrisp et al., 1990). Younger animals have a longer duration of infection. Recovered animals appear to be refractory to subsequent infection.

CLINICAL MANIFESTATIONS Clinical signs are more likely to be seen in young animals, with weight loss noted most commonly (Baker, 2007; Fox, 2002). If infection is severe, anorexia, a potbellied appearance and a greasy hair coat may be observed with or without

accompanying diarrhea (Baker, 2007). Morbidity and mortality, especially in young animals, can reach levels of 50% during an outbreak (Harkness and Wagner, 1995; Percy and Barthold, 2007). *Echinococcus coli* has been associated with clinical cases of *C. wrairi*, but the significance of this infection is unknown (Percy and Barthold, 2007). Subclinical infections with *C. wrairi* are thought to be possible (Baker, 2007; Fox, 2002).

PATHOLOGY Erosion, hyperemia, and inflammation of the small intestine have been observed with *C. wrairi* infection (Baker, 2007; Chrisp et al., 1992; Harkness and Wagner, 1995). Edema of the lamina propria and hyperplasia of the crypt epithelium occurs. In chronic infections, villous atrophy and bridging, metaplasia of the mucosal epithelium, and lymphocyte infiltration of the lamina propria have been noted. Developmental stages of *C. wrairi* can be seen throughout the intestine, with highest concentrations of the organism noted in the brush border of the ileum.

DIAGNOSIS Oocysts can be seen in fecal floats (Gressler et al., 2010; Percy and Barthold, 2007). Kinyoun staining of fecal smears and microscopic examination of mucosal scrapings or histological sections are also diagnostic options.

PREVENTION AND THERAPY Prevention is the best means of control for *C. wrairi*. Oocysts are resistant to many disinfectants or require high concentrations and/or long contact times before being rendered non-infectious. Heating above 65°C for greater than 5 minutes has been described to be successful for the destruction of *Cryptosporidium* organisms, as has exposure to temperatures below 0°C (Baker, 2007; Harkness and Wagner, 1995). Successful treatment with sulfonamides has been reported, but the efficacy of this treatment has been questioned (Fox, 2002; Percy and Barthold, 2007; Sebesteny, 1976). Harkness suggests the “extra-label” use of high doses of the coccidiostat, Decoquinat, to treat cryptosporidiosis (Harkness and Wagner, 1995). While *C. wrairi* is not known to infect humans, the genus has a general lack of specificity and precautions should be taken to prevent zoonotic transmission (Baker, 2007; Harkness and Wagner, 1995).

Eimeria

BACKGROUND Reports of coccidia in guinea pigs date back to the late 1800s, although the observed organisms were initially thought to be a variety of rabbit coccidian (Vetterling, 1976). In the early 1920s, Bugge and Heinke showed that coccidia noted in the guinea pig were indeed distinct from those of the rabbit and in 1924 Sheather named the guinea pig coccidia *E. caviae*.

ETIOLOGY *Eimeria caviae* is the causative organism.

PATHOGENESIS Transmission of *E. caviae* is fecal-oral, with ingestion of oocysts in feces (Baker, 2007).

CLINICAL MANIFESTATIONS Clinical signs due to *E. caviae* are noted in severe infections and include diarrhea, anorexia and a rough hair coat (Baker, 2007; Ellis and Wright, 1961; Rigby, 1976). The first appearance of diarrhea is often 10–11 days after initial infection (Baker, 2007; Elsheikha et al., 2009; Percy and Barthold, 2007). Watery, pasty, and hemorrhagic forms of diarrhea have all been reported (Baker, 2007; Elsheikha et al., 2009; Fox, 2002; Percy and Barthold, 2007). Severe infections can result in death (Baker, 2007; Fox, 2002). In mild infections or infections of older animals, diarrhea is likely to resolve in 4–7 days (Baker, 2007; Fox, 2002), after which constipation may follow (Fox, 2002). Stress, such as a diet change or transport, may exacerbate an otherwise non-pathogenic infection of *E. caviae* in the guinea pig (Ellis and Wright, 1961; Elsheikha et al., 2009; Rigby, 1976).

PATHOLOGY The large intestine is most affected by *E. caviae*, with organisms most often settling in the proximal colon (Baker, 2007; Elsheikha et al., 2009). Hyperemia, edema, and petechial hemorrhage of the colonic mucosa may be seen (Baker, 2007). White or yellow plaques may be present in the colon or cecum. Watery intestinal contents can contain blood (Baker, 2007; Percy and Barthold, 2007). Dilated cystic crypts of Liekberkuhn may be observed (Baker, 2007). Developmental stages of *E. caviae* can be seen in intact epithelial cells or free in the intestinal lumen. Enterocytes may slough and an infiltration of polymorphonuclear and mononuclear cells is possible (Baker, 2007; Percy and Barthold, 2007). Microgametocytes and macrogametocytes may be present in the cecal and colonic mucosa (Percy and Barthold, 2007).

DIAGNOSIS Oocysts are seen on fecal float (Baker, 2007; Fox, 2002; Percy and Barthold, 2007). Fox et al. (2002) recommend using a flotation medium of 1.33 specific gravity. The prepatent period of *E. caviae* is 11–12 days, yet diarrhea may occur before day 11; therefore, a fecal float performed at the beginning of diarrhea may result in a false-negative finding. Multiple floats performed every 4 or 5 days for several weeks is recommended (Vetterling, 1976). Organisms may also be identified on mucosal scrapings or histopathology sections (Baker, 2007; Fox, 2002; Percy and Barthold, 2007).

PREVENTION AND THERAPY Sulfonamides are recommended for treatment. Minimizing stress and providing an adequate level of vitamin C help to prevent clinical infection. Oocysts in the feces take 6 days to become infective, therefore regular cleaning of pans will help to

minimize the spread of infection (Rigby, 1976). Ammonia, followed by a thorough rinsing, has been used to clean cages and pans of infected animals (Elsheikha et al., 2009). Steam has also been used to clean enclosures. Calhoon notes that *Eimeria*-free colonies can be achieved via cesarean rederivation (Calhoon and Matthews, 1964).

Giardia duodenalis

ETIOLOGY The causative agent of guinea pig giardiasis is *Giardia duodenalis*, formally referred to as *G. caviae* (Baker, 2007; Vetterling, 1976).

PATHOGENESIS *Giardia duodenalis* is a flagellate of guinea pigs that is transmitted by the fecal-oral route or via ingestion of contaminated food or water (Baker, 2007).

CLINICAL MANIFESTATIONS Overt signs of infection, such as diarrhea, are rare, although some animals are severely infected and may present as weak and moribund (Baker, 2007).

PATHOLOGY The small intestine, primarily the duodenum, is colonized by trophozoites (Baker, 2007). Colonization may result in mild inflammatory lesions, decreased villar height, and cystic enlargement of duodenal crypts.

DIAGNOSIS Diagnosis of *G. duodenalis* is via direct fecal smear, where trophozoites or cysts may be observed (Baker, 2007). Only trophozoites, and not cysts, are found in diarrheic feces (Vetterling, 1976). Shedding of *G. duodenalis* is intermittent, so unless multiple fecal smears are performed, there is a high likelihood of obtaining a false-negative result. FELASA recommends including *Giardia* spp. on guinea pig breeding colony health monitoring reports (Rehbinder et al., 1996).

PREVENTION AND THERAPY Metronidazole and fenbendazole are treatment options for guinea pig giardiasis (Baker, 2007). Infection can be prevented by thorough environmental sanitation using a quaternary ammonium product or sodium hypochlorite. Hot temperatures will destroy cysts. Cysts thrive in moist areas, so environments must be kept dry. The zoonotic potential of *G. duodenalis* of guinea pigs is unknown, but the possibility of transmission between guinea pigs and humans is suspected.

Klossiella cobayae

BACKGROUND *K. cobayae* is also known as *Klassia caviae*, as it was described and named simultaneously by two individuals, Pearce and Sangiori (respectively) working independently of each other (Vetterling, 1976). Occurrence in modern laboratory guinea pigs is rare (Percy and Barthold, 2007).

FIGURE 23.5 *Klossiella* coccidial organisms (arrows) in renal epithelial cells. Photo provided by Tammy D. Utteridge.

ETIOLOGY *Klossiella cobayae* is the causative organism.

PATHOGENESIS *K. cobayae* is a parasite of the epithelial cells of the renal tubules, as well as the endothelial cells associated with glomerular capillaries and other organs, such as the spleen and lungs (Griffiths, 1971; Van Andel et al., 1995; Vetterling, 1976). Transmission is via ingestion of sporocysts in urine (Baker, 2007).

CLINICAL MANIFESTATIONS Clinical signs associated with *K. cobayae* are rare. If infection is severe, signs secondary to renal damage may result.

PATHOLOGY Infection can be non-pathogenic or result in nephritis (Figure 23.5) (Baker, 2007; Sebesteny, 1976). Heavy infection can lead to an irregular surface and a gray mottled appearance of the kidney (Baker, 2007; Fox, 2002). Interstitial and perivascular lymphocytic and histiocytic infiltration may occur (Baker, 2007). A large number of interstitial fibroblasts may also be observed.

DIAGNOSIS Sporocysts are passed in the urine, yet observation of this stage in the urine is difficult (Baker, 2007). Most often, diagnosis is made at the time of necropsy by identifying the different developmental stages of *K. cobayae* in glomerular capillaries or in the cytoplasm of epithelial cells lining the renal tubules (Baker, 2007; Percy and Barthold, 2007). FELASA recommends including *Klossiella* spp. as part of a health monitoring report for guinea pig breeding colonies (Rehbinder et al., 1996).

PREVENTION AND THERAPY Control of *K. cobayae* is best achieved through prevention. Contamination of food and bedding with infective urine should be

minimized (Baker, 2007). Sulfonamides might be effective forms of treatment.

Leishmania enrietti

BACKGROUND *Leishmania enrietti* was first noted in laboratory guinea pigs in 1948 in Brazil (Medina, 1946). According to the review by Machado et al., this flagellate was next reported in 1967 in a guinea pig captured from the outskirts of Curitiba (Machado et al., 1994). The sandfly, *Lutzomyia monticola*, which is frequently noted on the trunks of Curitiba pine trees, was proposed as a possible vector.

ETIOLOGY *Leishmania enrietti* is the causative organism.

PATHOGENESIS Little is known about the lifecycle of *L. enrietta*, but other members of the genus *Leishmania* have indirect lifecycles and sandfly vectors (Baker, 1998, 2007; Nie, 1950). *L. enrietta* results in cutaneous infection.

CLINICAL MANIFESTATIONS AND PATHOLOGY An infected guinea pig may present with a cutaneous nodule at the site of entry 1–2 weeks after infection (Baker, 2007). Additionally, ulcers can develop on the feet, ears, nose, and genitalia of infected animals. Ulcers will go through a series of pathologic changes, such as necrosis of surrounding macrophages 4–5 weeks after initial infection (especially in naive animals), followed by an infiltrate of giant cells, plasma cells, and lymphocytes at the periphery of the ulcer. By 7 weeks, giant cells are gone and fibroblasts appear, indicating resolution. Resolution is usually complete by 10 weeks post-infection. Hematogenous spread of the organism can occur and *L. enrietti* may be observed in the lymph nodes.

DIAGNOSIS Detection is via identification of amastigotes in lesion histology or via culture of the organism (Baker, 2007).

PREVENTION AND THERAPY Control is achieved by elimination of vectors. Treatment with meglumine antimoniate has been attempted, with inconsistent success (Thomaz-Soccol et al., 1996). Contact with possible sandfly vectors should be avoided.

Toxoplasma gondii

BACKGROUND This organism was first reported in Brazil by Carini and Migliano (Vetterling, 1976). In early reports, *T. gondii* was mistaken for *Sarcocystis* in the guinea pig (Kean and Grocott, 1945).

ETIOLOGY *Toxoplasma gondii* is the causative organism.

PATHOGENESIS Cats are the definitive hosts of *T. gondii* (Baker, 2007). Oocysts are released in cat feces and are ingested by guinea pigs which act as intermediate hosts for *T. gondii*. Cysts can remain viable in a guinea pig for up to five years before ingestion by the definitive host. In addition to the guinea pig, a large number of mammalian and avian species are intermediate hosts to *T. gondii*, including humans. Ingestion of contaminated biological material and transplacental transmission are alternative routes of transmission for the guinea pig (Baker, 2007; Percy and Barthold, 2007).

CLINICAL MANIFESTATIONS *T. gondii* infection in guinea pigs is often asymptomatic and, therefore, frequently goes undiagnosed (Baker, 2007; Griffiths, 1971; Percy and Barthold, 2007). Infection in pregnant sows can result in vulvar bleeding and abortion (Fox, 2002). In a case of spontaneous toxoplasma encephalitis in a guinea pig, spastic paralysis, opisthotonos, and loss of urethral and anal sphincter control were reported (Markham, 1937).

PATHOLOGY Hepatitis, pneumonia, encephalitis, and uterine infection (possibly blood-filled), have been noted in infected animals, as have cysts in both the myocardium and central nervous system (Baker, 2007; Fox, 2002; Percy and Barthold, 2007). In spontaneously infected animals that develop toxoplasma encephalitis, congested blood vessels of the meninges were noted and were surrounded by mononuclear leukocytes (Markham, 1937).

DIAGNOSIS Serology is often used for diagnosis in guinea pigs (Baker, 2007). Cysts can be observed on histology. Mice or hamsters can be inoculated with tissue homogenate from suspected positives and act as sentinels of infection. FELASA recommends including *Toxoplasma gondii* on guinea pig breeding colony health monitoring reports (Rehbinder et al., 1996).

PREVENTION AND THERAPY Sulfadiazine and pyrimethamine are reported treatment options for clinical cases of *T. gondii*, yet the effectiveness of such treatments is questionable (Baker, 2007; Fox, 2002). Temperatures above 60°C kill oocysts (Baker, 2007). Strict sanitation and periodic colony monitoring are necessary for *T. gondii* control.

Tritrichomonas caviae

BACKGROUND *Tritrichomonas caviae* has also been referred to as *Trichomonas caviae* and *T. flagelliphora* (Tanabe, 1925).

ETIOLOGY *Tritrichomonas caviae* is one of the largest intestinal flagellates of the guinea pig, measuring an average of 16 µm long by 8.5 µm wide (Baker, 2007). No cyst stage is known.

PATHOGENESIS Transmission of *T. caviae* is fecal-oral (Baker, 2007).

CLINICAL MANIFESTATIONS *Tritrichomonas caviae* is a non-pathogenic flagellate of guinea pigs (Baker, 2007).

PATHOLOGY *T. caviae* is most often noted in the cecum, although it has been observed in the duodenum, jejunum and lower ileum as well (Baker, 2007). Although rare, tissue invasion and cecal or colonic ulceration are possible.

DIAGNOSIS Diagnosis of *T. caviae* is via direct fecal smear (Tanabe, 1925).

PREVENTION AND THERAPY *T. caviae* does not usually result in clinical signs or pertinent pathology and does not routinely require treatment (Baker, 2007).

Trypanosoma cruzi

Guinea pigs, among other mammals, are reservoirs for the flagellate *T. cruzi* (Baker, 2007; Vetterling, 1976). Reduviid bugs act as vectors, becoming infected after a blood meal from a positive animal. *T. cruzi* mature and reproduce within the vector. The bugs then go on to deposit *T. cruzi*-containing feces on humans during another blood meal. The organism enters human skin through a wound (potentially the bug bite) or contact with mucous membranes. Chagas disease may result in humans.

In the guinea pig, *T. cruzi* can encyst in multiple organs, including the skin and cardiac muscle. *T. cruzi* has been noted in domesticated guinea pigs of South America exposed to reduviid vectors. Clinical and pathological signs are not described.

PARASITIC INFECTIONS

The reader is once again directed to Flynn's *Parasites of Laboratory Animals* for further discussion on many of the parasites discussed below, including anatomical appearances and detailed life cycles (Baker, 2007). The nomenclature used in this section is also in accordance with this reference.

Arthropods

Note: the common names of arthropod organisms have been used in place of the name of the resulting condition (e.g. Flies instead of Myiasis).

Fleas

Ctenocephalides felis has been noted on pet guinea pigs living in a household with cats and/or dogs.

Infected guinea pigs presented with pruritus, alopecia, dermal crusts, and anemia (White et al., 2003). Aqueous-based pyrethrin sprays have been recommended as the safest treatment option for such infection. *Nosopsyllus fasciatus*, the northern rat flea, can also inhabit guinea pigs, although similarly to *C. felis*, infection of laboratory guinea pigs is rare (Fox, 2002).

Flies

It has been stated that “fatal myiasis involving at least three species of flies, *Lucilia sericata*, *Calliphora vicina* and *Calliphora vomitoris*, have been reported in guinea pigs” (Baker, 2007). Eggs are deposited on the skin of a guinea pig by an adult fly, where larvae will develop and then feed on living or necrotic animal tissue (Baker, 2007).

TABLE 23.1 Other Parasites of Wild Guinea Pigs

Parasite	Location in Host	Method of Infection	Pathologic Effects
Arthropods			
FLEAS			
<i>Hectopsylla</i> spp.	Pelage	Direct contact	Unknown
<i>Leptopsylla seginis</i>	Pelage	Direct contact	Unknown
<i>Nosopsyllus fasciatus</i>	Pelage	Direct contact	Unknown
<i>Pulex irritans</i>	Pelage	Direct contact	Dermatitis
<i>Rhopalosylla clavicola</i>	Pelage	Direct contact	Unknown
<i>Tiamastus cavicola</i>	Pelage	Direct contact	Unknown
LICE			
<i>Polyplax spinulosa</i>	Pelage	Direct contact	Unknown
<i>Pteropthirus</i> spp.	Pelage	Direct contact	Unknown
MITES			
<i>Ornithonyssus bacoti</i>	Skin	Direct contact	Dermatitis
<i>Ornithonyssus braziliensis</i>	Skin	Direct contact	Unknown
<i>Ornithonyssus wernecki</i>	Skin	Direct contact	Unknown
<i>Eutrombicula</i> spp.	Skin	Direct contact	Unknown
CESTODES			
<i>Anoplocephala</i> spp.	Intestine	Unknown	None
<i>Monoecocestus parvitesticulatus</i>	Intestine	Unknown	None
NEMATODES			
<i>Ackertia borgosi</i>	Abdominal cavity	Arthropod host	None
<i>Capillaria hepatica</i>	Liver	Ingestion of embryonated egg	None
<i>Graphidioides mazzai</i>	Small intestine	Ingestion of infective larvae	None
<i>Trichuris gracilis</i>	Large intestine	Ingestion of embryonated egg	None
<i>Viannella travassosi</i>	Small intestine	Ingestion of infective larvae	None
TREMATODES			
<i>Pseudoquinqueserialis caviae</i>	Intestine	Ingestion of metacercaria	None
<i>Taxorchis caviae</i>	Cecum	Ingestion of metacercaria	None
<i>Taxochis ringueleti</i>	Cecum	Ingestion of metacercaria	None

Lice

ETIOLOGY Biting lice from the order Mallophaga, *Gyropus ovalis*, *Gliricola porcelli*, and *Trimenopon hispidum* (previously *Trimenopon jenningsi*) are often observed in guinea pigs (Baker, 2007). *G. porcelli*, the most commonly observed of the three, is known as the “slender louse” due to its general appearance, especially when compared to *G. ovalis* or the “oval louse” (Baker, 2007; Harkness and Wagner, 1995; Kim et al., 2008). Several species of sucking lice (order Anoplura) have been noted on wild guinea pigs in South America: *Pterophytirus alata* and *Polyplax spinulosa* (Dittmar, 2002). These latter lice are listed in Table 23.1, but not discussed here in detail.

PATHOGENESIS Biting lice attach to hair shafts and abrade the skin to ingest cutaneous fluids (Fox, 2002; Kim et al., 2008). Transmission is via direct contact (Harkness and Wagner, 1995; Kim et al., 2008). The life cycles of guinea pig lice are not specifically described, but in general, biting lice go through the following stages: egg, three nymphal stages, and adult (Baker, 2007).

CLINICAL MANIFESTATIONS *G. ovalis*, *G. porcelli* or *T. hispidum* infection of a guinea pig can be asymptomatic or may result in pruritus and a rough hair coat or alopecia (Baker, 2007; Coman et al., 2009; Harkness and Wagner, 1995; Kim et al., 2008; Percy and Barthold, 2007; Rigby, 1976). Scabs and crusts are sometimes noted secondary to scratching, especially around the ears (Harkness and Wagner, 1995).

PATHOLOGY Signs of louse infection are usually superficial. Dermatitis may be noted grossly.

DIAGNOSIS Lice (adults or nits) can be seen on the haircoat of an infected animal, with or without the aid of a magnifying lens (Figure 23.6) (Baker, 2007; Griffiths,

1971). On a dead animal, lice will migrate to the warm tips of the hair as the skin cools (Griffiths, 1971). Tape tests and flea combing can also be used to diagnose louse infestation (Coman et al., 2009). As stated previously, *G. porcelli* is slender in appearance (1.0–1.5mm × 0.3–0.4mm), compared to *G. ovalis* (1.0–1.2mm × 0.5mm) (Figure 23.7) (Huerkamp et al., 1996). *T. hispidum*’s dimensions are similar to those of *G. ovalis*, yet can be differentiated by the fact that *T. hispidum* has five abdominal segments as compared to *G. ovalis*’ eight.

PREVENTION AND THERAPY In reports of successful control of guinea pig louse infestations, both infected animals and the environment have been treated (Harkness and Wagner, 1995; Kim et al., 2008). Systemic ivermectin (Baker, 2007; White et al., 2003), carbamate or pyrethrin-based powders (Baker, 2007; Griffiths, 1971), Romavermectin B1 (Coman et al., 2009) and a combination of imidacloprid and moxidectin (Kim et al., 2008) have been noted as effective drug choices for treating infected guinea pigs. Hypochlorite bleach has been used for environmental decontamination (Kim et al., 2008).

Mites

Guinea pigs are susceptible to infection with several species of mites, some occurring more commonly than others. *Chirodiscoides caviae* and *Trixacarus caviae* are the most commonly noted infectious mites in guinea pigs, with *Demodex caviae*, *Myocoptes musculus*, *Sarcoptes scabiei* and *Notoedres muris* reported less frequently (Baker, 2007; Fox, 2002; White et al., 2003). Infection with the astigmatic mite, *Acarus farris*, was described in a case report of two guinea pigs (Linek and Bourdeau, 2005). *Psocoptes cuniculi* has been described on a pet guinea pig in close contact with a pet rabbit (Yeatts, 1994). White et al. (2003) note *Cheyletiella parasitivorax* as a cause of pruritus and scaling along the dorsum of guinea pigs. The more commonly noted mites, *C. caviae* and *T. caviae*, will be discussed below.

CHIRODISCOIDES CAVIAE

BACKGROUND The first reports and illustrations of *C. caviae* were by Stanley Hirst in the early 1900s (Hirst 1922). Hirst noted this mite attached to the hairs of the back of the guinea pig.

ETIOLOGY *Chirodiscoides caviae* is the causative organism (Figure 23.8).

PATHOGENESIS *C. caviae* is a species-specific fur mite that tends to concentrate in the lumbar area and the lateral aspects of the hindquarters (Harkness and Wagner, 1995; Percy and Barthold, 2007; Schonfelder et al., 2010). *C. caviae* feed on the scales of hair shafts (Hirsjarvi and Phyla, 1995) and transmission is via direct contact with

FIGURE 23.6 Adult and nymphal stages of *G. porcelli* found in a fur sample. Photo provided by Dr. Susan Szczepanski.

FIGURE 23.7 *Gliricola porcelli* (A), the slender louse, is more commonly noted on guinea pigs than is *Gyropus ovalis* (B), the oval louse. Both are biting lice from the order Mallophaga. Image courtesy of Dr. G. Van Hoosier.

FIGURE 23.8 *Trixacarus caviae* (A) and *Chirodiscoides caviae* (B) are two of the most reported species of mites to infect guinea pigs. *T. caviae* is a common cause of dermatitis in guinea pigs, while infection with *C. caviae* is often asymptomatic. Figure courtesy of Dr. G. Van Hoosier.

an infected animal (Fox, 2002; Schonfelder et al., 2010) or with infected cage debris or bedding (Fox, 2002). The life cycle of *C. caviae* has not been specifically described, although mites in general commonly go through egg, larval, nymphal, and adult stages (Baker, 2007). Concurrent infection with lice is not uncommon (White et al., 2003), and mixed infection with *Demodex caviae* (detected via

deep skin scrapping) has also been reported (Schonfelder et al., 2010).

CLINICAL MANIFESTATIONS Infection with *C. caviae* can be asymptomatic or, if infestation is heavy, pruritis, alopecia, hyperemia, and dermal crusts may be seen (Coman et al., 2009; Fox, 2002; Hirsjarvi and

Phyala, 1995; Lumeij and Cremers, 1986; Schonfelder et al., 2010). Anorexia may result secondary to grooming pruritic areas (Schonfelder et al., 2010).

PATHOLOGY The appearance of *C. caviae* mites themselves is the major pathologic finding (Fox, 2002). Mites and ova are located on the hair shafts of the guinea pigs, not burrowed into the skin.

DIAGNOSIS Mites may be seen with the unaided eye, hand lens or dissecting microscope. *C. caviae* can also be found on a superficial scrape (Harkness and Wagner, 1995; Percy and Barthold, 2007; Schonfelder et al., 2010). Combing, hair plucking, and cellophane tape testing can aid in isolating mites for observation (White et al., 2003).

PREVENTION AND THERAPY Many treatment options have been described in the literature for *C. caviae*. Dilute ivermectin (diluted in aqua/propylene glycol) sprays have been successful, especially for treating large colonies of infected animals (Baker, 2007; Hirsjarvi and Phyala, 1995; White et al., 2003). Selamectin, 12–15 mg/kg, applied twice at 2-week intervals has also eliminated infection (Baker, 2007; Fox, 2002; Schonfelder et al., 2010). Pyrethrin sprays and powders have been used to rid the environment of *C. caviae* (Harkness and Wagner, 1995; Hirsjarvi and Phyala, 1995). 1% Virkon S® was used to treat an automatic watering system (Hirsjarvi and Phyala, 1995). Older successful treatments include the use of dichlorvos vapors (Henderson, 1973) as well as immersion of shaved animals in 0.15% trichlorfon (Lumeij and Cremers, 1986).

TRIXACARUS CAVIAE

BACKGROUND *T. caviae* was discovered in a colony of albino guinea pigs in the early 1970s by Fain and was described as a disease very similar in appearance to sarcoptic mange in other animals (Dorrestein and Vanbronswijk, 1979; Fain et al., 1972). The first report of *T. caviae* in North America was in 1980 at Davis, California (McDonald and Lavoipierre, 1980).

ETIOLOGY *Trixacarus caviae* is the causative organism (Figure 23.8).

EPIZOOTIOLOGY AND PATHOGENESIS *Trixacarus caviae* is a species-specific sarcoptic mite that most commonly affects guinea pigs that are 1–3 years of age (Dorrestein and Vanbronswijk, 1979). If left untreated, the parasite load peaks 1 month post-infection, after which it slowly regresses (Fuentelba and Hanna, 1996). The life cycle of *T. caviae* includes an egg, larval, two nymphal, and a final adult stage, all of which inhabit the host guinea pig (Baker, 2007). Transmission is by direct

contact, with nymphal or larval stages indicated in establishing new infestations (Baker, 2007; Rothwell et al., 1991). Within 72 hours, pups born to an infected guinea pig dam will show clinical signs consistent with *T. caviae* infestation (Beck et al., 2007; Kummel et al., 1980).

Humans have been reported to develop transient pruritic, papulovesicular dermatitis after contact with infected animals, although mites appear to be incapable of persisting on human skin (Fuentelba and Hanna, 1996; Kummel et al., 1980; Mederle and Indre, 2009).

CLINICAL MANIFESTATIONS While infection with *T. caviae* may be asymptomatic and result in non-clinical carrier animals, *T. caviae* has been reported as the most common and important cause of dermatitis in guinea pigs (Dorrestein and Vanbronswijk, 1979; Fuentelba and Hanna, 1996; Percy and Barthold, 2007; White et al., 2003). Severe pruritis and excoriation along with erythema and alopecia can accompany dermatitis in some animals (Ackerman, 1987; Beck et al., 2007; Dorrestein and Vanbronswijk, 1979). In those guinea pigs that are clinical, grayish to yellow or white crusts may be present on the skin and can be dry or slightly greasy (Ackerman, 1987; Dorrestein and Vanbronswijk, 1979). Secondary bacterial infections of infected skin areas are possible (Fuentelba and Hanna, 1996). Infection usually starts on the face and ears, spreading to the lumbar regions and lateral aspects of the legs (Dorrestein and Vanbronswijk, 1979; Percy and Barthold, 2007). The intense pruritic response in some guinea pigs is reported to be due to an initial allergic reaction to mite antigen (Fox, 2002). Extreme restlessness and emaciation have been noted in affected animals, especially in those that seemingly scratch uncontrollably (Beck et al., 2007). This constant scratching can lead to “fits” of muscular spasms or sporadic epileptiform seizures (Ackerman, 1987; Beck et al., 2007; Dorrestein and Vanbronswijk, 1979; Kummel et al., 1980) caused by generalized pruritus-induced hyperesthesia (Baker, 2007).

PATHOLOGY Orthokeratotic hyperkeratosis and acanthosis have been noted in animals showing clinical signs of *T. caviae* infection (Ackerman, 1987; Dorrestein and Vanbronswijk, 1979; Fuentelba and Hanna, 1996; Zenoble and Greve, 1980). A polymorphonuclear leucocytic infiltrate is present in the dermis (Dorrestein and Vanbronswijk, 1979; Percy and Barthold, 2007; Rothwell et al., 1991; Zenoble and Greve, 1980). Adult mites may be noted in “tunnels” or burrows located in the hyperkeratotic areas (Dorrestein and Vanbronswijk, 1979; Zenoble and Greve, 1980). Such tunnels approach the epidermis perpendicularly, with some entering the mouth of hair follicles (Zenoble and Greve, 1980). Eggs may also be present in tunnels (Dorrestein and Vanbronswijk, 1979). *T. caviae* mites have sharp spines on

the cuticle of their dorsums (Zenoble and Greve, 1980), which differentiates them from *Notoedres* (Ackerman, 1987). The anus of the female *T. caviae* mite is located dorsally, while this structure is located terminally on *S. scabiei* (Ackerman, 1987; Baker, 2007; Fuentealba and Hanna, 1996).

DIAGNOSIS Deep skin scrapes of crusted areas with 10% KOH reveal *T. caviae* (Dorrestein and Vanbronswijk, 1979; Fain et al., 1972; Fuentealba and Hanna, 1996; Mederle and Indre, 2009). Zajac et al. (1980) report that live mites could be demonstrated for 5 days postmortem from deep skin scrapings taken from a guinea pig held at 4°C after death.

PREVENTION AND THERAPY Treatment of both affected animals and the environment has been employed to rid guinea pig colonies of *T. caviae*. Multiple treatment regimens have been reported as successful over the years, including lindane baths (Dorrestein and Vanbronswijk, 1979; Zajac et al., 1980), weekly lime sulfur dips (Ackerman, 1987; McDonald and Lavoipierre, 1980; Zenoble and Greve, 1980), ivermectin injections (White et al., 2003), and monthly spot-on treatment with 10% imidacloprid and 1% moxidectin (Beck et al., 2007). Dilute lime sulfur can also be used to treat the environment (White et al., 2003). Valium has been used to control seizure-like activity related to *T. caviae* infection by some, whereas others suggest that treating the mite infection alone eliminates this sequela to infection (Beck et al., 2007; White et al., 2003).

Cestodes

According to Harkness and Wagner (1995), tapeworms rarely infect guinea pigs. *Anoplocephala* spp. and *Monoecocystus parvitesticulatus* (Table 23.1) have been reported in the intestines of South American guinea pigs (Baker, 2007; Sardella and Fugassa, 2009).

Nematodes

Baylisascaris procyonis

ETIOLOGY *Baylisascaris procyonis* is the causative organism.

PATHOGENESIS Guinea pigs are paratenic hosts of *B. procyonis* and contract infection by ingesting eggs in raccoon feces (Baker, 2007). Once ingested, larvae will hatch and penetrate the small intestine of the guinea pig, migrate through the liver to the lungs and disseminate throughout the body via the circulatory system. Larvae then encapsulate where they remain until ingested by a raccoon.

CLINICAL MANIFESTATIONS No signs are present in the guinea pig due to *B. procyonis* unless organisms migrate to the brain. Migration can result in lethargy, head tilt and ataxia, which may progress to cachexia, stupor, hyperexcitability, lateral recumbency, torticollis, or opisthotonos (Van Andel et al., 1995).

PATHOLOGY In cases where *B. procyonis* migrates to the brain, multifocal eosinophilic granulomatous inflammation and neutrophilic infiltration is seen, along with perivascular lymphoid cuffing and malacia (Van Andel et al., 1995). Eosinophilic granulomata have been noted in the lungs of some infected animals.

DIAGNOSIS Histology is diagnostic for *B. procyonis* (Baker, 2007). The Baermann extraction technique can be used to extract organisms from the cerebral tissue of clinical animals (Van Andel et al., 1995).

PREVENTION AND THERAPY Prevention, rather than treatment, is the most logical approach for *B. procyonis* control, as clinical signs are often not noted until the end stage of infection and diagnosis relies on histopathology. Contamination of bedding or food with raccoon feces must be avoided. Ova can be viable for years in soil and weeks to months in straw and are resistant to most disinfectants (Fox, 2002). Removal of contaminated bedding and the autoclaving of caging may be required (Baker, 2007). Humans, similarly to guinea pigs, can contract infection by ingesting raccoon feces, but transmission from guinea pigs to humans is not feasible (Fox, 2002).

Paraspidodera uncinata

ETIOLOGY *Paraspidodera uncinata* is the causative organism.

EPIZOOTIOLOGY AND PATHOGENESIS *P. uncinata* is the cecal worm of guinea pigs and the most common nematode infecting this species (Griffiths, 1971). The prevalence of *P. uncinata* in wild guinea pigs of South America was found to be 37%, while the prevalence was noted as 23.8% in a laboratory colony of guinea pigs (Coman et al., 2009; Dittmar, 2002). Transmission is via ingestion of an embryonated egg in feces (Baker, 2007; Fox, 2002). Eggs become infectious 3–5 days after they are initially shed (Fox, 2002). The life cycle is not well described (Baker, 2007).

CLINICAL MANIFESTATIONS Infections are normally asymptomatic, but with heavy parasitic loads weight loss, diarrhea, and disability are possible (Fox, 2002).

PATHOLOGY Infection can, and often does, occur without pathologic changes (Baker, 2007; Percy and

FIGURE 23.9 The cecal worm, *Paraspidodera uncinata*, is the most common nematode of guinea pigs. The adult worm (A) is noted in the cecum, while the eggs (B) are shed in the feces. Figure courtesy of Dr. G. Van Hoosier.

Barthold, 2007; Rigby, 1976). If cecal worms migrate through the intestinal mucosa, a hemorrhagic typhlitis may be seen along with capillary ectasis in the submucosa (Coman et al., 2009).

DIAGNOSIS Adult worms may be seen in the cecum at necropsy and eggs may be observed in feces (Figure 23.9) (Baker, 2007; Rigby 1976).

PREVENTION AND THERAPY Levamisole administered at 25mg/kg, either orally or subcutaneously, has most often been reported as an effective treatment for *P. uncinata* in the guinea pig (Baker, 2007; Eliazian et al., 1975). Other reported treatment regimens include oral mebendazole at 50mg/kg (Baker, 2007) and Romavermectin B1 given subcutaneously at a dose of 0.2mg/kg twice at a three-week interval (Coman et al., 2009).

Pelodera strongyloides

ETIOLOGY *Pelodera strongyloides* is the causative organism.

PATHOGENESIS *P. strongyloides* organisms are usually found in damp soil or vegetation (White et al., 2003). Bedding can be a possible source of infection.

CLINICAL MANIFESTATIONS While typically non-pathogenic, if *P. strongyloides* invade hair follicles dermatitis can result (Baker, 2007; White et al., 2003).

PATHOLOGY Organisms may be found in hair follicles of clinically infected animals.

DIAGNOSIS The observation of larvae in skin scrapings or biopsies signifies infection (White et al., 2003). Adults may be observed in the bedding.

PREVENTION AND THERAPY Cages should be kept dry, as organisms thrive in moist environments (White et al., 2003). The bedding of any positive animal should be replaced. A 1–2% chlorhexadine bath has been recommended for infected animals as a means of preventing secondary infections.

Trichinella spiralis

Trichinellosis due to *Trichinella spiralis* is possible in guinea pigs, but rare, especially in laboratory animals that seldom come in contact with infected material (raw or undercooked meat) (Sebesteny, 1976). Enteritis could develop in infected animals if *T. spiralis* organisms migrate through the intestinal wall.

Trematodes

Fasciola

BACKGROUND Infection in present laboratory-housed guinea pigs is rare, but when *Fasciola* organisms are noted it is often in conjunction with recent diet supplementation of a leafy vegetable carrying encysted trematodes (Baker, 2007; Fox, 2002).

ETIOLOGY Two *Fasciola* species are noted in guinea pigs, *Fasciola hepatica* and *Fasciola gigantica* (Baker, 2007). *F. gigantica* is slightly larger in size than *F. hepatica*, although *F. gigantica* rarely reach patency in guinea pigs.

PATHOGENESIS Guinea pigs ingest encysted *Fasciola* metacercariae on vegetation (Baker, 2007; Fox, 2002). Once ingested, metacercariae hatch in the small intestine and migrate through the wall to the peritoneal cavity and the liver. Juvenile flukes develop in the liver and, once mature, burrow in the bile ducts. Eggs are shed and enter the gut, where they pass in the feces. A snail intermediate host is necessary for maturation from cercariae to infectious metacercariae. Metacercariae encyst on leafy vegetation.

CLINICAL MANIFESTATIONS Emaciation and anemia have been associated with *Fasciola* infection (Sebesteny, 1976). Posterior paresis was noted in animals that developed cysts in the lumbar musculature after aberrant fluke migration (Baker, 2007).

PATHOLOGY Hepatic congestion and hemorrhage, especially around portal vessels, central veins and sinusoids is possible (Baker, 2007). Fibronectin tracks and granulomas may also be observed in the liver. Other pathology due to fluke infection is often the result of aberrant migration, resulting in cysts in areas such as the kidney, the peritoneal cavity and the pelvic cavity. Cysts often contain coffee-brown-colored material.

DIAGNOSIS *Fasciola* spp. can be observed on fecal flotation (Baker, 2007).

PREVENTION AND THERAPY Prevention is best achieved by limiting the amount of leafy vegetation supplemented in a guinea pig's diet; if supplemented, do not feed vegetation from fluke-endemic locations. *Fasciola* in ruminants is treated with albendazole and clorsulon (Baker, 2007).

INTRODUCTION

This chapter covers the non-infectious conditions which have been described in guinea pigs, including nutritional, metabolic, congenital, and neoplastic diseases. Since the first edition of this chapter, ably penned by Dr. Joseph Wagner over 30 years ago, the available veterinary literature regarding diseases of guinea pigs has grown remarkably; however, publications of infectious diseases have greatly outnumbered those of non-infectious conditions. In today’s clean laboratory environment, the lab animal practitioner or pathologist is far more likely to encounter conditions described in this chapter, which should stress the continued importance of these “classic” entities in this species. The primary neoplasms of each organ system are included at the end of each respective section.

CARDIOVASCULAR SYSTEM

Rhabdomyomatosis

Over a quarter century after its first description in this species by Hueper (1941), the poorly named lesion, “rhabdomyomatosis,” is a morphologic change in cardiac myocytes whose exact etiology is still to be elucidated. This relatively common finding in the heart of guinea pigs may be grossly or microscopically mistaken for a neoplasm, but it is an incidental finding of little to no clinical significance. Rhabdomyomatosis may be seen in animals of all ages, even animals as young as 3 weeks. Rhabdomyomatosis is characterized by well-defined areas of cardiac muscle in which myocytes are swollen by excessive cytoplasmic glycogen, which gives them a characteristic pale appearance when viewed grossly (Takahashi et al., 1985). These lesions may occur in any region of the heart, but are most commonly seen in the left ventricle, especially subendocardially. The gross lesion may appear as a tan streak in the myocardium which is barely visible to the naked eye, or may incorporate large areas of myocardium. Microscopically, glycogen accumulation within cardiac myocytes results in

the formation of large cleared areas of the cell (resulting from dissolution of glycogen during routine histologic processing) separated by small threads of eosinophilic cytoplasm radiating outward from a centrally placed nucleus, resulting in the colloquial name “spider cells”. While rarely performed, the presence of glycogen may be demonstrated by staining of alcohol-fixed or unfixed fresh-frozen specimens with periodic acid-Schiff (PAS) preparations. Immunohistochemical procedures reveal that affected cells stain positively for desmin and myoglobin (attesting to their muscle origin), and negatively for smooth muscle actin and vimentin (Tanimoto and Ohtsuki, 1995). The origin of this lesion is still unknown in the guinea pig and other species in which it has been reported, such as swine, dogs, and man. These lesions are no longer regarded as neoplasms, current investigations point toward the possibility of hamartoma, glycogen metabolism disorder, or a degenerative condition affecting cardiac myofibers (Hoch-Ligeti et al., 1986). In man and swine, it is considered congenital, as it is often seen in children less than a year of age, and has been reported in certain breeds of swine in individuals as young as 3 weeks (McEwen, 1994). Investigations in humans have shown that rhabdomyomatosis arises as part of a hereditary autosomal-dominant syndrome related to TSC-1 and TSC-2 gene mutation (Vaughan et al., 2001). Even the cell of origin continues to be in dispute; ultrastructural analysis of rhabdomyomas in humans (Silverman et al., 1976) and swine (Tanimoto and Ohtsuki, 1995) have identified Purkinje cells and cardiac myofibers, respectively, as the cell of origin in rhabdomyomatosis. Some authors have hypothesized that “rhabdomyoma cells” may actually arise from pluripotential cells with combinations of the two (Silverman et al., 1976). Clinical signs associated with this lesion are rare; in one case in the dog, congestive heart failure and chylothorax were attributed to the presence of an intra-atrial rhabdomyoma (Mansfield et al., 2000). Clinical disease associated with rhadomyomas in the guinea pig has not been reported.

Cutaneous Vascular Malformation

A cutaneous vascular malformation was reported (Osofsky et al., 2004) in a young adult female guinea pig. The violaceous plaque measured 3×2 cm, was ulcerated and bled intermittently, eventually resulting in fatal blood loss. The lesion consisted of a mass of well-differentiated vessels which were distributed throughout the dermis, subcutis, and skeletal muscle. Vessels were lined by endothelial cells and surrounded by smooth muscle cells; hematopoietic cells were distributed between vessels.

Miscellaneous Cardiac Disease

Documented reports of non-infectious cardiac disease in the guinea pig are rare. A single case of presumptive cardiomyopathy, as evidenced by an enlarged heart, ascites, and pulmonary edema has been reported (Cox and Haworth, 2000); however, the patient was lost to follow-up following successful intervention with furosemide and enalapril therapy. The same hospital reported a case of fatal hemopericardium identified at necropsy of a guinea pig; the cause was not subsequently identified.

Cardiovascular Neoplasia

Reports of primary cardiac tumors are rare in guinea pigs. Mesenchymal tumors have been described (McConnell and Edinger, 1968) in several Hartley guinea pigs from the same colony, suggesting a familial genetic predisposition. These neoplasms were composed of well-differentiated fat, cartilage, bone, hematopoietic tissue, and smooth muscle.

RESPIRATORY SYSTEM

Pulmonary Perivascular and Peribronchiolar Lymphoid Nodules

Bronchiolar-associated lymphoid tissue (BALT) is a common finding in domestic and laboratory animals of all species. In general, the amount of BALT increases with age, exposure to inhaled antigens or any number of infectious agents (especially viruses). Lymphoid aggregates associated with pulmonary blood vessels, however, are uncommon in any animal species, and if present, are usually a sign of significant pulmonary inflammation.

In the guinea pig, nodular aggregates of lymphocytes are a common finding in association with the smaller branches of both pulmonary arteries and veins. These nodules are a peculiar anatomic feature of the

guinea pig which has likely caused great consternation with pulmonary researchers over the years (Thompson et al., 1962). The nodules appear to originate within the adventitia, and larger aggregates may extend into surrounding alveolar septa.

Perivascular lymphoid aggregates may be seen in animals as young as 5 days of age, and are commonly seen in older animals; they are restricted to the lung and present in no other tissue. Grossly, they may appear as pinpoint, white foci in the subpleural areas of the lung. Ultrastructurally, the aggregates are composed of morphologically normal lymphocytes, and studies have failed to identify infectious agents in association with them (Baskerville, 1982).

Thick Pulmonary Artery Musculature

Another common anatomic finding in guinea pigs is the thick muscular wall seen in pulmonary arteries and arterioles. This finding is not considered a true hypertrophy or hyperplasia of the smooth muscle. To investigators unfamiliar with the microscopic anatomy of the guinea pig lung, cross-sections of pulmonary arteries and arterioles show an apparent thickening of the muscular wall and a narrow lumen, especially when compared with that of other species. While these changes might be associated with pulmonary hypertension in other species, they are considered to be a normal finding in the guinea pig.

Osseous Metaplasia of the Lung

This is another common incidental finding in guinea pigs, as well as other lab animal species, including rats and hamsters. The incidence appears to increase with age. Affected animals have spicules of well-differentiated, mineralized lamellar bone within the pulmonary parenchyma, usually associated with little or no inflammation (Kaufmann, 1970). Foci of bone have also been reported in the eye (Donnelly and Brown, 2002) and kidney in a few individuals. While several investigators have commented on the possibility of these bone fragments being inhaled (Innes, 1956), the well-differentiated nature, presence of bone marrow, and lack of inflammation strongly suggest an endogenous origin. Foci of bone should not be considered to be the cause of pneumonia in the guinea pig. If such a histologic picture is seen, testing for common infectious agents, such as *Bordetella* sp., is strongly warranted.

Foreign Body Pneumonia

The presence of plant or food material within alveoli or airways is a direct result of living on contact bedding, the typical environment for most guinea pigs.

The problem is more commonly seen in young guinea pigs, but is rarely of clinical significance. The problem may be incorrectly labeled *pneumoconiosis*, which is more properly applied to the inhalation of mineral dusts, especially those of coal (anthracosis) or silicon (silicosis).

Most foci of plant material are found in smaller airways, as a result of being larger than the 5µm or smaller particle size needed to enter the alveoli (Muto, 1982). Grossly, airway obstruction as well as the inflammatory response to the foreign material leads to localized atelectasis characterized by depressed, reddened areas of the lung. Contaminated plant material usually incites a pyogranulomatous response. Neutrophils respond initially, often due to bacterial contaminants, but over time, a gradual shift in the inflammatory infiltrate to epithelioid macrophages and lymphocytes occurs. In more severe cases, multinucleated macrophages will be seen around plant material. Small airways are most commonly affected, but in severe cases, the inflammatory infiltrate will extend into the surrounding alveoli. Plant material is generally birefringent, and polarization of a lung section with multiple granulomas will usually disclose the location of any plant material (Percy and Barthold, 2007). Although rarely seen today, granulomas associated with the injection of Freund's complete adjuvant should be included in the differential diagnosis for this condition.

Pulmonary Granulomas Due to Injection of Freund's Complete Adjuvant

The injection of Freund's complete adjuvant in guinea pigs, as well as other species, will result in the production of granulomas in a number of organs, including the lung, liver, spleen, lymph nodes, and skeletal and cardiac muscle (Schiefer and Stunzi, 1979). In the lung, multifocal to coalescing areas of granulomatous inflammation, sometimes with granuloma formation, efface airways, alveolar septa, and alveoli. More chronic lesions may include abundant fibrous connective tissue. Vertebral osteolysis and posterior paresis were reported in addition to pulmonary lesions in several guinea pigs receiving epaxial injections of complete Freund's adjuvant in one report (Hill et al., 2006).

Respiratory Neoplasia

Bronchogenic neoplasms are the most common primary pulmonary neoplasms reported in the guinea pig (Greenacre, 2004; Manning, 1976). In guinea pigs over 3 years of age, these tumors are reported to have an incidence of up to 35%, with benign papillary adenomas being the predominant neoplasm. Malignant neoplasms are rare (Manning, 1976).

Microscopically, the papillary adenomas consist of cuboidal epithelial cells which line pre-existent alveolar septa, and are similar to neoplasms which may be caused in other species by infectious agents or other stimuli, but infectious agents have not been isolated. Clinically, these neoplasms, as they attain a large size, mimic pneumonia, but fail to respond to appropriate therapy. Radiography may help to identify single primary neoplasms and to differentiate them from infectious disease (Greenacre, 2004).

A single case of nasal adenocarcinoma was reported by Vannevel and Wilcock (2005). The neoplasm presented as a bleeding pink mass which infiltrated the maxilla, resulting in tooth loss.

GASTROINTESTINAL SYSTEM

Malocclusion

Like other rodents with continually growing hypsodont teeth, malocclusion is a common problem in the guinea pig. With the exception of fluorosis (Hard and Atkinson, 1967), a definitive cause has not been identified for malocclusion, although genetics, diet, and in some cases, trauma and infection may play a significant role. A genetic predisposition has been suggested in guinea pigs including inbred strains 2 (Rest et al., 1982), 2/N, and 13/N, and outbred Dunkin-Harley guinea pigs (Ediger et al., 1975). Scurvy has been suggested as a predisposing factor as movable teeth may predispose to uneven wear (Crossley and Aiken, 2004).

The most common clinical signs associated with malocclusion in the guinea pig include low feed intake, loss of condition, poor coat, low skin elasticity, increased amounts of fluid ingesta in the cecum, and scant feces (Jekl et al., 2008). In Jekl's study, bruxism was noted in only 15% of guinea pigs. Drooling, known colloquially as "slobbers", has also been described as a presenting clinical sign (Wagner, 1976), although it occurs less commonly in the guinea pig than in rabbits or chinchillas with malocclusion (Jekl et al., 2008).

Examination of the teeth, especially the cheek teeth, should be part of a thorough examination of every guinea pig. The narrow oral cavity and large buccal folds make oral examination difficult in this species. A thorough oral examination is facilitated by isoflurane anesthesia. Loops of gauze behind the incisors will allow opening of the jaws, and an otoscope, vaginal speculum, or a small-diameter flexible endoscope will allow visualization of all dental surfaces.

Gross elongation of the coronal surface, especially of the mandibular cheek teeth, is one of the most commonly seen types of malocclusion in the guinea pig. In the guinea pig, the rostral (mesial) mandibular cheek

teeth (especially PM 4) elongate, forcing the mouth open. As the coronal surfaces of the premolars elongate, the mandible is pushed forward, predisposing to even more severe malocclusion. In advanced cases, the cheek teeth may grow medially, entrapping the tongue and impairing the animal's ability to pass a food bolus into the esophagus. In one study, 25% of affected animals had this "bridge-like" malocclusion (Legendre, 2002). For obvious reasons, the medial growth of the mandibular teeth, along with the normal lack of lateral excursion in this species (Legendre, 2002), provides an opportunity for lateral overgrowth of the maxillary cheek teeth and damage to the buccal mucosa.

Treatment of malocclusion involves shortening the coronal surface and restoring a normal occlusal surface. Short-term control is possible, but a long-term prognosis is guarded at best. Clipping of any teeth with scissors or rongeurs is not acceptable as it predisposes to fracture of the crown (Crossley and Aiken, 2004). The use of a low-speed dental handpiece and flat or fissured bar is the easiest way to reshape the teeth; a dental drill with diamond bur may also be used to good effect (Crossley and Aiken, 2004; Legendre 2002). Retrimming should be done every 4–6 weeks.

Gastric Ulcers

Gastric ulcers are relatively common in guinea pigs and this species is often used as test subjects for new anti-ulcer medications. A wide range of infectious agents and chemicals have been used to incite ulcer formation in this species, including *Helicobacter pylori*, non-steroidal anti-inflammatory agents, histamine, and alcohol, among others (Lee, 2000). However, as a clinical condition, most gastric ulcers are secondary to other diseases, and likely a result of stress. The first report of gastric ulceration in a guinea pig occurred over a century ago in association with *Streptococcus pneumoniae* infection (Curtis, 1899). In one study over a 5-year period, one author reported 15 cases of gastric ulcers, mostly secondary to other diseases (Wagner, 1976). In this report, one ulcer perforated, resulting in a septic peritonitis.

Gastric Dilation and Volvulus

Gastric dilation with or without volvulus in guinea pigs has been well-documented. Facility "outbreaks" have been reported (Keith et al., 1992) but underlying dietary or husbandry factors are yet to be identified.

Clinical signs are non-specific, if observed at all. Anorexia, inappetance, dyspnea, and scant feces are sometimes observed. At necropsy, most cases have a 180-degree rotation along the mesenteric axis, and the stomach is dilated with fluid and gas (Lee et al., 1977). In most cases, the cause of death is respiratory insufficiency

due to lung compression from the expanded stomach, as well as concomitant vascular compromise and shock. A single case of omental torsion with partial gastric torsion has been reported in one animal (Shrubsole-Cockwill et al., 2008).

Antibiotic-Associated Typhlocolitis

This condition is well-documented. The first report described it as a penicillin "toxicity" (Hamre et al., 1943), and over the years ampicillin, erythromycin, lincomycin, chlortetracycline, oxytetracycline, streptomycin, and bacitracin were added to this list. However, other antibiotics in common use during this time, such as chloramphenicol (Eyssen et al., 1957), were found not to result in death of treated animals. Newton et al. (1964) discovered that penicillin had no toxicity for germfree animals.

A common hypothesis for this condition lies in the fact that the flora of the intestinal tract in the guinea pig is primarily Gram-positive. Administration of the antibiotic agents listed above, even at appropriate pharmacologic doses, will result in severe perturbations of the intestinal flora and a process known as "dysbiosis" or "dysbacteriosis" (Percy and Barthold, 2007). Moreover, the pharmacokinetics of many of these antibiotics includes biliary excretion, which concentrates them in the intestinal tract.

In the small intestine, cecum, and colon of guinea pigs, streptococci and lactobacilli predominate. Administration of antibiotics with broad efficacy against these bacteria may result in a hundred-fold decrease in "beneficial" Gram-positive bacteria and a ten-million-fold increase in Gram-negatives within only 12 hours. In addition, high levels of clostridia, particularly *Clostridium difficile*, have been recovered from affected animals as well as demonstration of *C. difficile* enterotoxin (Rehg and Pakes, 1981). Occasionally, *E. coli* bacteremia has been reported in affected animals as well (Farrar and Kent, 1965).

Affected animals have profound diarrhea, with up to 100% mortality within 5 days. Most lesions occur in the cecum and colon, occasionally extending into the terminal ileum (Figure 24.1). The primary gross finding is in the cecum, which is massively distended with gas and fluid. There is at least mucosal hemorrhage, which is often transmural and can be seen from the serosa. Due to the extensive necrosis associated with *C. difficile* cytotoxins, the cecal wall may be friable and tear easily with minimal traction. In cases of *C. difficile* intoxication, the toxin produces a very distinct band of coagulation necrosis and hemorrhage, beginning in the superficial mucosa and progressing deeper into the tissue over time. The mucosa is denuded of epithelium, and edema and hemorrhage is seen in the lamina propria and deeper layers. Infiltration of neutrophils and other inflammatory cells

FIGURE 24.1 Marked enlargement of the cecum (arrow) in a guinea pig following administration of broad-spectrum antibiotics and marked alteration of normal flora. (Photo courtesy of the Armed Forces Institute of Pathology.)

is seen only in animals surviving for a length of time. Mucus cell hyperplasia has been reported in the terminal ileum; this reparative change is likely seen only in animals which survive the initial insult.

Diagnosis of this condition includes a careful history, microscopic examination of necropsy samples, anaerobic culture of cecal contents, and ELISA assay for toxin. The cytologic finding of large numbers of robust bacilli in feces or gut contents is non-specific and not diagnostic for this condition. Characteristic histologic findings in the small intestine may yield a provisional diagnosis prior to return of culture and toxicology results.

Appropriate antibiotics for the treatment of bacterial disease in the guinea pig are trimethoprim-sulfa, chloramphenicol, and enrofloxacin. One author recommends supplementing the animals with a *Lactobacillus*-containing probiotic whenever antibiotics are used in this species (O'Rourke, 2004).

Cecal Impaction and Torsion

Impaction of the cecum or obstruction of the cecocolic orifice with bedding, phytobezoars, or inspissated fecal material has been reported (Wagner, 1976). Deaths due to cecal torsion have also been reported with the massively enlarged and hemorrhagic organ, filled with gas and fluid occupying a large part of the abdomen. In such cases, infectious causes such as *Eimeria caviae* and *Clostridium* sp., often associated with the administration of antibiotics, should be considered (Percy and Barthold, 2007).

Rectal Impaction

This condition is well-known in older pet guinea pigs. As a result of muscle wasting in older animals,

FIGURE 24.2 Aged sows and boars may experience rectal impaction as a result of muscle wasting.

the rectum and anus may become plugged with a large fecal mass, which often necessitates manual removal (Figure 24.2). This condition appears to be more common in boars than in females or neutered males. The use of a combination of mineral oil and warm water will soften harder pellets and careful cleaning of the perineum (also called the perineal sac) will prevent scald. Older animals may require assistance on a daily basis. Genetic predisposition and diet may be contributing factors, but evidence is lacking.

Prolapsed Rectum

Rectal prolapse is a non-specific finding in guinea pigs as it is in a number of other species. Any disease resulting in straining may result in prolapse of the rectum; the incidence increases with age and as the muscles of the perineum grow weaker. Common causes include rectal or anal impaction, enterocolitis, or dystocia, and the condition may occur in conjunction with vaginal prolapse at parturition (Wagner, 1976).

Focal Coagulative Hepatic Necrosis

This condition is occasionally seen at necropsy in guinea pigs, as it may be seen in other laboratory rodents. This finding may be seen in control animals as well as in animals afflicted with systemic disease (Cuba-Caparo et al., 1977). These lesions might be mistaken for other conditions causing hepatic necrosis, such as *Salmonella enteritidis* or *Clostridium piliforme* infection.

Grossly, this change appears as sharply demarcated areas of pallor in one or multiple lobes of the liver, usually in subcapsular areas. Microscopically, these areas are composed of regionally extensive coagulative necrosis of hepatocytes with minimal hemorrhage. This

finding lends credence to the current hypothesis that this change is the result of terminal hepatic vascular insufficiency and locally impaired blood flow to certain regions (Percy and Barthold, 2007).

Idiopathic Cholangiofibrosis

In one report, of a colony of 167 animals of the Jena:Alb outbred stock, between the ages of 2 and 47 months, 36 (21.5%) had post-necrotic, multilobular cirrhosis. Affected animals had roughened hair coats, emaciation, weakness, apathy, and occasionally abdominal distention (Guttner and von Zychlinski, 1981). Grossly, all hepatic lobes had a micronodular appearance. Microscopic examination revealed an ongoing necrotic process, with affected livers containing large foci of coagulative necrosis, which was eventually replaced by large bands of mature collagen separating proliferating biliary ductules. While labeled “cirrhosis”, the characteristic lesion of macronodular hepatocellular regeneration was not identified in this report, so the term cholangiofibrosis appears more appropriate (Percy and Barthold, 2007). The etiology of this particular lesion was not elucidated, and the lesion was attributed to an unidentified toxin (Guttner and von Zychlinski, 1981).

More recently, xenobiotics have been used to create a guinea pig model of primary biliary cirrhosis, a condition of autoimmunity in which lymphocytes infiltrate and destroy small interlobular biliary ducts (Leung et al., 2007).

Neoplasia of the Alimentary System

Primary neoplasms of the gastrointestinal tract are rare in the guinea pig. Tumors of the alimentary tract consist primarily of gastric leiomyomas, usually in the region of the pylorus (Papanicolaou and Olcott, 1942). Reports of tumors of the hepatobiliary system are equally rare. A bile duct carcinoma was reported in a guinea pig which also had a nasal adenocarcinoma (Vannevel and Wilcock, 2005). The biliary neoplasm was successfully treated through surgery. A single case of abdominal mesothelioma affecting the serosa of the liver and gastrointestinal tract has been reported in a guinea pig (Wilson and Brigman, 1982).

URINARY SYSTEM

Chronic Interstitial Nephritis

Guinea pigs, like other rodents, develop a syndrome of progressive renal insufficiency with advancing age. Evidence of chronic renal disease is present in almost all guinea pigs 3 years and older. This condition results

FIGURE 24.3 Irregular contour and linear areas of fibrosis in an older guinea pig with chronic interstitial nephritis. (Photo courtesy of Dr. Paul Stromberg.)

in progressive debility in older guinea pigs, and complicates renal research conducted in aging guinea pigs.

Clinical signs include anorexia, cachexia, polyuria, and polydipsia. Clinicopathologic data reveal increased blood urea nitrogen, creatinine, and phosphorus levels, and a non-regenerative anemia associated with decreased erythropoietin levels. The urine specific gravity is low or isosthenuric. Ultrasound can demonstrate shrunken kidneys with areas of hyperechogenicity. At necropsy, kidneys are small with an irregular outline and the cortices are pitted. On cut section, white areas of fibrosis extend downwards from the capsule into the medulla (Figure 24.3). Microscopically, there are multifocal to coalescing areas of roughly linear interstitial fibrosis which entrap tubules and glomeruli (hence the colloquial name “nephrosclerosis”). In these areas, there is loss and marked atrophy of tubules, which worsens toward the renal pelvis. Remaining tubules in these areas are often ectatic and may contain proteinaceous fluid and cellular debris. Rarely, tubules (especially in the deeper cortex) exhibit regenerative or hypertrophic changes. Glomeruli, while generally normal, may have dilated Bowman’s capsules. Aggregates of lymphocytes and plasma cells may be scattered throughout the kidney. In severe cases, renal arterioles and arteries have marked medial thickening.

The cause of chronic interstitial nephritis has not been established in the guinea pig, although hypotheses include vascular disturbance, autoimmune disease, and diet as causative factors. The distribution of fibrosis (both anatomic and temporal) and the presence of arterial lesions suggest the possibility of periodic disturbances in blood flow (Percy and Barthold, 2007). In addition, a mild degree of hypertension has been recorded in affected animals (Takeda and Grollman, 1970). In one study, complement and IgG were demonstrated in the glomerular basement membranes, suggesting that antigen–antibody

disease contributes to the lesion (Steblay and Rudosfsky, 1971). Further investigation has failed to disclose an infectious agent common to affected individuals (Foltz et al., 1994). An increased incidence and severity of this condition has been identified in guinea pigs fed a high-protein diet.

Urolithiasis

Urolithiasis is a common problem in older female guinea pigs, but is occasionally seen in older boars as well. Affected animals may exhibit dysuria, stranguria, hematuria, and pain on caudal abdominal palpation. In a study of 19 cases, older female guinea pigs approaching 3 years of age were most frequently represented (Peng et al., 1990). The majority of uroliths are composed of calcium carbonate (Hawkins et al., 2009). Uroliths may range in size from sand-like crystals to large stones. Bacterial infection has been identified as a major predisposing cause in the guinea pig. In a colony outbreak of *S. pyogenes* in Dunkin-Hartley guinea pigs, 50% of breeders and adults had evidence of urolithiasis; *Streptococcus pyogenes* was often isolated from the urinary bladder (Okewole et al., 1991). *Corynebacterium renale* and *E. coli* have also been isolated. In addition, the anatomy of the female urogenital tract and immunosuppressive diseases such as diabetes mellitus have been purported to be contributing factors.

Diagnosis of urolithiasis is most often made by radiography (O'Rourke, 2004). The majority of successful treatments involve surgical removal. A recent report described cystoscopic removal (Pizzi, 2009). Urinary acidifiers appear to be of little use in guinea pigs as the animals cannot easily remove an acid load (Harkness and Wagner, 1989).

One study (Wood, 1981) reported an incidence of 0.6% of cystitis in parous breeding-colony female guinea pigs with accompanying nephritis and pyelitis; bacteriologic examination performed in six of 19 cases revealed a variety of bacterial agents including alpha-hemolytic streptococci, staphylococci, and one case of *E. coli*.

Nephrotoxicity

Acute renal failure was diagnosed clinically in a pet guinea pig that had ingested peace lily. The diagnosis was made by clinical history, signs of azotemia, hypercreatininemia, hyperphosphatemia, non-regenerative anemia, and isosthenuria, and the finding of calcium oxalate crystals in the urine. Peace lily (*Spathiphyllum* sp.) is a member of oxalate-containing plants that rarely cause toxicity in domestic species due to its propensity for causing oral lesions, salivation, and vomiting. A confirmatory necropsy was not performed in this case (Holowaychuk, 2006).

Urinary Neoplasia

Reports of neoplasia of the urinary system of the guinea pig are uncommon and poorly documented. An early report of osteosarcoma in the urinary bladder described a pleomorphic spindle cell tumor with multinucleated cells interpreted as osteoclasts but did not describe osteoid production (Twort and Twort, 1932). A second report describes four neoplasms of the urinary bladder, including one transitional cell carcinoma, and three pleomorphic tumors, one "anaplastic tumor", one "epidermoid carcinoma", and one "epidermoid papilloma" (Manning, 1976). While being described as "morphologically malignant", metastases were not noted.

A single case of "proliferative urocystica" along with a transitional cell adenoma has been reported and attributed to the long-term feeding of *Christella dentata* fern (Somvanshi and Sharma, 2005). Finally, a mural urinary bladder papilloma was reported in a guinea pig with concurrent urolithiasis and hydroureter (Stieger et al., 2003). Based on the relatively poor descriptions of these neoplasms and the questionable morphologic diagnoses in the literature, it is probably best simply to realize that urinary system neoplasia is rare in the guinea pig.

ENDOCRINE SYSTEM

Diabetes Mellitus

Diabetes mellitus has been reported in the guinea pig (Vannevel, 1998) and this species has been identified as an animal model for juvenile diabetes (Lang et al., 1979). It can be a significant problem in both research colonies and individual pets.

Affected animals have chronic weight loss, cachexia, polydipsia, and polyuria. In a colony setting, glucosuria (>250mg/dl urine), hyperglycemia, ketonuria, and abnormal glucose tolerance were noted as early as 3 months. In pets, diabetes is typically diagnosed at several months of age. Fasting blood glucose and ketonuria are variable, even in glucosuric animals, and measured levels of glucose in blood and urine are often no different from controls (Lang et al., 1979). Affected sows experience a marked decrease in fertility. In some animals, researchers described a subclinical form with transitory clinicopathologic abnormalities and minimal lesions (Lang et al., 1979).

Diabetes occurs in male Abyssinian-Hartley guinea pigs. Affected animals also develop bladder hypertrophy and voiding dysfunction (Belis et al., 1996). Diabetes has also been induced in this species by administration of high levels of glucocorticoids (Herberg, 1982).

In both the colony report and in single animal reports, one common theme is that the condition may be transient and animals may undergo spontaneous remission

(Lang et al., 1979; Vannevel, 1998). Spontaneous remission is defined by a lack of glucosuria and normal blood glucose readings. Another interesting finding in the colony “outbreak” was the predilection for normal animals, once introduced into the colony, to develop hyperglycemia and glucosuria. The cause for this condition was never found.

Pathologic findings in affected animals are similar to those seen in other species and include marked vacuolation of beta cells and fibrosis of islets. In some advanced cases, diabetic glomerulopathy (thickening of glomerular basement membranes and accelerated glomerular senescence) and diabetic cataracts occur (Lang et al., 1979). One diabetic pet guinea pig had dysuria resulting from a bladder infection presumably as a result of high levels of urine glucose which served as a substrate for bacterial growth.

The spontaneous remission of this condition has led some authors to suggest a dietary cause for transient diabetes mellitus and advocate restricting access of affected animals to high-fat dietary components such as seeds, as well as maintaining affected animals on quality hay and dark leafy greens as staples (Vannevel, 1998). Glucosuric animals appear to respond well to neutral protamine Hagedorn (NPH) insulin (O’Rourke, 2004).

Fatty Ingrowth of the Pancreas

With age, the proportion of exocrine tissue within the pancreas decreases, resulting in apparent increases in the amount of adipose tissue and to a less noticeable extent, islet tissue. This should be considered an aging change of no clinical significance (Wagner, 1976).

Hyperadrenocorticism (Cushing’s Disease)

There are currently two reports of Cushing’s disease in the literature and all cases appear to be the result of functional adrenocortical lesions (Gaschen et al., 1998; Zeugsweter et al., 2007). Clinical signs in both affected animals included alopecia, apathy, obesity, and lethargy, and one animal had polydipsia and weight loss. In one animal (Gaschen et al., 1998), hyperadrenocorticism was suspected clinically and enlarged adrenal glands were noted on ultrasound during a pre-surgical workup, however, the animal died during surgery to remove a concurrent urolith. In the second case (Zeugsweter et al., 2007), clinical testing, including the measurement of salivary cortisol levels both before and after ACTH stimulation, was performed. Urine glucose levels were consistently negative; however, urine specific gravity was consistently dilute (around 1.012). Both resting and post-ACTH cortisol levels were consistently elevated. The animal was successfully treated with trilostane (Vetoryl, Arnolds Veterinary Products) at a therapeutic level of 2 mg/lb.

Thyroid Disease

Currently, non-neoplastic thyroid disease has not been reported in the guinea pig. However normal levels of thyroxine have been reported in this species (Muller et al., 2009). Thyroxine levels do not appear to differ significantly between males and females, or intact and neutered animals. Thyroxine concentrations ranged from 14.2–66.9 nmol/L (1.1–5.2 µg/dl).

Endocrine Neoplasia

Insulinoma has been reported in the guinea pig (Vannevel and Wilcock, 2005). In both cases, animals presented with ataxia and head tilt. Hypoglycemia, which responded temporarily to intravenous glucose administration, was noted in both animals. Both animals were euthanized and red pancreatic masses were noted at necropsy. Microscopic examination revealed neoplasms composed of nests and packets of epithelial cells on a vascular stroma. Mitotic figures were not observed. In this case, insulin assays were not performed; normal insulin levels have not been reported in guinea pigs and testing has not been validated in this species.

Adrenal gland neoplasms have been identified in the guinea pig. Previous reports included both adrenocortical adenoma and adrenal carcinoma (Manning, 1976). Two adrenocortical neoplasms, previously mentioned, resulted in a syndrome of hypercortisolism (Gaschen et al., 1998; Zeugsweter et al., 2007). A syndrome of multiple cortical nodules, presumably hyperplastic, was reported in association with neonatal castration.

In the absence of true thyroid disease, there have been several reports of thyroid neoplasia in this species; however, early reports did not clearly specify the tumor type (Manning, 1976). However, there is at least one well-documented case of thyroid papillary adenoma in the literature (LaRegina and Wightman, 1979). This well-encapsulated neoplasm was composed of papillary projections of cuboidal epithelial cells with well-developed incipient and mature follicles. A medullary carcinoma with osseous foci has also been reported (Zarrin, 1974). In short, thyroid neoplasia should be considered rare in this species.

REPRODUCTIVE SYSTEM

Unique Features of the Guinea Pig Reproductive System

There are a number of peculiarities of the reproductive tract and physiology of this species. In males, the curled seminal vesicles are extremely large, filling a large part of the caudal abdomen. Unlike most rodents,

the female has two conical inguinal nipples. Sows whelp one to two large precocious pup, whereas other rodent species generally have larger litters. In addition, the vagina of the female is generally closed by a waxy, hardened mucus plug, and is patent only during times of breeding and parturition.

Posthitis in Boars

Posthitis is an accumulation of bedding material and detritus within the preputial folds. This may occur in one of two ways: either following coitus, as the bedding adheres to the moist penis, or as a result of poor husbandry. As guinea pigs are indiscriminate and voluminous eliminators, it is not uncommon to see them sitting in moist, dirty litter. Accumulation of bedding, feces, hair, and other debris within the preputial orifice may further impair elimination, worsening the situation and perhaps preventing elimination altogether. Moreover, bacterial infections of the prepuce may result in adhesions and decreased fertility (Lee et al., 1978). Gentle removal of the debris by soaking in a dilute chlorhexidine solution and administration of systemic antibiotics has been recommended for treatment (O'Rourke, 2004). Other cases of preputial dermatitis in the guinea pig have been precipitated by trauma, possibly bite wounds.

Seminal Vesiculitis/Urethritis in Boars

Urethritis is an unrelated problem to posthitis in the boar, but also results in urethral plugging and post-renal obstruction (Wagner, 1976). In most cases, the plug is due to an inspissated plug of proteins from the seminal vesicles and sperm. In some cases, the plug can be visualized extending from the urethral orifice. Clinical signs include frantic activity followed by dullness and abdominal tension. Attempts to express the bladder are often unsuccessful. Microscopically, there is minimal reaction within the occluded region of the urethra, and hemorrhages within the wall of the urinary bladder. There may be suppurative inflammation within the seminal vesicles. Coliform bacteria, including *Pseudomonas aeruginosa*, have been cultured from the seminal vesicles of affected individuals.

Ovarian Cysts

Ovarian cysts are a very common age-related finding in sows. In one report, cysts were observed in 76% of sows between 18 and 60 months of age (Keller et al., 1987). As these cysts enlarge, they compress adjacent ovarian tissue, resulting in atrophy and eventual effacement of the ovary. The major result of these growing cysts is infertility of the older sow. However, they have been associated with other syndromes such as alopecia,

FIGURE 24.4 Older sow with bilateral multilocular cystic ovaries due to expansion of the ovarian rete. (Photo courtesy of Dr. John King.)

mucometra, cystic endometrial hyperplasia, endometritis, and various reproductive neoplasms, such as uterine fibroleiomyomas (Keller et al., 1987). The reproductive status of the individual sow appears to have no bearing on their development or eventual size (Nielsen et al., 2003).

Clinical signs of ovarian cysts include alopecia, abdominal distention, anorexia, and apathy. The cysts are readily identified by ultrasound examination, and ovariohysterectomy is the recommended treatment (O'Rourke, 2004).

Serial sections of ovaries from affected sows reveal that the cysts apparently arise from the epithelial-lined ovarian rete, and communicate with follicles and the outer mesothelial lining of the ovary (Percy and Barthold, 2007). Ovarian cysts range from a millimeter up to 7 cm in diameter (Figure 24.4). Small cysts are most commonly found near the ovarian hilus. The cysts may be uni- or multilocular, are filled with clear fluid, and are lined by flattened cuboidal ciliated epithelium. The condition is usually bilateral. Testosterone administration is reported to be an experimental cause of cyst formation within the ovarian rete in the guinea pig, as well as subsequent formation of epithelial ovarian neoplasms (Silva et al., 1997).

Dystocia

Dystocia is also a common problem in guinea pigs and the most common cause of perinatal mortality. Guinea pigs give birth to one to two large precocious pups per litter; in fact, female guinea pigs may gain up to 60% of their body weight during gestation.

The birth canal of the sow is narrow at the level of the os coxae. The release of relaxin by the pituitary gland and endometrium the week before parturition results in dissolution of the fibrocartilage of the pubic

symphysis and allows stretching and passage of the large offspring. However, if the sow is not bred prior to fusion of these bones at approximately 6 months of age, this separation of the pelvic bones cannot occur at parturition, and dystocia is far more likely to occur. Obesity in older sows may also result in dystocia.

Ectopic pregnancy has been reported with implantation in the peritoneal cavities of two multiparous strain 13/N guinea pigs (Hong and Armstrong, 1978).

Pregnancy Toxemia

This poorly named syndrome is another major cause of perinatal mortality in guinea pigs. Contrary to its name, the condition, while most commonly seen in pregnant or lactating guinea pigs, can also be seen in non-gravid females and even boars.

This metabolic syndrome of ketoacidosis shares some similarities with that seen in other species; however, studies in the guinea pig have identified two distinct conditions, the nutritional (or fasting) form, and the circulatory form (Percy and Barthold, 2007). Both forms are characterized by occurring during the last 2 weeks of gestation or the first week after parturition, as well as marked acidosis (even lowering the normal pH of urine from approximately 9.0 to 5.0–6.0), ketosis, ketonuria, proteinuria, and the clinical signs of lethargy, adipisia, hypersalivation, and incoordination (Brower, 2006).

The nutritional form is, in essence, the end result of reduced carbohydrate intake and marked systemic mobilization of fat stores for energy. While the name *pregnancy toxemia* indicates that it is primarily a disease of gestation, a similar condition occurs in guinea pigs undergoing carbohydrate reduction for a number of reasons – poor dietary management, changes in feeding times, or any other stressful condition that may put an animal off feed. Obese animals, presumably those with the largest fat stores, appear more at risk than lean ones. The disease has been experimentally reproduced in guinea pigs fed initially a high-carbohydrate diet, followed by sudden feed withdrawal (Lachmann et al., 1989). Gravid or lactating animals would develop the full manifestations of the syndrome, whereas non-gravid animals develop a non-clinical ketosis.

In the nutritional form, affected animals exhibit hypoglycemia (<60 mg/dl) and hyperlipidemia in addition to the aforementioned ketoacidosis, ketonuria, and proteinuria. Clinical depression occurs rapidly, with the animal becoming prostrate and dyspneic within 1 day (O'Rourke, 2004). The condition progresses to coma within 5–6 days. In this form, the primary gross finding is marked fat accumulation within hepatocytes, with yellow-to-white discoloration of the liver. The liver is moderately enlarged, with rounded edges. Microscopically, fat is present in large quantities within hepatocytes, renal

tubular epithelium, and cells of the adrenal cortex, and may be seen within vessels in glomerular and alveolar capillaries (Percy and Barthold, 2007).

A second form of pregnancy toxemia is the circulatory form. Thought to be a possible model for pre-eclampsia in humans, this form has other morphologic features of note, in addition to the metabolic derangements. In pregnant guinea pigs with pregnancy toxemia, one study demonstrated a 22% compression of the aorta in the area of the renal arteries with a resulting 30% reduction in blood pressure (Seidl et al., 1979). This reduction in arterial flow may result in vascular insufficiency to a number of abdominal organs including the liver, kidneys, adrenal glands, and the gravid uterus itself. Microscopically, there is hemorrhage and necrosis in these organs, including the placenta. Infiltration of white blood cells in areas of necrosis heralds a more long-standing insult. Diminished flow in these organs may also result in thrombosis, and eventually, consumptive coagulopathy. Experimentally, the condition has also been reproduced in gravid female guinea pigs by occlusion of the uterine vessels (Golden et al., 1980).

In both types of pregnancy toxemia, the prognosis is poor. Hypoglycemia may be treated with intravenous glucose, and shock may be treated with corticosteroids, calcium gluconate, and fluid replacement. Keys to prevention are keeping guinea pigs lean, especially breeding sows; eliminating potential stressors in a colony situation; and providing a varied, adequate well-balanced diet and water ad libitum. It is important to remember that pregnant sows in the last stages of gestation may triple their food intake.

Neoplasia of the Reproductive System

Tumors of the reproductive tract account for about 25% of spontaneous tumors in this species (Percy and Barthold, 2007). Tumors of the uterus are primarily benign and of smooth muscle origin (leiomyoma); however, leiomyosarcomas have been reported (Field et al., 1989). Other less common neoplasms of the uterus include fibromas and myxoid fibrosarcomas (myxosarcomas) (Blumenthal and Rogers, 1960).

In reports of spontaneous ovarian tumors, teratomas are well-represented. These neoplasms have well-differentiated tissues of ectodermal, mesodermal, and endodermal derivation, including skin, bone, muscle, and nervous tissue, among others (Frisk et al., 1978; Manning, 1976; Vink, 1970). Granulosa cell tumors and ovarian cystadenomas have also been reported in the guinea pig (Burns et al., 2001). Malignant epithelial neoplasms have been experimentally induced in the guinea pig ovary via the use of carcinogens in order to create an animal model for human ovarian carcinoma (Silva et al., 1997). Reports of spontaneous malignancies in the

guinea pig are rare, two papillary cystadenocarcinomas have been reported (Hong, 1980), as well as a single case of ovarian stromal sarcoma (Olson and Anver, 1980).

Interestingly, only one testicular tumor, an embryonal carcinoma, has been reported in the guinea pig (Manning, 1976). This may partially reflect the scarcity of intact males within colony settings and the pet populations.

MUSCULOSKELETAL SYSTEM

Hypovitaminosis C

Ascorbic acid is an important antioxidant and reducing agent. It is required for the hydroxylation of proline and lysine, a process that is essential in the formation of collagen. A number of animal species, including most fish, insects, fruit bats, guinea pigs, non-human primates, and man lack the enzyme gulonolactone oxidase, which catalyzes the last step of the synthesis of vitamin C, and require dietary intake. There is no storage of vitamin C within the body.

The lack of vitamin C (known traditionally as "scurvy") results in a host of systemic defects within susceptible individuals, but the most obvious are the result of blood vessel fragility. The lack of prolyl and hydroxyl hydroxylase results in formation of collagen fibrils that are not cross-linked and lack tensile strength, leading to blood vessel fragility and poor wound healing (Mahmoodian and Peterkofsky, 1999). Lesions associated with scurvy, such as subperiosteal, subcutaneous, intramuscular, and gingival hemorrhage, reflect this defect. Joint bleeding (Figure 24.5), one of the most obvious signs of scurvy in the guinea pig, is due to damage to synovial vessels and microfracture of bone. There may also be non-hemorrhagic joint effusions. In young growing individuals, significant changes occur in the growth plate due to defective and insufficient osteoid production. Clarke et al. (1980) reported changes in subclinical cases of scurvy to include attenuated and irregular epiphyses, and acute enteritis with numerous hemosiderin-laden macrophages in the intestinal lamina propria.

Hair loss and poor haircoat are reported; vitamin C is important in the disulfide bonding of hair. Tooth mobility may be the result of improper collagen formation in the dental socket and may lead to malocclusion. Conjunctival and intraocular bleeding is also common, and there is disruption of corneal epithelial and stromal organization with stromal vascularization in later stages. Animals with hypovitaminosis C also have poor wound healing. Vitamin C is known to promote wound healing through stimulation of collagen synthesis and deposition, increased fibroblast density, and tissue vascularity.

FIGURE 24.5 Bilateral femorotibial joint hemorrhage in a guinea pig with hypovitaminosis C. (Photo courtesy of the Armed Forces Institute of Pathology.)

Ascorbic acid is also an important antioxidant and reducing agent. It functions as a scavenger of free radicals and maintains the Fe^{++} and Cu^{+} cofactors of a variety of oxygenases in a reduced state. In this regard, ascorbic acid functions similarly to vitamin E in prevention of membrane peroxidation. Ascorbic acid also functions in the hydroxylation of dopamine to norepinephrine and serves to prevent oxidation of tetrahydrofolate, thereby maintaining folic acid stores. Furthermore, vitamin C increases the absorption of non-heme iron by catalyzing the reduction of ferric iron in the stomach, as well as increasing the amount of iron stored as ferritin (Padayatty and Levine, 2001).

Clinically, the earliest signs of vitamin C deficiency are generally non-specific, such as weakness, anorexia, diarrhea, and weight loss. Affected animals are reluctant to move and may vocalize and grind their teeth due to arthralgia and myalgia, as well as a result of hemorrhage into joints (especially the stifle joints) and muscles. Anorexia and weight loss are noticed within 2 weeks on a deficient diet. After 3 weeks, serum 25-OH vitamin D_3 , calcium, and albumin levels are significantly reduced, bone mineral density and bone content are significantly lower than normal, and bone volume is reduced in long bones (Fain, 2005).

Laboratory findings are non-specific. Anemia is seen as a result of folate deficiency more than the result of hemorrhage. Foods high in vitamin C are also sources of folate so folic acid deficiency is marked. Leukopenia and hypoalbuminemia, markers of malnutrition, are also common.

Gross skeletal lesions of scurvy include bowing of long bones, outward projection of the ends of the ribs ("scurvitic rosary," Figure 24.6), subperiosteal hematomas, loosening of teeth, and epiphyseal fractures. Cortices are thin due to decreased appositional growth and break easily.

FIGURE 24.6 Flaring at the costochondral junction and hemorrhage in a guinea pig with hypovitaminosis C. (Photo courtesy of the Armed Forces Institute of Pathology.)

Microscopic skeletal features of scurvy are most profound within the growth plate, but may be seen in the bones of adults as well. As vitamin C is required for their differentiation from progenitor cells, osteoblasts are rare, and osteoid deposition on trabeculae of cartilage is scant or absent. In immature animals with open physes, a lattice of vascularized, calcified cartilage is formed in the metaphysis and is not replaced by bone as it increases in thickness. This “scorbutic lattice” is inherently weak and predisposed to microfracture and hemorrhage (Thompson, 2007). Scorbutic animals also have increased dilation of metaphyseal vessels which predispose to hemorrhage. The deep metaphysis often contains loosely arranged mesenchymal cells in areas normally occupied by hematopoietic cells (Percy and Barthold, 2007). Proliferation of spindle cells between the fibrous periosteum and the cortical bone surface thickens the periosteum of long bones, resulting in widening at the metaphyseal–epiphyseal junction (“metaphyseal flaring”). In mature bone, osteoid deposition on previously formed trabecular bone and endosteal and periosteal surfaces is also scant or absent.

Diagnosis is usually based on characteristic history, clinical signs, and radiographic findings, although serum ascorbic acid levels may be used in academic situations for diagnosis or to monitor treatment. Response to therapeutic trial of 50mg vitamin C per day may assist in presumptive diagnosis of the condition. Response to treatment is rapid, with most clinical signs reversed within a week of onset of adequate intake. In severely scorbutic guinea pigs, complete restoration of normal trabecular bone structure takes about 20–25 days.

Dietary recommendations for guinea pigs include 15–25mg/kg body weight of vitamin C per day, and up to 40mg/kg for pregnant sows. Most commercial chows are adequate but must be stored at or below 50°F

and fed within 90 days of milling (O’Rourke, 2004). Leafy green vegetables, such as kale or cabbage, should be part of the normal diet of guinea pigs as 50g of either can supply the recommended amount of vitamin C. Guinea pigs should not be fed rabbit chow, as it does not supply the recommended amount of vitamin C for guinea pigs.

Osteoarthritis

Osteoarthritis in Hartley guinea pigs resembles human osteoarthritis both morphologically and epidemiologically. Lesions first appear at about 3 months of age and progress with age (Jimenez et al., 1997). Obesity is a predisposing factor.

A 2003 study compared stifle joints of captive and wild-caught guinea pigs. No evidence of osteoarthritis was seen in wild-caught guinea pigs, suggesting osteoarthritis to be a problem of captivity, or of the “artificial environment” (Rothschild, 2003). The issue of genetic differences between “wild” and Hartley guinea pigs was not addressed in this study.

Radiographic changes in chronic osteoarthritis include marginal osteophytes of the tibia and femur, sclerosis of the subchondral bone of the tibial plateau, cystic changes of the femoral condyle, and calcification of the collateral ligaments (Jimenez et al., 1997). Histologically, unilateral focal degeneration of the hyaline cartilage of the joint surface, characterized by proteoglycan loss within the superficial zones, can be observed on the medial tibial plateau as early as 3 months. Over the next 3 months, these lesions worsen, and there is marked loss of the proteoglycan matrix of the superficial and middle zones, chondrocyte death, and fibrillation of the hypocellular matrix with proliferation of chondrocyte clones in deeper layers. Severe cases have degenerative changes within the medial femoral condyle, menisci, and eventually osteophytes will appear on the medial femoral and tibial condyles. Synovial changes include fibrosis, hyperplasia of synoviocytes and occasional papillary projections into the joint itself. Inflammatory cell infiltration is usually not marked. As a result of biomechanics of the stifle joint, lesions are seen primarily on the medial tibial plateau with sparing of the lateral side (Bendele and Hulman, 1988).

A recent study in guinea pigs demonstrated that high levels of vitamin C may actually worsen osteoarthritis in the guinea pig as a result of activating latent transforming growth factor-beta within osteophytes in damaged knees (Kraus et al., 2004).

Fibrous Osteodystrophy

Fibrous osteodystrophy has been reported in two guinea pigs with clinical signs of lethargy and apathy

(Schwarz et al., 2001). Radiographically, both animals had skeletal deformities, pathologic fractures, malocclusion, and marked osteoarthritis. Diagnosis of osteopenia was confirmed by use of dual-energy X-ray absorptiometry. The diagnosis of fibrous osteodystrophy was confirmed at necropsy and in the absence of renal disease, dietary calcium/phosphorus imbalance was considered to be the cause of this condition.

Nutritional Myopathy

A multisystemic condition with marked degenerative changes of skeletal muscles, especially of the hindlimbs, has been documented in guinea pigs deficient in vitamin E and selenium (Howell and Buxton, 1975). Clinical signs included hindlimb weakness, conjunctivitis, depression, decreased reproductive performance, and in severe cases, death. Laboratory values included elevated serum creatine phosphokinase. The disease has been reproduced experimentally in animals fed diets deficient in vitamin E as well as both vitamin E and selenium, with more severe lesions seen in animals deficient in both substances (Hill et al., 2001).

At necropsy, both skeletal and cardiac muscle may be affected; grossly, affected muscles are pale. Microscopically, myofiber changes include coagulative necrosis, hyalinization, fragmentation, and occasionally regeneration as evidenced by nuclear rowing. Mineralization of fibers is not a feature of this disease (Ward et al., 1977).

Testicular degeneration may be seen in boars, and encephalomalacia in fetuses in vitamin-E-deficient dams (Howell and Buxton, 1975). In one report, a group of affected animals showed a positive clinical response to injectable sodium selenite and alpha tocopherol (Howell and Buxton, 1975).

Traumatic Injury

Traumatic injury may result from falls, fighting within colonies, and improper flooring. Guinea pigs catching their legs in improperly slotted flooring may result in traumatic soft tissue injury, torn nails, and broken toes. Falls from cages to a hard floor have been reported to result in posterior paralysis from broken backs and spinal cord damage (Wagner, 1976). Guinea pigs have a very thin diaphragm. Traumatic injuries, including falls, may result in tears and extrusion of the abdominal viscera through a tear in the diaphragm near the esophageal hiatus into the thorax (Wagner, 1976).

Neoplasia of the Musculoskeletal System

Reports of neoplasia of the musculoskeletal system are rare. Osteosarcoma has been reported three times. In one report, the neoplasm arose in the lumbar vertebra in two animals, metastasizing widely to multiple organs in one (Hong and Liu, 1981). In a second report, the neoplasm originated within the femur and metastasized to the lung (Leader, 1937). In all cases, the neoplasm consists of large numbers of spindle cells which produce abundant osteoid. A single report of osteosarcoma arising in the proximal epiphysis of the right humerus and metastasizing to multiple organs is interesting in that the neoplasm was transplantable and was maintained through 11 generational transplants within both random-bred and inbred individuals (LaPorte and Sillard, 1963). Single reports of other neoplasms arising in the skeletal system include a fibrosarcoma of the maxilla, a chondrosarcoma of the ilium, and a rib enchondroma (Manning, 1976). Reports of neoplasms of the muscles are even rarer with a single report of an infiltrative lipoma (lipomyxofibroma) within the psoas muscle (Manning, 1976).

INTEGUMENTARY SYSTEM

Alopecia

Alopecia in the guinea pig is a common non-specific sign that can be the end result of a number of endocrine and non-endocrine diseases. Alopecia is present in almost all pregnant sows during late gestation and through lactation. This finding appears to be more severe in animals bred intensively, older sows, and those carrying a large litter. While a number of factors such as genetics and nutrition may play a part, the major reason is thought to be decreased anabolism of the maternal skin associated with fetal growth (Wagner, 1976). In affected dams, hair loss is most severe over the back, flanks, and rump, and will grow back in most, if not all, cases. Alopecia may be seen in pups at the time of weaning, but appears to be the result of a hair coat change as the more coarse "guard hairs" of the adults begin to appear.

Alopecia may be seen in any guinea pig as a result of stress or intercurrent disease – as the so-called "telogen effluvium." It is a documented clinical sign of hyperadrenocorticism in the guinea pig, and has been associated with cystic rete ovarii (O'Rourke, 2004). In one breeding colony study, alopecia was seen in animals receiving less than 200g of hay as part of their daily diet; addition of hay to the ration significantly improved both hair quality and quantity (Gerold et al., 1997).

Barbering

Barbering is a vice in individuals and evidence of a dominance hierarchy in group housing situations. In group situations, juvenile animals are usually barbered by adults. Individual animals may also barber, but hair loss is restricted only to places on the body that they can reach, so the head, neck, and shoulders are spared. Patterns of hair loss, occasional broken skin, and evidence of fighting should suggest the possibility of barbering in a group situation. Often, the dominant animal in the group will be the one without hair loss. In a group setting, separation of animals or removal of the dominant animal from the group may be the best option. Self-barbering is a more difficult issue for which provision of hay or supplemental leafy green vegetables has been recommended.

Ear chewing is a variant of this condition, and may result in notching, deformity, and in some cases, traumatic amputation (Wagner, 1976). Ear chewing is often a sign of aggression within an enclosure, and is usually attributable to males (Figure 24.7). Ear tags may often be the cause of ear chewing and may be rendered unreadable or pulled out.

Fight Wounds

Bite wounds, scratches, dermatitis, and alopecia are evidence of aggressiveness and fighting within an enclosure and usually can be attributable to a single individual. The composure of a particular group may have great impact on the predilection for fighting (Paterson, 1972). Intact boars should not be housed together – fighting is common with severe injuries and even death as a possible outcome. In general, older animals placed together have a greater tendency to fight than juveniles or adults that have lived together since they were juveniles.

Pododermatitis

Pododermatitis is a common problem in guinea pigs, especially pet ones. The condition is generally bacterial, with several predisposing. Heavy or obese animals kept in poor sanitation are predisposed. Wire or abrasive flooring and moist litter aggravate this condition, as do other debilitating diseases that inhibit movement. Clinical signs of pododermatitis include sedentary behavior, inactivity, vocalizing when moving, and lameness. One or multiple feet may be swollen, and both front and hind feet may be affected.

Clinically, foot pads and toes are erythematous, swollen, and may be eroded or ulcerated. Guinea pigs may vocalize when they are touched. The most common bacterial agent isolated from infected feet is *Staphylococcus aureus*, which usually enters through wounds on the

FIGURE 24.7 Trauma on the ear margin of a guinea pig. Ears are a common site of trauma between fighting individuals.

bottom of the feet. Rarely, traumatized tissues may be seeded from an infected site elsewhere in the body. Pododermatitis does not involve the formation of a discrete abscess which can be drained; the infection usually results in cellulitis, with infection of the skin and subcutaneous tissue, and a proliferation of granulation tissue. Osteomyelitis of the foot may accompany severe infections, and long-standing infections may result in systemic sequelae, such as amyloidosis.

Treatment of pododermatitis is prolonged, difficult, and often unrewarding (Brown, 2008). The vascularity of the granulation bed accompanying many such wounds predisposes to excessive, occasionally life-threatening bleeding when surgical options are pursued. Successful regimens include cleaning, dressing, administration of appropriate systemic antibiotics, and elimination of predisposing factors. Wound cleansing should focus on removal of detritus and necrotic tissue; use of wound cleansers which impair wound healing and leukocyte activity, such as povidone-iodine, chlorhexidine, and hydrogen peroxide should be avoided if possible. Hydrogel or hydrocolloid wound gels may be applied to the wound underneath a clean dressing. Dressings should allow mobility of the leg and avoid constriction and loss of circulation.

Systemic antibiotic therapy is usually required over a period of months. Ciprofloxacin or enrofloxacin are broad-spectrum antibiotics which do not result in dysbiosis. Analgesia may be required in some cases; buprenorphine at 0.03–0.05 mg/kg may be used up to three times daily (Brown, 2008). Treatment for pododermatitis generally requires several months, and periodic assessment is required. Elimination of any unsanitary practices, provision of dry, clean litter, and soft flooring is required for successful resolution.

Tumors of the Integument and Mammary Glands

The skin and subcutaneous tissues, after the respiratory system, are the second most common site for neoplasia in the guinea pig. In all reports, trichofolliculoma, a benign neoplasm arising from the epithelium of the pilosebaceous unit, is the most common (Tuch and Tuch, 1979; Zwart et al., 1981). These expansile neoplasms often arise in the lumbosacral area, and grossly are firm nodules which may have a central pore. Microscopically, the neoplasms are composed of a central cystic follicle with smaller variably well-differentiated follicular structures radiating from it in an arborizing pattern. Traumatized neoplasms may evoke a profound inflammatory response if keratin debris is extruded into the surrounding dermis. Surgical excision is curative.

Other cutaneous neoplasms are reported to be common, including fibrosarcoma (Steele, 2001), lipoma, sebaceous gland adenoma, and hemangioma (Hammer et al., 2005).

Several mammary gland neoplasms have been reported in guinea pigs, with benign fibroadenomas being the most numerous. These neoplasms are composed primarily of proliferating glandular tissue and large amounts of fibrous connective tissue. Approximately 30% of reported mammary neoplasms in guinea pigs are classified as mammary adenocarcinomas; most of these neoplasms were interpreted to be of duct origin (Greenacre, 2004). An unusually high incidence of adenocarcinoma in male guinea pigs has been reported (Andrews, 1976). As mammary adenocarcinomas have been reported to metastasize to the lung, preliminary workup should include a thoracic X-ray (Greenacre, 2004).

SPECIAL SENSES

Cataracts

Cataracts have been reported in guinea pigs of all ages on well-balanced rations. In strain 13/N guinea pigs, a mutation in the gene for lenticular zeta-crystallin results in juvenile cataracts as early as 13 weeks of age (Bettelheim et al., 1997). Diabetes mellitus and decreased levels of dietary tryptophan (Wagner, 1976) have been theorized to cause cataracts in this species. The guinea pig has been often used as an animal model for cataract research induced by UVB radiation (Hockwin et al., 1999) and galactosamine (Kosegarten and Maher, 1978).

Ocular Dermoid

Ocular dermoids have been reported in two unrelated outbred guinea pigs (Wapplier et al., 2002). The

dermoids consisted of dermal and epidermal elements, including stratified squamous epithelium, hair follicles, smooth muscle, and fatty mesenchymal elements. Both were removed by superficial keratectomy and corneal debridement.

Osseous Metaplasia of the Eye

Heterotopic bone, similar to that seen in the lungs, may appear in other tissues as well, including the eye. Well-differentiated bone has been reported in the ciliary body of a guinea pig (Donnelly and Brown, 2002).

Conjunctival Eversion (“Pea Eye”)

This condition, colloquially referred to as “pea eye,” is a focal eversion of the conjunctiva. This condition appears grossly as small white-to-pink extrusions of conjunctiva, usually on the lower lid. In the absence of corneal abrasion or obvious infection, treatment is not usually required. Large eversions of conjunctiva may be removed by laser therapy.

Ototoxicity

A number of drugs have been reported to cause ototoxicity in the guinea pig; most of these compounds are known for causing ototoxicity in other species. Topical gentamicin (Conlon et al., 1998), otic suspensions of neomycin and polymyxin B (Perry and Smith, 1996), and cisplatin (Saito et al., 1997) have all been reported to cause ototoxicity in experimental applications.

HEMATOLYMPHATIC SYSTEM

Foa-Kurloff Cells

One of the unusual features of the immune system of the guinea pig is the presence of a unique line of white blood cells, known as Foa-Kurloff (or simply Kurloff) cells. These lymphocytes possess a single large, granular mucopolysaccharide cytoplasmic inclusion which displaces the nucleus, and can be visualized in large numbers in PAS-stained sections or impression smears of the spleen. While the true nature of the Kurloff cell is unknown, these cells have been shown to possess anti-neoplastic capability both in vitro and in vivo against leukemia cells, suggesting they function like null killer cells in other species. Some authors surmise that the presence of these cells may be responsible for the relatively low incidence of neoplasms documented in this species.

Kurloff cells are seen in greater numbers in adult female guinea pigs, and their numbers peak during

pregnancy or following estrogen stimulation in sows. They occur in high numbers within the placenta, and their secretions, toxic for macrophages, are thought to help modulate local immunity and prevent rejection of the fetal placenta.

In non-pregnant animals, Kurloff cells are seen in highest numbers in the splenic sinusoids and lining the stroma of the bone marrow and thymus, but may make up 4% of the circulating leukocyte population (Pilny, 2008). These cells are rarely seen before 3 months of age, and numbers are approximately the same in boars and non-gravid females.

Cavian Leukemia

Cavian leukemia is a spontaneous hematopoietic neoplasm that can occur in inbred strains of guinea pigs (2/N and 13/N) as well as non-inbred lines. This disease tends to arise in young adults under 3 years of age and has been proposed as a model for acute lymphoblastic leukemia in humans (Kaplow and Nadel, 1979). In one colony, over a 3-year period, the reported incidence was 0.02%. Type C virus particles have been identified in neoplastic lymphoid cells by electron microscopy, suggesting the possibility of a retroviral cause; however, similar particles have been noted in lymph node germinal centers from normal guinea pigs. A guinea pig herpes-like virus has also been isolated from lymphoid cells derived from leukemic guinea pigs in vitro (Nayak, 1971). Its role, if any, is also unknown.

Experimentally,avian leukemia is 100% transplantable in inbred strains usually by intraperitoneal or subcutaneous inoculation of fresh or frozen blood or tissue. However, in non-inbred strains, transmissibility decreases quickly with age (Kaplow and Nadel, 1979).

Affected animals are usually young adults and may present with either a generalized lymphadenomegaly and/or a leukocytosis (up to 18000mm^3) with a significant number of circulating lymphoblastic cells. At necropsy, in addition to enlarged peripheral lymph nodes, there is marked splenomegaly and hepatomegaly. Microscopically, there is diffuse infiltration of lymphoblastic cells in the liver, lung, spleen, bone marrow, thymus, gastrointestinal-associated lymphoid tissue (GALT), heart, eyes, and adrenal gland. The prognosis for this condition is grave and animals generally die within 4 weeks (Pilny, 2008). Reports on the responsiveness of this condition to traditional chemotherapy vary widely.

Spontaneous T-Cell Lymphoma

Spontaneous T-cell lymphoma has been reported in a guinea pig with marked ocular involvement as well as peripheral lymphadenopathy (Steinberg, 2000).

Neoplastic cells were immunopositive for CD-3, a marker for T-cells. No specific cause was identified.

MULTISYSTEMIC CONDITIONS

Metastatic Calcification

Metastatic calcification occurs occasionally in guinea pigs older than 1 year of age. While the true cause of this condition has not been elucidated, a number of reports suggest an imbalance between dietary magnesium, calcium, and phosphorus to be responsible, most commonly diets high in phosphorus and low in magnesium (Galloway et al., 1964). A 1968 study of 140 guinea pigs necropsied between 20 and 24 months of age in a closed breeding colony found that 75% of animals had calcification, most commonly in the kidney. Other common sites of calcification include the periarticular soft tissues, stomach, aorta, lung, trachea, liver, uterus, and heart (Sparschu and Christie, 1968). Clinical signs in affected animals are non-specific and include alopecia, poor thrift, and muscle stiffness.

Amyloidosis

Amyloidosis occurs occasionally in guinea pigs, usually in association with chronic inflammatory conditions such as bacterial pododermatitis (Taylor et al., 1971). Amyloid deposits are of the AA-amyloid type, which is deposited in the tissues in chronic inflammatory conditions and are most commonly seen in the kidney, spleen, and liver, but may occur in any organ. Microscopically, the deposits appear as a waxy, homogeneous, pink material primarily within the walls of blood vessels, but occasionally extending into the surrounding interstitium. Renal failure resulting from amyloid deposition has not been reported in the guinea pig.

Alpha-Mannosidosis

Naturally occurring cases of alpha-mannosidosis have been reported by Crawley et al. (1999). Two guinea pigs with stunted growth, progressive mental dullness, and abnormal behavior, posture, and gait were examined at necropsy. Widespread neuronal vacuolation was observed throughout the CNS, as well as vacuolation in the pancreas, thyroid, epididymis, and ganglia. Extracts of whole liver, leukocytes, fibroblasts, and plasma showed a deficiency of lysosomal (acidic) alpha-mannosidase activity. Urine and tissue extracts contained stored and excreted oligosaccharides normally seen in human patients. The authors suggested that this line of guinea pig might prove to be a valuable model for human alpha-mannosidosis.

Lethal White Syndrome in Guinea Pigs

Approximately 25% of the offspring of the mating of color-diluted roan or dalmation guinea pigs are homozygous for the spotted roan or "lethal factor." Homozygosity for this allele is linked to a constellation of developmental defects that is known as the "lethal white syndrome" among fancy guinea pig breeders. There is no relationship to a similar condition in white overo foals, in which the main defect is aganglionosis of the large intestine.

The lethal white syndrome in the guinea pig consists of various combinations of microphthalmia, anophthalmia, partial or complete blindness, partial or complete deafness, missing or deformed incisors and cheek teeth with elongated roots, intestinal malabsorption, and decreased immune responses.

Lethal white guinea pigs have a decreased lifespan, often dying during weaning as a result of infectious diseases. Anecdotal reports suggest that affected guinea pigs can live for 2–3 years with excellent care.

INTRODUCTION

The guinea pig, like many animals used in biomedical research today, first became popular to enthusiasts and fanciers. So popular were guinea pigs in England that even Queen Elizabeth I kept one as a pet (Endersby, 2007). This popularity fostered familiarity with its behavior, physiology, and suitable husbandry conditions, and this knowledge about care and husbandry subsequently allowed successful transition into laboratory housing, making it a popular research model. Over time, “guinea pig” became synonymous with experimentation.

The guinea pig first served as a useful animal model of disease in the late 1700s when Antoine Lavoisier, a French biologist and chemist, used the species in his study of respiratory physiology. In the 1800s, guinea pigs were used in studies of infectious disease, and seminal work on the role of certain vital amines (aka vitamins) in maintaining health was done in the early 1900s. Through time it was learned that, beyond the virtues of its relatively small size and docile nature, the guinea pig possesses anatomical and physiological features that make it uniquely suited to certain studies (Wright and Churg, 2002; Wright et al., 2008). For example, guinea pigs are useful in reproductive studies

because they and humans share similarities in placental structure, their gestation period of 68 days can be divided effectively into trimesters akin to the human condition, and they can develop pregnancy toxemia (Golden et al., 1980; Seidl et al., 1979).

For the 2007 fiscal year, the USDA reports that 207,257 guinea pigs were used in research (APHIS, 2007), a slight increase of approximately 1% over the previous year, but this represents an overall steady decline in use from the all-time high of 599,000 used in 1985 (Harkness et al., 2002). The most commonly used variety is the Hartley albino stock, but the inbred strains 2 and 13, and euthymic hairless stock are also used with some frequency. A principal reason for the overall decline in use is, not surprisingly, the increased use of mice as a favored animal model. The paucity of inbred guinea pig strains and the limited number of specific reagents for use with the species are two factors that generally limit the use of this species in research in the foreseeable future.

MODELS OF DISEASE

Hearing

The National Institutes of Health estimate that 17 million Americans suffer from some degree of hearing loss. Cochlear hair cell loss from any number of causes such as toxins, acoustic trauma, or infection is the most common cause of permanent sensorineural hearing loss in humans (Raphael, 2002). Subsequent to the loss of hair cells, pathologic changes in the associated type I and type II spiral ganglion nerve cells also occur through retrograde degeneration (Dodson, 1997). The experimental method most commonly used in guinea pigs to model this condition is chemical deafening. Chemical deafening can be achieved through the administration of aminoglycoside compounds such as kanamycin, gentamicin, and neomycin. These compounds have been shown to cause complete inner and outer hair cell death within hours after administration and variable degrees of ganglion neuron death over subsequent days and hence this method quite accurately reflects sensorineural hearing loss in humans (Dodson, 1997; Dodson et al., 1994; Dupont et al., 1993). The partial death of ganglion cells is important because the survival of some neurons is necessary in order to test cochlear implants as a mode of therapy.

The two routes of aminoglycoside administration used most commonly are subcutaneous injection or direct infusion into the perilymph through the cochlear round window requiring a surgical approach (Shibata et al., 2009; Su et al., 2008). Systemic chemical deafening has the advantage of technical simplicity and will

deafen bilaterally, but there is some risk of nephrotoxicity, and the deafening is often not complete. In contrast, direct application of aminoglycoside within the cochlea is technically demanding, but systemic toxicity is not a concern, and the lesion in the affected ear is more robust, i.e. deafening is complete.

In addition to the induction of total deafness through chemical means, it is possible to induce partial hearing loss through the mechanical creation of lesions in the organ of Corti (Dong et al., 2009). A surgical approach is required for this technique, in this case so that a micropipette can be inserted into the organ of Corti and puncture Reissner's membrane. This technique is useful to study conditions like high-frequency hearing loss which is only a partial loss of function.

Subsequent to inducing hearing loss, the animals can be used to study therapeutic modalities such as cochlear implants and gene-mediated therapies. Both of these commonly studied therapies involved surgical approaches that come with inherent potential for negative clinical sequelae. In particular, animals used in studies of gene therapy can experience transient loss of equilibrium manifested as a head tilt associated with the injection of the fluid carrying the viral vector into the cochlear space (Husseman and Raphael, 2009). There is also the potential for inflammatory reactions to the viral vector, particularly adenoviruses. This issue is addressed by using vectors "stripped" of the ability to produce many endogenous antigens so that they incite less reaction (Husseman and Raphael, 2009; Thomas et al., 2003). It is also important to bear in mind that animals exposed to the vector require special consideration by the Institutional Animal Care and Use Committee (IACUC) in conjunction with the institution's biosafety committee.

There are several ways in which hearing physiology can be assessed in studies of therapy. These include structural analysis of hair cells and neurons using electron and light microscopy and functional measures. A method commonly used to study function is the auditory brainstem-evoked response (ABR), which assesses brainstem electrical potentials elicited by sound (Husseman and Raphael, 2009; Shibata et al., 2009). To measure ABR, electrodes are placed subcutaneously, often in the neck region, and the animal is subsequently subjected to clicks of varying duration and intensity (Grindal et al., 2009). A higher ABR threshold value indicates poor hearing function. A simple and effective way to determine the presence of hearing function in a guinea pig is to evaluate for the Preyer reflex, which is the "pricking" of the ears in response to noise. Although fairly insensitive, testing for the presence of a reflex is a good screening tool to determine if animals are suitable for study (Orita et al., 2009). Finally, behavioral response

such as lever pressing has been described as another means of assessing hearing function (Su et al., 2008).

Toxicology

Guinea pigs are often used in developmental and reproductive toxicology (DART) studies and studies of contact hypersensitivity or dermatitis (Rocca and Wehner, 2009). The former takes advantage of the prenatal brain development and the substantial gestation length of 68 days in the guinea pig (Cudd, 2005), which can be effectively divided into trimesters akin to humans, and the robust type IV hypersensitivity exhibited by guinea pigs makes them useful in studies of the latter. Guinea pigs are also one of the species, in addition to mice, used in the General Safety Test for toxic contaminants in biological products as defined by the Food and Drug Administration (FDA) in the Code of Federal Regulations, Title 21 (FDA, 2009).

In DART studies, the impact of alcohol on the developing fetus is a fairly robust area for study because trimesters of gestation can be targeted and brain development is rapid throughout fetal growth (Cudd, 2005; Gauthier et al., 2009), which is in contrast to other rodents such as rats and mice. The model is useful in studying the array of alcohol's effects on the developing fetus, termed fetal alcohol spectrum disorders (Olmstead et al., 2009). The basis of the model is oral intake of ethanol by the pregnant dam at varying gestational time points and for varying durations dictated by the objective of the study. Oral exposure can be accomplished by provision of a 4% ethanol solution in the drinking water, or by oral gavage at a dosage of 4g per kg of bodyweight (Gauthier et al., 2005; Kimura et al., 1996). Control animals are typically given a sucrose solution that is isocaloric to the ethanol administered to ensure that food intake and bodyweight gain are comparable among cohorts in the study. In the authors' experience, if ethanol is administered in the drinking water, it is imperative to monitor fluid intake at the onset of the study to ensure adequate hydration as some animals do not readily drink the ethanol solution.

In studies of a test compound's potential to cause contact dermatitis, there are several protocols that have been developed over the past 50 years. These include the Draize, the open epidermal, and the split adjuvant tests, all of which are used infrequently at this time. The two tests that are used most commonly with guinea pigs are the Buehler test and guinea pig maximization (MAX) test, also called the Magnusson-Kligman test, which were first described in the 1960s (Buehler, 1965; Magnusson and Kligman, 1969; Maurer, 2007; Weaver et al., 2003).

The Buehler test, the regimen most commonly used in the United States and the MAX test, often used in

Europe, are similar in many respects. It is recommended that animals to be used in the test are between 300–450 grams in bodyweight at the beginning of the study (Maurer, 2007). Both regimens include an induction phase where test subjects are exposed to the test compound repeatedly, typically in the scapular region following depilation of the area. Additionally, a bandage or occlusive material is used to enhance the absorption of topically applied agents. The principal difference between the two models is that the Buehler test uses topical administration typically repeated three times, while the MAX test includes intradermal injections of the compound combined with Freund's complete adjuvant (FCA) in an effort to reduce the number of false-negative reactions thereby increasing the sensitivity of the test (Maurer, 2007). Following the induction protocol, animals are exposed or challenged with a single, topical application of the compound in question. The degree of reaction is then scored on parameters such as erythema and swelling and can be compared to control compounds such as a negative control carrier vehicle and a positive control such as dinitrochlorobenzene (Tang et al., 2008).

In the General Safety Test, healthy guinea pigs weighing less than 400 grams must be used. Mice are also used. This test is required for all biological products administered to humans with some exceptions as put forth in CFR 21. Briefly the test is conducted by injecting at least two animals intraperitoneally with the test compound. Those animals are then observed for any untoward effects such as weight loss or death for 7 days, at which time the tested product is reported to have passed or failed the test. For additional details, the reader is directed to the statute (FDA, 2009).

The use of guinea pigs to study the toxic effects of other compounds are numerous and varied, and a complete discussion of those studies is beyond the scope of this chapter. Similar to their use in DART studies of alcohol, the effects of various agents such as cadmium (Trottier et al., 2002) or dioxin (Kransler et al., 2007) on the fetus are reported in the literature as well as the toxicity of xylene (Gagnaire et al., 2007) and dental resin (Seiss et al., 2009) on adult animals, to name a few. Looking forward, guinea pigs could become popular models for cutaneous toxicokinetic studies as it was recently reported that they exhibit dermal permeability properties nearly identical to those of humans (Barbero and Frasch, 2009).

Allergic Diseases

Guinea pigs were one of the first species to be used in studies of allergic conjunctivitis and remain popular for such studies. Allergic conjunctivitis, particularly the seasonal (more appropriately termed "intermittent")

variety, a type I hypersensitivity reaction is a very common condition affecting the human population (Sanchis-Merino et al., 2008). Beyond its designation as either seasonal or persistent, allergic conjunctivitis is further classified as either IgE-mediated or non-IgE-mediated, and guinea pigs are suitable models for both (Groneberg et al., 2003).

In the study of IgE-mediated disease, an active immunization protocol is typically followed. Animals are often sensitized to an antigen such as ovalbumin (OVA) using intraperitoneal injections (Groneberg et al., 2003; Meijer et al., 1996), although there are also studies using ragweed and Japanese cedar extracts (Merayo-Llves et al., 1995; Takada et al., 2000), which represent the allergens to which humans are routinely exposed in the environment. Subsequent to sensitization, the same antigen is instilled into the eye eliciting a robust inflammatory response in the tissues of the eye that can be evaluated as early as 30 minutes post-challenge. Endpoints examined can include clinical manifestations such as eyelid edema and ocular discharge, the nature and degree of cellular infiltration with eosinophils, and the level of inflammatory mediators such as substance P that are present. Once the model is induced, the effectiveness of therapies such as topical antihistamines can be investigated (Sanchis-Merino et al., 2008). An extension of these studies would include the examination of therapeutic effectiveness. Within this experimental framework it should be noted that highly immune-responsive (IMM/S) and a less immune-responsive (IMM/R) inbred strains have been developed and characterized (Lundberg et al., 1987). Studies of non-IgE-mediated disease are performed in much the same way except that a hapten is used to sensitize instead of a protein antigen (Saiga et al., 1992).

The guinea pig has recently been shown to be a valid model of allergic rhinitis, closely mimicking the clinical symptoms and pathology seen in the human condition. The methods employed are quite similar to those used in studies of allergic conjunctivitis and asthma and involve sensitization to an antigen such as OVA (Bahekar et al., 2008; Brozmanova et al., 2008), with subsequent exposure to the antigen. The principal differences are that the challenge exposure is via nasal instillation and that the endpoints studied such as degree of rhinorrhea reflect the symptoms of the disease.

Other allergic conditions for which guinea pigs have been used include food allergy, with most studies addressing cow's milk protein allergy (Helm and Burks, 2002; Kitagawa et al., 1995; Piacentini et al., 1994). Their use in such studies is limited however by their IgG response profile (Fritsche, 2003), which does not very accurately reflect the IgE-mediated disease in humans, making other species such as the mouse, dog, and pig more suitable (Helm and Burks, 2002).

Non-Infectious Respiratory Disease: Asthma and COPD

The guinea pig has been used extensively as a model of human asthma, airway hypersensitivity (Zosky and Sly, 2007), and other diseases that affect the airway. Airway anatomic features that make the guinea pig a good model of respiratory disease include abundant lung tissue, three major lobes in the right hemithorax and two in the left hemithorax, well-defined terminal bronchioles, alveoli that are nearly fully developed at birth, and a well-innervated trachea (Brewer and Cruise, 1997; Wright and Churg, 2002). Functionally, the guinea pig airway is quite reactive to certain inhaled compounds, and they exhibit a cough reflex similar to humans, attributes that have been useful in elucidating the mechanisms controlling cough (Canning and Chou, 2008; Oh et al., 2006).

Asthma is defined as a chronic inflammatory condition of the airway that compromises air flow resulting in clinical manifestations such as wheezing and coughing. The disease affects approximately 17 million Americans (Braun et al., 2008) and 300 million people worldwide (Bahadori et al., 2009). Models developed to study asthma hinge on a common theme, sensitization of the airway with compounds that produce a robust response. One method used to sensitize the airway is by exposing a guinea pig to OVA (Angeli et al., 2008; de Vries et al., 2006; Tohda et al., 2000). In this model, the animals receive repeated injections of OVA combined with an adjuvant such as aluminum hydroxide intraperitoneally (Muraki et al., 2008). The schedule of injections can vary, but a typical schedule is an initial injection repeated at days 2 and 21 (Muraki et al., 2008) or some variation on that schedule (Mokry et al., 2008). After undergoing this regimen, the animal is considered hypersensitized. These hypersensitized animals are then exposed to or "challenged" by OVA administered via nebulization, which induces a robust airway type I allergic and inflammatory response in the airways similar to what is observed in humans experiencing symptoms associated with asthma. As part of these studies, it is common to evaluate cellular infiltrates and tissue reactions using bronchoalveolar lavage and histopathology. The mechanical properties of affected airway smooth muscle such as contractility are also of interest and are evaluated following post-mortem tissue harvest (Angeli et al., 2008; Chitano et al., 2008). The ultimate goal of most studies is to determine therapeutic effectiveness of test compounds, with much attention paid to regulating mediators of the disease process such as leukotrienes, prostaglandins, and nitric oxide (Angeli et al., 2008; Canning and Chou, 2008).

Guinea pigs are also used to study chronic obstructive pulmonary disease (COPD), an inflammatory

condition that affects the airway much like asthma and is estimated to affect up to 10% of the human population (Wright et al., 2008). Like asthmas, several inflammatory mediators promote COPD, but in contrast COPD is a progressive disease leading to death in 30–70% of those diagnosed as a result of diminishing lung capacity (Seamark et al., 2007). The four anatomic lesions characteristic of COPD include emphysema, small airway remodeling, pulmonary hypertension, and excessive large airway mucus secretion (Churg and Wright, 2009). The most significant cause of COPD in the human population is smoking cigarettes. Exposure to cigarette smoke is one way to induce a COPD-like syndrome in guinea pigs that exhibits lung pathology mimicking in some ways that seen in humans, particularly small airway remodeling (Canning and Chou, 2008; Churg and Wright, 2009). Various inhalation chamber configurations are used to expose the animals, and protocols can range from acute exposure as short as 10 minutes to chronic exposure that lasts for months (Wright and Churg, 2002). In humans, chronic or latent respiratory viral infection is thought to exacerbate or cause COPD. Guinea pigs have been latently infected with adenovirus 5 prior to cigarette smoke exposure to model this condition, and they exhibit cellular and molecular changes similar to those seen in humans under similar conditions (Hogg, 2001; Vitalis et al., 1998).

Reproduction and Pregnancy-Related Diseases

Guinea pigs share many reproductive traits with humans and hence are used extensively in studies of reproductive physiology, anatomy, and endocrinology. Like humans, guinea pigs have a hemomonochorial placenta, trophoblast invasion patterns, and uterine vasculature akin to humans (Lee and DeMayo, 2004; Mess et al., 2007; Valdes et al., 2008). There is substantial evidence suggesting that guinea pigs can serve as suitable models of placental antibody transfer (Pentsuk and van der Laan, 2009), and genes encoding the proteins such as vascular endothelial growth factor (VEGF) and insulin-like growth factor (IGF) show expression patterns that are similar to humans (Grant et al., 2005; Valdes et al., 2008). Notable structural differences include the presence of a subplacenta in the guinea pig, a structure which seems to have no human counterpart (Carter, 2007; Oliveira et al., 2006) and a labyrinthine instead of the villous structure observed in humans (Mess, 2007).

Because of their gestational length and rapid brain development in utero, guinea pigs are the best rodent species for use in studies of chronic maternal stress and the effects of glucocorticoid administration on the dam, development of the neonate, and conditions such as chorioamnionitis that might impact brain development in utero (Emack et al., 2008; Kapoor and Matthews,

2008; Kapoor et al., 2009; Kemme et al., 2008; Owen and Matthews, 2007; Patrick et al., 2004; Setiawan et al., 2007; Sohlstrom et al., 1998). The long gestation period allows chronic, repeated or acute and precisely timed exposure (e.g. during maximal brain development at 50 days gestation) to various stressors such as food restriction, noise and light, and unfamiliar conspecifics with subsequent measurement of growth patterns and hormonal responses. These studies have shown that maternal glucocorticoid administration, commonly used in humans to promote lung development in at-risk pregnancies, can have profound effects on the hypothalamic–pituitary axis of the offspring. Guinea pigs are also considered by many to be the best non-primate model of hormonal control of parturition, in particular because their progesterone levels closely mirror those of humans during pregnancy (Mitchell and Taggart, 2009; Rodriguez et al., 2008; Welsh et al., 2005). Lastly, guinea pigs have been used somewhat infrequently to model intrauterine growth restriction (IUGR). To study IUGR as a result of compromised uterine blood flow, the uterine arteries or branches are surgically ligated with subsequent monitoring of fetal growth using imaging such as ultrasound (Turner and Trudinger, 2009).

Osteoarthritis

Osteoarthritis (OA) is the most common joint disease in humans, with 68% of adults showing some degree of the disease (Elders, 2000). The disease is progressive, involving all joint structures and is associated with distinctive histological changes in joint tissues, most notably cartilage loss (Bowyer et al., 2009). Guinea pigs have served as valid models, both spontaneous and induced, of the disease. Dunkin-Hartley guinea pigs, particularly males, develop notable, consistent degenerative lesions primarily in the medial tibial aspect of the stifle joint beginning around 3 months of age, and these lesions progress in severity with aging, becoming substantial by 9 months of age (Anderson-MacKenzie et al., 2005; Bendele et al., 1989; McDougall et al., 2009; Quasnichka et al., 2005). The lesions resemble those seen in humans with excellent fidelity with the exception of osteochondral and synovial blood vessel formation, which is less severe in the guinea pig compared to humans (Jimenez et al., 1997; Mapp et al., 2008). It has also been shown that Strain 13 and Bristol strain-2 can serve as suitable control strains as OA lesions are insignificant or absent respectively, and they express lower levels of pro-inflammatory biomarkers in synovial fluid and serum (Anderson-MacKenzie et al., 2005; Huebner and Kraus, 2006; Huebner et al., 2002; Quasnichka et al., 2005).

To induce disease, the most commonly performed procedure is a partial medial meniscectomy (Bendele, 2001; Pastoureaux et al., 2003). This procedure is easily

reproducible and the resultant OA lesions are consistent and develop by 1 month post-surgery with lesions becoming quite severe within 3 months (Bendele, 2001; Bolbos et al., 2008). As a non-surgical model, intracapsular injections of sodium mono-iodoacetate have also been used to induce chondrocyte death. A single injection, or two injections separated by 24 hours, is sufficient to induce lesions (Bendele, 2001; Vermeirsch et al., 2007). The clear advantages of both induced models over the spontaneous are the rapidity with which lesions form, and the fact that the contralateral joint can be used for comparison.

Atherosclerosis

Atherosclerosis is a condition that affects approximately 57% of the population between 40 and 59 years of age with an increased incidence associated with age (Kiechl and Willeit, 1999). It is considered a type of arteriosclerosis affecting large arteries characterized principally by endothelial damage with subsequent inflammation and lipid plaque (atheroma) formation (Badimon et al., 2009). Several risk factors such as elevated cholesterol and low-density lipoproteins, have been identified. While they are not used as commonly as some other species to study atherosclerosis, guinea pigs have unique attributes that make them well-suited to studies of this disease. Guinea pigs have triacylglycerol, lipoprotein, and cholesterol profiles that are influenced by gender, diet, and exercise in the same ways that are observed in humans (Ensign et al., 2002; Roy et al., 2000). The most unique feature of guinea pigs is that the majority of their cholesterol is present as low-density lipoprotein, which is not seen in most other animal species (Fernandez, 2001; Fernandez and Volek, 2006). Atherosclerosis is being recognized as a chronic inflammatory condition in humans, and guinea pigs exhibit a pro-atherogenic inflammatory profile in arteries when fed a high-cholesterol diet (Fernandez and Volek, 2006).

Infectious Disease

Introduction

Much of this chapter focuses on the common contemporary uses of guinea pigs in infectious disease research. Guinea pigs have provided significant contributions to research for some diseases for which they are no longer used, and these diseases are not covered in this chapter. For example, the guinea pig was a classic model for the study of *Treponema pallidum*, the causative agent for syphilis. This model was popular in the 1980s and 1990s, but no studies have been published using this model since 2001. Guinea pigs have also been used sporadically for other infectious diseases that are

beyond the scope of this chapter. Readers are referred to Padilla-Carlin et al. (2008) for a review of bacterial infections that have been studied utilizing guinea pigs, including syphilis. Guinea pigs have also been used for investigations of *Coxiella burnetii* (Aboudharam et al., 2000; Elliott et al., 1998; Heggers et al., 1975; Moos and Hackstadt, 1987; Russell-Lodrigue et al., 2006; Wilhelmsen and Waag, 2000), fungal infections with *Cryptococcus* (Carroll et al., 2007; Kirkpatrick et al., 2007) and parasite infections such as toxocariasis which are not included in this chapter (Faccioli et al., 1996, 1997, 1998; Fenoy et al., 2001; Sa-Nunes et al., 2003).

Genital Herpesvirus Infections

Genital herpes can be caused by herpes simplex virus (HSV)-1 or HSV-2, but is most commonly caused by HSV-2. Genital herpes caused by infection with either virus infects approximately 20–30% of adolescents and adults in the United States (Quenelle et al., 2008b; Rose et al., 2008). Most infected people develop subclinical or mild signs that they do not recognize as genital herpes lesions, but HSV infection can result in blisters that become ulcers around the genitals and rectum. The disease recurs within weeks to months between outbreaks, and the number of outbreaks tends to decrease over time. Infection can be severe in immunosuppressed people and neonates. There is currently no vaccine or cure, but antivirals such as acyclovir can decrease outbreaks and reduce transmission. Research utilizing the guinea pig model of HSV infections has primarily focused on developing more effective treatment and vaccine strategies (Bernstein, 2001; Bernstein et al., 2000; Rose et al., 2008).

The majority of research on genital herpesvirus infections in guinea pigs has focused on HSV-2. Guinea pigs are highly susceptible to HSV-2 and the pathogenesis associated with this virus has been well characterized. Guinea pigs develop genital lesions similar to those in humans, and a review of the pathology of this virus in guinea pigs is available (Hsiung et al., 1984). Females are usually inoculated by introducing the virus directly into the vagina, but may also be infected by placing viral solutions externally near the genital skin (Bernstein and Stanberry, 1986). Following intravaginal inoculation, viral shedding peaks prior to the development of genital lesions, with lesions detectable 3–4 days after infection (Hsiung et al., 1984; Lukas et al., 1975; Stanberry et al., 1982). The lesions progress to pustules, ulcers, and crusts. Lesions typically heal by days 10–15 post-infection, but resolution may require up to 18–20 days (Bernstein, 2001; Fotouhi et al., 2008b; Hsiung et al., 1984; Krinke et al., 1975; Manservigi et al., 2005; Stanberry et al., 1982). The virus initially replicates in the vagina and then spreads via the peripheral nerves to the external genital area, resulting in the typical ulcerative

lesions. The virus also spreads to the dorsal root ganglia and spinal cord which can lead to a severe ascending myelitis (Bernstein, 2001; Hsiung et al., 1984; Krinke et al., 1975; Lukas et al., 1975; Stanberry et al., 1982). Male guinea pigs are less frequently used, but can be inoculated on the penis or thigh with lesions and clinical sequelae similar to those seen in females (Kobrinskii et al., 1991; Stephanopoulos et al., 1989). Infection in neonates has rarely been used and is associated with higher mortality (Mani et al., 1996). Attempts at transplacental transmission have not been successful (Hsiung et al., 1984).

The HSV virus becomes latent in the dorsal root ganglia and spontaneously reactivates to cause recurring genital lesions (Hsiung et al., 1984; Landry and Bull, 1992; Rose et al., 2008; Scriba, 1976, 1981; Simms et al., 2000; Stanberry et al., 1982, 1985). Animal studies may last for 35–120 days in order to evaluate for recurrent disease. Recrudescence can be induced by UV radiation (Bratcher et al., 1993; Harrison et al., 1991; Stanberry, 1991). As in humans, virus can be isolated from the genital tract in between outbreaks. Inbred strain 2 and Hartley guinea pigs require the same dose to become infected, but strain 2 guinea pigs are less likely to develop initial and recurrent disease than Hartley guinea pigs (Fowler et al., 1992; Hsiung et al., 1984). Even within a guinea pig strain, infection and the incidence of lesion recurrence can be variable in animals from different sources or shipments (Hsiung et al., 1984). Parameters evaluated in these studies include genital lesion scores, incidence of recurrent lesions, the incidence of clinical sequelae and recovery of the virus from the dorsal root ganglia and genital swabs (Bernstein and Stanberry, 1986; Bernstein et al., 2000; Harrison et al., 2001; Heineman et al., 2004; Quenelle et al., 2006; Stanberry et al., 1982, 1989).

The clinical sequelae associated with HSV infections in guinea pigs can be severe. The neurologic side effects can include urinary retention, hindlimb paralysis, and colonic stasis between 5 and 10 days after infection. These neurologic effects often resolve 5–10 days later if animals recover from the infection (Stanberry et al., 1982; Thornton et al., 1984). Other clinical sequelae that can occur with the initial disease include anorexia, weight loss, mild fever, secondary bacterial and yeast infections, encephalitis and death (Hsiung et al., 1984; Lukas et al., 1975; Manservigi et al., 2005; Stanberry et al., 1982; Thornton et al., 1984). Primary disease is more severe than recurrent disease, and supportive care should be considered even if death is not used as an endpoint (Thornton et al., 1984). Urinary retention should be assessed and relieved by pressing on the abdomen to empty the bladder. Although virulence varies with viral strain, the severity of lesions is primarily affected by the dose of virus used and most

strains that are commonly used can be associated with high mortality (Heineman et al., 2004; Hsiung et al., 1984; Landry et al., 1982; Prichard et al., 2005; Pronovost et al., 1982; Stanberry et al., 1982).

Guinea pigs have been inoculated with HSV-2 and HSV-1 to evaluate host responses and factors that influence pathogenesis of genital herpesvirus infections. This model has been used to evaluate the host immune response to infection including local and systemic cell-mediated immunity (Stanberry, 1991). The immune response and disease progression have been evaluated with HSV-2 genital reinfection, following previous genital infections with HSV-2 or HSV-1 or oral infections with HSV-1 (Bernstein et al., 1989; Hoshino et al., 2009; Landry and Zibello, 1988; Stanberry et al., 1986). These models reflect situations that commonly occur in humans, and reinfection is usually associated with decreased lesion severity relative to infections in naïve animals. This model has also been used to look at the pathogenesis associated with acyclovir-resistant viral strains (Bernstein et al., 2000). The differences in pathogenesis between HSV-1 and HSV-2 have been studied because both can cause genital infection, but they differ in their efficiency of reactivation that causes recurrent disease. HSV-1 reactivates more readily from trigeminal ganglia, while HSV-2 reactivates more readily from dorsal root ganglia (Bertke et al., 2007). The genetic factors that affect latency and reactivation have been studied, including creating mutant viruses or HSV-1 and HSV-2 chimeras (Bertke et al., 2007; Blakeney et al., 2005; Bourne et al., 1994; Burke et al., 1991; Krause et al., 1995; Lekstrom-Himes et al., 1998; Wang et al., 1997; Yoshikawa et al., 1996).

Guinea pigs have been used extensively in evaluating treatments for genital HSV infections. Acyclovir is a nucleoside analog that is commonly used for the management of HSV infections. It has been tested in both adult and neonatal guinea pigs by a variety of routes, including oral, topical, intramuscular, and intraperitoneal (Bravo et al., 1996; Ellis and Barry, 1985; Hsiung et al., 1984; Kern, 1982; Landry et al., 1982; Pronovost et al., 1982; Stanberry et al., 1990). Although these studies primarily focus on the treatment of HSV-2, acyclovir treatment for genital HSV-1 infections has also been described (Myerson and Hsiung, 1983). Because some viral strains have developed resistance to acyclovir, research has also focused on other treatments including acyclovir derivatives, other nucleoside analogs, other antivirals, and non-steroidal anti-inflammatories (Bratcher et al., 1993; Bravo et al., 1993; Jennings et al., 1999; Kern et al., 2000; Kleymann et al., 2002). This has included evaluating topical microbicides in their ability to prevent or reduce disease transmission (Bernstein et al., 2003; Bourne et al., 1999a, 1999b; Chen et al., 2004). In addition to resistance, antivirals also have

limitations in that recurrence occurs at previous levels once the medications are discontinued (Bernstein, 2001). These limitations have led to the development of immunotherapy strategies with vaccines or immunomodulators that could prolong the therapeutic effects of standard treatments (Bernstein, 2001; Bernstein et al., 1993, 2001; Bourne et al., 2002; Burke, 1991; Fujihara et al., 1989; Harrison et al., 1991, 2001; Hoshino et al., 2005; Manservigi et al., 2005; Miller et al., 1999; Pyles et al., 2002; Quenelle et al., 2008b; Rose et al., 2008; Wachsmann et al., 2001).

Guinea pigs have also been used extensively for studying vaccines to protect against genital HSV-2 challenge. Because treatment options are limited, vaccine development has been a large segment of the research related to HSV. Parameters measured often include the presence of neutralizing antibodies, cellular immunity, infection rates, virus replication in the genital tract, lesion severity, lesion recurrence, and virus isolation from the dorsal lumbosacral ganglia. Vaccinations with HSV glycoproteins have been the focus of the research, and are administered by various strategies including protein subunits, recombinant glycoproteins, and in plasmid expression vectors (Berman et al., 1985; Bourne et al., 1996, 2003, 2005; Bowen et al., 1992; Burke, 1991; Byars et al., 1994; Erturk et al., 1991; Fotouhi et al., 2008a, 2008b; Hoshino et al., 2005, 2009; McClements et al., 1996, 1997; Mester et al., 1999; O'Hagan et al., 1999; Quenelle et al., 2006, 2008a; Simms et al., 2000; Stanberry, 1991; Stanberry et al., 1987, 1990). Recombinant viral vectors expressing HSV glycoproteins have also been used as a vaccine, including vesicular stomatitis virus, varicella-zoster virus, and vaccinia virus (Bernstein et al., 2000; Heineman et al., 1995, 2004; Natuk et al., 2006). Another common strategy is to utilize live virus vaccines attenuated by genetic manipulation (Boursnell et al., 1997; Da Costa et al., 1997, 2001; McLean et al., 1994; Morrison et al., 1998; Prichard et al., 2005; Quenelle et al., 2008b; Spector et al., 1998; Wachsmann et al., 2001). Although most vaccines are administered by the subcutaneous or intramuscular route, subunit vaccines have also been evaluated by alternative routes including vaginal and nasal administration. These alternative routes have had variable responses relative to the traditional routes for vaccination (Bernstein 2000; Bowen et al., 1992; Hoshino et al., 2005; Morrison et al., 1998; O'Hagan et al., 1999). Optimizing the adjuvants included in the vaccine preparation is also crucial for efficacy, and a variety of adjuvants have been used (Berman et al., 1985; Bourne et al., 2003; Bui et al., 1994; Ho et al., 1992). Many of these vaccines have had efficacy in decreasing primary disease and recurrence, but have variable results in the ability to reduce viral shedding and incidence of infection. The degree of protection for some vaccines against primary disease correlates with the

humoral immune response, but this has not correlated with protection in human vaccine trials (Prichard et al., 2005; Simms et al., 2000; Stanberry 1991). Vaccines have also been evaluated in animals that had been exposed to HSV-1 prior to HSV-2 challenge because a glycoprotein vaccine was partially efficacious in HSV-1-seronegative but not -seropositive women (Hoshino et al., 2009).

Cytomegalovirus

Human cytomegalovirus (CMV) is a Betaherpesvirus that is distributed worldwide. It is the most common congenital infection and occurs in 0.5–2% of all births (CDC, 2006; Kern, 2006; Schleiss, 2006). In the United States, the majority of adults are infected by the age of 40 because people do not clear the infection (CDC, 2006). Although most infections are asymptomatic, the virus can cause both temporary disease and permanent disabilities in newborns including decreased birth weight, purpura, seizures, and liver damage (CDC, 2006; Levinson, 2008). Permanent disabilities often involve the nervous system and sensorineural hearing loss is a common lesion with congenital infection, but it can also result in mental retardation, vision loss, and death (CDC, 2006; Schleiss, 2006). CMV can also cause serious complications in immunocompromised adults, such as HIV-infected patients and transplant recipients. These infections can become systemic leading to one or multiple conditions, including pneumonia, CNS disease, hepatitis, enteritis, and retinitis (Booss and Kim, 1989; Levinson, 2008). In healthy adults, CMV rarely causes a temporary mononucleosis that is accompanied by fever and lethargy (Levinson, 2008).

The guinea pig model relies on a host-specific CMV because human CMV will not infect other species of models of this infection, including the guinea pig (Barry et al., 2006; Bia et al., 1982, 1983; Reddehase et al., 2008; Schleiss, 2005; Yue and Barry, 2008). Naturally occurring guinea pig cytomegalovirus (GPCMV) has historically been called salivary gland virus because it is primarily found in the salivary gland, but inclusions may be found in other organs as well (Van Hoosier, 1976). Natural infection of guinea pigs is usually subclinical, but reports of clinical disease do exist (Pappenheimer and Slanetz, 1942; Van Hoosier et al., 1985). Experimental studies in guinea pigs typically use a strain isolated from the salivary glands of guinea pigs infected by Hartley in 1957 (Schleiss, 2006). GPCMV was first described in 1920, and early studies characterized the nature of intranuclear and intracytoplasmic inclusions, pathogenicity, and transmission of the virus (Bia et al., 1983). Research efforts were later focused on using this model for the development of prevention and treatment options in humans, which remain the primary goals of current research. Although CMV vaccines have been tested in humans, at the time of this writing there is no

effective vaccine for preventing congenital infections. In addition, the treatments that are currently used for CMV infections have significant side effects, may require long-term therapy, and are not adequate for drug-resistant strains. These drawbacks could be particularly dangerous for pregnant women and immunocompromised patients, therefore more options are needed (Kern, 2006). Guinea pigs are preferable to other rodent models for congenital infection because the virus crosses the placenta in guinea pigs, similar to its pathogenesis in humans. Guinea pig models of congenital disease have primarily been used to test vaccines, but are also used to test treatments. Guinea pigs may also be used as models for disseminated infection to simulate disease in immunocompromised patients. More recently, the complete viral genome of GPCMV has been sequenced, and recent studies have focused on genetic manipulations of GPCMV (Schleiss, 2002; Schleiss et al., 2008b; Schraff et al., 2007; Yamada et al., 2009). These genetic studies could contribute to understanding the similarities between guinea pig and human CMV, pathogenesis, vaccine development, and treatment.

The guinea pig model of congenital CMV infection usually involves inoculation of the dam with GPCMV during pregnancy. Early studies characterized the distribution of infection and outcomes in congenitally infected pups and established that the disease is similar to that seen in human newborns. The outcomes of congenital infection in the pups can be variable, and include labyrinthitis and auditory defects, CNS damage, disseminated disease, and death (Griffith et al., 1982, 1986; Katano et al., 2007; Kern 2006; Schleiss 2006; Woolf et al., 1989).

A common protocol for current vaccine studies is vaccination of a young, Hartley guinea pig prior to mating, followed by CMV inoculation in the late second or third trimester. This timeframe for inoculation is chosen to increase the chance that infection will result in newborn mortality instead of fetal resorption (Kern, 2006). Parameters that are evaluated for experimental outcomes include maternal viremia, maternal immune response, maternal weights, maternal mortality, pup viremia, pup mortality, congenital transmission rates and infection distribution in the pups (Crumpler et al., 2009; Schleiss et al., 2004). A review of vaccine developments in this model is available (Schleiss, 2008). This model has been used to test many vaccine strategies including live attenuated, subunit vaccines and DNA vaccines (Bia et al., 1980, 1982; Crumpler et al., 2009; Schleiss et al., 2004).

Some studies of congenital infections of GPCMV rely on modes of infection other than inoculation of the mother during pregnancy. Treatment options are difficult to evaluate in congenitally infected newborns because of the high mortality rates. Newborn guinea

pigs have been inoculated IP within 48 hours of birth to test antivirals, although mortality is still considerable at 50% (Bravo et al., 2003; Kern 2006). Viral labyrinthitis can be replicated by intracochlear or intrathecal injections of newborns (Woolf et al., 1985). The model of intracochlear injections has also been used in weanling guinea pigs (200–350 g) to study the pathogenesis and potential treatments of CMV-associated hearing loss (White et al., 2006).

The severity of disease and mortality associated with GPCMV depends on multiple factors, including animal strain, pregnancy status, and viral dose. Pregnant animals are more susceptible to disease than non-pregnant, and mortality can also vary depending on when during pregnancy the animal is infected (Griffith et al., 1982). Hartley guinea pigs are the most commonly used guinea pigs for GPCMV studies, but they are less susceptible to infection than the inbred strain 2 guinea pigs that can have high mortality even as adults. Mortality will also vary depending on the dose of the virus used, but mortality is lower in Hartley guinea pigs than strain 2 even at the same dose (Bia et al., 1980; Griffith et al., 1986). For example, one study demonstrated that a dose of virus that caused 50% mortality in strain 2 guinea pigs resulted in only 15% mortality in Hartley guinea pigs (Bia et al., 1980; Woolf et al., 1989).

Because of their decreased susceptibility to disease, non-pregnant Hartley guinea pigs have been used as a model of mild disease that is associated with mononucleosis, as can occur in immunocompetent adult people. Subcutaneous inoculation in 1–2-month-old Hartley guinea pigs results in hematopoietic and lymphoid changes similar to human CMV mononucleosis (Griffith et al., 1981). This model of mononucleosis has also been used to evaluate treatment (Lucia et al., 1984).

The increased susceptibility of strain 2 guinea pigs provides a good model of the disseminated CMV infection that can occur in immunosuppressed people. Strain 2 guinea pigs can develop generalized infection, including common features of the disease in humans such as pneumonia (Bia et al., 1982). Strain 2 guinea pigs develop generalized infection within 5–17 days of inoculation, with 44–100% mortality 8–13 days after inoculation (Bia et al., 1982; Fong et al., 1983). The low end of the mortality range does not include animals that are euthanized due to a moribund condition (Bia et al., 1982).

In addition to strain 2 guinea pigs, other guinea pig models have been utilized for diseases associated with disseminated CMV infection. Disseminated disease can be reproduced in Hartley guinea pigs with the administration of immunosuppressive agents. Cyclophosphamide can increase mortality associated with infection to 87% by 19 days after infection (Schleiss et al., 2008a). Young Hartley guinea pigs (8–18 days old)

are more susceptible than adults, and may also be used as a model of generalized CMV (Connor and Johnson, 1976). Others have developed a model of CMV encephalitis, a complication associated with AIDS, using intracerebral inoculation (Bia et al., 1983; Booss and Kim 1989; Booss et al., 1990). Although not frequently used, intratracheal administration of the virus can produce a pneumonia, which is a common clinical feature of disseminated disease in humans (Bia et al., 1983).

Hemorrhagic Fevers

BACKGROUND

Viral hemorrhagic fever viruses are a group of RNA viruses belonging to the families Arenaviridae, Bunyaviridae, Filoviridae, and Flaviviridae. Of the arenaviruses that cause hemorrhagic fevers, guinea pigs have primarily been used as models for Lassa fever and Argentine hemorrhagic fever (Junin virus). They are less commonly used to study Venezuelan hemorrhagic fever (Guanarito virus) and Bolivian hemorrhagic fever (Machupo virus) (Hall et al., 1996; Khmelev et al., 2009; Tesh et al., 1994). Guinea pigs have also been used as models for the filoviruses, Marburg and Ebola. A few studies also utilized guinea pigs to research the bunyavirus that causes Crimean-Congo hemorrhagic fever, primarily focusing on transmission by the tick vector (Dohm et al., 1996; Gordon et al., 1993). The hemorrhagic fever viruses can cause severe disease and mortality in humans. Early clinical signs include flu-like symptoms that can progress to polysystemic signs, hemorrhage, and death. Filoviruses cause sporadic outbreaks, but infections can result in mortality of up to 90% depending on the viral strain (Bausch et al., 2008). The South American arenaviruses are less pathogenic than filoviruses but can be associated with significant mortality. For example, Junin and Guarnito viruses have 15–30% mortality if untreated (Doyle et al., 1998; Tesh, 2002). Lassa fever has a lower mortality rate than many other hemorrhagic fevers, but this virus is more common and results in approximately 100 000–300 000 infections and 5000 deaths per year in West Africa (CDC, 2004).

Guinea pigs have been used primarily to study the pathogenesis and host interactions with these viruses, but have also been used for developing vaccines and treatments. Although non-human primates are the gold standard as models for these diseases, the high virulence and BSL-4 conditions associated with these infections make rodents valuable models for practical and ethical reasons. Most of these viruses have animal reservoirs, but the viruses do not cause significant disease in the reservoir species and hence do not serve as good models (Gowen and Holbrook, 2008). It is important that the rodent models have a similar pathogenesis as in

primates; the virus infects macrophages and dendritic cells and then spreads to cause a systemic infection (Gowen and Holbrook, 2008). Rodents are not always reliable predictors for treatment or vaccine efficacy in humans, but are useful as models for screening preliminary products and continue to be used for understanding virulence and pathogenesis (Bente et al., 2009).

LASSA FEVER

Guinea pigs can develop severe disease with Lassa fever virus infection and this model is used primarily for vaccine development. Mortality in strain 13 guinea pigs can be 80–100% within 14–16 weeks of inoculation (Auperin et al., 1988; Carrion et al., 2007; Clegg and Lloyd, 1987; Jahrling et al., 1982). Hartley guinea pigs are less susceptible to lethal disease with infection (Jahrling et al., 1982). After inoculation, the virus is found in many organs including spleen, lymph nodes, and liver, but the brain is minimally involved. Interstitial pneumonia is a consistent finding in animals with fatal infection. Clinical signs in guinea pigs include fever, weakness, labored breathing, hindlimb paralysis, anorexia, and death (Carrion et al., 2007; Clegg and Lloyd 1987). Infected animals can also have elevated liver enzymes. Neutralizing antibodies are only found in outbred guinea pigs that survived infection (Jahrling et al., 1982). Aerosol transmission of the virus has been documented and appears to have the same tissue tropism as subcutaneous inoculation (Stephenson et al., 1984). Virulence for some viral strains has correlated well between guinea pigs and humans, particularly those strains isolated from pregnant women and infants (Jahrling et al., 1985). The guinea pig has been used to test live-attenuated vaccines that are clones of the Lassa fever virus (Carrion et al., 2007; Lukashevich et al., 2005) and recombinant viral vectors (Auperin, et al., 1988; Bredenbeek et al., 2006; Clegg and Lloyd 1987; Morrison et al., 1989). This model has also been used to test treatments such as antivirals and neutralizing antibodies (Huggins 1989; Jahrling 1983; Jahrling et al., 1985).

Pichinde virus is a favorable surrogate for Lassa fever because it does not cause disease in humans and can be handled as a BSL-2 agent. The classic model involves Pichinde virus infection in inbred strain 13 guinea pigs. Pichinde virus is more virulent in strain 13 than Hartley guinea pigs, and the pathogenesis in strain 13 guinea pigs more closely models the pathogenesis of Lassa fever virus infections in people that develop severe disease (Gowen and Holbrook, 2008; Jahrling et al., 1981). Pichinde virus must be passaged in guinea pigs to become lethal in this species (Aronson et al., 1994, 1995; Lan et al., 2009). Inoculation with as little as three plaque-forming units (PFU) of adapted Pichinde virus is fatal in strain 13 guinea pigs with death in

12–19 days after post-inoculation (Aronson et al., 1994, 1995; Jahrling et al., 1981). Mortality can be as high as 100% with adapted strains, and as low as 15% with less adapted strains (Aronson et al., 1994, 1995). Mortality is usually preceded by fever, followed by hypothermia, severe weight loss, and decreased water consumption (Aronson et al., 1994, 1995; Guo and Liu, 1995; Jahrling et al., 1981). Virus is present in many tissues, and pathologic changes are similar to those seen in non-human primates and humans, including hepatocellular necrosis and fatty changes, splenic necrosis, adrenal necrosis, and interstitial pneumonia. Strain 13 guinea pigs also develop coagulation disorders including abnormal platelet function and thrombocytopenia (Cosgriff et al., 1987).

Although Hartley guinea pigs are not as susceptible to disease from Pichinde virus infections as strain 13, Hartley stock are becoming more common in these studies. In addition to the greater availability of Hartley guinea pigs, some researchers believe that the variability in susceptibility more closely reflects the disease condition in humans (Scott and Aronson, 2008). The reason for this variability is unknown, and could provide a model for evaluating disease resistance factors (Gowen and Holbrook, 2008). Resistant animals have been shown to have immune responses different to susceptible animals (Scott and Aronson, 2008). In addition, Pichinde virus strains that can be highly lethal in Hartley guinea pigs have been developed (Lan et al., 2008). For example, a low passage (P2) strain only causes mild clinical signs and no mortality, while a higher passage (P18) strain causes 88–100% mortality (Fennewald et al., 2007; Lan et al., 2009). The disease progression of the P18 strain in Hartley guinea pigs is similar to the classic lethal Pichinde virus infections seen in strain 13 guinea pigs. The typical progression includes a pronounced fever during the first week of infection followed by severe weight loss and death by 12–21 days. Death coincides with hypothermia, metabolic acidosis, microvascular leakage, and myocardial suppression (Scott and Aronson, 2008).

Pichinde virus in both inbred strain 13 and Hartley guinea pigs is used to study the pathogenesis and host responses to viral infections. Pichinde virus has a tropism for macrophages and monocytes. After intraperitoneal injection, the virus infects the peritoneal, liver, and alveolar macrophages and then spreads to the spleen and other reticuloendothelial organs (Aronson et al., 1994; Fennewald et al., 2002). The viral loads in the liver are higher than in serum. Liver pathology includes fatty changes, minor necrosis, elevated liver enzymes, and decreased coagulation factors (Chen et al., 1993; Lucia et al., 1990). Animals can also develop respiratory failure due to obstruction of the small airways (Guo and Liu 1991; Schaeffer et al., 1993). Other pathologic changes include intestinal villous blunting and

infiltration of macrophages, leaky gut capillaries, and splenic necrosis (Aronson et al., 1994; Katz and Starr, 1990). Infected animals can also develop cardiovascular dysfunction (Qian et al., 1994).

The guinea pig's immune response to Pichinde virus infection has been well-characterized. The virus suppresses the normal macrophage response to infection (Fennewald et al., 2007). Studies have compared the immune response to infection with avirulent to virulent strains to determine how the viruses differ in modulation of the host immune response (Aronson et al., 1994, 1995; Bowick et al., 2009; Fennewald et al., 2002). The genetic sequences of both virulent and avirulent strains have been reported, and have led to the development of molecular clones that mimic the pathogenesis of natural viruses (Lan et al., 2008, 2009; Liang et al., 2009). This will facilitate analysis of the genetic differences that contribute to variability in mortality. Potential treatment options have also been evaluated in Pichinde-virus-infected guinea pigs (Soares et al., 2008).

FILOVIRUSES

The guinea pig model for Ebola virus uses the Zaire viral subtype that has been passaged in guinea pigs. The wild-type Zaire virus causes only transient febrile illness and is not lethal in guinea pigs (Bente et al., 2009; Chepurinov et al., 2001). Adapted viral strains produce a disease that is similar to that seen in humans and non-human primates (Connolly et al., 1999). The virus targets macrophages throughout the infection and viremia increases in the first 7 days. The accumulation of viral proteins in different cells has been evaluated (Steele et al., 2001a). Guinea pigs develop clinical signs within 4–7 days post-inoculation, including fever, anorexia, weight loss, and dehydration (Bente et al., 2009; Connolly et al., 1999). Gross evidence of hemorrhage is not typically a clinical feature of the disease in guinea pigs. The disease quickly progresses to death by days 8–11 post-infection. Virus is detected in multiple tissues, with viral loads highest in the spleen and liver. Animals often have elevated liver enzymes, a neutrophilic leukocytosis, coagulopathy, and a thrombocytopenia, but are not typically anemic (Connolly et al., 1999). Findings at necropsy can include enlarged, reddened lymph nodes, pale friable livers, petechiae, gastric erosions, and hemorrhage in the stomach and colon (Bray et al., 2001). Histologic lesions include splenic necrosis, lymph node necrosis, hepatic necrosis, and inflammation and diffuse marked necrosis of the lamina propria of the colon (Bray et al., 2001; Connolly et al., 1999). The inflammation in the liver can be severely granulomatous (Ryabchikova et al., 1996a). Rodent adapted viral strains are lethal in both strain 2 and strain 13 guinea pigs (Bray et al., 2001). The host immune response has been evaluated using both adapted and non-adapted

strains to determine differences that are associated with viral virulence (Chepurinov et al., 2001, 2003).

Guinea pigs have been used to evaluate prophylactic and treatment options for Ebola virus. Guinea pigs are commonly used to study vaccines prior to trials in non-human primates (Burton and Parren, 2000). Vaccines that have been tested include viral vectors or plasmids expressing glycoproteins and nucleoproteins (Bukreyev et al., 2009; Feldmann et al., 2007; Yang et al., 2008), live attenuated Ebola virus (Halfmann et al., 2009), recombinant proteins (Mellquist-Riemenschneider et al., 2003), and DNA vaccines (Steele et al., 2001b). There have also been efforts to develop a general vaccine for filoviruses, and a single vaccine with virus-like particles has protected guinea pigs from challenge with both Ebola and Marburg viruses (Swenson et al., 2005). Neutralizing antibodies have had some efficacy in treatment in guinea pigs with Ebola (Jahrling et al., 1999; Kudoyarova-Zubavichene et al., 1999; Takada et al., 2007). Small interfering RNAs that disrupt viral RNA have also had some efficacy in treating guinea pigs (Mellquist-Riemenschneider et al., 2003).

Guinea pigs have been used less frequently for the study of Marburg virus. Similar to Ebola, experimental infections with wild-type virus only causes a mild febrile disease (Bente et al., 2009). Lake Victoria Marburg virus has been adapted through serial passage in guinea pigs to make the virus lethal in this species (Bente et al., 2009; Gowen and Holbrook 2008). Some viral variants are non-lethal, and the genetic differences between variants with different virulence have been analyzed (Lofts et al., 2007). The adapted virus is lethal 7–17 days after infection (Bente et al., 2009). The pathogenesis of viral migration from the liver to the vascular system has been studied (Kolesnikova et al., 2007; Ryabchikova et al., 1996b). Infected animals show weight loss, fever, edema, and impaired clotting times. The pathogenesis after respiratory challenge has also been characterized (Ryabchikova et al., 1996b). The immune response to infection has been studied in efforts to develop novel treatments for the virus (Ignatyev et al., 2000). Vaccines of glycoprotein subunits and viral vectors have offered some protection against infection (Hevey et al., 1998). Vaccines using virus-like particles or viral vectors have offered protection from multiple isolates of Marburg virus (Swenson et al., 2005, 2008; Wang et al., 2006; Warfield et al., 2004). Treatment with monoclonal antibodies was also partially protective in infected animals (Hevey et al., 1998).

SOUTH AMERICAN ARENAVIRAL HEMORRHAGIC FEVERS

Guinea pigs have been useful for understanding the pathogenesis of Junin virus, the etiologic agent of Argentine hemorrhagic fever. Guinea pigs infected with

virulent strains produce the main features of Argentine hemorrhagic fever including fever, weight loss, hemorrhage, leukopenia, thrombocytopenia, and lymphoid necrosis (Carballal et al., 1981; Enria et al., 2008; Yun et al., 2008). The virus has tropism for lymphoid tissues and has severe cytopathic effects in these tissues, depresses the humoral and cellular immune response, and animals can die without detectable antibody to the virus. Evidence from electron microscopy of peripheral blood and bone marrow has suggested that viral activity on megakaryocytes is responsible for the acute thrombocytopenia (Carballal et al., 1977). Guinea pigs develop some but not all of the coagulation and complement abnormalities of humans (Molinas et al., 1989). Inbred and outbred guinea pigs can both be highly susceptible to the disease (Yun et al., 2008). Immunosuppression can increase the pathology associated with avirulent strains but does not affect the course of disease with virulent strains (Kenyon et al., 1985). Interestingly, cyclophosphamide actually delayed time to death for infected animals, but this was more likely to do with the antiviral characteristics of the drug than immunosuppression (Ponzinibbio et al., 1989).

The pathogenesis of Junin virus is highly dependent on viral strain and history of in vivo or in vitro viral passage (Kenyon et al., 1988). Viscerotropic viruses replicate primarily in lymph nodes, spleen, and bone marrow, with progression to necrosis of those organs and hemorrhage. Viremia increases from day 7 post-infection until death at approximately days 13–15 (Enria et al., 2008; Kenyon et al., 1988). Neurotropic strains have only transient replication in the spleen and lymph nodes, followed by distribution to the brain. These viruses cause poliomyelitis and animals frequently exhibit rear leg paralysis followed by death 28–34 days after inoculation (Kenyon et al., 1988; Medeot et al., 1992). The pathogenesis associated with attenuated strains has also been characterized and is more similar to the neurotropic viruses (Boxaca et al., 1984a; Laguens et al., 1983). Attenuated viruses are more likely to be found in the brain and cause a meningoencephalitis with lower mortality than virulent strains. Increased passage of the virus in guinea pigs can enhance the neurotropism of the virus (Boxaca et al., 1984a). More recent studies have indicated that the XJ viral strain, which was once highly virulent in guinea pigs, has become avirulent through in vitro passage of the virus (Yun et al., 2008). Transplacental transmission has been documented using both attenuated and virulent strains (Boxaca et al., 1984b; Gomez and Boxaca, 1985; Sangiorgio and Weissenbacher, 1983). This model of Junin virus in guinea pigs has been used to evaluate host immune responses and potential treatments (Dejean et al., 1988; Gonzalez et al., 1987). Immune serum treatment decreases mortality, but

surviving animals can develop a hindlimb paralysis, encephalitis, and meningitis (Enria et al., 2008). This is similar to humans in that neurologic complications can develop after treatment with serum. Ribavirin has been used with variable efficacy in this model (Huggins, 1989; Kenyon et al., 1986).

Influenza

Influenza viruses are enveloped RNA viruses that belong to the family Orthomyxoviridae. Influenza viruses are divided into three types (A, B, and C) and influenza A viruses are further divided into subtypes based on the two surface proteins hemagglutinin (H) and neuraminidase (N). Influenza B viruses are not classified by subtype but do have different strains. Influenza viruses are responsible for both the annual seasonal flu and periodic pandemics. Each year in the United States, approximately 21000–41000 deaths are associated with the seasonal flu (CDC, 2009; Lowen et al., 2006). The CDC recommends a yearly vaccine for the seasonal flu, but additional vaccine strategies are needed because some populations that are particularly susceptible to complications from the infection, such as the elderly and immunocompromised, may not respond well to the vaccine (Fiore, 2008; Glezen, 2006; Kumar and Burns, 2008). Guinea pigs have been used primarily for studies on the pathogenesis and transmission of the influenza A viruses, but have also occasionally been used for studies on vaccines, treatments, and diagnostics (Havlickova et al., 2006; Robuccio et al., 1995; Van Hoeven et al., 2009).

The pathogenesis and host response to influenza infection in the guinea pig have been characterized. Animals are usually inoculated intranasally, but aerosol infection has also been used. Intragastic inoculation does not produce infection (Kwon et al., 2009). Animals are typically evaluated using clinical observations, weights, body temperature, replicating virus in nasal washes and tissues, and histology. Early studies evaluated cellular and humoral immune responses after intranasal infection with influenza A viruses (Kauffman et al., 1978; Phair et al., 1979). Guinea pigs are susceptible to infection without prior host adaptation of the virus, but do not develop obvious clinical illness or fevers with most influenza A viruses (Kauffman et al., 1978; Lowen et al., 2006; Mubareka et al., 2009; Phair et al., 1979; Van Hoeven et al., 2009). Animals in one study developed severe bronchopneumonia and weight loss with some influenza A viruses, but the authors intentionally produced a severe infection by using a dose higher than is considered standard (Tang and Chong, 2009). Guinea pigs have also been used to evaluate the virulence of high pathogenicity influenza viruses, including the avian influenza (H5N1) and the H1N1 virus that caused the 1918 pandemic (Kwon et al.,

2009; Van Hoeven et al., 2009). In contrast to mice and ferrets that have severe disease with these highly pathogenic strains, guinea pigs only develop modest lethargy and weight loss followed by recovery from the infection.

The guinea pig has been suggested as a good model for non-lethal influenza virus infection in humans because of their decreased susceptibility to disease relative to mice and ferrets (Azoulay-Dupuis et al., 1984; Lowen et al., 2006; Van Hoeven et al., 2009). Infection in guinea pigs is characterized by lesions appearing approximately 24 hours after infection, followed by a focal interstitial pneumonia at 96 hours and widespread inflammation by 7 days. However, the virus is cleared from the nose and lungs by day 9, and the pathology is reversible with complete repair within 5 weeks. Even with highly pathogenic viral strains, guinea pigs only develop a mild to moderate interstitial pneumonia (Kwon et al., 2009; Van Hoeven et al., 2009).

Guinea pigs have been suggested as an alternative to ferrets as a model for influenza transmission. Mice are the most commonly used species for influenza studies, but mice fail to transmit the virus to other mice housed in close proximity. Ferrets are suitable for transmission studies, but guinea pigs are easier to obtain and house and are less likely to have been previously exposed to the virus (Lowen et al., 2006). For transmission studies, guinea pigs are infected by intranasal or aerosol inoculation and then placed in transmission cages. These cages have wire tops and perforations on the side, and can be placed next to each other or at a distance to simulate short- or long-range aerosol transmission (Mubareka et al., 2009). Guinea pigs can transmit both seasonal influenza A, highly pathogenic viruses, and 1918 influenza pandemic virus by direct contact, short- and long-range transmission (Lowen et al., 2006). Guinea pigs have been used to demonstrate that influenza A viruses vary in their efficiency of transmission by aerosol or fomites (Mubareka et al., 2009). This model has also been used to evaluate the effect of environmental temperature and humidity on viral transmission, vaccine efficacy and how drug resistance affects transmission (Bouvier et al., 2008; Lowen et al., 2008, 2009).

Influenza virus infections can be severe in neonates, and one study evaluated the pathology after the intranasal infection of pregnant guinea pigs because of the similarities in human and guinea pig placental structure. Guinea pigs have primarily transplacental transmission of antibodies as do humans, which was the impetus for another study that evaluated the susceptibility of infant guinea pigs to influenza based on the immune status of the mother (Ali et al., 1989). Additional uses of this model have included the pathogenesis of influenza A in otitis media and after intraocular inoculation (Ohashi et al., 1991, 1993; Rozina et al., 1987).

Respiratory Syncytial Virus

Respiratory syncytial virus (RSV) is a member of the family Paramyxoviridae that was initially isolated from a chimpanzee, and since then has been recognized as a common pathogen in humans (Blount et al., 1956; Byrd and Prince, 1997). RSV causes mild disease in healthy adults, but can be severe in infants, children, and the elderly. This virus is the leading cause of bronchiolitis and pneumonia in children less than 1 year old in the US (CDC, 2008b). Infants that recover from lower respiratory disease may go on to develop asthma (Sly and Hibbert, 1989; Sutton et al., 2007). The immune response in humans provides only short-term protection, and there is currently no vaccine available (Byrd and Prince 1997; CDC, 2008b). Previous attempts at developing a vaccine with formalin-inactivated virus resulted in widespread infection with up to 80% of children hospitalized and two deaths (Byrd and Prince, 1997; Kim et al., 1969). Many species have been used as models of RSV infection, including mice, cotton rats, ferrets, cows, guinea pigs, hamsters, chimpanzees, and other non-human primates.

Guinea pigs develop bronchiolitis and airway hyper-responsiveness after RSV infection. Guinea pigs, particularly juveniles, are useful for this model because of the extensive knowledge available about airway physiology and reactive disease in this species, even though they are not as easily infected as some other models (Byrd and Prince, 1997). One study evaluated immunosuppressed animals with cyclophosphamide to more closely approximate the disease usually observed in humans (Tan et al., 2008). Airway hyper-responsiveness is usually determined by the response to an acetylcholine challenge, although a histamine challenge has also been used (Bramley et al., 1999b; Riedel et al., 1997). The peak viral replication occurs at 3 days and maximal bronchial hyper-responsiveness and inflammation is usually observed 6–7 days after inoculation (Dakhama et al., 1997; Robinson et al., 1996; Streckert et al., 1996). Histology also indicates a reactive component with an abundance of eosinophils. Inoculation with 4×10^3 PFU results in replicating virus in 90% of animals by day 6, but bronchiolitis and replicating virus decreases by 14 days post-infection (Hegele et al., 1993). RSV-specific antibodies are present as early as 7 days after infection (Dakhama et al., 1997). After the acute disease resolves, guinea pigs develop persistent lung infection (Bramley et al., 1999a; Dakhama et al., 1997; Sutton et al., 2007).

The reactive component of the disease and persistent infection in guinea pigs is a common area for research because asthma can be a long-term effect of RSV infections in humans. Outbred guinea pigs are routinely used because they are more susceptible to allergic sensitization than strain 2 or strain 13 guinea pigs, but

strain 2 have been used as allergy-resistant models and compared to outbred guinea pigs or strain 13 (Bramley et al., 2003; Sutton et al., 2007). Early experiments indicated that viral RNA and viral proteins continued to be present at least 60 days after inoculation despite negative viral cultures, and a later study confirmed that this correlated with replicating virus (Dakhama et al., 1997; Hegele et al., 1994). Guinea pigs have been evaluated 100 days after inoculation and still exhibited increased airway hyper-responsiveness and increased eosinophils (Bramley et al., 1999a). Although inflammation does decrease after acute infection, it does persist with the virus (Hegele et al., 1994; Riedel et al., 1997). Recent studies have evaluated specific immune components that may contribute to reactive disease (Sutton et al., 2007; Tan et al., 2008). Some researchers have also proposed that a predisposition to allergies may correlate with a predisposition to severe consequences of RSV infection. This was studied in guinea pigs by comparing infections in the allergy-resistant strain 2 guinea pigs with the allergy-susceptible strain 13 guinea pigs, or by inducing allergic sensitization by inhalation exposure to OVA in outbred guinea pigs (Bramley et al., 2003; Robinson et al., 1997). While guinea pigs are primarily used to study pathogenesis and immune response in these infections, they have sporadically been used for other studies including vaccine, treatments, and diagnostics (Dakhama et al., 1998; Tayyari et al., 2005).

Mycobacterium tuberculosis

Tuberculosis (TB) continues to be a major focus of medical research because of its widespread distribution and devastating consequences. *M. tuberculosis* infects approximately one-third of the world's population, resulting in disease in 9 million people and almost 2 million deaths annually. The bacteria are spread primarily by airborne transmission, and active disease usually involves the lungs but other organ systems can be affected. The majority of infections are latent and these people do not develop symptoms and are not contagious, but 5–10% of this population will develop active disease if not treated. Reactivation is a particular concern in immunosuppressed individuals, and TB is a leading cause of mortality in people with HIV (LoBue, 2009). One factor contributing to the failure of disease control is the lack of an effective vaccine. The Bacille Calmette-Guerin (BCG) vaccine is the only available vaccine but has variable efficacy. Another concern is the emergence of drug-resistant TB which is associated with increased treatment cost and treatment failure. Multi-drug-resistant (MDR) TB is resistant to two first-line antibiotics used, isoniazid and rifampin, and extensively drug-resistant (XDR) TB is also resistant to the next most commonly effective drugs. Both of these

strains have been found in the US and with increasing frequency worldwide. National and international organizations have indicated that animal models are necessary for TB research priorities such as vaccine development and treatment, particularly of drug-resistant strains. In addition, animal models are still needed to understand basic bacterial biology, pathogenesis, and host–pathogen interactions, including understanding reactivation of latent disease (LoBue, 2009).

The guinea pig is a well-characterized model that has both historical and current relevance for tuberculosis research. Robert Koch used guinea pigs for his research on tuberculosis, which led to the identification and naming of the etiologic agent as *Mycobacterium tuberculosis* in 1882 and a Nobel Prize in 1905 (Kaufmann and Schaible, 2005). Koch fulfilled the third of his postulates for the definition of microbial pathogens by inducing disease in guinea pigs inoculated by the intraperitoneal route with bacteria derived from the lung of an infected person. Many reviews are available that cover tuberculosis in animal models, including guinea pigs (Basaraba 2008; Orme and Gonzalez-Juarrero 2007; Padilla-Carlin, et al., 2008; Smith and Wiegeshaus 1989). Guinea pigs are a valuable model because of their high susceptibility to the disease which facilitates evaluation of treatment and vaccines (Gupta and Katoch, 2009). Unlike the mouse model, guinea pigs develop a caseating necrosis with TB lesions that is a hallmark of the disease in humans (Helke et al., 2006; Nuermberger, 2008). The current guinea pig model usually involves aerosol infection of young, Hartley guinea pigs (200–350 grams). Some studies use slightly older animals of up to 500 grams, but fully grown animals are rarely used (Baldwin et al., 1998; Basaraba et al., 2006; Garcia-Contreras et al., 2006; Henao-Tamayo et al., 2009; Ordway et al., 2007). Guinea pigs can be infected with as few as 3–5 infectious bacilli, but 30 or more are often used (Ahmad et al., 2009; Ly et al., 2008; Orme and Gonzalez-Juarrero, 2007). A specific protocol using the Madison Chamber developed at the University of Wisconsin for aerosol exposure has been described (Orme and Gonzalez-Juarrero, 2007). These procedures are carried out under animal biosafety level (ABSL) 3 conditions.

Once infected with tuberculosis, guinea pigs develop a progressive and eventually fatal disease (Helke et al., 2006). They develop classic granulomas with Langerhans multinucleated giant cells in the lungs and pulmonary necrosis followed by dissemination to and necrosis of extra-pulmonary tissues including lymph nodes and spleens (Palanisamy et al., 2009; Rao et al., 2009). The enlargement and necrotizing lymphadenitis of the hilar lymph nodes in infected guinea pigs can be severe, which is similar to the disease in children (Basaraba et al., 2006). Extra-pulmonary lesions

can occur in the eyes, brain, small intestine, pancreas, adrenal gland, and heart (Palanisamy et al., 2008; Rao, et al., 2009). Guinea pigs do have several drawbacks as a tuberculosis model. They are more expensive and have fewer reagents available for immunologic and molecular techniques than mice, although more are being developed (Flynn, 2006; Gupta and Katoch, 2009; Yamada et al., 2005). The pathology is different from humans in that most humans do not develop active disease and guinea pigs do not develop liquefaction and cavitary lesions (Gupta and Katoch, 2009; Orme 2006; Orme and Gonzalez-Juarrero, 2007).

Although TB infection is invariably fatal in guinea pigs even with a low number of bacilli inoculated, the disease usually takes months to a year to be fatal. Weight loss and mortality typically occur 100 days after inoculation (Flynn, 2006; Orme and Gonzalez-Juarrero, 2007). Study endpoints range from death or moribund status to predetermined time points (Ahmad et al., 2009; Baldwin et al., 1998; Orme and Gonzalez-Juarrero 2007). If study endpoints necessitate that an animal is allowed to develop clinical disease, monitoring for weight loss and euthanasia prior to death is preferred from both an animal welfare perspective and in allowing the collection of viable samples (Orme and Gonzalez-Juarrero, 2007). Weight loss of 15–20% has been used as a benchmark, although some studies that use weight loss as an endpoint do not indicate what percentage was used (Cardona et al., 2009; Palanisamy et al., 2008; Weldingh and Andersen, 2008; Williams et al., 2005). Some studies have used endpoints based on other parameters such as anorexia, lethargy, and a modified Karnofsky score (Weldingh and Andersen, 2008; Xing et al., 2009). The Karnofsky Performance Status Scale score was initially developed in 1948 for the assessment of status in human oncology patients. This scoring system has been modified for many conditions and uses physical parameters such as weight loss, appearance, and respiratory rate. The time course of disease often results in studies that last for months. After euthanasia, most studies evaluate bacterial loads and lesions in the lungs and other relevant tissues to assess virulence, treatment, or vaccine efficacy.

Guinea pigs have been used to study both the pathogenesis and host–pathogen interactions associated with tuberculosis. Many naturally occurring strains of *M. tuberculosis* vary in phenotype, and guinea pigs have been used to characterize the difference in pathology and virulence associated with different clinical strains (Palanisamy et al., 2008, 2009). Guinea pigs have also been used to evaluate the host immune response to infection after aerosol or intravenous infection, particularly cell-mediated immunity which is a significant component of the human host reaction (Lasco et al., 2005; Ly and McMurray, 2009; Ly et al., 2008; Ordway

et al., 2007). Specifically, the host immune response may play an important role in the establishment of secondary lesions in the lung. In the guinea pig, TB causes a primary lung lesion at the site of entry, and is then transported to lymph nodes, spleen, and then lung. Secondary lesions in the lung occur through hematogenous spread back to the lung instead of spread from the primary lesion (Ly et al., 2008; McMurray, 2001; Ordway et al., 2007; Turner et al., 2003). The immune responses associated with these primary and secondary lesions differ, which could have implications for humans because the secondary lesions are the most likely cause of reactivated TB disease (Balasubramanian et al., 1994; Ly et al., 2008; McMurray, 2001; Turner et al., 2003). Guinea pigs do not easily replicate the process of reactivation from latency because of their sensitivity to the initial exposure, but the use of mutant strains of tuberculosis can be helpful in evaluating this process (Drumm et al., 2009; Kashino et al., 2008). The host immune response has also been studied in the context of a guinea pig model of pleurisy. Bacteria were injected into the pleural space bilaterally, and animals were euthanized to collect pleural fluid and focal granulomatous tissue for bacterial counts and cell analysis (Allen and McMurray, 2003; Ly et al., 2009; Phalen and McMurray, 1993).

Guinea pigs have been widely used to assess treatments and treatment failures of TB. Basaraba (2008) and Nuermberger (2008) offer two independent reviews on this topic. Because of the similarity in lung lesions between guinea pigs and humans, they have been used to evaluate the interaction between lesion morphology and treatment efficacy. In contrast to other rodents, guinea pigs may be a better model for studying treatment efficacy if the caseous necrosis alters the bacteria's ability to persist or makes treatment more difficult (Basaraba, 2008; Nuermberger, 2008). Guinea pigs have been used widely to test antibiotic efficacy and relapse after treatment (Basaraba, 2008; Nuermberger 2008). For example, isoniazid treatment is immediately effective in improving clinical outcomes but this drug can select for tolerant strains which leads to decreased drug efficacy later in disease (Ahmad et al., 2009). Guinea pigs have also been used to test aerosolized versions of drugs, which could improve efficacy by reducing treatment frequency, decreasing systemic side effects, and increasing concentrations in tissues where it is most needed. For example, rifampicin-loaded polymeric microspheres have been compared to nebulized rifampicin suspension (Garcia-Contreras et al., 2006; Suarez et al., 2001). Nanotechnology has been proposed as an improved method of drug delivery that could increase bioavailability and deliver controlled-release drug with either oral or aerosol administration. Guinea pigs have been used to determine pharmacokinetics and tissue

concentrations after delivery of intratracheal administration of rifampicin encapsulated in nanoparticles (Pandey and Khuller, 2006; Sung et al., 2009). Guinea pigs have also been used to specifically study potential treatments for multi-drug-resistant strains of TB (Stover et al., 2000).

Research related to the development of tuberculosis vaccines has been a large component of recent efforts utilizing guinea pigs, and multiple reviews are available (Gupta and Katoch, 2009; Gupta et al., 2007; Orme, 2006). Mice are usually the first model used to evaluate a vaccine because of lower cost and availability of reagents associated with the former species, but guinea pigs are considered a better model and are often used in subsequent studies of vaccines that demonstrated promising results in mice. The guinea pig is a good model for vaccine candidates because the disease is consistently fatal without protection (Flynn, 2006; Gupta and Katoch, 2009). In addition, the BCG vaccine is more effective in the guinea pig than other rodent models, which allows more sensitive comparisons of efficacy between BCG and new vaccines (Gupta and Katoch, 2009). The BCG vaccine itself has been studied extensively in the guinea pig (Basaraba, 2008; Basaraba et al., 2006; Cho and McMurray, 2007; Fok et al., 1976; Harding and Smith, 1977; Jeevan et al., 2006; Lasco et al., 2005; Ly et al., 2008; Ordway et al., 2008; Roche et al., 1995; Smith and Wiegshauss, 1989; Smith et al., 1970; Wiegshauss et al., 1970; Yamamoto et al., 2007). After vaccine administration, challenge with bacteria is done at least 1 month later or at longer intervals. Even though the BCG vaccine has limitations in its use in humans, the vaccine's benefits such as safety and long-term immunity have led some researchers to investigate a recombinant BCG vaccine that may have increased immunogenicity in guinea pigs (Gupta et al., 2007; Horwitz and Harth, 2003; Horwitz et al., 2000; Orme 2006; Sun et al., 2009). DNA vaccines have been tested in guinea pigs with variable results (Baldwin et al., 1998; Gupta et al., 2007; Khera et al., 2005; Orme, 2006). In addition, guinea pigs have been used to study subunit (Gupta et al., 2007; Olsen et al., 2004; Reed and Lobet, 2005) and attenuated live vaccines (Cardona et al., 2009; Sampson et al., 2004). Another vaccine strategy is using a novel vaccine as a booster to the BCG vaccine, which has also been evaluated in guinea pigs (Orme, 2006; Williams et al., 2005). Recombinant viral vectors such as adenovirus and poxvirus have also been shown to have some efficacy in the guinea pig model (Williams et al., 2005; Xing et al., 2009). Studies have also looked at the potential benefits of post-exposure vaccination (Henao-Tamayo et al., 2009).

Guinea pigs have been used less frequently for other aspects of TB research. For example, a few studies have looked at diagnostic tests for TB in guinea pigs,

including characterizing lesions on MRI (Geisbrecht et al., 2006; Weldingh and Andersen, 2008). In addition, several classic studies have described the use of guinea pigs to detect airborne transmission of tuberculosis in hospital wards and this process has been used more recently as a potential method to assess mechanisms to decrease airborne transmission of the bacteria (Escombe et al., 2007; Koenig, 2008; Riley et al., 1995). Basically, the animals are exposed to air from tuberculosis wards and tested routinely by the tuberculin skin test. Guinea pigs that test positive on the skin test are submitted for necropsy to confirm infection. Guinea pigs have also been used to study the relationship between malnutrition and infection or vaccine efficacy (Cegielski and McMurray, 2004; Roche et al., 1995).

Chlamydia

Chlamydia trachomatis is an obligate intracellular bacterium that is a leading cause of sexually transmitted disease and preventable blindness (Wilson et al., 2009). Most people with reproductive tract infections do not develop symptoms, but untreated infections in women can lead to pelvic inflammatory disease, infertility, and ectopic pregnancy. This bacterium is also the etiologic agent of trachoma, which is a chronic follicular conjunctivitis that can lead to corneal ulceration, opacities, and blindness secondary to inversion of the eyelashes. The host's immune response is an important factor in the pathology of the disease for both reproductive and ocular infections (Wilson et al., 2009).

The guinea pig model of reproductive chlamydial infection utilizes the guinea pig pathogen *Chlamydomphila caviae*. This bacterium is the etiologic agent of guinea pig inclusion conjunctivitis, and was formerly the guinea-pig-associated strain of *Chlamydia psittaci*. Natural conjunctival infections in guinea pigs can range from asymptomatic to severe with conjunctivitis and uveitis, and the disease can progress to the lower respiratory tract (Lutz-Wohlgröth et al., 2006). *Chlamydomphila caviae* is species-specific for guinea pigs, but it has been associated with clinical disease in other species including horses, rabbits, and dogs (Pantchev et al., 2009). Reviews of both the male and female guinea pig model are available (Padilla-Carlin et al., 2008; Rank and Whittum-Hudson 1994).

Guinea pigs are a useful model because of the similarities with humans in the pathology and immune response to chlamydial infection. The guinea pig female reproductive tract is more similar than mice to humans, and chlamydial infections in female guinea pigs have a propensity for ascending infection, which has been suggested as a model for pelvic inflammatory disease (Rank et al., 1993). Both human and guinea pig offspring can acquire chlamydial conjunctivitis from the mother during parturition (Padilla-Carlin et al., 2008).

Chlamydial infection in male guinea pigs also models the condition in humans in that they are usually asymptomatic, with no urethral discharge (Padilla-Carlin et al., 2008). Another key similarity that guinea pigs share with humans is they are the only animal model where sexual transmission of the bacteria has been documented. Guinea pigs differ from non-human primates and humans in that they develop acute, short infections that steadily diminish to a negative culture state, whereas humans and non-human primates can have intermittent positive cultures (Golden et al., 2000).

Investigations of chlamydial infections in guinea pigs usually use young but sexually mature animals (usually about 500 g bodyweight). Females are infected by intravaginal inoculation or sexual transmission. For intravaginal infection, the vaginal membrane must be broken prior to inoculation. Males can be infected with bacterial suspension placed on the extruded penis or directly into the urethra. After inoculation, infection is usually assessed by the percentage of inclusion bearing cells or isolation of the bacteria from urethral or vaginal scrapings. For sexual transmission, male guinea pigs are infected by administration of the bacteria into the urethra and then mated with females. The model of sexual transmission has been used to determine an inoculum for artificial infection that most closely resembles natural infection (Rank et al., 1993). The course of artificial infection with 10^2 inclusion-forming units (IFU) most closely resembled natural infection, and infected 70% of the animals, which was similar to the infection rate resulting from mating. Infection with 10^4 IFU was required for a 100% infection rate. The authors recommended 10^2 – 10^3 FU based on these results, but many prior studies had used higher doses (Darville et al., 1995, 2000; Rand and Whittum-Hudson, 1994).

The pathology and disease course after infection with *C. caviae* have been well-characterized. The histology associated with genital infections in female guinea pigs has been described (Barron et al., 1979; Rank, 1994). Bacterial numbers and inflammation are most pronounced in the cervix, with peak inclusion scores usually at 6–9 days post-inoculation (Barron et al., 1979; Rank, 1994). The bacteria are present in approximately 80% of uterine horns and oviducts within 7 days of inoculation, although the incidence of salpingitis was lower (Rank, 1994; Rank and Sanders, 1992). Inflammation resolves and inclusion scores decrease considerably by approximately 20 days (Barron et al., 1979; Rank, 1994). Early studies used cyclophosphamide for immunosuppression to assess ascending infection, but studies have indicated that increasing the sample size and refining timepoints allows for the evaluation of ascending infection without immunosuppression (Rank and Sanders, 1992; White et al., 1979). Infection can also result in long-term oviductal damage that is

seen at 75–80 days (Rank and Sanders, 1992; Rank and Whittum-Hudson, 1994). The course of infection is not altered by the stage of the estrous cycle during inoculation, but timing can affect the incidence of pathologic findings (Rank et al., 1993). The pathology of disease in the females can be altered by hormones. This has been evaluated because many women take oral contraceptives. Contraceptive hormones, particularly estradiol, prolong infection, delay the humoral immune response and increase the incidence of salpingitis, endometritis, and cystitis (Barron et al., 1988; Pasley et al., 1985; Rank and Barron, 1987; Rank et al., 1982). In the male, intraurethral infection can last for 2 weeks (Howard et al., 1976). Cyclophosphamide increases the number of successfully infected males and prolongs the time the bacteria can be found in the bladder from 18 days to 50 days (Patterson and Rank, 1996; Rank et al., 1981).

Both male and female guinea pigs have at least partial immunity to reinfection of *C. caviae* in the genital tract after primary infection, but reinfection in females can increase the chance of tubal damage (Rank et al., 1995). Females that are reinfected have a shorter disease course with decreased shedding following intravaginal inoculation or sexual transmission of the bacteria (Golden et al., 2000; Lamont et al., 1978; Rank and Barron, 1983). Animals are most resistant to reinfection 30 days after the initial infection (Rank et al., 1988). Although males are resistant to reinfection of the genitals, they are still susceptible to ocular infections after primary genital infection (Howard et al., 1976).

The host immune response is a factor both in the pathology and resolution of the diseases associated with chlamydial infections, and both the humoral and cellular responses have been studied in the guinea pig (Darville et al., 1995, 2000; Howard et al., 1976; Rank, 1994; Rank et al., 2000). The immune responses of guinea pigs and humans share more similarities compared with mice and humans (Rank et al., 2000). Studies have evaluated the antibody response and both serum and local antibodies have a role in resolution and protection (Batteiger et al., 1993). Resistance to reinfection is dependent on the humoral immune response, but cellular immunity also plays a role (Igietsme and Rank, 1991; Rank and Barron, 1983; Rank and Batteiger, 1989). Because of the partial protection conveyed by infection and serum-derived antibody from infected animals, a few studies have used this knowledge of the immune response to look at protection conferred by vaccines (Rank and Batteiger, 1989). The vaccines studied included both inactivated bacteria and subunit vaccines, but they have failed to provide full protection (Batteiger et al., 1993; Patterson and Rank, 1996; Rank et al., 1990).

As a model of human conjunctivitis, guinea pigs have demonstrated value. The model was first described in the 1960s, and simply involves inoculating the

conjunctiva with the organism (Murray, 1964). This model differs from humans and non-human primates in that the guinea pig model is more acute and has a low incidence of crossover if only one eye is infected (Rank and Whittum-Hudson, 1994). Lesions are graded based on the presence and extent of erythema, edema, and exudates. Animals are evaluated by the lesion scores and the presence of organisms in conjunctival scrapings. The pathology lasts for a mean of 7 days and is the most severe at 1.5 days post-inoculation (Wilson et al., 2009). The lesions can progress to pannus with multiple challenges of the bacteria (Rank and Whittum-Hudson, 1994). Inbred and outbred strains are both susceptible to ocular infection (Rank and Whittum-Hudson, 1994). This model has primarily been used to study pathology of the infection (Rank et al., 2008, 2009). Infection of the eye can result in immunity to reinfection of both the eye and genitals in male guinea pigs (Howard et al., 1976). It is interesting to note that estradiol does not alter the course of ocular infection as it does for reproductive infection (Rank and Barron, 1987).

Legionella pneumophila

Legionella pneumophila is a Gram-negative, facultative intracellular bacterium that is the etiologic agent of Legionnaires' disease. This disease was originally described in an outbreak at a 1976 convention of the American Legion in Philadelphia. The primary lesion is pneumonia, and clinical signs can include high fever, chills, cough, muscle aches, and headaches. Symptoms usually begin 2–14 days after exposure. Many people that are infected have no or mild symptoms and are not diagnosed. However, it can progress to severe pneumonia and approximately 8000–18000 people are hospitalized annually in the US and fatalities can occur in 5–30% of these cases (CDC, 2008a). Most healthy people respond to treatment with antibiotics, but the disease is more severe and difficult to treat in the elderly, immunocompromised, and people with underlying respiratory disease. The bacteria are not readily spread from person to person, but are found naturally in the environment. Outbreaks are usually caused by exposure to a common source of contaminated water vapor, such as whirlpool spas.

Guinea pigs develop severe pneumonia with *L. pneumophila* and have been a classic model for Legionnaires' disease in humans. Reviews of the guinea pig as a model of this disease are available (Armstrong and Haas, 2007; Padilla-Carlin et al., 2008). Other rodents are relatively resistant to infection and have immune systems that share fewer similarities with humans than guinea pigs (Armstrong and Haas, 2007; Davis et al., 1982; Winn et al., 1982). Guinea pigs are highly susceptible to infection even without passage of the bacteria through this species, but some studies do

passage strains before experimental infection (Berendt et al., 1980; Davis et al., 1983a, 1983b). The guinea pig pneumonia model usually relies on aerosol infection, but intratracheal and intranasal instillation of the bacteria have also been used. Aerosol is a more efficient mechanism for infection than intranasal inoculation (Fitzgeorge et al., 1983). Organisms are less virulent when administered intraperitoneally, but the bacteria can cause a peritonitis and mortality at high doses (Berendt et al., 1980; Dournon and Rajagopalan, 1988; Fitzgeorge et al., 1983). Aerosol infection usually involves a mechanism to deliver droplets less than or equal to 5 μm . The numbers of retained bacteria are estimated based on an assumed 50% retention rate and/or by evaluating the dose retained in the lung at necropsy. Aerosol infection produces a severe pneumonia and clinical signs include fever, ruffled fur, weight loss, lethargy, and dyspnea, often associated with high mortality (Baskerville et al., 1981; Berendt et al., 1980; Davis et al., 1982, 1983a, 1983b; Fitzgeorge et al., 1983). The bacterial strains vary in virulence in guinea pigs, and the same strain can lose virulence over time by many passages in culture (Jepras et al., 1985). For example, inoculation with the Philadelphia-1 strain originally resulted in 100% mortality (Berendt et al., 1980), while later studies indicated no mortality (Jepras et al., 1985). Virulence can also be affected by growth temperatures for the bacteria prior to infection (Edelstein et al., 1987).

The pathology and host defenses associated with *L. pneumophila* infection have been extensively studied in the guinea pig model. Animals develop pneumonia by 1–3 days after infection characterized by diffuse foci of mixed inflammation and consolidation (Baskerville et al., 1981; Davis et al., 1983a; Fitzgeorge et al., 1983). Bronchoalveolar lavage done at different time points during infection indicates that an increase in bacteria coincides with an influx of inflammatory cells that begins at 16 hours after infection, peaks at 3 days and subsides by 11 days if the animals are going to recover (Davis et al., 1983a, 1983b). Most viable bacteria are associated with alveolar macrophages (Davis et al., 1983a; Hui et al., 2009). Both humoral and cell-mediated immune responses have been studied, and cellular immunity is the primary factor in preventing lethal infection in surviving animals (Blander and Horwitz, 1991, 1993; Klein et al., 1984; Weeratna et al., 1994). Activated monocytes and alveolar macrophages inhibit intracellular multiplication of the bacteria and are a large component of host defenses against this disease (Blander and Horwitz, 1991, 1993). In addition, studies have evaluated lesions induced by particular proteases of the bacteria to determine their role in the pathology of the lesions (Baskerville et al., 1986; Conlan et al., 1986). Studies have also evaluated the genes that may be involved in pathogenesis by infecting guinea

pigs with mutant strains and analyzing bacteria–macrophage interactions (Edelstein et al., 1999). Similar to humans, transmission of the bacteria from one animal to another does not readily occur (Katz et al., 1982).

Guinea pigs have been used to assist with diagnosis of *L. pneumophila*, including the virulence of clinically isolated strains. Historically, guinea pigs were exposed to test water and clinical samples for detection of the bacteria because it is slow-growing and difficult to isolate (Edelstein et al., 1982; McDade et al., 1977; Meenhorst et al., 1983). Since 1979, it has been recognized that *Legionella* antigens can be detected in the urine of infected patients and that is now a common method for diagnosis. Guinea pigs have been suggested for use as a model of refining these urinary antigen tests but are used infrequently (Kim et al., 2003; Williams and Lever, 1995). They have also been used to test the reliability of PCR tests for diagnosis and have been compared to protozoan models and found to be a reliable predictor of virulence (Fields et al., 1986; Maiwald et al., 1995). Guinea pigs continue to be a good model for human risk extrapolation because of their high susceptibility to the disease as well as similar disease course and macrophage–bacterial interactions (Armstrong and Haas, 2007).

Guinea pigs are also useful in testing vaccine and therapeutic options for *L. pneumophila* infections. The animals in these studies are often challenged with lethal doses of the bacteria in order to maximize the difference between control and experimental groups. Killed bacteria elicit high antibody responses but do not elicit a cellular immune response and are not protective against subsequent aerosol challenge (Blander and Horwitz 1991, 1993; Breiman and Horwitz 1987). In contrast, vaccines composed of *L. pneumophila* membranes or proteins induce strong cellular immunity and protection (Blander and Horwitz, 1991, 1993; Breiman and Horwitz, 1987). Edelstein (1995) offers a review of research related to antimicrobials for this disease, including the use of the guinea pig model. Generally, efficacy in humans is consistent with efficacy demonstrated in the guinea pigs (Edelstein, 1995). Novel fluoroquinolones and macrolides have been studied, and are usually compared to erythromycin for efficacy (Dournon and Rajagopalan, 1988; Dournon et al., 1986; Edelstein et al., 1999, 2001a, 2001b; Garcia-de-Lomas et al., 1998).

Staphylococcus aureus

Guinea pigs are used for a variety of investigations of *S. aureus* infections because of their size, but are most commonly used to study wound infections. Some of these studies also include infection with other bacteria including other *Staphylococcus* species, *Streptococcus*, *Bacteroides*, and *Pasteurella*. *S. aureus* is a common cause

of surgery-related infections and can be difficult to manage, particularly with the emergence of drug-resistant strains such as methicillin-resistant *Staphylococcus aureus* (MRSA). A common guinea pig model uses superficial dorsal lacerations to the level of the fascia, followed by bacterial contamination. One study used liquid nitrogen to break down the skin integrity before application of the bacteria (Kratzer et al., 2007). For the superficial wound infection model, at least 10^4 bacteria are needed to cause reliable infection (Stratford et al., 2002). Animals are subsequently evaluated by quantitative bacterial counts of the tissue and/or clinical scores of the lesions. This model has been used to evaluate the efficacy of different antibacterial irrigating solutions, including iodine, normal saline, and cefazolin (Howell et al., 1993a, 1993b; Lammers et al., 2001). Additionally, antibiotic creams for treating MRSA, the anti-inflammatory effects of ketoconazole, the effects of local anesthetics on infection, and the use of silver products to control infection in skin grafts have been examined in guinea pigs (Kawai et al., 2001; Kratzer et al., 2007; Mazurak et al., 2007; Stratford et al., 2002; Van Cutsem et al., 1991).

A superficial wound model has also been used to study the association of various types of suture and tissue adhesives with bacterial infections (Edlich et al., 1968; Howell et al., 1995; Ming et al., 2007, 2008; Quinn et al., 1997; Storch et al., 2004). This guinea pig model has been used to evaluate the use of topical antibiotics and antibiotic-impregnated beads for surgical wounds infected with both drug-susceptible and MRSA bacterial strains (Boon et al., 1985; Galandiuk et al., 1997). Also, because hypothermia is commonly associated with anesthesia, researchers have studied the relationship between hypothermia and infection utilizing guinea pigs (Sheffield et al., 1994).

S. aureus infection associated with surgical implants is a significant clinical problem. This infection is commonly simulated in guinea pigs with the use of a tissue cage implanted subcutaneously. The tissue cage is a perforated Teflon tube with or without additional foreign bodies inside the tubes. The perforations allow for the influx of inflammatory cells and fluid. After the animal has healed from the surgery for the cage implantation, a fluid sample is taken percutaneously from the tissue cage to confirm sterility. Bacterial suspensions are then inoculated into the tissue cage for subsequent tests of pathogenesis and treatments of foreign body infections. Fluid samples can also be analyzed for toxins and RNA expression of various genes to determine factors involved in the pathogenesis of infection (Goerke et al., 2001; Senn et al., 2005). In order to study the factors influencing adherence of *S. aureus* to materials, plastic or glass foreign bodies are placed inside the cage and tested for viable bacteria at the study's end (Falcieri et al., 1987; Fluckiger et al., 2005; Francois et al., 2003;

Wolz et al., 2002). This model is also useful in evaluating antibiotic therapies. The fluid samples can be analyzed for bacterial counts and drug concentrations to determine efficacy and compared to in vitro models for reliability (Blaser et al., 1995). The same model has been used to evaluate antibiotics such as fluoroquinolones, vancomycin, and rifampicin for the prophylaxis and treatment of both drug-susceptible strains and MRSA (Baldoni et al., 2009; Bouchenaki et al., 1990; Cagni et al., 1995; Schaad et al., 1994; Vaudaux et al., 2002). The treatment studies also have included the use of foreign bodies inside the cages, and culture results from fluid samples have correlated well with those taken directly from the foreign body itself (Cagni et al., 1995).

The tissue cage model is not the only model of foreign-body-related infection in guinea pigs. Metallic implants have been fixed onto the iliac bones or implanted subcutaneously to mimic infections associated with orthopedic devices (Fischer et al., 1996). A model utilizing dextran microbeads as a foreign body has been developed (Kaiser et al., 1992). The microbeads are mixed with a bacterial suspension and administered by intramuscular injection over the back, between the panniculus carnosus and superficial trunk musculature. Punch biopsies are taken for bacterial cultures at necropsy 3–4 days later. This model has been used to test the prophylactic and treatment efficacy of drug-susceptible and -resistant strains with treatments such as of ampicillin, cefazolin, vancomycin, fluoroquinolones, immunomodulatory agents, and drugs that inhibit bacterial entry into the cell (Kaiser et al., 1992; Kernodle and Kaiser, 1993a, 1993b, 1994; Kernodle et al., 1998; Menzies et al., 2002). Early experiments that used this model had high numbers of deaths from colitis secondary to the antibiotic therapy, and were able to decrease mortality from 40% to less than 10% by using gentamicin and polymyxin B in the water (Kaiser et al., 1992). These antibiotics are poorly absorbed from the gastrointestinal tract, so they did not affect the experimental infections.

Because of its ubiquitous nature, *S. aureus* can be associated with many other types of infections. *S. aureus* is a common cause of Gram-positive sepsis, and guinea pigs have been inoculated intravenously or by implantation of an intraperitoneal osmotic minipump to simulate disseminated disease. These studies have focused on pathogenesis including the development of disseminated intravascular coagulation (DIC), vascular leakage, and even the role of diet (Imamura et al., 2005; Kessler et al., 1991, 1997; Nelson et al., 1996). This model can be associated with high mortality. Guinea pigs have also been used to compare the virulence of drug-resistant and -susceptible strains (Cutler, 1979; Mizobuchi et al., 1994). A burn injury model was developed where injuries are created under anesthesia and then experimentally infected with *S. aureus* to evaluate the host immune

response and treatments (Bjornson et al., 1984; Kaufman et al., 1990; Orenstein et al., 1997). Other conditions that have been infrequently studied include *S. aureus* infective endocarditis (Maurin et al., 1997), mastitis (Vandeputte-Van Messom et al., 1995), dermonecrotic reactions (Miedzobrodzki and Tadeusiewicz, 1987), and middle ear infections (Sutbeyaz et al., 1996).

Listeria monocytogenes

Listeria monocytogenes is a Gram-positive foodborne pathogen that primarily affects immunocompromised, pregnant, or elderly people. It has been a reportable infection since the year 2000 with 2500 cases and 500 deaths in the United States annually (CDC, 2008d; Nieves, 2009). Listeriosis can vary from a mild, flu-like illness to gastroenteritis, sepsis, and severe CNS infections including meningitis and encephalitis. Infections in pregnant women can lead to stillbirth, spontaneous abortions, premature delivery, and disease in the neonate. The bacteria enter through the small intestine and then spread to target organs, including liver, spleen, and the fetus (Cabanes et al., 2008). Many laboratory animal species have been used as models. Early studies determined the LD50 of *L. monocytogenes* in the guinea pig after intraperitoneal and intravenous administration (Dustoor et al., 1977; Kautter et al., 1963). The advantage of the guinea pig model is that the bacteria cross the intestinal epithelium and cause gastroenteritis similar to the disease in humans (Cabanes et al., 2008). *Listeria* has a surface protein, internalin A that interacts with an intestinal epithelium receptor, E-cadherin (Lecuit et al., 1999, 2001). The E-cadherin of mice and rats differs in amino acid sequence from humans, which inhibits interaction with internalin A. In contrast, the E-cadherin homolog in guinea pigs permits entry of *Listeria* in the intestinal epithelium (Lecuit et al., 1999, 2001). Although subsequent spread to the brain and placenta does not occur as frequently in guinea pigs as it does in humans, placental infections do occur in guinea pigs and pregnant animals are used as models of fetoplacental transmission (Cabanes et al., 2008). The low incidence of spread to the CNS has been argued as one of the model's shortcomings (Gray and Killinger, 1966; Lecuit et al., 2007). Another potential limitation is that the guinea pig may lack one of the specific receptors for bacterial surface proteins thereby affecting tissue tropism (Khelef et al., 2006; Lecuit et al., 2007). Despite these potential limitations, the model continues to be popular. Readers are referred to Lecuit et al. (2007) for a review of the disease and animal models.

The guinea pig models often rely on administration of a product inoculated with *Listeria monocytogenes* into the gastrointestinal tract. Young Hartley guinea pigs are frequently used for these studies. Because it is a BSL2 pathogen, experimental procedures must involve the

appropriate precautions. Although specific protocols have been published that describe gavage and intragastric administration (Cabanes et al., 2008; Dussurget et al., 2002; Garner et al., 2006; Pang et al., 2007), many studies rely on consumed palatable products (Irvin et al., 2008; Jensen et al., 2008; Roldgaard et al., 2009; Williams et al., 2007). Some of these studies fasted animals for 12–48 hours, but most do not indicate a fasting period. Whipping cream is often used as the vehicle because the high-fat content mimics many of the natural modes of infection through high-fat foods such as cheese. During the study, fecal pellets are collected for bacterial counts. Animals are then euthanized at determined time points depending on the goals of the study, and bacterial counts determined in target organs such as jejunum, spleen, and liver and less commonly lymph nodes. Sublethal infective doses are typically used, because severe clinical signs and mortality can result from high doses (Bakardjiev et al., 2005; Cabanes et al., 2008; Lecuit et al., 2001).

Strains of *Listeria monocytogenes* vary greatly in virulence, and guinea pigs have been used to assess virulence and the potential risk the bacteria could pose to consumers. Bacterial strains that have been found in food-processing plants have been compared to clinical strains using the guinea pig model (Jensen et al., 2008a). Jensen et al. (2008) demonstrated a difference in fecal shedding between bacterial strains after oral administration that was consistent with predictions from other models of bacterial virulence, which helps validate the guinea pig as a method for distinguishing virulence. Anderson et al. (1980) showed that environmental conditions in which the bacteria grow prior to infection can affect virulence, which has implications for human safety if virulence varies for the same strain. Bacteria grown under oxygen-restricted conditions resulted in significantly higher bacterial counts in feces and tissues after oral administration. This study also attempted to evaluate a novel method of *L. monocytogenes* infection that would reduce the animal numbers needed to complete experiments. Multiple bacterial strains or monocultures were administered to the animals, and fluorescent labels were used to differentiate the different strains. Based on these results, the authors suggest that mixed infections do not decrease the ability of the model to discriminate between strain virulence and can utilize fewer animals than administering the bacteria as monocultures. These results were supported by another study that used these techniques to compare virulence between three strains (Roldgaard et al., 2009). Results were similar for each strain regardless of whether they were administered as monoculture or mixed infection.

Pregnant guinea pigs have been used to compare strain virulence and evaluate factors that can contribute to placental infections with *L. monocytogenes*. As with

other infections, the guinea pig model can be a useful model because both guinea pigs and humans have a hemochorial placenta (Bakardjiev et al., 2006). Pregnant guinea pigs are usually administered the bacteria via the gastrointestinal system or intravenously and euthanized prior to delivery (Bakardjiev et al., 2004, 2005, 2006; Irvin et al., 2008a; Jensen et al., 2008b; Williams et al., 2007). Parameters that are evaluated include maternal weight loss and clinical signs, fecal shedding of the bacteria, premature delivery or abortions, fetal viability, and bacterial counts in tissues from both the fetus and the sow. Fetal viability is determined based on physical characteristics indicating if the fetus had reached an expected stage of development and the general appearance including cyanosis, the placental blood and cord, and skin color. Williams et al. (2007) helped define this model by evaluating different infective doses administered orally to determine the appropriate dose for inducing stillbirths and infections of desired tissues. That study determined that 10^7 CFU was sufficient for this strain to adversely affect 50% of the pregnancies and result in disease with pathology similar to humans. Jensen et al. (2008b) evaluated orally administered strains found at a food-processing plant and determined that the strain isolated from the plant was capable of crossing the placenta. Oral inoculation in pregnant guinea pigs has also been used to evaluate the immune response and placental apoptosis as potential factors for negative consequences for the fetus during infection (Irvin et al., 2008a, 2008b). Several studies have utilized intravenous infection via the pedal or ear veins in pregnant guinea pigs to model vertical transmission. These studies characterize infection of the placenta and how it can serve as a nidus of infection to reinfect the sow (Bakardjiev et al., 2004, 2005, 2006). This model also results in bacteria crossing the placenta and inducing abortion with doses of at least 10^6 CFU of bacteria, which can be achieved without clinical illness in the mother.

L. monocytogenes infection has been used sporadically in other guinea pig studies. Pang and co-authors (2007) used older guinea pigs (approximated 2 years old) to determine the effects of immunomodulation with the immunostimulant vitamin E or the immunosuppressant cyclosporin A on the outcome of infection. There have also been reports of attempts to inoculate by other routes such as intratesticular (Sanui et al., 1982, 1983) and CNS (Nairn et al., 1995; Sanui et al., 1982). Bacteria have also been genetically altered to determine the role of certain proteins in pathogenesis after administration by both the gastrointestinal and intravenous routes (Dussurget et al., 2002; Garner et al., 2006).

Streptococcus pneumoniae

Streptococcus pneumoniae can cause a variety of clinical diseases in humans including pneumonia, bacteremia,

otitis media, meningitis, sinusitis, peritonitis, and arthritis. Sequelae can include tympanosclerosis from otitis media and sensorineural hearing loss from pneumococcal meningitis (Ozcan et al., 2008; Skinner et al., 2004). These diseases can be fatal, and high-risk groups are particularly susceptible to serious disease including the elderly, children under 2 years old and those with underlying medical conditions. The use of vaccines has decreased rates of infection since 2001, and the CDC currently recommends vaccination of infants, young children, and adults (CDC, 2008c). As with other bacteria, resistant bacteria are an emerging problem and beta-lactam resistance is common. *S. pneumoniae* is a pathogen for many species, and has caused outbreaks in guinea pig laboratory colonies (Saito et al., 1983). This bacterium can also be found in the respiratory tract of normal animals and disease may not occur unless precipitated by a stressor. Guinea pigs are used as models of this disease primarily for research related to bacterial pathogenesis and the development of treatments. Although this generally involves the CNS or inner ear, guinea pigs have also been used to test antibiotics after experimentally induced fatal pneumonia from intratracheal instillation of *S. pneumoniae* (Ponte et al., 1996).

A guinea pig model of intrathecal administration has been used to evaluate pathogenesis and antibiotic effectiveness for meningitis. This model can involve intrathecal injection of bacteria into the cistern magna (Blank et al., 1994; Force et al., 2008, 2009). Others have injected bacteria into the subarachnoid space after drilling a hole over the parietal skull bone (Winter et al., 1996, 1997). Infection can lead to labyrinthitis, meningitis, and death. After infection, cerebrospinal fluid (CSF) is taken at various time points to assess for inflammation, protein, and bacterial counts. Blood may be evaluated to assess for bacteremia. Other parameters measured may include auditory integrity and evaluation of the organ of Corti by electron microscopy or histology (Blank et al., 1994; Winter et al., 1996, 1997). This model has been used to test antibiotics such as meropenam, rifampin, ceftriaxone, and vancomycin (Force et al., 2008, 2009; Nairn et al., 1995). Force et al. (2008) compared the guinea pig to the traditional rabbit model of meningitis. The disadvantage of the guinea pig is that their small size only allows for CSF collection at a maximum of two time points, whereas rabbits allow collection of a larger volume. However, the authors suggest that guinea pigs are a more reliable model for testing efficacy of certain drugs. For example, rabbits easily hydrolyze the drug meropenam and metabolize it more quickly than guinea pigs and humans.

Guinea pigs have also been used to study the ototoxicity of *S. pneumoniae* by direct administration into the ear as a model of otitis media. Bacteria or pneumococcal

proteins are inoculated through the tympanic cavity and directly into the middle ear or cochlea. Parameters often measured include otomicroscopic exams and auditory nerve function, followed by euthanasia for histology and bacterial cultures (Cook et al., 1999; Hori et al., 2000; Ozcan et al., 2008; Skinner et al., 2004; Winter et al., 1998). This model has also been used to evaluate treatments such as topical doxycycline (Hori et al., 2000; Ozcan et al., 2008; Winter et al., 1998).

Helicobacter pylori

Helicobacter pylori causes active chronic gastritis and is a factor in the development of peptic ulcer disease and gastric cancer in humans (Keenan et al., 2003; Lee, 2000). The Mongolian gerbil is the model with the most severe pathology, but many animal models including non-human primates, cats, guinea pigs, ferrets, pigs, and mice have been used (Lee, 2000). Unlike other rodents, guinea pigs have several characteristics in common with humans that may facilitate the significant gastritis that occurs with *H. pylori* infection (Lee, 2000; Shomer et al., 1998). Guinea pigs have a homolog of interleukin-8, and *H. pylori* induces IL-8 secretion which attracts neutrophils and this cytokine may contribute to the gastric pathology (Keenan et al., 2003; Lee, 2000; Shomer et al., 1998). The anatomy of the guinea pig stomach is also similar to humans because it lacks a non-glandular portion that is present in other rodents (Shomer et al., 1998). In addition, guinea pigs have dietary requirements for vitamin C and levels of vitamin C in gastric juices comparable to humans. This is important because humans with *H. pylori* infections have low levels of vitamin C in gastric juices, which may contribute to the progression of disease (Nedrud, 1999; Shomer et al., 1998; Sjunnesson et al., 2003). Guinea pigs may also be good models because they have no natural *Helicobacter* species as pathogens that could complicate the model (Sjunnesson et al., 2003).

The pathology associated with *H. pylori* in guinea pigs has been well established. Most studies use the rodent-adapted Sydney strain or human clinical isolates that have been passaged in guinea pigs, but some do use clinical isolates directly from human biopsies. The adapted strains are associated with higher recovery of bacteria from the tissue after infection and better colonization of tissue than non-adapted strains (Rijpkema et al., 2001; Sturegard et al., 1998). *H. pylori* is usually administered via the oral cavity, but intra-gastric administration in several doses is also used, in both cases followed by euthanasia to evaluate pathology utilizing techniques such as culture, PCR, and histology (Shomer et al., 1998; Sturegard et al., 1998). *H. pylori* produces reliable infection in guinea pigs with severe antral gastritis and the formation of lymphoid follicles, and the lesion distribution is similar to that seen

in humans (Shomer et al., 1998; Sjunnesson et al., 2003; Sturegard et al., 1998). Infection with the Sydney strain of *H. pylori* can persist for at least 5 months (Sjunnesson et al., 2003). Recovery of bacteria and gastritis scores can be lowered by supplementing guinea pig diets with antioxidants, including vitamin C (Sjunnesson et al., 2001). Investigations have also evaluated the role of bacterial outer-membrane proteins and gastric proteins in the pathogenesis and ability to colonize the stomach (de Jonge et al., 2004; Lueth et al., 2005). Studies have also evaluated immune responses, and animals reliably seroconvert after infection (Rijpkema et al., 2001; Shomer et al., 1998; Sjunnesson et al., 2001; Sturegard et al., 1998).

In addition to pathogenesis, guinea pigs have been used to study treatments and prevention of *H. pylori* infections. Gonzalez-Segovia et al. (2008) looked at the effectiveness of the flavanoid quercetin on the inflammation and lipid peroxidation induced by *H. pylori*. Studies on the use of vaccines have indicated that the vaccine can induce an immune response and may reduce infection, but the humoral immune response does not correlate with protection (Durrani and Rijpkema, 2003; Keenan et al., 2003).

Superficial Fungal Infections

Guinea pigs are used as a model for superficial fungal infections because of their susceptibility to dermatophytosis. In humans, onychomycosis and dermatophytosis are most commonly caused by the organisms of the genera *Trichophyton*, *Microsporum*, and *Epidermophyton* (Ghann, 2009). Dermatophytosis is described more specifically as infections of the scalp (tinea capitis), feet (tinea pedis), and body (tinea corporis). Children in particular are prone to tinea capitis (Saunte et al., 2007). *Trichophyton* is the most common causative agent of tinea pedis (Treiber et al., 2001). *Microsporum canis* is primarily a pathogen of dogs and cats, but is contagious to other species including humans and is a frequent cause of tinea capitis (Saunte et al., 2007; Vermout et al., 2008). Animal models are necessary, particularly for the development of new treatment options, because of the side effects that can be associated with systemic antifungals and the possibility of treatment failures or relapse after standard treatments are discontinued (Ghannoum et al., 2009; Nagino et al., 2000; Saunte et al., 2008).

The guinea pig model of infection with both *T. mentagrophytes* and *M. canis* has been characterized. Since early studies indicated that guinea pigs could be reliably infected with multiple dermatophytes, including *T. mentagrophytes*, *M. canis*, and *Epidermophyton floccosum*, studies have attempted to optimize these protocols (Chittasobhon and Smith, 1979; Greenberg et al., 1976). Some researchers perform these studies under ABSL-3 conditions because of the high risk of transmission to other animals, but dermatophytes do not meet

the typical characteristics of ABSL-3 agents from the perspective of human health (Saunte et al., 2007, 2008). Guinea pigs are usually shaved with electric clippers, and then the area is abraded prior to inoculation. Items used for abrasion have included pumice stone, sandpaper, hand razor, roughened glass pestle, razor blades, or even repeated application of tape (Chittasobhon and Smith, 1979; Ghannoum et al., 2004; Nagino et al., 2000; Petranyi et al., 1987; Saunte et al., 2007; Treiber et al., 2001). However, one study that compared removing hair with a razor or tape found reliable infection with both *T. mentagrophytes* and *M. canis* without additional abrasion, and the hand razor was the preferred method only for practical reasons (Saunte et al., 2008). Studies have indicated that *T. mentagrophytes* is most infectious 10–12 days after inoculation in culture, so that is the best time to use the fungus for animal inoculation (Treiber et al., 2001). Although some studies use occlusive bandages during infection, most studies do not and results indicate that it can have variable effects (Kerbs and Allen, 1978; Saunte et al., 2008; Valiant and Frost, 1984). Studies have also evaluated the optimal concentrations of *T. mentagrophytes* and *M. canis* for infection and found the severity of infection was associated with the inoculum concentration for *T. mentagrophytes* but not *M. canis* (Ghannoum et al., 2004; Saunte et al., 2008). After infection, animals are assessed based on clinical scores of the lesion that consider erythema, alopecia, crusting, and duration of lesions and mycology by microscopy, culture, histopathology, and the hair root invasion test. The hair root invasion test involves incubating hairs on a Petri dish for 2 days followed by counting the number of hairs showing fungal growth at the hair root (Saunte et al., 2008; Treiber et al., 2001). Majima and co-authors (2005) created a novel method for evaluating treatment efficacy with a mycological assessment that focuses on the size of colonies grown from skin specimens in guinea pigs, while the conventional mycological assessment relies on positive culture but is limited in ability to quantify recovery of the fungus. A model of tinea pedis has also been developed that results in consistent infection with the appropriate dose of inocula with *T. mentagrophytes* without the need for abrasion (Arika et al., 1990; Fujita and Matsuyama, 1987; Majima et al., 2005; Ohmi et al., 1991).

The guinea pig model has primarily been used to assess topical and systemic treatments for superficial fungal infections. The efficacy of drugs against both *T. mentagrophytes* and *M. canis* has been compared with medications such as allyamines (e.g. terbinafine) and azoles (e.g. ketoconazole, econazole, fluconazole) and mitotic inhibitors (griseofulvin) and others (Arika et al., 1990; Borgers et al., 1993; Ghannoum et al., 2004; Meerpoel et al., 2005; Nagino et al., 2000; Ohmi et al., 1991; Petranyi et al., 1987; Saunte et al., 2008; Uchida

and Yamaguchi, 1984; Yamaguchi and Uchida, 1984). Ghannoum and colleagues (2009) evaluated terbinafine solutions with nail penetration enhancers that would allow treatment of deep nail infections, although this study still evaluated the treatments using the standard skin models instead of nails (Ghannoum et al., 2009; Uchida and Yamaguchi, 1984). In addition to standard mycological and clinical assessment, drug studies also may measure drug concentrations in the blood and in skin biopsies (Saunte et al., 2007). This model has also been used to assess alternative treatments that may be supplements to traditional treatments, such as compounds isolated from Japanese cypress oil (Lee et al., 2007).

The guinea pig model has been used to study other aspects of dermatophytosis, including pathogenesis, diagnostics, and vaccines. Vermout et al. (2008) studied proteins involved in pathology of dermatophytosis by testing the proteins' ability to induce skin reactions and by detecting expression of these proteins in experimental infections. PCR has been found to be more sensitive for diagnosis of superficial fungal infection in guinea pigs than the standard diagnostics of microscopy and culture (Saunte et al., 2007, 2008). Guinea pigs have also been used to produce spores of fungi for analysis from clinical samples when only mycelial forms are available (Moriello et al., 2004). Subunit and DNA vaccines have been evaluated and can be partially effective, but efficacy does not correlate with antibody response (Descamps et al., 2003; Mignon et al., 1999; Vermout et al., 2004).

Taxonomy and History

Gerald D. Smith

Lilly Corporate Center, Indianapolis, IN, USA

OUTLINE

Taxonomy	747	Genetics	750
Geographical Distribution	747	Acknowledgments	751
Origin and Domestication	748	References	751

TAXONOMY

Hamsters are classified within Rodentia, the largest mammalian order. Rodents are classically divided into three suborders: Sciuromorpha, Myomorpha, and Hystricomorpha. Muroidea, a superfamily within the suborder Myomorpha, includes the closely related families Muridae and Cricetidae, murine rodents and hamsters, respectively. Taxonomists believe that Cricetidae were the older radiation once common in North Asia, Europe, and Africa that then extended to North and South America. Muridae evolved from an early cricetine rodent and spread to Southeast Asia, Australia, Europe, North Asia, and Africa. The family Cricetidae includes 681 species distributed world-wide except Australia. The subfamily Cricetinae includes seven genera: *Allocricetulus*, *Cansumys*, *Cricetulus*, *Cricetus*, *Mesocricetus*, *Phodopus*, and *Tscherskia*. Cricetinae are all found in Europe, Asia, and the Middle East (Wilson and Reeder, 2005). The Syrian hamster, *Mesocricetus auratus*, was first described and originally named *Cricetus auratus* by Waterhouse in 1839. The original description was based on study of the skin and skull of a female. Nehring (1902) was the second known person to study the Syrian hamster. He used a preserved female at the

Beirut Museum, and in 1898 established the genus *Mesocricetus* for certain hamsters from southeastern Europe and Asia Minor. In 1902, he renamed the Syrian hamster *Mesocricetus auratus*. However, for several decades, the Syrian hamster was still considered to be a subgenus of *Cricetus* and was termed *Cricetus (Mesocricetus) auratus*. In 1940, Ellerman pointed out that *Mesocricetus* was a well-characterized and distinct genus (Granados, 1951).

GEOGRAPHICAL DISTRIBUTION

The natural habitat of Syrian hamsters is a small area in northwest Syria in the vicinity of Aleppo. Syrian hamsters construct deep, chambered burrows in which they store grain and other feedstuffs foraged from the fields (Billingham and Silvers, 1963). Continued presence of Syrian hamsters in the wild was most recently confirmed by expeditions to northern Syria and southern Turkey in 1997 and 1999 (Gatterman et al., 2001). Their natural habitat is dry, rocky steppes or brush slopes. Hamsters are primarily granivorous, but also eat green plant parts and shoots, roots, insects, and fruit. Adults generally live one to a burrow and will readily

fight one another (Anderson and Jones, 1984; Nowak and Paradiso, 1983).

ORIGIN AND DOMESTICATION

Laboratory hamsters are believed to have originated from three or four littermates captured near Aleppo in Syria in 1930. Thus, they not only have a very narrow genetic base, but they have been domesticated for a relatively short time in comparison with mice, rats, and guinea pigs. More recently, additional wild hamsters have been trapped and studied (Murphy, 1971) and a comprehensive history of the capture and domestication of the Syrian hamster has been published (Murphy, 1985).

In the late 1920s, Dr. Saul Adler of the Hebrew University, Jerusalem, was studying leishmaniasis in Chinese hamsters, the only suitable experimental animals for these studies at the time. Chinese hamsters did not reproduce well in captivity and it was necessary to import them from the Far East; thus, he was interested in finding an indigenous species for experimental use, preferably *Cricetulus phaeus*, a close relative of the Chinese hamster (Yerganian, 1972). In 1930 Professor I. Aharoni, a zoologist from Hebrew University agreed to collect and provide specimens of *C. phaeus* for Dr. Adler's work. Professor and Mrs. Aharoni went on a zoological expedition to Syria where they collected *C. phaeus*, but also recovered a litter of *Mesocricetus auratus*. A local Sheikh hired a team to excavate a hamster burrow on a farm located 30 km from Aleppo, Syria (latitude, 40° 10'; longitude 44° 30'). A nest 30 cm in diameter containing a female with 11 young was found 2.5 meters underground. Professor and Mrs. Aharoni successfully reared nine hamsters from this litter and presented them to Mr. H. Ben-Benachen, head of Hebrew University Animal Facilities. Unfortunately, the animal caretakers underestimated the hamster's ability to escape and only one or two females survived to produce young. (There is discrepancy regarding the sex and number of the remaining hamsters. In Adler's account, one male and two females remained (Adler, 1948) but Aharoni stated in his memoirs that only one female and three males remained (Yerganian, 1972).) The first known litters born in captivity were produced from these animals. Thereafter, a laboratory-reared colony of Syrian hamsters was quickly established.

Dr. Adler quickly realized that Syrian hamsters were useful laboratory animals. He decided to distribute the animals as widely as possible to avoid the risk of maintaining a valuable species in one laboratory. In 1931, he carried a few animals to Professor Edward Hindle of the Wellcome Bureau of Scientific Research in England (Bruce and Hindle, 1934). He also distributed them

FIGURE 26.1 Gulf Hamstery ad from *Mechanix Illustrated*, circa 1949.

to the Medical Research Council and the College of France. In 1938, animals were sent from Palestine to the U.S. Public Health Service Hospital, Carville, Louisiana and Western Reserve University in Ohio (Bond, 1945). A third colony of Syrian hamsters was established at the Rockefeller Foundation in 1938 (Poiley, 1950). Therefore, it appears that most of the Syrian hamsters used as laboratory animals or pets are descendants of the original three or four surviving littermates.

After 1950, research demands for laboratory hamsters were met by two major commercial suppliers in the United States: Engle Laboratory Animals in Farmersburg, Indiana and Lakeview Hamster Colony, Newfield, New Jersey.

Engle Laboratory Animals was founded in 1949 by a 14-year-old boy, Everett Engle, when he responded to a classified ad in *Mechanix Illustrated* placed by Albert F. Marsh, Gulf Hamstery, Mobile, Alabama (Figure 26.1). With money loaned from his father, young Everett purchased a trio of two females and one male hamster for \$15; included with his purchase was *The Hamster Manual*, a complete manual for breeding and raising of hamsters, authored and published by Mr. Marsh. His father's coal shed was furnished for raising hamsters and within 2 years Everett was filling orders for Gulf Hamstery and shipping hamsters by rail express out of Farmersburg to customers throughout the Midwest (Figure 26.2). Customers began calling Everett's high school to place orders until the principal found out; Everett's customer service department was thereafter limited to his home phone. Upon graduation from high school, Everett married his high-school sweetheart; her father had reluctantly consented to giving his daughter's hand in marriage to the young hamster entrepreneur. Everett worked for the A & P Food Plant until his mid-20s when he decided to devote all of his efforts to his hamster business. The A & P manager was skeptical and would not permit him to resign but instead gave him a leave of absence. Everett never returned to his job at the A & P. His early customers were Midwestern pharmaceutical firms (Pfizer, Mead Johnson, Dow and Lilly), but many more customers came on board after he began advertising in *Laboratory Animal Care*, the bimonthly journal

FIGURE 26.2 Hamster production, Everett Engle, 1951.

Pregnant Hamsters

FIGURE 26.3 Advertisement for Engle Hamsters.

published by the American Association for Laboratory Animal Science (Figure 26.3). In 1961, the Engle family's graciousness was acknowledged by the White House when they received two hamsters to replace Caroline Kennedy's escaped pet. By 1970, Engle Laboratory Animals was producing 14000 hamsters per week for research laboratories throughout the world. Engle attributed his success in raising hamsters to minimizing stress during weaning and shipping. "Wet tail" was not a problem if shipping boxes were not overcrowded and carefully packed by the Engle family. In 1984, Engle Laboratory Animals and the hamster colony were sold to Harlan Laboratories; Everett has retired and his three sons Mike, Mark, and Tony have continued their careers in laboratory animal production with Harlan (Engle, 2009).

LAKEVIEW HAMSTERS

PROFITABLE — ENTERTAINING — EASY TO RAISE

FIGURE 26.4 Lakeview Hamster Colony brochure.

The field of laboratory animal science is indebted to a glass company, Owens-Illinois, for asking one of their ceramic engineers, Mr. Steven Slater, to transfer from their New Jersey location to a job in Ohio. Mr. Slater turned down the job move because he wanted to keep his family in New Jersey and founded his own company, Lakeview Hamster Colony in 1949 (Figure 26.4). His vision and business plan were to establish and market the Syrian hamster to the research community on the eastern seaboard. Lakeview hamsters were established with breeding stock from Gulf Hamstery (Mobile, Alabama); Hudson Hamstery, (Newfoundland, New Jersey); and the South Jersey Hamster Colony (Newfield, New Jersey). The Hudson Hamstery was also established with breeding stock from Gulf Hamstery. In 1951, the Lakeview Hamster Colony was merged with a hamster colony that was purchased from Mr. Angelo from Leesburg, New Jersey; Mr. Angelo's colony was established from stock obtained from Albert Hayner of Normal, Illinois. After 1951, Lakeview Hamster Colony was closed to the introduction of new breeding stock. Mr. Slater diligently marketed the Lake View hamster to research laboratories in the Philadelphia/New York area. Much of the growth in the use of hamsters for infectious disease research was attributed to research publications from poliovirus pioneers Salk and Sabin (Slater, 2009).

Endemic wet-tail was initially a challenge for the Lake View organization; the incidence was greatly reduced by selecting replacement breeders from litters derived from parents that produced progeny without wet-tail. In spite of consulting with a leader in the field, Dr. Lisabeth Kraft, Mr. Slater was unable to develop the germ-free hamster by foster suckling or hand-feeding young derived by caesarian section. Slater developed the defined-flora hamster by first using diagnostic assays to select a large cohort of viral antibody-free hamsters. These hamsters were treated with antibiotics

and introduced through a Wescodyne® dunk tank into a germ-free isolator where they were reassociated with a defined flora cocktail. In 1969, Lake View was sold to Charles River Laboratories and Gil Slater, Steven's son, continued to serve in the business of laboratory animal production.

Both major U.S. suppliers of research hamsters, Lake View and Engle, obtained their breeding stock from the Gulf Hamstery colony in Mobile, Alabama. The owner of this business, Albert F. Marsh (Figure 26.5), told a reporter from the Mobile Press-Register that he had won a Syrian hamster as payment of a \$1 gambling debt (Helms, 2008). Most likely this hamster originated from the colony held at Carville, Louisiana. Mr. Marsh marketed the hamster through several common periodicals and published 80000 copies of the *The Hamster Manual* during the period 1948 to 1951 (Marsh, 1951).

Since the Aharoni expedition in 1930, an additional 12 Syrian hamsters were captured by Syrian farmers and imported to the United States. The hamsters were sent to the Massachusetts Institute of Technology, for observations on their natural history and comparisons with domesticated stock (Murphy, 1971). Descendants of these animals are maintained at the National Institutes of Health, Bethesda, Maryland (Murphy, 1985). New breeding stock were also transported to Germany from expeditions to Syria and Turkey in 1997 and 1999 (Gatterman, 2001).

Syrian hamsters were introduced to the scientific community by Adler and Theodor (1931), who reported on their use in Kala-azar studies (visceral leishmaniasis). They were quickly accepted as research animals and were used in a variety of studies (Anonymous, 1969; Granado, 1951). Some examples of early studies involving hamsters included breeding and growth (Bruce and Hindle, 1934); susceptibility to *Brucella abortus* (Tchernomoretz and Ellenbogen, 1937); susceptibility to human leprosy (Adler, 1937); reproductive physiology (Klein, 1938); reproductive cycle (Deansely, 1938); susceptibility to tubercle bacilli (Griffith and Pagel, 1939); host for St. Louis encephalitis (Broun et al., 1941); influenza virus infection (Wheeler and Nungester, 1942); effect of hormones on reproduction (Peczenik, 1942); experimental rickets (Jones, 1945); experimental cholesterol arteriosclerosis (Altschul, 1946); tumor transplantation (Crabb, 1946); inoculation with Newcastle disease virus (Reagan et al., 1947); effect of X-radiation (Kivy, 1947); biological exchange of trace elements (Smith, 1947); and toxic effect of beryllium (Sprague et al., 1948).

Before 1954, over half of the publications regarding use of Syrian hamsters involved microbiology, parasitology, or dental disease (Magalhaes, 1954). By 1963, the relative use of the Syrian hamster in these fields of study had declined, but hamsters were being actively used in cancer research and reproductive physiology

FIGURE 26.5 Albert F. Marsh, founder and owner of Gulf Hamstery, Mobile, Alabama.

(Magalhaes, 1968). Use of hamsters in research reported to the United States Department of Agriculture has gradually declined in absolute number and percentage animal use since 1972. In the federal Fiscal Year 2006–2007, registered research facilities in the United States reported use of 172498 hamsters or 19% of total animal use reported (United States Department of Agriculture, 2008).

GENETICS

In the recommended rules for a nomenclatural system, the symbol for *M. auratus* is (SYR) (Institute of Laboratory Animal Resources, 1970). Information regarding inbred strains, genetically defined stocks, and mutants for coat color and other coat characteristics has been provided (Nixon, 1979; Nixon et al., 1979; Slater, 1979; Yoon and Peterson, 1979). Variants include white, cream, piebald, albino, hairless, and longhair (teddy bear) (Fukuta, 1993). Studies of strain-specific responses have been published for the following strains: CAN, CN, APA, APG, CBN, GN, and ACNT (Frank, 2004); LPN (Férezou et al., 2000); Bio F1B (Cheema and Cornish, 2007); BIO 1.5 and Bio 87.20 (Vitaterna, 1993); KVL (Salem et al., 1993); MHA, PD4, LSH, CB, LVG, and LHC (Genovesi, 1988).

Acknowledgments

This chapter is a revision of "Historical Perspectives and Taxonomy" by J. Derrell Clark from Laboratory Hamsters, G.L. Van Hoosier, Jr., and C. W. McPherson, eds. Academic Press, 1987. Much of the original text and references was unchanged because Dr. Clark's astute perspective should be maintained.

INTRODUCTION

The anatomical, physiological, and behavioral characteristics of the laboratory golden Syrian hamster (*Mesocricetus auratus*) are summarized in this chapter.

EXTERNAL FEATURES

An adult Syrian hamster is approximately 14–19 cm in length and weighs approximately 114–140 grams.

Hamsters have thick compact bodies with short legs, a short tail, large cheek pouches, and excess loose skin. Dorsal flank glands, which are more prominent in males, are another noticeable external feature. Flank glands are sebaceous glands that are responsive to androgens and used to mark territory. A reddish gold dorsum with a grayish white ventral surface is the most common coloration pattern of the short and smooth haircoat found in hamsters purpose-bred for biomedical research. The number of pattern mutant and coat color genes observed in hamster colonies has increased

FIGURE 27.1 Dorsal view of a male hamster (left) and ventral view of a female hamster (right). A, Vibrissae; B, flank glands; C, mammary glands; D, urethral opening; E, vaginal opening; F, anus.

during the past six decades (Robinson, 1990). A variety of colors and hair lengths, such as the popular long-haired or “teddy bear” have been bred and maintained in the pet industry. Dorsal and ventral views of an adult hamster are outlined in Figure 27.1. The sexually mature male is characterized by an enlarged, rounded posterior when the testes are in the scrotal sacs, a long anogenital distance, and a penis that is retracted. The mature female has a pointed posterior end, a short anogenital distance, a vaginal opening, and a separate urethral opening. As with other rodents, newborns can be sexed by comparing the distance between the anus and the genital papilla. The distance is greater in the male than in the female and the male genital papilla is larger than that of the female.

MUSCULOSKELETAL SYSTEM

The hamster vertebral formula is seven cervical, 13 thoracic, six lumbar, four sacral, and 13–14 caudal (Salih and Kent, 1966). There are four digits on the front paws and five digits on the hind paws. There is little information in the literature regarding the musculature system of the hamster. Salih and Kent (1964) describe the muscle groups including origins and insertions of the epaxial musculature. Several inbred lines of Syrian hamsters, BIO 1.50 and BIO 12.14, have been reported to develop muscular dystrophy and are described by Homberger (1972).

DIGESTIVE SYSTEM

Oral Cavity

The free margins of the lips form a three-cornered flap which seals the mouth opening when closed and aids in filling the cheek pouches. The oral opening is approximately 12 mm × 17 mm (Schwarze and Michel, 1960). The hard palate, 15.0–16.5 mm in length, begins at the caudal edge of the incisors and extends to the end of the last molar where the soft palate, 4–6 mm in length and smooth, begins. The hard palate mucous membranes form two groups of seven ridges located on either side of the midline. The ridges slope labially near the molars and in a pharyngeal direction when not near the molars. The nasopalatine duct enters the oral cavity on the labial surface of the first pair of ridges.

Dentition

The dental formula is: 2/2 incisors 1/1, canines 0/0, premolars 0/0 and molars 3/3. Incisors are open-rooted and continually erupt throughout the hamster’s life. Dentition is monophyodont, bunodont, and brachyodont. Incisors erupt shortly after birth with molars eruption beginning between days 7–10 (M1), days 12–20 (M2) and days 30–35 (M3) (Gaunt, 1960; Hinrichsen, 1955; Keyes and Dale, 1944; Schwarze and Michael, 1960). Age, sex, diet, and season may affect rate of incisor growth. The short (2.5 ± 0.5 mm) maxillary incisors can replace themselves in 1 week while the longer (10.0 ± 1.8 mm) mandibular incisors can require 2.5–3 weeks for replacement. Both incisor sets extend lingually and end in a notch at the gingival margin. The maxillary diastema which separates the incisors from the molars is larger (9–11 mm) than the mandibular diastema (4–6 mm). Mandibular incisors may be located on either the labial or lingual side of the maxillary incisors. The mandibular symphysis may not fuse throughout life (Schwarze and Michel, 1960).

The molar teeth form a convex arch with the maxillary molars pointing outward and mandibular molars pointing inward (Schwarze and Michel, 1960). Molar cusps are conical, pointed, and in rostrocaudal alignment. The cusps are separated by broad buccolingual sulci with deep occlusal fossae and grooves (Keyes and Dale, 1944). Newly erupted molar crowns are completely covered by enamel, and roots are covered by a thin layer of cell-free cementum. Attrition causes exposed primary dentin to become metamorphosed with secondary dentin deposited on the underlying pulpal wall. Secondary dentin is deposited at the root apices. Occlusion is by cuspal interdigitation. Attrition is initiated on the mesial slopes of mandibular cusps and distal slopes of maxillary cusps, and spreads over the occlusal surface (Keyes and

Dale, 1944). Morphologically, the crowns allow retention of fine food particles, making the hamster susceptible to caries and a model for human dental caries (Arnold, 1942; Dale et al., 1941; Lovelace et al., 1958).

Salivary Glands

The hamster salivary glands consist of submaxillary, retrolingual, parotid, and sublingual (Boerner-Patzelt, 1956) and are compound tubuloacinar structures. Acinar elements complete their differentiation early in postnatal development. Convolved granule tubules have a more gradual and prolonged postnatal development, becoming completely differentiated upon sexual maturity. Submaxillary gland acini are morphologically and histochemically intermediate between mucous and serous acini (Shackelford, 1961). The sialic acid content of the submaxillary gland is influenced by the presence of female sex hormones, therefore the content is greater in females than males (Shackelford and Klapper, 1962a). The organization of the parenchyma of the hamster submaxillary gland is similar to that of the rat and mouse (Flon and Gerstner, 1968). Narrow intercalated ducts connect the acini to the branches of the granular convoluted tubules. These tubules are continuous with the striated duct segments of the excretory system. The major part of the submaxillary gland consists of acinar elements, closely resembling the rat's gland (Devi and Jacoby, 1966). The tubule/acinus ratio, size, and appearance of the cells of the convoluted tubules are similar for both male and female.

The parotid gland, located below the ear, is structurally similar to other mammals (Shackelford, 1961). Four salivary ducts (two dorsal, one central, and one ventral) emerge from each parotid salivary gland. The gland is covered by the cheek pouch and ends near the maxillary edge of the entrance to the cheek pouch, 3mm labially from the first maxillary molar (Schwarze and Michel, 1960). In the hamster, most proteolytic enzyme activity is confined to the parotid gland (Shackelford, 1961), whereas the rat and mouse have the most proteolytic enzyme activity in the submaxillary gland (Shackelford and Klapper, 1962b). Proteolytic enzyme activity is lowest in the hamster submaxillary gland.

The sublingual gland is composed of mucous acini, serous demilunes, and numerous myoepithelial cells (Alm et al., 1973; Shackelford, 1961).

Cheek Pouches

The hamster has large bilateral buccal cheek pouches that are located along the side the head. These distensible, well-vascularized structures are thin-walled, lined with stratified squamous epithelium, devoid of lymphatic tissue and rich in mast cells (deArruda and

Montenegro, 1995). The cutaneous mucosa has fine folds covered with tiny protrusions that are more numerous near the entrance of the pouch (Schwarze and Michel, 1960). The pouch wall is composed of four layers: stratified squamous epithelium on the surface, dense fibrous connective tissue, longitudinal striated muscle fibers, and loose areolar or submuscular connective tissue where the pouch joins the underlying structures. Blood vessels and nerves are found in the connective tissue and muscle layers (Billingham et al., 1960; Fulton et al., 1946; Lindenmann and Strauli, 1968).

The pouches are approximately 35–40mm long and 4–8mm wide when empty and up to 20mm wide when full. They are relatively easy to evert. Feed and bedding may be stored in cheek pouches. Female hamsters with newborn pups may place the young in cheek pouches if stressed. The pouches are emptied by a massaging action with the front feet and action of the tongue. The pouches have been termed, "immunologically privileged" due to the lack of an intact lymphatic drainage system (Bergstresser et al., 1980). The unique anatomical and physiological characteristics of the cheek pouches have contributed to their extensive use for microvascular studies of tumor growth, carcinogenesis, and inflammation (Gimenez-Conti and Slaga, 1993; Hedqvist et al., 1990; Svensjo, 1990).

Stomach

The hamster stomach is approximately 3.5cm long and 2.0cm wide and is divided into two distinct areas: glandular stomach and non-glandular forestomach. The forestomach and glandular stomach are separated from each other by the incisurae of the greater and lesser curvatures (Magalhaes, 1968). The esophagus enters into the forestomach, which is lined with keratinized epithelium, has a higher pH than the glandular region, and contains microorganisms that enable fermentation which may aid in the digestive process. The pyloric region of the glandular stomach empties into the small intestine.

Small Intestine

The duodenum begins at the pylorus of the stomach and runs caudally as the descending duodenal loop. This loop is located ventral to the transverse colon and the beginning of the jejunum. The duodenum then reverses and returns to the left as the ascending duodenal loop. At the point where the ascending loop crosses the descending duodenal loop it becomes the jejunum. The jejunum, which is formed into multiple small loops, is approximately 2.5 times the length of the duodenum. Duodenal villi first appear at 13.5 days of gestation. By birth the villi have changed from a square

to a columnar shape. After birth, absorbed colostrum appears as distinct round lipid droplets in the intestinal epithelium. The droplets can be found for up to 6 days (Koruhmaru et al., 1979). The ileum is short, less than 2 cm in length, and connects the jejunum to the cecum (Malgalhaes, 1968).

Cecum

The hamster cecum is slightly sacculated and divided into apical and basal portions (Krueger and Rieschel, 1950). A groove in the external cecal wall corresponds to the location of a semilunar valve delineating the division between the two portions (Yonce and Krueger, 1952). There are four valves in the hamster ileocecal–colic junctions: the ileocecal valve, the apicobasal valve, the basal semilunar valve, and the chevron valve. The ileocecal valve has a semilunar lip projecting into the lumen of the ileum. The apicobasal semilunar valve, located on the apical side of the ileocecal junction, functions to shunt the contents of the small intestine directly into the colon. The basal semilunar valve is located 5 mm toward the colon from the apicobasal semilunar valve, while the chevron valve is located at the cecal–colonic junction and is formed from the ends of the muscular chevrons located in the colon (Krueger and Rieschel, 1950).

Large Intestine

The ascending colon runs cranially from the cecal–colonic junction, under the jejunum, before turning to form a horseshoe-shape that becomes the transverse colon. The transverse colon runs from right to left, just caudal to the liver and stomach prior to turning caudally to become the descending colon which empties into the rectum and anus.

Pancreas

The hamster pancreas consists of three lobes: gastric, splenic, and duodenal, and averages 0.46 g of weight or approximately 0.4–0.5% of total body weight. The gastric lobe of the pancreas, which comprises approximately 25% of the weight of the pancreas, is attached to the stomach and pylorus by the mesogastric membrane formed from the greater omentum. The splenic lobe, which comprises approximately 40% of the pancreatic weight, is located caudal to the spleen along the greater curvature of the glandular stomach. The splenic lobe has a connective tissue attachment to the cranial descending colon. The smallest lobe, the duodenal lobe, comprises approximately 12% of the pancreatic weight and is enclosed in mesentery between the duodenum and cranial ascending colon (Takahashi et al., 1977).

The common bile duct passes through the head of the pancreas and merges with the three major pancreatic ducts prior to emptying into the duodenum, similar to mice and rats, but different than other mammals including man.

Organogenesis of the pancreas begins at 10.5 days of gestation (Boyer, 1968). The islets of Langerhans develop during the first 2 weeks of life and double in size by 4 weeks of age but do not reach full size until about 1 year of age. The acini of the hamster pancreas reach full size at 4 weeks of age (Orgrowsky et al., 1980).

Liver and Gall Bladder

The hamster liver consists of four lobes: right dorso-caudal, left dorsocaudal, dorsal median, and ventral median. The dorsal median lobe is divided into a large right dorsal part and a smaller left dorsal part. The ventral median lobe is divided by the umbilical fissure into a right cranioventral part and a lateral left cranioventral part (Nettleblad, 1954). The gall bladder is located in the right cranioventral section of the ventral median lobe of the liver. The gallbladder wall consists of three major layers: mucosa, muscularis, and serosa. Goblet cells are completely absent from the epithelium, while cask-like and crayon-like cells are prominent in the bottom folds (Yamada, 1959, 1969). Hamster bile acids have a similar composition to human bile (Reyes and Kern, 1979).

Liver weight significantly increases during pregnancy and at a rate that is proportionately greater than the increase in body weight. Concurrent with this increase in liver weight is a decrease in bile flow such that the mean rate of bile flow in an 8-day pregnant and a 14-day pregnant hamster is reduced by 37% and 64%, respectively, when compared to a non-pregnant female hamster (Reyes and Kern, 1979). In addition, a reduced secretion of total bile acids due to decreased cholic acid secretion, a decrease in sodium, potassium, ATPase activity and a decrease in the acid-dependent bile flow is observed (Reyes and Kern, 1979).

CIRCULATORY SYSTEM

Heart and Vascular System

The four-chambered heart is located at the level of the third to fifth thoracic ribs. The pulmonary and aortic valves are tri-cuspid. Both the left and right atrioventricular valves have two major and two minor accessory leaflets. Figures 27.2 and 27.3 are schematics of the major blood vessels. Walls of the pulmonary vein have muscle fibers similar to myocardium, like mice and rats. The media of the coronary arteries in the hamster

FIGURE 27.2 Schematic of the major veins of the golden hamster.

consists of circular muscle, which is different than the rat, where the media is composed of longitudinal muscle fibers (Kovalevskii, 1966). Physiologic characteristics of the cardiovascular system are described in Table 27.1.

Orbital Venous Sinus

The hamster has an orbital venous sinus similar to the mouse. This sinus is an elongated venous channel formed by the confluence of the ophthalmic veins in a groove of bone formed in the presphenoid and maxillary bones. Pre-rinsing blood collection equipment with an anticoagulant such as 1:1000 heparin is recommended to facilitate blood collection from the hamster due to a relatively rapid coagulation time (Edwards, 1967; Pansky et al., 1961; Timm, 1979).

Lymphatic System

The lymphatic system in the hamster is depicted in Figure 27.4. The 16 groups of lymph nodes are located in similar areas in the hamster as those locations described for other rodents (Belisle and Saint-Marie, 1981; Kawashima, 1972).

PULMONARY SYSTEM

The respiratory system of the hamster consists of the nasal cavity, nasal sinuses, pharynx, larynx, trachea, and lungs. The hamster nasal cavity consists of vestibular, olfactory, and non-olfactory portions. The larynx is composed of the epiglottic, thyroid, cricoid, and arytenoid cartilage. The trachea bifurcates at the level of the fourth rib. The lung lobes, illustrated in Figure 27.5,

consist of a single lobe on the left and four lobes on the right (Malgalhaes, 1968). Limited glandular structures are found in the conductive airways of the hamster (Hayes et al., 1977). Various respiratory physiologic characteristics are listed in Table 27.2.

GENITOURINARY SYSTEM

Kidneys and Ureters

The kidneys are reddish brown, bean-shaped organs located on either side of the median plane between the second and fourth lumbar vertebrae. The right kidney is located more cranial than the left kidney and generally weighs less as well. The kidney has rounded poles, a flat dorsal surface, and a protruding ventral surface.

The hamster kidney is further characterized as having a type II renal pelvis which enables high urine concentration (Pfeiffer, 1968). It has a single, long papilla that extends into the ureter, allowing for in vivo collection of urine from a single collecting tubule (Jarausch and Ullrich, 1957).

Hamster kidneys are very responsive to estrogen because the same embryonic germinal ridge develops into the urogenital and reproductive tracts. Renal tumors induced by estrogen administration in male hamsters have been used as a model for human renal cancer (Li et al., 1993).

Bladder and Urethra

The gross anatomy of the hamster's bladder and urethra is similar to that described for the dog (Schwarze and Michel, 1960). The dog and the hamster are two

FIGURE 27.3 Schematic of the major arteries of the golden hamster.

of the most reliable models for studying the effect of chemical carcinogens on the urinary bladder (Van Hoosier and Ladiges, 1984).

Male Reproductive System

The urogenital system of the mature male hamster is depicted in Figure 27.6. The gonads and accessory reproductive organs grow and continue to develop during the first 2 weeks after birth. By 26 days of age,

TABLE 27.1 Cardiovascular Function of the Hamster^a

all male accessory glands have fully developed and the testes have descended (Ortiz, 1948). Hamster spermatazoa have sickle-shaped and flattened heads, similar to other rodents (Yanagimachi and Noda, 1970). The male has an os penis with a dorsal prong and two distal lateral prongs (Callery, 1951). Male accessory glands include interior and exterior ampulla glands, seminal

vesicles, coagulating glands, a three-lobed prostate, and bulbourethral glands (Schwarze and Michel, 1960). Like mice and rats, adult male hamsters have a urethral plug which is a white, rubber-like cast of the urethra (Campean et al., 1980; Kunstner et al., 1982; Rosenbauer et al., 1980).

Sexual maturity in the male hamster occurs at approximately 12 weeks of age and 90 grams of body weight (Van Hoosier and Ladiges, 1984). Exposure to at least 12.5 hours of light per day is required for normal levels of testosterone and breeding activity in male hamsters (Elliot, 1976; Gaston and Menaker, 1967; Morin and Zucker, 1978). The major source of testosterone is the interstitial cells of Leydig which contain abundant endoplasmic reticulum in the reproductively active hamster. Compared to other mammals which have an agranular tubular form of endoplasmic reticulum, the hamster has a flattened cisternae form. Serum cholesterol levels are inversely related to the amount of agranular tubular reticulum, thus the hamster has high levels of serum cholesterol (Wing and Lin, 1977).

Hamsters, like mice and rats, have superficial rete testis which lies immediately beneath the tunica albuginea. The extratesticular rete is particularly well developed in the hamster (Martin, 1976). As the hamster ages, there is little change in the reproductive hormone profile. Serum follicle-stimulating hormone (FSH) levels increase between 4- and 11-month-old hamsters but then remain at that level. There is no significant difference between serum testosterone and luteinizing hormone (LH) level in hamsters ranging in age from 4 month to 31 months of age. There are also very few differences observed with age in the weight of the testes and accessory sex organs as hamsters age, regardless of breeding activity. This is different to both rats and mice which show age-related declines in both serum hormones (testosterone, LH, and FSH), as well as weights of testes and accessory sex glands (Swanson et al., 1982).

Female Reproductive System

The urogenital system of a mature female hamster is depicted in Figure 27.7. Unlike most rodents where

FIGURE 27.6 Ventrodorsal view of the male urogenital system of the hamster illustrating the kidney (K), bladder (B), seminal vesicle (S), urogenital opening (Ug), anus (An), scrotum (Sc), and adipose tissue (A). The insert is a ventral view of the accessory sex organs. The bladder and urethra have been opened to show entrances of ducts. Shown in the insert are the seminal vesicle (S), ureter (U), ductus deferens (Dd), urethra (Ut), coagulating gland (C), prostate (P), and ampullary gland (Am). A bulbourethral gland enters the urethra further caudally and is not illustrated.

the vagina opens at approximately sexual maturity, the hamster vagina opens when the animal is approximately 10 days old (Ortiz, 1948, 1955). Sexual maturity in the female hamster occurs at approximately 12 weeks of age and at a body weight of about 90–100 grams (Van

Hoosier and Ladiges, 1984). Hamsters have a 4-day estrous cycle. Unlike mice and rats, where multiple sets of corpora lutea are present from previous cycles, the hamster corpus luteum rapidly develops and regresses during a single cycle (Nakano, 1960).

Hamsters have an average of seven pairs of mammary glands with a range of six to 11 pairs (Anderson and Sinha, 1972). Paired, oval-shaped ovaries surrounded by an ovarian bursa and covered by fat, are located dorso-ventrally to the kidneys. The uterus is duplex with an undivided part and two horns. Dual cervical canals lead to the two uterine horns. The caudal cervix is a single canal. The oviducts are long and tightly coiled (Oeri, 1960; Strauss, 1956).

Hamsters have an average of seven pairs of mammary glands with a range of six to 11 pairs (Anderson and Sinha, 1972). Paired, oval-shaped ovaries surrounded by an ovarian bursa and covered by fat, are located dorso-ventrally to the kidneys. The uterus is duplex with an undivided part and two horns. Dual cervical canals lead to the two uterine horns. The caudal cervix is a single canal. The oviducts are long and tightly coiled (Oeri, 1960; Strauss, 1956).

NERVOUS SYSTEM

The average total weight of the hamster brain is 1.4 grams. The cerebral hemispheres consist of large frontal, lateral, and occipital lobes. The sulcus parame-dius is low and flat, while the caudal uvula is lengthened considerably. The paraflocculus and flocculus have only one layer. The paleocortex is very broad and the caudal area is wider than the rostral area. The pons and medulla oblongata are longer than wide. The corpus callosum is short and narrow. The medial region of the cerebellum, near the sigmodon, is differentiated into ten layers (Pilleri, 1960).

The hamster has eight cervical, 13 thoracic, six lumbar, three sacral, and 2–3 caudal pairs of nerves. Nerve plexuses are located in the cervical, brachial, and lumbosacral areas (Michel, 1963).

SPECIAL SENSES

Vision

The newborn hamster is an excellent model for experimental manipulation of the developing visual pathway as it is born with a poorly developed visual system (Tiao and Blakemore, 1976). The hamster has a panoramic field of vision, long streak-shaped specialization areas in the retina, an obvious area centralis or fovea and a large binocular visual field. The hamster has a rather uniform retinal organization. The center of the area centralis does not occupy corresponding points in the two eyes (Greiner and Weidman, 1978; Tiao and Blakemore, 1976).

Visual function in the hamster appears to be divided between the visual cortex and the superior colliculus. This hypothesis of two visual systems within a single brain provides mechanisms for identifying novel stimuli, commanding the orienting response in the colliculus and for pattern recognition in the visual cortex (Tiao, 1976). In addition, there is little physiological evidence to support the theory that the visual cortex is more involved with the identification of visual stimuli than the colliculus (Chalupa, 1981).

The divergent area centralis points into the middle of the hamster's view of its own vibrissae. In the superior colliculus there is good correspondence between the visual and somatic maps, consistent with the fact that the presumed region of maximum resolution in the retina is the vibrissae which the hamster relies on for somatic sensory input (Tiao, 1976; Tiao and Blakemore, 1976a).

Marked sexual dimorphism of the Harderian gland has been described in Syrian hamsters but not other species of hamsters. The dimorphism is androgen-dependent, with female hamsters secreting 100–1000 times more porphyrin than males and containing a different lipid profile (Buzzell, 1996).

Olfaction

The hamster, like other mammals, has keen olfactory capabilities. The hamster has four nasal endoturbinates and three ectoturbinates which project into the lumen of the nasal cavity. Localized olfactory neurons are found within the nasal turbinate mucosa (Constanzo and O'Connell, 1980). The hamster has several nasal serous glands which open into the internal ostium of the external nares, some nasal glands with mucus components and the vomeronasal gland (Adams and McFarland, 1972).

The vomeronasal organ is located bilaterally in the rostromedial nasal septum. It is completely enclosed in a bony capsule and consists of a 7 mm long tubular structure which is embryologically derived from the olfactory placode. The cranial end communicates with the nasal cavity through a rostral orifice. The lateral wall is lined with non-sensory respiratory epithelium, devoid of goblet cells, and the medial wall is lined with sensory olfactory epithelium with surface cilia and microvilli. PAS-positive mucous and serous acini are located on the dorsolateral and ventromedial sides of the lumen (Taniguchi and Mochizuki, 1982; Taniguchi et al., 1982). The male hamster has vomeronasal chemoreceptors that are important in sexual behavior (Meredith et al., 1980; Powers and Winans, 1975; Winans and Powers, 1977).

Somatosensation

Vibrissae are important for spatial orientation and communication in many species. The hamster is unique in that it moves its cranial vibrissae in various complex patterns keyed to particular exploratory situations. This movement repertoire suggests that a precisely operating motor system controls the vibrissae. The facial musculature, vibrissal vasculature, and vibrissal connective tissue have been proposed as important components of the vibrissal motor system (Wineski, 1985).

Taste

Four different types of papillae are located on the hamster tongue: filiform, fungiform, foliate, and vallate. Filiform papillae are abundant, conical in shape with the vertex pointed caudally, and are located on the rostral, dorsal, and lateral surfaces of the tongue. The dorsal surfaces of fungiform papillae have a single taste bud. Fungiform papillae are found on the dorsal rostral surface of the tongue. A single vallate papilla is located on the dorsal midline of the tongue. Multiple taste buds are found in the epithelial depressions on either side of the vallate papilla. Foliate papillae are found on the lateral caudal surface with taste buds arranged in longitudinal rows in the epithelium of the interpapillary clefts (Miller and Chaudhry, 1976).

Morphologically, all taste buds are spindle-shaped and 100–125 µm long by 50–80 µm wide. They communicate with the oral cavity through a taste pore and the taste buds extend through the stratified squamous epithelium of the tongue to the basement membrane (Miller and Chaudhry, 1976). Ultrastructurally, hamster taste buds are similar to those of other mammals (Farbonann, 1965; Murray and Murray, 1967; Uga, 1969).

Each taste bud responds to one or two basic tastes. If two, the combinations are either acid-salt or sweet-salt. Sweet and acid responses are negatively correlated.

The ordering for stimuli for sweet receptors is sweet > bitter > salt > acid, while the ordering for acid receptors is acid > salt > bitter > sweet (Frank, 1973).

BEHAVIOR

Hamsters are nocturnal animals that live singly or as a mother with litter in the wild. Hamsters spend a significant amount of their time asleep (41%) and the amount of time spent sleeping increases with age. When unexpectedly startled or awakened, hamsters may exhibit aggressive behavior towards handlers as well as cage-mates. Hamsters are prone to escape if the cage top is not secure. Gnawing and hoarding are common hamster behaviors and may be stereotypic (Arnold and Estep, 1994).

In the laboratory setting, both male and female group-housed animals may fight. If animals are group housed when young, stable groups may be formed. Use of enrichment devices such as PVC pipe and glass jars may reduce cage-mate aggression (Arnold and Westbrook, 1998).

Both male and female hamsters build nests, with nest-building activity greatly increased during pregnancy and lactation (Richards, 1966). The hormonal basis of nest building in female hamsters is dependent on the presence of both estrogen and progesterone, unlike female mice where progesterone alone was sufficient to increase nest-building activity (Richards, 1969).

INTRODUCTION

This chapter provides a review of the management, husbandry, and colony health requirements of the Syrian or golden hamster, *Mesocricetus auratus*, utilized in biomedical research. Hamsters are rodents belonging within the family Cretidae. Members of the Cretidae family are characterized by large cheek pouches, relatively thick bodies, and a short tail. Additional publications that provide comprehensive descriptions of hamster husbandry and care are [Hankenson and Van Hoosier \(2002\)](#) and [Hoffman et al \(1968\)](#).

HOUSING

Caging Systems

Hamsters are generally housed in cages that are appropriate for housing other laboratory rodents. Contemporary cages are generally made of commercially manufactured rigid plastic materials (i.e. polycarbonate, polysulfone, and polypropylene) or stainless steel. Hamsters are agile and have considerable ability to escape by means of chewing or gnawing on the cage material and by dislodging the cage lid. To reduce the

TABLE 28.1 Cage Space Requirements for Hamsters^a

Body Weight (g)	Minimum Floor Area/Animal in ² (cm ²) ^b		Height ^c in (cm)
<60	10	(64.5)	6 (15.2)
60–80	13	(83.8)	6 (15.2)
80–100	16	(103.2)	6 (15.2)
>100	19	(122.6)	6 (15.2)

^aSummarized from CFR (rev. 2008) and ILAR (2011).^bA nursing female hamster with litter must be housed in a cage without other adult hamsters and that provides at least 121 in² (780.5 cm²).^cMeasured from cage floor to cage top.

opportunity for escape by chewing, caging should not be manufactured with wood or soft metals such as aluminum. Hamsters may also chew plastics, around the hole in the cage for the water bottle, and escape. Caging must also be equipped with secure, tight and close-fitting doors and lids to prevent escape of animals. Plastic shoebox-style cages with tight-fitting wire bar lids are commonly employed in research institutions and commercial breeding operations. Hamsters may be housed successfully in solid-bottom cages with contact bedding. Excluding breeding colonies, hamsters may be housed in suspended cages with raised floors, i.e. caging with stainless steel wire-mesh, slatted, or perforated suspended floors over catch pans. Suspended wire floor caging is not recommended for breeding colonies as smaller animals may fall through or become entrapped in the wire mesh flooring. Preference testing has indicated that hamsters generally prefer solid floor caging with contact bedding over stainless steel suspended floor caging, but the preference for solid floor caging decreased with increased duration of exposure to suspended wire flooring (Arnold and Estep, 1994).

Requirements for both floor space and cage height for hamsters are defined in the Animal Welfare Regulations (CFR, rev. 2008). The Institute of Laboratory Animal Resources (ILAR, 2011) provides similar non-regulatory recommendations for cage size and height for hamsters (see Table 28.1). Nursing female hamsters, together with a litter, must be housed without other hamsters and provided a minimum of 121 sq. in. (780.6 sq. cm.) of floor space (CFR rev., 2008). Cage size has been shown to affect core body temperature and febrile response in hamsters (Kuhnen, 1999). Housing hamsters in small cages was associated with increased baseline rectal temperature when compared with hamsters housed in large cages. Febrile response to lipopolysaccharide injection was greatest in hamsters housed in large cages and smallest in animals housed in small cages.

The cage sanitation practices applied to the common laboratory rodents also apply to hamster caging. Soiled bedding material should be removed and replaced with

clean material, or animals transferred to a clean bedded cage, as often as necessary to keep the cage occupants clean and dry. Unlike most common laboratory rodents, hamsters tend to defecate and urinate in one corner of the cage and, because they are desert-adapted animals, hamsters produce relatively scant amounts of urine. U.S. Animal Welfare Regulations (CFR rev. 2008) prescribe that, at a minimum, hamster cages must be sanitized at least once every 2 weeks (14 days).

Bedding

A variety of contact bedding materials can be used with hamsters, including processed wood shavings and chips, corn cob, pelleted wood, as well as virgin and recycled paper products. Preference testing of bedding materials with hamsters is limited. Lantaigne and Reeb (2006) showed that without nesting material, hamsters have a preference for pine shavings over aspen shavings, corn cob over wood pellets, pine shavings over corn cob, and aspen shavings over wood. The preferences were eliminated, however, when animals were provided a piece of paper towel as nesting material. Provision of long-term access to running wheels can result in development of foot lesions in hamsters, but the development of lesions was not affected by use of pine shavings or hard wood chip bedding (Beaulieu and Reeb, 2009). Hamsters build nests, and, for breeding animals, the addition of nesting material (i.e. tissue paper, cotton wool) is recommended. It is not recommended to use cedar and untreated (non-kiln-dried) soft wood bedding, such as pine, as it contains aromatic hydrocarbons capable of inducing hepatic microsomal enzymes and cytotoxicity in rodent species, including hamsters (Harkness, 1994; Vesell, 1967).

ENVIRONMENTAL CONDITIONS

Ventilation

Specific ventilation rates for the primary enclosure (cage) and the secondary enclosure (room) housing hamsters have not been described and ventilation rate recommendations for housing other research rodents are acceptable. Animal Welfare Regulations (CFR rev. 2008) require that facilities housing hamsters be adequately ventilated to provide for the health and comfort of the animals and to minimize the development of drafts, odors, and moisture condensation. In contrast, ILAR (2011) provides a general recommendation of 10–15 air changes per hour (ACH) for the secondary enclosure housing research animals, including hamsters. The use of individually ventilated caging systems, which provide intra-cage ventilation rates in excess of 10–15 ACH, may

allow decreased air exchange rates in the rooms housing the caging system, while preserving an acceptable cage environment for the animal (Reeb et al., 1998).

Illumination

Recommendations for acceptable illumination levels within vivaria are generally based on providing levels sufficient to allow safe working conditions for personnel, good housekeeping, adequate observation of animals, and to preserve circadian cycles (ILAR, 2011). The level of illumination required for optimal maintenance and health of hamsters has not been described and light intensity levels of approximately 325 lux measured approximately 1 m (3.3 ft) from the floor are generally acceptable to allow adequate illumination for husbandry purposes and observation of animals (ILAR, 2011).

Hamsters are strictly nocturnal in captivity, whereas females in the wild are primarily diurnal (Gattermann et al., 2008). Hamsters are seasonal breeders that in a natural setting will modulate reproduction in association with photoperiod, the duration of light and dark contributing to a 24-hour cycle. In a natural setting, hamsters restrict reproduction to the long days of spring, summer, and fall. In captivity, hamsters can be maintained under a 12:12 light cycle (12h light:12h dark) for general research purposes. For reproductively active animals, such as breeding colonies, a long 14-hour light cycle is recommended and thus breeding colonies are maintained under 14:10 light:dark cycle (Brainard et al., 1986). Alterations of photoperiod in hamsters have been shown to affect circulating levels of luteinizing hormone (LH) and follicle stimulating hormone (FSH) and to produce altered testicular development and spermatogenesis (Ellis and Follett, 1983). Alteration in the photoperiod during pregnancy of hamsters has been shown to affect the timing of parturition (Viswanathan and Davis, 1992).

Temperature

The Syrian hamster originates from an arid, desert environment and their thermoneutral zone, the temperature range associated with minimal metabolic expenditure, is approximately 82.4–86°F (28–30°C) (Gordon, 1993). Unless required for scientific purposes, hamsters are commonly housed and maintained in research institutions at temperatures appropriate to other common laboratory rodents. The Animal Welfare Regulations specify that hamsters maintained within an indoor housing facility must be provided ambient temperatures that neither fall below 60°F nor rise above 85°F (CFR rev. 2008). ILAR (2011) recommends that hamsters be maintained in a range of 68–79°F (20–26°C). Hamsters are adaptable to cooler temperatures, and

short-term hibernation can be induced in hamsters by exposure to cold temperatures, approximately 3–5°C, and a shortened light cycle (Hoffman, 1968). A study by Gumma et al. (1967) showed that pre-hibernation hamsters may show a preference for 8°C whereas post-hibernation hamsters show a preference for higher temperatures (24°C).

Humidity

As with previous recommendations for ambient temperature, hamsters are commonly housed and maintained at relative humidity levels generally acceptable for other common research rodents. Recommendations are that relative humidity be maintained between 30–70% for most research species, including hamsters (ILAR, 2011).

Environmental Enrichment

A primary goal of environmental enrichment is to provide animals with the opportunity to perform species-specific behavioral patterns (Hutchinson et al., 2005). Numerous enrichment devices have been described for use with hamsters including tubes, pipes, shelters, nest material, and deep bedding. In the wild, hamsters are solitary, living either singly or as mothers with nursing pups in burrow systems. Burrow systems include a nest chamber, a chamber for urination, and a chamber for food storage (Gattermann et al., 2001; Sorensen et al., 2005). Because hamsters spend considerable time underground in the wild, it is generally recommended that some form of burrow, pipe, tube, and shelter be provided to hamsters (Arnold and Westbrook, 1998; Baumans, 2005). McClure and Thompson (1992) showed that aggression in hamsters housed in suspended wire cages was diminished after the addition of a polyvinyl chloride (PVC) pipe. Provision of nesting material, or bedding that provides the ability for nest building, is generally recommended as both wild and captive-bred hamsters will create nests (Gattermann et al., 2001; Lanteigne and Reeb, 2006); and female nest-building behavior has been shown to increase during pregnancy (Richards, 1969). Hamsters that were provided deep bedding (i.e. 40 and 80 cm deep) showed significantly less gnawing of cage wire bars, a possible indicator of sub-optimal housing conditions, and increased the construction of burrows used for sleeping than did animals provided shallow amounts (10 cm) of bedding (Hauzenberger et al., 2006). Hamsters readily utilize exercise wheels (i.e. running wheels), and the use of exercise wheels has been proposed as a method of environmental enrichment as well as a means to measure activity in chronobiology research (Beaulieu and Reeb, 2009; Gattermann et al., 2004). Hamsters naturally forage and hoard food and they

should be provided with food pellets inside the cage, preferably on the cage floor (Baumans, 2005; Sorensen et al., 2005).

NUTRITION

Feed Type

Hamsters are generally provided commercially produced pelleted rodent diet intended for mice and rats, and animals raised on such diets show normal growth and reproduction (Hankenson and Van Hoosier, 2002; Slater, 1972). Hamsters can also be raised and maintained successfully on purified and semi-purified diets. Colocolic intussusception has been described in hamsters following a change in diet from a standard pelleted rodent chow to a semi-purified diet with sucrose as the primary carbohydrate (Cunnane and Bloom, 1990). Although once common, when fed a nutritionally adequate diet formulated for mice and rats, dietary supplementation with grains, fruits, and vegetables is generally considered unnecessary (Slater, 1972). Additionally, dietary supplementation with grains, fruits, and vegetables may increase the risk of exposure to unwanted microbiologic agents and contaminants (Coates, 1991).

The method of feed presentation to hamsters differs from that for mice and rats, in that hamsters are generally provided food on the cage floor. Harkness et al. (1977) observed that when a hamster colony originally provided pelleted rodent food from feed hoppers with 7/16-inch slots were fed from feed hoppers with narrower 5/16-inch slots morbidity and mortality of animals in the colony increased significantly. Adult animals showed cachexia, delayed weight gain, broken incisors, and an inability to obtain food from the feed hopper. Nursing hamsters demonstrated agalactia resulting in pup mortality and decrease in conception rate. Upon feeding hamsters from the cage floor, animals regained a normal pattern of weight gain. It was postulated that because hamsters have a relatively broad muzzle compared with similarly sized rodents, they have difficulty accessing adequate food from narrow-slotted feed hoppers. Consequently, providing food solely from feed hoppers is not recommended and hamsters are commonly provided food on the cage floor. In addition, young hamsters will begin to eat solid food at 7–10 days of age and nursing hamsters with litters may become preoccupied with hopper-bound food and neglect their young (Harkness and Wagner, 1995).

Nutritional Requirements

Hamsters maintained on commercially produced rodent diet show normal growth and reproduction.

General nutrient levels associated with acceptable rates of growth and reproduction have been reported with diets consisting of 15–25% protein, 35–40% carbohydrate, 4–5% fat, and 5% crude fiber (Arrington et al., 1966, 1979; NRC, 1995; Newberne and Fox, 1980; Newberne and McConnell, 1979). Feed consumption in hamsters is similar in males and females, with published ranges between 5.0–8.9 g per day for growing and adult animals (Arrington et al., 1979; Banta et al., 1975; Newberne and McConnell, 1979).

Although hamsters are commonly maintained on laboratory diets formulated for mice and rats, relatively little has been published on the specific nutritional requirements of hamsters, and the nutritional requirements of hamsters are not identical to those of other rodents (NRC, 1995; Newberne and McConnell, 1979). Hamsters possess a distinctly compartmentalized stomach consisting of a forestomach and a glandular stomach. The forestomach shares physical characteristics with a rumen, contains microorganisms similar to those found in a rumen, is a source of volatile fatty acid production, and has been postulated to allow fermentation, prior to passage of ingesta into the gastric stomach (Hoover et al., 1969; Warner and Ehle, 1976). It has been proposed that the apparent rumen-like functions of the hamster forestomach may allow the animal to digest and utilize lower-quality protein in comparison to other rodents such as the rat (Newberne and McConnell, 1979). The forestomach, however, is not required for maintenance of proper nutrition, survival, or growth of the hamster fed a nutritionally adequate diet, as surgical removal of the forestomach was shown not to affect growth and feed utilization in the animal (Ehle and Warner, 1978).

Published requirements for amount of protein in the hamster diet are variable. For hamsters fed semipurified diets utilizing casein as the sole source of protein, satisfactory growth rates have been reported for diets containing 12–24% casein; satisfactory weight gain has been associated with natural-product diets containing 5–25% protein (Newberne and McConnell, 1979). Soybean meal as a protein source has been shown to promote increased weight gain and improved protein utilization (i.e. increased protein efficiency ratio) compared with diets containing wheat gluten and fish protein concentrate (Banta et al., 1975). Nutritional studies have also shown increased survival of hamsters fed a diet containing 20 g lactalbumin/100 g diet (Birt et al., 1982). Cornstarch has been shown to be a good carbohydrate source for hamsters, promoting satisfactory growth, reproduction, and longevity and it is generally provided in the range of 30–40% as a source of dietary energy (Newberne and McConnell, 1979). Dietary carbohydrates can affect circulating glucose

and lipid metabolism in hamsters. Hamsters fed a diet containing 60% fructose showed increased food consumption and development of obesity, hyperinsulinemia, and hypertriglyceridemia (Kasim-Karakas et al., 1996). The dietary fat requirement for hamsters has been described for growing hamsters as 5%; commercially prepared rodent diets with 4% fat also appear adequate for growth, reproduction, and maintenance (Knapka and Judge, 1974; Newberne and McConnell, 1979). Requirements for fiber have not been described for the hamster and 4–5% fiber found in commercial rodent diets appears appropriate for normal growth, reproduction, and maintenance. Diets containing high levels of refined sugars and no fiber have been associated with high mortality, and the substitution of corn-starch for glucose or sucrose or the addition of 12–20% alfalfa to the diet increased survival (Ershoff, 1956). There is a paucity of information regarding mineral and vitamin requirements of hamsters. It has been recommended that levels for copper, magnesium, potassium, and zinc should be increased in comparison to dietary requirements of the rat; recommended levels in semipurified diets are 12ppm copper, 0.12% magnesium, 20ppm potassium, and 0.6% zinc (Newberne and Fox, 1980; Newberne and McConnell, 1979). Studies have described minimal levels of dietary vitamin A for the hamster as 1.1mg/kg retinol and 2mg/kg retinyl palmitate/kg in semi-purified diet (Newberne and McConnell, 1979; Rogers et al., 1974). The hamster does not require a dietary source of vitamin D when provided a calcium–phosphorus ratio of 2:1 (NRC, 1995; Newberne and McConnell, 1979). Hamsters are coprophagic and it is presumed that a considerable amount of vitamin K is provided by ingestion of feces (NRC, 1995). Minimal dietary requirement for vitamins B₆, B₁₂, E, biotin, choline, folic acid, niacin, pantothenic acid, riboflavin, and thiamin have not been described for the hamster and sufficient dietary levels for growth and reproduction are provided in diets formulated for the rat. Satisfactory dietary levels for vitamins and minerals for the hamster are provided in Table 28.2.

Hydration

Hamsters should be provided access to clean, potable water at all times. Water can be provided via water bottles with stainless steel sipper tubes or automatic water systems with stainless steel lixits. Hamsters have been reported to consume, on average, 8.5ml water per 100g body weight. Consumption of water can vary significantly; male consumption ranges from 4.5–5ml/100g body weight and female consumption ranges from 13.6–14ml/100g body weight (NRC, 1995).

TABLE 28.2 Satisfactory Vitamin and Mineral Dietary Levels for the Hamster

Vitamin/Mineral	Natural Product Diet (mg/kg)	Semi-purified Diets (mg/kg)

Nutrition-Related Disease

Nutrition-related diseases are uncommon in hamsters fed commercially produced rodent diets. Numerous nutritional deficiencies have been induced in the hamster by feeding diets formulated to be deficient in specific nutrients, minerals, and vitamins. For a comprehensive review see NRC (1995). Hamsters fed a diet deficient in vitamin E, starting at weaning,

develop testicular degeneration, muscular dystrophy, and experience decreased growth, which is reversible by treatment with dietary vitamin E (Granados, 1968). Supplementation of vitamin E has been shown to reduce aortic fatty streak accumulation in hypercholesterolemic hamsters (Xu et al., 1998). Deficiency of vitamin E, possibly combined with oxidative stress, may be important in development of clinical disease in cardiomyopathic hamsters (Sakanashi et al., 1991). Spontaneous hemorrhagic necrosis (SHN) of the central nervous system of fetal hamsters has been described when pregnant dams are fed vitamin-E-deficient diets, and the syndrome is alleviated by intraperitoneal administration of vitamin E (Keeler and Young, 1979). Vitamin A deficiency, similar to other rodent species, can lead to abnormal development, alopecia, a coarse hair coat, xerophthalmia, and altered morphology of tracheal epithelium (Chopra et al., 1990; Keeler and Young, 1979).

BREEDING

Reproductive Biology

Sexual maturity in the hamster generally occurs at approximately 6 weeks (42 days) of age, although copulatory activity can begin as early as 4 weeks of age. Sexual maturity can be verified in the male hamster by performing the penile smear technique to identify the presence of spermatozoa on the glans penis (Vandenbergh, 1971). Female hamsters generally begin estrus between 6–8 weeks of age. It is recommended that breeding animals be allowed to mature to 90–100 g body weight before breeding to achieve maximum production. Females are generally 8–10 weeks of age and males 10–12 weeks of age prior to initial breeding. The use of slightly older and larger males appears beneficial when placing males with more aggressive females (Slater, 1972). Reproductive senescence occurs at approximately 14 months of age in both sexes.

Female hamsters have a regular 4-day estrous cycle. The end of ovulation, typically day 2 of the 4-day estrous cycle, is identifiable by the presence of a readily observable postovulatory vaginal discharge. The vagina, and often the vaginal orifice, is filled with an opaque, white, viscous discharge. The postovulatory discharge is indicative of the animal having reached estrus the day before and it is predictive of the next estrus 3 days after the appearance of the discharge, followed by estrus on days 7, 11, and so forth. Female hamsters can be successfully mated in the evening of the third day following the postovulatory discharge. In commercial breeding operations, large groups of hamsters can be selected based on the postovulatory discharge and mated with a resulting 90% breeding success rate (Balk and Slater, 1987). Females

may show pseudopregnancy lasting 9–10 days following non-fertile copulation, with return of a postovulatory vaginal discharge on postcopulatory days 10–11 (Richards, 1966). Pregnant animals are identifiable by rapid weight gain and abdominal distension at 10 days post mating. Implantation occurs on day 6 of pregnancy. Postpartum estrus in hamsters is generally anovulatory (Harkness and Wagner, 1995).

The female hamster is tolerant of the presence of a male only during estrus, and females will readily attack males if paired together outside of estrus. When in estrus and receptive to males, the female will display lordosis upon approach of a male and maintain the posture while the male remains in the vicinity. When copulation occurs, males will mount the female multiple times. Females in estrus will accept males beginning approximately 1 hour before start of the dark cycle (i.e. lights out) and end receptivity to the male approximately 15 hours later (Ciaccio and Lisk, 1971).

As mentioned earlier, hamsters are seasonal polyestrous breeders that will modulate reproduction in association with photoperiod. For reproductively active animals, such as those in breeding colonies, a long 14-hour light cycle is recommended and thus breeding colonies are maintained under 14:10 light:dark cycle (Brainard et al., 1986). Alterations of photoperiod in hamsters have been shown to affect circulating levels of luteinizing hormone (LH) and follicle stimulating hormone (FSH) and to produce altered testicular development and spermatogenesis (Ellis and Follett, 1983). Alteration in the photoperiod during pregnancy of hamsters has been shown to affect the timing of parturition (Viswanathan and Davis, 1992).

The gestational period for the hamster is approximately 15.5 days. Parturition is preceded by the female displaying an increase in activity and restlessness with alternating bouts of eating, grooming, and nest building. Immediately prior to parturition, an increase in respiration rate and a bloody vaginal discharge are observed. Litter sizes range from 4–16 pups, with average litter sizes reported as 5–9 (Harkness and Wagner, 1995) and 11 (Slater, 1972). The first litter from a primiparous female is generally smaller than subsequent litters.

Common Breeding Systems

Multiple breeding schemes have been described for hamsters including hand-mating, pair mating, and polygamous mating (Harkness and Wagner, 1995). A common method for breeding hamsters utilizes hand-mating of the animals. On the third day following a post-ovulatory discharge, the female hamster is placed into a male hamster's cage 1–2 hours prior to the start of the dark cycle. Animals are then observed for fighting, and the female removed if she shows aggression towards the male. If the female is receptive, she will

show a posture of lordosis with tail erect and hindlimbs spread apart. Animals will often mate within 5–10 minutes of being placed together, at which time they may be separated; or animals may be left paired overnight and separated the following morning. Hamsters may also be bred by polygamously pairing one male with 1–2 females for 7–14 days, followed by separation of the animals and housing of the females individually for parturition and until pups are weaned. Monogamous pairing of one male with one female continuously has also been described. This breeding scheme requires placing a prepubital male and female together, and allowing them to remain together throughout breeding and parturition. Sequential monogamy mating of hamsters involves rotating seven females through a male's cage in series, with each female paired with the male for 7 days. Using this breeding system, after a female weans a litter at 3 weeks of age, the female is rotated back to the male's cage every 7th week. Because female hamsters can be aggressive, breeding pairs of hamsters must be checked daily for fight wounds and animals separated if needed.

Care of Young

Approximately 2 days prior to parturition, females should be transferred to a clean cage and provided with nesting material. Sufficient food should be added to the cage to allow the female to remain undisturbed with a newborn litter for 7–10 days following parturition. Disturbing a dam, especially a primiparous dam, with a newborn litter can lead to litter abandonment and cannibalism by the dam. During the first 7–10 days following parturition, food and water may be added to a cage if needed, but bedding should not be changed. If it is necessary to disturb a dam with a young litter, the dam should be provided with fresh food with which she may fill her cheek pouches reducing the likelihood of cannibalism of the new pups ([Hankenson and Van Hoosier, 2002](#)). When moving neonatal hamsters between cages, care should be taken to transfer the neonates within their nest to minimize the disturbance as much as possible.

Hamsters are born hairless, with teeth, and with eyes and ears closed. Ears open at 4–5 days of age, eyes open at 14–16 days of age, and hamsters begin to eat solid food at 7–10 days of age. Consequently, water should be available by 10 days of age when the young hamster begins to ingest solid food. Care should be taken to ensure that if animals are provided water via a bottle that the sipper tube is appropriately sized to provide accessibility to the neonates from the floor of the cage. Hamsters can be weaned as early as 15 days of age, but it is suggested that young be left with the mother until at least 19 days of age ([Slater, 1972](#)), and it is common to

wean hamsters at 21–28 days of age. At weaning, animals are generally separated and housed in groups by age and sex.

COLONY HEALTH

Preventive Medicine

A preventive medicine program for hamsters is contingent upon selection of a high-quality source of hamsters. A quality source of hamsters should have a well-defined health-monitoring system in place to allow periodic assessment of the breeding colony for common infectious agents of hamsters. As with other rodents, infection by adventitious microbial agents can adversely affect animal health, alter the physiology of animals, introduce experimental variables that can alter experimental outcomes (i.e. data) generated from the use of animals, and pose a zoonotic risk to the people working with the animals. For a summary of natural pathogens of hamsters and the effects of those organisms on research, see [Baker \(2003\)](#). If hamsters intended for research originate from a non-commercial source without adequate health monitoring information for the colony, animals should be placed into quarantine and microbiologic testing performed to identify infectious agents that may compromise the health of the animals or their usefulness in research. A rigorous biosecurity program, defined as all measures taken to prevent the introduction, contain, and when necessary eradicate adventitious infections, is also required to protect the microbiological integrity of hamsters maintained and used in research and breeding facilities ([Shek and Gaertner, 2002](#)). Maintenance of healthy hamsters within a research facility is also contingent upon providing adequate husbandry and care, including provision of a nutritionally complete diet formulated for laboratory rodents, continuous access to clean water, appropriately designed and maintained caging, proper sanitation of cages, equipment, and facilities supporting the hamsters, and appropriate environmental conditions as outlined earlier in this chapter.

Colony Health Monitoring

Infection of rodents, including hamsters, by adventitious agents can negatively affect animal health and interfere with research outcomes derived from the animals ([Baker, 2003](#)). Health monitoring of research rodent colonies involves subjecting animals to a battery of assessments, including macro- and microscopic pathology, bacteriology, parasitology, and serum and microbiologic diagnostic tests with a goal of identifying whether the test animal, a surrogate for the source colony, is infected with specific microbiological agents considered important for

the particular rodent species under study. Although this process is often referred to as health monitoring, microbiologic monitoring may be the more appropriate term (Hansen, 2003) and is used as a synonymous term. Shek and Gaertner (2002) describe the components to be considered when designing and implementing a microbiologic monitoring program for rodents, including detailed discussions on diagnostic methodologies, design and implementation of a surveillance program, and interpretation of results. Important parameters that must be defined when developing a microbiologic monitoring program are the number of animals to test, the frequency of testing, the agents for which to screen, and the diagnostic methodology that is most appropriate for each agent. Selection of the appropriate testing methodology for hamster infectious agents is beyond the scope of this chapter and the reader is referred to the relevant literature (Livingston and Riley, 2003; Shek and Gaertner, 2002; Waggle et al., 1994). Frequency of testing is dependent upon many variables, including historical contamination rates, general health quality of the colony, i.e. gnotobiotic health status versus specific pathogen-free status, financial resources, and sensitivity of the research to contamination by common hamster infectious agents. Many organizations develop schedules whereby samples are submitted for serologic testing relatively frequently, i.e. quarterly, in conjunction with submissions of live animals that combine serologic testing with more comprehensive testing including bacteriology, parasitology, and pathological exam less frequently, i.e. once to twice yearly.

Selection of agents to include in a microbiological testing program for hamsters should be based on selection of agents that pose a risk to human health (i.e. zoonotic agents), cause disease in hamsters (i.e. primary pathogens), and interfere with research outcomes. When possible, decisions regarding frequency of testing and the selection of specific agents to include in a monitoring program should also involve a risk-based approach that requires knowledge of the general prevalence of infectious agents found within the research population of interest (Pritchett-Corning et al., 2009; Shek and Gaertner, 2002). The prevalence of infectious agents in research mice and rats has been well-documented (Jacoby and Lindsey, 1997; Livingston and Riley, 2003; Pooley, 1970; Pritchett-Corning et al., 2009; Schoondermark-van de Ven et al., 2006), whereas prevalence rates of infectious agents in research hamsters is limited (Suzuki et al., 1982). In general, prevalent agents are more likely to contaminate a facility and such agents should be tested for more frequently than agents that are rarely found in research colonies. Table 28.3 provides a summary of positive test results for hamster samples, excluding samples from commercial rodent vendors, submitted from 2003–2008 to a commercial diagnostic laboratory (Charles River Research Animal

Diagnostics Service, Wilmington, MA), unpublished data (Cosentino, 2009). The Federation of European Laboratory Animal Science Associations (FELASA) has provided recommendations on microbiologic agents to include in a hamster health monitoring program (Nicklas et al., 2002).

The following agents are commonly included in hamster microbiologic monitoring programs. The primary zoonotic concern associated with research hamsters is infection with lymphocytic choriomeningitis virus (LCMV), a virus of the family *Arenaviridae*, genus *Arenavirus*. Human cases of LCMV have been reported after exposure to infected research and pet hamsters (Baum et al., 1966; Bigger et al., 1975; Lewis et al., 1965). Additional viral agents for which colonies are routinely screened are pneumonia virus of mice (PVM) and Sendai virus. PVM is a *Pneumovirus* in the family *Paramyxoviridae*. Infection of hamsters with PVM is clinically silent, and experimental infection has produced interstitial pneumonia in hamsters (Baker, 2003). Sendai virus (parainfluenza 1) is a *Paramyxovirus* within the family *Paramyxoviridae*. Sendai virus infection in hamsters can produce respiratory disease including tracheitis, bronchitis, and interstitial pneumonia and it may alter renal potassium flux (Genovesi and Peters, 1987). The prevalence of LCMV, PVM, and Sendai virus in research hamster colonies is considered to be low (Baker, 2003).

A limited number of bacterial agents are generally included in hamster microbiologic monitoring programs. Infection with *Clostridium piliforme* (i.e. Tyzzer's disease) can cause disease and mortality in hamsters (Motzel and Gibson, 1990), although reports of disease in research colonies are rare. Screening for *Salmonella* spp. is recommended by FELASA (Nicklas et al., 2002) and practiced by many commercial hamster breeders; reports of salmonellosis in research hamsters appear rare, although outbreaks have been reported (Innes et al., 1956). A number of bacteria, including *Pasteurellaceae* and *Streptococcus pneumoniae* that were associated with pneumonia in a survey of hamster diseases (Renshaw et al., 1975) and *Corynebacterium kutscheri*, which can colonize the upper respiratory tract of hamsters (Amao et al., 1991), are frequently also reported on hamster health monitoring reports. Their importance in producing clinical disease in hamsters is unclear. A number of *Helicobacter* spp. have been isolated from research hamsters, and infection by several species of *Helicobacter* has been associated with clinical disease (Whary and Fox, 2004). Hamsters are an established host for *H. cinaedi*, although the prevalence in research colonies has not been described, and hamsters have been proposed as a reservoir species for zoonotic helicobacteriosis (Gebhart et al., 1989; Orlicek et al., 1993).

Hamsters can also serve as hosts for a variety of parasitic agents. Acariasis is a common finding during

TABLE 28.3 Prevalence of Common Rodent Infectious Agents in Hamsters, 2003–2008^a

^bELISA (enzyme-linked immunosorbent assay of serum), PCR (polymerase chain reaction of feces), Direct (examination of pelt under a stereomicroscope for ectoparasites; examination of macerated cecum and colon with stereomicroscope for nematodes), Wet mount (high-magnification phase-contrast microscopy of wet mount of duodenal and cecal mucosa scrapings for protozoal agents).

colony health screening of hamsters; the two common mites identified are *Demodex criceti* and *D. aurati*. Prevalence of *Demodex* infestation in research colonies is high, although clinical signs are uncommon (Baker, 2003). A number of protozoal organisms have been identified in the intestinal tracts of hamsters, but their association with enteric disease is unclear, as their presence is common in both healthy and ill animals (Hankenson and Van Hoosier, 2002). The primary nematodes found in the intestinal tract of hamsters are pinworms of the genus *Syphacia*; hamsters may be infected by *S. mesocriciti*, *S. criceti*, *S. obvelata*, and *S. muris* (Baker, 2003; Hankenson and Van Hoosier, 2007). The prevalence of pinworm infections in hamsters has not been described.

RECORD KEEPING

Use of Records

Record keeping is an important aspect of any scientific endeavor and fundamental to good science. Records show what data have been collected and under what conditions the data were collected. Accurate records provide accountability and are necessary for a laboratory to replicate earlier experimental procedures and research outcomes. In animal studies, the requirement for accurate and full record keeping extends to the care and husbandry provided to the animals. Minimal animal identification records for hamsters are often satisfied by a cage card with the following data: source of animal, strain or stock, name(s) of responsible individual (i.e. investigator), pertinent dates (i.e. purchase date, date of birth, dates of experimental procedures), and Institutional Animal Care and Use Committee protocol number, when applicable. If animals are bred for research, accurate records must be maintained to document items such as parentage of animals, litter size, and age of animals as these parameters are important for proper management of breeding colonies and may provide information on the health of the colony. Health records are necessary to accurately treat and evaluate the response of treatment of ill and injured animals and medical records provide valuable information on the general health of research animal colonies.

Breeding Records

The maintenance of accurate breeding records is essential for proper management of breeding and production colonies. For ongoing breeding programs, such as in a commercial breeding operation and for research efforts that rely on multi-generational breeding of

hamsters, a computer database is helpful for maintenance of records. For small-scale breeding programs, typical in research settings breeding small numbers of hamsters, breeding records may be maintained on paper such as in a laboratory notebook or by retention of animal cage cards. Minimal information that should be recorded and maintained in breeding records includes animal identification (i.e. unique animal identification numbers for males and females), the date a breeding pair or breeding group is established, the date of birth of the litter, total number of pups born, the number of pups by sex, the number of surviving animals at weaning, segregated by sex, and the date of weaning. If ongoing breeding of females is planned (i.e., multiple litters from the same female), it is recommended to routinely evaluate the litter size for each female. A decrease in litter size is commonly observed as an animal ages and this information is used as criterion to retire breeders. For a detailed discussion on management and design of breeding colonies, including development of foundation colonies and breeding colony structure, see White (2007).

Husbandry Records

Records documenting the environmental conditions within the vivarium as well as the activities of animal facility staff provide important information to animal facility management staff, veterinary care staff, and researchers. Common environmental records maintained within animal facilities include documentation of housing room temperature, humidity, and light cycle. These parameters can be recorded automatically via electronic building management systems or manually via paper records. Electronic building management systems are beneficial as alarm parameters can typically be programmed to detect when environmental parameters exceed predetermined limits (i.e., high and low temperature limits), and the building management system will automatically notify personnel that can then take action to rectify the problem before animal welfare is adversely impacted. If using a paper-based documentation system, animal husbandry staff can be tasked to record temperatures and humidity levels daily within each animal holding space. Under this system, it is recommended to utilize a thermometer that registers both the peak (high) and low temperature over a set period of time, typically daily, and record both temperatures. This allows assessment of temperatures within the space during periods when staff are not present. Relative humidity in an animal housing space can be measured using a hygrometer or sling psychrometer. If housing room light cycles are not controlled through a centralized system, individual room light timers

must be routinely assessed to insure that timers are working properly and that animals are not exposed to alterations in light cycle. Husbandry activities that are important to maintaining animal health and wellbeing should also be recorded. Such records include dates when animals are provided clean food and water, cages are cleaned, and when animal rooms are cleaned and sanitized. Sanitation records are also useful for tracking key aspects of the cage sanitation process. For example, facilities utilizing mechanical cage washers routinely maintain records indicating that rinse water temperatures reach prescribed minimums to achieve adequate sanitation. Recording this information provides animal care management, research personnel, and regulatory officials the ability to regularly review key aspects of animal care, husbandry, and housing environment provided to the animals to insure they meet acceptable standards.

Health Records

Health records, also referred to as clinical records, can be maintained as group records for large populations, such as commercial breeding colonies, or as individual animal records. Health records should include pertinent clinical observations and diagnostic information, history of surgical procedures, postoperative care, and information on experimental use as it pertains to clinical care of the animal. For rodents, this information may be relatively simple and maintained on the cage card accompanying an animal or extensive and maintained as a stand-alone record.

INTRODUCTION

The use of hamsters in biomedical research peaked at over 500 000 animals per year in the mid-1970s and then progressively declined to the current level of approximately 146 000 animals per year (United

States Department of Agriculture, 2010). Nevertheless, hamsters are still used for a multitude of biomedical research purposes including studies in oncology, dentistry, cardiology, and neuroscience. The purpose of this chapter is to provide the reader with descriptions of specific techniques, or references to techniques, that

FIGURE 29.1 Lifting a Syrian golden hamster. Note the large amount of loose skin in the dorsal cervical area.

have important applications in biomedical research. Some techniques, such as those that are more appropriate for use by exotic animal practitioners or are infrequently used in research, have not been included. Unless otherwise noted, the descriptions presented are for the Syrian golden hamster (*Mesocricetus auratus*).

GENERAL NON-SURGICAL PROCEDURES

Handling and Restraint

Most laboratory hamsters do not relish being handled and can inflict a painful bite if given the opportunity to do so. There is a large amount of loose skin by the dorsal cervical area that can be used to restrain and lift the animal, but be sure to include a generous amount of that skin when lifting a hamster, otherwise the animal can turn around and bite (Figure 29.1). Hamsters that are regularly handled by their owners tend to be calmer and less prone to biting. Hamsters also are very apt to bite when awakened from their sleep (they will often roll over on their back before biting); therefore, it is a good idea to ensure the animal is awake before handling. Interestingly, in the experience of some authors, gentle arousal of hamsters does not lead to biting (Quesenberry and Carpenter, 2003). Perhaps the latter finding is more typical of pet hamsters. Although Syrian golden hamsters will hibernate at low temperatures (e.g., 5°C), that is unlikely to occur in typical laboratory research environments and therefore it is doubtful that a sleeping hamster is hibernating. Nevertheless, this author has noticed that the European hamster (*Cricetus cricetus*) will enter

a torpor-like state when the outside daylight becomes shorter, even though the laboratory light cycle is maintained at 12h light:12h dark (Silverman and Chavannes, 1977).

Numerous other methods have been used to help restrain or move hamsters short distances, such as scooping the hamster up into one's cupped hands or scooping the animal into a wide-mouthed jar or similar container. Caution is advised when using these methods because hamsters are prone to jump out of such loose confinement and in the author's experience they can injure themselves severely if they fall all the way to the floor. If you are unfamiliar with handling hamsters, consider learning how to do so while working at floor level.

Radiology

Either permanent or portable radiograph machines can be used, but as recommended by Silverman and Tell (2005) the machine should be capable of 5.0–7.5 mA exposures (at least 300 mA at 0.017 seconds or faster), have a range of 40–100 kVp and be adjustable in 1–2 kVp increments. We commonly use 3M Ultra Detail Plus Veterinary X-ray Film (3M Animal Care Products, St. Paul, MN) with a 3M Veterinary SA2 Fine Detail, Green Light Emitting, Rare Earth intensifying screen (3M Animal Care Products, St. Paul, MN) using a tabletop technique of 102 cm focal-film distance for whole body imaging and 97 cm for extremities. For most applications the hamster must be sedated or anesthetized. An easily removed paper adhesive tape or radiolucent foam can be used to aid positioning the animal.

Another imaging option is digital radiography. This technology uses a digital detector consisting of a scintillator that converts X-rays into light. The light is captured by pixels (similar to those in a digital camera) which in turn are transmitted to a computer monitor. Because there is a large gray-scale bandwidth the image can be enhanced, filtered, softened, sharpened, etc. It can also be saved to a file or sent electronically to another computer. Although the initial outlay can be expensive, by using a high-quality detector in a small frame (i.e., a small footprint), digital radiology of hamsters and other small research animals can be more cost-effective than the use of larger digital units designed for clinical veterinary practice with species such as dogs. Specific machine settings are not provided in this chapter because a high-quality digital radiograph unit incorporates AEC (automatic exposure control) technology which will take a pre-exposure image and provide electronic feedback to the X-ray source. In turn, the machine is automatically calibrated to provide the best image possible. The entire process, from pre-exposure to seeing the image on a computer monitor, may take as few as 12–15 seconds.

Magnetic Resonance Imaging (MRI)

Eichhorn et al. (2008) performed contrast-enhanced MRI studies on hamsters. The MRI scans were performed on a 9.4-Tesla magnetic resonance microimaging system with a maximum gradient strength of 200mT/meter and a 1H birdcage resonator with a 38mm inner diameter transmit/receive coil. The isoflurane anesthetized and pre-positioned hamsters were placed in the resonator and electrocardiogram and breathing were continuously monitored with a MRI-compatible monitoring unit. Body temperature was maintained with a warm air heating system.

Using a special plastic restrainer, Parzy et al. (2007) used MRI to image the heart of unanesthetized cardiomyopathic hamsters. After 15–30 minutes the animals remained still enough to be imaged with a 4-Tesla horizontal bore 4/60 spectrometer/imager equipped with shielded gradients delivering 200mT/meter with 260 ms rise time.

Body Temperature Measurement

It is difficult and impractical to use a standard rigid glass rectal thermometer to obtain a hamster's body temperature. However, a variety of thin, flexible, and rigid temperature thermocouples and thermistors are available commercially from scientific supply houses for use with electronic thermometers. Rectal temperatures are displayed in a matter of seconds. Young hamsters 6–14 days old have a rectal temperature of 35.1°C, 1-month-old animals have a temperature of approximately 37°C, while 160-day-old animals were found to have a rectal temperature of 37.4°C (Desautels et al., 1985). Infrared thermometers, which do not directly contact the animal, have been used for hamsters (e.g., Ohta et al., 2006) but may have limited applications because infrared measurements are typically taken from the tail surface, a notably small feature in the hamster. Body temperature can also be monitored via an implantable temperature transponder.

Respiratory Function Assessment

Although hamsters are often used in respiratory disease research, very few studies have focused on techniques specifically designed for measuring their respiratory functions. Reviews of invasive and non-invasive methods for studying pulmonary functions in mice have been published (Glaab et al., 2007; Pichavant et al., 2007) and they can be adapted to hamsters. Raub et al. (1983) tracheotomized hamsters and measured lung function in a whole-body plethysmograph. They found an end-expiratory volume of approximately 1.4ml, vital capacity of 5.7ml, residual volume of 0.75ml, total lung capacity

of 6.5ml, and respiratory system compliance of 0.4ml/cm water.

Sato et al. (1989) used a whole-body plethysmograph and a hot-wire flow sensor that measured gas volume respired through a tracheal cannula. This allowed for the measurement of airway resistance in male hamsters that was free of artifacts caused by temperature and humidity. Those authors found airway resistance to be 0.44 ± 0.06 (SE) cm H₂O.ml⁻¹.second. This had a strong correlation with pulmonary resistance (0.42 cm H₂O.ml⁻¹.second, $r = 0.93$). Mean respiratory frequency was $77.2 \text{ min}^{-1} \pm 6.8$ (S.E.), tidal volume was $0.61 \text{ ml} \pm 0.01$, and functional residual capacity was $1.52 \text{ ml} \pm 0.06$.

Lung volume has been estimated in hamsters by traditional radiography (Canals et al., 2005) and in mice by magnetic resonance imaging (Martin et al., 2008). The former method used a standard small animal radiograph machine to help develop formulas for estimating lung volume in anesthetized hamsters weighing ~42g. Radiographically calculated lung volume was $2.44 \text{ ml} \pm 0.28$ (S.D.) while the measured lung volume from water displacement was $1.56 \pm 0.37 \text{ ml}$.

Dental Procedures

Tooth Trimming

As with mice, rats, and gerbils, hamsters have open-rooted (elodont) incisors that grow continuously. To prevent malocclusions the incisors must be worn down by their proper occlusion with each other and by their diet. In contrast, the molar teeth (there are no premolars) do not grow continuously (anelodont). Significantly overgrown incisors are fairly easy to see and they can be trimmed back by the use of a variety of different types of tooth clippers (e.g., toe nail clippers). Although this sounds easy, in reality it can be quite difficult to determine, without radiographs, the amount of tooth to trim. This is particularly true with the lower incisors, which are normally longer than the upper ones. One must also assure that the hamster's tongue is not cut during the clipping process. Tooth clipping can lead to a tooth fracture or disrupt the periodontal membrane; therefore, if possible the tooth should be ground down with a dental burr. Unfortunately, this is not often possible in a research setting. Overgrown teeth frequently must be trimmed every 2–3 weeks. The technician or veterinarian should become very familiar with the normal appearance of hamster teeth.

Dental Abscesses

Dental abscesses of the molars are occasionally seen in hamsters. Unless the laboratory animal practitioner has the prerequisite dental training to treat or remove these teeth, these therapeutic procedures should be left

FIGURE 29.2 Endotracheal intubation using a fiberoptic endoscope.

to a veterinarian with the appropriate experience and skills.

Endotracheal Intubation and Intratracheal Instillations

Endotracheal intubation in hamsters is complicated by the small size of the oral cavity and glottis. Before attempting intubation, first make sure that there is no food in the oral cavity and especially in the cheek pouches. The endotracheal tubes used for hamsters rarely completely occlude the tracheal lumen and it is important to minimize the potential for food particle inhalation. We prefer to use a technique similar to that described by [Hawkins and Graham \(2007\)](#). The anesthetized hamster can be hand held; however, we prefer to have the animal placed on a nearly vertical board (about 70° angle) suspended by its upper incisors. Use of a laryngoscope with a size 0 blade (used for premature infants) may help to visualize the glottis. [Costa et al. \(1986\)](#) described a custom-made fiberoptic laryngoscope for small rodents. A similar commercial product (BioLite, [Figure 29.2](#)) is now available as part of a rodent intubation system (Bioseb, Chaville, France). Otherwise, a narrow otoscope cone with most of one side cut out can be used. One drop of 2% lidocaine is placed on the larynx to help prevent laryngospasm. The animal's tongue is either pulled out of the way with a forceps or pushed to the side with a cotton-tipped applicator.

A variety of different tubes can be used for endotracheal intubation (e.g., thin rubber urinary catheters, intravenous catheters, plastic tubing). Tubes should be approximately 1.5 mm in diameter (slightly smaller than a 14-gauge needle). The length should be no less than 6.5 cm ([Costa et al., 1986](#)). The sides and oral opening of the endotracheal tube must be smooth. Small

endotracheal tubes are often very flexible and difficult to insert, therefore, if necessary, a blunt stylet can be passed into the trachea prior to passing the tube over the stylet (the stylet is then removed). It is important that the oral end of the endotracheal tube is secured to the hamster and is capable of being attached to a standard anesthesia tube fitting if the latter will be used. Similar to [Hawkins and Graham \(2007\)](#), we have also found that mucus plugs in the tube can be a problem.

For intratracheal instillations once an endotracheal tube is in place, approximately 0.15 ml of liquid or suspension can be administered per 100 g of body weight ([Brain and Valberg, 1979](#)).

Pulse Oximetry

Pulse oximetry measures hemoglobin oxygenation. The rapid heart rate of the hamster requires pulse oximetry equipment that can record at well over 400 heart beats/min. Fortunately, such equipment is now available (e.g., MouseOx[®], Starr Life Sciences, Oakmont, PA; PulseSenseTMVET, Nonin Medical, Inc., Plymouth, MN). The sensor can be placed on an ear, a foot, and in some instances on the hamster's small tail.

Electrocardiography (ECG)

Cardiomyopathic hamsters have a long history of use in biomedical research. The Syrian golden hamster's rapid heart rate (~400 beats/min) requires special recording equipment. The animal is anesthetized and alligator clips attached to a hypodermic needle, spring clip electrodes, or needle electrodes are placed in one of the standard ECG arrangements. To prevent excessive cooling of the animal minimal alcohol or gels should be used ([Hawkins and Graham, 2007](#)).

To record the ECG in conscious hamsters one can use a surgically implantable telemetry device (e.g., Mini-Mitter, Bend, OR; Data Sciences, St. Paul, MN) or an ECG recording platform. The latter is an array of gel-coated ECG electrodes embedded in a platform on which the animal stands. It has been described for recording the ECG in unanesthetized mice ([Chu, 2001](#)) and would likely be applicable for use by hamsters. A commercial version of the recording platform is the ECGenieTM (Mouse Specifics, Inc., Quincy, MA).

Blood Pressure Measurement

Direct blood pressure measurements are made with techniques similar to those used in other species. For example, catheters can be inserted into the carotid artery (see below). Indirect measurement of blood pressure is more difficult due to the hamster's relatively small size and lack of a long tail. [Kato and colleagues](#)

(2003) described the use of a modified tail-cuff placed around the left brachial artery of anesthetized hamsters which weighed ~123 g. Details of the modification were not provided, however, a statistical analysis indicated strong positive correlation with a simultaneous direct blood pressure measurement.

A Doppler ultrasonic probe can also be used to detect arterial flow when used with a pressure cuff to occlude arterial flow and a sphygmomanometer or oscillometric device to measure the blood pressure (Hawkins and Graham, 2007). Nevertheless, this can be difficult to use in the hamster. ECG methods for assessing general systolic function and other indices of left ventricular function have been reported for the Syrian golden hamster (Martino, 2008; Salemi et al., 2005).

Electroencephalography (EEG)

Hamsters are often used in neuroscience and behavioral research. A procedure for hamster electroencephalography has been described (Bali et al., 2008). After light isoflurane anesthesia seven EEG needle electrodes were placed subcutaneously over the left and right frontal, parietal, and central areas of the unshaved skull and recordings made as required for the study.

INJECTIONS AND INTUBATIONS

Gastric Intubation

The technique used for gastric intubation is similar to that used in other species. The length of the gavage needle should be a little shorter than the distance from the tip of the animal's nose to the end of its rib cage (~4 cm). A curved or straight, flexible or rigid, 18–20-gauge gavage needle (with a ball head) is inserted into the mouth of a manually restrained hamster. When using a straight needle, the needle is slid caudally along the roof of the animal's mouth while using the needle as a lever to assure the hamster's head is in a straight line with the remainder of its body. At times, slight dorsoflexion of the animal's head, using the needle, makes the intubation easier. With gentle pressure the needle is advanced down the esophagus and into the stomach. The animal is generally not anesthetized for this procedure and if anything more than mild resistance is felt the gavage needle should be removed and redirected. Even with a small ball head on the gavage needle the chance of entering the trachea is extremely low and is readily detected via the animal's gag reflex. A maximum volume of 3–5 ml/100 g body weight can be administered (Heatley and Harris, 2009).

For newborn hamsters a silicon catheter of 0.63-mm outer diameter can be passed directly into the stomach

FIGURE 29.3 Subcutaneous injection in the flank.

FIGURE 29.4 Subcutaneous injection between the scapulae.

(Silverman, 1987). The animal is gently restrained with the thumb and index finger of one hand. The catheter, gently held by a forceps, is directed into the animal's mouth and then into the stomach.

Subcutaneous (SC, SQ) Injection

The flank area of the hamster, as in other small mammals, can be used for SC injections (Figure 29.3). The abundant amount of loose skin along the back of the hamster also allows for easy SC injections, although caution must be used to properly restrain the animal while making the injection (Figure 29.4). It is suggested that if multiple SC injections must be used as part of a research project, the site of the injections should be rotated if that is compatible with the study. The hamster is lifted and restrained with one hand and the injection is made with the syringe and needle that is in the other hand. Once the needle is inserted under the skin it is moved slightly left and right to assure that it can be seen moving, thereby assuring it is not intraperitoneal. The plunger on the syringe is then depressed.

It is suggested that the novice practice on an inanimate object to assure that his or her fingers are positioned in a manner that allows the plunger of the syringe to easily be depressed while the needle is under the skin. A maximum of 3–5 ml can be injected (Heatley and Harris, 2009).

Intraperitoneal (IP) Injection

Intraperitoneal injections are typically made in the lower right or left quadrant of the hamster's abdomen, not on the midline. A relatively short needle (e.g., 0.5-inch or less) is suggested to help prevent puncture of the intestines or cecum. Once the animal is properly restrained (as described above for SC injections) the injection site is visualized, the needle is inserted at approximately a 60° angle to the body wall and the plunger on the syringe immediately depressed or, if desired, withdrawn slightly to assure the needle is not in an organ or hollow viscera. Injections that enter viscera, solid organs, or are SC rather than IP, will usually be absorbed but often slower than when the injection is truly IP. As with SC injections, it is suggested that an inexperienced person first practice on an inanimate object. A maximum of 3–4 ml can be injected (Heatley and Harris, 2009).

Some texts (e.g., Field and Sibold, 1998; Hrapkiewicz and Medina, 2006) have recommended tilting the animal's head downwards when performing IP injections, presumably to have the intestinal viscera slide forward and decrease the potential for injections into hollow viscera such as the cecum. A search of the biomedical literature did not discover any research that supports or refutes the rationale for this practice.

Intramuscular (IM) Injection

Hamsters have relatively little muscle mass in their hind limbs and IM injections must be made carefully. The only site we routinely use is the muscle mass anterior to the femur (the quadriceps group). A small needle (e.g., 0.25-inch, 25-gauge) is advanced into the muscle, somewhat parallel to the femur, and the injection is made. The author does not routinely use the muscles caudal to the femur due to the increased potential for injecting into or near the sciatic nerve. It is suggested that two people be used to perform IM injections (one to restrain the animal and the other to make the injection). A maximum of 0.1 ml/site is injected (Heatley and Harris, 2009).

Intrarectal (IR) Instillation

Although relatively easy to perform, IR instillations should be performed under light anesthesia to prevent struggling and possible colonic perforation. A standard

ball-tipped feeding needle can be used (e.g., 18 gauge, 4 cm). The animal is placed in dorsal recumbency and, if compatible with the research, a light coating of water-soluble lubricant is placed on the anus to ease the passage of the feeding needle. The needle is inserted to the desired length and the infusion is made slowly. The skin around the anus should be held somewhat taut to prevent its invagination into the anus (Silverman, 1987).

Intraosseous (IO) Injection

An IO catheter can be used for the rapid injection of non-toxic fluids, for maintaining open access to the vascular system over a period of days, and for therapeutic needs when intravenous catheterization is not possible, which is often the case with laboratory hamsters. The catheter itself is the needle that is used to penetrate the bone, and it should be ~30–50% of the length of the long bone into which it will be inserted (typically the tibia or femur) (Hawkins and Graham, 2007). It should occupy 30–60% of the marrow cavity at its thinnest point (Lennox, 2008). A 24–25-gauge needle is adequate for most adult hamsters. For a healthy hamster general anesthesia is required and post-procedural analgesia should be considered. If the tibia is to be used, the proximal area should be prepared for aseptically and the catheter is introduced at the tibial crest, approximately where the patellar ligament inserts (Lennox, 2008). A 4-0 monofilament stainless steel suture can be used as a stylet in a 25-gauge needle to help prevent blockage of the catheter's lumen (Hawkins and Graham, 2007). It is important to avoid penetration into the femorotibial joint. The catheter is advanced until it is stopped by the bony cortex. After insertion, the catheter is flushed with 1:10000 heparinized saline. An injection cap is then placed on the needle, the area of insertion is covered with neomycin-polymixin-bacitracin antibiotic ointment, and the catheter is secured with a bandage-tape butterfly and sutures (Hawkins and Graham, 2007). If possible, the entire area can be bandaged to help prevent gnawing through to the catheter.

Intraspinal (IS) Injection

An early description for IS injections was provided by Habel and Li (1951) who performed the procedure through a skin incision in anesthetized mice and hamsters at the "lumbar enlargement" of the spinal cord, using a 0.25-inch, 25-gauge needle on a 0.25-ml syringe. The needle, inserted between the slightly flexed vertebrae, was held at a 45° angle with the tip pointed cranial. It was inserted just to the right of midline and also pointed slightly toward the midline. They stated that when the needle entered the spinal canal a "giving" sensation was felt. Twenty µl could be injected. Kimberline

et al. (1987), using adult female hamsters, cut out a small window in the skin over the area of the 9th–11th thoracic vertebrae. Using a 30-gauge needle they injected 30 μ l over a period of 5–10 seconds so as to avoid damaging the spinal cord by excessive pressure.

Intravenous (IV) Injection

Ferm (1967) indicated that 2.0ml may be administered IV over a 1-min period while Gaertner et al. (2008) recommended a maximum of 0.3ml as a bolus and 25ml/kg body weight by infusion.

1. Cephalic vein. There are a limited number of readily accessible veins for IV injections. Although small, the cephalic vein can be accessed using a 27–30-gauge needle. The injection technique is similar to that used with cephalic IV injections in other species (the vein is initially constricted proximal to the injection site, the needle bevel is faced upwards and the needle is inserted nearly parallel to the vein).
2. Lateral saphenous vein. This vein can be entered where it crosses the tarsus, although this author has not had much success in using it. The technique used is the same as that for the cephalic vein, described above.
3. Retroorbital venous sinus. The retroorbital venous sinus, which is often used for blood collection (see below), can also be used for IV injections. (Popesko et al. (1990) illustrate an orbital venous plexus (*plexus orbitalis*). Other authors (House et al., 1961; Reznik et al. 1978; Tassoni 1955) all state that there is an orbital venous sinus in the Syrian golden hamster but none provide any documentation. In a newsletter article, Timm (1980) reported having prepared latex injected and corrosion casts of the venous structures of the head and diagrammed a venous sinus occupying the caudal one-half to two-thirds of the hamster orbit.) The hamster is lightly anesthetized and the eyelids are gently retracted manually, which will proptose the eye. A 25–27-gauge needle on a 1-ml syringe is inserted through the conjunctiva of the medial canthus of the orbit, at about a 45° angle and in a caudal–medial direction (Figure 29.5). Care must be taken not to pierce the thin bone of the skull. The needle is carefully advanced into the post-orbital venous sinus (a backflash of blood is occasionally seen in the syringe) and the injection is made. Do not inject more than 0.3ml. Because the injection is directly into the bloodstream, no clumped material should be used although Handler (1968) indicated that about 0.05ml of a cell suspension can be inoculated by this method. After removing the needle put direct pressure over the eye for about 30 seconds. Injections should not be made more often than every other day in the same eye.

FIGURE 29.5 Intravenous injection into the retroorbital venous sinus of the anesthetized hamster.

4. Jugular vein. The jugular vein can be used for IV injection by inserting an indwelling catheter using the general approach described below for jugular vein catheterization while the animal is under general anesthesia. In addition, a simple venous cutdown is often sufficient for a single injection using a 25–27-gauge, 0.5-inch needle. Additionally, the technique described later in this chapter for percutaneous collection of blood from the jugular vein can also be used for injections into the vein. Yohn et al. (1968) indicated that the left jugular vein of a newborn hamster could be used for IV injection of 0.05ml of virus inoculum or 0.1 ml of a cell suspension but details of the technique were not provided.
5. Lingual vein. This vein can be used for IV injections using the general technique for blood collection from that vein as described later in this chapter. A maximum of approximately 0.3ml can be injected.

Jugular Vein Catheterization

Catheterization of the jugular vein is typically performed when repeated blood collections or infusions are required. The jugular veins are located on either side of the neck, running in the jugular groove that parallels the trachea. In the anesthetized and surgically prepped hamster, a 1.5–2.0-cm incision is made over the caudal aspect of the right jugular vein while the hamster is in dorsal recumbency. The vein is located by blunt dissection and surrounding connective tissue and muscle is cleared away. Silk ligatures (3-0 or 4-0) are carefully passed under the cranial and caudal aspects of the cleared vein and the cranial ligature is tied tightly enough for the venous flow to be occluded. A small cut is made in the caudal part of the exposed vein using fine iris scissors. Using a fine forceps the sterile silicon or polyurethane catheter is threaded into the cut vein, pointing toward the heart. The

caudal suture is then tied to secure the catheter in place, being careful not to tie it so tight as to occlude the lumen of the catheter. A typical catheter size for an adult female hamster is 0.65mm inner diameter and 1.2mm outer diameter (Lisciotto and DeBold, 1991). The catheter can be advanced about 1.8–2.0cm into the vein to reach the right atrium of a 150-g hamster (Terpstra et al., 1999). The open end of the catheter can be exteriorized to the dorsal cervical area and secured to the skin in a standard manner (e.g., sutured to the skin directly or by using a catheter bead). The skin incision is closed routinely. Terpstra et al. (1999) have described an imbedded prosthesis to help secure the catheter, although commercially available catheter beads can be used. Once inserted, the catheter can be used for either withdrawing blood or administering intravenous products. The catheter should be capped and flushed daily with a 1:10000 heparin:saline mixture.

Carotid Artery Catheterization

Only a general outline is presented here. The reader should refer to the original publication (Elliott et al., 2005) for a comprehensive description. A 2-cm incision is made over the trachea. The left carotid artery is exposed by blunt dissection in the left paratracheal groove, and it is ligated cranially. A temporary second ligature is placed around the artery at the caudal end of the incision. A small arteriotomy is made in the artery and PE-10 polyethylene or another suitable tubing cannula is inserted into the arteriotomy incision. A third ligature is placed between the first and second one, within 1mm of the incision, and tightened around the cannula with a single half-hitch. The temporary ligature is then released. The cannula can then be attached to a 27-gauge needle for research procedures (e.g., blood transfusion). After the study is completed, the half-hitch ligature is further tightened to close off the artery and the surgical openings are closed with simple interrupted sutures.

Arterial Injection into the Pancreas

The induction of pancreatic cancer in hamsters by SC or IP chemicals such as N-nitrosobis(2-oxopropyl)amine or N-methyl-N-nitrosourea is an established and valuable research technique. Nevertheless, only one study has addressed vascular access to the arterial side of the pancreas (Sørensen and Seljelid, 2003), a procedure with importance for chemotherapy and immunotherapy research. The arterial blood supply of the pancreas is primarily derived from the celiac artery. Branches of this artery can be used for experimental therapeutic injections. A midventral incision is made just posterior to the xiphoid process and the stomach, spleen, duodenum, and transverse colon are exteriorized. The liver is retracted as needed. Using a surgical microscope, the

gastroduodenal artery is ligated as it branches off the celiac artery. The celiac artery itself is then ligated distal to where the splenic artery branches off. The celiac artery is punctured with a 30-gauge cannula close to the aorta and the cannula is advanced 5–6mm into the celiac artery. The cannula is then secured to the artery and exteriorized (if appropriate to the study). The exteriorized organs are replaced and the wound is closed routinely.

BIOLOGICAL SPECIMEN COLLECTIONS

Blood Collection

Blood collection is often required in studies with hamsters but because of the animal's very short tail, sampling from that location is impractical and techniques using other sites are described below. If collected blood is to be separated for plasma or serum, consider the use of commercially available micro-collection tubes such as the Microtainer® (Becton Dickinson, Franklin Lakes, NJ). In general, the use of heparin as an anticoagulant is preferred over ethylenediaminetetraacetic acid (EDTA) (McClure, 1999). For most research purposes a volume of blood equal to approximately $0.01 \text{ ml} \times \text{body weight}$ (in grams) can be safely sampled. Thus, for a healthy 100-g hamster one can safely remove about 1.0ml of blood. This can be repeated in approximately 3 weeks (Joint Working Group, 1993). Even with dwarf hamsters (e.g., *Phodopus sungorus*) modern equipment allows plasma chemistry analyses on as little as 150µl of whole blood (Jenkins, 2008).

1. Retroorbital. Retroorbital blood collection is not difficult but the operator must be skilled so as not to damage the bony orbit or the eye. The animal is lightly anesthetized and placed on its side. The ocular globe is easily proptosed by having the index finger and thumb of one hand gently pulling the eyelids apart while the same thumb is used to exert slight pressure over the area of the jugular vein. A small capillary tube (such as those used for hematocrit determinations) is advanced into the lateral canthus, perpendicular to the long axis of the body. The capillary tube is gently rotated until the conjunctiva is ruptured and the underlying orbital venous sinus is reached. After a sufficient amount of blood is collected in the tube, remove the tube and exert direct pressure over the ocular globe for about 30 seconds. Although a hypodermic needle (e.g., 22-gauge) can also be used to withdraw blood from the retroorbital sinus, one must be very careful not to perforate the bone of the orbit or injure the eye itself. MacDonald (1988) reported obtaining 1 ml of blood by retroorbital collection and suggested first flushing

the collecting tube with 1:10 000 heparin:saline, stating that hamster blood is "highly coagulable." Alternately, commercially available heparinized tubes can be used.

The medial canthus also can be used as a site for capillary tube insertion, but the insertion should be directed medially and posterior. Usually, more blood can be obtained using the lateral rather than the medial canthus. Another site, which is quite effective with hamsters, is along the superior border of the ocular globe, half way between the medial and lateral canthi (Silverman, 1987). A capillary tube is inserted through the conjunctiva and blood is collected as described above.

2. Small veins. Hawkins and Graham (2007) described methods for collecting blood from small vessels. A 0.3-ml insulin syringe with a swaged-on 27–29-gauge needle is used. The syringe plunger is removed, the needle is introduced into a small vessel (e.g., the saphenous vein) and blood is collected by introducing a heparinized microhematocrit tube into the syringe barrel. The syringe barrel acts as a stabilizing device. Blood also can be collected by inserting a small gauge needle into a vein and using a heparinized microhematocrit tube to collect blood as it exits through the rear of the needle, without the use of the insulin syringe.

A skilled person can obtain a small amount of blood from the cephalic vein or the caudal branch of the lateral saphenous vein as it crosses the tarsus. In both of these techniques the fur is wetted with alcohol and, if possible, a small tourniquet is placed proximal to the vein. A little silicon grease or petroleum jelly can be applied to prevent clotting. The vein is punctured (not cut) with a small needle (e.g., 23-gauge). Alternately, for the cephalic vein, it is possible to directly insert a 27-gauge needle attached to a tuberculin or insulin syringe and gently withdraw a small amount of blood. The technique requires one person to hold off the vein and another to withdraw the blood. Anesthesia is usually not required for the cephalic vein, but we have found that anesthesia or a tranquilizer is often needed for the lateral saphenous vein due to the movements of the hamster. A detailed description of saphenous venipuncture has been published (Hem et al., 1998). The hamster sublingual vein (lingual vein) is relatively easy to use for blood collection. The animal is anesthetized and held in a supine position by the scruff of the neck to slightly compress the jugular and lingual veins. A second person manually extends the animal's tongue and the caudal part of the sublingual vein is punctured with a 24-gauge, 1-inch hypodermic needle. The animal is turned ventrally and held horizontally over a blood collection tube. To

stop the bleeding, release the pressure on the neck. Approximately 750 μ l can be collected (Heimann et al., 2009).

3. Nail clip. Clipping a nail short can provide a drop of blood, but it is not a recommended procedure as it is likely to be painful, some animals have developed infections in that area, and subsequent serum chemistries can be compromised by tissue fluids. If this procedure is used the bleeding nail should be cauterized with silver nitrate or other means.
4. Cranial (anterior) vena cava. This procedure is used to collect relatively large volumes of blood. A detailed technique, using isoflurane anesthesia, has been described by Picazo et al. (2009). The hamster is maintained in dorsal recumbency. On the animal's left or right side, a 25-gauge needle on a 1-ml syringe is inserted 0.4 cm lateral to the manubrium of the sternum and cranial to the first rib. The needle is inserted at a 30° angle in the direction of the head of the opposite femur. Pulling on the syringe plunger to create slight negative pressure once the skin is pierced, the needle is inserted 0.3–1.0 cm until blood begins to flow. After the collection the needle is removed and direct pressure is applied for 30 seconds at the injection site. A slight modification of this technique is suggested by Hawkins and Graham (2007) who use a 27-gauge, 0.5-inch needle, inserted at a 45° angle.
5. Jugular vein. Percutaneous jugular vein blood collection can be performed using the general technique described by Kassel and Levitan (1953) or Hoff (2000). For a right-handed person the anesthetized hamster is held in the left hand with its head toward the operator's fingers. The area over the right jugular vein is either clipped or wetted with alcohol. The neck is hyperextended by placing a thread or piece of gauze sponge over the upper incisors, pulling it backwards and holding it with the left hand, along with the animal. The needle (23–25-gauge) is introduced in a caudal to cranial direction, over the sternum, puncturing the skin about 2 mm below the sternoclavicular junction. Remove the blood slowly. Jugular blood also can be collected via a catheter, as described earlier in this chapter.
6. Cardiac puncture. Cardiac puncture can be used for blood collection in an anesthetized animal. Approximately 3 ml can be collected from an adult hamster. The animal is placed in dorsal recumbency. Use a 1–3-ml syringe with a 22–23-gauge, 0.5-inch needle. The needle is inserted in a cranio-dorsal direction, at about a 30° angle to horizontal, and a little to the left of the xiphoid cartilage. If inserted correctly blood will enter the needle. Slowly withdraw the syringe plunger. It is suggested that cardiac blood collection be used as a

terminal procedure due to the potential for cardiac tamponade. Often, blood can be aspirated from the heart immediately after carbon dioxide euthanasia as the heart continues to beat for a short while.

7. Major blood vessel cut. Large amounts of blood can be collected as a terminal procedure by anesthetizing the animal and cutting any of the major blood vessels. Commonly, the axillary vessels, caudal vena cava, and abdominal aorta are used.

Urine Collection

Non-surgical catheterization is not practical in the male. The use of a standard metabolic cage is recommended if urine collection is required over a period of time. For a single urine collection, restraining the hamster often causes the animal to urinate one or two drops. If the animal urinates on a stainless steel table top or even in a plastic bag, the small amount of urine present can be used for a basic urinalysis using a commercially available reagent test strip.

Females can be catheterized if necessary. In the past polyethylene tubing has been used, but the typical PE-10 tubing (about 0.60mm outer diameter) does not have a smooth end and can injure the mucosa of the urethra. Waynforth and Flecknell (1992) suggest using the catheter part of an over the needle IV catheter as an alternative for rats. This can be tried for hamsters. Another option is to use a 2-French polyurethane catheter (0.64mm outer diameter). Although polyurethane catheters with a rounded tip are available in varying degrees of stiffness, the stiffness sold commercially for most IV applications is suitable. Polyurethane is available pre-sterilized by ethylene oxide (e.g., Solocath,TM Instech Solomon, Plymouth Meeting, PA). The actual procedure is performed on an anesthetized animal. For a right-handed operator the dorsally recumbent animal is placed in the left hand with its head toward the operator. The urethral papilla is stretched somewhat by using the left thumb to pull the caudal abdominal skin somewhat cranially. The catheter is now placed in the urethral orifice and inserted as far as it can go without excessive pressure. The catheter is then tilted caudally while the operator continues to push it gently cranially until it enters the bladder.

Pancreatic Duct Catheterization

The basic technique has been described by Permert et al. (2001). A dissecting microscope is used to aid the surgery. After a 12-h fast a midline laparotomy is performed and the pancreatic duct is identified and ligated at its entrance into the duodenum. The duct is opened with fine scissors just proximal to the ligature and a PE-10 polyethylene or other suitable cannula is inserted and secured. Although not noted in the published

surgical description, for survival surgery the tubing must be exteriorized and secured to the body wall. One way of doing this is to pass a large-bore needle through the abdominal wall (from the exterior to the interior), pass the open end of the tubing through the needle, remove the needle and then secure the tubing to the body wall (Waynforth and Flecknell, 1992).

Bile Collection

The hamster is an appropriate model to study human cholesterol metabolism (Spady and Dietschy, 1983). Like the mouse, but unlike the rat, the hamster has a gallbladder. The hamster gallbladder is attached to the middle lobe of the liver. After anesthesia and surgical preparation a midline abdominal incision is made up to the level of the caudal aspect of the xiphoid cartilage. A large-bore needle is passed through the aseptically prepared skin, pointed toward the hamster's back, and then into the abdominal cavity (Waynforth and Flecknell, 1992). The needle's bore will later be used for exteriorizing the catheter. The proximal part of the common bile duct (*ductus choledochus*) is located and dissected from the tissues of the hepatoduodenal ligament. The bile duct (*ductus cysticus*) is ligated with either a suture or a hemostatic clip. A small longitudinal cut in the common bile duct is made with fine scissors and the common bile duct is cannulated with a 33-cm, 1.0-mm inner diameter and 1.8-mm outer diameter silicon catheter (Fuchs et al., 1992) or PE-10 polyethylene tubing, directed toward the liver. The tubing is secured to the duct. The open end of the catheter is pushed through the bore of the large-bore needle and secured to the skin.

Cerebrospinal Fluid (CSF) Collection

After anesthesia the hamster is placed in a stereotaxic holder with its neck maximally ventroflexed. The dorsal cervical area and skull is prepped for surgery. A 5–7-mm midline incision is made from between the scapulae to the dorsum of the skull. A sterile 30-gauge needle (without the hub) is attached to approximately 25cm of 0.25-mm inner diameter microbore tubing. A 1.0-ml syringe is attached to the other end of the tubing via a needle on the end of the syringe. The 30-gauge needle is placed in the arm of the stereotaxic device and inserted vertically into the neck 4-mm caudal to the occipital crest. Maintaining mild suction with the syringe, the needle is slowly advanced until fluid is seen entering the tubing. Thirty to 70µl can be collected (modified from Morrey et al., 2007). The surgical wound is then closed. A slight modification of this method was used in rats by Nirogi et al. (2009) who did not make an initial incision in the skin.

FIGURE 29.6 Cerebrospinal fluid collection in the anesthetized hamster.

Another method of CSF collection is similar to that of [Nirogi et al. \(2009\)](#) in that a skin incision is not made but it is further modified by holding the anesthetized hamster in the operator's hand with the animal's head ventroflexed. After the needle insertion area is surgically prepped a 29-gauge, 0.5-inch needle on a 0.5-ml syringe is inserted on the midline just posterior to the most caudal aspect of the skull (the *squama occipitalis*). The needle is pointed rostrally at approximately a 45° angle ([Figure 29.6](#)). The needle is advanced into the cisterna magna and using slight negative pressure on the syringe plunger the CSF is collected.

Saliva Collection

Hamsters are injected IP with 3.0mg of pilocarpine hydrochloride. Over a period of 2–3h about 0.5ml can be collected from one hamster if the animal is placed in a restraint apparatus with its head over a beaker ([Haakenstad and Coe, 1971](#)). Gravity collection from a hand-held hamster can be used to recover smaller amounts of saliva.

Milk Collection

Milk can be collected from anesthetized or unanesthetized lactating hamsters by using a simple suction device as described for mice ([Haberman, 1974](#)), however, the collection pipette is made somewhat longer due to the longer teat of the hamster. Specifically, we drill two holes into a rubber stopper which is used to plug a 30–40-ml test tube. A smaller test tube (~3.5ml) is placed in the larger tube and the narrow end of a Pasteur pipette is passed through one of the drilled holes and into the smaller test tube. This Pasteur pipette (with or without some minor modifications) is the collecting pipette. A small piece of glass tubing is passed through the second hole in the stopper and eventually

connected to a simple suction pump via flexible tubing. The collecting pipette is placed over the nipple of the hamster and the milk flows into the smaller test tube.

With a lactating hamster it is usually not necessary to prime milk letdown with oxytocin, but if a greater quantity of milk is needed or if milk letdown is minimal, 0.5–1.0IU of oxytocin can be administered SC. This dosage is based on limited experience by the author. Others have suggested 0.1IU ([Haakenstad and Coe, 1971](#)) or 6.25IU/kg ([Nordenhäll et al., 1995](#)). Typically 0.1–0.3ml of milk can be collected from each hamster during the first 2 weeks postpartum with no milk being collected after the second week ([Nordenhäll et al., 1995](#)). The hamster can have milk expressed manually from the gland if a smaller quantity is sufficient.

Superovulation and Ova Collection

Sexually mature hamsters are superovulated by IP injection of 30IU of pregnant mare's serum gonadotrophin on day 1 of the estrous cycle and 30IU of human chorionic gonadotropin (hCG) is injected 48–56h later. The animals are euthanized 15–16h after the hCG administration. Ova with their cumulus oophorus masses are collected by flushing the oviducts with normal saline at 22–25°C ([Yuan and Shi, 2000](#)).

An alternate method of superovulation was described by [Venditti et al. \(2009\)](#). Ovulation is determined by placing a male hamster briefly into a female's cage during the dark phase of the light cycle and observing her behavior. The day in which the female shows lordosis is designated as estrous day 4, indicating ovulation will occur just prior to lights on. The hamsters are superovulated by intraperitoneal injection of 25IU pregnant mare serum gonadotropin dissolved in 0.1ml water 1h after the lights come on.

Sperm Collection

Electroejaculation has been described in many species; however, no literature references have been found for using this technique in hamsters. [Bedford and Yanagimachi \(1992\)](#) studied hamster sperm activation by allowing males to mate with females and then removing the sperm from the vagina of the female subsequent to euthanasia. Ejaculate without sperm can be collected by the IP injection of 400–600mg/kg body weight of potassium chloride ([Rockhold and Hiestand, 1956](#)).

OTHER SURGICAL PROCEDURES

Eye Enucleation

Hamster eyes normally appear somewhat more proptosed than other rodents and from time to time

the laboratory animal practitioner will be required to remove an eye damaged from fighting, other forms of trauma, or for research requirements. Given the small size of the eye, the technique is much easier than that required for a larger species such as a dog. After general anesthesia a small lateral canthotomy can be made if needed. The eye is either further proptosed or the sclera is grabbed with a hemostat or other suitable instrument and pulled away from the orbit. The periorbital and ocular tissues (including muscles, optic nerve, and blood vessels) are cut with iris scissors and the eye is removed. [Arce et al. \(1995\)](#) described the removal of a healthy eye for research needs. The technique is similar to that just described, however, they placed a ligature around the optic nerve and cut the nerve distal to the ligature. Direct pressure is used to suppress any bleeding (or a small amount of oxidized cellulose can be placed in the orbit) and the lids can be oversewn with absorbable suture material. Post-operative analgesia is provided.

Adrenalectomy and Adrenal Medulla Resection

The technique is similar to that used in other species ([Waynforth and Flecknell, 1992](#)). The anesthetized and surgically prepped hamster has a 1–2-cm skin incision made on the dorsal midline, over the general area of the kidneys. The skin incision is retracted to either side of the midline and scissors and forceps are used to bluntly (and sharply when needed) dissect the connective tissue. A small longitudinal incision is made behind the ribs and a few mm ventral to the spinal epaxial muscles (i.e., about a third of the distance down from the hamster's dorsum for the left adrenal and about a quarter way down for the right adrenal). The peritoneum is opened and using two pairs of curved hemostatic forceps (one to hold the spleen out of the way and the other to search for the adrenal gland), the adrenal gland is found in a mass of fat anterior to the kidney. It must be carefully teased out of the incision by pulling out the fat. It is important not to use the forceps to grasp the actual gland as a piece may break off and remain in the abdomen. The tissue and vessels are double-clamped at the base of the gland and the clamping forceps pulled apart to effect hemostasis. Muscle suturing is usually not needed although the skin incision must be routinely closed.

To remove the adrenal medulla, bilateral incisions are made as described for adrenalectomy. The adrenal glands are gently extirpated but not clamped. With the aid of a dissecting microscope a small incision is made on the adrenal cortex and the adrenal medulla is removed using minimal pressure to squeeze it out. The adrenal cortex is left intact ([Demas et al., 2004](#)).

Liver Perfusion

Many laboratories have developed their own procedures for liver perfusion, based on unique research needs. Two are presented here. One common *in situ* method is to make a ventral midline incision on the anesthetized animal from the xiphoid cartilage to the pubis and place a loose tie around the caudal vena cava near the liver. A 21-gauge butterfly needle is inserted into the portal vein and secured. As soon as the perfusion is started the loose loop around the caudal vena cava is tightened and the vein is cut caudal to the ligature to allow the perfusate to drain freely. The right atrium is cut with a scissor for further draining of the perfusate ([Silverman, 1987](#)).

A second perfusion method can be used in preparation for isolated liver perfusion. After a large midline incision is made on the anesthetized animal, the bile duct (*ductus cysticus*) is tied off. The common bile duct (*ductus choledochus*) is cannulated with PE-10 polyethylene tubing and a 21-gauge angiocatheter is placed into the portal vein. The liver is flushed with oxygenated Krebs Ringer bicarbonate and the caudal vena cava is cut. An angiocatheter is placed into the right cranial vena cava by entering it through the right atrium after a thoracotomy. The caudal vena cava is ligated cranial to the right kidney. The isolated liver is removed and placed in a perfusion chamber ([Cheng et al., 1996](#)).

Orchiectomy

Hamsters can be castrated using a closed or open technique. In a closed castration, which is preferred as a consequence of the open inguinal canal of hamsters, a single midline incision is made just anterior to the testicles. After the skin and subcutaneous tissue are cut, one testicle is exteriorized through the incision and a 4-0 ligature is passed around its spermatic cord and tunics. The ligature can be transfixed through the cremaster muscle for extra fixation. Once ligated, the spermatic cord is transected distal to the ligature and removed. The second testicle is then exteriorized through the same midline incision and the process is repeated. The tunics and subcutaneous tissue are sutured closed. The skin is then closed with appropriate sutures, skin staples, or surgical adhesive.

Our method for an open castration is to prepare the area for aseptic surgery and then incise the skin and subcutaneous tissue over the testicle. The incision is continued through the spermatic cord fascia and parietal vaginal tunic. The ligament of the tail of the epididymis is stretched or separated to exteriorize the testicle. The vascular cord and ductus deferens are individually ligated and the tunic closed with sutures. The testicle is removed distal to the ligature and the process is repeated for the second testicle.

Ovariectomy and Ovariohysterectomy

After anesthesia and surgical site preparation the hamster is placed in dorsal recumbency and a 1.0–1.5-cm midline incision is made between the umbilicus and pubis. The ovaries, which are found in a large fat pad just caudal to the kidneys, are easily exteriorized, ligated, and removed. If an ovariohysterectomy is required, one of the two fat-surrounded uterine horns is exteriorized and its blood vessels are ligated if required. The horn is then double-ligated and transected just cranial to the cervix, leaving the ligated stump in the abdomen. The same procedure is followed for the other horn, and the skin and subcutaneous tissues are then closed in a routine manner. The surgeon may also choose to transect both uterine horns at the same time by ligation of the uterus just cranial to the cervix, rather than ligating each horn separately. (The hamster has a separate cervix for each uterine horn but during ovariohysterectomy they can be ligated together as if there was a single cervix.)

Alternatively, for an ovariectomy, a dorsal approach can be used. The animal is placed in ventral recumbency and the dorsum is shaved and prepped. A 1–2-cm, midline dorsal skin incision is made approximately half way between the middle of the back and the base of the tail. The skin incision is retracted to one side, allowing for an incision to be made through the muscle belly posterior and parallel to the last rib and approximately half way down the side of the body (~3mm ventral to the spinal epaxial muscles). The ovary on that side can then be pulled out through the incision by grasping the periovarian fat. Care should be used not to grasp the ovary, as small pieces may detach and remain active in the peritoneal cavity. The junction of the Fallopian tube and the uterine horn is located and the distal end of the Fallopian tube and proximal end of the uterus are crushed with mosquito forceps. The ovarian vessels may be ligated, cauterized, or transected along with the Fallopian tube (just proximal to the crushed portion), allowing for complete removal of the ovary. If the muscle incision is small enough (e.g., ~0.5cm or less), no sutures are required, or, if necessary, a single suture can be used. The process is repeated on the other side and the skin incision closed.

Vomeronasal (VM) Organ Removal

Mating in naïve male Syrian golden hamsters requires sensory input from either the main olfactory or VM systems. To surgically remove all or most of the VM organs a midline incision is made through the anterior part of the hard palate of the anesthetized hamster. This exposes the bony VN capsules on either side of the midline. The natural openings in the palatine bones are

extended (i.e., the palatine fissures) anteriorly with a dental drill. A U-shaped groove is then made with the drill, forward and across the midline, to connect the two openings. A forceps is used to break the medial palatine process of the maxillary bones in order to disconnect the VN capsules at the posterior end. The VN capsules are separated by pressing the midline bony suture with a scalpel. The last connection with the palate is broken by drilling anterior to their rostral connection. Using a small forceps each capsule, with one VN organ, is removed separately. The incision is closed with sutures and sealed with tissue glue (Westberry and Meredith, 2003).

Olfactory Bulbectomy

In Syrian golden hamsters the olfactory bulbs (bulbus olfactorius) provide tonic inhibition of the hypothalamic–pituitary–gonadal (HPG) neurosecretory system (Pieper and Newman, 1999). This is in contrast to the Siberian hamster (*Phodopus sungorus*) where the bulbs provide little functional input to the HPG axis (Prendergast et al., 2009). Surgical removal of the bulbs is accomplished by immobilizing the anesthetized animal's head in a stereotaxic holder and making a 1-cm longitudinal midline skin incision in the frontal bone near the caudal extent of the nasal bones (approximately behind the position of the second molar tooth). The skin is retracted as needed and a hole is made in the anterior portion of the left and right frontal bones using a 0.4-mm diameter stainless steel burr. A 200- μ l pipette is inserted into each burr hold in an anterior–ventral direction. The pipette tip is connected to a vacuum pump with a water trap and the olfactory bulb is aspirated from each hole, being careful not to disturb the superior sagittal sinus. The resulting bone defect can be filled with oxidized cellulose if needed to control bleeding. The skin incision is then closed. The bulbectomy procedure removes the main olfactory bulb, the accessory olfactory bulb, and the *nervus terminalis* (Pieper et al., 1994).

Pinealectomy

Syrian hamsters are seasonal breeders and the effects of the exposure to a short photoperiod on their reproductive organs can be prevented by pinealectomy (Juszczak et al., 1997). Anesthetized hamsters can be handheld but it is recommended to use a stereotaxic holder to stabilize the animal's head. The method of Gündüz et al. (2008) is suggested. After anesthesia and surgical preparation a longitudinal midline scalp incision is made between the ears and eyes. The periosteum and any overlying muscle insertions are scraped away. Using a dental burr drill, an incomplete-depth circular cut (~5mm diameter) is made where the readily visible transverse and superior sagittal

sinuses meet. Fine scissors are used to carefully remove somewhat more than one-half of the posterior part of the circle. The piece of cranium covering the pineal gland is then lifted and folded anteriorly. If still adherent, the dura mater is removed with fine scissors. Using fine-tipped forceps, the pineal gland is grasped and removed. The bone flap is then replaced, using a small amount of absorbable gelatin sponge to help control bleeding. The scalp incision is closed routinely. A modification of this technique involves double ligating the superior sagittal sinus using a curved atraumatic needle, well anterior (rostral) to the confluence of the superior sagittal and transverse sinuses. This helps control bleeding and allows for easier removal of the gland at the confluence of the sinuses (Senoglu et al., 2009). Analgesia should be used postoperatively.

Hypophysectomy

Hypophysectomy requires strict attention to technique as the operator is working close to the jugular veins and numerous nerves. The parapharyngeal technique is the method most often used in hamsters and the surgical procedure noted herein is that previously described by Silverman (1987). The anesthetized animal is placed in dorsal recumbency with the animal's tail toward the operator. An endotracheal tube is not usually used. The animal's body, and particularly its head, must be well secured so that it does not move during surgery. A 1.5-cm incision begins in the mid-cervical area and extends anteriorly almost to the mandibular symphysis. The skin and mandibular salivary glands are retracted, exposing the trachea, sternohyoid, and omohyoid muscles. Using two 4.5-inch fine forceps, the muscles are separated and then retracted. The trachea is carefully retracted, but only when needed to obtain better visualization of the underlying cranium. A dental scraper is used to remove about a 1-cm circle of periosteum from the ventral cranium immediately dorsal to the trachea. This will reveal a faint blue suture line between the basisphenoid and occipital bones, which will be the area for subsequent trephining. The bone can now be removed by first gently scoring with a small trephine and then using a second trephine to remove the bone or by using a dental drill with a burr. The pink-colored gland is now visible and it can be sucked out using a 16–18-gauge needle (with a blunted end) and 10lb of vacuum pressure. Any bleeding is controlled with cotton-tipped or oxidized cellulose swabs. The pars distalis of the hamster pituitary extends forward and laterally making it somewhat difficult to fully remove and the gland often separates into numerous pieces during removal (Knigge, 1954). Postsurgical analgesics are routinely provided and a 10% glucose solution, given orally, will help prevent hypoglycemia.

FIGURE 29.7 Manual eversion of the hamster cheek pouch.

A detailed description of parapharyngeal hypophysectomy in the mouse is available (Hoff et al., 2006).

Cheek Pouch Preparations

The everted hamster cheek pouch can be used to study microcirculation and human tissue grafts. The thin pouch is very vascular and easy to transilluminate. The pouch has been called an immunologically privileged site, based on a deficiency of an afferent pathway to drain antigenic material to a lymphoid area which would recognize it and initiate an immune response (Hochman et al., 2004). The hamster is anesthetized and any food or bedding in the cheek pouch is washed out. The pouch can be everted manually by pushing from the outside of the pouch (Figure 29.7) or by using Adson-Brown tissue forceps to grasp the tissue deep in the pouch. The forceps should be kept closed while being inserted. When the forceps reaches the end of the pouch the pouch is grasped and slowly everted (Handler and Shepro, 1968).

To implant tissue, a small incision is made with fine scissors in an avascular area of the pouch, cutting through the epithelium. The cut is initially made near the buccal end of the pouch, carefully avoiding the retractor muscle fibers. (The retractor muscle originates from the lumbodorsal fascia and the spinous processes of the last three thoracic vertebrae. It then passes ventrocranially to insert on the cheek pouch. It lies just below the panniculus carnosus and platysma muscles and serves to prevent accidental eversion of the cheek pouch (Priddy and Brodie, 1948) and increases pouching efficiency for food items subsequent to the first item (Buckley et al., 2007).) Beginning at the cut end a tunnel is undermined in the pouch, in the aboral direction, taking care to avoid blood

vessels. The tissue fragment is placed in the aboral end of the tunnel and the epithelial borders of the incision are united by simple digital compression. The everted pouch is invaginated back into the oral cavity (Hochman et al., 2004).

To observe cheek pouch microcirculation, a number of techniques are available as acute preparations. The most basic is to evert the cheek pouch as described above and then pin the pouch over an acrylic or similar transparent support. A longitudinal cut is then made parallel to the saccular arteries and a transverse cut is made along the aboral border. This allows the pouch to be viewed as a single-layer preparation (Duling, 1973). The evaginated pouch is kept moist (e.g., using Ringer's solution). A non-acute (i.e., survival) preparation can be made using the same technique, but the cheek pouch epithelium is not cut (a so-called double-layered membrane preparation). This has the disadvantage of poor optical resolution when used for certain purposes and the operator should consider using analgesia after the procedure.

Although the above methods are satisfactory for many purposes, they put stress on the retractor muscle, which in turn may affect the circulation of the pouch. To avoid this problem, other researchers have developed methods to cut through the skin of the hamster's cheek and neck, ligate and cut the retractor muscle, and withdraw the pouch through the skin incision (Yamaki and Kritchman, 1981). Modifications of the skin incision method, using glass support and viewing chambers have been described (Davis and Gore, 1985; Greenblatt et al., 1969).

Yet another option for the chronic observation of vascular patterns of implanted tumors in cheek pouches is the use of a tissue chamber. The inner part of an acrylic disk is placed as far inside the pouch as possible. The skin, subcutaneous tissue, and muscle are removed and the two parts are joined by nylon rivets which pass through the pouch. Tumor tissue is inoculated at the time of insertion of the chamber and the operator uses microscopy to examine the growth of tumor and vasculature (Handler and Shepro, 1968).

Cheek pouch "painting" is the topical application of a carcinogen (or other material) to the epithelial surface of the everted cheek pouch. The entire procedure (including eversion of the pouch) can be performed without anesthetizing the animal, as described by Haisley (1980).

Dorsal Skin Fold Preparation

The dorsal skin fold preparation is another way of viewing the hamster's microcirculation and is conceptually similar to the tissue chamber described above. The major advantage is that microcirculatory studies can be performed repeatedly in unanesthetized animals

over a period of 3–4 weeks (Menger et al., 2002). The advantage of using the hamster over rats or mice is that in hamsters the retractor muscle is only loosely attached to the underlying panniculus carnosus muscle. This allows easy removal of the retractor muscle and aids later microscopic analysis. To prepare a dorsal skin fold, the skin of the back, just caudal to the neck of the anesthetized hamster, is lifted upwards (tenting) and maintained in that position with stay sutures. Using a stereomicroscope a 15-mm circular area of skin, subcutis (with the panniculus carnosus), and retractor muscle are completely removed. This is essentially a full-skin-thickness removal. Next, remove the retractor muscle from the inner surface of the opposite side of the tented skin. This leaves the subcutis and panniculus carnosus of the opposite side available for study of the microcirculation. The tented skin is then sandwiched between two titanium plates (which have a hole or "window" to observe the microcirculation) and the plates are joined with bolts. A removable cover glass is positioned in the titanium window to provide access to the tissue under investigation. Details of the procedure have been published (Menger et al., 2002).

INTRODUCTION

The incidence of bacterial diseases in laboratory hamsters has declined in recent decades. This decrease is primarily due to improved husbandry activities including more frequent and effective sanitation practices, and the use of microisolation and barrier technologies. A reduction in occurrences of bacterial diseases is also associated with the reduced use of hamsters as a laboratory animal species. However, bacterial diseases of hamsters remain significant because many of these diseases have the potential for high morbidity, high mortality, zoonosis, and economic loss. Conversely, mycotic infections are extremely rare and are poorly documented in the scientific literature.

BACTERIAL DISEASES

Proliferative Ileitis

Background

Proliferative ileitis is a serious infectious disease of hamsters and usually results in high morbidity and mortality. The disease is characterized clinically by diarrhea in weanling hamsters and pathologically by segmental proliferative lesions of the epithelium of the terminal ileum. The disease, proliferative ileitis, has also been referred to as regional enteritis, terminal ileitis, enzootic intestinal adenocarcinoma, atypical ileal hyperplasia, hamster enteritis, and "wet-tail". All of the above synonyms describe the same disease syndrome, which will be referred to as proliferative ileitis in this chapter. The term "wet-tail" has been used, especially in the pet industry, to denote this disease. However, this descriptive clinical appearance can be caused by several conditions that may cause diarrhea; and, thus, the term's use can result in confusion. The literature on proliferative ileitis has been reviewed by several authors (Cooper and Gebhart, 1998; Frisk, 1987; Frisk

and Wagner, 1977b; Jacoby and Johnson, 1981; Lawson and Gebhart, 2000).

The first major outbreak of proliferative ileitis recorded in the literature was in 1958 (Friedman, 1965). The naturally occurring disease in hamsters has only been reported from North America (Jasni et al., 1994b). The search for the etiologic agent of proliferative ileitis of hamsters has included many diagnostic and experimental studies. In the past, speculation as to the cause of the characteristic hyperplastic lesions included bacteria (Amend et al., 1976; Booth and Cheville, 1967; Friedman, 1965; Frisk et al., 1981; Jacoby and Johnson, 1981; Jacoby et al., 1975; La Regina and Lonigro, 1982; Lentsch et al., 1982; Wagner et al., 1973), viruses (Tomita and Jonas, 1968), and nutrition (Goldman et al., 1972). A review of the early studies regarding the quest for the causative agent was done by Frisk (1987). Since the 1980s, research regarding proliferative ileitis was focused almost exclusively on identification of the intracytoplasmic organism observed within the affected ileal epithelial cells. Identification of this organism was made very difficult because of its inability to be propagated on artificial media. This organism was ultimately characterized and named *Lawsonia intracellularis* (McOrist et al., 1995).

Several intestinal organisms have been shown to act as opportunists in hamsters with proliferative ileitis including *Campylobacter jejuni* (Lentsch et al., 1982), enteropathogenic *Escherichia coli* (Frisk et al., 1978), *Chlamydia trachomatis* (Fox et al., 1993), *Cryptosporidium* sp. (Davis and Jenkins, 1986), and protozoan parasites (Booth and Cheville, 1967; Jackson and Wagner, 1970; Sheffield and Beveridge, 1962). The above-listed bacterial and parasitic agents are not consistently present in all cases of proliferative ileitis, and may be observed or isolated from hamsters without proliferative lesions. Also, typical lesions of proliferative ileitis can be experimentally produced without the presence of these agents (Amend et al., 1976; Johnson and Jacoby, 1978; Stills, 1991).

Etiology

In 1995, *Lawsonia* was established as a new genus through 16S ribosomal genetic sequence analysis (McOrist et al., 1995). It was shown to be genetically similar to but distinct from *Desulfovibrio* (Fox et al., 1994; Smith and Lawson, 2001). The bacterium was classified in the Proteobacteria subdivision and was named *L. intracellularis* (McOrist et al., 1995). Isolates from proliferative lesions show close 16S ribosomal genetic sequence similarities between pigs and several different species including hamsters (Cooper et al., 1997a, 1997b; Peace et al., 1994).

L. intracellularis is a Gram-negative, non-spore-forming, slightly curved rod (1.5 by 0.35 μm). Organisms within ileal epithelial cells are usually not membrane bound, being observed free in the cytoplasm. *L. intracellularis* are observed in the apical cytoplasm just beneath the terminal web. These bacteria can not be grown on artificial media or in embryonated eggs. *L. intracellularis* has been isolated and propagated in cell culture on rat enterocyte and human fetal Intestine 407 cell lines in a microaerophilic environment (Smith and Lawson, 2001; Stills, 1991).

L. intracellularis is an obligate intracellular bacterium which is the causative agent of the proliferative enteropathies that occur in pigs, hamsters, ferrets, horses, deer, ostriches, and rabbits (Cooper et al., 1997a, 1997b; Fox et al., 1994; Lawson and Gebhart, 2000). The organisms isolated from many of these species have been compared using 16S ribosomal gene sequencing. Pure cultures of *L. intracellularis* isolated from hamsters have fulfilled Koch's postulates having been shown to cause proliferative ileitis in hamsters (Stills, 1991). Oral inoculation of pure cultures of *L. intracellularis* isolated from proliferative lesions of pigs can cause proliferative ileitis in weanling hamsters (Jasni et al., 1994a). This is suggestive that the organisms from these disparate species are the same or at least very closely related.

Epizootiology

Proliferative ileitis is a contagious disease, which is caused by *L. intracellularis*. The disease is transmitted by the fecal-oral route. Cannibalism of affected hamsters by cage mates may contribute to spreading the disease (Jacoby and Johnson, 1981).

Although the incidence of proliferative ileitis has decreased (Cooper and Gebhart, 1998), high morbidity and mortality in colony outbreaks makes proliferative ileitis one of the most feared diseases of commercial hamster breeders. It can complicate research projects by causing clinical signs and death in hamsters on experimentation. Increased severity and development of the disease have been associated with overcrowding, transport, surgery, limited diets, purified diets (Decker and Henderson, 1959), transplantation of neoplasms

(Lussier and Pavilanis, 1969), and experimental visceral leishmaniasis (Frenkel, 1972).

A proliferative ileitis outbreak is typically characterized by variable morbidity (20–60%) and high mortality (up to 90%) (Boothe and Cheville, 1967; Friedman, 1965; Goldman et al., 1972; Jonas et al., 1965). In affected hamster colonies, proliferative ileitis is first manifested as an epizootic disease (Friedman, 1965; Jackson and Wagner, 1970). Usually only a few hamsters in a disease outbreak recover; and, in some instances, no survivors have been reported (Jonas et al., 1965). Some animals may initially recover, but later succumb to ileal obstruction associated with chronic scarring of the ileum (Boothe and Cheville, 1967; Jacoby et al., 1975).

Hamsters affected with proliferative ileitis are usually between 3 and 8 weeks of age, but cases in adults have been reported (Jonas et al., 1965; Trum and Routledge, 1967). In experimental transmission studies, hamsters were susceptible to infection by oral inoculation of ileal homogenates up to 9 weeks of age (Frisk, 1987). Jacoby and Johnson (1981) showed that susceptibility to experimentally induced disease is age-related. Hamsters were less susceptible beginning at 6 weeks of age and resistant at 10 weeks.

Clinical Manifestations

Hamsters usually die 24–48 hours after clinical signs of proliferative ileitis are noted, and deaths may occur in animals without premonitory signs. Early signs include lethargy, anorexia, irritability, ruffled hair coat, and rapid weight loss. As the disease progresses, there is the appearance of a fetid, watery diarrhea which causes moist matted fur on the perineum, tail, and ventral abdomen (Figure 30.1). Signs associated with the diarrhea include dehydration, inactivity, and a hunched back which has been proposed to be indicative of

FIGURE 30.1 Weanling hamster with clinical signs of proliferative ileitis ("wet-tail") including matting of fur with feces in the perianal and posterior ventral abdominal areas.

FIGURE 30.2 The dissected gastrointestinal system (esophagus to rectum) of a hamster with proliferative ileitis demonstrating significant enlargement of the ileum.

abdominal pain (Friedman, 1965). A severe drop in body temperature, abdominal distention, and convulsions can occur just prior to death. Prolapse of the rectum or more commonly, intussusceptions with extension through the anus can be observed. Fresh blood around the anal region usually indicates an internal intussusception, the prognosis being grave.

Jacoby et al. (1975) closely observed hamsters after experimental transmission of proliferative ileitis and divided clinical signs into acute, subacute, and chronic. Acute signs occurred in 10% of hamsters 7–10 days after inoculation, the primary sign being hemorrhagic diarrhea. Subacute signs of retarded growth and diarrhea appeared 21–30 days after transmission. The chronic disease did not produce clinical signs, these animals showing normal growth rates.

Pathology

GROSS LESIONS

Gross lesions described with proliferative ileitis vary from acute enteritis to chronic inflammation with fibrosis. Acute enteritis lesions include hyperemia of the ileum which contains a fetid, yellow-gray fluid, blood, and/or gas (Boothe and Cheville, 1967; Sheffield and Beveridge, 1962). Sheffield and Beveridge (1962) reported that the mucosal surface of the cecum was sometimes ulcerated.

Segmental proliferative ileal lesions are observed in outbreaks of the disease. Typically, the posterior 4–8 cm of small intestine is progressively thickened, which abruptly terminates at the ileocecal junction (Figure 30.2). Occasionally, the proximal colon or cecum can be involved (McOrist et al., 1989). Affected ileal walls are 4–6 times thicker than normal, turgid, edematous, and friable (Figure 30.3). White patches of necrotic mucosa are commonly observed. Ileal serosa appears hyperemic,

FIGURE 30.3 Abdominal viscera of a male hamster with proliferative ileitis showing a markedly enlarged ileum.

rough, or granular. Subserosal abscesses are occasionally present, which can rupture causing focal or generalized peritonitis (Boothe and Cheville, 1967; Sheffield and Beveridge, 1962). There may be focal fibrinous lesions between affected intestinal segments and adjacent intestines, mesentery, or peritoneum. Intussusceptions of the ileum are observed, some of which extend into the cecum, colon, and at times through the anus. Intussusceptions of the colon and prolapses of the rectum have also been described. Chronic ileal lesions are characterized by a circumferential fibrotic scar which may cause partial or complete obstruction.

Peyer's patches and mesenteric lymph nodes of hamsters with proliferative ileitis are typically enlarged two to three times, hyperemic, and edematous.

MICROSCOPIC LESIONS

Microscopic lesions have been classified into the categories of acute enteritis, proliferative ileitis, proliferative ileitis with epithelium in muscle layers, and chronic ileitis (Frisk and Wagner, 1977b). Lesions of acute enteritis range from mild catarrhal enteritis to severe diffuse hemorrhagic necrosis of ileal mucosa. Proliferation of absorptive epithelial cells is not observed in cases with acute lesions (Frisk and Wagner, 1977b).

Proliferative lesions, which are characteristic of the disease, typically show ileal villi that are wider and longer than normal which may eventually fuse (Figure 30.4). There is usually a distinct demarcation between the affected ileum and a normal-appearing cecum. In studies involving the experimental production of the ileal lesions, epithelial cell proliferation is first observed in crypt epithelium (Frisk and Wagner, 1977a; Jacoby, 1978). "Focal proliferation" (Jackson and Wagner, 1970) is characterized by individual crypts which show proliferative changes among normal-appearing crypts.

Hyperplasia first occurs with the movement of crypt epithelium onto the villus within 10 days after

FIGURE 30.4 Microscopic section of ileum from a hamster with proliferative ileitis showing hyperplastic epithelium covering elongated villi. Hematoxylin-eosin stain. Magnification: 3130.

experimental infection (Jacoby, 1978). These hyperplastic epithelial cells are enlarged two to four times and contain large hyperchromatic nuclei with prominent nucleoli (Jonas et al., 1965). Their cytoplasm appears more basophilic than unaffected ileal epithelial cells. Absorptive epithelium is markedly thickened and pseudostratified beginning near the villar base. Immature epithelium ascends to eventually replace normal mature villar epithelium (Jacoby, 1978). Increased numbers of mitoses are observed within crypts, and mitotic figures are also observed on affected villi. The number of epithelial cells from the crypt to the villar tip is increased two to three times 3–4 weeks after infection (Jacoby, 1978). There is total absence of goblet cells.

Silver stains (Warthin-Starry) reveal myriads of curved bacteria in the apical portion of hyperplastic ileal epithelial cells (Jasni et al., 1994b; Stills, 1991) (Figure 30.5). Intracytoplasmic inclusions within epithelial cells have been described (Frisk and Wagner, 1977a; Jacoby, 1978; Jonas et al., 1965); however, this finding is not consistent.

FIGURE 30.5 Hyperplastic ileal epithelial cells from a hamster with proliferative ileitis showing *Lawsonia intracellularis* organisms in the apical portion of epithelial cells. Toluidene Blue stain. Magnification: 31000.

FIGURE 30.6 Light micrograph of an ileum from a hamster with proliferative ileitis demonstrating inflammation within the lamina propria and extension of crypt epithelium through the muscularis mucosa. Hematoxylin-eosin stain. Magnification: 3100.

Necrosis of villi and infiltration of the lamina propria by neutrophils, lymphocytes, and macrophages are common features. This inflammation becomes pyogranulomatous as the lesions progress. Subserosal abscesses may develop, which may communicate with the lumen via crypts. Hyperplastic epithelial cells may penetrate the muscularis mucosa and muscle layers and extend into inflamed tissue to produce pseudodiverticula (Figure 30.6). This type of lesion led Jonas et al. (1965) to classify the disease as neoplastic rather than inflammatory describing this change as “carcinoma in situ.” Jacoby and Johnson (1981) critically interpreted this “intrusive behavior”, and felt it was due to mechanical pressures from proliferation and was not invasion of a neoplastic epithelium.

Chronic lesions are characterized by marked thickening and hypertrophy of muscle layers, which may be

FIGURE 30.7 Microscopic section of ileum from a hamster with lesions of proliferative ileitis that demonstrate chronicity including increased numbers of goblet cells in crypts and granulomatous inflammation extending from the lamina propria into smooth muscle layers. Hematoxylin-eosin stain. Magnification: 3130.

secondary to partial luminal obstruction (Boothe and Cheville, 1967). Fibrosis of the ileocecal valve may lead to stenosis which may cause fatal obstruction (Jacoby et al., 1975). Scattered granulomas and epithelial-lined diverticula are present in the submucosa and subserosa. The ileal epithelium consists of large numbers of goblet cells (Figure 30.7).

Mesenteric lymph nodes can show reticuloendothelial hyperplasia, edema, granulomatous inflammation, and focal necrosis. Epithelial cells have not been observed within lymph nodes. Focal lesions of hepatitis are occasionally observed (Frisk and Wagner, 1977b).

TRANSMISSION ELECTRON MICROSCOPY

L. intracellularis have been described within the cytoplasm of hyperplastic ileal epithelial cells in natural and experimental cases of proliferative ileitis (Frisk and Wagner, 1977a; Jasni et al., 1994b; Johnson and Jacoby, 1978; Wagner et al., 1973). Cells containing organisms

FIGURE 30.8 Electron micrograph from a hamster with proliferative ileitis showing many profiles of *Lawsonia intracellularis* in the apical portion of the cytoplasm of ileal epithelial cells.

have been observed as early as 5 days after experimental inoculation of hamsters (Frisk and Wagner, 1977a; Johnson and Jacoby, 1978). Intracellular organisms are slightly curved, rod-shaped, measure $0.3\text{--}0.4 \times 1\text{--}2\mu\text{m}$ and divide by binary fission (Frisk and Wagner, 1977a; McOrist et al., 1989). Organisms are most prominent in the apical portion of hyperplastic cells (Figure 30.8) and are more numerous in epithelial cells that are further out on the villus (Johnson and Jacoby, 1978). *L. intracellularis* are usually free within the cytoplasm, however, occasionally they are observed bounded by lysosomal membranes (Frisk and Wagner, 1977a; Jasni et al., 1994b). Clusters of organisms observed by electron microscopy within the cytoplasm of hyperplastic epithelial cells could account for the occasional observation by light microscopy of intracytoplasmic inclusion bodies. Degenerative or toxic changes of the invaded cell are not observed. *L. intracellularis*, in fact, appear to have a cell-stimulating effect on infected cells, being reported primarily within hyperplastic cells and within cells in normal stages of mitosis (Frisk and Wagner, 1977a; Johnson and Jacoby, 1978).

Hyperplasia of ileal epithelial cells is observed by 10 days after experimental inoculation (Johnson and Jacoby, 1978). Hyperplastic cells resemble undifferentiated crypt cells with microvilli that are much shorter, less regularly arranged, and less densely packed than

mature villus epithelial cells (Kim and Jourden, 1977; Smith and Lawson, 2001). There may be focal necrosis of crypt epithelial cells and penetration of the muscularis mucosa as evidenced by bacteria between myofibers. Macrophages and leukocytes infiltrate crypts, lamina propria, submucosa, and adjacent muscle layers.

In chronic cases, goblet cells appear which do not contain *L. intracellularis*. Absorptive epithelial cells contain increased numbers of lysosomes and large membrane-bound vacuoles containing degenerative organisms (Frisk and Wagner, 1977a).

SCANNING ELECTRON MICROSCOPY

By scanning electron microscopy, Johnson and Jacoby (1978) noted that villi from hamsters with proliferative ileitis were elongated, broader, and flatter than normal. The crypt-villus junction was elevated above the basal lamina. In fractured blocks examined with the scanning electron microscope, crypts were observed to be four to five times normal length with only rudimentary villi at the surface. Villi sometimes appeared leaf-like, were fused into plateaus and the surface obscured by bacteria and cellular debris. Microvilli were sparse on villi covered by hyperplastic cells.

Pathogenesis

Although the causative agent of proliferative ileitis has been determined to be *L. intracellularis*, the detailed pathogenesis of the disease processes has not been completely elucidated. The literature regarding the pathogenesis of proliferative enteropathies in several species including hamsters associated with *L. intracellularis* has been reviewed (Smith and Lawson, 2001).

The pathogenesis of proliferative ileitis in hamsters has been studied by experimentally reproducing the disease by orally inoculating weanling hamsters with either pure cultures of *L. intracellularis* grown in cell culture (Jasni et al., 1994a, 1994b; Stills, 1991; Yeh et al., 2006) or with ground ileal lesions (Amend et al., 1976; Frisk and Wagner, 1977a; Jacoby, 1978; Jacoby et al., 1975; Johnson and Jacoby, 1978; Stills and Hook, 1989).

Proliferation, which is the hallmark of this disease, has been shown to be associated with the intracytoplasmic organisms identified as *L. intracellularis* (Frisk and Wagner, 1977a; Jasni et al., 1994; Johnson and Jacoby, 1978). Jacoby et al. (1975) showed by indirect immunofluorescence that experimentally infected hamsters produced antibodies to this intracytoplasmic organism. Antibody was detected by 10 days after infection (Jacoby, 1978). Attempts at protecting hamsters by passive immunization with hyperimmune serum failed (Jacoby and Johnson, 1981).

L. intracellularis enter the enterocytes of the ileum from the lumen. The mechanism of entry into the cell has been described (Jasni et al., 1994b). Organisms enter ileal

epithelial cells via membrane-bound endocytic vacuoles at the brush border (Jasni et al., 1994b). Once organisms are within the cell, vacuoles immediately breakdown, which leaves *Lawsonia* free within the cytoplasm.

Once established within the cell, *L. intracellularis* do not appear to have a degenerative effect on infected cells (Frisk and Wagner, 1977a; Jasni et al., 1994b; Johnson and Jacoby, 1978; Wagner et al., 1994). The onset of hyperplasia is closely associated with the intracellular presence of *L. intracellularis*. Organisms can be observed within normal-appearing mitotic cells (Frisk and Wagner, 1977a; Johnson and Jacoby, 1978). The physiological interaction between *L. intracellularis* and the enterocyte to cause hyperplastic lesions remains to be discovered. A synergism between normal intestinal microflora and *L. intracellularis* may be necessary to produce epithelial hyperplasia (Cooper and Gebhart, 1998).

Proliferative ileitis of hamsters has similarities to porcine proliferative enteropathy. Cross species transmission has been demonstrated with hamsters being susceptible to the pig agent (McOrist and Lawson, 1987). *L. intracellularis* has been identified as the causal agent of both diseases. The clinical and epizootiological aspects of swine with proliferative enteritis are very similar to hamsters with proliferative ileitis. The gross, microscopic, and electron microscopic changes observed in swine with proliferative enteritis are identical to those in hamsters with proliferative ileitis (Lomas and Glock, 1982; McOrist and Lawson, 1987; Rowland and Lawson, 1974, 1975). Because the same etiological agent can cause proliferative lesions, the hamster and swine diseases most likely have a very similar pathogenesis, and thus data and information learned about the disease in one species may be helpful in understanding the disease in the other.

L. intracellularis is not believed to be infectious for humans. The experimental production of proliferative ileitis of hamsters could be exploited as a model for studying the regulatory mechanism of mucosal proliferation (Jacoby and Johnson, 1981). Crypt hyperplasia occurs in man as a response to mucosal injury, such as cytolytic agents, radiation injury, and tropical and celiac sprue. The mechanism by which crypt hyperplasia is produced has been proposed to be through a feedback regulatory system, and this particular hamster lesion may give investigators valuable insights into this system (Jacoby and Johnson, 1981).

Diagnosis

Proliferative ileitis should always be suspected with the observance of clinical signs of diarrhea in young hamsters. Diarrhea may occur with other diseases such as salmonellosis, hymenolepiasis, Tyzzer's disease, or colonic hyperplasia. Their exclusion is primarily based

on gross and microscopic lesions. The proliferative changes involving the ileum, so typically observed, are pathognomonic for the disease. With Warthin-Starry silver stains, diagnosis can be confirmed by observing intracytoplasmic organisms within ileal epithelium. PCR assays for *L. intracellularis* are available commercially. Palpable, ropelike intra-abdominal masses can be detected 2 weeks post exposure, prior to the observation of clinical signs at 3 weeks (Jacoby et al., 1975).

Prevention and Therapy

Antibiotics administered orally have been the most commonly recommended treatment for proliferative ileitis but are only moderately successful. Tetracycline hydrochloride (400 mg/liter drinking water) was found to be most effective in reducing the numbers of hamsters contracting proliferative ileitis after experimental inoculation (La Regina et al., 1980). Dimetridazole (500 mg/liter drinking water) was much less effective than tetracycline, and neomycin (125 mg/liter drinking water or 10 mg/hamster) was considered ineffective when compared to untreated controls. Jacoby and Johnson (1981) reported that metronidazole (2 mg/ml drinking water) was nearly as effective as tetracycline, and neomycin was ineffective at a dose rate of 2000 mg/liter of drinking water.

Strict quarantine of affected hamsters and good sanitation practices are useful in controlling proliferative ileitis. Amend et al. (1976) stated that filter covers were effective in preventing cage-to-cage transmission of the disease. Colony depopulation, thorough sanitation of the facility, and repopulation with hamsters from a source without a history of the disease are the most effective steps to eliminate proliferative ileitis.

Colibacillosis

Background

Enteropathogenic *Escherichia coli* have been isolated from hamsters associated with some outbreaks of proliferative ileitis. Prior to *L. intracellularis* being identified as the etiological agent of proliferative ileitis, the possible role of *E. coli* in the pathogenesis of the disease was investigated (Frisk and Wagner, 1977a; Frisk et al., 1978, 1981; Wagner et al., 1973). Although *E. coli* isolated from hamsters with proliferative ileitis may cause secondary intestinal inflammatory lesions, it does not contribute to the production of ileal hyperplasia. *E. coli* isolated from hamsters have been demonstrated to be enteropathogenic and can cause acute enteritis (Amend et al., 1976; Boothe and Cheville, 1967; Frisk and Wagner, 1977a; Frisk et al., 1981).

E. coli was isolated from the intestines of hamsters with enteritis without proliferative lesions by Sheffield

and Beveridge (1962). They surmised that the *E. coli* was the cause of the fatal diarrhea and compared the condition to infantile diarrhea of man; and colibacillosis in piglets, chickens, and calves. Thomlinson (1975) isolated *E. coli* from a colony of hamsters with a fatal form of acute enteritis. The isolated serotype was identified in eight of ten affected and one of six unaffected hamsters. The organism was cultured from stomach, intestine, and spleen. This particular isolated serotype has also been reported as an intestinal pathogen of calves. Thomlinson (1975) believed that stress was a part of the enteritis disease similar to colibacillosis of calves and pigs.

Etiology, Epizootiology, and Clinical Manifestations

The *E. coli* isolated from hamsters with signs of diarrhea, including those with lesions of proliferative ileitis, have been shown in some cases to be enteropathogenic. The *E. coli* have been shown with some isolates to invade ileal epithelial cells and are either non-lactose or slow lactose fermenters.

Within the first 9 days after inoculation with ground proliferated ilea, Frisk and Wagner (1977a) showed by isolation, electron microscopy and indirect fluorescent antibody techniques, that a non-lactose-fermenting *E. coli* was present within ileal epithelial cells. These intracellular *E. coli*, with serologic and pathogenic characteristics similar to shigella, were found in experimentally infected hamsters (Frisk and Wagner, 1977a). Lesions of acute enteritis were present concurrent with these organisms. The finding of an intracellular *E. coli* after inoculation with ground proliferative ileal lesions is not consistent, Johnson and Jacoby (1978) did not observe *E. coli* by electron microscopy.

E. coli organisms were observed within ileal epithelial cells by Frisk and Wagner (1977a). These organisms were identified as *E. coli* by indirect fluorescent antibody techniques and measured $0.5\text{--}1 \times 2.2\text{ }\mu\text{m}$ by electron microscopy. Organisms were present within ileal epithelial cells in hamsters 1–9 days after inoculation. Detection of *E. coli* was associated with microscopic lesions of acute enteritis.

Pathology and Pathogenesis

Frisk et al. (1981) inoculated a non-lactose-fermenting *E. coli* that was isolated from ilea with proliferative lesions into weanling hamsters. The organism was able to produce clinical signs of diarrhea and lesions of acute enteritis. By electron microscopy and indirect fluorescent antibody techniques, *E. coli* were observed within intestinal epithelial cells. This organism was able to divide within cells and produce a disease which was comparable to shigellosis. Amend et al. (1976) isolated a slow-lactose-fermenting *E. coli* from hamsters with

proliferative ileitis. Oral inoculations of this *E. coli* into weanling hamsters resulted in lesions of acute enteritis. [Boothe and Cheville \(1967\)](#) isolated an *E. coli* from hamsters with typical lesions of proliferative ileitis. When weanling hamsters were orally inoculated with pure cultures of the isolated *E. coli*, diarrhea and generalized enteritis were observed.

Production of acute enteritis with pure cultures of *E. coli* inoculated into weanling hamsters is not a consistent finding. [Jackson and Wagner \(1970\)](#) isolated a hemolytic *E. coli* from hamsters with proliferative ileitis, but they also reported similar cultures from hamsters without proliferative lesions. From a separate outbreak, [Wagner et al. \(1973\)](#) isolated a non-lactose-fermenting *E. coli* from proliferated ileal lesions. Pure cultures inoculated orally into weanling hamsters did not produce disease. [Jacoby et al. \(1975\)](#) isolated a slow-lactose-fermenting *E. coli* from hamsters with proliferative ileitis lesions. Pure cultures of *E. coli* could not consistently produce disease.

[Frisk et al. \(1978\)](#) investigated the enteropathogenicity of several *E. coli* isolates from hamsters with proliferative ileitis. In an intestinal loop technique developed in weanling hamsters, three *E. coli* isolated from hamsters with proliferative ileitis were shown to be enteropathogenic, when compared to a non-enteropathogenic *E. coli* that was isolated from a normal hamster.

Campylobacteriosis

Background, Etiology, and Epizootiology

Campylobacter jejuni has been recognized as a major cause of enteritis in humans and has been isolated from a wide range of domestic and wild animals ([Fox, 1982](#)). There appears to be a high incidence of campylobacter infection in hamsters from the United States, up to 100% of hamsters tested in some colonies. In a survey of hamsters obtained from pet stores, 80% were carriers of *C. jejuni* ([Fox et al., 1983](#)).

C. jejuni is a motile, slender, comma-shaped, Gram-negative rod that requires a microaerophilic environment for growth. Route of transmission from animal to animal is by the fecal-oral route. *C. jejuni* has been recovered from ileal, cecal, jejunal, duodenal, and colonic contents ([Fox et al., 1986](#)).

Clinical Manifestations

Most hamsters naturally infected with *C. jejuni* are asymptomatic. Signs of diarrhea have been observed in a small percentage of animals ([Fox et al., 1983](#)). In hamsters with proliferative ileitis, there appears to be a high incidence of *Campylobacter*-positive animals ([La Regina and Lonigro, 1982](#); [Lentsch et al., 1982](#); [Stills et al., 1989](#)).

Pathogenesis

In the past, studies investigated the role of *Campylobacter* spp. in the pathogenesis of proliferative ileitis. [Lentsch et al. \(1982\)](#) isolated *C. jejuni* from fecal swabs and proliferated ilea of hamsters that were from a natural outbreak of the disease. The organism was isolated from all animals showing gross lesions of ileal proliferation. [La Regina and Lonigro \(1982\)](#) isolated *Campylobacter* sp. from hamsters with experimentally induced proliferative ileitis. Inoculations of *C. jejuni* isolated from hamsters with proliferative ileitis were attempted ([La Regina and Lonigro, 1982](#); [Lentsch et al., 1982](#)). Colonization of the intestinal tract was established in all inoculated hamsters, mild enteritis being noted in a few. However, typical lesions of proliferative ileitis were not produced ([La Regina and Lonigro, 1982](#); [Lentsch et al., 1982](#); [Stills et al., 1989](#)).

In a survey of three commercial hamster colonies, *Campylobacter* sp. was isolated from a colony that had previously experienced proliferative ileitis ([La Regina and Lonigro, 1982](#)). Hamster breeders with no history of proliferative ileitis were negative for *Campylobacter* sp. ([La Regina and Lonigro, 1982](#)).

L. intracellularis has since been identified as the causal agent of proliferative ileitis, and the isolated *C. jejuni* from affected hamsters is considered an opportunist. Although *Campylobacter* sp. has the ability to colonize the intestine and stomach, hamsters inoculated with pure cultures typically do not develop significant disease ([Fox et al., 1982](#)).

Diagnosis

Detection of *C. jejuni* is made by sampling feces or intestinal contents. Culture may be attempted on selective media incubated under microaerophilic conditions. Commercially available PCR assays are used to detect *Campylobacter* spp. In humans, PCR was found to be a more sensitive detection method than culture ([Sinha et al., 2004](#)).

Prevention

Because of the relatively high incidence of *Campylobacter* carriers, hamsters should be considered as a potential reservoir for zoonosis for pet owners and laboratory personnel ([Fox et al., 1983, 1986](#)).

Helicobacter

Background

Hamster intestines are naturally colonized with several *Helicobacter* spp. including *H. cinaedi*, *H. mesocricetorum*, *H. cholecystus*, *H. aurati*, and unnamed *Helicobacter* spp. ([Fox et al., 2009](#); [Nambiar et al., 2006](#); [Whary and Fox, 2004](#)). Clinical disease is usually not associated with these carrier animals.

Etiology

Helicobacter spp. are Gram-negative bacteria, motile, and are curved to spiral to fusiform in shape. Isolation of this organism requires microaerophilic conditions. Speciation is accomplished with biochemical testing and PCR analysis. This genera of bacteria shares many characteristics with *Campylobacter* spp. A number of helicobacters have been isolated from hamsters from research and commercial colonies.

Epizootiology and Pathology

HELICOBACTER MESOCRICETORUM

H. mesocricetorum was isolated from the feces of normal hamsters (Simmons et al., 2000). Gross and microscopic lesions were not observed. The organism was thought to be a non-pathogenic commensal of the intestine.

HELICOBACTER CINAEDI

H. cinaedi was isolated from the intestinal tract of clinically normal hamsters (Gebhart et al., 1989). Pathologic lesions in hamsters were not associated with the organism. *H. cinaedi* is a significant pathogen for immunocompromised humans. This organism may cause enteritis, proctocolitis, and rectal infection in man (Gebhart et al., 1989; Whary and Fox, 2004). Septicemia and meningitis occurred in a 5-day-old infant whose mother cared for pet hamsters during the first two trimesters of her pregnancy (Orlicek et al., 1993). *H. cinaedi* was isolated from blood and cerebrospinal fluid of the newborn. The organism could not be isolated from the mother. Hamsters should be considered a reservoir host for *H. cinaedi* and may be a source of infection for humans.

HELICOBACTER CHOLECYSTUS

H. cholecystus can cause cholangiofibrosis and centrilobular pancreatitis in hamsters (Franklin et al., 1996). *H. cholecystus* was isolated from the gallbladders of 3–8-week-old hamsters. Histologically, hepatic lesions were characterized by portal lymphoplasmacytic infiltration, some forming lymphoid follicles. In severe cases, bile duct hyperplasia was extensive and periportal fibrosis bridged to adjacent portal triads. Centrilobular pancreatitis consisted of extensive periductular inflammation and extension of inflammatory cells into ductal epithelium. Pathogenesis of this disease was suggestive of an ascending *H. cholecystus* infection of the common bile and pancreatic ducts, which resulted in the hepatic and pancreatic lesions.

HELICOBACTER AURATI

In aging (18–24 months) hamsters infected with *Helicobacter* spp. (including *H. aurati*), chronic progressive typhlocolitis and associated dysplastic lesions

were noted in the large intestine (Nambiar et al., 2006). Clinical signs were either absent or included chronic weight loss and poor body condition. Gross lesions included a thickened ileoceocolic junction with serosal cysts. Histopathologically, inflammation of the intestine was characterized by expansion of lamina propria by mixed inflammatory cells and multiple large cystic crypts. Inflammation extended into the submucosal and muscular layers and multiple crypt abscesses were evident. Dysplastic lesions were noted, which were similar to lesions of humans with irritable bowel disease. Dysplastic lesions include atypical, tortuous, hyperplastic crypts with areas of inflammation. Areas of epithelial hyperplasia showed loss of goblet cells. Although two tumors (round cell sarcoma and malignant fibrous histiocytoma) were noted, their association with the chronic inflammatory process was suggestive but not established. Although three *Helicobacter* spp. were isolated from all affected hamsters, the organisms could only be implicated as causal. Naturally occurring progressive proliferative and dysplastic typhlocolitis in aging hamsters may be a valuable model for studying irritable bowel disease of humans (Whary and Fox, 2004). Because *Helicobacter*-free hamsters have not been established, experimental inoculations of hamsters with pure cultures are not possible.

H. aurati was isolated from the inflamed stomach and cecum of adult hamsters (Patterson et al., 2000a). Chronic gastritis and intestinal metaplasia without cancer was observed in 7–12-month-old hamsters naturally infected with *H. aurati* and two other microaerobic species (Petterson et al., 2000b). The most severe gastric lesions were found in the distal antrum near the pyloric-duodenal junction. Gastric inflammation extended from the mucosa to the serosa. Increased numbers of goblet cells were indicative of intestinal metaplasia. In a follow-up study, a 2-year-old hamster positive for *Helicobacter* spp. had a gastritis-associated adenocarcinoma which was invasive but not metastatic (Nambiar et al., 2005). *Helicobacter*-infected aging hamsters may be a potential model of the development of intestinal metaplasia and gastric adenocarcinomas in chronic *H. pylori*-infected humans (Whary and Fox, 2004).

HELICOBACTER SP.

A novel *Helicobacter* sp. was identified by *Helicobacter*-specific PCR from livers of aged hamsters (Fox et al., 2009). The livers from these hamsters had lesions of chronic hepatitis, hepatic dysplasia, and biliary hyperplasia. Hepatic inflammation was also a prominent feature including cellular infiltration by lymphocytes, neutrophils, and macrophages. This novel *Helicobacter* sp. is closely related to *H. bilis* and may have a role in hepatobiliary disease.

Tyzzler's Disease

Background

Prior to reports of spontaneous outbreaks of Tyzzler's disease in hamsters, it was shown that hamsters could be infected experimentally (Craigie, 1966; Takagaki et al., 1966). During an outbreak of Tyzzler's disease in a colony of gerbils, unconfirmed cases were reported in hamsters (White and Waldron, 1969). Naturally occurring confirmed cases of Tyzzler's disease have been sporadic (Nakayama et al., 1975; Takagaki et al., 1974; Timmons and Dickey, 1981; Zook et al., 1977). *Clostridium piliforme* is able to infect and cause an enterohepatic disease in many different species. In addition to hamsters, Tyzzler's disease has been reported in the mouse, rat, rabbit, gerbil, cat, rhesus monkey, horse, guinea pig, and dog.

Etiology

The causative agent of Tyzzler's disease is the obligate intracellular bacterium, *C. piliforme*. The organism is a Gram-negative, motile, pleomorphic bacillus measuring $0.5 \times 8\text{--}10\mu\text{m}$, some being up to $40\mu\text{m}$ in length. *C. piliforme* is spore-forming, showing monilial subterminal swellings. Spores play an important role in establishing infection by the oral route. Contaminated materials can be infective up to one year at room temperature (Craigie, 1966). *C. piliforme* has not been grown on cell-free artificial media. The organism can be grown in the yolk sac of embryonated chicken eggs and in cell culture (Waggie et al., 1987; Zook et al., 1977).

The antigenicity of *C. piliforme* isolated from hamsters has been compared to isolates from other species by complement fixation, immunofluorescence, and double-diffusion techniques (Fujiwara et al., 1974). Hamster organisms and the organism isolated from a kitten during a hamster outbreak showed strong cross reaction. There was weak or no cross reaction with Tyzzler organisms isolated from rats or mice. Nakayama et al. (1975) showed common antigens by complement fixation when organisms from hamsters with enteric lesions were compared with organisms from hamsters with hepatic lesions. It appeared that the antigenic specificity of *C. piliforme* was dependent upon the host species from which it was derived. Franklin et al. (1994) demonstrated that the *C. piliforme* isolated from a natural case of Tyzzler's disease in a hamster was specific for that host and, when inoculated experimentally, did not infect mice or rats. This host specificity may be due to bacterial and host factors most likely involving the organism's ability to attach to and enter host enterocytes and hepatocytes. A *C. piliforme* isolated from a hamster outbreak was shown to produce a cytotoxin which may result in a more severe disease than isolates that are non-toxicogenic (Franklin et al., 1994; Riley et al., 1992).

In tissue sections, organisms are intracytoplasmic and are most often arranged in parallel bundles or starburst arrays. Tyzzler organism has a predilection for multiplication in the hepatocyte and epithelial cell of the intestine. Organisms are poorly visible in tissues stained with hematoxylin-eosin and Gram stains. The organisms are most easily visible, as light brown to black filamentous rods, with the silver stains of Warthin-Starry or Levaditi (Ganaway et al., 1971). Other effective stains are Giemsa, toluidine blue, Gomori methenamine silver, and periodic acid Schiff.

Epizootiology

Although there have been widespread reports of Tyzzler's disease from many countries in mice, there have been only scattered reports in hamsters. There is a possibility of Tyzzler's disease occurring in hamsters whenever they are housed near susceptible species. It is possible that the prevalence of Tyzzler's disease in hamsters may be higher because some cases may go undiagnosed. For instance, gross lesions in a retail pet supplier colony included cecal distention and enlargement of mesenteric lymph nodes without gross hepatic lesions (Motzel and Gibson, 1990). Diagnosis may not be confirmed in some cases because lesions are not always characterized by focal hepatic necrosis, *C. piliforme* will not grow on artificial media, and special stains are needed to observe the organism histologically.

The transmission of *C. piliforme* from animal to animal is by the oral route. If a hamster in a cage contracts the disease, usually its cage mates become ill (Zook et al., 1977). Nakayama et al. (1975) exposed hamsters to contaminated bedding 3 months after the hamsters housed on it died of Tyzzler's disease. After a few days of exposure, all hamsters died with enteric lesions.

Clinical Manifestations

Tyzzler's disease outbreaks may be characterized by high mortality with the sudden unexpected loss of primarily weanling hamsters with few clinical signs. Hamsters may die within 24 hours to a few weeks after onset. Diarrhea is the most characteristic sign, however, it is not always observed. Affected hamsters have pale, yellow, watery feces which result in wet hairs in the perianal area. Other clinical signs include a ruffled or dry hair coat, lethargy, anorexia, and dehydration. The diseased hamster may appear hunched and can progress to a moribund condition.

Pathology

Lesions can vary in the hamster; in some outbreaks the predominant lesions involve liver (Takagaki et al., 1974), some involve enterocolitis without liver lesions (Motzel and Gibson, 1990; Nakayama et al., 1975), and others involve heart lesions (Zook et al., 1977). Typical liver

lesions consist of organ enlargement with white-yellow or white-gray plaques that are pinpoint to 2 mm in diameter. Gross lesions involving the intestinal tract most commonly occur in the ileum, cecum, and proximal colon. These regions show edema, hyperemia to hemorrhage, and dilatation with semi-liquid, foamy, yellow contents. Focal necrotic gray plaques, 1–3 mm in diameter, can be observed on the mucosal surface. Multiple white nodules, 2–5 mm in diameter, may extend the full thickness of the ventricle in the heart (Zook et al., 1977). Other less notable gross lesions include markedly enlarged and congested mesenteric lymph nodes and enlarged spleens.

Histologically, liver lesions consist of periportal foci of coagulative necrosis of variable size (Figure 30.9). There is infiltration of affected areas by neutrophils and lymphocytes. *C. piliforme* are observed primarily in viable hepatocytes immediately adjacent to necrotic foci with fewer numbers in necrotic hepatocytes or the center of necrotic foci (Figure 30.10).

FIGURE 30.10 *Clostridium piliforme* organisms are present within an area of hepatic necrosis from a hamster with Tyzzer's disease. Warthin-Starry silver stain. Magnification: $\times 640$. Courtesy of Dr. K. S. Waggle.

Intestinal lesions can generally be classified as acute inflammation with focal mucosal erosions. The mucosa of the ileum, cecum, and colon shows degenerative and necrotic changes. There is edema, hyperemia, and inflammatory cell infiltration of the lamina propria. The most severe mucosal erosions include edema and inflammation of the submucosa and muscle layers. Organisms can be observed within the cytoplasm of mucosal epithelial cells in the intermediate zone of villi and less predominantly in crypts. Organisms may also be observed within smooth muscle cells bordering areas of necrosis within the tunica muscularis (Waggle et al., 1987).

Myocardial histopathologic lesions consist of ill-defined granulomas and focal areas of necrosis with accompanying inflammation (Zook et al., 1977). Organisms can be observed within these myocardial lesions.

Pathogenesis

Tyzzer's disease in hamsters has been studied by inoculating *C. piliforme* contained within liver homogenates, cecal contents or spore suspensions produced from embryonated chicken eggs. Although hamsters have been experimentally infected by many routes, oral inoculation produces results which are the closest to the naturally occurring disease.

The organ in which Tyzzer organism first grows is the cecum, its physiology being favorable to the proliferation of *C. piliforme* (Nakayama et al., 1976). Dissemination of the organism is rapid throughout the remainder of the intestinal tract, affecting all regions from duodenum to rectum by the third day post inoculation. Microscopic intestinal lesions were first detected 2–3 days after oral inoculation (Waggle et al., 1987). Foci of necrosis were present within the smooth muscle layers of the ileum, cecum, and colon 7 days after inoculation. Through cecal ligation experiments, it was demonstrated that the route of *C. piliforme* from the cecum to the liver was via portal circulation (Nakayama et al., 1976). *C. piliforme* were observed in hepatocytes on the periphery of necrotic foci 3–5 days after oral exposure (Waggle et al., 1987). Hepatic lesions showed a healing process involving granuloma formation containing giant cells 12–14 days post inoculation.

Diagnosis

The definitive diagnosis of Tyzzer's disease is dependent upon the demonstration of typical bacilli adjacent to regions of necrosis within the cytoplasm of hepatocytes, intestinal epithelial cells, or myocardial cells. Diagnosis is most commonly made with special stains of tissue sections. PCR assays for detection of *C. piliforme*, typically using feces or colon samples, are available commercially. Serologic methods, including indirect fluorescent antibody, enzyme-linked immunosorbent assays, and complement fixation testing, detect

exposure to *C. piliforme*. Cecal contents from hamsters suspected of Tyzzer's disease may be orally inoculated into gerbils, or cortisone-treated hamsters, or mice to reproduce the disease (Motzel and Gibson, 1990).

Prevention and Therapy

The most important factors in the control and prevention of Tyzzer's disease involve improved sanitation and isolation. Spores of *C. piliforme* are most likely the most important factor in maintaining an outbreak. Cleaning the environment to eliminate spores and preventing cage-to-cage spread with microisolation filter covers are helpful in controlling spread of the disease.

Treatment of hamsters with Tyzzer's disease was not described in most of the reported outbreaks. Oxytetracycline added to the drinking water of a pet store supplier of hamsters was attempted without success (Motzel and Gibson, 1990). This particular outbreak of Tyzzer's disease was believed to be precipitated by stressors including overcrowding, poor sanitation, high environmental temperatures and humidity, marginal diet, and parasitism.

Although there have been only sporadic outbreaks of Tyzzer's disease in hamsters, the disease can be significant because of high morbidity and high mortality. If an outbreak of Tyzzer's disease occurs in any species within an animal care facility, other susceptible species including the hamster may be at risk of infection. Outbreaks in hamsters have been reported associated with diseased gerbils in one case (White and Waldron, 1969) and a kitten concurrently infected in another (Takagaki et al., 1974). *C. piliforme* is not believed to be transmissible to humans.

Investigators who carry out experimental protocols that involve immunosuppression of hamsters, especially with cortisone or irradiation, should be observant for Tyzzer's disease. Cortisone administered subcutaneously at 2.5mg per hamster enhanced infection (Nakayama et al., 1976). Organisms were more abundant in affected tissues; and lesions involving the alimentary tract and liver were accentuated. Hamsters treated with cortisone died 4–7 days after inoculation as compared to 7–13 days if not given cortisone (Nakayama et al., 1976). Hamsters exposed to whole body irradiation (500r) at the time of inoculation with *C. piliforme* resulted in the production of much more severe lesions (Takagaki et al., 1966).

Antibiotic-Associated Enterocolitis (*Clostridium difficile*)

Background

Many antimicrobial agents can cause enterocolitis in hamsters including lincomycin, clindamycin, ampicillin, vancomycin, erythromycin, cephalosporins,

gentamicin, and penicillin (Percy and Barthold, 2001; Small, 1987). Because high mortality may occur following antibiotic administration, the risks of therapy with antibiotics in hamsters must be carefully considered. The hamster has been used as an animal model for antibiotic-associated enterocolitis in humans because of its sensitivity to antibiotic use and the resulting intestinal lesions. The literature regarding antibiotic-associated enterocolitis has been reviewed (Small, 1987).

Etiology

The enterocolitis that occurs following the use of antibiotics is caused by the toxins from *C. difficile*. It is believed that alterations to the hamster's intestinal microflora are also important in causing the disease. In hamsters treated with clindamycin, the cecal contents were shown to have toxic activity (Chang et al., 1978; Rifkin et al., 1978). Experimentally, the mortality rate for hamsters administered vancomycin may approach 100% (Wilson et al., 1981). However, when cecal contents from normal hamsters were administered orally to those animals receiving vancomycin, nearly all of the animals were protected from disease development. Therefore, it is believed that bacteria from the normal intestinal flora are necessary to suppress *C. difficile* growth. A yeast, *Saccharomyces boulardii*, has been found to prevent fatalities in hamsters following clindamycin treatment (Toothaker and Elmer, 1984).

Epizootiology

From reports regarding the use of antibiotics in hamsters, some have recorded toxicity while others indicated that no problems were experienced (Small, 1987). It is postulated that variations in toxicity are due to differences in intestinal microflora and/or the presence of *C. difficile* in the cecum.

Antibiotic-associated enterocolitis is an infectious disease. The sources of infection with *C. difficile* for hamsters after treatment with an antibiotic are believed to be carrier hamsters or the environment including contaminated technicians' hands, cage equipment, food, and contaminated air flow (Fekety et al., 1980). In a controlled experiment where a conventional room was compared with a clean room including the use of gloves, garbing, and sterile equipment; hamsters administered antibiotics survived twice as long in the clean room (Toshniwal et al., 1981). Therefore, it was postulated that antibiotic use causes hamsters to become susceptible to *C. difficile* that is usually acquired from the environment.

The route of administration that is used in treating hamsters is important with some antibiotics to determine if enterocolitis will develop (Small, 1987). If a route is used (for example subcutaneous with an antibiotic such as chloramphenicol) that is excreted through the urine, the cecal microflora are not affected because

the antibiotic is not present in the gastrointestinal tract (Fekety et al., 1979b). Thus, fatal enterocolitis will not develop.

In experiments investigating treatment of clindamycin-induced colitis in hamsters, disease was prevented by treating with orally administered vancomycin or metronidazole (Fekety et al., 1979a). When these antibiotics were discontinued, hamsters succumbed to fatal enterocolitis. This same type of relapsing syndrome after vancomycin treatment occurred in a group of hamsters with naturally occurring non-antibiotic-associated *C. difficile* enterocolitis (Boss et al., 1994). This high incidence of relapse in clindamycin-induced enterocolitis in hamsters is a model for humans with a similar syndrome occurring with *C. difficile*-associated diarrhea. Relapse enterocolitis may be associated with persistence of spores, reinfection from the environment, and/or failure to develop an effective immunity. In clindamycin-induced colitis of hamsters, relapse of enterocolitis did not occur after oral administration of either rifoximin or rifalazil for 5 days (Anton et al., 2004; Kokkotou et al., 2008).

Clinical Manifestations

Clinical signs and lesions of antibiotic-associated enterocolitis are similar in hamsters regardless of the antibiotic that induces the disease. Clinical signs include ruffled hair coat, dehydration, and diarrhea. Signs are usually observed within a few days, and death is observed 4–10 days post treatment.

Pathology

Characteristic gross lesions are cecal distention with fluid contents and hemorrhage of the distal ileum, colon, and cecum. Microscopically, there is acute to pseudomembranous typhilitis (Percy and Barthold, 2001). The lamina propria is edematous and infiltrated by neutrophils; and the mucosa may show hyperplasia.

Pathogenesis

Although alterations to the intestinal microflora following the use of antibiotics in hamsters have been shown to be an important component, the exact pathogenesis of antibiotic-associated enterocolitis remains uncertain. *Lactobacillus* and *Bacteroides* are the primary bacterial flora in the hamster intestine (Hagen et al., 1965). *C. difficile* can be cultured from the intestinal tract of a low percentage of normal hamsters; however its toxic effects are suppressed. The dysbiosis that may occur within 2–10 days following antibiotic administration allows toxigenic *C. difficile* to be established. It has been postulated that *C. difficile* colonization is suppressed by Gram-negative anaerobes and other clostridia in untreated hamsters (Wilson et al., 1981). The loss of these inhibitory organisms from antibiotic use allows colonization of *C. difficile* and its toxins

are released. These toxins cause the typical lesions of acute colitis, which leads to death. *C. difficile* can elaborate two antigenically distinct toxins (A and B) (Taylor et al., 1981). These toxins cause different inflammatory lesions. Enlarged moderately hemorrhagic cecitis is caused by toxin A; and normal-sized hemorrhagic cecitis is caused by toxin B (Libby et al., 1982).

Diagnosis

The diagnosis of antibiotic-associated enterocolitis is usually made based on the history of antibiotic use, clinical signs, and typical gross and microscopic lesions. *C. difficile* can be detected by PCR and enzyme immunoassay testing of feces, cecum, or colon. Isolation of the organism can be made using anaerobic techniques. Because hamsters can be carriers of *C. difficile*, isolation or detection of the organism is not diagnostic. Toxins of *C. difficile* can be detected by PCR, mouse inoculation, or by cell culture of large intestinal contents (Percy and Barthold, 2001). Differential diagnoses include any disease which can cause diarrhea, such as proliferative ileitis, enteropathogenic *E. coli* infections, campylobacteriosis, salmonellosis, and Tyzzer's disease.

Non-Antibiotic-Associated Clostridial Enteropathy (*Clostridium difficile*)

Background

C. difficile can cause disease in hamsters unrelated to a history of antibiotic use. Hamsters may unexpectedly die with or without signs of diarrhea and have lesions of cecitis. Affected hamsters may vary in age from juveniles to adults. Multiple hamsters died in an outbreak from a *C. difficile*-associated disease with a peracute clinical course (Hart et al., 2010). Most affected hamsters in this outbreak did not receive experimental manipulations. In a separate outbreak, *C. difficile* organisms were able to infect and cause enterocolitis in hamsters that were untreated with antibiotics, but were exposed to hamsters within the same room that did have antibiotic treatment (Rehg and Lu, 1982).

Etiology

C. difficile is a Gram-positive, anaerobic, spore-forming bacterium (Hart et al., 2010). Disease from this organism has been attributed to the production of two exotoxins, toxins A and B (Goulding et al., 2009). Hamsters are the most sensitive species to naturally acquired *C. difficile* infections compared to other common laboratory animals (Hart et al., 2010).

Epizootiology

The prevalence of asymptomatic carriers of *C. difficile* in hamsters has not been determined (Hart et al., 2010).

C. difficile may cause a potentially fatal diarrheal disease in humans. It is considered one of the most important nosocomial infections worldwide (Goulding et al., 2009). Experimental infection of hamsters with *C. difficile* serves as an important model for studying the human disease. Clinical signs of diarrhea, histopathologic lesions, and relapse of disease following removal of treatment are all important aspects of the human disease that can be produced in the hamster model (Goulding et al., 2009). Experimental studies using the hamster model have provided valuable information with regard to the role of toxins in the pathogenesis and potential treatments of the disease (Goulding et al., 2009).

Clinical Manifestations

C. difficile-associated cecitis in hamsters is characterized by sudden death. Hamsters of all ages in a colony may be affected and outbreaks may continue for up to 4 months. Clinical signs include primarily diarrhea which can be profuse and watery. In hamsters with hemorrhagic or watery diarrhea, mortality is high. Hamsters may also die peracutely without diarrhea having formed fecal pellets in the gastrointestinal tract with food in the stomach (Hart et al., 2010). Feces in chronic cases are semi-formed, which are matted in the perineal area. Signs may include dehydration, emaciation, rough hair coat, and hunched back.

Pathology

Gross lesions in hamsters are very similar to the ileocectitis that occurs after antibiotic use. The cecum is predominantly involved, showing enlargement with serosal hemorrhage varying in distribution from diffuse areas to multiple petechiae. Affected ceca are distended with odiferous contents. Intestines have a moderate amount of gas, are congested, and contain a yellow mucinous fluid. The cecum and colon may be thickened and firm (Chang and Rohwer, 1991; Ryden et al., 1991).

Microscopically, the cecum shows acute inflammation, submucosal edema, necrosis, loss of epithelium, and hemorrhage. A lymphoplasmacytic cellular infiltrate is present in the lamina propria of the cecum and colon. Chronically affected hamsters may have cecal mucosal hyperplasia (Ryden et al., 1991). Mucosal hyperplasia has also been reported in both the cecum and colon of affected hamsters (Chang and Rohwer, 1991; Hart et al., 2010). Hyperplastic lesions show increased height of villi and increased basophilia with many mitotic figures. In a group of hamsters fed an atherogenic diet, colonic hyperplasia was also present in most of the affected hamsters (Blankenship-Paris et al., 1995). Intracytoplasmic organisms are not observed in any of the hyperplastic epithelial cells.

In chronic cases, other organ systems may be involved. Livers may have cholangiohepatitis with biliary hyperplasia, and renal and hepatic amyloidosis.

Pathogenesis

It has been postulated that cecal dysbiosis may result in cecal hyperplasia which leads to overgrowth of *C. difficile* and the resulting necrotic cecitis (Ryden et al., 1991).

Acute toxigenic lesions from *C. difficile* have been attributed to toxins A and B acting synergistically (Hart et al., 2010). Toxin A is an enterotoxin which causes mucosal damage followed by toxin B, a cytotoxin affecting epithelial cells. High titers of *C. difficile* toxin B were detected in a hamster breeding colony with mortality due to cecocolitis (Ryden et al., 1991). Toxin B was also demonstrated in a group of aged hamsters that developed cecitis and colitis on a scrapie study (Chang and Rohwer, 1991).

Colitis caused by *C. difficile* can be caused by compounds other than antibiotics such as methotrexate (Cudmore et al., 1980). Non-antibiotic-associated enterocolitis developed in hamsters treated with fenazaquin, which is a miticide (Boss et al., 1994). *C. difficile* cecitis occurred in this group of hamsters that were being gavaged daily and fed a purified powdered diet (Boss et al., 1994). It was theorized that stresses associated with daily gavaging, a purified diet, and treatment with a miticide modified the intestinal flora which allowed proliferation of *C. difficile* that resulted in enterocitis. In this case, daily oral administration of vancomycin (20 mg/kg) for 3 months protected against the development of fatal *C. difficile* enteritis.

Diet has also been implicated to have a role in non-antibiotic-associated clostridial enteropathy. Hamsters administered neomycin on a purified diet developed enterocolitis due to *C. difficile*, where neomycin-treated hamsters on a commercial diet did not show disease (Micheli et al., 1981).

C. difficile infection occurred in hamsters fed an atherogenic (39% fat content) diet (Blankenship-Paris et al., 1995). The disease was characterized by a high mortality rate (50%). Acute hemorrhagic cecitis was evident at necropsy. The composition of the diet definitely was involved in the pathogenesis of the disease. The infection reoccurred in hamsters fed the high-fat diet, but was not present in hamsters on control diets housed within the same room. This reported case of *C. difficile*-associated enterocolitis occurring in hamsters on a high-fat diet may show that factors other than alteration of cecal flora are involved in the pathogenesis (Blankenship-Paris et al., 1995). It was postulated that slowed gastrointestinal motility in these animals may have been important to increase the colonization of *C. difficile*. The pathogenesis of this clostridial enteropathy could be due to disruption

of the gut flora and/or increased susceptibility of hamsters fed this atherogenic diet.

Diagnosis

C. difficile infection should be considered in hamsters with lesions of enteritis especially those affecting the large intestine (Hart et al., 2010). Diagnosis of *C. difficile* can be made by PCR testing on feces, cecum, and/or colon. The PCR test is very sensitive and, with specific primers, can detect toxins A and B (Hart et al., 2010). In a study involving detection of *C. difficile* from humans, PCR following combined antigen and toxin detection by enzyme immunoassay provided rapid turnaround time and reliable diagnostic accuracy (Swindells et al., 2010). Isolation of the organism from feces or large intestinal contents can be made using anaerobic culture techniques.

Prevention

Control of an outbreak of *C. difficile*-associated disease may be accomplished by depopulation, decontamination of animal holding rooms with chlorine dioxide, and repopulation (Hart et al., 2010).

Cecal Mucosal Hyperplasia

Background, Etiology, and Epizootiology

Cecal mucosal hyperplasia occurred in a colony of 800 breeding adult hamsters (Barthold et al., 1978). The disease affected suckling (8–14 days of age) and weanling hamsters with a mortality rate of approximately 80%. The disease was transmitted by close contact between hamsters, its incubation period being approximately 4 days.

The epizootiology of the disease was characteristic of an infectious organism, however none could be identified. Aerobic cultures of affected ceca revealed presumed non-pathogenic organisms from the families *Enterobacteriaceae* and *Pasteurellaceae*. Bacteria or viruses could not be demonstrated in cecal lesions by transmission electron microscopy. Hamsters experimentally inoculated with ground cecal lesions orally and by direct cecal injection did not develop the disease.

Clinical Manifestations and Pathology

The most prominent clinical sign was diarrhea evidenced by matted fur at the base of the tail by liquid feces. Other signs included runting and dehydration, the syndrome progressing to a moribund condition.

Affected ceca had thickened, opaque walls and hyperemic serosal vessels. Ceca were contracted containing a small amount of ingesta. Histologically, there was cecal mucosal hyperplasia. Crypts were two to three times normal height, mitoses were numerous and

extended onto villi, and cellular differentiation was diminished. Mucosal erosion with acute inflammation was also occasionally observed within the cecum and lower portions of the small intestine. Mild non-suppurative portal hepatitis was often observed.

Diagnosis and Prevention

The differential diagnosis for cecal mucosal hyperplasia should include any disease which causes diarrhea. Proliferative ileitis occurs in the same age group of hamsters and proliferation of the large intestine has been associated with typical ileal lesions (Frisk and Wagner, 1977b; Jackson and Wagner, 1970; Jonas et al., 1965). Intracytoplasmic organisms, however, could not be demonstrated in lesions of cecal mucosal hyperplasia nor were proliferative ileal lesions observed (Barthold et al., 1978). Also, hyperimmune serum to *L. intracellularis* from hamsters with proliferative ileitis was reacted with hyperplastic cecal lesions and was negative. It appears, therefore, that cecal mucosal hyperplasia is distinct from proliferative ileitis. Other diagnoses which can be differentiated by culture and lesions include non-antibiotic-associated cecitis (*C. difficile*), salmonellosis, Tyzzer's disease, and hymenolepiasis. This outbreak of cecal mucosal hyperplasia was eradicated by colony depopulation.

Salmonellosis

Background, Etiology, and Epizootiology
